Copulation is distinctive in this group. In at least one species, the male rolls on his side and, if receptive, so does the female. Mating will not occur unless both partners “roll.” Then, facing in opposite directions, the male grabs one of the hind tibiae of the female, not damaging her, positions his hind tarsi near her coxae, and curls his abdomen between his and her hind legs toward her subgenital plate. After several minutes, the male’s telescoping abdomen nears the female’s subgenital plate, and he grasps her with his hooks. With this anchor, he everts the phallic lobes and attaches a spermatophore with a larger spermatophylax. In many ensiferans, the spermatophylax is eaten, providing a source of nutrition for the mother and her eggs; the Jerusalem cricket female, however, does not consume the organ. Sometimes, though, the female consumes the male after mating; males offer no resistance to cannibalistic females.

**TETTIGONIOIDEA** This is the largest superfamily, with more than 6500 species. Katydid species (bush crickets or long-horned grasshoppers) can be of economic concern at times. Some flying species can swarm in the manner of locusts. With the “proper” environmental conditions, even flightless species can build in numbers that can affect crops and cause serious losses. The most notable example in the latter category is the Mormon cricket (*Anabrus simplex*) of western North America. It damages a variety of crops and rangeland plants. In Australia, Asia, and Africa, meadow katydids of the genus *Conocephalus* can build in numbers and move in large swarms. On a local level, many species cause damage to rice and crops from time to time.

On the other hand, the same species are often predaceous, feeding on eggs and larvae of other more important crop pests. In tropical regions, rice is attacked by the coprophilous *Euconocephalus* sp. Phaneropterines seem to provide the majority of species that damage crops. *Scudderia* spp. in North America and *Caedicia* spp. in Australia both feed on the developing fruits and new leaves of citrus varieties. *Phaneroptera* species feed on a wide range of crops as well as citrus and coffee, kapok, and mimosas. Another phaneropterine *Hokochlora pygnaea* feeds only on tea. *Ducetia* species feed on rice on two continents. *Eliamea chloris* feeds on a range of economic plants, the most notable of which are soybean, sugarcane, tobacco, and tea. The pseudophylline *Chloracris prasina* damages cacao, dadap, and rubber by its ovipositional habits. The widespread tropical mecopodine *Mecopoda elongata* feeds on beans, betel, cassava, castor, dadap, maize, potato, rice, sorghum, and tobacco. There are abundant literature references to “sexavae” or coconut treehoppers of two genera, *Sexa* and *Segestidia*. They are major pests of coconut and oil palm. They also feed on banana, karuka, manila hemp, and sago palm. With agriculture ever expanding to more remote areas, additional species not usually associated with economic damage can be expected to cause economic problems.

Katydids are widely distributed throughout the world, but the majority of species can be expected in tropical regions, especially the New World tropics. Many species are arboreal or bush dwelling. Some live in reeds or grasses, and many live on the ground. A few species can be found in alpine regions far above treeline. Most species exhibit cryptic behavior, especially during the daytime when they are inactive. Other species are aposematic and display warning colors. These species are primarily diurnal in their habits. Immature stages (nymphs) of some species mimic wasps, ants, beetles, bugs, and spiders. Ancestors of katydids probably were predaceous, but
Tettigoniidae. Many subfamilies are recognized, with several having been escalated to family rank as a result of recent investigations. Following the pattern adopted at the beginning of this article, these controversial changes are not recognized here.

The Brachypterinae contain 17 genera with over 160 species found from the Mediterranean area to Central Asia. It now contains the Epliippigerini with nine genera in the Mediterranean, which was formerly regarded a separate subfamily. The Hetrodinae contribute 14 genera (74 species) in Africa that often occur in aggregations. In some species, both sexes can stridulate. They are characterized by a spiny appearance. The Acridoxeninae, or dead-leaf katydids, are remarkable insects. The group is represented by a single genus with two species in equatorial West Africa, where they are apparently found on spiny plants.

The Phaneropterinae, or leaf katydids, bush katydids, or lyre bush crickets, are the largest assemblage of genera (340) in the family. It has been accorded family status by some investigators. About 2200 species are known, distributed throughout the world, but the majority of species live in tropical climes. Many species are involved in mimicry complexes. Most nymphs resemble foliage or plant parts, but many are mimics of ants, bugs, spiders, or cicindelid ground beetles.

The Pseudophyllinae, true katydids or bark crickets, include giant, fully winged, leaflike species (with wings spanning more than 20 cm) and smaller, micropterous ones. Most species are splendid examples of twig, foliage, and bark mimicry. Some species that resemble leaves, transparent holes, and irregular, “bitten” pieces, and even colors resembling fungus or lichens, are not uncommon in this group. Over 1000 species are known in 250 genera, with the majority in the New World tropics. The species that provided the name “katydid” is a member of this subfamily. All known species are phytophagous, and all known species use the often large falcate ovipositor to deposit eggs in plant tissue—in bark, twigs, or dead wood. Some species have unusual lifestyles. A Mexican species of Pterophylla has been observed crossing a stream underwater. One species of the southeast Asian genus Callimunella occurs in marine littoral rock crevices; others live in leaf litter on the forest floor.

The Microtetitgioninae are represented by a single genus, Microtetitgionia from southern Australia. These are minute (males as small as 5 mm) micropterous diurnal katydids that are extraordinarily fast moving. They live in grasses and lilies, and they seem to feed on floral parts.

The Conocephalinae is a large cosmopolitan group that comprises at least four tribes with more than 1000 species in 172 genera. The Gondwana-distributed Coniugopterini is represented by three genera: two occur in Australia and New Guinea, and a third is found in Chile. The genus Conocephalus is represented by more than 50 species in Australia alone; worldwide there are over 170 species. They are small, agile katydids with a relatively broad, blunt tarsus. They are similar in appearance and habit and often occur in large numbers. Some species are diurnal, others nocturnal, and still others are active both day and night. Conocephalus species can be of economic concern at times. At least one species has been distributed through commerce.

Other genera have a much smaller number of species and are widely distributed. The Copiphorini are often associated with grasses, where their slender, bladelike appearance renders them almost invisible as they perch on the stems. The species associated with grasses and reeds feed largely on the floral parts of the host plants, preferring seeds. The mandibles are unusually strong, and this is an adaptation for seed predation. The buzzing calls are familiar sounds to most residents and visitors to appropriate habitats on all continents, but few people have ever seen the producers of the sounds they frequently hear because of the insects’ secretive and cryptic habits. Thus, many attribute their sounds to cicadas. The other subfamily, the Agraccini, is a disparate assemblage that most likely comprises a number of higher taxa. Members of this group have an extraordinary size range, with some of the world’s most robust species represented.

The Mecopodinae (56 genera, 151 species) or Kutsuwa bush crickets are usually large (some species have wingspans >20 cm), and most species are fully winged and resemble either dead or living leaves to a remarkable degree. Others are short winged or wingless in at least one sex. Females sometimes stridulate. Most species are confined to the Old World. The subfamily is represented by two tribes, the Mecopodini and Moristini (Sexavini). Members of three genera are called coconut treehoppers because of the damage they cause to coconuts. Some species of this subfamily are kept in cages in Asia for the songs they produce.

The Phyllophorinae, or giant leaf katydids, are among the largest of all tettigoniids, with wingspans greater than 25 cm. Some 10 genera and over 60 species are known, mostly from the rain forests of Indo-Malaysia, New Guinea, and northern Australia. They are related to the mecopodines and the phaneropterines.

The Phasmodinae, or stick katydids, are wholly confined to southwestern Australia. They occur in winter and spring and are largely gone as the hot days of summer approach. They are very elongate and wingless in both sexes. They can cause economic concern when they feed on wildflowers in plantings in parks adjacent to natural areas. The remarkable resemblance to Phasmatoidea is one of the most striking examples of convergence in the orthopteroid insects.

The Zaprochilinae, or pollen- and nectar-feeding katydids, are represented by four genera comprising 18 species from Australia. They are usually gray, setose, soft-bodied insects, and some species are fully winged, with the tegmina held at an angle and rolled; some species are micropterous in males and wingless in females. The Kanaanaphila species have been important study organisms in studies of sexual selection.

The Tettigoniinae, in nearly 150 genera with over 850 species, comprising shield-backed katydids, wart-biters, or great green grasshoppers, is one of the largest and most widespread of tettigoniid subfamilies, with the majority of representatives in temperate climes of both hemispheres. The common name, shield-backed katydids, is derived from the development of the pronotum, which is often extreme. While most are predaceous or specialized feeders, the Mormon cricket (Anabrus simplex), the Coulee cricket (Peranubus scabricollis) of North America, and Decticiosides brevipennis of Africa can occur in large numbers during favorable years, causing enormous damage to crops. The wart-biter (Decticiosides verrucitorus) was used during the Middle Ages to “cure” warts by allowing the aggressive insects to bite them off. Perhaps a substance in the insect’s saliva contributed to the cure. The subfamily is diverse in form, ranging from among the smallest of tettigoniids to some of the largest. Fully winged and micropterous (Fig. 1E) species are known. The Oonocotini are unusual micropterous katydids living in shrubbery.

The Saginae is a small but characteristic subfamily of voracious predators or large insects. Four genera are represented, all from the Old World. Saga species can enter a cataleptic state characterized by complete immobility lasting some 20 min followed by a slow recovery. The function of this behavior is unknown.
The Austroagasinae comprises five genera, some of which use the powerful mandibles to crack seeds and feed on fruits. Listroscelidinae is a disparate assemblage of genera, many of which will probably be moved to other subfamilies when the group is fully revised. All species appear to be predaceous, some nocturnal and others diurnal. Some of the world’s most spectacular katydids are members of this subfamily. Many are capable of delivering a painful bite when handled. The center of distribution for this group seems to be Australia.

The Meconematinae (80 genera, over 500 species), or oak crickets or swayers, are small, delicate, greenish-yellow katydids; their distribution is tropical or subtropical. The notable exception is Meconema thalassinum, which occurs in Europe and Asia and has been introduced into the eastern United States. This species has lost the terminal stridulatory apparatus but produces sound by drumming with a hind leg on the substrate. The meconematines have been confused with the Phisidini of the Listroscelidinae, which, although somewhat similar in appearance, have an entirely different lifestyle. The phisidine species are nocturnal predators and have typical listroscelidine eggs. Eggs of meconematines are incredibly large for the size of the katydid and can be seen through the thin integument of the female. They are laid in decaying wood or other plant tissue, such as galls made by wasps, with the flattened, hard cap protruding from the substrate. The Tympanophorinae, or timbral bush crickets, comprise a single genus confined to temperate Australia. The tegmina are unique in that some species bear four kinds of stridulatory teeth on an expanded “rib.” There is evidence that soft structures on the rib may provide openings for a lubricant or a substance released from a chamber or reservoir beneath it. This feature is probably associated with the unusual reproductive biology of species. In other tettigonids, females are drawn to stridulating males, or answer them with their own calls, and the pairs are eventually brought together. The situation must be different in the tympanophorines, since the females are flightless and incapable of producing sounds. Male stridulatory behavior is unusual: they sing from perches for a short time and then fly 50 m or more to another perch and continue their song. How a flightless female can attract the attention of the transient male is unknown. All tympanophorines are nocturnal and predaceous. They use the short forelegs to capture small-insect prey. The power of the mandibles to crack seeds and feed on fruits.

The arrangement of crickets into higher units changed several times in recent history. A broader, more classical view is adopted here.

**RHAPHIDOPHOROIDEA** It has the single family Rhaphidophoridae. Camel, cave, and sand-treader crickets are fairly similar in appearance (Fig. 1C). An extinct subfamily is known from amber inclusions. All members are apterous, but some can produce sounds by rubbing the inner faces of the hind femora against the opposing side of the abdomen and by rhythmic drumming of the abdomen against a substrate, be it the ground, a twig, or a branch. All have a humpbacked body structure with very long hind legs and antennae. Some of the sand-dwelling species have the hind legs modified into “sand baskets” for digging. Some groups are wholly confined to caves and others are obligate burrowers; the majority, however, live in leaf litter or dark crevices, where they spend the daylight hours and emerge only on humid nights to feed on detritus and leaf litter. Some feed on fungi, and there is at least one record of a cave-dwelling species that feeds on newly hatched birds. One camel cricket is cosmopolitan in its distribution, being moved in commerce, and is said to be a pest of greenhouses. About 550 species in 80 genera are known, with most species coming from the Indo-Australian area and Polynesia.

**SCHIZODACTYLOIDEA** It has the single family Schizodactylidae. The splay-footed crickets are among the most bizarre of orthopteroids (Fig. 1D). There are fully winged as well as apterous species. They are broadly expanded by the possession of lobelike or digitiform processes, which enable the crickets to run across dry sandy surfaces with efficiency. One interesting feature of the group is that members that have been studied have lower chromosome numbers than most typical orthopteroids. The splay-footed crickets are primarily predaceous, but one is considered to be a minor crop pest. Two genera together with 15 species are known. They occur in parts of India, Myanmar, southwest Asia (*Schizodactylus*), and South Africa (*Comicus*).

**GRYLLOIDEA** It includes the true crickets and mole crickets that range in size from less than 1 mm to more than 6 cm. Most species possess “ground colors,” and few green forms are known. This is an adaptation to living on or in the ground.

The Gryllidea can be divided into a few very unequal families. Nearly 600 genera are known, encompassing over 4000 species, that comprise the Gryllidae; only about seven genera and almost 100 species comprise the Gryllotalpidae. Although the majority of species are tropical, large numbers occur in all the temperate parts of the world. All terrestrial habitats seem to be inhabited, except the highest mountain peaks. A few species can “skate” on water surfaces, and several live in mangrove swamps, where they use the stems to submerge themselves in saltwater when danger threatens. Many species burrow deep into the ground and seldom emerge. Others are blind, lack pigmentation, and live deep in subterranean caves. A number of species are commensal, living with rodents, ants, termites, and even mankind. Eggs are laid singly and deposited in the ground or in plant tissue such as decaying wood or grass stems.

Many crickets are crop pests, and population explosions sporadically occur with devastating results. Invasions of human habitations by crickets cause angst owing to the interminable chirping. Crickets around the world have been known to ravage foods and furnishings.

The arrangement of crickets into higher units changed several times in recent history. A broader, more classical view is adopted here.

**Gryllidae** The true crickets comprise the principal family of the superfamily. Body size can range from less than 5 mm to more than 50 mm. The family is currently divided into 26 subfamilies, and various classifications elevate some of these taxa to family level. Only some subfamilies can be highlighted shortly. The Gryllinae contain the crickets known to almost everyone. There are more than 1000 species in over 100 genera known from all parts of the world. Field crickets and house crickets belong to this group. Almost all species live on the ground, and some construct elaborate burrows that are often modified to amplify sound production. The house cricket, *Acheta domesticus*, can be considered to be a domesticated insect. It is used in commerce as a food for mammals, birds, and reptiles and seems unable to exist for any length of time in nature.

Several cricket species are kept, mostly in Asian countries, for the songs they produce. They are the source of a rich folklore and are regaled in poetry and song. Fighting crickets are an important part of the social scene in many Asian countries. The short-tailed crickets, a group that is quite prominent in Asian culture, are notable for the extensive galleries they make. There are brood chambers where
the young are looked after. Several species cause damage to crops by feeding or destroying the roots of the plants.

The Nemobiinae, or pygmy or dwarf crickets, comprise nearly 300 species in more than 50 genera and, as the name suggests, are small. While most forms are winged, there are many apterous species only a few millimeters in body length (Fig. 1G) that can easily be mistaken for nymphs of other species. Several genera exist in marine habitats. A number of genera in several parts of the world are adapted for life deep in caves and lava tubes. The majority of species live on the ground, often in moist habitats. Their numbers can be incredible in certain situations. Both diurnal and nocturnal species are known.

The Trigonidiinae, or leaf-running or sword-tailed crickets, are small, ground-dwelling or bush-dwelling crickets that are usually diurnal. They are active and often brightly colored. Some have a metallic sheen. Many species mimic spiders, ants, or wasps to mask their edibility. Eggs are deposited in stems and bark. More than 500 species are known in 36 genera. Many genera are cosmopolitan or at least occur on more than one continent. Preferred habitats are in rank vegetation, including shrubs, grasses, and small trees, but several genera occur in leaf litter. One genus with long tibial spurs can skate over water.

The Eucterinae and Podoscirtinae, or bush crickets, are small- to medium-sized slender crickets. These crickets usually live in shrubs, trees, herbaceous vegetation, or grasses. A small number can be found in leaf litter. There is a range of color in this group depending on the habitats occupied. Over 100 genera with more than 600 species are known. Most examples are from the tropics. Virtually none are of economic significance.

The Philanopsinae, or spider crickets, are long-legged, rather flimsy crickets that are often gregarious in habit. This and some closely related subfamilies together comprise 130 genera and over 600 species, with the majority in the Old World tropics. Some species occur on the ground or in tree holes or decaying logs. Large numbers live in caves, crevices, or in the cavities created by large animals. Similar habitats afforded by dams, bridges, and buildings attract these crickets. True cave crickets belong to this subfamily. The cheerful songs of oriental species are prized, and these crickets are often kept in cages for such reasons.

The Sclerogryllinae, or stiff-winged crickets, are represented by only two genera and few species. These crickets occur in Africa and southern and eastern Asia, where they live in leaf litter. The Pteroplismatinae, or feather-winged crickets, are represented by 10 genera and 23 species. The Cachoplistinae are sometimes called beetle crickets because members of at least one species strongly resemble small beetles.

The Oecanthinae (9 genera, 162 species), or tree crickets, have a worldwide distribution, but only nine genera and many species are known. Their nocturnal calls are well known to many people, although the insects themselves are seldom seen by humans. Some males utilize holes in leaves to amplify and direct their songs. They are also kept in cages in Asian countries because of the melodious songs they produce. Tree crickets are both beneficial and important local crop pests. Nymphs are often predaceous, feeding on a variety of insects, including aphids and scales. At times, females oviposit in developing fruits and have been involved in transmitting plant diseases. Tree crickets have a characteristic appearance (Fig. 1H) and are usually pale greenish white, ranging from 1.0 to 1.5 cm in length.

The Mogoplistinae, or scale crickets, are a widespread and often common assemblage of small, flattened species, all of which are covered with minute scales. About 30 genera are known, comprising over 300 species. The majority of species live in the Old World tropics. Many species live on the leaf surfaces, and there is an abundance of species that live in leaf litter. A single European species is considered to be intertidal. One tribe is known to be associated with rodent burrows. Both nocturnal and diurnal species are known. They are mostly small, ranging from 1.0 to 20 mm. The beautiful tones and sequences of the male song are valued in the Orient, and several species are kept in cages and sold in market for their songs. The Myrmecophilinae, or ant crickets, are minute, scale-covered, wingless crickets. There are six genera in this small subfamily, with more than 70 species found throughout the world, although most are known from tropical and subtropical regions. They are associated with ants, often living in the nests with them or following them along their trails. Some species have a wide range of hosts; others are known from only one species. Their commensal relations are unclear, but they seem to be unable to live independently for any period of time. A few species exist with termites. Some species seem to be parthenogenetic. Eggs are relatively large for the size of the female producing them. They are robust crickets that live in association with ants.

**Gryllotalpidae** The mole crickets comprise seven genera with about 100 species worldwide. Most species are found in the cosmopolitan genus *Gryllotalpa*. Mole crickets use the extraordinarily developed forelegs for digging deep, permanent galleries and foraging for plant roots. Some mole crickets are known to collect seeds and store them in larders in circular chambers underground for future use. Some species brood eggs in chambers, and in many species, both sexes stridulate. The calling songs are often of short duration and very loud. The horn-shaped entrance chamber of the burrow is used differently by different species to increase the male’s acoustical output. Most species are herbivorous, but a few are carnivorous. Several cause major damage to crops by feeding on roots, on seedlings, or both.

**Suborder Caelifera**

The short-horned grasshoppers and locusts and their relatives comprise the large and well-known suborder Caelifera. Rarely, this group is treated as a separate order.

Most caeliferans are diurnal, but increasingly investigators are discovering that many species are active both day and night. Males of many species stridulate in bright sunshine; rarely, those of others sing on warm nights. Although primarily tropical, many species occur in all parts of the world. Some are semiaquatic, and only a few are true burrowers. Almost all species feed on plant material, but many feed on dead members of their own or other species. None are communal. Aposematic coloration is a feature among many species.

Copulation in the Caelifera is rather uniform, with the male clinging to the back of the female for a considerable period of time with the spermatophore elongated and occupying the female’s genital tract. There is no visible external spermatophylax. Eggs are laid in pods or oothecae that are enclosed in a reticulate membrane and covered by a foamy secretion that dries out eventually. Eggs of most species are deposited directly into the ground, but others lay eggs in plant tissue or in cracks in bark.

Many species are disposed to gregarious behavior and swarming, with locusts offering the best example of this behavior. All true locusts are placed in the Caelifera. However, many other species not properly designated as locusts can become extraordinarily numerous and cause great damage to crops and other vegetation. Many species are eaten in Asia and Africa, usually fried. Many others are dangerously poisonous, and deaths have been recorded from eating these insects in Africa. After fires, the predominant colors among
nymphs are dark, often black. This characteristic, called fire melanism, is found in almost all grasshoppers in all areas. The time span for these changes is extremely short. However, some surviving adults that become very dark after a fire produce nymphs that show little or no melanism.

The more than 2400 genera and 11,000 species comprising the Caelifera are arranged in superfamilies, suborders, or infraorders depending on the classification followed. Here they are regarded as superfamilies and are as follows (Fig. 1): Acridoidea, Emmastacoida, Pygymorhioidea, Tanacoroidea, Pneumoroidea, Trigonopterygoidea, Tetrigoidea, and Trithactyloidea.

**ACRIDOIDEA (SENSU LATO)** This includes the grasshoppers and locusts, which comprise the largest superfamily of the suborder Caelifera. More than 5000 species in nearly 1700 genera are known worldwide. Adults range in size from less than 1 cm to more than 25 cm.

Many grasshoppers have a disparity in size between males and females, with the former being much smaller than the latter. In many species, males ride “piggyback” on females, not always copulating but “protecting” their prize and defending their potential progeny from other males with similar intent.

Grasshoppers have a short, almost invisible ovipositor. The eggs are laid in a pod covered by a protective coating. Many species oviposit on grasses, wood, and other plant tissue. A North American species has been observed ovipositing in dry buffalo dung. A number of species, especially locusts, utilize “lekking sites” to oviposit. Large numbers of females lay eggs in the same place year after year. Knowledge of such behavior can be valuable in planning the control of pest species. Many grasshoppers take advantage of walking tracks or unpaved roads for such activity. In oviposition, the female uses muscular contractions to extend the abdomen into the ground, often telescoping many times its length. The digging process is also performed by contractions and is aided by the teeth at the end of the abdomen. Upon hatching, the vermiform larva wriggles to the surface of the soil and upon reaching the surface, molts into the miniature form that will eventually become the adult. Nymphs undergo a series of approximately four to six molts, each one resembling more and more the adult in color pattern and shape. Gregarious grasshoppers illustrate synchronized molting, with all nymphs shedding their skins within hours of one another.

Locusts are species that occasionally form dense migratory swarms. These are often so large that they cross oceans but mostly occur in inland regions. Worldwide, more than 20 species from several subfamilies of Acrididae form migratory locust swarms.

The number of families depends on the classification followed. The scheme followed here (Fig. 1A) reflects the latest molecular attempts to establish a phylogenetically based classification based on defensible evidence.

**Pamphagidae** The Pamphagidae comprises generally larger, sluggish grasshoppers often resembling stones and bark. They have an array of body shapes (Fig. 1). The family has an Old World distribution, with the majority of species occurring in Africa and a few in Europe and Asia. It is absent from Australasia. Several species are known in which unmated females produce sounds, not the males as in other families. This is done by flapping the forewings that are reduced to hardened scales against the body.

**Lentulidae** The lentulid grasshoppers have been called “nymph-like” grasshoppers and range in size from 8 to 25 mm in body length. These (Fig. 2A) grasshoppers are wingless. They occur in southern, eastern, and central Africa. Most species live in bushes, and at least one species causes feeding damage to nursery stock. One species prevents a weedy shrub from becoming a pest.

**Tristiridae** The Tristiridae, or Andean wingless grasshoppers, are small to moderate in size. The body shape is variable, but the integument is always wrinkled and the color is brown or grayish. The family has three subfamilies found only in the mountains of Cordilleran and Patagonian South America. They are found at high altitudes (2800–3000 m). Their protective coloration renders them almost invisible on pebbles and gravel, but aside from that nothing is known of their biology.

**Ommexechidae** The Ommexechidae are called South American toad-hoppers. The family includes 13 genera with some 30 species, all from South America. They live on the ground, inhabiting “coarse”
vegetation in dry, sandy, or stony areas. They are of no economic importance.

**Romaleidae** The Romaleidae, or lubber grasshoppers, are regarded as a subfamily of the Acrididae in most older works. Recent molecular investigations, however, show that full family status is more appropriate. These grasshoppers are moderately large to very large in size and are often very colorful. The family has nearly 500 species in two subfamilies all found in the Americas. They occur in many habitats from desert to tropical rain forest. Some live on the ground, closely resembling stones or "toads"; others are found in bushes, and still others high in trees. Many species show aposematic coloration—if not in the adult stage, then as nymphs. Some species can produce a hissing sound when disturbed, and bubbles can be produced from spiracles when the insects are greatly disturbed. In many aspects of both appearance and behavior, these grasshoppers resemble the pyrgomorphs. Few romaleines, however, are associated with grasses or sedges. The lubber grasshopper, *Brachystola magna*, of the southwestern United States, can be a serious road hazard when killed by automobiles. Their crushed bodies have caused cars to skid and accidents have occurred. The largest of grasshoppers occur in this family. The tropical American genera *Tithlacris* and *Tropidacris* normally feed on vines, but at times they can become pests of plantations by defoliating plantation trees. They are called "giant locusts," but they are not really locusts at all because they do not form swarms.

**Lathiceridae** The Lathiceridae have been called desert grasshoppers. They are another peculiar small group known only from Africa. There are only three genera and four species, and nothing is known of their biology except that they burrow in sand and spend considerable time underground. They strongly resemble pebbles.

**Pamphagodidae** The Pamphagodidae (Charilaidae) are called the twin-keeled grasshoppers because of the parallel longitudinal carinae in the surface of the pronotum. There are four genera, comprising only five species, in this very small group from Africa.

**Acrididae** The Acrididae, or true locusts or grasshoppers, comprise the largest family of the suborder, and a full range of most of the features already described can be found here. Species range in size from less than 5 mm to more than 12 cm. The body form reflects grasshopper's role in the habitat. Short, stout, stone- or toadlike species are known, as well as stem- or twiglike grasshoppers. The colors span the complete range for the order, with browns or earth colors predominating.

Grasshoppers occur everywhere that orthopteroids are found. Many of the higher groups have restricted distributions, but the majority of species are tropical. Until recently, around 25 subfamilies were recognized, with more than 1500 genera. The characteristic songs are produced by males to attract females. Since these grasshoppers are primarily diurnal, color and behavior play important roles in species recognition. Some species have more than a dozen movements necessary for mate recognition. Elaborate colors and patterns and modifications of body pairs are associated with this behavior. But not all courtship occurs during the day. Some groups mate under the cover of darkness and rely on chemical clues to find mates. With these species, color is mostly protective, and bright colors are associated with aposematic features. Grasshoppers have a worldwide distribution and extend into some of the very cold regions of north and south. In this respect, they occupy more territory than the Ensifera. Only a few subfamilies can be highlighted here.

The Oxyinae include many species associated with water and grasslands. *Oxya japonica*, one of the most destructive grasshoppers in rice in southeast Asia, does only minimal damage in Australia. *Bermiella acuta* from Australia occurs on sedges, rushes, and grasses near water and has adaptations for aquatic life such as dense, water-excluding patches of hairs on the distal abdominal sterna and tegmina, and an "air chamber" formed by the doming of the costal area of the tegmen over the first abdominal spiracle.

The Gomphocerinae are an important component of the acridid grasshoppers. The songs of stridulating males are a summertime characteristic in the meadows of the Northern Hemisphere. Several species of the same genus may occupy similar habitats and have similar feeding habits. The calling songs of the respective species are different and serve as isolating mechanisms. Females are attracted only to the males that perform the calls of their own species.

The Catantopinae, or spur-throated grasshoppers, comprise many species (84% of the fauna in Australia). Some are very colorful. Many catantopines produce no audible sound, but some perform drumming actions on their host plants with the hind legs, thereby announcing the presence of a mate without the need of acoustical amplification. The responding members of the opposite sex merely move to the point of the drummer to consummate the union. A few other species produce a soft sound by rubbing the mandibles together. This can serve two functions. Some do this only when grasped, a startling reaction that might cause a would-be predator to drop the grasshopper. Others produce a similar sound from perches in shrubbery, obviously as an attractant to potential mates.

The Cyrtacanthacridinae, or large spur-throated grasshoppers, comprise some of the world's most important locust pests. *Valanga irregularis* from Australasia is one of the world's largest grasshoppers. It feeds on the leaves of trees and shrubs and can cause damage to fruit, nut, and plantation trees. Grasshoppers and locusts of the genus *Schistocerca* are members of this subfamily.

The Acridinae and the Oedipodinae are large groups (Fig. 2B) with a worldwide distribution. Many Oedipodinae have brightly colored hind wings, while some Acridinae have prolonged bodies with long, slanted heads. These groups contain some of the most phylogenetically advanced grasshoppers. Several locusts are included in the Oedipodinae, such as Australia's most important locust pests, *Chortoicetes terminifera*, or the plague locust *Locusta migratoria*.

The Pauliniinae, or aquatic grasshoppers, contain a single, small- to medium-sized species with a smooth body integument. Some authors regard it a separate family. It is only known from South America. Although other grasshoppers are aquatic, these grasshoppers are more wholly aquatic than any others. They can skate on the surface or dive and swim beneath it. Eggs are laid on the submerged parts of water plants. Their terrestrial behavior seems to be mostly nocturnal. They feed on aquatic plants, and one species, *Faisunia aequatoria*, has been introduced into Africa for the control of *Salvinia*.

**TANAOCEROIDEA** This includes a single family, the Tanaoceridae. Once considered to be related to both the eumastacids and xyronotids, the family Tanaoceridae comprises two genera with a few species from the deserts of western North America and Mexico. Members of *Mohatoecus* have been found on sagebrush (* Artemisia tridentata*), where they closely resemble the bark of the thick stems. *Tanaocerus* species occur on the ground or on shrubbery. Both genera are nocturnal and are active on the cold nights of winter. Eggs are apparently laid in the ground and hatch in early autumn.

**PYRGMORPHOIDEA** This now includes only the Pyrgomorphidae, comprising a most diverse assemblage of genera. The size and
shape of the grasshoppers are extremely variable, but the head has a characteristic fastigial furrow. The family comprises some 30 tribes with 150 genera and nearly 500 species; two subfamilies are recognized at the most. The family is mostly tropical, with the greatest number of species being from Africa and Madagascar, but the greatest diversity of genera is from the Australasian. Only few species are known from Mexico and South America.

Pyrgomorphs live on bushes, herbage, grasses, and sedges and on soil and sand. Although many are camouflaged and show adaptation in body shape with twigs, grasses, leaves, and so on, many are stunning examples of aposematic coloration. They perform impressive displays when annoyed or threatened. Several species eject irritant fluids or a foamy froth when irritated. Not only are some of these substances toxic to mammals, birds, and reptiles, they are poisonous to humans. The majority of species oviposit in the ground like other grasshoppers, but some have been observed ovipositing in rotting logs, epiphytes and, most likely, the soil in trees caused by the presence of epiphytes. A few species are facultatively aquatic. Many species are gregarious, especially in the juvenile stages, and move together in the manner of locusts. At times they cause damage to crops but, in general, they are not pests.

PNEUMOROIDEA (BLADDER HOPPERS OR FLYING GOOSEBERRIES) This comprises a single, most peculiar family, the Pneumoridae. They are usually large, with some species reaching 10 cm or more in length. The body shape of males is characteristic (Fig. 2C), that of females more resembling a normal grasshopper. The major part of the abdomen in males forms a huge, inflated, resonating chamber that is highly translucent. Females produce sounds but in a different way. Biological observations made more than 200 years ago indicate that males produce a loud noise after dark from shrubs in dry habitats. The sound, with its deep resonance, is often mistaken for that of a larger animal such as a bullfrog. There are two subfamilies with nine genera and some 20 species. They are all confined to southern and eastern Africa. They are of no economic importance.

EUMASTACOIDEA It consisted of two families, the Proscopiidae and the Eumastacidae. Both have short antennae and an angular head that often appears too large for the body. Most species are wingless, but there are winged species that often resemble damselsfies. The proscopiids, or false stick insects, are readily distinguished by elongate and twiglike appearance. They have an exaggerated head. All species are wingless, and some can be quite large (2.5–16.5 cm). Sixteen genera are all confined to South America.

The Eumastacidae, or monkey grasshoppers, is a much larger group. Seven subfamilies, regarded as separate families by some authors, have been recognized with more than 1000 species. Most species are small, with the body seldom exceeding 4.5 cm. Many are wingless, but there are many Old World forms that are fully winged and readily fly. Most species have a characteristic way, shared with the proscopiids, of sitting, exposed, with the hind legs splayed akimbo. They are diurnal and readily fly in the sun, and they resemble damselsfies in several respects. Eumastacids feed on a variety of plant types ranging from grasses and sedges to desert shrubs and ferns in Old World rain forests. Probably the majority of species are nocturnal.

The Australian endemic subfamily, Morabinae, comprises 42 genera with 123 species. They are elongate, matchsticklike plain brown or green grasshoppers that do not sit with legs akimbo. They live on a wide variety of plants and are often very localized in their distribution. A fossil species of the extant genus Erucius, of the Eruciinae, has been discovered in Oligocene deposits in western North America. Present-day species in this genus are found in Malaysia and the Philippines.

TRIGONOPTERYGOIDEA It comprises two families: Trigonopterygidae and the Xyronotidae. The Trigonopterygidae have been called broad-leaf bushhoppers (Fig. 1A). The group is confined to Asia, and several of the species occur in Borneo, where they live on the ground in dead leaves they resemble.

The Xyronotidae, or razor-backed bushhoppers, comprise a single genus with only two species with no known relatives. These grasshoppers live on the ground in leaf litter and have continuous generations. They are found only in Mexico.

TETRIGOIDEA This contains the grouse locusts or pygmy grasshoppers. These are small, usually gray, black, or mottled grasshoppers seldom exceeding 20 mm in body length (Fig. 2D). Depending on the classification, there are two families, or one family and many subfamilies. About 1500 species are known in 255 genera, with the majority of species in the Tetriginae. Most species live on the ground, most often on moist ground or along streams and ponds, where they feed on algae and diatoms. Members of the tribe Scelimini are fully aquatic and can swim effectively underwater. In tropical climes, some species are arboreal and live among lichens and mosses in tree buttresses or even higher in the canopy. Eggs of the terrestrial species are laid in the soil and bear a peculiar terminal filament that is directed upward when the eggs are laid. They are mostly of little economic concern, although some species are said to feed on rice.

TRIDACTYLOIDEA This is a small group containing some of the most bizarre of the orthopteroids. The pygmy mole crickets, pygmy sand crickets and mud crickets, and sand gropers are peculiar in many respects. They range in size from less than 4 mm to more than 80 mm. Three families are recognized. The Tridactylidae and Rhipipterygidae are more closely related to one another than to the Cylindrachetidae.

Tridactylidae and Rhipipterygidae The tridactylids and rhipipterygids are small, usually variegated black, yellowish, or reddish minute cricketlike insects (Fig. 2E). The two families comprise about 220 species in 19 genera.

Most of the tridactylids and rhipipterygids are associated with damp habitats. They seem to be gregarious, and those that live in these situations can construct “nests” out of mud and debris to spend the night or to “hibernate.” Many are active swimmers. There is another group that is arboreal, living on leaf surfaces in tropical climes, where they feed on the rain of particulate matter from the canopy. Many of these species have wasplike color patterns and “jerky” movements. Others living in the same habitats are dark blue and have white tips to the antennae.

Cylindrachetidae The Cylindrachetidae, or sand gropers, have an elongate or wormlike appearance. There are nine known species in three genera. They reflect a Gondwanan distribution, with species in Australia, New Guinea, and Patagonia. Sand gropers build galleries in moist soil by compressing the soil with their powerful forelegs, burrowing up to 2 m depth. In some seasons and after rain, they burrow close to the soil surface producing long, conspicuously raised trails. Nymphal development may extend over several years. Sand gropers consume a wide array of plant, fungal, and arthropod material. At least one species causes considerable damage to wheat in Western Australia, where large populations build up in the soil and feed on the root of plants.
Ovarioles

Diana E. Wheeler
University of Arizona, Tucson, AZ

Ovarioles are egg-producing tubules that are the fundamental units of ovaries in female insects. The number of ovarioles in each ovary is typically 4–8, but varies widely depending on the particular insect and its ecology.

GENERAL ARRANGEMENT AND STRUCTURE

Each ovariole is a tube in which oocytes form at one end and complete development as they reach the other. The terminal filament and the germarium, which contains germ cells, are at the distal end. Ovarioles may have one of several topological arrangements within an ovary. In some species ovarioles join the end of an oviduct radially around a central point. In others, ovarioles arise in single file off the oviduct, like teeth on a comb.

NUMBER

The number of ovarioles per ovary varies with taxon, size, and life history. All Lepidopteran females have four ovarioles, but many groups tend to be more variable, both within and across species. Variability in ovariole number is particularly spectacular in social insects. Obligately sterile workers in ants can lack ovarioles entirely, and the most fecund queens in ants and termites have about 1200 ovarioles per ovary.

DEVELOPMENTAL ORIGIN

The period during which ovarioles form varies widely in insects, ranging from embryonic development in aphids to the pupal stage in flies. In some taxa, the number of ovarioles can be adjusted based on environmental factors. In Drosophila, for example, ovarioles form during the pupal period. This timing provides the opportunity for the number of ovarioles constructed to be adjusted based on previous diet and temperature. In honey bees, however, ovarioles form in early larval development. The number of ovarioles formed is at first the same in future queens and workers. In workers, however, most ovarioles undergo cell death, whereas those in developing queens persist.

SOMATIC TISSUE AROUND DEVELOPING OOCYTES

Each ovariole is made up of both somatic and germ cells. The somatic tissue includes a tubular sheath surrounding all the developing eggs as well as follicle cells around each oocyte. The sheath consists of inner and outer layers. The outer sheath is an open network of cells, sometimes containing muscle. The tissue is rich in lipids and glycogen and is metabolically active. Even so, there is no evidence of direct involvement in oocyte development. Tracheoles form part of the outer sheath but do not penetrate below it. The outer sheath can be important in sequestering bacterial symbionts that will be passed on to offspring. The inner sheath is a layer of extracellular matrix. In addition to physical support, the inner sheath can function as a sieve.

A layer of follicle cells surrounds each developing oocyte. Follicle cells are very active metabolically, contributing a variety of materials essential to developing eggs. During yolk uptake, follicle cells can separate slightly, allowing vitellogenin-laden hemolymph to contact the oocyte surface directly. The oocyte then can take up vitellogenin and other nutrients. As egg development nears completion, follicle cells secrete the eggshell, which consists of vitelline envelope and layers of chorion.

PATTERNS OF OOCYTE DEVELOPMENT

Ovarioles can be categorized based on how oocytes are produced from stem germ cells (Fig. 1). A stem germ cell produces two daughter cells when it divides; one remains a stem cell and the other becomes a cystoblast. Most commonly, cystoblasts undergo rounds of division but remain connected by intercellular bridges. This process is called cluster formation. Generally, only one of the daughter cells in a cluster becomes an oocyte, while the remainder degenerate or become nurse cells. The type of oocyte development in which an oocyte is connected to sister cells that contribute to the contents of the egg is termed meroistic.
Stem cells in ovarioles of the most primitive insects do not undergo cluster formation. Instead, each cystoblast develops into an oocyte. Such ovarioles are called panoistic. Insect orders that have primitively panoistic ovaries are Archeognatha, Thysanura, Odonata, Embioptera, and most of the orthopteroid orders. Plecoptera shows an interesting intermediate condition, in which cluster formation occurs, but all the daughter cells become oocytes. Panoistic ovaries are also found in more recently derived insect groups, in which the design has evolved secondarily, and these taxa include Siphonaptera, Strepsiptera, and Thysanoptera.

Meroistic ovaries can be subdivided into two types based on the location of accessory germ cells relative to the oocyte. In polytrophic ovaries, accessory germ cells maintain short connections and accompany the oocyte as it moves down the ovariole. In telotrophic ovaries, accessory tissue remains at the distal end of the ovariole.

In polytrophic ovaries, follicle cells encapsulate both the nurse cells and the oocyte. Nurse cells generally are polyploid and express genes whose products are transported to the growing egg. Trichoptera, Lepidoptera, Hymenoptera, Diptera, aphagan Coleoptera, Mecoptera, and Neuroptera all have polytrophic ovaries.

In telotrophic ovaries, accessory nurse cells remain in the anterior part of the ovariole and so, as an oocyte moves away, cords of oocyte tissue lengthen to maintain the connection. Telotrophic ovaries have apparently evolved independently several times. In Heteroptera, Coleoptera (Polyphaga), Raphidioptera, and Megaloptera, they evolved from polytrophic ovaries. Telotrophic Ephemeroptera evolved directly from panoistic ancestors.

Ovariole architecture is related to both phylogeny and life history. Both panoistic and meroistic ovarioles can support very rapid egg production as illustrated by the more than 40,000 eggs/day produced by both the panoistic ovarioles of the most fecund termite queens and the polytrophic ovarioles of the most fecund ants (Fig. 2). An important consequence of panoistic vs meroistic eggs is duration of embryonic development. The design of meroistic ovarioles facilitates the production of eggs well-stocked with ribosomes, mRNA, tRNA, and other macromolecules. Such eggs generally develop rapidly, as exemplified by Drosophila melanogaster. In contrast, autonomous oocytes produced by panoistic ovaries require longer periods to complete embryogenesis.

### Further Reading
Oviposition behavior comprises one of the final steps in insect reproduction. It involves the deposition of the mature egg outside the body of the female and includes a series of behavioral and physiological events that begin with the movement of the egg through the oviduct and end with the placement of the egg on a substrate that will support the development of the larva. Specialized behaviors and structures on the female allow her to place the eggs within a protected environment during oviposition.

OVULATION

Insect eggs develop within the ovaries, the reproductive structures of the female that are composed of tapering units called ovarioles. The oocytes differentiate from stem cells at the tip of the ovariole, and as they begin their downward movement in the ovariole they are first completely surrounded by a monolayer of follicle cells (Fig. 1). These follicle cells are involved in the transport of substances from the hemolymph into the cytoplasm of the oocyte that are stored for later use during embryogenesis. Nurse cells may also be present to provide the oocyte with other maternal contributions, such as messenger RNA and mitochondria. The nurse cells subsequently degenerate, and the bulk of the yolk proteins deposited in the oocyte cytoplasm must then cross the layer of follicle cells after their synthesis in the fat body. During a later stage of development, the follicle cells also synthesize the eggshell (or chorion), which provides protection and waterproofing once the egg has been laid. After deposition of the chorion, the follicle cells degenerate, leaving the chorion as the outermost egg layer. With the follicle cells no longer on the outside of the egg, the egg is free to move out of the ovariole and into the oviduct, under the impetus of contractions of muscles in the oviduct walls. This movement of the egg to the outside of the ovariole is termed ovulation. Ovulation of the egg must occur before oviposition can take place.

The muscular contractions of the ovariole and oviduct that propel the egg through the reproductive tract are coordinated by hormones called myotropins. Myotropins are secreted by neurosecretory cells in the brain once the central nervous system has received the physiological confirmation that mating has occurred and that the eggs are mature. For example, in the bloodsucking bug Rhodnius prolixus, ovulation is initiated by a myotropin that is released only after the spermatheca has been filled with enough sperm and male accessory gland substances to produce a factor that induces the maturing eggs to begin producing 20-hydroxyecdysone. In the tsetse fly, Glossina, ovulation is initiated when a mature egg is present in the ovariole and the female has mated, but the stimulus from mating is not released until the female has received prolonged mechanical stimuli associated with copulation in addition to substances from the male accessory glands. Even several short copulatory experiences that fail to transfer sperm can initiate ovulation if their total duration is as long as a single successful copulation.

FERTILIZATION

As the egg passes through the median oviduct, it is fertilized by sperm already stored within the female’s capsulelike spermatheca (Fig. 2). Sensory receptors within the oviduct are mechanically
stimulated by the distension the egg creates as it descends; motor neurons activate the muscular walls of the spermathecal duct that allow the sperm to exit the spermatheca.

In hymenopterans, where sex determination occurs by haplodiploidy, the process of sperm release is controlled more directly by the female. Eggs that are fertilized develop into female workers, but those that are not fertilized develop into male drones. The workers ultimately control whether the queen fertilizes the egg; they determine the size of the cells for rearing the larvae into which the queen deposits the egg. Before the egg is laid, the queen evaluates each cell with sensory receptors on her ovipositor, opening her spermathecal duct only when placing an egg into the larger cell for female rearing.

The sperms enter the egg through the micropyle, a small channel built into the normally impermeable chorion. Some insect eggs have several of these micropyles. The oocyte has been arrested in metaphase of the first meiotic division prior to fertilization, but shortly after the sperm has penetrated the egg and oviposition has occurred, the oocyte completes its meiosis. The meiotic division results in a haploid oocyte nucleus and three polar nuclei that inhabit the periplasm at the periphery of the egg. The oocyte nucleus, surrounded by an island of cytoplasm, then moves to the interior of the egg, where it meets the sperm that has already entered. Syngamy, the union of sperm and egg, occurs in the interior. In some insects whose eggs develop by parthenogenesis (i.e., without the fertilization by sperm), a haploid polar nucleus combines with the haploid oocyte nucleus to restore the diploid number without requiring fertilization by male gametes.

**OVIPOSITION**

After ovulation and fertilization, the eggs are usually deposited outside the female’s body during oviposition. The eggs move down the common oviduct by peristaltic waves of muscle contractions and out of the body through the ovipositor. The movement of the egg downward through the oviducts is facilitated by backwardly directed scales inside the oviduct, which act like a ratchet mechanism, allowing the egg to move in only one direction, down toward the genital opening.

Modified dermal glands known as female accessory glands may also be present on the common oviduct. These glands produce cement that allows the deposited eggs to be glued together or attached to the substrate. In some insects that retain their eggs after the young hatch, such as the tsetse Glossina, the accessory glands produce a nutritive secretion that nourishes the larvae during their entire larval period. In cockroaches and mantids, the female accessory glands produce the hardened egg case, or ootheca.

The spermathecae are used for the storage of sperm in the inseminated female. Also ectodermal in origin, the spermatheca generally opens into the common oviduct and releases sperm as the fully formed egg passes by. The spermathecal duct may contain glycogen deposits that can serve as an energy source for the sperm as they pass through to the egg. Nearest its opening to the outside, the common oviduct may be modified into a genital chamber that can be used to incubate eggs internally. The bursa copulatrix is an additional pouch within the chamber that is present in some insects into which sperm may first be deposited after mating. The sperm leave the bursa and then move into the spermatheca, where they are permanently stored. The bursa may have a series of toothlike structures that disrupt the spermatophore, the vessel in which the sperm are contained in more primitive insects, and facilitate their release. It may also secrete chemical signals into the hemolymph when it is filled with sperm to signal to the female that mating has occurred.

The control of oviposition in the cockroach *Spodromantis* is a good example of how environmental and physiological information must be integrated for egg laying to occur. This insect normally lays its eggs at the beginning of the photophase. The brain integrates the information it receives about the photoperiod and the presence of mature oocytes, and triggers the release of an oviposition-stimulating hormone that activates the ovipositor, ovariole, and oviduct muscles. As the substrate is probed with the insect’s ovipositor, tactile sensations from sensilla are sent to the terminal abdominal ganglion, where further movements of the egg and secretions by the accessory glands are controlled.

In most species, ovulation and oviposition may be part of a continuum, but in others they may be separate events in which the eggs are retained for a variable period between ovulation and oviposition. Some species of ovoviviparous cockroaches retain within a brood sac eggs that have been ovulated, until the female finds a suitable place to lay them. The nymphs hatch inside the female. The viviparous tsetse that retain and nourish their larvae after they have hatched from the egg larviposite late instar larvae that pulate after they burrow into the soil.

Most insects lack specialized structures for the deposition of eggs, but in some species the terminal segments of the abdomen form a telescoping ovipositor that can be used to deposit eggs into crevices or even, when the tip is modified into sawlike blades, into hardened substrates such as wood. This ovipositor may be derived from the modified appendages just described or from the modified terminal abdominal segments themselves. Special muscles within the ovipositor allow it to engage in superextension, lengthening considerably to reach hidden sites into which the eggs can be placed. Both the tips of the abdomen and the ovipositor may contain sensory receptors that can provide the female with information about the nature of the oviposition substrate. Sensory cues that are evaluated by the receptors are important in locating an oviposition site and in initiating oviposition once the site has been found.

Prior to depositing her eggs, the female must engage in behaviors that will bring her to an environment that is suitable for larval development. This is especially necessary for the eggs of holometabolous insects, since the larvae are very different from the adults. Being relatively immobile, the larvae depend on the adult to locate a site on which they can develop. For example, adult mosquitoes are terrestrial but their larvae must develop in water. Although the adults are generally attracted to stimuli from vertebrate hosts for blood, when they carry mature eggs they become more sensitive to the stimuli from potential oviposition sites. The presence of mature eggs appears to trigger a physiological switch that changes the behavior of the female, attracting her to oviposition sites suitable for her eggs. In the absence of mature eggs, the female is more attracted to a host for a blood meal that would support another batch of eggs.

Lepidopterans undergo a sequence of behaviors, including searching, orientation, encounter, landing, evaluation of the surface, and acceptance. Stimuli received during each phase are integrated by the central nervous system, which processes the sensory information from sensory receptors on the antennae, tarsi, and ovipositor. Visual cues such as plant color and shape are important during searching behavior. Volatile chemicals produced by the plant initiate the orientation and encounter behaviors that attract the female from a distance of several meters. Visual cues are once again important in landing behavior, with the involvement of chemical cues that act as attractants, arrestants, or repellents. Once on the host plant, the female evaluates the physical and chemical cues from the plant surface and often begins drumming her front legs on the leaf surface, perhaps to provide more chemical information about the plant to tarsal sensory receptors. By using the
total sensory input to the central nervous system, the female is able to recognize the suitability of the substrate for her eggs before they are laid.

The torsalo, *Dermatobia hominis*, has an unusual way of finding an oviposition site. The gravid female captures another bloodsucking fly and glues her eggs to the underside of the carrier’s body. When the carrier seeks out a vertebrate host for a blood meal, the larva hatches and burrows through the skin of the host. The larva develops in the vertebrate host, exits prior to the pupal stage, and pupates in the soil.

Parasitoids

Nick Mills

University of California, Berkeley

Parasitoids are insects with a parasitic larval stage that develops by feeding on the body of a single host insect or other arthropod. Feeding by the larval parasitoid invariably results in the death of its host, and the resulting adult parasitoid is a free-living insect. Thus parasitoids occupy an intermediate position between predators and true parasites; in contrast to predators they kill their host like a predator, but in contrast to parasites they require only a single host to complete their development as is the case for parasites.

Nearly 10% of described insect species are parasitoids and, as they often belong to poorly known groups of insects, it has been suggested that they are more likely to represent 20–25% of all insect species. Since the first accounts of insect parasitism at the beginning of the 18th century, parasitoids have attracted considerable attention because of their potential to regulate the abundance of insect hosts in both natural and managed ecosystems. Numerous insect pests have been effectively controlled through releases of insect parasitoids in biological control programs around the world. Although not always applicable or successful, biological control continues to provide some dramatic examples of sustained long-term control of invasive insect pests. As a result of the research conducted through biological control programs, parasitoids have also become important model organisms for the study of ecology, behavior, and evolution.

ORIGIN AND DIVERSITY OF PARASITISM

About 77% of the known parasitoid species belong to the parasitic Hymenoptera, an arbitrary division of the suborder Apocrita of the order Hymenoptera. It is generally believed that parasitism evolved just once in the Hymenoptera, and that the Apocrita together with the sawfly family Orussidae form a holophyletic group that includes all of the known parasitic wasps. Although the larvae of some species may initially feed on microorganisms in the tunnels of wood-boring insects, the young larvae of others feed externally and subsequently internally on larvae of the borers themselves. Many horntails and wood wasps (sawfly superfamily Siricoidea) carry symbiotic fungi in pouches located at the base of the ovipositor (mycangia) that are inoculated at oviposition, allowing the larvae to feed on infected and partially digested wood. However, not all siricoids carry fungal symbionts and some may have evolved to kill those that did, and subsequently feed on the more nutritious dead insect rather than the wood. This trait is seen among the present day orussids.

Within the parasitic Hymenoptera there are more than 66,000 described species of parasitoids in 10 superfamilies that are, with rare exception, exclusively parasitic (Table 1). However, parasitoids are also known from five other insect orders. In contrast to the Hymenoptera, parasitism has evolved repeatedly within these orders, either from an external feeding (e.g., Rhipiphoridae), dead organism feeding (e.g., Ploridae, Sarcophagidae), predatory (e.g., Carabidae, dipteran families) or phytophagous (e.g., Lepidoptera) ancestor. For example, parasitism is estimated to have occurred 17 times in the Diptera producing over 17,000 described parasitoid species, and 14 times in the Coleoptera producing a further 2450 parasitoid species (Table 1). Parasitism is unusual and rare among the remaining three orders.

PARASITOID LIFE STYLES

Parasitoids are frequently categorized as having larvae that are either ectoparasitic (external feeders) or endoparasitic (internal feeders), and either solitary (one per host) or gregarious (several per host) in their development. However, a more useful categorization of the life styles of parasitoids is the dichotomy between idiobiosis and koinobiosis. Idiobionts paralyze and/or arrest the development of a host at oviposition, providing their larvae with an immobilized static resource on which to feed. In contrast, koinobionts allow the host to continue to feed and/or develop after oviposition, such that their larvae feed on an active host that is only killed at a later stage. Although ecto- and endoparasitism are distinct modes of parasitism, the separation of idiobiont and koinobiont life styles is less clear. There should be no problem in correctly categorizing parasitoids that attack an active stage of the host life cycle (larva or adult) or those that allow a transition between life-cycle stages of the parasitized host (egg–prepupal and pupal–adult parasitoids). However, the distinction is not always so obvious for parasitoids that attack and complete their development in an inactive stage of the life cycle (egg or pupa).

Idiobionts

Idiobiont parasitoids frequently attack hosts that are concealed in plant tissues or exposed hosts that provide some other form of physical protection, such as the scale covering of armored scale insects. Thus, many have long ovipositors to reach their concealed hosts, and strong mandibles to escape from concealed locations. The

Source: Data updated from Godfray (1994).

Endoparasitic egg and pupal parasitoids are also considered to be idiobionts, although as noted above, this categorization is less clear. In this case the hosts are frequently exposed rather than concealed, and in place of paralysis, development of the host appears to be arrested by secretions either from the ovipositing adult (egg parasitoids) or from the young larva (pupal parasitoids). Endoparasitism of host eggs is facilitated by the lack of an immune defense, but it is not known how pupal idiobionts avoid such defenses in their hosts.

The absence of an intimate association between the juvenile stages of an ectoparasitic idiobiont and its host allows this group of parasitoids to have a broader host range, using a variety of hosts that share a common habitat or host plant. Some endoparasitic idiobionts are more restricted in their host range, however, perhaps because of a need for more specific cues in host recognition, or for detoxification of the chemical defenses of exposed hosts.

Koinobionts

All dipteran parasitoids, the majority of coleopteran parasitoids, and many hymenopteran parasitoids adopt a koinobiont way of life. Koinobiont parasitoids attack both exposed and concealed hosts, and the majority of species have endoparasitic larvae. Endoparasitic koinobionts attack a broad range of developmental stages of their hosts. Access to concealed hosts is facilitated either by attacking the more accessible egg or young larval stage of their host (hymenopteran koinobionts only) or by production of a free-living first-instar larva that can complete the location of a suitable host.

Koinobionts typically oviposit into the body of their hosts with minimal disruption to the normal activity of the host. The hemocytic immune response of the host can result in the encapsulation of parasitoid eggs and larvae, and is a significant obstacle to endoparasitism. This response can be overcome by (1) avoidance by placing eggs in host tissues such as the salivary gland or nerve ganglia; (2) evasion by producing an egg with a fibrous coat or a coating of proteins that are not recognized as foreign to the host; (3) suppression by injecting immunosuppressive polydnaviruses or virus-like particles at oviposition; or (4) subversion by allowing host hemocytes to form a sheath around the developing larva that is attached to the host tracheal system to avoid asphyxiation. Koinobiont are also mostly synovigenic, but differ from idiobionts in having a much greater fecundity with the majority of their eggs produced early in adult life. Koinobiont eggs are relatively small and enrichment occurs after oviposition through absorption of nutrients from the host hemolymph. The greater emphasis on early reproduction is often associated with a shorter adult life, although longevity is greatly influenced by access to a sugar food source.

Many koinobionts exhibit protracted larval development, remaining as a first-instar larva within the host until the latter has retreated to its pupation site. This both allows the host larva to complete its development without suffering any debilitating effects from parasitism, and permits the parasitoid to remain in its most competitive stage, as first-instar larvae bear strong defensive mandibles, until the host has gained maximum size as a resource for parasitoid larval development. Thus, koinobiont parasitoids are often more specialized in their host range than idiobionts, because of their more intimate relationship with an actively feeding or reproducing life stage of the host and the need to overcome its immune defenses.

BEHAVIOR AND INTERACTIONS

Host Feeding

Many idiobiont adult females acquire nutrients from host by feeding on the body fluids that exude from wounds inflicted by the majority of idiobionts that attack concealed hosts have larvae that are ectoparasitic and feed on hosts in the later stages of their development. An ovipositing adult first injects venom into the host, to induce temporary or permanent paralysis, and then oviposits on or near to the immobilized host. In a few cases (some Bethylidae, Braconidae, and Eulophidae in the Hymenoptera), the parent female remains with the parasitized host, either to defend her young offspring against competitors or hyperparasitoids, or to ensure continued paralysis of the host. Ectoparasitic idiobionts are often long lived, feeding for somatic maintenance on honeydew, nectar, or other plant exudates. They are synovigenic, meaning that they continue to mature eggs throughout adult life, and produce large yolk-rich eggs using nutrients gained from host feeding (see below). Consequently, ectoparasitic idiobionts have a relatively low rate of host attack and a low fecundity. The hatching larvae are protected from desiccation by the host concealment, but develop continuously and rapidly to consume the host before it is attacked by scavengers or microbial decay.
ovipositor, a process known as host feeding. Some small gregarious parasitoids are able to host feed on the same host individuals used for oviposition, but in most cases host feeding is destructive and can be responsible for substantial levels of host mortality. Destructive host-feeders select smaller host individuals for host feeding because they are unsuitable for parasitism, and then use larger hosts for oviposition.

**Interactions among Parasitoids**

As the majority of host insects are attacked by several different parasitoid species, a variety of trophic and competitive interactions occur among them. Hyperparasitism is a trophic interaction that occurs when a secondary parasitoid parasitizes a primary parasitoid (see section on Hyperparasitism). Competitive interactions include superparasitism and multiparasitism. Superaesperitism occurs with more than one oviposition by one or more individuals of the same parasitoid species into the same host individual. The resulting intraspecific competition between parasitoid larvae leads to the death of all but one individual in the case of solitary parasitoids, and to male bias in the sex ratio and reduced adult size among the progeny of gregarious parasitoids. Multiparasitism is the corresponding interspecific competition that results from oviposition by two or more different parasitoid species in the same host individual. The outcome of multiparasitism is often indeterminate; it can favor the species that attacked first but it can also be fixed with a strong competitor being the victor whatever the sequence of attack. A particularly interesting form of the latter is cleptoparasitism, in which the success of host location by a cleptoparasitoid is facilitated by its response to chemical markers used by an inferior competitor to avoid reattacking a previously parasitized host. The cleptoparasitoid is able to steal the host from its inferior competitor by having an aggressive first-instar larva that is able to kill the original occupant of the host.

**Clutch Size and Sex Ratio**

One of the most important “decisions” for a gregarious parasitoid is how many eggs to lay on a particular host. Clutch size increases with the size and quality of a host, but decreases as the rate of host encounters increases and often decreases with the age of the parasitoid. Gregarious parasitoids adjust clutch size to match the quality and frequency of hosts encountered, thereby balancing the need to maximize reproductive output and to minimize intraspecific competition among the larval brood. As hymenopteran parasitoids use haplodiploid reproduction (males develop from unfertilized haploid eggs, females from fertilized diploid eggs), parent females can choose the sex of their offspring. Solitary parasitoids tend to allocate male eggs to small or low quality hosts and female eggs to large or high-quality hosts, but typically produce a balanced sex ratio. In contrast, female bias is frequent in the sex ratio of gregarious parasitoid broods where the probability of sibling mating is high and sons compete within broods for mates. Thus, local mate competition within broods of gregarious hymenopteran parasitoids leads to the allocation of just enough sons to be able to mate effectively with all the daughters in the brood.

**PARASITOID COMMUNITIES**

Parasitoids can utilize hosts in a variety of ways to support the development of their progeny. For example, a lepidopteran host such as the gypsy moth (*Lymantria dispar*) is attacked at different stages through its life cycle by a series of 13 species in 6 parasitoid guilds (Fig. 1). Very few terrestrial insects escape the attention of parasitoids, exceptions being the few taxa that are either too small (e.g., Adelgidae) or too well defended (e.g., *Dactylopius* mealybugs). However, the parasitoid load, or number of parasitoid species supported by a host species, varies tremendously. For example, the average number of parasitoid species associated with an aphid is 1.7 in comparison with 12.4 for bivoltine Lepidoptera. In contrast, aquatic insects support relatively few parasitoids and are most vulnerable during the nonaquatic stages of their life cycle. It is notable, however, that a few mostly very small parasitoids are known to be truly aquatic using their legs or wings to swim through the water to locate submerged host eggs.

![FIGURE 1 The parasitoid assemblage associated with the gypsy moth (*Lymantria dispar*) as it passes through its life cycle in Eurasia. Arrows indicate the host stages attacked and killed by the six different guilds of parasitoid species.](image)

Parasitoid load is determined by a combination of phylogeny, feeding niche, abundance, and chemical defense. The absence of a pupal stage greatly reduces the parasitoid load of a host, but even among the holometabolous insects, beetles consistently support far fewer parasitoids than moths, indicating the importance of host phylogeny. The feeding niche of a larval host also has an important influence on parasitoid load, being greatest amongst those hosts that have restricted mobility but poor protection (e.g., leafminers, casebearers) and reduced either by greater mobility (e.g., external feeders) or by greater protection (e.g., borers). The greater the abundance of a host, the greater its parasitoid load, as a number of less specialized parasitoids and even incidental species are able to make use of an abundant resource. Then, finally, the sequestration of defensive plant chemicals by externally feeding host larvae appears to offer a further line of defense that can lead to a reduction in parasitoid load.

It has frequently been suggested that parasitoid diversity declines from temperate zones to the tropics. Such a pattern is evident for the very species rich superfamily, the Ichneumonoidae (Ichneumonidae and Braconidae), but is not upheld among the Chalcidoidea. Nonetheless, the decline, or absence of an increase, in overall parasitoid diversity in the tropics is an interesting anomaly in comparison to the increase in diversity of their insect hosts in the tropics. An increased level of predation (notably by ants) in the tropics, a general reduction in the abundance of each host species due to fragmentation of resources, and a greater availability of plant-based chemical defenses for host insects to use for protection may all help to account for this anomaly.

Parental Care

Further Reading

Parental Care

Michelle Pellissier Scott
University of New Hampshire

Parental care in insects ranges from covering eggs with a protective coating to remain in the female’s body mass; spermatophore nutrients have been shown to be a spermatophore during copulation that may be as much as 40% of a male’s body mass. Male katydids, for example, provide spermatophore nutrients that are used to form the egg case. In some insects, paternal care is provided by males alone. For example, eggplant lace bugs, Gargaphia solani, guard their eggs and gregarious nymphs until maturity; if a predator approaches, the female rushes at it, fanning her wings.

In some insects, maternal investment takes the form of a period of internal development. Among insects, cockroaches carry this investment to the extreme and show the entire range of reproductive modes and maternal care. The oviparous German cockroach, Blattella germanica, carries her egg sac externally until nymphs hatch, and Blattella vaga produces maternal secretions on which her neonates briefly feed. In ovoviviparous species, eggs develop inside the body of the mother and have sufficient yolk to complete development. The viviparous cockroach, Diploptera punctata, displays a remarkable form of parental care. Females undergo a 60-day “pregnancy” during which highly nutritious milk, secreted from the walls of the brood sac, is ingested orally by the developing young. At birth, young are in an advanced state of development, and care is terminated shortly after birth.

Paternal Care

Exclusive paternal care of eggs or young is restricted to about 100 species of insects, almost all within the Hemiptera. For example, in a giant water bug, Abedus herberti, females adhere their eggs to the wing covers of a male, who stops feeding and instead spends his time until eggs hatch aerating and protecting them from predators. Males of the subsocial spider-hunting wasp, Trypoxylon superbum, are an unusual example from the Hymenoptera. After females provision and seal the cells, males remain to guard nests against parasitism and ant predation.

Indirect paternal contributions to offspring are widespread in a number of taxa. Males may invest in offspring with nutritional offerings to the female in the form of nuptial gifts of captured prey items or even their own bodies. They may transfer proteins or protective substances in a spermatophore. Male katydids, for example, provide a spermatophore during copulation that may be as much as 40% of their body mass; spermatophore nutrients have been shown to...

⁵Number of orders in which parents exhibit the behaviors listed.

⁶Key: EP, either or both parents cover eggs before abandonment; EC, either or both parents remain and guard eggs; YC, either or both parents remain with young and care for them; YP, either or both parents provision young or regurgitate food to them; OV, females extend development internally and are ovoviviparous, larviparous, or viviparous; PZ, males provide prezygotic investment.

Form of Parental Care

Maternal Care

The most rudimentary form of maternal care is provided by females that incorporate toxins into their eggs, oviposit them in protected places, or cover their eggs with a hard shell or wax-like compound before abandoning them (Table 1). For example, embiopteran webspinner females, Antipalurae urichi, cover their eggs with layers of macerated bark and other substrate materials and silk to protect them from hymenopteran parasites. Webspinner maternal care is more complex and extensive than egg protection, and these females construct silk galleries and remain with their eggs and nymphs.

Many species of insects guard their young against predators by using chemicals or defensive behaviors. Care may end when young hatch, or it may extend until larvae or nymphs are mature. For example, eggplant lace bugs, Gargaphia solani, guard their eggs and gregarious nymphs until maturity; if a predator approaches, the female rushes at it, fanning her wings.

A second major function of maternal care is to facilitate feeding. A plant-feeding membracid bug, Umbonia crassicornis, cuts slits in the bark with her ovipositor to facilitate nymphal feeding. She remains with the nymphs, actively maintaining feeding aggregations until the young reach adulthood. Parental care often comprises a suite of adaptations of multiple behaviors that serve multiple functions. A well-cited example of a complex of behaviors is the female salt-marsh beetle, Bledius spectabilis, which maintains a burrow shaped in a way that prevents flooding during high tide. She also provisions the young with algae, prevents mold, and protects the vulnerable first instars from attack by parasitic wasps.

In some insects, parental investment takes the form of a period of internal development. Among insects, cockroaches carry this investment to the extreme and show the entire range of reproductive modes and maternal care. The oviparous German cockroach, Blattella germanica, carries her egg sac externally until nymphs hatch, and Blattella vaga produces maternal secretions on which her neonates briefly feed. In ovoviviparous species, eggs develop inside the body of the mother and have sufficient yolk to complete development. The viviparous cockroach, Diploptera punctata, displays a remarkable form of parental care. Females undergo a 60-day “pregnancy” during which highly nutritious milk, secreted from the walls of the brood sac, is ingested orally by the developing young. At birth, young are in an advanced state of development, and care is terminated shortly after birth.
be important to the reproductive success of females. Male arctiid moths, *Uitehisia ornatrix*, provide a different sort of indirect paternal contribution when they transfer protective pyrrolizidine alkaloids to females during mating. These alkaloids are passed to the eggs, which are then unappealing to predators.

**Biparental Care**

Biparental care of offspring is restricted to beetles, termites, and cockroaches, and may include earwigs. It can be very elaborate and extensive. For example, the woodroach, *Cryptocercus punctulatus*, and all termites form life-long family associations. Male and female construct and guard an extensive tunnel system or a nest, and they protect and facilitate feeding of young until the offspring reach maturity. Woodroaches care for a single brood for 3 or more years, feeding them on hindgut secretions containing symbiotic fauna necessary to digest their wood diet. In many of the “higher termites” (e.g., Rhinotermitidae and the Termitidae), few or no workers or soldiers reproduce; rather, they remain as alloparents. Task specializations based on morphology and sex is strongly expressed. Primary reproducitives may live 20 years or more, whereas workers and soldiers often live less than a year.

In another well-studied example, male and female burying beetles cooperate to bury and prepare small vertebrate carcasses to serve as the food source for their young. Both parents treat the carcass with preservative anal and oral secretions; both regurgitate semidigested protein to the begging larvae (Fig. 1). In the burying beetle, *Nicrophorus orbicollis*, males commonly remain in the nest until larvae are half-grown and the carcass is substantially consumed; females remain until larval development is complete and may even accompany larvae during the wandering stage. As with most species with biparental care, male and female burying beetles do not have exclusive, specialized tasks. When both parents are present, females feed larvae more often than males; but if the male becomes a single parent, he compensates for the loss of a mate with increased feeding rates. However, in another species with biparental care, the dung beetle, *Cephalodesmius arniger*, there is some task specialization. Male and female form a permanent pair-bond to rear one brood in a subterranean nest. Males forage outside for plant material that females process into brood balls into which they lay a single egg. Males continue to forage, and females enlarge the brood ball as the larvae grow.

**EVOLUTION OF PARENTAL CARE**

Problems of resource exploitation are central to the evolution of parental care. The spatial and temporal distribution of food sources and their physical and ecological characteristics have shaped the convergent life-history characteristics and behavior of insects that provide care. The dispersion, quality, and persistence of resources influence how sedentary or nomadic a species is and what competitors, predators, and parasites it must deal with. These in turn, determine if parental care can be an effective strategy; that is, when there is something that parents are able to do to increase the survival of young. Parental care is often associated with territoriality and spatial fidelity. Thus, wood is a stable resource that provides both food and shelter but is difficult to exploit. Once a nest has been established, it can be defended; adults are often necessary to inoculate young with gut symbionts to digest wood or to otherwise prepare it for consumption. Dung and carrion feeders exploit a rich but unpredictable resource that can be buried to reduce competition. Foli vores may be somewhat more nomadic and are usually exposed to heavy predation and parasitism. Parental defense of eggs or young can be effective and can considerably improve survival. Predators and detrivores often depend on patchy resources. Parents may collect and transport food to young that are sequestered in a sheltered nest or burrow.

Parental care is also favored by limited lifetime reproductive opportunities. Valuable but unpredictable resources (carrion or dung) or resources that are hard to acquire (a tunnel system) are especially potent selective forces for parental care. Both involve the construction of elaborate nests that represent a substantial investment. These resources are associated with the production of fewer and smaller clutches of larger young. Burying beetles, dung beetles, and woodroaches produce on average only a single brood in a lifetime. Biparental care is associated with these species both because male assistance in guarding and provisioning can often greatly increase the survival of the young and because there are few additional mating/breeding opportunities. The improved survival of his young offsets the male parent's potential gain if he were to leave and search for rare carrion or females when most individuals in the population are mated.

Exclusive paternal care is rare in insects because external fertilization is rare. Internal fertilization both reduces the certainty of paternity if females have multiple mates and dissociates the father from his offspring when they appear. These factors discourage paternal care and encourage maternal care in other taxa. Exclusive paternal care is associated with fidelity to a nest site, including a “nest” of his own wing covers, and with the ability of the male to guard the clutch of multiple females. Under these conditions, a male does not forgo additional matings; in fact, the demonstration of paternal behavior may increase his attractiveness to females.

No single factor or suite of factors can predict the evolution of care. Parental behaviors serve multiple functions, and seemingly the same environments and resources harbor parental and nonparental members of a family. In addition, the evolution of parental care involves a suite of secondary changes, including greater dependence on the part of the young and the loss of adaptations for independence.
from parents. Burying beetle larvae, for example, have no defenses and are initially dependent on parental regurgitations unlike their carrion beetle relatives that are fully armored and independent.

Thus, insects not only show a variety of forms of parental care, but also many demonstrate behavioral plasticity that allows them to adjust the level or form of care to changing circumstances, such as the loss of a mate. As more examples come to light and familiar ones are better studied, it becomes clear that the functions of care are also varied and complex even within a single species. This variety is not surprising, since parental care has evolved independently many times in insects in response to different selective forces.

Parthenogenesis in Insects and Mites

Benjamin B. Normark

University of Massachusetts, Amherst

Lawrence R. Kirkendall

University of Bergen, Norway

Specialized Terms

apomixis (-mictic) Parthenogenesis in which eggs are produced without meiosis.

automixis (-mictic) Parthenogenesis in which eggs undergo meiosis.

diploid Having two complete sets of chromosomes (like a typical adult animal).

haploid Having one complete set of chromosomes (like a typical egg or sperm cell).

haplodiploidy (arrhenotoky) A genetic system in which unfertilized, haploid eggs develop into males and fertilized, diplloid eggs develop into females.

parthenogenesis (-genetic) Reproduction without fertilization (in the sense of fusion of sperm and egg nuclei).

polyploid Having more than two complete sets of chromosomes (e.g., triploid, having three sets, tetraploid, having four sets).

pseudogamy (-mous) A form of sperm-dependent parthenogenesis in which eggs require activation by entry of sperm, but only maternal chromosomes are expressed and passed on.

thelytoky (-kous) Parthenogenesis in which only female offspring are produced.

tychoparthenogenesis (-genetic) The rare or occasional production of eggs that start developing without having been fertilized.

Most insects, like most other animals and plants, reproduce sexually. Each gamete (egg or sperm) contains one complete set of chromosomes, and the fusion of a sperm and an egg results in a zygote, which then develops into a new individual. In some insects, however (as in many other groups), offspring can develop from an egg alone, without sperm, a process known as parthenogenesis (partheno-, virgin, + -genesis, origin, from gen-, to be produced).

Insects have always played a central role in our understanding of parthenogenesis; Charles Bonnet first demonstrated the occurrence of this phenomenon in the 1740s by careful experiments with isolated females of three species of aphids. During the next hundred years, further experiments with aphids and with bagworm moths, drone bees, and silkworm moths verified the reality of virgin birth, though the term “parthenogenesis” was not coined until the 1840s. Parthenogenesis has fascinated biologists since it was first described. Especially interesting are life cycles in which males and mating are completely lacking, because they call into question cherished assumptions about the importance of genetic variability in nature.

FORMS OF PARTHENOGENETIC REPRODUCTION

Thelytoky and Arrhenotoky

The technical term for parthenogenesis in which all the unfertilized eggs develop into females is “thelytoky.” Thelytoky represents a radical departure from ordinary sexual reproduction, and has dramatic consequences for individuals, populations, and species. It allows females to: (1) pass along their successful genotypes to all of their offspring; (2) produce only daughters, maximizing the rate of increase; and (3) eliminate the need for finding or attracting a mate. Sexual reproduction, in contrast, results in: (1) offspring with a diversity of genotypes; (2) production of males, which cannot themselves produce offspring; and (3) an inability to reproduce without males being locally present and without diverting a certain amount of time and energy to the mating process.

Faculative or obligate thelytoky occurs sporadically but is found in over 80 families of the superclass Hexapoda, and is also scattered
Parthenogenesis in Insects and Mites

throughout the mites (Acari: we use mites as a collective term for all acarines, including ticks). Generally, thelytoky occurs as scattered instances in hexapods, though there are several families of mites (in the suborder Oribatida) that are strictly thelytokous.

Thelytoky is found in most orders of hexapods but the orders with the highest frequency of strictly thelytokous species are Thysanoptera, Psocoptera, Hemiptera (especially in the suborder Sternorrhyncha), and Hymenoptera. The largest insect orders (Lepidoptera, Diptera, Coleoptera, Hymenoptera) have a low incidence of thelytoky overall, but very high rates of thelytoky in some families, such as weevils (Coleoptera: Curculionidae), bagworm moths (Lepidoptera: Psychidae), and chironomid midges (Diptera: Chironomidae). Thelytoky has never been reported from several species-poor orders (Protura, Diplura, Zoraptera, Grylloblattodea, Mantophasmatodea, Megaloptera, Raphidioptera, Mecoptera, Siphonaptera), or from Plecoptera, and there have been only unsubstantiated reports of thelytoky in Dermaptera, Neuroptera, and Strepsiptera.

Most of this article deals with the various types of thelytoky and their consequences. But it is important to note that there is another, very different kind of parthenogenesis found in insects and mites: arrhenotoky, in which the individuals that develop from fertilized eggs are male. Almost always these parthenogenetically produced males are haploid, and thus arrhenotoky is commonly referred to as “haplodiploidy”. In two orders (Hymenoptera and Thysanoptera), haplodiploidy is the only known sexual system, and it is widespread in prostigmatid and astigmatid mites. Haplodiploidy also occurs in some scale insects (Hemiptera: Margarodidae), whiteflies (Hemiptera: Aleurodidae), some bark beetles (Curculionidae), and the bizarre beetles of the monotypic family Micromalthidae. Although arrhenotokous males arise parthenogenetically, a haplodiploid species as a whole reproduces sexually, and the genotype of each parthenogenetically produced male is a unique recombinant product of meiosis. Thus, arrhenotoky has more in common with typical sexual systems than with other forms of parthenogenesis and therefore we do not dwell on it in this article.

One also sometimes comes across the term “deuterotoky,” meaning the parthenogenetic production of both males and females. For instance, in some species that usually reproduce by thelytoky, a very small percentage of individuals develop into males, which may or may not be able to mate. The term deuterotoky is also sometimes applied to cyclic and facultative parthenogenesis, which we discuss later in this article. For the rest of this article, and in most of the scientific literature, the word “parthenogenesis” can be assumed to refer to thelytoky.

**Apomixis and Automixis**

The most fundamental feature of the life cycle of sexual eukaryotes is the alternation between meiosis, in which the DNA content of a diploid nucleus is halved, and syngamy, in which two haploid nuclei (usually from a sperm and an egg) fuse to form a new diploid nucleus. In many insects, this ancestral cycle has been replaced by apomixis, in which there is neither meiosis nor syngamy; instead, new individuals arise from mitotically produced cells that are genetically identical (except for new mutations) to the parent that produced them. Genetically speaking, apomixis is the simplest form of parthenogenesis.

Another form of parthenogenesis is automixis, in which meiosis does occur, but eggs nonetheless develop without being fertilized by sperm. Instead of relying on sperm to restore the haploid egg to diploidy, there are a variety of different mechanisms for restoring the egg’s diploidy (Fig. 1). Some of these do so by duplicating the genome of a single cell; others by fusion of two different cells. The exact mechanism of diploidization determines whether homozygosity is enforced in every generation or heterozygosity is maintained for at least some time.

**FIGURE 1** Three forms of automictic parthenogenesis and their genetic effects. For simplicity, only a single chromosome and a single crossing-over event are illustrated. The two shades of blue represent the mother’s two chromosome sets. “I” indicates the first meiotic division, “II” the second. (A) The second polar nucleus fuses with the egg nucleus, a process called “terminal fusion”; found in some Orthoptera, Hemiptera, Thysanoptera, Diptera, and Hymenoptera. (B) A derivative of the first polar body fuses with the egg nucleus; found in Lepidoptera. (C) The two central polar nuclei fuse, “central fusion”; found in Lepidoptera, Diptera, and Hymenoptera. Note that in A, heterozygosity is lost immediately in regions adjacent to centromeres, while in B and C heterozygosity is retained in regions adjacent to centromeres. Farther from the centromere, probability of loss of heterozygosity is closer to 50%, depending upon crossing over, for all three systems. More extreme systems (retaining all or no heterozygosity) are described in the text.
At one extreme are the automictic mechanisms that are genetically equivalent to apomixis, preserving the parent’s entire genome with all of its heterozygosity. This can happen if the entire genome is duplicated before meiosis ("premeiotic doubling," Orthoptera, and Coleoptera), or if the two products of meiosis fuse (Collembola, Lepidoptera). At the other extreme is the instantaneous enforcement of homozygosity across the entire genome, which occurs when the haploid egg nucleus divides and then fuses again ("gamete duplication," in some Orthoptera, Hemiptera, Lepidoptera, Diptera, and Hymenoptera). In between these extremes are automictic mechanisms involving the fusion of two of the four haploid products of meiosis, which result in preservation of heterozygosity at some loci but loss of heterozygosity at others. Figure 1 illustrates three examples.

All of the above forms of automixis are considered to be parthenogenetic in the traditional sense. However, there is another form of reproduction that involves only a single parent—self fertilization, which is the fusion of egg and sperm cells from a single individual. Only hermaphrodites, producing both eggs and sperm, can self-fertilize, and hermaphroditism is exceedingly rare in insects and mites. Indeed, only three species—all of them scale insects in the genus *Icerya*—are known to be hermaphroditic, and all three regularly reproduce by self-fertilization. Self-fertilization results in a loss of about 50% of the parent’s heterozygosity in every generation.

**Obligate, Cyclic, and Facultative Parthenogenesis**

An obligately parthenogenetic lineage is one that has no means of gene exchange with other lineages, and no means of reproduction other than parthenogenesis. But many insects have more complex life cycles that encompass both sexual reproduction and parthenogenesis. Cyclic parthenogenesis involves an alternation of one generation of sexual reproduction with one or more generations of parthenogenetic reproduction. The term facultative parthenogenesis potentially covers a number of possible life cycles, but always implies that a given individual can reproduce either sexually or asexually. In some groups of insects, sexual reproduction is the norm, but if a clump of eggs is left unfertilized for sufficiently long, a small proportion of them will begin development. Rare overall in insects and mites, this type of facultative parthenogenesis—often called tychoparthenogenesis—is rather common in mayflies (*Odonata*) and in some polyneopteran orders (Orthoptera, Blattodea, Phasmatodea, and Mantodea) and also occurs in Pscoptera, Lepidoptera, and Diptera. The proportion of eggs that develop successfully into adults is low, often extremely low; hatching of unfertilized eggs of tychoparthenogenetic mayfly species varies from 4 to 8%, but for caught-in-the-wild *Drosophila mercatorum*, the chance of an unfertilized egg developing is only about 1/10,000. Where the cytology of tychoparthenogenesis is known, it is always automictic. Tychoparthenogenesis shows that a capacity for parthenogenesis exists within many normally sexual species, and artificial selection experiments with drosophilids and stick insects have shown that there is genetic variation underlying the capacity for parthenogenesis. The experimenters were able to increase by up to a thousand-fold the proportion of eggs that develop parthenogenetically.

The categories of cyclical and facultative parthenogenesis intergrade when the number of parthenogenetic generations intervening between sexual ones is variable, as in certain cicadomyid midges, all aphids, and micromalthid beetles, all of which switch from parthenogenesis to sexuality in response to environmental cues. But in cyclic parthenogenesis, there is never more than one sexual generation before the switch back to parthenogenesis occurs. Only cynipid gall wasps are regularly cyclical in the sense that there are never two successive parthenogenetic generations, although in cynipids, as in every other group with cyclic or facultative parthenogenesis, obligately parthenogenetic lineages have arisen multiple times.

One unusual system that deserves mention here is polyembryony. It is similar to cyclical parthenogenesis in that there is an asexual proliferation of offspring in between successive sexual generations, but polyembryony is not strictly speaking a form of parthenogenesis (which involves unfertilized eggs). Instead it is a process of "vegetative" fission of multicellular embryos. As many as 2,500 individuals can develop in this way from a single egg. Polyembryony in insects occurs regularly in parasitoids in a few families of Hymenoptera and in Strepsiptera, and has been reported to occur sporadically in grasshoppers. Polyembryonically produced siblings will be genetically identical to each other, but not to their parents.

A remarkable feature of both cyclic parthenogenesis and polyembryony is the differentiation in some cases of a sterile "soldier" morph, analogous to the soldier caste often found in eusocial insects. In some cyclically parthenogenetic aphids, soldiers attack intruders into the plant gall that houses the aphid colony. In polyembryonic wasps, the soldiers are traditionally called "teratogenic larvae" and may attack other wasp larvae within a host caterpillar.

**Mating-Dependent Systems**

Thelytoky is characterized by absence of mating; indeed, the first indication that an insect species might be parthenogenetic is the observation that no males exist in collections. In pseudogamy (also called gynogenesis or sperm-dependent parthenogenesis), mating with males of the same or a different species is necessary; egg development is activated by contact with or penetration by sperm. After entry into the egg, paternal chromosomes degenerate, and only maternal chromosomes survive in the offspring. This process can be considered pseudofertilization because offspring develop clonally, and all will be female, and is thus genetically a form of parthenogenesis. Pseudogamy is difficult to observe, since mating does occur; it is usually discovered by noting that mated females regularly produce all-female broods. In insects, pseudogamy is found only in Coleoptera (two origins in *Ips* bark beetles and one species of ptilid beetle), two species of Lepidoptera, and in one species each of Collembola, Orthoptera, and Hymenoptera. Possible cases of pseudogamy in acarines have not been confirmed.

In hybridogenesis, the paternal genome is excluded during oogenesis such that ova have only maternally derived chromosomes. The intact maternal genome is paired in each new generation with sperm from males of a sexually reproducing host species. Such hemi-clonal reproduction was first discovered in vertebrates, and to date is known in only the genus *Bacillus* (order Phasmatodea). Although classed along with pseudogamy as "sperm-dependent parthenogenesis," it is actually a hybrid form of reproduction; it combines sexual reproduction with respect to spermatogenesis, with nonrecombining, clonal maternal genomes.

An extraordinary system similar to hybridogenesis has recently been discovered in the ant *Wasmannia auropunctata*. Ants are typically haplodiploid: unfertilized eggs develop into males and fertilized eggs develop into females which may be either sterile workers or reproductive (queens). But in *W. auropunctata*, queens lay a certain proportion of apomictic diploid eggs which develop into the next generation of queens, as clones of their mother. Fertilized eggs develop, for the most part, into sterile workers. But in a proportion of fertilized eggs, the father’s genome replaces the mother’s completely (an unusual reversal of pseudogamy that is usually referred
to as androgenesis), resulting in haploid male clones of the father. Thus, males and females both reproduce clonally, and the hybrids between them are sterile.

Finally, regular inbreeding between close relatives has genetic consequences very similar to those of self-fertilization or some forms of autotomic parthenogenesis: extreme inbreeding (such as brother–sister mating) should result in homozygous lineages within a few generations. Because of this, some evolutionary biologists include extreme inbreeding under a broader definition of parthenogenesis, despite the involvement of mating. The similarity to autotomic parthenogenesis is enhanced by the fact that species with regular sibling mating usually produce only one or a few males per brood, such that populations consist mostly of females. An important difference from autotomic parthenogenesis is that rare outcrossing—which can have enormously important evolutionary consequences—is likely to occur from time to time in the case of extreme inbreeders when multiple females colonize a small patch, but may be much rarer or entirely absent in autotomic parthenogenesis. The taxonomic distribution of extreme inbreeding is not precisely known; it has evolved frequently in bark beetles (Scolytinae), occurs sporadically in Hymenoptera (where it has been intensively studied in parasitic wasps, but also is absent in automictic parthenogenesis). The wingless stick insect genus Bacillus provides an excellent example. Endemic to the Mediterranean region, the genus includes two sexual species, B. rossius (which also has thelytokous females) and B. grandit (strictly bisexual), and a thelytokous lineage known as B. atticus. Where two or three species occur in sympatry (as on the island of Sicily), hybridization occurs, which has resulted in the production of two hybridogens, the diploid autotomic B. whitei, and the tritypic apomictic B. lynceorum. Each Bacillus hybrid uses a different egg maturation process; however, they share the common cytological feature of an intramiotic extra-doubling of DNA, resulting in four-stranded chromosomes, which enables the meiotic process to produce balanced chromosome complements in gametes.

A few studies have revealed something of the genetic basis for parthenogenesis, and it is likely that it will prove as varied as are the mechanisms of parthenogenesis. In Rhopalosiphum padi (the bird cherry-oat aphid), obligate parthenogenesis appears to be determined by a single locus, and is recessive to cyclical parthenogenesis. In contrast, the predisposition for parthenogenesis in Drosophila mercatorum was induced by genes at a number of independent loci. Some lineages of R. padi reproduce largely by parthenogenesis but do produce some males (although no sexual females). There is some evidence that, in several cases, genes carried by these males have “converted” cyclical parthenogenetic lineages of R. padi into obligate parthenogens.

In many cases, what was thought to be a single parthenogenetic insect lineage has turned out to consist of a variety of genetically distinct clones, each of which was derived independently from the ancestral sexual populations. These clones may vary in ploidy and in their genetic composition, and as a result parthenogenetic populations can exhibit considerable diversity in morphology, behavior, and life history. Although much less than the variability within an outbreeding sexual population (in which each individual is genetically unique), the clonal polymorphism within such thelytokous populations implies a potential for adaptation to a wider range of ecological conditions than would be possible for an invariant population. In other parthenogenetic populations, evidence for genetic variation is lacking, and what appears to be a single clone with a “general-purpose genotype” is able to thrive in a wide range of environments. Some insect species with very long lists of host plants appear to consist of a single parthenogenetic lineage with remarkably little genetic diversity.

**PATTERNS IN PARTHENOGENESIS: BIOGEOGRAPHY AND ECOLOGY**

Many parthenogenetic hexapods and mites, whether sexual or parthenogenetic, are common and abundant. In many cases, clonal forms are more widespread than their closest sexual relatives. Frequently, parthenogens have different geographic distributions from the sexual taxa to which they are most closely related, a phenomenon known as geographic parthenogenesis. Geographic parthenogenesis in hexapods (but not acarines) often takes the form of parthenogens being closer to the poles (a latitudinal gradient) and at higher altitudes. Thus, the bisexual forms of several European
weevils (e.g., Otiorhynchus seaber, Polydrosus mollis) and Solenobia bagworm moths are found only in a few alpine sites thought to have been glacial refugia, whereas thelytokous forms of the same species are widespread in central and northern Europe. Psocopteran species with both thelytokous and bisexual forms follow a similar pattern in North America.

A number of ecological patterns have been elucidated to describe the distribution of parthenogenesis in hexapods and mites. For example, parthenogenesis seems to be associated with low dispersal capabilities (with winglessness in Phasmatodea, Orthoptera, and Lepidoptera) and disturbed or ephemeral habitats (parthenogens often being categorized as “weedy”). Among mites, clusters of thelytokous taxa (including entire families and genera of “Endoestigmatida,” Mesostigmatida, Prestigmatida, and Oribatida) are strongly associated with soil-dwelling (particularly with stable soil horizons), and thelytokous (vs. nonthelytokous) oribatids are strongly over-represented on oceanic islands. In Collembola, too, there is a strong association between soil-dwelling and thelytoky, and the only cockroach with thelytokous races (Pyenoscelus indicus) is a burrower.

CONCLUSION

Parthenogenesis encompasses a variety of reproductive systems and is often considered synonymous with “clonal reproduction.” Indeed, the central feature of thelytokous parthenogenetic reproduction is that maternal genomes are normally passed on intact through a series of all-female broods. It is important to emphasize, however, that there are forms of automictic parthenogenesis in which recombination is possible, and that in pseudogamous parthenogenesis, mating is necessary even though reproduction is essentially clonal.

Parthenogenetic reproduction requires a mechanism to circumvent the normal halving of ploidy that results from gametogenesis. In insects, many mechanisms for the preservation or restoration of diploidy have evolved. Either meiosis is eliminated (apomixis) or diploidy is restored (autonixis) during or after meiosis. Apomixis and some forms of automixis result in maintenance of heterozygosity, whereas other forms of autonixis result in instant homozygosity. Far from being a reproductive curiosity, parthenogenesis has arisen in most insect groups, and many parthenogenetic species are both abundant and widespread. Many economically important pests of agriculture and horticulture are parthenogenetic. Thelytokous and pseudogamous taxa are so ecologically successful that we cannot simply view them as reproductive aberrations. The success of parthenogenetic lineages poses something of a paradox. Either genetic variation in nature is less important than we sometimes assume, or parthenogenetic lineages are more genetically diverse than we suppose.

The study of parthenogenesis can illuminate one of the central problems in biology, that of explaining the ubiquity of sex and recombination, and the adaptive significance of the laws of genetics, by revealing when and where in nature the laws of genetics are suspended or overthrown. Insects and mites, because of their short life cycles and often large population numbers, are ideal organisms for studying the evolutionary and ecological consequences of parthenogenesis.

Pathogens of Insects

Brian A. Federici
University of California, Riverside

Pathogens are viruses or microorganisms that cause disease. Like all other organisms, insects are susceptible to a variety of diseases caused by pathogens. Many of these pathogens cause diseases that are acute and fatal and therefore are used as models to study processes of infection and pathogenesis as well as to control populations of insects that are pests or vectors of plant and animal diseases. Generally, insect pathogens have a relatively narrow host range and thus are considered to be more environmentally friendly than synthetic chemical insecticides. The pathogens that cause disease in insects fall into four main groups: viruses, bacteria, fungi, and protozoa. This article discusses the primary biological properties of each of these pathogen groups, with specific emphasis on how these pathogens have been used to benefit humans.

VIRUSES

Viruses are obligate intracellular parasites, meaning that they can reproduce only in living cells and are composed in the simplest form of a nucleic acid, either DNA or RNA, and a protein shell referred to as the capsid. More complex viruses also contain a lipoprotein envelope. Insect viruses can be cultured in living hosts (in vivo) or in cultured insect cells (in vitro). In general, insect viruses are divided into two broad nontaxonomic categories, the occluded viruses and the nonoccluded viruses. Occluded viruses are so named because after formation in infected cells, the mature virus particles (virions) are occluded within a protein matrix, forming paracrystalline bodies that are generically referred to as either inclusion or occlusion bodies. In the nonoccluded viruses, the virions occur freely or occasionally form paracrystalline arrays of virions that are also known as inclusion bodies. These, however, have no occlusion body protein interspersed among the virions.

The five most commonly encountered types of insect viruses are iridoviruses, cytoplasmic polyhedrosis viruses, entomopoxviruses, ascoviruses, and baculoviruses.

Iridoviruses

Nonoccluded viruses with a linear double-stranded DNA genome, the iridoviruses (family Iridoviridae) produce large, enveloped,
icosahedral virions (125–200 nm) that replicate in the cytoplasm of a wide range of tissues in infected hosts. Virions form paracrystalline arrays in infected tissues, imparting an iridescent hue to infected hosts, from which the name of this virus group is derived. Over 30 types are known, and these have been most commonly reported from larval stages of Diptera larvae, such as mosquito larvae, as well as from larvae of Coleoptera and Lepidoptera. Generally, the iridoviruses occur very broadly, and they are known from other invertebrates, such as isopods, as well as from certain vertebrates including frogs and fish. Observations of natural occurrence in host field populations suggest that one host range of each type is quite narrow, although in the laboratory iridoviruses are readily transmitted from one insect species to another by inoculation. Prevalence and mortality rates in natural populations of host insects are typically less than 1%.

**Cytoplasmic Polyhedrosis Viruses**

The cytoplasmic polyhedrosis viruses (family Reoviridae) are occluded double-stranded RNA viruses with a genome divided into 9 or 10 segments of RNA. These viruses, commonly referred to as CPVs, cause a chronic disease and reproduce only in the stomach of insects, where typically they form large (ca. 0.5–2 μm) polyhedral to spherical occlusion bodies in the cytoplasm of midgut epithelial cells. Infection in early instars retards growth and development, extending the larval phase by weeks. The disease is often fatal. In advanced stages of disease, the infected midgut is white rather than translucent brown, because of large numbers of accumulated polyhedra. This virus type is relatively common among lepidopterous insects and among dipterous insects of the suborder Nematocera (e.g., mosquitoes, blackflies, midges). CPVs are typically easy to transmit by feeding to species that belong to the same family of the host from which they were isolated, and thus the host range of this virus type is quite broad.

**Entomopoxviruses**

The entomopoxviruses (family Poxviridae) are occluded double-stranded DNA viruses that produce large, enveloped virions (150 nm × 300 nm) that replicate in the cytoplasm of a wide range of tissues in most hosts, causing an acute, fatal disease. Occlusion bodies vary from being oval to spindle shaped and generally occlude 100 or more virions. These viruses have been most commonly reported from coleopterans, from which there are over 30 isolates, but they are also known from lepidopterous, dipterous (midges), and orthopterous (grasshoppers) insects. This virus type is easily transmitted by feeding, although where the experimental host range of individual isolates has been tested, it has been found to be relatively narrow, generally being restricted to closely related species. Insect poxviruses are related to vertebrate poxviruses, such as the variola virus, the etiological agent of smallpox, and they may be the evolutionary source of the vertebrate poxviruses.

**Ascoviruses**

The ascoviruses (Ascoviridae) are a new family of DNA viruses, at present known only from larvae of species in the lepidopteran family Noctuidae, where they have been reported from several common pest species such as the cabbage looper, cotton budworm, corn earworm, and fall armyworm. Ascoviruses cause a chronic, fatal disease of larvae. The virions of ascoviruses are large (130 nm × 400 nm), enveloped, and reenform to bacilliform in shape; they exhibit complex symmetry and contain a circular, double-stranded DNA genome. During the course of ascovirus disease, large numbers of virion-containing vesicles accumulate in the blood of infected caterpillars, changing its color from translucent green to milky white. These virion-containing vesicles are formed by a unique developmental sequence resembling apoptosis (cell death) in which each infected host cell cleaves into a cluster of vesicles as virion assembly proceeds.

An interesting ascovirus feature is that transmission from host to host depends on vectoring by female endoparasitic wasps. Ascoviruses are very difficult to transmit by feeding, with typical infection rates averaging less than 15% even when larvae are fed thousands of vesicles in a single dose. In contrast, infection rates for caterpillars injected with as few as 10 virion-containing vesicles are typically greater than 90%, and experiments with parasitic wasps show that these insects can transmit ascoviruses.

**Baculoviruses**

Baculoviruses (family Baculoviridae) are large, enveloped, double-stranded, occluded DNA viruses. These viruses are divided into two main types, commonly known as the nuclear polyhedrosis viruses (NPVs) and the granulosis viruses (GVs). Both NPVs and GVs are highly infectious by feeding, and in some insect species periodically cause epizoitoses, that is, widespread outbreaks of disease, that result in significant (>90%) declines in caterpillar populations.

**NUCLEAR POLYHEDROSIS VIRUSES** The NPVs (Fig. 1) are known from a wide range of insect orders but have been most commonly reported by far from lepidopterous insects, from which well over 500 isolates are known. Many of these are different viruses (i.e., viral species). NPVs replicate in the nuclei of cells, generally causing an acute fatal disease. The virions are large (80–200 nm × 250 nm) and consist of one or more rod-shaped nucleocapsids with a double-stranded circular DNA genome enclosed in an envelope. The occlusion bodies of NPVs are referred to commonly as polyhedra because typically their shape is polyhedral. Polyhedra are large (ca. 0.5–21 μm) and form in the nuclei, where each occludes as many as several hundred virions. The NPVs of lepidopterous insects infect a range of host tissues, but those of other orders are typically restricted to the midgut epithelium. Some NPVs have a very narrow host range and may replicate efficiently only in closely related species, whereas others, such as the AcMNPV (i.e., the NPV of the alfalfa looper, *Autographa californica*), have a relatively broad host range and are capable of infecting species in other genera.

**GRANULOSIS VIRUSES** The GVs, of which over 100 isolates are known, are closely related to the NPVs but differ from the latter in several important respects. The virions of GVs are similar to those of NPVs but contain only one nucleocapsid per envelope. GVs are known only from lepidopterous insects. Like NPVs, they initially replicate in the cell nucleus, but pathogenesis involves early lysis of the nucleus (as virions begin to assemble), which in the NPVs occurs only after most polyhedra have formed. After the nucleus has lysed, GV replication continues throughout the cell, which now consists of a mixture of cytoplasm and nucleoplasm. When completely assembled, the virions are occluded individually in small (200 nm × 600 nm) occlusion bodies referred as granules. Many GVs primarily infect the fat body, whereas others have a broader tissue tropism and replicate throughout the epidermis, tracheal matrix, and fat body. One, the GV of the grapeleaf skeletonizer *Harrisina brilians*, is unusual in that it replicates only in the midgut epithelium.

**Use of Viruses as Insect Control Agents**

The best example of the use of a virus as an insect control agent is the use of the NPV of the European spruce sawfly, *Gilpinia hercyniae,*
as a classical biological control agent. The European spruce sawfly was introduced into eastern Canada from northern Europe around the turn of the last century and had become a severe forest pest by the 1930s. Hymenopteran parasitoids were introduced from Europe in the mid-1930s as part of a biological control effort, and inadvertently along with these came the NPV, which was first detected in 1936. Natural epizootics caused by the virus began in 1938, by which time the sawfly had spread over 31,000 km². Most sawfly populations were reduced to below economic threshold levels by 1943 and remain under natural control today, the control being effected by a combination of the NPV, which accounts for more than 90% of the control, and the wasp parasitoids.

Although viruses, particularly NPVs, are frequently associated with rapid declines in the populations of important lepidopterous and hymenopterous (sawfly) pests, G. hercyniae NPV is the only example of a virus that has proven effective as a classical biological control agent. Another putative baculovirus, the “nonoccluded” baculovirus of the palm rhinoceros beetle, Oryctes rhinoceros, has been a quasi-classical biological control success in that once introduced into populations in certain South Pacific islands, can yield control for several years, but ultimately it dissipates and must be reapplied. Moreover, augmentative seasonal introductions have been effective only rarely and are not well documented. Thus, the control potential of most viruses is best evaluated by assessing their utility as microbial insecticides. From this perspective, the iridoviruses are not effective because of their poor infectivity by feeding. Cytoplasmic polyhedrosis viruses are not much better because, although highly infectious by feeding, the disease they cause is chronic. CPVs have, however, been useful in some situations, such as for suppression of the pine caterpillar, Dendrolimus spectabilis, in Japan. Ascorviruses and entomopoxviruses have not been developed as control agents for any insect owing to lack of efficacy.

For several reasons, the viruses most commonly used or considered as microbial insecticides in industrialized as well as less developed countries are the NPVs. First, NPVs are common in and easily isolated from pest populations. In addition, production in their hosts is cheap and easy, and the technology for formulation and application is simple and adaptable to standard pesticide application methods. Most NPVs, however, are narrow in their host range, infecting only a few closely related species. Furthermore, although several can be grown in vitro in small to moderate volumes (ca. 20- to 300-l cell cultures), no fermentation technology currently exists for their mass production on a scale that would permit repeated applications to hundreds of thousands of acres, which is possible with Bacillus thuringiensis (Bt) chemical insecticides. These two key limitations have been major disincentives for the commercial development of NPVs, especially in industrialized countries.

Despite these drawbacks, several NPVs have been registered as microbial insecticides even though the market size for most is small. And registered or not, several are used in many less developed countries, particularly for control of lepidopteran pests of field and vegetable crops. Moreover, over the past decade there has been renewed interest in developing NPVs because recombinant DNA technology offers potential for improving the efficacy of these viruses.

In addition to the NPVs, a few GVs have also been successfully developed for pest control. These in the GVs of the codling moth and potato tuberworm moth, which are, respectively, serious pests of apples and potatoes in many regions of the world.

Other Uses

In addition to the use of NPVs in insect control, one baculovirus, the AcMNPV noted earlier, has been developed as an expression vector for producing a large number of foreign proteins in vitro. This expression system takes advantage of the strong polyhedrin promoter system, which in the wild-type viruses produces large amounts of the polyhedria used to occlude virions. By substituting foreign genes for the polyhedrin gene, it is possible to synthesize in insect cell cultures large quantities of foreign proteins, such as the capsid proteins of viruses that attack the vertebrates used for vaccine development and basic biomedical research.

BACTERIA

Bacteria are relatively simple unicellular microorganisms that lack internal organelles such as a nucleus and mitochondria, and reproduce by binary fission. With a few exceptions, most of those that cause disease in insects grow readily on a wide variety of inexpensive substrates, a characteristic that greatly facilitates their mass production. A variety of bacteria are capable of causing diseases in insects, but those that have received the most study are spore-forming bacilli (family Bacillaceae), especially B. thuringiensis. Many subspecies of Bt are used as bacterial insecticides and as a source of genes for insecticidal proteins added to make transgenic plants resistant to insect attack, especially attack by caterpillars and beetles. The other bacterial insect pathogens that have received various degrees of
study are *B. sphaericus*, *Paenibacillus popilliae*, and *P. larue*, the latter being the etiological agent of foulbrood, an important disease of honey bee larvae, *Serratia entomophila* and *S. marcescens*. Several of these, in order of importance, are discussed here to represent the diversity of bacteria that cause disease insects.

**Bacillus thuringiensis**

*B. thuringiensis* is a complex of bacterial subspecies that occur commonly in such habitats as soil, leaf litter, on the surfaces of leaves, in insect feces, and as a part of the flora in the midguts of many insect species. Bts are characterized by the production of a parasporal body during sporulation that contains one or more protein endotoxins in crystalline form (Fig. 2). Many of these are highly insecticidal to certain insect species. These endotoxins are actually proteotoxins activated by proteolytic cleavage in the insect midgut after ingestion. The activated toxins destroy midgut epithelial cells, killing sensitive insects within a day or two of ingestion. In insects species only moderately sensitive to the toxins, such as *Spodoptera* species (caterpillars commonly known as armyworms), the spore contributes to pathogenesis. Bt also produces other insecticidal compounds including β-exotoxin, zwittermicin A, and vegetative insecticidal proteins (Vips).

The most widely used Bt is the HD1 isolate of *B. thuringiensis* subsp. *kurstaki* (Btk), an isolate that produces four major endotoxin proteins packaged into the crystalline parasporal body (Fig. 2B). This isolate is the active ingredient in numerous commercially available bacterial insecticides used to control lepidopterous pests in field and vegetable crops, and in forests. Another successful Bt is the ONR60A isolate of *B. thuringiensis* subsp. *israelensis* (Bti), which is highly toxic to the larvae of many mosquito and blackfly species. This isolate also produces a parasporal body that contains four major endotoxins (Fig. 2B), but these are different from those that occur in Btk. Several commercial products based on Bti are available and are used to control both nuisance and vector mosquitoes and blackflies.

Bti has proven to be an important environmentally compatible insecticide, and now has replaced the use of synthetic chemical insecticides for control of mosquito larvae in many countries around the world. A third isolate of Bt that has been developed commercially is the DSM2803 isolate of *B. thuringiensis* subsp. *morrisoni* (pathovar *tenebrionis*). This isolate produces a cuboidal parasporal body toxic to many coleopterous insects and is used commercially to control several beetle pests.

All the above-mentioned isolates are essentially used as bacterial insecticides, applied as needed. A variety of commercial formulations are available, including emulsifiable concentrates, wettable powders, and granules, for use against different pests in a variety of habitats. On a worldwide basis, millions of hectares are treated annually with products based on Bt. Estimates indicate the worldwide market is about $80–100 million. Although used as a bacterial insecticide, plants have been engineered to produce Bt Cry (crystal) proteins for resistance to insects, and this use has now far surpassed the use of Bt insecticides worldwide. Crops that produce Bt Cry proteins against lepidopterous and coleopterous pests, such as Bt cotton and Bt maize are now used in many countries including the United States, China, India, and Argentina, where the total market value now is several billions of dollars per year. This technological development has proven of great environmental benefit in that it has reduced the use of synthetic chemical insecticides by millions of pounds per year. As the technology of Bt crops is improved and public acceptance expands, Bt crops will become commonly used in many other countries during this century.

**Bacillus sphaericus**

Since the mid-1960s it has been known that many isolates of *B. sphaericus* (Bs) are toxic to certain mosquito species. Over the past three decades, three isolates have been evaluated for their mosquito...
control potential, 1593 from Indonesia, 2297 from Sri Lanka, and 2362 from Nigeria. The 1593 and 2297 isolates were obtained from soil and water samples at mosquito breeding sites, whereas 1593 was isolated from a dead adult blackfly.

Like Bt, Bs acquires its toxicity as the result of protein endotoxins that are produced during sporulation and assembled into parasporal bodies. Bs is unusual in that the main toxin is a binary toxin (i.e., composed of two protein subunits). These are proteolytically activated in the mosquito midgut to release peptides having molecular masses of, respectively, 43 and 39kDa, that associate to form the binary toxin, with the former protein constituting the binding domain, and the latter the toxin domain. The toxins bind to microvilli of the midgut epithelium, causing hypertrophy and lysis of cells, destroying the midgut and killing the mosquito larva.

*Paenibacillus popilliae*

*P. popilliae* is a highly fastidious bacterium that is the primary etiological agent of the so-called milky diseases of scarab larvae. These insects are the immature stages of beetles, such as the Japanese beetle, *Popillia japonica*, that are important grass and plant pests belonging to the coleopteran family Scarabaeidae. The term “milky disease” is derived from the opaque white color that characterizes diseased larvae and results from the accumulation of sporulating bacteria in larval hemolymph (blood). The disease is initiated when grubs feeding on the roots of grasses or other plants ingest the bacterial spores. The spores germinate in the midgut and vegetative cells invade the midgut epithelium, where they grow and reproduce, changing in form as they progress toward invasion of the hemocoeol (body cavity). After passing through the basement membrane of the midgut, the bacteria colonize the blood over a period of several weeks and sporulate, reaching populations of 100,000,000 cells ml⁻¹. For larvae that ingest a sufficient number of spores early in development, the disease is fatal. Dead larvae in essence become foci of spores that serve as a source of infection for up to 30 years.

Despite decades of research, suitable media for the growth and mass production of *P. popilliae* in *vitro* have not been developed. Thus, the technical material (i.e., spores) used in commercial formulations is produced in living, field-collected scarab larvae. Nevertheless, a small but steady market remains for *P. popilliae* in the United States because of serious problems due to scarab larvae, such as damage to turf grass by larvae of the Japanese beetle.

*Serratia entomophila*

A novel bacterium named, *S. entomophila* causes amber disease in the grass grub, *Costelytra zealandica*, an important pest of pastures in New Zealand, and has been developed as a biological control agent for this pest. This bacterium adheres to the chitinous intima of the foregut, where it grows extensively, eventually causing the larvae to develop an amber color; the result of infection is death. The bacterium is easily grown and mass-produced in *vitro* and can now be grown to densities as high as 4 × 10¹⁶ cells ml⁻¹. Successful mass production of *S. entomophila* led to its rapid commercialization. It is now used to treat infested pastures in New Zealand at a rate of one liter of product per hectare. Liquid formulations of this living, nonspore-forming bacterium are applied with subsurface application equipment. The rapid development and commercialization of the bacterium, even though the use is rather restricted, shows how microbials can be successful in niche markets, where there are few alternatives, and mass production methods, the most critical factor, are available.

Fungi

The fungi constitute a large and diverse group of eukaryotic organisms distinguished from others by the presence of a cell wall, as in plants, but lacking chloroplasts and thus the ability to carry out photosynthesis. Fungi live either as saprophytes or as parasites of plants and animals, and require organic food for growth, obtained by absorption from the substrates on which they live. The vegetative phase, known as a thallus, can be either unicellular, as in yeasts, or multicellular and filamentous, forming a mycelium, the latter being characteristic for most of the fungi that attack insects. During vegetative growth, the mycelium consists primarily of hyphae, which may be septate or nonseptate, and these grow throughout the substrate to acquire nutrients. Reproduction can be sexual or asexual, and during this phase the mycelium produces specialized structures such as motile spores, sporangia, and conidia, typically the agents by which fungi infect insects. Fungi usually grow best under wet or moist conditions, and those that are saprophytic as well as many of the parasitic species are easily cultured on artificial media.

The fungi are divided into five major subdivisions, and these reflect the evolution of the biology of fungi from aquatic to terrestrial habitats. For example, species of the genera *Coelomomyces* and *Lagenidium* (subdivision Mastigomycotina) are aquatic and produce motile zoospores during reproduction, whereas members of the genera *Metarhizium* and *Beauveria* (subdivision Deuteromycotina) are terrestrial and reproduce and disseminate via nonmotile conidia.

Unlike most other pathogens, fungi usually infect insects by active penetration through the cuticle. The typical life cycle begins when a spore, either a motile spore or a conidium, lands on the cuticle of an insect. Soon after, under suitable conditions, the spore germinates, producing a germ tube that grows and penetrates down through the cuticle into the hemocoeol. Once in the hemolymph, the fungus colonizes the insect. Hyphal bodies bud off from the penetrant hyphae and either continue to grow and divide in a yeastlike manner or elongate, forming hyphae that grow throughout the insect body. Complete colonization of the body typically requires 7–10 days, after which the insect dies. Some fungi produce peptide toxins during vegetative growth, and in these strains death can occur within 48 h. Subsequently, if conditions are favorable, which generally means an ambient relative humidity of greater than 90% in the immediate vicinity of the dead insect, the mycelium will form reproductive structures and spores, thereby completing the life cycle. Depending on the type of fungus and species, these will be produced either internally or externally as motile spores, resistant spores, sporangia, or conidia.

Fungi are one of the most common types of pathogens observed to cause disease in insects in the field. Moreover, outbreaks of fungal diseases under favorable conditions often lead to spectacular epizootics that decimate populations of specific insects over areas as large as several hundred square kilometers. As a result, there has been interest in using fungi to control insects for well over a century; the first efforts, in Russia in the late 1880s, used *Metarhizium anisopliae* to control the wheat cockchafer *Anisoplia australis*. Although there have been numerous attempts since then to develop fungi as commercial microbial insecticides, very few of these efforts have met with success. Thus, at present barely a handful of commercially available fungal insecticides are available for use in industrialized countries, and true commercial success has remained elusive. On the other hand, in developing countries (e.g., Brazil and China), “cottage industry” technology like that used to produce viruses has been turned to the production fungi such as *M. anisopliae* and *Beauveria bassiana*. A quasi-commercial product Boverin, developed and used in Russia...
Aquatic Fungi

Aquatic fungi of two types that attack mosquito larvae have received considerable study: species of Coelomomyces (class Chytridiomycetes; order Blastocladiales) and Lagenidium giganteum (class Oomyctetes; order Lagenidiales).

The genus Coelomomyces comprises over 80 species of obligately parasitic fungi that have a complex life cycle involving an alternation of sexual (gametophytic) and asexual (sporophytic) generations. The sexual phase parasitizes a microcrustacean host, typically a copepod, whereas the asexual generation develops, with rare exception, in mosquito larvae. In the life cycle, a biflagellate zygospore invades the hemocoel of a mosquito larva, where it produces a sporophyte that colonizes the body and forms resistant sporangia. The larva dies and subsequently the sporangia undergo meiosis, producing uniflagellate meiospores that invade the hemocoel of a copepod host, where a gametophyte develops. At maturation, the gametophyte cleaves, forming thousands of uniflagellate gametes. Cleavage results in death of the copepod and escape of the gametes, which complete the life cycle by fusing to biflagellate zygospores, which then seek out another mosquito host. The life cycles of these fungi are highly adapted to those of their hosts. Moreover, as obligate parasites these fungi are very fastidious in their nutritional requirements, and as a result no species of Coelomomyces has been cultured in vitro.

Coelomomyces, the largest genus of insect-parasitic fungi, has been reported worldwide from numerous mosquito species, many of which are vectors of important diseases such as malaria and filariasis. In some of these species, Anopheles gambiae in Africa, for example, epizootics caused in some areas by Coelomomyces kill greater than 95% of the larval populations. Such epizootics led to efforts to develop several species as biological control agents. For several reasons, however, these efforts were discontinued. One important factor was the discovery that the life cycle requires a second host for completion. Also contributing were the inability to culture these fungi in vitro and the development of Bti as a bacterial larvicide for mosquitoes.

Although it is unlikely that Coelomomyces fungi will be developed as biological control agents, interest remains in developing L. giganteum. This oomycete fungus is easily cultured on artificial media and does not require an alternate host. In the life cycle, a motile zoospore invades a mosquito larva through the cuticle. Once within the hemocoel, the fungus colonizes the body over a period of 2–3 days, producing an extensive mycelium consisting largely of nonseptate hyphae. Toward the end of growth, the hyphae become septate, and out of each segment an exit tube forms which grows back out through the cuticle and forms zoosporangia at the tip. Zoospores quickly differentiate in these, exiting through an apical pore to seek out a new substrate. In addition to this asexual cycle, thick-walled resistant sexual oospores can be formed in the mosquito cadaver.

Terrestrial Fungi

The fungi that have received the most attention for use in biological control are terrestrial fungi, with most emphasis placed on the development of selected species of hypomycetes such as M. anisopliae and B. bassiana for use as microbial insecticides. In addition, the more specific and nutritionally fastidious entomophthoraceous fungi continue to receive attention, but for their potential use as classical biological control agents rather than as microbial insecticides. Representative examples of these terrestrial fungi are discussed in the subsections that follow.

ENTOMOPHTHORALES

These fungi comprise a large order of the class Zygomycetes that contains numerous genera, many species of which are commonly found parasitizing insects and other arthropods. The fungi routinely cause localized and sometimes widespread epizootics in populations of hemipterous and homopterous insects, particularly aphids and leafhoppers, but also in insects of other types such as grasshoppers, flies, beetle larvae, and caterpillars. In addition, a few species of the genus Conidiobolus are able to cause mycoses in some mammals, including humans. Apart from these few species, most of the entomophthoraceous fungi are highly specific, obligate parasites of insects and therefore their use for biological control poses no threat to nontarget organisms. As with Coelomomyces, however, the complex nutritional requirements, which have thus far prevented mass production in vitro, and high degree of host specificity, make these fungi poor candidates for development as microbial insecticides. Moreover, the conidia are very fragile, providing a challenge to formulation, and the resistant spores, like the oospores of L. giganteum, are difficult to germinate in a predictable manner. Nevertheless, there is evidence that if cultural practices in crop production are modified, these fungi can provide effective insect control where they occur naturally, and through the introduction of foreign strains and species (i.e., a classical biological control approach).

The most important genera found attacking insects in the field are Conidiobolus (aphids), Erynia (aphids), Entomophthora (aphids), Zoophthora (aphids, caterpillars, beetles), and Entomophaga (grasshoppers, caterpillars). Although many species of these genera cause epizootics and have received considerable study, none really seems to have much potential for development as a commercial microbial insecticide. On the other hand, cultural control, classical biological control, and environmental monitoring methods continue to show promise for using entomophthoraceous fungi for insect control. For example, the introduction of Erynia radicans from Israel into Australia to control the spotted alfalfa aphid, Therioaphis maculata, has proven a classical biological control success.

A relatively recent example of apparent classical biological control can be found in the natural outbreaks of Entomophaga maimaiga in larval populations of the gypsy moth, Lymantria dispar, an important pest of deciduous forests throughout several states comprising the middle Atlantic and New England regions of the United States. Outbreaks of E. maimaiga have reduced larval populations to below economic thresholds, and the fungus is spreading westward naturally, and with human assistance, to gypsy moth populations established in other states. The source of this fungus is Japan, although it is not clear when the fungus causing present outbreaks of disease first appeared in the United States. The fungus was purposely introduced into the United States around the turn of the century, but seems not to have become established at that time. Then in the late...
1980s, outbreaks of *E. asinaiga* began to occur in Connecticut and New York, and later in Virginia. In areas where it has established, given sufficient rainfall, the fungus seems to be capable of keeping the gypsy moth population below defoliation levels. It will require another 10 years of evaluation to determine whether this is a valid instance of classical biological control by a fungus.

**CLASS HYPHOMYCETES** The hyphomycete fungi belong to the fungal subdivision Deuteromycotina (imperfect fungi), a grouping erected to accommodate fungi for which the sexual phase (perfect state) has been lost or remains unknown. This group contains the fungal species that most workers consider to have the best potential for development as microbial insecticides, *B. bassiana* and *M. anisopliae*, the agents of, respectively, the white and green muscardine diseases of insects. Unlike the fungi already discussed, these two species have very broad host ranges and probably are capable of infecting insects of most orders.

With respect to the general life cycle of these fungi, the process of invasion, colonization of the insect body, and formation of conidiophores and conidia is similar to that described for the other fungi. During invasion and colonization, some fungal species produce peptide toxins that quicken host death. The infectious agent is the conidium (Fig. 3), and the taxonomy for the hyphomycetes is based primarily on the morphology of the reproductive structures, particularly the conidiophores and the conidia. Most of the hyphomycete fungi used or under development grow well on a variety of artificial media, and this attribute, along with their ability to infect insects via the cuticle, favors commercial development. In the "cottage industry" commercial operations in Brazil, China, and the former Soviet Union, solid or semisolid substrates are used for production, and the primary ingredients are grain or grain hulls.

In general, the development of *B. bassiana* and *M. anisopliae* is being targeted for control of insects that live in cooler and moist environments, such as beetle larvae in soil and plant hoppers on rice, though the former species is also being evaluated against whiteflies in glasshouses, as well as grasshoppers, especially locusts, in field crops. In addition to these two species, several species with much narrower host ranges are considered to have potential for development, including *Paecilomyces fumosoroseus* (for whiteflies), *Verticillium lecanii* (for aphids and whiteflies in glasshouses), *Hiratella thompsonii* (for mites), and *Nomurea rileyi* (for noctuid caterpillars).

With these apparent advantages, it is natural to ask why none of the hyphomycete fungi have been commercially successful as microbial insecticides in developed countries. There are several reasons related to their biological properties. First and foremost is that the production of conidia or mycelial fragments that are used as the active ingredient of formulations is not cost-effective because too much material is required to allow the achievement of an acceptable level of control. In addition to the problem of inefficient yields, the formulations are bulky, and preservation of fungal viability beyond a few months is low because the conidia are fragile. In mosquito and blackfly control, similar constraints apply. In addition, the discovery of cost-effective strains of *B. thuringiensis* and *B. sphaericus* has generally eliminated imperfect fungi, as well as many other microorganisms, for consideration as biological control agents for these important nuisances and vector insects.

In developing countries, *B. bassiana* and *M. anisopliae* were used in the past in some crops with considerable success. For example, in China, *B. bassiana* was used to control the European corn borer and *Ostrinia nubilalis* in maize. The fungus was produced in large covered pits on maize stalks. In Brazil, a preparation of *M. anisopliae* known as Metaquino has been used for many years on sugarcane plantations and in pastures to control the spittlebug, *Mahanarva posticata*. Fungal conidia are produced in sealed plastic bags on rice. Figures indicate that as many as 50,000 ha are treated annually, and reductions in spittlebug populations are sufficient to keep populations below damaging levels. In the South Pacific, *M. anisopliae* has also been used to assist control of the rhinoceros beetle, *Oryctes rhinoceros*, a serious pest of coconut palms. Application of conidia at a rate of 50 g ha\(^{-1}\) of soil yielded 80% larval mortality and improved coconut yields by 25%. Although these are examples of local successes, their applicability to agricultural production in developed countries is questionable. Moreover, the use of Bt crops such as Bt maize, noted above, has proven more effective than using fungi for control of important lepidopteran and coleopteran pests. Thus, in the future, genetic engineering techniques are likely to dominate crop development where insecticidal proteins are available to control the most important pests. In other situations, however, fungi such as *M. anisopliae* and *B. bassiana* may prove particularly useful. Examples include the control of sucking insect pests like aphids, white flies, and sharpshooters, or insects such as locusts and adult mosquitoes, where other effective pathogens are not available. As with bacterial insecticides, these fungi are amenable to genetic engineering techniques. It has already been shown recently in the case of *M. anisopliae* that its insecticidal efficacy can be improved by adding insecticidal proteins and enzymes to the battery of virulence agents that it produces during the process of infecting insects.
PROTOZOA

Protozoa is a general term applied to a large and diverse group of eukaryotic unicellular motile microorganisms that belong to what is now known as the kingdom Protista. Members of this kingdom can be free-living and saprophytic, commensal, symbiotic, or parasitic. The cell contains a variety of organelles, but no cell wall, and cells vary greatly in size and shape among different species. Feeding is by ingestion or more typically by adsorption, and vegetative reproduction is by binary or multiple fission. Sexual reproduction, often useful for taxonomy, can be very complex, but asexual reproduction occurs as well. Many protozoa produce a resistant spore stage that is also used in taxonomy. Divided into a series of phyla based primarily on mode of locomotion and structure of locomotory organelles, the kingdom includes the Sarcomastigophora (flagellates and amoebae), Apicomplexa (sporozoa), Microspora (microsporidia), Acetospora (haptosporidia, now thought to be a type of parasitic alga), and Ciliophora (ciliates). Protozoa of some types, such as the free-living amoebae and ciliates, are easily cultured in vitro, whereas many of the obligate intracellular parasites have not yet been grown outside cells.

As might be expected from such a large and diverse group of organisms, many species of protozoans are associated with insects, and the biology of these associations covers the gamut from being symbiotic to parasitic. Those that are parasitic have the general feature of causing diseases that are chronic. Many of the parasitic types, especially the microsporidia, build up slowly in insect populations, eventually causing epizootics that lead to rapid declines in populations of specific species. These epizootics attracted interest in the possibility of using protozoa to control pest insects, and over the past several decades numerous studies have been aimed at evaluating this potential. In general, these studies have shown that protozoa hold little potential for use as fast-acting microbial insecticides because of the chronic nature of the diseases they cause and because commercially suitable methods for mass production are lacking. However, as with the entomophthoraceous fungi, the possibility exists that protozoans, particularly microsporidia, may be useful as classical biological control agents. Clear examples of the effectiveness of such strategies remain to be demonstrated.

The life cycles and biologies that occur among the various protozoa that attack insects are too diverse in relation to their pest control potential for even a few to be covered here. Instead, the group with the most potential—the microsporidia—is described in terms of general biology and possible use in insect control.

General Biology of Microsporidia

The microsporidia (phylum Microspora) are the most common and best studied of the protozoans that cause important diseases of insects. Although still referred to as protozoa, recent molecular phylogenetic studies have shown that these pathogens evolved from fungi. Well over a 1000 species are known, and most of these have been described from insects. Microsporidia have been most commonly described from insects of the orders Coleoptera, Lepidoptera, Diptera, and Orthoptera, but they are also known from other orders and probably occur in all. The epizootics in insect populations caused by protozoa are usually due to microsporidia. All microsporidia are obligate intracellular parasites and are unusual in that they lack mitochondria. In addition, they produce spores that are distinguished from the spores of organisms of all other known types by the presence of a polar filament (Fig. 4), a long coiled tube inside the spore used to infect hosts with the sporoplasm.

The typical microsporidian life cycle begins with the ingestion of the spore by a susceptible insect. Once inside the midgut, the polar filament everts, rapidly injecting the sporoplasm into host tissue.
the field through inundative releases, in essence using microsporidia as microbial insecticides.

Because they are obligate intracellular parasites that lack mitochondria, microsporidia cannot be grown on artificial media. Several species have been grown, however, in established insect cell lines, although this is not practical for field use. For field application, whether for microbial insecticide trials or for introductions into populations, spores are grown in living hosts. With such methods the yield can be quite high ($10^8$–$10^{10}$ spores per host). These yields in terms of the number of larvae that must be grown to treat a hectare and infect most of the target population are comparable to the requirements for nuclear polyhedrosis viruses. Thus, if the microsporidia could cause acute diseases, they would be on an equal footing with many of the NPVs. However, the diseases are chronic, and even if a high percentage of the target pest population is infected, there all too often is little, if any, crop protection. In fact, if advanced instars such as thirds and fourths are treated, the larvae may live longer and cause greater crop damage than if the fields were left untreated. Thus, microsporidia are not useful as microbial insecticides.

There is now a general realization that microsporidia and other protozoans have virtually no potential for use as microbial insecticides. They may, however, be useful as population management tools.

Phasmida

(Stick and Leaf Insects)

Erich H. Tilgner

University of Georgia
Fernbank Science Center

Phasmida are nocturnal exopterygote insects. They exhibit a variety of unpredictable and bizarre shapes. Some look like twigs or tree bark (Figs. 1 and 2) and may seem to be covered by lichens or moss. Others are indistinguishable from living or dead leaves (Fig. 3), mimicking even leaf veins and mildew spots to perfection. Phasmida are large, and a few are remarkable for their gigantic size. The longest insect species in the world is Phobaeticus kirbyi from Borneo, with one documented female measuring 55 cm in length.

**FIGURE 1** A female of Oxyartes spinosissimus, a lichen mimic.

**FIGURE 2** A male and female of Aplopus sp. in the act of mating. The smaller male is hanging off the back of the female.
The taxonomy of the order is problematic. No workable classification scheme exists, and those that are available are not based on phylogenetic relationships. Assignment to a category such as family, tribe, even suborder provides so little information that it is almost meaningless. This is in contrast other insect orders, such as Coleoptera, where a suborder, or family-level identification, provides a wealth of biological information about the specimen. In spite of the lack of an acceptable classification, the fauna of a few areas (e.g., Europe, Malaysia, Borneo, Japan, United States, Canada, New Zealand) have been sufficiently studied to permit tentative identification of species by nonspecialists.

**BIOLOGY**

Sexual dimorphism is extreme in the Phasmida, and it is difficult to associate the sexes unless mating adults are found under natural conditions, or if males and females are obtained from the rearing of eggs in captivity. Reproduction is usually sexual, but many species are parthenogenetic. Eggs resemble plant seeds, are laid singly, and are either dropped, flicked, buried, glued to a surface, or riveted to a leaf. Some species rely on ants to disperse them. After successive molts, nymphs regenerate limbs lost by autotomy (the purposeful shedding of appendages). The entire life cycle takes from several months to several years depending on the species. Phasmida feed primarily on flowering plants, but a few eat either gymnosperms or ferns. The primary defense against predation is crypsis. Secondary defenses can include catalepsy (e.g., death feigning), startle displays, or the ejection of an irritating spray fired from a pair of prothoracic exocrine glands.

**Pheromones**

Ring T. Cardé, Jocelyn G. Millar

*University of California, Riverside*

Pheromones are chemical messages that induce a behavioral reaction or developmental process among individuals of the same species. The term is derived from the Greek for “carrier of excitation” and was coined in 1959 by the German biochemist Peter Karlson and the Swiss entomologist Martin Lüscher during their investigations of the chemicals that regulate caste development in termites. In 1963, E. O. Wilson and W. H. Bossert of Harvard University formally distinguished two classes of pheromones. Releaser
Pheromones are messages that induce an immediate behavioral reaction in the receiver. The kinds of behavioral responses evoked in insects are incredibly diverse, and they include alarm, defense, aggregation, attraction, kin and colony recognition, marking of territories and egg deposition sites, mating behaviors, recruitment, trail following, and even thermoregulation. In contrast, primer pheromones cause a physiological change in the receiver, such as development of a particular caste or sexual maturation, which eventually modifies the organism’s behavior.

All pheromones fall under the broader umbrella classification of semiochemicals—chemicals that are involved in communication. The two major classes of semiochemicals besides pheromones are allomones and kairomones. These are solely interspecific cues, in contrast to pheromones, which are always intraspecific signals. Allomones are chemicals that provide some advantage to the emitter (e.g., defensive secretions), whereas kairomones are cues that confer an advantage to the receiver (e.g., emanations used by a parasite to locate a host). This article only touches on the diversity and complexity of pheromone-mediated behaviors and developmental changes in insects. Communication among social insects, especially among ants, bees, wasps, and termites, involves a highly sophisticated pheromonal language, in which the interpretation of the individual chemical constituents or “words” depends on their particular combinations, ratios, concentrations, and even order of presentation. Context, that is, the recent experiences of the receiver and its physiological state, is all-important in response.

**SEX-ATTRACTANT PHEROMONES OF LEPIDOPTERA**

The first definitive evidence of pheromone communication dates to experiments performed with the great peacock moth *Saturnia pyri* by the French naturalist Jean-Henri Fabre in the 1870s. Fabre sequestered a female moth in a screened cage following her morning emergence, to permit her wings to expand and harden. That evening more than 40 male moths arrived at Fabre’s study, “eager to pay their respects to their marriageable bride born that morning.” Further observations showed that cages that had housed virgin females also were attractive; this and other observations led Fabre to conclude that “effluvia of extreme subtility” mediated attraction. Nearly 90 years would pass before microanalytical techniques would permit identification of the minute quantities of pheromone involved.

The first pheromone to be identified was the sex-attractant pheromone of *Bombyx mori*, the commercial silkworm. This silkworm is an entirely domesticated species that is no longer capable of flight; its female-emitted pheromone (Fig. 1) induces upwind walking and courtship behaviors in conspecific males. The German biochemist Adolf Butenandt (who received the Nobel Prize in 1939 for his work identifying the human sex hormones) spent more than two decades in this quest. In 1959 he identified (E,10,12)-hexadecadienol as the single compound causing upwind walking and copulatory attempts and named it “bombykol.” To provide some perspective on this remarkable achievement, Butenandt and his coworkers extracted half a million female moths, finally isolating a few milligrams of the pure pheromone. Today’s modern methods of isolation and characterization (especially coupled gas chromatography and mass spectrometry) were not yet available.

The amount of pheromone that is secreted from or is present in a pheromone-producing gland varies enormously with species and, to some extent, behavioral function. Sex-attractant pheromones may be present in microgram, nanogram, and even picogram (10⁻¹²g) quantities per individual. Microanalytical techniques are now so advanced that identifications on occasion can be made from either gland extracts or airborne collections from a few individuals, and with just nanogram or even lower quantities of natural chemical. Even the always tedious behavioral bioassays, long used to monitor for behaviorally active components of gland extracts and airborne collections, have been largely supplanted by using a living insect antenna as a detector. The electroantennogram (EAG) was pioneered in the mid-1950s by Dietrich Schneider, working at the Max Planck Institute near Munich, Germany. In the 1970s, Wendell Roelofs of Cornell University adapted this assay to speed up identifications. A moth antenna was used to monitor which fractions separated by gas chromatography contained the active components. Later applications mounted the EAG apparatus at the outflow of a gas chromatograph column, and this living detector indicated the presence (and the retention times) of compounds that were likely to be behaviorally active by means of the electrical signal elicited by the interaction of pheromone and the antennal receptors. These advances allowed chemists to zero in quickly on the compounds present in crude extracts that were most likely to comprise the pheromone.

**FIGURE 1** Representative structures of lepidopteran (moth) pheromones. (A) *Bombyx mori*, the commercial silkworm (Bombycidae), (B) *Hemileuca lectra* (Saturniidae), (C) *Pectinophora gossypiella*, pink bollworm (Gelechiidae), (D) *Keiferia lycopersicella*, tomato pinworm, (Gelechiidae), (E) *Lymantria dispar*, gypsy moth (Lymantriidae), and (F) *Grapholita molesta*, oriental fruit moth (Tortricidae).
The sensitivity of male silkworm to bombykol is legendary. It has been investigated by recording the electrical response of individual sensory hairs on their antennae (each antenna is equipped with 40,000 such hairs) and by monitoring a male’s change from quiescence to wing fanning and upwind walking. The estimates are astonishing: one bombykol molecule is sufficient to induce the firing of an individual receptor, and a behavioral response can be evoked with only 200 molecules ($\sim 10^{-19}$ g).

Pheromone structures now have been described for several hundred species of moths. Nearly all these pheromones induce upwind flight by the male to the pheromone-releasing female. The majority of known structures for moth pheromones (examples in Fig. 1) are hydrocarbon chains, usually 10–18 carbons in length, with 1–3 double bonds and terminal acetate, alcohol, or aldehyde. Less common structural motifs in moth pheromones include epoxides, ketones, and hydrocarbons with one or more double bonds or methyl branches; chain lengths known so far range from C$_{10}$ to C$_{25}$. Many pheromones, such as those of the moths *Hemileuca electra* and *Grapholita molesta*, comprise blends of two, three, or even more components. Specificity of the chemical message is accomplished in many species by females emitting and males responding to precise ratios of their pheromone blend. For example, for males of *G. molesta*, the ratio of the (Z)-8- and (E)-8-dodecenyl acetate components must be very close to the 95:5 mix produced by the female for maximum attraction. The use of blends and, in some species, precise ratios allows many closely related moth species to have “exclusive” communication channels, even though they share some components of their respective blends. Other strategies for partitioning of the communication channel include restricting sexual activity to specific times of the day or night (Fig. 2).

Pheromones of other types are produced by males of many moths and facilitate close-range recognition and acceptance by the female. In a few species the sexual roles are reversed, with male moths being the attractive sex and recruiting females. Many male butterflies also use pheromones in courtship, disseminating an “aphrodisiac” scent from scales on their wings or, in some butterflies, from specialized paired brushes located at the tip of the abdomen. However, butterflies do not attract mates with long-distance pheromones; instead they rely on visual signals for mate finding.

### ATTRACTANT AND AGGREGATION PHEROMONES

Although long-distance communication by attractant pheromones is well established in nearly all moth lineages, pheromones are widely used by many insect groups in mate finding. Such messages are categorized as either sex-attractant pheromones, if one sex attracts the other (as in moths), or aggregation pheromones, if both sexes are attracted. Feeding on a plant host and release of aggregation pheromones typically are linked, and mating often occurs in such aggregations. Therefore, aggregation pheromones can play a multifunctional role. Representative structures (Fig. 3) of sex attractants of insects other than moths include those of the cockroach, aphid, scale insect, caddisfly, sawfly, beetle, and true fruit fly. The chemistries of these messages are diverse, as are the locations of the glands responsible for their production.

![Figure 2](image2.png) Female of the day-active saturniid moth *Hemileuca electra* exposing her pheromone gland, located at the tip of her abdomen. Such pheromone-releasing behavior, termed “calling,” and the male’s mate-finding behaviors typically occur at set times of the day or night. In the Mojave Desert of California *H. electra* calls from midmorning to early afternoon; the closely related species *H. burnsi*, which shares pheromone components with *H. electra*, calls from midafternoon to dusk. Without exclusive times for mating activities, these species would cross-attract. (Photograph courtesy of Chris Conlan.)

![Figure 3](image3.png) Examples of sex attractant pheromones of insects from nonlepidopteran orders: (G) periplanone B, from the American cockroach, *Periplaneta americana*, (H) nepetalactone, a pheromone component of a number of aphid species, (I) pheromone of California yellow scale, *Aonidiella citrina*, (J1 and J2) pheromone components of caddisflies, (K) pheromone component of diprionid sawflies, (L) (2R,3R)-2,3-hexanediol, a pheromone component of the cerambycid beetle *Hylotrupes bajulus*, and (M) (R)-1,7-dioxaspiro[5,5]decane, from the olive fruit fly *Dacus oleae*.
Pheromones

BARK BEETLE PHEROMONES

Bark and ambrosia beetles (Scolytidae) use pheromones to facilitate colonization of host trees (aggregation) and to attract mates. Many scolytid species must attack a tree en masse if they are to overwhelm the tree's defense, which consists of exuding sap into the tunnel that each beetle bores. The first beetles to arrive may identify the host by means of chemicals emitted by the host tree itself; as they bore into the tree, they release pheromones and increase emission of tree chemicals that together attract both male and female beetles. David Wood of the University of California at Berkeley and Robert Silverstein, then at Stanford Research Institute, worked out these intricate interactions in *Dendroctonus brevicomis*, the western pine beetle. Infestations begin when females are attracted to their principal host, ponderosa pine, by myrcene, a monoterpane the tree emits as a defensive compound (allo-mone) when injured or stressed, and by the tree's silhouette. As the “pioneer” females bore into the tree's bark, they release their pheromone, (+)-exo-brevicomin (Fig. 4), which is augmented by increased release of myrcene from the host tree. Males are attracted and, after one enters the female's tunnel, he emits (-)-frontalin. The combination of host-, female-, and male-released volatiles attracts many more males and females, ensuring that the tree's sticky sap defense will be insufficient. Once males and females have mated, they alter their chemical message: males and females emit verbenone and *trans*-verbenol and males release (+)-ipsdienol (Fig. 4). Together, these three chemicals interrupt further attraction of males and females, thereby helping to regulate the level of infestation and avoiding overexploitation of the tree.

PHEROMONES OF SOCIAL INSECTS

Pheromones mediate many activities of social insects, including defense of the colony, recruitment to food, recognition of individuals and nestmates, and regulation of caste development. The exocrine glands that produce the various pheromones are dispersed throughout the body, as exemplified by those of leafcutter ants (Fig. 5).

Alarm and Defense

Charles Butler was the first to describe the behavioral effects of an insect alarm signal. He recognized in 1609 that the stinger of a honey bee (*Apis*) worker impaled on human skin or clothing attracts more bees to sting that site. The multifunctional role of this signal is shown by the reactions to the same chemical signal of guard honey bees at the entrance to their hive. The presence of an intruder can cause a guard bee to release alarm pheromone from her sting chamber; she disseminates this message into the hive by wing fanning, thereby summoning many bees. These alerted bees seem to be “agitated,” with rapid movements and mandibles agape, poised to defend their colony. The sting chamber has more than 20 known pheromone components, most of which induce either alerting or stinging. The other behavioral reactions evoked by components of the sting chamber include lowering the number of foragers departing the hive and repelling foragers that have arrived at a food source. The main constituent of this mixture-evoked alerting and, to a lesser extent, stinging is isopentyl acetate, and the amount per worker changes dramatically with the behavioral task that bees are performing. In the first few days of an adult worker's life, when she is confined to housekeeping and brood-tending tasks inside the hive, essentially no isopentyl acetate is present. The amount rises to 4–5 μg at several weeks of age, when she either assumes guard duties or starts foraging outside the hive. For the remainder of her life as a forager, the amount falls to approximately 2 μg per stinger. Stinging itself seems to be released by many components of the sting chamber, including isopentyl acetate, and especially n-butyl acetate and 1-pentanol. As with many reactions of social Hymenoptera, the context in which the signal is released is crucial to the kinds of behavior evoked. Context must be taken into account in interpreting behavior and in devising diagnostic behavioral bioassays. For assays of honey bee stinging, for example, one standardized procedure is to provide a vibration of set intensity to the hive, followed by presentation in front of the hive entrance of a swinging target such as a cotton ball or piece of leather containing a candidate alarm pheromone. The number of bees attacking and stinging the target is used to score the level of response.

Defensive behaviors of social insects are quite varied and difficult to categorize into mutually exclusive behaviors. Detection of an alarm pheromone by an ant, for example, can cause it to splay its mandibles, raise its head, bite, and spray an odoriferous and irritating defensive secretion toward a perceived enemy. Unlike attractant and aggregation pheromones, which typically are carried downwind...
in a turbulent wind flow, alarm pheromones are often released either in relatively still air within the confines of the colony or at ground level, where wind is attenuated. In such situations, molecular diffusion largely or exclusively governs the distribution of pheromone, and the resulting concentration gradient of pheromone supplies potentially useful information about the direction toward the source of alarm. Thus, ants may run toward the source of pheromone (essentially up the odor gradient) or, at lower concentrations farther away from the odor source, movements may seem to be undirected with respect to the odor source. There are many kinds of defensive reactions and, in leafcutter ants, several glandular sources for alarm pheromones (Fig. 5).

An instructive example is provided by the defensive reactions evoked by some of the more than 30 mandibular gland components of the weaver ant, Oecophylla longinoda, worked out in considerable detail by John Bradshaw, Philip Howse, and Ray Baker at the University of Southampton. If a droplet of mandibular gland secretion is danned onto a flat surface in still air, the volatile pheromone diffuses outward at a rate that is dependent on its molecular weight and its diffusion coefficient. A region in which the concentration of pheromone is above the minimum required to elicit a particular behavioral reaction is termed an “active space.” The active spaces of each of the four principal components of the mandibular gland secretion 20 s after its deposition are shown in Fig. 6. The sequence of defensive activities seems to be ordered by proximity to the odor source. At the outer limit of the active space, worker ants encounter only hexanal above threshold levels. Ants show heightened levels of running with open mandibles, but their trajectory is not aimed toward the odor’s source. Ants that enter the 1-hexanol region, however, move up the odor gradient toward the odor’s source. Once they have reached the active space of 3-undecanone, this compound further facilitates orientation and lowers the threshold for biting, as does 2-butyl-2-octenal. Together these four compounds ensure that the ants are recruited to the site at which the alarm pheromone was released, and that they attack an adversary that has been marked with this secretion. Mandibular gland components involved in defense, including other active constituents in addition to the four main constituents, vary within a colony among castes and even between major and minor workers. There also is substantial variation in a given caste among colonies, suggesting that different colonies may have unique defensive codes.

**Trail Following and Recruitment**

Social insects use trails of varying permanence to exploit food resources and sometimes for colony movement and relocation. E. O. Wilson’s exhaustive study of what governs the persistence of the food trail of the fire ant, Solenopsis invicta, provides an example of how such systems function. A foraging worker that has encountered a suitable food source lays down a chemical trail by dragging its stinger sporadically along the ground as it returns to the nest. The trail pheromone is a mixture of farnesenes [mainly (Z,E)-α-farnesene] from their Dufour’s gland, and at any given moment each ant contains only about a nanogram of trail pheromone. The trail from one individual does not persist for long—the active space falls below threshold in less than 2 min, and its effective length is not much more than a meter. Solenopsis can even adjust the amount of pheromone deposited on the trail by altering how firmly it drags its sting. The amount of pheromone on the trail is regulated by three factors: the number of ants returning, the proportion of ants laying a trail, and the amount that each ant contributes to the trail. When the food is gone or an ant cannot reach the food source because of other ants, any ant that cannot feed simply does not reinforce the trail.

The number of ants recruited to leave the nest for foraging is a direct function of the quantity of trail pheromone released by a returning forager: to induce nestmates to leave the nest and forage along the trail, the returning forager releases much more pheromone than is found along the trail itself. These simple rules followed by individuals allow mass recruitment, a sophisticated system whereby one group of ants transfers information about the quality of a food source some distance away to another group of ants. The seeming disadvantage of the impermanence of such trails is actually a useful feature of the system that permits ants to match the number of foragers to the quantity of the resource.

Trail communication also is used in relocation of Solenopsis colonies. Scouts that have discovered a suitable nest location lay down a trail that other workers follow to the same site. If the location is indeed deemed favorable by new workers inspecting the site, these workers add pheromone to the trail upon their return trip to the nest; this leads to an exponential increase in traffic. Eventually the brood is transferred to the new nest, and the queen follows. Trails close to the nest of some ant species can be relatively permanent, lasting days, and these are called trunk trails. The constituents of the trail pheromones are known for many ant groups, and they are produced from a variety of glandular sources, including the Dufour’s, poison, and sternal glands, and the hindgut. Trail pheromones also are widely used by termites in foraging activities. Chemical trails are also important in regulating foraging activities of colonial tent caterpillars (Lasiocampidae). Caterpillars that have located food on distant branches add pheromone to the silken trail on their return trip to the silk nest at which they spend their nonfeeding time. These marked paths are then followed preferentially by future foragers.

**Queen Pheromone of the Honey Bee**

As emphasized for alarm pheromones, a pheromone can communicate many meanings depending on context. The queen pheromone of the honey bee (Apis mellifera) exemplifies this principle, which has been...

*FIGURE 6* Active spaces in still air of the principal components from the mandibular gland of the weaver ant, *Oecophylla longinoda*. The pheromone has been deposited in the center and the boundaries of behavioral activity of each component 20 s later are represented. [After Howse et al. (1998).]
termed “pheromonal parsimony” by Murray Blum of the University of Georgia. The queen pheromone is produced by the queen’s mandibular glands and its five known components are 9-oxo-(E)-2-decenoic acid, (+)- and (−)-9-hydroxy-(E)-2-decenoic acid, methyl 3-hydroxybenzoate, and 4-hydroxy-3-methoxyphenylethanol. The queen produces about 500 μg of this mixture daily, most of which is picked up by the continually changing retinue of a dozen or so workers that constantly groom the queen. Trophallaxis (interchange of food), antennation, and grooming among colony members in turn disperse queen pheromone throughout the colony. The releasing functions of the queen pheromone include the “retinue” behavior (attendance and grooming of the queen)—these behaviors require all five components), suppression of construction of new queen cells, and a delay in swarming.

Outside the hive, swarming bees without a queen are attracted to a source of 9-oxo-(E)-2-decenoic acid, but they will not form a cluster without the addition of 9-hydroxy-(E)-2-decenoic acid. Drones (males) are attracted to virgin queens flying 10 or so meters above ground level by her release of 9-oxo-(E)-2-decenoic acid. Perhaps the most dramatic effect of the queen pheromone is in its governance of colony productivity. Without queen or queen pheromone in the colony, many workers remain idle. Queen pheromone stimulates comb construction, brood rearing, foraging, and food storage. Artificial application of queen pheromone increases all these activities. The queen pheromone also has a clear primer effect inasmuch as it inhibits development of the workers’ ovaries. In the absence of the queen (and the queen pheromone), egg production is triggered in up to one quarter of the workers, and these “false queens” and other workers in turn produce some queen pheromone.

**Pheromones of Honey Bee Workers**

Honey bee workers produce diverse messages from a number of exocrine glands. The Nasonov gland (which queens and drones lack) is situated on the seventh abdominal tergite. A worker exposes this gland by flexing its abdomen, usually while wing fanning and elevating its abdomen. The secretion contains mainly geraniol, geranial, and geranic acid, and these influence foraging, marking, and, when coupled with queen pheromone, clustering. Nasonov pheromone also is important to swarming. After a swarm has departed the hive, the first workers to arrive at a clustering site expose their Nasonov gland, and the scent attracts other flying workers. Nasonov secretions also are used in “house hunting.” A scout that has found a potentially suitable nest site returns to the swarm and communicates direction and distance by the dance language. Scouts release Nasonov pheromone at the site, thereby helping to attract more bees to evaluate its suitability. Nasonov pheromone also is released by bees fanning at the hive’s entrance; this odor (probably mixed with odors from the hive) seems to aid disoriented foragers in finding the hive’s entrance.

The mandibular gland produces mainly 2-heptanone, which is released by guard bees as an alerting pheromone, and possibly to mark an intruder. This compound, perhaps in combination with other components of the mandibular gland, also may be used to mark flow- ers that are no longer productive, thereby improving foraging efficiency. Other pheromones labeled “footprint” pheromones mark the nest entrance, and a thermoregulatory pheromone causes nurse bees that are incubating pupae to raise their body temperature by means of muscle contractions. Capping of brood cells is induced by a pheromone consisting of mixture of four fatty acid esters. The examples of pheromonal communication in A. mellifera considered here provide a glimpse into the pervasiveness of pheromonal communication in this insect, and the diversity of reactions that can be mediated by pheromonal messages.

**Termite Pheromones**

The development of castes in termites seems to be governed by complex interactions between juvenile hormone, pheromones, and environmental conditions such as food availabilty and time of year. For example, in a colony of Kalotermes (a “lower termite”), the absence of a king and queen in the colony causes development of replacement (supplementary) reproductives from pseudergate workers, but with the establishment of a reproductive pair (or more), they secrete pheromones that induce pseudergates to eat the excess of reproductives. A queen-produced pheromone inhibits female pseu- dergates from becoming reproductively competent, and a male-produced pheromone similarly inhibits male pseudergates from becoming reproductive. In the absence of a queen, the king secretes a pheromone that stimulates production of females. The proportion of soldiers in the colony is also regulated by similar interactions. The identity of the pheromones that modulate the proportion of castes in a colony remains unknown.

**WHEN PHEROMONES BECOME KAIROMONES**

It is also worth noting that parasitoids and predators have coevolved to exploit and manipulate the pheromones of their prey. For example, a group of clerid beetles uses the pheromonal signals of bark beetles to locate and invade the tunnels of their prey in the bark and cambium layers of conifers. Similarly, pentatomid bug species frequently suffer high levels of parasitism from parasitic flies from several families, or from specialist wasp predators. It has been unequivocally demonstrated that these parasitoids use the bugs’ pheromones as kairomonal cues to locate hosts. The flies and wasps are attracted specifically to components of their host’s pheromone blend. For both the predatory clerids attacking bark beetles and the fly and wasp species attacking pentatomid bugs, the attraction to the pheromones of their prey can be so strong that traps baited with the prey pheromones actually catch more of the parasitoids or predators than the target species.

However, illicit use of the pheromones of prey can go well beyond simply eavesdropping on pheromonal signals. In a fascinating example of coevolution, bolas spiders in the genus Mastophora (and several other genera) produce the pheromonal signals of their prey to lure the prey close enough to be caught by a swinging, sticky thread of silk. The prey are male noctuid moths responding to copies of the female pheromone. Even more extraordinary, there is evidence to suggest that within an hour or so, the spiders can change the pheromone lures they produce, to maximally exploit the different times of flight of prey species that respond to differing pheromone blends.

A variety of insects that live inside nests and sometimes parasitize colonies of social insects such as ants and termites also have developed the ability to aggressively mimic the pheromonal signals of their hosts. For example, several staphylinid beetle species live inside termite nests, where they receive all their food from their hosts, and are groomed and cared for by their hosts as though they were termite brood. The chemical cues that both prevent the termites from recognizing the inquilines and induce the feeding and grooming behaviors closely mimic the true pheromones used by the termites for these functions. In an even more aggressive example, the larvae of some syrphid flies are obligate predators on the brood of their ant hosts. The fly larvae produce a blend of cuticular hydrocarbons that closely matches the hydrocarbon profile of the host’s brood, effectively camouflaging the fly. The camouflage is so good that if the nest is attacked, the worker ants will carry the fly larvae to safety as though they were ant brood.
APPLICATION OF PHEROMONES IN PEST MANAGEMENT

Insect pheromones have proven useful in pest control. Most of these applications use synthetic copies of pheromones that mediate either attraction or aggregation. Compounds are formulated in protective matrices or reservoirs that emit the pheromone over weeks or months. Pheromone-baited traps are used to detect exotic invaders, to decide whether pest levels are sufficient to warrant intervention, and to time the application of conventional insecticides or other control measures. For example, the spread of the gypsy moth (Lymantria dispar) in the United States is monitored with inexpensive pheromone-baited traps whose sticky internal surface ensnares males. Approximately 350,000 traps are deployed yearly to determine the extent of spread of the European strain of the gypsy moth from the eastern portions of the United States to the Midwest and South, or, especially along the west coast, to signal the occasional invasion of the Asian gypsy moth strain.

Pheromones also are used for direct population control. The tomato pinworm (Keiferia lycopersicella), for example, is a devastating pest of tomatoes in Mexico, largely because this moth is highly resistant to insecticides. Application of “cocktails” (mixtures of two or more insecticides) as many as 40 times during a crop cycle may not prevent complete crop loss. However, if a tomato field is blanketed with plastic dispensers that release micrograms per hour of synthetic pheromone, the emitted pheromone will interfere with normal mate-finding activities of males, even if the pinworm population is initially at high density. Just how mating disruption works is not fully established, but efficacy likely involves the additive effects of habituation of responsiveness (a presumed central nervous system phenomenon) and some competition for the male’s attention between the natural emitters, i.e. females, and the numerous sources of synthetic pheromone. The amount of synthetic pheromone needed to disrupt mate finding is quite small: typical application rates are several grams per hectare per week, and nearly all pheromones are nontoxic and nonpersistent. This technique is now commonly used to control several dozen moth species.

CONCLUSION

Pheromones are a dominant form of communication in most insects, and the messages conveyed serve myriad behavioral and physiological functions. Current microanalytical techniques permit identification of many of these messages, even though they occur in minuscule quantities. Studies expanding our understanding of the chemistry of these messages continue, although in many pheromone systems our ability to characterize the chemicals produced is in advance of our progress in understanding the evoked behaviors, particularly among the complex communication systems of social insects. Current frontiers of investigation in insect pheromones include establishing how genes control biosynthesis, how these chemicals are transduced into an electrical signal in the receptor cells of the responder, and how the signals are processed in the brain, leading to a behavioral output. Only a few structures of primer pheromones have been elucidated, and consequently much remains to be learned about their mode of action.

Phoresy

Marilyn A. Houck
Texas Tech University

Phoresy is a special kind of commensal relationship in which one organism (the phoretic or phoront) attaches to another (the host) for a limited time period to enhance dispersal of the phoront from the natal (or birth) habitat, resulting in colonization of a new and potentially better habitat. In addition to transport, the phoretic host may incidentally provide substrate, shelter, and even some indirect defense or protection for the phoront, but the strict definition of phoresy excludes any direct physiological benefit during transit. For example, the host does not provide the phoretic with food while in transit nor does it contribute to the ontogeny (development) of the phoretic during transit. If feeding does occur, the more appropriate term to describe this relationship would be parasitism. Although phoresy is not a form of parasitism, phoresy can eventually extend into a parasitic association (see below). Alternatively, if the host receives a benefit from its passenger the relationship is again not phoresy, but a form of mutualism. Thus, this discrete definition of phoresy separates phoresy from all other forms of symbiotic interactions.

The term phoresy is uniformly applied throughout the plant and animal kingdoms and does not exclusively apply to interactions of, or with, insects. Seeds that hitchhike on fur and pants are phoretic. The remora fish (Echeneidae: Remora remora) has a dorsal fin modified into a sucker that allows it to attach to the sides of larger fish and turtles, using them for phoretic transport. However, if the remora also
snatches pulverized leftovers created during feeding by the host, this act violates the strict definition of phoresy. It soon becomes clear that it can be difficult to distinguish phoresy from other forms of symbiosis. Detailed aspects of behavior, natural history, and physiology are essential to a firm understanding of interspecific associations.

**PHORESY AMONG INSECTS AND ARACHNIDS**

Phoresy among arthropods has been recognized since at least the mid-1700s. It was formalized and defined by Lesne in 1896 as “those cases in which the transport host serves its passenger as a vehicle.” The etymology of the word unites the perspective of both the phoretic (phor (Gr.) = thief) and the host (phorás (Gr.) = bearing) within the interaction and has a counterpart to most forms of human transport: a “boat” in aquatic phoretic interactions, a “bus” in terrestrial settings, and an “aircraft” in aerial transport. Despite the medium being traversed, there are general principles that seem to be consistent among phoretic relationships, but these are not inclusive and exceptions occur: (1) the phoretic is usually much smaller than its host; (2) there are often several phoretic passengers on any individual host, and mass transit is not uncommon; (3) the phoretic does not have an effective means of independent dispersal (e.g., wings or oars), whereas the host usually is quite mobile; (4) phoresy has played a role in dispersal for a long time and evidence of phoretic relationships can be found in Baltic and Dominican amber from as far back as the early Tertiary (40 mya); (5) phoresy is a response to degradation of an ephemeral habitat (transient habitats available for relatively short periods of time, e.g., beach wrack, dung, etc.) or depletion of a limited resource; (6) phoretic dismount from the host when a suitable new habitat is encountered by the host, indicating that the phoretic has sensory recognition and interpretation of some element in that habitat; (7) usually only one member of a complex life cycle participates in the phoresy and the other members in the life cycle are not phoretic; in such cases, the phoretic may come from among any of the life stages (adult, nymph, or larva); (8) phoresy may be highly coevolved and stenoecic when both the phoretic and the host are trophic specialists or very indiscriminant, in which case many “buses” may lead to alternate and appropriate habitats; (9) phoresy may be obligate (required) or facultative (occurring under some conditions); (10) phoretics may have little morphological adaptation specific to the attachment to the host (e.g., hold on with mouthparts or clasp with legs) and some have extensive modifications specific to attachment (e.g., extensive sucker plates or highly modified grasping legs); (11) enhanced by wind currents, phoresy is effective across impressive distances and there is even evidence of transoceanic voyages; (12) phoresy may be continual or seasonal, period, or cyclical; (13) the phoretic and the host may come from very different branches of the “tree of life,” as divergent as humans and plants, or from within related lineages (e.g., different insect orders); and (14) phoresy has originated independently several times within one lineage, in some instances (e.g., Melioidae or the blister beetles).

Most insect orders have members in the phoresy. However, the Diptera and Coleoptera form some of the most extensive phoretic associations with vertebrates, other insects, and mites. They can participate in phoresy as phoronts, as well as phoretic hosts. An interesting example of an insect as a phoretic host is the case of a common phoretic nematode, *Pelodera coarctata*, and its dung beetle host, *Aphodius*. As a dung pat deteriorates and dries, a special resistant phoretic nematode larva is produced that attaches to visiting dung beetles. The phoretic nematodes remain in a dormant state on the beetles until the beetles arrive at a fresh dung pat. Then the nematodes emerge, become active, and begin a new population of free-living nematodes.

Pseudoscorpions (arachnids that look like small scorpions) are notorious phoronts, found on an impressively large array of insect hosts: Diptera, Hymenoptera, Coleoptera, Odonata, Orthoptera, Heteroptera, Lepidoptera, Trichoptera, harvestmen (Opiliones), spiders, birds, and even small mammals. Pseudoscorpions attach by the chela, or venomous pedipalps, and hold on tightly enough to prevent being brushed off or blown off the host during transit. In one interesting phoretic interaction, a neriid fly that began as a phoretic host for a species of pseudoscorpion then becomes a postdispersal meal at the end of the journey: a case of turning the bus into a lunch wagon at the point of destination.

However, by far the most impressive radiation of phoretic associations occurs among the mites (Fig. 1). Intense selection pressure results in phoresy when organisms are of such extremely small size and they do not possess wings for dispersal. Small body size allows mites to exploit limited ephemeral resources that would be too small to be useful to larger organisms (e.g., a dead snail or nectar within a single flower). Because these resources are small, they degrade quickly and disappear rapidly. And, there may be large distances between them.

![Example of a mite–beetle phoretic relationship. The mites on the head and body of the *Nicrophorus* beetle are likely *Plocilochirus* (Mesostigmata: Parasitidae), which feed on mites in the beetles’ nest chamber. (Photographed in Carrer County, Minnesota, by Raphael Carter.)](image)

To survive, mites must travel to a better resource. Thus, they spend their lives tracking transient habitats. Establishing phoretic relationships with other organisms traveling among the same kinds of habitats gives them more rapid and direct access to a potentially better future and enhances their chances of survival.

Dung beetles, for example, thrive on dung, but as the dung dries and turns to soil it is no longer useful to the dung beetles. As the beetles depart, mites using the dung patties climb on board and hitch a ride to the next site. The journey would be perilous if these soft-bodied mites had to depend on walking the distance to their next meal. As the phoretic association progresses, the mites becomes increasingly dependent on those organisms that provide the most direct route to the best habitats.

**EVOLUTION OF PARASITISM FROM PHORESY**

Phoresy may begin with unrelated organisms moving independently among shared habitats. A relationship between a phoretic and a potential host can be established when some of the members of the population incidentally and randomly climb on board and are then delivered.
fortuitously to a habitat suitable for population growth. If encounters are repeated and consistent, mites develop cues to the most productive of these associations. Successful relationships become even more specialized and eventually stenoxenic. In some instances, phoretic association can become an intermediate step that grades into parasitism when the phoretic finds a way to get a meal, as well as shelter, from the host.

A well-documented case of a phoretic relationship becoming parasitic is that of the mite Hemisarcoptes and the coccinellid beetle Chilocorus. Both feed on diaspid scale insects and the association originated as a phoretic relationship. However, coccinellid beetles are reflex bleeders and Hemisarcoptes has become adapted to the reflexed alkaloid toxins in the hemolymph and now requires it to molt and complete its development. Because feeding and completion of ontogenesis are part of the contribution of the host, this relationship has graded into parasitism. Other related members of the same mite family (Hemisarcoptidae), which use other phoretic hosts, remain phoretic. This is good evidence that phoresy can be an end point and that it can also progress to other forms of symbiosis (e.g., parasitism). Phoresy thus benefits the individual, but it can also act to enhance the diversity and complexity of community interactions within and among habitats.

Photography of Insects

Mark W. Moffett

University of California, Berkeley

Quality photography of small animals in the field depends on rapid response to opportunities; this requisite is often impeded by the need to constantly root around in overstocked camera bags for the “right” piece of equipment. This article describes the author’s personal approach to insect photography, which is to improvise with as little gear as possible. If it does not fit comfortably in your backpack, why have it at all? This philosophy may not be relevant to the intended audience of most insect photography essays, namely, the museum curator, studio photographer, artist, or laboratory scientist, who have time to “set up” a picture. Specific brands are not considered here. In part this is because the market is in flux with the ongoing technological shift to autofocus and digital cameras and, in part, because the quality of lenses produced by any of the major camera lines today is sufficient to produce excellent photographs. Expensive gear is not a necessity for the best results.

For all but the largest insects or insect-produced structures such as nests, capturing insects on film typically requires macrophotography, which is photography at a magnification of 1:1 ("life size") or greater, which is the focus of this article. At 1:1, subjects are the same size on the film as they are in life. That is, the image of a 30-mm-long beetle measures 30 mm in length on the film negative or slide, which means it fills most of the frame in a photograph on 35-mm film. For a 3-mm beetle to appear just as large (i.e., so that it is likewise 30 mm in length on the film) requires 10 times life-size magnification, which is typically described as “×10,” or 10:1. The measurements are taken from the original film exposed in the camera, so prints made from a negative or slide would enlarge the subject beyond this size. For example, a 35-cm-wide print of the 3-mm-long beetle at ×10 on 35-mm film shows the beetle 3 cm in length, or 100 times its natural size.

One of the wonders of a well-executed insect photograph is that the subject’s original size is forgotten: the small beetle is just as imposing as the large one. This actually makes photography a wonderful medium for entomologists. Not realizing this, photographers often concentrate on insects that are impressive merely for their size. In fact, when not photographed on the photographer’s hand, many insects can look small on film. Similarly, elephants may be spectacular in life, but on film we can only make one appear smaller than it really is. I recall my mentor at National Geographic, editor Mary G. Smith, taking her first look at my first “macro” images in 1986 (Fig. 1), which were photographs of marauder ants killing prey. She exclaimed that
they reminded her of the movie “Terminator,” even though the ants looming over doomed prey in my pictures were just a few millimeters long. A criterion for a good insect photograph is that viewers are as surprised as Mary when a subject’s size is revealed.

LENSES

Although regular lenses can be used in combination with other equipment to produce images of life size or greater, for example, by adding extension tubes or magnifying filters, the results can be inferior to the photographs made with standard “macro lenses.” Although the term “macro” has been watered down in recent years by its application to lenses that focus relatively closely to the subject, true macro lenses focus all the way to 1:2 or 1:1 (sometimes an extension tube may be required for 1:1). These macro lenses are the sharpest, most optically corrected lenses produced by most companies and thus can be a wise investment. Many of them (typically those with focal lengths of about 50, 100, or sometimes 200 mm) can also be used as regular lenses, in which case they completely replace any other lens of a similar focal length. It should be noted that some of the optical precision of macro lenses relates to their having a “flat field” of focus. This characteristic is seldom important when working with live insects, unless perhaps one is in the habit of photographing straight down on flat insects living on the kitchen floor. Thus, when used with care, some less expensive lenses may be just as good in the field as true macro lenses, even when used at magnifications as high as 1:1.

A constant problem in insect photography is the distance from the front of the lens to the subject. With a macro lens set to a high magnification this distance may be only a few millimeters, so it takes practice not to disturb the insect when preparing to take a picture. In this regard stalking an insect is little different from stalking a leopard or a deer. As one moves the camera until the quarry comes into focus, one can learn to recognize through the viewfinder the moment when an insect detects the photographer. Each insect can require a different stalking technique.

If a short working distance causes the subject to be knocked or startled, the photographer should shift to a longer focal-length lens. A 200-mm macro lens provides a much greater working distance than a 50-mm macro set to the same magnification. Yet the longer lens is likely not to be quite as sharp, is harder to hold steady enough to focus precisely, requires heftier (and more unwieldy) brackets to hold the flashes, and needs more extension tubing to achieve magnifications beyond 1:1. If one can handle its short working distances, a 50-mm lens is therefore the ideal macro, but the 100-mm lens comes a very close second.

To achieve magnifications beyond life size with standard macro lenses, extension tubes are placed between a lens and the camera mount. Bellows are a more flexible alternative to tubes, because they provide every conceivable magnification between some upper and lower limit, but they are unwieldy and fragile in the field. The fixed lengths of the tubes are seldom a liability outdoors where being able to quickly frame and shoot insects is more important than precise cropping. In fact, tubes shorter than about 25 mm generally have little value with macro lenses because their effect on magnification is so slight.

In addition to standard macro lenses some manufacturers offer lenses designed exclusively for macrophotography (e.g., the ×1 to ×5 zoom lens made by Canon). Most of these lenses are built for high magnifications. An article by the author on soldier aphids in 1989 (Fig. 2) contains images between ×5 and ×20 on the film taken with a hand-held camera in the field. Whereas a standard macro lens can be used with only two or three extension tubes before working distance becomes too small to be practical or image quality declines, with some of these specialized lenses it may be possible to use several tubes at once.

Rotating the lens barrel either manually or with autofocus accomplishes focusing in normal photography, but it changes the magnification of an image in macrophotography, making it difficult to achieve the desired results. Autofocus therefore should be disengaged. Instead, focusing must be done as a manual, multistep process. Begin by deciding what magnification is desired, based on a subject’s size. Select the lens and extension tubes needed to achieve that magnification. Then aim the camera toward the subject, rocking slowly in and out until the subject appears in focus.

Photographs at the highest magnifications require a steady hand, a sharp eye, and a lot of practice. Each photographer needs to understand his or her own limits from experience. The problem is not only in seeing and composing the shot but also in the limited depth of field at higher magnifications. The depth of field is the depth (from front to back) that appears in focus within an image. All the significant parts of the image must fall within this area for a photograph to make sense. At times the author has used a half meter of extension tubing in the field, and in these situations the depth of field can be the length of a paramecium! To increase the chance of success, take a few images after focusing on the subject by rocking back and forth slightly to subtly change the plane of focus each time.

As in all high-magnification photography, automatic film advance comes in handy not so much to allow rapid-fire picture taking but to allow one to keep a subject correctly framed and in focus while these frame-to-frame shifts in the film plane are made. Another aid is to use a flashlight, even at midday (illuminate crevices and other small shadows or the shadow of the lens itself). Using Velcro, tape, or glue, attach a small penlight to either the lens or one of the flashes so that it can be aimed at the subject. Camping stores have many flashlights that can work. It is best to bring in a camera and try out specific designs.

FIGURE 2 Soldiers of the aphid Pseudoregma jamming their needlelike “horns” into the cuticle of a syrphid fly larva that was attacking their colony in Japan. Photographed at magnification 14×.
FLASHES

It is possible, but seldom advisable, to photograph a large insect with natural light using a tripod. With sufficient photographic skill, any image of an insect can be improved by the addition of flashes. Flashes provide a consistent and high quality of light, though flashes with colder (bluer) light can be improved by leaving a “warming gel,” like a Kodak CC10Y filter, taped over the flash window (one layer of frosted scotch tape can by itself sometimes do the trick). Flashes freeze any motion of the subject or camera—including most importantly any motion caused by the trembling of the photographer’s hands—and do so far more effectively than a tripod (particularly at high magnification). Furthermore, in the time it takes to set up a tripod, most insect subjects will have moved on to greener pastures. Flashes allow one to move in quickly and to constantly adjust the angle of approach as the action unfolds. For these reasons, the author seldom carries a tripod and even then never for macro work. Nonetheless, views of large insects in their environment, often at a high aperture with a wide-angle lens focused on a close subject, can be taken using natural light and a tripod, though with ground- or bark-dwelling species the camera may be steadied sufficiently by pressing it firmly against the stable substrate.

Not only can flash light increase the quality of any insect photograph, but when used with skill, two flashes are always an improvement over one flash; and two regular flash units are always an improvement over any method using a ring flash. The second flash serves as a “fill light,” that is, it is weaker (usually one-half the strength or one stop weaker) than the other, “main flash.” A fill-flash results in photographs with nicely defined, pleasant shadows and lots of three-dimensional information about the subject. The fill flash can be a weaker flash model, but often it is the same kind of flash placed at the same distance as the primary flash, but set at a lower power output or filtered to reduce the light (a sheet of tissue or artist’s tracing paper over the fill-flash head can do the trick). The flashes should be aimed toward the subject at about 45° from the axis of the lens and positioned anywhere from 90 to 120° apart around the lens barrel. For insects on reflective surfaces such as flowers and bright leaves, the light bounces off the surfaces and “fills” shadows somewhat, reducing the necessity of a fill flash. For shooting under these conditions, a single flash method as described by Shaw may suffice.

Ring flashes present problems with insects. The lower part of the ring impedes one from shooting low to the ground, blocking the most dramatic views. Also, the ring projects forward beyond the front of the lens all around the circumference, reducing the working distance. Further, because their light circles the lens and is directed forward rather than angled at the insect, ring flashes reduce the image’s three-dimensional content, making a subject look relatively shapeless and flat (ring lights were developed for flat objects such as stamps). This problem can be partially remedied by taping over parts of the ring. On the positive side, ring flashes provide good color saturation for photographers unsure of their photographic technique, especially when they are used in combination with a fill light.

The greatest stumbling block to great macrophotography is the scarcity of good two-flash systems. Some flash brackets have been marketed, but most are bulky (making it hard to photograph in the tight corners, where many insects dwell), are difficult to hold steady for long periods because of their weight, and are easily knocked out of position in the field. The author makes his own systems, from various flashes, power packs, brackets, cords, and slaves. Because flashes can be used in their nonautomatic (manual) settings, items from various camera brands can be mixed to achieve the lightest, most compact results with the flashes at optimal positions. Camera brands must be mixed with care, for example, by taping over flash shoe connections if flashes of one brand are used with a camera body of another brand. No design is perfect, but some are better than others, and all of them can be modified.

The position of the flashes is most critical. When a small flash head is even a few centimeters away from the insect, viewed from the subject’s position it appears as a point of light—much as the sun (although it is in fact a huge disc) appears as a point in the sky because of its distance from us. This kind of “point source” of light causes the most intensely illuminated spots to be “burned out” (too bright) and casts deep shadows that no film can handle (as occurs with any sunlit object on a cloudless day). To avoid such problems flashes should be placed as close to the subject as comfortably possible. So positioned, the lights resemble the light boxes used in studio photography for portraits. What is desired, in fact, is to replicate such a studio in miniature. One can even add a third light traditional in portrait studios, the “hair light,” that is aimed from behind to define the edges of the subject, but for most field photographers this light is often unnecessary.

SHARPNESS AND EXPOSURE

Achieving a sharp, correctly exposed macro image usually takes knowledge that comes from testing the system being used. Exposure tables and other textbook information are seldom accurate and are no substitute for judging for oneself what is pleasing. Tests that are done carefully the first time will never have to be done again—good results are guaranteed.

Light meters are not always effective with many macro scenes, which often include objects that can be either black or brightly lit depending on slight changes in camera position relative to the subject and its background. For this reason, manual exposure techniques provide greater accuracy, but if a camera meter is preferred, these problems in a scene must be recognized and exposure bracketed accordingly. The best flashes for manual exposure work have multiple manual settings, that is, full power, half-power, quarter-power, and so on.

To test both the flashes and the lens and to develop a technique, select a fine-grained slide film (many with an ISO of 100 or less work well). Slides allow one to accurately gauge the exposure and sharpness of the images. As a test subject, put a dead insect of a kind likely to be photographed on an 18% gray card (available at most major photography stores). Then take a series of test photographs, recording magnification, flash position, flash power, and f-stop for each frame of the film as follows:

1. Set the lens so that it gives a certain magnification (say, 1:1) or has a certain number of tubes that can be remembered (say, one 25-mm tube).
2. Select the power settings of the two flashes (perhaps put one on full power and the fill flash on half-power).
3. Take a series of photographs of the insect on the gray card at a standard angle (say about 45° from the horizontal), the first at the lens’ minimum aperture (say, f32) and then at one-f-stop intervals below that, down to f8.
4. Select another set of power settings for the flashes, say making both of them one stop weaker (i.e., one at half-power and the other at quarter-power).
5. Repeat steps 2 and 3 with weaker flash power settings.

The developed slides should be checked for image detail (such as the texture of the gray card and the sculpturing on the insect) and...
exposure (have the original gray card on hand to see if the brightness of the slide matches the gray of the card). Pick the combination of flash powers and f-stop that gives the most pleasing result (see below). That result might be, for example, F22 with the flashes set at half- and quarter-power (but if F22 looks a bit too dark and F16 looks too light, record the intermediate setting as correct, i.e., F18). Write the settings down and use them thereafter for that magnification (although, as in any photographic situation, one can bracket slightly, for example, by opening up to F16 when the subject or its background is very dark). If it turns out the test photographs are all dark, move the flashes closer or purchase stronger units. If they are all too bright (or if the correct exposure occurs at an f-stop that has too little depth of field, as is explained below), weaken both flashes and test again.

Results from the first magnification can be used as the starting point for testing other magnifications, because results tend not to differ radically from one magnification to the next. For example, try a series of magnifications such as ×2, ×3, and ×6 (or, if preferred, the same lens with 50, 100, and 200 mm of lens tubing). After working out the correct exposure for each magnification, write up an exposure table and tape it to the back of the flash heads for reference.

Most people choose images that are overexposed (i.e., too bright), which for macrophotography means that valuable flash battery power has been wasted in producing too much light. If in doubt, choose a slightly darker image over a slightly bright one. To correctly judge exposure and image quality use a color-corrected (5500 K) light table. For slide film the highlights (bright parts of the image) should not be entirely burnt out except perhaps for tiny areas, and the colors over most of the image should be saturated (richly hued and not faded by strong light). Meanwhile, the darkest parts of an image should be inky black, but not so much as to lose detail by rendering an image blotchy. If burnt areas or blotchiness occur, try repositioning the flashes.

The tests may show the classic trade-off in macrophotography between depth of field and image quality. Thus, even though most macro lenses tend to close down to 32 and this f-stop provides the most depth of field, to produce sharp images it is best to open the aperture at least one stop from this setting (in this example, F22). The best quality—highest resolution and contrast—may actually occur at a stop lower that that (e.g., at F16), but the difference may be marginal enough so that the best choice is to use F22 because of the greater depth of field it provides. If a lot of extension tubing is added to a lens, image quality for the same f-stop setting on the lens may drop further, perhaps to an aperture of f11. This adjustment is a problem because the depth of field also declines as extension tubes are added or magnification is otherwise increased. Therefore the highest magnification attainable by a lens depends on the accuracy of the photographer with focusing and the optical limits of that lens. At some point, it becomes necessary to purchase a lens better designed for the magnification in question.

**TECHNIQUE**

The most difficult subjects require considerable patience and a lot of time—sometimes a hundred attempts for every usable image. Ways of improving one’s chances can be found, such as having on hand a supply of food items in photographing predation, but such techniques must be used with care. Usually, the best image results from capturing the animal in the act of normal behavior in its normal habitat. This image is “best” not necessarily because of its technical perfection (on the contrary, the gritty realism of a slightly imperfect image sometimes enhances its drama, as is often true in photojournalism), but because of its accuracy. For example, a knowledgeable person might detect that the prey provided to the subject for a photograph is not a species that it normally would find and catch. Even more egregious is the refrigeration of specimens to slow them down for a picture. Despite their stiff exoskeletons, insects express themselves by subtle postures and actions (see Fig. 1). To the expert, a staged picture of a chilled insect appears as unnatural as one of a frozen human being.

With time and experience, one may want to attempt a photoessay or lecture on a particular subject. To hold a viewer’s interest, try to incorporate a variety of compositions and magnifications. A critical overview of nature photojournalism was provided by Moffett in a 1995 article.

Ocelli are absent, eyes are reduced or absent, and antennae are short with 3–5 segments. Body length of adults ranges from 0.3 to 12 mm.

**EVOLUTION AND DIVERSITY**

Over 5000 louse species are recognized. Lice formerly were classified in two orders, Mallophaga (chewing lice) and Anoplura
sucking lice). However, they now are combined into the order Phthiraptera, with the former Mallophaga comprising three suborders (Amblycera, Ischnocera, and Rhyynchophthirina) and the Anoplura a fourth. Although the suborders show substantial differences, they are believed to form a hemipteroid monophyletic unit whose sister group is the Psocoptera (psocids or booklice). Chewing lice have mandibulate mouthparts and probably evolved on birds. They are thought to have fed initially on skin and feathers, with some groups ultimately expanding their diets to include tissue fluids and blood. Some chewing lice eventually made a transition from birds to mammals and some Ricinidae (Amblycera) have mouthparts adapted to pierce host skin.

Sucking lice are restricted to mammalian hosts and have unusual piercing-sucking mouthparts that consist of three stylets, probably derived from the fused maxillae, hypopharynx, and labium. The stylets, retracted into the head when not in use, are everted to pierce skin and feed on host blood. Salivary secretions injected into the host include an anticoagulant to prevent blood coagulation during feeding.

Lice are recorded from approximately 4500 bird and mammal species, encompassing about 27% of mammal species and 34% of bird species. As many as 50% of the extant louse species remain undescribed. Lice are found on all bird orders but are not known to be associated with the mammalian order Monotremata (monotremes), the marsupial orders Microbiotheria (the monito del monte) and Notoryctemorphia (marsupial “moles”), Afrotheriidae (tenrecs and golden moles), Chiroptera (bats), Cetacea (whales, dolphins, and porpoises), Sirenia (dugong, sea cow, and manatees), or Pholidota (scaly anteaters).

**LIFE HISTORY**

Details of louse life history are known for only a relatively few species, especially those of economic importance. Eggs (also known as nits) typically are cemented to hairs or feathers of the host and all life stages are confined to a single host. Some notable exceptions to this egg-laying behavior include the human body louse, Pediculus humanus humanus (Anoplura: Pediculidae), which attaches its eggs to clothing fiber and spends most of its time between feedings on clothing rather than on the host itself, and several genera in the chewing louse family Menoponidae (Amblycera) that spend their entire life cycles and deposit eggs inside the quills of primary and secondary feathers.

Immatures emerge from eggs by exerting pressure on an operculum at the free end of the egg. The timing and duration of the egg, three instars, and adult stages vary among species and may be affected by environmental temperature and humidity. Nymphs of the human head louse (P. humanus capitis) take 6–9 days to hatch and reach the adult stage in about 1 week. Adults remaining on the host live about 1 month, with each female laying as many as eight eggs per day. Immatures and adults normally feed twice each day and cannot survive off of the host for more than a few days.

Dispersal of lice typically requires close contact between hosts, although immature lice have been found attached to flying insects that move between hosts, and phoresy may play a role in the dispersal of some species. The human body louse is dispersed by sharing infested clothing, the head louse (Fig. 1A) by personal contact or sharing combs and brushes, and the crab louse, Pthirus pubis (Anoplura: Phthiridae) (Fig. 1B), by sexual contact or, less commonly, through infested bed linens, towels, or clothing.

**LOUSE–HOST SPECIFICITY AND COSPECIATION**

Many lice show a high degree of host specificity, causing them to play an important role in studies of host–parasite cospeciation. For example, the 36 species of pocket gophers (Rodentia: Geomyidae) are parasitized by 122 species and subspecies of Geomydocaecus and Thomomysocécus chewing lice (Ischnocera: Trichodectidae), many of which have distributions that conform closely to host–subspecies groups that are genetically similar. However, host specificity is not universal because many louse species occur on more than a single host species. Anatoceccus dentatus and A. icterodes in the Philopteridae (Ischnocera), for example, each occur on more than 60 different species of ducks, geese, and swans (Anseriformes: Anatidae).

Many host species are parasitized by more than one louse species. For example, a single subspecies of brown tinamou, Crypturellus obsolus pusenisis (Tinamiformes: Tinamidae), is infested by 11 species of lice, representing 10 genera in two families. When multiple louse species infest a single host individual, the different species may congregate in different areas of the body. In mammalian lice, habitat specialization often is associated with hair diameter. For example, the crab louse tends to be confined to the relatively coarse hair associated with the genital areas, the face, and the underarms, whereas the head louse tends to be associated with the smaller diameter hair of the scalp.

**ECONOMIC IMPORTANCE**

The economic importance of most louse species is unknown, although they are known to cause irritation, inflammation, and itching and serve as vectors of diseases and other parasites. High louse densities often are found on weakened or sick hosts, especially on birds with damaged bills or those unable to perform normal grooming activities. Lice infest a number of domestic animals including poultry, domestic dogs and cats, cattle, sheep, goats, horses, pigs, and porpoises, Sirenia (dugong, sea cow, and manatees), or Pholidota (scaly anteaters).

**FIGURE 1** Lice of humans (dorsal view of adult females). (A) Head louse, P. humanus capitis (Anoplura: Pediculidae), adult body length 2.1–3.3 mm (body lice look similar to head lice, but tend to be slightly larger). (B) Crab louse, P. pubis (Anoplura: Phthiridae), average adult body length about 1.75 mm for females and 1.25 mm for males. (Illustrations adapted from Ferris, 1951, courtesy of the Pacific Coast Entomological Society and Stanford University Press.)
and rabbits. Animals in zoos and laboratory colonies of rats and mice also may become infested. Economic loss to the livestock and poultry industry in the United States caused by lice has been estimated at more than $550,000,000 per year, with about two-thirds of this resulting from weight and egg production losses in poultry caused by chewing louse infestations.

The human body louse serves as the vector of epidemic typhus and epidemic relapsing fever and as an occasional vector of murine typhus. Epidemic louse-borne typhus, a rickettsial disease caused by *Rickettsia prowazekii*, is an important scourge of humans often associated with wars and disasters. It still is endemic in cold areas of Africa, Asia, and Central and South America. Zinsser gives a remarkable account of the impact of this disease on human history. For example, the disastrous failure of Napoleon’s Grand Armée to conquer Russia during the campaign of 1812 is attributed largely to the effects of epidemic louse-borne typhus fever combined with malnutrition, dysentery, and exposure. The effectiveness of the pesticide DDT was demonstrated in 1943 during World War II in the control of lice responsible for an outbreak of typhus fever after the Allied bombing of Naples, Italy.

The name typhus is derived from Greek *typhos*, meaning stupor or fever. Infected humans experience high fever often accompanied by severe headaches, mental confusion, chills, coughing, and muscular pain. A rash generally appears on the 5th to 6th day and usually spreads to much of the body except the face, palms, and soles of the feet. The mortality rate usually is 1–20%, but can be much greater under epidemic conditions in populations that are weakened by malnutrition or other diseases. Transmission is by contamination of wounds with louse feces rather than through the bite or feeding of the louse. Brill–Zinsser disease is a relatively mild form of typhus that can remain viable in humans for years and can serve as a reservoir of the disease and the source of future epidemics. Although not associated with disease transmission, outbreaks of the human head louse are epidemic throughout the world, with treatment complicated by the development of louse resistance to some commonly used chemical control agents.

### CLASSIFICATION AND HOST ASSOCIATIONS

Amblycera is regarded as the most primitive louse suborder, and the Rhynchophthirina and Anoplura are thought to be the most advanced. The suborder Amblycera (Fig. 2A) includes six families: Boopiidae (mostly on marsupials, with one species infesting dogs and another the cassowary), Gyropidae (mostly on rodents, but with one genus occurring on New World monkeys and another on peccaries), Laemobothriidae (found on six bird orders), Menoponidae (widely distributed on birds), Ricinidae (on passerines and hummingbirds), and Trimenoponidae (on marsupials and rodents). The suborder Ischnocera (Fig. 2B) includes two families: Philopteridae (widely distributed on birds, with two species on primates, one on lemurs and the other on the indri) and Trichodectidae (on seven mammalian orders). The suborder Rhynchophthirina (Fig. 2C) contains a single family, Haematomyzidae, found on elephants, wart hogs, and the red river hog. The suborder Anoplura (Fig. 2D) includes 15 families, all restricted to mammalian hosts: Echinopthiridae (on seals, sea lions, the walrus, and the North American river otter), Endelieellidae (on squirrels), Haematopinidae (on horses and their relatives, pigs, cattle, and deer), Hamophthiridae (on flying lemurs), Hoplopleuridae (on 8 families of rodents, a few shrews, and one species of pika), Hybophthiridae (on the aardvark), Linognathidae (on deer, cattle and their relatives, camels, and dogs and their relatives), Microthoraciidae (on the llama, alpaca, guanaco, and drummy), Neolinognathidae (on elephant shrews), Pecarocidae (on peccaries), Pedicinidae (on Old World monkeys), Pediculidae (on humans, chimpanzees, and New World monkeys), Polypilidae (on 13 families of rodents, shrews, tree shrews, hares, and 5 families of primates), Phthiridae (on humans and gorillas), and Ratemiidae (on horses and their relatives).

There is disagreement as to whether the human head louse should be recognized as a distinct species (*Pediculus capitis*) or as a subspecies of *P. humanus* (*P. humanus capitis*). Those favoring its recognition as a separate species cite differences in behavior, size, coloration, and ability to transmit disease. Those favoring subspecies

![FIGURE 2](https://example.com/figure2.png)

recognition note that populations of head and body lice are separable only statistically on the basis of minor differences in body size; that coloration in human lice is highly variable, with lice often taking on the color of their surroundings; and that hybridization between head and body lice has been demonstrated in the laboratory and is thought to occur in nature.

Phylogeny of Insects

Peter S. Cranston, Penny J. Gullan
University of California, Davis

Idea concerning the phylogenetic relationships among the major taxa of arthropods, and the included insects, are dynamic. Although there is a single evolutionary history, efforts to uncover this phylogeny vary between different researchers, techniques, and character systems studied. No technique or character system alone can guarantee to reveal the true relationships of the studied taxa; in actuality, convergent (homoplastic) similarity that confuses relationships is common to all data. The evidence behind traditional systems, representing perhaps the thorough understanding of a single character system rather than an integration of all knowledge, sometimes cannot withstand detailed scrutiny. Molecular sequence data often appear to overturn previous ideas derived from morphological interpretation, but may be misleading due to undersampling, unrecognized sampling of alternative gene duplicates (paralogs), and/or inappropriate analyses. In this article, the different sources of evidence for the phylogenies that we have chosen to portray are assessed critically. Well-founded and less well-founded traditional, even refuted, relationships are discussed, and if resolution appears to be lacking, this inadequacy is identified.

RELATIONSHIPS OF THE HEXAPODA TO OTHER ARTHROPODA

Insects belong to arguably the most successful major lineage of the phylum Arthropoda, the joint-legged animals. The latter clade comprises myriapods (centipedes, millipedes, and their relatives),

Specialized Terms

apomorphy ( -ic) A feature of an organism in the derived state, contrasted with an alternative one in the ancestral (primitive) state—a plesiomorphy ( -ic) For example, with the character of forewing development, the sclerotized elytron is an apomorphy for Coleoptera, and the alternative, a conventional flying fore wing, is a plesiomorphy at this level of comparison.
cladogram Diagrammatic illustration of the branching sequence of purported relationships of organisms, based on distribution of shared derived features (sympomorphies).
monophyletic Referring to a taxonomic group (called a clade) that contains all descendants derived from a single ancestor and recognized by the possession of a shared derived feature(s). For example, the clade Diptera is monophyletic, recognized by shared derived development of the hind wing as a haltere (balancing organ).
paraphyletic Referring to a taxonomic group (called a grade) derived from a single ancestor but not containing all descendants; grades share ancestral features (e.g., Mecoptera relative to Siphonaptera).
polyphyletic Referring to a taxonomic group derived from more than one ancestor and recognized by the possession of one or more features evolved convergently. For example, if the primitively wingless silverfish were united with secondarily wingless grasshoppers, beetles, and flies, the resulting group would be polyphyletic.
sister groups Species or monophyletic groups that arose from the stem species of a monophyletic group by a singular, identical splitting event. For example, the Lepidoptera and Trichoptera are sister groups; they shared a common ancestor that gave rise to no other lineage.
synapomorphy ( -ic) A derived state shared among the members of a monophyletic group, in contrast to a symplesiomorphy—a shared ancestral (plesiomorphic) state from which phylogenetic relationships cannot be inferred.
taxon (pl. taxa) The general name for a taxonomic group at any rank.
taxonomic rank The classificatory level in the taxonomic hierarchy, for example, species, genus, family, order. No rank is absolute, and comparisons between ranks of different organisms are inexact or even misleading; despite this, traditional ranks used for insects—notably orders and families—have useful didactic and synoptic value.
chelicerates (horseshoe crabs and arachnids), crustaceans (crabs, shrimps, and relatives), and hexapods (the six-legged arthropods, Insecta, and their relatives). Lobopods (onychophorans) sometimes have been included, but now almost universally are considered to lie outside of Arthropoda. Although traditionally each major arthropod group has been considered monophyletic, most have been suspected of non-monophyly by at least a few investigators. Results of molecular analyses have provided frequent challenges, particularly in suggesting the possible paraphyly of myriapods and of crustaceans. Even if considered monophyletic, estimation of inter-relationships has been a most contentious issue in biology, with almost every possible higher-level relationship finding some support. A once influential “Mantonian” view proposed three groups of arthropods, each derived from a different non-arthropod group, namely Uniramia (lobopods, myriapods and insects, united by single-branched legs), Crustacea, and Chelicerata. More recent morphological and molecular studies reject this hypothesis, proposing instead monophyly of arthropodization, but postulated internal relationships are diverse. Part of Manton’s Uniramia group—Atelocerata (also known as Tracheata) comprising myriapods and hexapods—finds support from morphological features including the occurrence of a tracheal system, Malpighian tubules, unbranched limbs, movable coxal vesicles, postantennal organs, and anterior tentorial arms, the lack of any evidence of the second antenna of crustaceans or a homologous structure, and the mandible comprising a complete limb, rather than the limb base of the crustacean mandible. Proponents of this relationship saw either Crustacea grouping with chelicerates and extinct trilobites, separate from Atelocerata, or forming its sister group, in a clade Mandibulata. Among all these schemes, the closest relatives of Hexapoda were proposed to be with, or possibly within, Myriapoda.

In contrast, novel and some rediscovered shared morphological features, including from the nervous system (e.g., brain structure, neuroblast formation and axon development), the visual system (e.g., fine structure of the ommatidia, optic nerves), and the process and control of development, especially segmentation, argued for a close relationship of Hexapoda to Crustacea, a group termed Pancrustacea, excluding myriapods. Furthermore, all analyzed molecular sequence data with adequate signal to resolve relationships supports Pancrustacea rather than Atelocerata. As more nuclear, mitochondrial gene order and protein-encoding gene data have been examined, for an ever-wider set of taxa, little or no support has been found for any alternative to Pancrustacea. This does not imply that such analyses all recover Pancrustacea—sometimes certain “problematic” taxa have had to be removed, even from sparsely sampled data sets, and evidently certain genes do not retain strong phylogenetic signal from very old radiations.

Clearly features understood previously to infer monophyly of Atelocerata must be re-considered. Postantennal organs occur in Hexapoda, but only in Collembola and Protura, and are suggested to be convergent with the organs in Myriapoda. Shared absence of features (such as lack of second antenna) cannot be taken as positive evidence of relationship. Malpighian tubules also are present (surely convergently) in arachnids, and evidence for homology between their structure in hexapods and myriapods remains inadequately studied. Coxal vesicles are not developed in all clades and may not to be homologous in Myriapoda and in those Hexapoda possessing these structures. Thus, morphological characters traditionally used to support Atelocerata include states that may be non-homologous and convergently acquired associated with development of terrestriality, are not distributed across all included taxa, or are inadequately surveyed across the immense morphological diversity of the arthropods.

A major finding from molecular embryology, that the developmental expression of a homeotic gene (Distal-less) in the mandible of studied insects was the same as in sampled crustaceans, challenges the independent derivation of hexapod mandibles from those of crustaceans. This developmental homology for mandibles substantiates an earlier morphological hypothesis, and undermines Manton’s argument for arthropod polyphyly. In summary, data derived from the neural, visual, and developmental systems, even though sampled across relatively few taxa, appear to reflect more accurately phylogeny than data from many earlier studies of external morphology.

The question remains as to whether part or all of Crustacea constitutes the sister-group to Hexapoda. Morphology generally supports a monophyletic Crustacea, but recent molecular data imply paraphyly, with only part of the Crustacea (generally either Malacostraca alone or Branchiopoda alone) being sister to Hexapoda.

**THE EXTANT HEXAPODA**

Hexapoda (ranked usually as superclass) contains all six-legged arthropods; diagnosis includes possession of a unique tagmosis, namely specialization of successive body segments that more or less unite to form sections or tagmata: head, thorax, and abdomen. The head is composed of a pregnathal region (often considered to be 3 segments) and 3 gnathal segments bearing mandibles, maxillae and labium respectively; the eyes are variously developed, and sometimes absent. The thorax comprises 3 segments each of which bears one pair of legs, and each thoracic leg has a maximum of 6 segments in extant forms, but is argued to have been primitively 11-segmented with up to 5 exites (outer appendages of the leg), a coxal endite (an inner appendage of the leg) and 2 terminal claws. Primitively the abdomen has 11 segments plus a telson or homolog, abdominal limbs, if present, are smaller and weaker than those of the thorax, and primitively occurred on all segments except the 10th.

Hexapods undoubtedly include taxa whose ancestors were wingless and terrestrial. The extant non-insect hexapods, treated as orders, are Protura (proturans), Collembola (springtails), and Diplura (diphrans). Recent data from ribosomal RNA gene sequences suggest that this grouping of three orders, traditionally named the Entognatha, may be monophyletic, in contrast to results of previous morphological analyses. True Insecta are the Archaeognatha (bristletails), the Zygentoma (=Thysanura; silverfish), and the huge radiation of Pterygota (primary winged hexapods); Insecta is treated as a class, and if monophyly of the Entognatha is confirmed, then it also would be a class, although at present most classifications recognize each of the Collembola, Diplura, and Protura as classes of equal rank to Insecta.

Relationships among the component taxa of Hexapoda are uncertain, although the cladogram shown in Fig. 1 and the classification presented in the sections that follow reflect one current view based on morphology. Traditionally, Collembola, Protura, and Diplura were grouped as the Entognatha, based on the apparently similar morphology of the mouthparts. The mouthparts of Insecta (Archeognatha+Zygentoma+Pterygota) are exposed (ectognathous), whereas those of Entognatha are encased in folds of the head. Two different types of entognathy have been recognized, one shared by Collembola and Protura and the second found only in Diplura. Other morphological evidence indicates that Diplura may be closer to Insecta than to other entognathans and thus Entognatha may be paraphyletic (as indicated by the broken line in Fig. 1). In contrast to the relationships suggested in Fig. 1, nucleotide sequence data from ribosomal RNA genes suggest that the Diplura may be the sister group to Protura, a grouping termed the “Nonoculata” due to
Phylogeny of Insects

the absence of eyes in these hexapods, with the Collembola sister to Diplura + Protura.

Protura (Proturans)

Proturans are small, delicate, elongate, mostly unpigmented hexapods, lacking eyes and antennae, with entognathous mouthparts consisting of slender mandibles and maxillae that slightly protrude from the mouth cavity. Maxillary and labial palps are present. The thorax is poorly differentiated from the 12-segmented abdomen. Legs are 5-segmented. A gonopore lies between segments 11 and 12, and the anus is terminal. Ceri are absent. Larval development is anamorphic, that is, with the number of body segments constant during development. Protura either is sister to Collembola, forming Ellipura in a weakly-supported relationship based on similarity of the entognathous mouthparts and lack of cerci, or is sister to just the Diplura, as suggested by ribosomal RNA genes.

Collembola (Springtails)

Collembolans are minute to small and soft bodied, often with rudimentary eyes or ocelli. The antennae are 4- to 6-segmented. The mouthparts are entognathous, consisting predominantly of elongate maxillae and mandibles enclosed by lateral folds of head, and lacking maxillary and labial palps. The legs are 4-segmented. The abdomen is 6-segmented with a sucker-like ventral tube, a retaining hook and a furcula (forked jumping organ) on segments 1, 3, and 4, respectively. A gonopore is present on segment 5, the anus on segment 6. Ceri are absent. Larval development is epimorphic, i.e., with segment number constant through development. Collembola form either the sister group to Protura comprising Ellipura, or the sister group to Dilpura + Protura, or are sister to Diplura + Insecta, depending on the character data analyzed.

Diplura (Diplurans)

Diplurans are small to medium-sized, mostly unpigmented, possession long, moniliform antennae (like a string of beads), but lack eyes. The mouthparts are entognathous, with tips of well-developed mandibles and maxillae protruding from the mouth cavity, and maxillary and labial palps reduced. The thorax is poorly differentiated from the 10-segmented abdomen. The legs are 5-segmented and some abdominal segments have small styles and protrusible vesicles.

Class Insecta (True Insects)

Insects range from minute to large (0.2–360 mm in length) and are very variable in appearance. They typically have ocelli and compound eyes, at least in adults, and the mouthparts are exposed (ectognathous), with the maxillary and labial palps usually well developed. The thorax is variably developed in immature stages, but distinct in adults with degree of development dependent on the presence of wings. Thoracic legs have more than 5 segments. The abdomen is primitively 11-segmented with the gonopore nearly always on segment 8 in the female and segment 9 in the male. Ceri are primitively present. Gas exchange is predominantly tracheal with spiracles present on both the thorax and abdomen, but variably reduced or absent (e.g., in many immature stages). Larval or nymphal development is epimorphic, that is, with the number of body segments constant during development.

The insects may be divided into two groups. Monocondylia is represented by just one small order, Archaeognatha, in which each mandible has a single posterior articulation with the head, whereas Dicondylia (Fig. 1), which contains the overwhelming majority of species, is characterized by mandibles with secondary anterior articulation in addition to the primary posterior one. The once traditional group "Apterygota" for the primarily wingless taxa Archaeognatha + Zygentoma is paraphyletic and rejected (Fig. 2).

ARCHAEOGNATHA (ARCHAEOGNATHANS, BRISTLETAILS) Archaeognathans are medium-sized, elongate-cylindrical apterygotes, with some 500 species in two extant families. The head bears three ocelli and large compound eyes that are in contact medially. The antennae are multisegmented; the mouthparts project ventrally and can be partially retracted into the head and include elongate mandibles with two neighboring condyles each, and elongate 7-segmented maxillary palps. Coxal styles are present on the legs; the tarsi are 2- to 3-segmented. The abdomen, which continues in an even contour from the humped thorax, bears ventral muscle-containing styles (representing reduced limbs) on segments 2–9, and generally 1–2 pairs of eversible vesicles medial to the styles on segments 1–7. Ceri are multisegmented and shorter than the median caudal appendage. Sperm transfer is indirect via sperm droplets

FIGURE 1 Cladogram depicting one view of relationships among, and inferred classification of, the higher ranks Hexapoda (six-legged Arthropoda). Dashed lines indicate uncertainty in relationships or paraphyly in classification.
attached to silken lines or by stalked spermatophore. Development occurs without change in body form.

The two families of recent Archaeognatha, Machilidae and Meinertellidae, form an undoubted monophyletic group, whose position as sister group to Dicondylia (Zygentoma + Pterygota) (Figs. 1 and 2) appears undisputed.

**ZYGENTOMA (THYSANURA, SILVERFISH)** Zygentomans (thysanurans) are medium-sized, dorso-ventrally flattened apterygotes with almost 400 species in five extant families. Eyes and ocelli are present, reduced, or absent, and the antennae multisegmented. The mouthparts are ventrally to slightly forward projecting and include a special form of double-articulated (dicyclidous) mandibles and 5-segmented maxillary palps. The abdomen continues the even contour of the thorax, and includes ventral muscle-containing styles (representing reduced limbs) on at least segments 7–9, sometimes on 2–9, and with eversible vesicles medial to the styles on some segments. Cerci are multisegmented and subequal to the length of the median caudal appendage. Sperm transfer is indirect via a spermatophore that the female picks up from the substrate. Development occurs without change in body form. Zygentoma is the sister group to the Pterygota.

**PTERYGOTA** Pterygotes are winged or secondarily apterous insects, in which the thoracic segments of adults are usually large with the meso- and metathorax variably united to form a pterothorax. The lateral regions of the thorax are well developed. The 8–11 abdominal segments lack styles and vesicular appendages, and only Ephemeroptera ever have a median terminal filament. The spiracles primarily have a muscular closing apparatus. Mating is by copulation. Metamorphosis is hemi- to holometabolous, with no adult ecdysis, except for the ephemeropertan subimago (subadult).

**“Palaeoptera”: An Informal Grouping or a Monophyletic Group of Pterygotes?** Palaeopteran wings are unable to be folded against the body at rest because articulation is via axillary plates that are fused with veins. Extant orders typically have triadic veins (paired main veins with intercalated longitudinal veins of opposite convexity/concavity to the adjacent main veins) and a network of cross-veins. This wing venation and articulation, substantiated by paleontological studies on similar features, has suggested that Odonata and Ephemeroptera form a monophyletic group, Palaeoptera, sister to Neoptera (all remaining extant and primarily winged orders). However, some assessments of morphology and some molecular evidence reject a monophyletic Palaeoptera. At present, relationships among the Ephemeroptera, Odonata, and Neoptera must be considered unresolved. Here Ephemeroptera is treated as sister to the Metapterygota, the Odonata+Neoptera, with Odonata alone as the sister group to Neoptera, giving a higher classification of Pterygota into three divisions. Metapterygota is defined by the loss of the submarginal molt, loss of the median caudal filament of the abdomen, fixation of the anterior mandibular articulation, and by features of the wing and leg tracheation.

**Ephemeroptera (Mayflies)** Ephemeroptera has a fossil record dating back to the Carboniferous and is represented today by a few thousand species. In addition to their palaeopteran features, mayflies display a number of unique characteristics including the non-functional, strongly reduced adult mouthparts, the presence of just one axillary plate in the wing articulation, a hypertrophied costal brace, and male forelegs modified for grasping the female during copulatory flight. Subimago (subadult stage) retention is unique. Nymphs (larvae) are aquatic and the mandible articulation, which is intermediate between monocoaly and the dicyclidous ball and socket joint of all higher Insecta, may be diagnostic. Historic contraction of ephemeropteran diversity, and remnant high levels of homoplasy renders phylogenetic reconstruction difficult. Ephemeroptera traditionally was divided into two suborders: Schistonota (with nymphal forewing pads separate from each other for over half their length) containing superfamilies Baetioidea, Heptagenioidea, Leptophlebioidea and Ephemeroidea, and Pannota ("fused back"—with more extensively fused forewing pads) containing Ephemeroelloidea and Caenidae. Recent studies suggest this concept of Schistonota is paraphyletic. Families Baetisidae and Prospistomatidae, whose nymphs have unusually developed thoracic shields, have been withdrawn from the Caenidae and placed now in suborder Carapacea. Currently three or four suborders are recognized: Carapacea (Baetisidae + Prospistomatidae), Furcatergalia (the pannote families plus some other families such as Leptophlebiidae), Pisciforma (the minnow-like mayflies), and Setisura (the flat-headed mayflies); sometimes the Setisura are placed in the Pisciforma.

**Odonata (Dragonflies and Damselflies)** Odonates have palaeopteran as well as many additional unique features, including the presence of two axillary plates (humeral and posterior axillary) in the wing articulation and many features associated with specialized copulatory behaviour, including possession of secondary copulatory apparatus on ventral segments 2 and 3 of the male and the formation of a tandem wheel during copulation. The immature stages are aquatic and possess a highly modified prehensile labium for catching prey.

There are nearly 6000 species of odonates. Traditionally, odonatologists recognized three groups of taxa, Zygoptera (damselflies), Anisozygoptera, and Anisoptera (dragonflies), generally ranked as suborders, but the extant Anisozygoptera now are included with Anisoptera in the suborder Epiprocta (with living Epiphelebiidae sister to rest of Anisoptera). Assessment of the monophyly or paraphyly of the suborders has relied very much on characters derived from the very complex wing venation, but homology of these features within the odonates and between other insects has been substantially prejudiced by prior phylogenetic ideas. Thus, the Comstock and Needham wing vein naming system implies that the common ancestor of modern Odonata was anisopteran and the zygopteran venation arrived by reduction. In contrast, the Tillyard system implied Zygoptera is a grade on the way to Anisozygoptera, which itself is a grade on the way to Anisoptera. The recent consensus, based on morphological and molecular data, has both Zygoptera and Epiprocta monophyletic, and Anisoptera as the monophyletic sister group to some extinct anisozygopterans with Epiphelebiidae (formerly recognized as the only living anisozygopterans) sister to Anisoptera+extinct anisozygopterans.

**Neoptera** All winged and secondarily wingless insects except for the two palaeopterous orders belong to this large clade of the Pterygota. Neopteran insects diagnostically have wings capable of being folded back against their abdomen when at rest, with wing articulation deriving from separate movable sclerites in the wing base, and wing venation with fewer (or lacking completely) triadic veins and mostly lacking anastomosing (joining) cross-veins.

The phylogeny (and hence classification) of the neopteran orders is still the subject of debate, mainly concerning (a) the placement of many extinct orders described only from fossils of variously adequate
Phylogeny of Insects

preservation, (b) the relationships among the Polyneoptera (orthopteroid and plecopteroid orders), and (c) the relationships of the highly derived Strepsiptera.

However, the summary that follows reflects one possibility among current interpretations, based on both morphology and molecules. No single or combined data set provides unambiguous resolution of insect order-level phylogeny, and there are several areas of controversy (such as the position of the Strepsiptera) arising from both inadequate data (insufficient or inappropriate taxon sampling) and character conflict within existing data. In the absence of a robust phylogeny, ranking is somewhat subjective and “informal” ranks abound.

A group of up to 11 orders termed the orthopteroid-plecopteroid assemblage (if monophyly is uncertain) or Polyneoptera (if monophyletic) is considered to be sister to the remaining Neoptera. The remaining neopterans can be divided readily into two monophyletic groups, namely Paraneoptera and Endopterygota (= Holometabola). These three clades may be given the rank of subdivision.

Polyneoptera (or Orthopteroid–Plecopteroid Assemblage of Neoptera) [Isoptera, Blattodea, Mantodea, Dermaptera, Grylloblattaria (= Grylloblattodea or Notoptera), Plecoptera, Orthoptera, Phasmataodea, Embiidina (= Embiophora), Zoraptera, Mantophasmatodea] The relationships of these neopteran orders are poorly resolved with several, often contradictory, relationships being suggested by morphology. The 11 included orders may form a monophyletic group, based on the shared presence of tarsal plantulae (lacking only in Zoraptera) and by limited, but increasing, molecular information. Within Polyneoptera, only the grouping comprising Blattodea (cockroaches), Isoptera (termites), and Mantodea (mantis)—the Dictyoptera (Fig. 3)—is robust. Although each of these three orders is distinctive, certain features of the head skeleton (perforated tentorium), mouthparts (paraglossal musculature), digestive system (toothed proventriculus), and female genitalia (shortened ovipositor above a large subgenital plate) demonstrate monophyly of Dictyoptera, substantiated by nearly all molecular analyses. However, as seen below, views on the internal relationships are changing. Dermaptera (earwigs) may be sister to Dictyoptera, and Grylloblattaria (rock crawlers; now apterus, but with winged fossils) may be sister to this grouping.

Some molecular data suggest that Orthoptera (crickets, katydids, grasshoppers, locusts, etc.), Phasmataodea (stick insects or phasms), and Embiidina (webspinners) may be closely related, forming Orthopteroidea in the sense of Hennig. The relationships of Plecoptera (stoneflies), orthopteroids, Zoraptera (zorapterans), and the recently discovered Mantophasmatodea to each other and to the above groupings are less well understood.

Isoperta (Termites, White Ants) Isoptera forms a small order of eusocial hemimetabolous neopterans, with more than 2600 described species, living socially with polymorphic caste systems of reproductives, workers, and soldiers. The mouthparts are typically blattoid, being mandibulate but varying among castes, with some soldiers having bizarre development of mandibles or a nasus (snout). The compound eyes are frequently reduced, the antennae are long and multisegmented, and the fore wings and hind wings are generally similar, membranous, and have restricted venation. Mastotermes (Mastotermitidae) has complex wing venation and a broad hind wing anal lobe and is exceptional among termites in that the female has a reduced blattoid-type ovipositor. The male external genitalia are weakly developed and symmetrical, in contrast to the well complex, symmetrical genitalia of Blattodea and Mantodea.

Isopteran relationships are somewhat controversial, although they have always been considered to belong in Dictyoptera close to Blattodea. Recent studies that include the structure of the proventriculus and molecular sequence data suggest that termites arose from within the cockroaches, thereby rendering the latter group paraphylactic. Under this scenario, the (wingless) woodroaches of North America and eastern Asia (genus Cryptocercus) form the sister group to Isoptera. This contrasts with alternative suggestions that the semisociality (parental care and transfer of symbiotic gut flagellates between generations) of Cryptocercus was convergent with certain features of termite sociality, and independently originated within the true cockroaches. These two contrasting views are shown in Fig. 4. The social system and general morphology of Mastotermes suggests a cockroach-like condition, and most phylogenies place this group as sister to remaining extant Isoptera. Of considerable interest is the wide distribution and species richness of Mastotermitidae in Cretaceous times, compared to the reduced diversity of the extant family, which comprises just one species in northern Australia.

Blattodea (Cockroaches) Blattodea contains about 4000 species in at least seven families worldwide. They are hemimetabolous, dorsoventrally flattened insects with filiform, multisegmented antennae, and mandibulate, ventrally projecting mouthparts. The prothorax has an enlarged, shield-like pronotum, often covering the head; the meso- and metathorax are rectangular and subequal. The fore wings are sclerotized as tegmina, which protect membranous hind wings folded fan-like at rest beneath the tegmina and characterized by many vein branches and a large anal lobe; wings are often reduced. Often the legs are spiny and the tarsi are 5-segmented. The abdomen has 10 visible segments, with a subgenital plate (sternum 9), bearing in the male well-developed asymmetrical genitalia, with one or two styles, and concealing the reduced 11th segment. Ceri have 1 or, usually, many segments; the female ovipositor valves are concealed beneath tegrum 10.

Although long considered an order (and hence monophyletic), convincing evidence has been produced by several independent researchers that the termites arose from within the cockroaches, and
the “order” thus is rendered paraphyletic. The sister group of the Isoptera appears to be the cockroach genus Cryptocercus (Fig. 4).

**Mantodea (Mantids)** Mantodea contains some 2300 species in 8–14 families. Mantids are hemimetabolous predators, with males generally smaller than females. The small, triangular head is mobile, with slender antennae, large, widely separated eyes and mandibulate mouthparts. The prothorax is narrow and elongate, with the mesoand metathorax shorter. The fore wings form leathery tegmina with a reduced anal area; the hind wings are broad and membranous, with long unbranched veins and many cross-veins, but often are reduced or absent. The forelegs are raptorial, whereas the mid and hind legs are elongate for walking. The abdomen has a visible 10th segment, or absent. The forelegs are raptorial, and the male genitalia are asymmetrical.

Mantodea form the sister group to Blattodea + Isoptera, and share many features with Blattodea such as strong direct flight muscles and weak indirect (longitudinal) flight muscles, asymmetrical male genitalia and multisegmented cerci. Derived features of Mantodea relative to Blattodea involve modifications associated with predation, including leg morphology, an elongate prothorax, and features associated with visual predation, namely the mobile head with large, separated eyes, and several peculiarities of the proventriculus. Internal relationships of Mantodea have been uncertain, and many of the existing families and subfamilies have been shown to be paraphyletic based on recent molecular data.

**Grylloblattaria (Notoptera, Grylloblattodea) (Grylloblattidae or Rock Crawlers)** Grylloblattaria contains one family (Grylloblattidae) with fewer than 30 species, restricted to western North America and central to eastern Asia, and particularly tolerant of cold and high elevations. Grylloblattidae are moderate-sized, soft-bodied insects with anteriorly projecting mandibulate mouthparts and compound eyes that either are reduced or absent. The antennae are multisegmented and the mouthparts mandibulate. The quadrate prothorax is larger than the meso- or metathorax, and the wings are absent. The legs are adapted for running, with large coxae and 5-segmented tarsi. There are 10 visible abdominal segments with rudiments of segment 11, including 5–9-segmented cerci. The female has a short ovipositor, and the male genitalia are asymmetrical.

The phylogenetic placement of Grylloblattaria is controversial, generally being argued to be relictual, either “bridging the cockroaches and orthopterans” or “primitive amongst orthopteroids.” The antennal musculature resembles that of mantids and embiids, mandibular musculature resembles Dictyoptera, and the maxillary muscles those of Dermaptera. Embryologically grylloblattids appear closest to the orthopteroids. Some molecular phylogenetic data place the Grylloblattaria as sister to the Mantophasmatodea.

**Dermoptera (Earwigs)** Dermoptera is a worldwide order, modest in size, with an unstable family classification and about 1900 species. Adult earwigs are elongate and dorsoventrally flattened with mandibulate, forward-projecting mouthparts, compound eyes ranging from large to absent, no ocelli, and short antennae. The tarsi are 3-segmented with a short second tarsomere. Many species are apterous or, if winged, the fore wings are small, leathery, and smooth, forming unveined tegmina, and the hind wings are large, membranous, semi-circular, and dominated by an anal fan of radiating vein branches connected by cross-veins; when at rest, the hind wings are folded fan-like and then longitudinally, protruding slightly from beneath the tegmina.

The five species of suborder Arxeniina are commensals or ectoparasites of bats in Southeast Asia. A few species of semi-parasites of African rodents have been placed in a suborder Hemimerina. These earwigs are blind, apterous, have rod-like forceps, and exhibit pseudoplacental viviparity. Recent morphological study of Hemimerina suggests derivation from within Forficulina, rendering that suborder paraphyletic. The relationships of Arxeniina to more “typical” earwigs (Forficulina) are uninvestigated. Within Forficulina, only four (Karshiellidae, Apachiidae, Chelisochidae, and Forficulidae) of nine families proposed appear to be supported by synapomorphies. Other families may not be monophyletic, as much weight has been placed on plesiomorphies, especially of the penis specifically and genitalia more generally, or homoplasies (convergences) in furcula form and wing reduction.

The relationship of Dermoptera to other polyneopteran orders is uncertain, although a sister group relationship to Dictyoptera has been suggested based on morphology, including many features of the wing venation.

**Plecoptera (Stoneflies)** Plecoptera contains some 16 families and more than 2000 species, predominantly living in temperate and cool areas. The adult is mandibulate with filiform antennae, bulging compound eyes, two or three ocelli, and subequal thoracic segments. The fore wings and hind wings are membranous and similar except that the hind wings are broader; when folded, the wings partly wrap the abdomen and extend beyond the abdominal apex; aptery and brachyptery are frequent. The abdomen is soft and variably 10-segmented, although remnants of segments 11 and 12 are present, including cerci. Nymphs have many (up to 33) aquatic instars, which have fully developed mandibulate mouthparts, and wings pads first become visible when half-grown.

Monophyly of the order is supported by a few morphological features, including in the adult the looping and partial fusion of gonads and male seminal vesicles, and the absence of an ovipositor. In nymphs the presence of strong, oblique, ventrolongitudinal muscles running intersegmentally allowing lateral undulating swimming, and the probably widespread “cercus heart,” an accessory circulatory
Phylogeny of Insects

organ associated with posterior abdominal gills, support the monophyley of the order. Gills may be present in nympha Plectoptera on almost any part of the body, or may be absent, causing problems of homology of gills among families, and between Plectoptera and other orders. Whether Plectoptera are derived from an aquatic or terrestrial ancestor is debatable.

The phylogenetic position of Plectoptera is certainly amongst "lower Neoptera," possibly as sister group to the remainder of Neoptera. However, some molecular and combined molecular plus morphological evidence tends to support a more derived position with the Polynota.

Internal relationships have been proposed as two predominantly vicariant suborders, the austral Antarctoperlaria and northern Arctoperlaria. The monophyly of Antarctoperlaria is argued based on the unique sternal depressor muscle of the fore trochanter, lack of the usual tergal depressor, and presence of floriform chloride cells, which may have a sensory function. Some of the included taxa are the large-sized Eustheniidae and Diaphlipinidae, the Gripopterygidae and Australioperlidae—all families with a southern hemisphere "Gondwanan"-type distribution. Recent molecular studies support this clade.

The sister group Arctoperlaria lacks defining morphology, but is united by a variety of mechanisms associated with drumming (sound production) associated with mate finding. The component families Scoporiidae, Taeniopodopteraidae, Leuctridae, and Nemouridae (including Notonemouridae) are essentially distributed in the northern hemisphere with a lesser radiation of Notonemouridae into the southern hemisphere. Molecular studies suggest the paraphyly of Arctoperlaria, with most elements of Notonemouridae forming the sister group to the remainder of the families. Relationships amongst extant Plectoptera are proving important in hypothesising the origins of wings from "thoracic gills" and in tracing the possible development of aerial flight from surface flapping with legs trailing on the water surface, and forms of gliding.

Zoraptera (Zorapterans) Zoraptera is one of the smallest (32 species) and probably the least known pterygote order. Zorapterans are small, rather termite-like insects, found worldwide in tropical and warm temperate regions except Australia. Their morphology is simple, with biting, generalized mouthparts, including 5-segmented maxillary palps and 3-segmented labial palps. Sometimes both sexes are apterous, and in alate forms the hind wings are smaller than the fore wings; the wings are shed as in ants and termites. Wing venation is highly specialized and reduced.

Traditionally the order contained only one family (Zorotypidae) and one genus (Zorotypus), but has been expanded to include seven genera delimited predominantly on wing venation. This subdivision of Zorotypus is not accepted by some authors. The phylogenetic position of Zoraptera based on morphology has been controversial, ranging through membership of the hemipteroid orders, sister to Isoptera, an orthopteroid, or a blattoid, or sister to Embiidina. Analysis of major wing structures and musculature suggests that Zoraptera belongs in the blattoid lineage. Although the wing shape and venation resembles that of narrow-winged Isoptera, cephalic and abdominal characters indicate an early divergence from the blattoid stock, prior to the divergence of Dermaptera, and much before the origin of the Dictyoptera lineage.

Orthoptera (Grasshoppers, Locusts, Katydid, Crickets) Orthopterans belong to at least 30 families and more than 20,000 species, and mostly are medium-sized to large insects with hind legs often enlarged for jumping (saltation). The compound eyes are well developed, the antennae are elongate and multisegmented, and the prothorax is large with a shield-like pronotum curving downward laterally. The fore wings form narrow, leathery tegmina, and the hind wings are broad, with numerous longitudinal and cross-veins, folded beneath the tegmina by pleating; aptery and brachyptery are frequent. The abdomen has 8-9 annular visible segments, with the 2 or 3 terminal segments reduced, and 1-segmented cerci. The female has a well-developed ovipositor formed from highly modified abdominal appendages.

Virtually all morphological evidence, and much of the molecular data suggest that the Orthoptera form the sister group to Phasmatoidea. Some authors have united the orders, but the different wing bud development, egg morphology, and lack of auditory organs in phasmatids suggests separation. Molecular evidence indicates Embiidina may be sister to the orthopteran-phasmatid clade.

The division of Orthoptera into two monophyletic suborders, Caelifera (grasshoppers and locusts—predominantly day-active, fast-moving, visually acute, terrestrial herbivores) and Ensifera (katydids and crickets—often night-active, camouflage or mimetic, predators, omnivores, or phytophages) is supported on morphological and molecular evidence. Grylloidea probably are the sister group (but highly divergent, with a long branch separation) of the remaining ensifera taxa, Tettigonioidae, Hagloidea, and Stenopelmatoidea. In Caelifera, a well-supported recent proposal for four higher taxa, namely [Tridactyloidea (Tetrigidae (Eumastacoidea +"higher Caelifera")]) reconciles molecular evidence with certain earlier suggestions from morphology. The major grouping of acridoid grasshoppers (Acridoidea) lies in the unnamed clade "higher Caelifera," which also includes superfamilies Tanaoceroidea, Pygromorphoidea, Pneumoroidea, and Trigonomorphoidea.

Phasmatodea (= Phasmida) (Phasmatids, Phasmids, Stick Insects or Walking Sticks, Leaf-insects) Phasmatodea are a worldwide, predominantly tropical order of more than 3000 species of hemimetabolous insects, conventionally classified in three families (although some workers assign many subsfamilies to family rank). Body shapes are variations on elongate cylindrical and stick-like or flattened, or often leaf-like. The mouthparts are mandibulate. The compound eyes relatively small and placed anterolaterally, with ocelli only in winged species, and often only in males. The antennae are short to long, with 8-100 segments. The prothorax is small, and the mesothorax and metathorax are long in wingless species, shorter if apterous. The wings, when present, are functional in males, often reduced in females, but with many species apterous in both sexes; the fore wings form short leathery tegmina, whereas the hind wings are broad with a network of numerous cross-veins and with the anterior margin toughened to protect the folded wing. The legs are elongate, slender, and adapted for walking, with 5-segmented tarsi. The abdomen is 11-segmented, with segment 11 often forming a concealed supra-anal plate in males or a more obvious segment in females.

Phasmatodea are sister to Orthoptera in the orthopteroid assemblage. Novel support for this grouping comes from the dorsal position of the cell body of salivary neuron 1 in the subesophageal ganglion and presence of serotonin in salivary neuron 2. Phasmatodea are distinguished from the Orthoptera by their body shape, asymmetrical male genitalia, proventricular structure and lack of rotation of nymphal wing pads during development. The higher classification of the Phasmatodea is poorly studied and current schemes are not based on phylogenetic relationships. The genus Timena (Timematidae) is considered to be sister to all other phasmatids, which are placed in Euphasmatodea (= Euphasmida).

Embiidina (Embioida) (Embiids, Wespisers) Embiidina comprise some 400 described species (perhaps up to an order of magnitude more remain undescribed) in at least eight families. The
body is elongate, cylindrical, and somewhat flattened in males. The head has kidney-shaped compound eyes that are larger in males than females, and lacks ocelli. The antennae are multisegmented and the mandibulate mouthparts project forwards (prognathy). All females and some males are apterous, but if present, the wings are characteristically soft and flexible, with blood sinus veins stiffened for flight by blood pressure. The legs are short, with 3-segmented tarsi, and the basal segment of the fore tarsi is swollen because it contains silk glands. The hind femora are swollen by strong titibal muscles. The abdomen is 10-segmented with rudiments of segment 11 and with 2-segmented cerci. The female external genitalia are simple (no ovipositor), and those of males are complex and asymmetrical.

Embids are undoubtedly monophyletic based, inter alia, on the ability to produce silk from unicellular glands in the anterior basal tarsus. They have a general morphological resemblance to Plecoptera based on reduced phallosomes, a trochantin-episternal sulcus, separate coxopleuron, and premental lobes. However, molecular evidence suggests closer relationship to Orthoptera and Phasmatodea; they also have some similarity to the Dermaptera, notably deriving from their prognathy, and to Zoraptera. Internal relationships amongst the described higher taxa of Embidini suggest that the prevailing classification includes many non-monophyletic groups. Evidently much further study is needed to understand relationships within Embidina, and among it and other neopterans.

**Mantophasmatodea (Heelwalkers)** Mantophasmatodea was recognized for a species in Baltic amber and two museum specimens representing two species from south-west and east Africa, and freshly collected material from Namibia. Since 2002, at least 20 extant species in three families have been recognized from Africa. All species are apterous and less than 2.5 cm in body length. They have a hypognathous head, generalized orthopteroid mouthparts, and freshly collected material from Namibia. Since 2002, at least 20 extant species in three families have been recognized from Africa. All species are apterous and less than 2.5 cm in body length. They have a hypognathous head, generalized orthopteroid mouthparts, and long, multisegmented antennae. The legs have elongate coxae and, characteristically, the distal part of each tarsus is held off the substrate, leading to the common name of “heelwalkers.”

This taxon cannot be placed within any of the existing insect orders, and its phylogenetic relationships based on morphology are unclear, although it has some resemblances to Grylloblattaria, Dictyoptera, and Phasmatodea. Molecular data most strongly support a sister group relationship with the Grylloblattaria, although an analysis of whole mitochondrial genomes of one representative species of several of the hemimetabolous orders found the included phasmatid, rather than the gryllobattid, to be sister to the included species of mantophasmatid.

**Paraneoptera (Acerocaria or Hemipteroid Assemblage)** This group contains Psocoptera+Phthiraptera, Thysanoptera, and Hemiptera and is defined by derived features of the mouthparts, including the slender, elongate maxillary lacinia separated from the stipes, and the swollen postclypeus containing an enlarged cibarium (sucking pump), and the reduction in tarsomere number to three or less.

Within Paraneoptera, the monophyletic superorder Psocodea contains Phthiraptera (parasitic lice) and Psocoptera (book lice and bark lice). Phthiraptera appears to have arisen from within Psocoptera, rendering that group paraphyletic. Although sperm morphology and some molecular sequence data imply the relationship [Hemiptera (Psocoptera+Thysanoptera)], a grouping of Thysanoptera+Hemiptera (= superorder Condylognatha) is supported by head and mouthpart synapomorphies including the stylet mouthparts, features of the wing base, and the sclerotized ring between antennal flagellomeres. Condylognatha thus forms the sister group to Psocodea (Fig. 5).

**Psocoptera (Bark and Book Lice)** Psocoptera is a worldwide order of cryptic small insects, with a large, mobile head, bulbous postclypeus, and membranous wings held roof-like over the abdomen. About 6000 extant species are described in 39 families. Evidently Psocoptera belong with Phthiraptera in a monophyletic clade Psocodea. However, Psocoptera is rendered paraphyletic by a postulated relationship of some Phthiraptera to the psocopteran family Liposcelididae. Traditionally the order has been divided into three suborders, Psocomorpha (25 families), Troctomorpha (9 families), and Trogonomorpha (5 families); the Psocomorpha and Trogonomorpha have been studied phylogenetically and internal relationships are partly resolved. However, the Liposcelididae (book lice) appears to be the sister group of the just chewing lice (Amblycera).

**Phthiraptera (Lice)** Phthirapterans are wingless obligate ectoparasites of birds and mammals, lacking any free-living stage, with nearly 5000 species in some 28 families. Each of the four lice suborders Anoplura, Amblycera, Ischnocera, and Rhynchophthirina are monophyletic, but the Phthiraptera appears paraphyletic. The latter three suborders have been treated traditionally as a monophyletic Mallophaga (biting and chewing lice) based on their feeding mode and morphology, in contrast to the piercing and blood-feeding Anoplura. Cladistic analysis of morphology has disputed mallophagan monophyly, suggesting the relationship Amblycera [Ischnocera (Anoplura+Rynchophthirina)]. Molecular data have supported a classification in which Amblycera is sister to Liposcelididae (book lice), suggesting that parasitism arose twice in Psocodea. Resolution of these issues is important in estimation of degree of cospeciation between lice and their bird and mammal hosts.

**Thysanoptera (Thrips)** Thysanoptera is a worldwide order of nearly 6000 species in nine families. The development of thrips is intermediate between hemi- and holometabolous. Their head is elongate and the mouthparts are unique in that the maxillary laciniae formed grooved stylets, the right mandible is atrophied, and only the left mandible forms a stylet; all three stylets together form the feeding apparatus. The tarsi are 1- to 2-segmented, and the pretarsi has an apical protrusible adhesive aorlum (bladder or vesicle). Female thrips are diploid, whereas males (if present) are haploid, being produced from unfertilized eggs.

Molecular evidence supports one of the traditional morphological divisions of the Thysanoptera into two suborders, Tubulifera containing the sole, speciose, family Phlaeothripidae, and Terebrantia. Terebrantia includes one very speciose family, Thripidae, plus the smaller Aeolothripidae, Heterothripidae, and Melanothripidae, and four even smaller families. Relationships among families in Terebrantia are poorly resolved, although phylogenies are being generated at lower levels particularly concerning aspects of the evolution of sociality, the
Phylogeny of Insects

origins of gall-inducing thrips, and of “soldier” castes in Australian gall-inducing Thripidae.

Hemiptera (Bugs, Cicadas, Leafhoppers, Planthoppers, Spittle Bugs, Aphids, Psyllids, Scale insects, Whiteflies, Moss Bugs, Stink Bugs, etc.) Hemiptera is the largest of the non-endopterygote orders, with more than 90,000 species in about 140 families. Hemipteran mouthparts diagnostically have the maxillae and maxillae modified as needle-like styllets, lying in a beak-like, grooved labium, collectively forming a rostrum or proboscis within which the styllet bundle contains two canals, one delivering saliva, and the other uptaking fluid. Palps are lacking. The thorax usually has a large prothorax and mesothorax and a small metathorax. Both pairs of wings often have reduced venation; some species are apterous; and male scale insects have only one pair of wings. Legs often possess complex prelarval adhesive structures. Cerci are lacking.

Hemiptera and Thysanoptera are sister groups within Paraneoptera. Hemiptera used to be divided into two groups, Heteroptera (true bugs, including assassin bugs, backswimmers, lace bugs, stink bugs, waterstriders, and others) and its sister group, variously called Coleorrhyncha, Peloridioidea, or Peloridiomorpha lace bugs, stink bugs, waterstriders, and others) and its sister group, containing only family Peloridiidae or moss bugs, form suborder Prosorrhyncha (sometimes called Heteropterodea). Although small, cryptic, and rarely collected, moss bugs have generated considerable phylogenetic interest due to their combination of ancestral and derived hemipteran features, and their exclusively “relictual” Gondwanan distribution. Heteropteran diversity is distributed amongst some 50 families and almost 40,000 described species, forming the largest hemipteran clade. Heteroptera is most easily diagnosed by the presence of metapleural scent glands, and monophyly is never disputed.

Endopterygota (or Holometabola) (Coleoptera, Neuroptera, Megaloptera, Raphidioptera, Hymenoptera, Trichoptera, Lepidoptera, Mecoptera, Siphonaptera, Diptera, Strepsiptera) Endopterygota comprise insects with immature (larval) instars that are very different from their respective adults. Thus development is holometabolous, with a complete metamorphosis separating immature and adult stages. The adult wings and genitalia are internalized in their pre-adult expression, developing in imaginal discs that are evaginated at the penultimate moult. Larvae lack true ocelli. The “resting stage” or pupa is non-feeding, and precedes an often active pharate (“cloaked”) pupal cuticle adult. Unique derived features are less evident in the adults than in immature stages, but the clade is consistently recovered from morphological, molecular, and combined analyses.

Two or three groups currently are proposed amongst the endopterygotes, of which one of the strongest is a sister group relationship termed Amphiesmenoptera between Trichoptera (caddisflies) and Lepidoptera (butterflies and moths). A plausible scenario of an ancestral amphiesmenopteran taxon has a larva living in damp soil amongst liverworts and mosses followed by radiation into water (Trichoptera) or into terrestriality and phytophagy (Lepidoptera).

A second (usually) strongly supported relationship is between three orders: Neuroptera, Megaloptera, and Raphidioptera—Neuropterida (sometimes treated as a group of ordinal rank)—showing a sister group relationship to Coleoptera.

A third postulated relationship—Antliophora—unites Diptera (true flies), Siphonaptera (lice), and Mecoptera (scorpionflies and hangingflies). Debate continues about the relationships of these taxa, particularly concerning the relationships of Siphonaptera. Fleas were considered sister to Diptera, but molecular and novel anatomical supports a relationship with a curious-looking mectopteran group, the Boreidae or snowfl eas.

Strepsiptera is phylogenetically enigmatic, but resemblance of their first-instar larvae (called triangula) to certain Coleoptera, notably parasitic Blattiphoridae, and some wing base features has been cited as indicative of relationship. In contrast, some molecular

---

**FIGURE 6** Cladogram depicting relationships among and inferred classification of, Hemiptera. Dashed line indicates paraphyly in classification.
Phylogeny of Insects

Within Coleoptera, four modern lineages (treated as sub-orders) are recognized: Archostemata, Adephaga, Polyphaga, and Myxophaga. Archostemata includes only the small families Ommatidae, Crowsoniellidae, Copedidae, and Micromalthidae, and forms the sister group to the remaining extant Coleoptera. The few known larvae are wood-miners with a sclerotized ligula and a large mola on each mandible. Adults have movable hind coxae with usually visible trochantins, and five (not six) ventral abdominal plates (ventrites), but share with Myxophaga and Adephaga wing folding features (apex spirally rolled, major transverse fold crossing vein MP), absence of cervical sclerites, and the external prothoracic pleuron. In contrast to Myxophaga, the pretarsus and tarsus are unfused.

Adephaga is diverse, second in size only to Polyphaga, and include ground beetles, tiger beetles, whirligigs, predaceous diving beetles, wrinkled bark beetles, among others. Larval mouthparts are adapted for liquid-feeding, with a fused labrum and no mandibular mola. Adults have the notopleural sutures visible on the prothorax and have six visible abdominal sternites with the first three fused into a single ventrite which is divided by the hind coxae. Pygidial defense glands are widespread in adults. The most speciose included family is Carabidae, or ground beetles, with a predominantly predaceous feeding habit, but Adephaga also includes the aquatic families, Dytiscidae, Gyriinidae, Halplidae, and Noteridae, which are algivorous or predaceous. Morphology has suggested that Adephaga is sister to the combined Myxophaga and Polyphaga, but molecular data (18S rDNA) suggests Adephaga as sister to Polyphaga, with Myxophaga sister to them.

Myxophaga is a clade of small, primarily riparian aquatic beetles, comprising families Lepiceridae, Torridincolidae, Hydroscaphiidae, and Sphaerisuidae (= Microsporidae), united by the synapomorphic fusion of the pretarsus and tarsus. The 3-segmented larval antenna, 5-segmented larval legs with a single pretarsal claw, fusion of trochantin with the pleuron, and ventrite structure support a sister group relationship of Myxophaga with the Polyphaga. This has been challenged by some workers, notably because some interpretations of wing venation and folding support [Polyphaga (Archostemata (Myxophaga + Adephaga))].

Polyphaga contains the majority (>90% of species) of beetles, with more than 300,000 described species. The suborder includes rove beetles (Staphylinoidae), scarabs and stag beetles (Scarabaeoidea), metallic wood-boring beetles (Buprestoidea), click beetles, and fireflies (Elateroidea), as well as diverse Cucujiformia, including fungus beetles, grain beetles, ladybird beetles, darkling beetles, blister beetles, longhorn beetles, leaf beetles, and weevils. The prothoracic pleuron is not externally visible, but is fused with the trochantin and remnant internally as a "cryptopleuron." Thus, one suture between the notum and the sternum is visible in the prothorax in polyphags, whereas two sutures (the sternopleural and notopleural) often are visible externally in other suborders (unless secondary fusion between the sclerites obfuscates the sutures, as in Micronalthus). The transverse fold of the hind wing never crosses MP, cervical sclerites are present, and hind coxae are mobile and do not divide the first ventrite. Female polyphagan beetles have trophotropic ovarioles, which is a derived condition within beetles.

The internal classification of Polyphaga involves several superfamilies or series, whose constituents are relatively stable, although some smaller families (for which rank even is disputed) are allocated to different clades by different authors. Large superfamilies include Hydrophiloidea, Staphylinoidae, Scarabaeoidea, Buprestoidea, Byrrhoidea, Elateroidea, Bostrochioidea, and the grouping Cucujiformia. This latter includes the vast majority of phytophagous (plant-eating) beetles.
beetles, united by cryptophagous Malpighian tubules of the normal type, a cone ommatidium with open rhabdom, and lack of functional spiracles on the 8th abdominal segment. Constituent superfamilies of Cucujiformia are Cleroidea, Cucujoida, Lynxyloidea, Tenebrionoidea, Chrysocheloidea, and Curculionoidea. Evidently, adoption of a phytophagous lifestyle correlates with speciessity in beetles, with Cucujiformia, especially weevils (Curculionoidea), forming a major radiation.

**Neuroptera or Neuropteroid Orders: Megaloptera (Alderflies, Dobsonflies, Fishflies), Raphidioptera (Snakeflies), and Neuroptera (Lacewings, Antlions, Owlflies)** Neuroptera comprises three orders with holometabolous development, with approximately 6500 species of Neuroptera in almost 20 families, 300 of Megaloptera in two widely recognized families, and 220 of Raphidioptera in two families. Adults have multisegmented antennae; large, separated eyes; and mandibulate mouthparts. The prothorax may be larger than the meso- and metathorax, which are about equal in size. Legs sometimes are modified for predation. The fore wings and hind wings are quite similar in shape and venation, with folded wings often extending beyond the abdomen. The abdomen lacks cerci.

Megalopterans are predatory only in the aquatic larval stage; although adults have strong mandibles, they are not used in feeding. Adults closely resemble neuropterans, except for the presence of an anal fold in the hind wing. Raphidiopterans are terrestrial predators as adults and larvae. The adult is mantid-like, with an elongate prothorax, and the head is mobile and used to strike, snake-like, at prey. The larval head is large and forwardly directed. Many adult neuropterans are predators, and have wings typically characterized by numerous crossoveins and “twisting” at the ends of veins. Neuropteran larvae usually are active predators with slender, elongate mandibles and maxillae combined to form piercing and sucking mouthparts.

Megaloptera, Raphidioptera, and Neuroptera may be treated as separate orders, or united in Neuropteraida or Raphidioptera may be included in Megaloptera. There is little doubt that Neuroptera is monophyletic with new support from wing base morphology. This latter feature also supplements data supporting the long-held view that Neuropteraida forms a sister group to Coleoptera. Each component appears monophyletic, although a doubt remains concerning megalopteran monophyly. There remains uncertainty about internal relationships, which traditionally has Megaloptera and Raphidioptera as sister groups. Recent re-analyses with some new character suites have postulated Megaloptera as sister to Neuroptera and proposed a novel scenario of the plesiomorphy of aquatic larvae (all Megaloptera, Sisyridae in Neuroptera) in Neuropteraida.

**Strepsiptera (Twisted-wing Parasites)** Strepsiptera form an enigmatic order of nearly 600 species of highly modified endoparasitoids, most commonly of Hemiptera and Hymenoptera, and show extreme sexual dimorphism. The male has a large head with bulging eyes comprising few large facets and lacks ocelli; the antenna are flabellate or branched, with 4–7 segments; the fore wings are stubby and lack veins, whereas the hind wings are broadly fan-shaped, with few radiating veins; the legs lack trochanters and often also claws. Females are either cocoon-like or larviform, wingless, and usually retained in a pharate (clocked) state, protruding from the host. The first-instar larva is a triungulin, without antennae and mandibles, but with three pairs of thoracic legs; subsequent instars are maggot-like, lacking mouthparts or appendages. The pupa, which has immovable mandibles but appendages free from its body, develops within a puparium formed from the last larval instar.

The phylogenetic position of Strepsiptera has been subject to much speculation because modifications associated with their endoparasitoid life style mean that few characteristics are shared with possible relatives. In having posterior motor flight (only metathoracic wings) they resemble Coleoptera, but other attributes traditionally argued to be synapomorphies shared with Coleoptera are suspect or mistaken. However, strepsipterans have a similar life history and triungulin larva to certain beetles, notably the parasitic Rhipiphoridae, in which the adult males have pectinate or flabellate antennae not unlike those of male strepsipterans. The forewing-derived halteres of strepsipterans are gyroscopic organs of equilibrium with the same functional role as the halteres of Diptera, although the latter are derived from the hind wing. Phylogenetic analysis of sequences from the small subunit ribosomal RNA gene (18S rRNA) indicates that Strepsiptera possibly is a sister group to Diptera (if long-branch attraction can be discounted), and some tantalizing information from developmental biology suggests that wings and halteres might be “reverse-expressed” on meso- and metathoracic segments. However, strepsipteran halteres differ in structure from those of Diptera, and Strepsiptera also lack certain other features characteristic of Diptera or the group (Antliophora) to which Diptera belongs. Further data are required to resolve the phylogenetic position of the Strepsiptera.
setae and spines, some of which form combs, especially on the head and anterior thorax. The metathorax houses very large muscles associated with the long and strong hind legs, which are used to power the prodigious leaps made by these insects.

After early suggestions that the fleas arose from a mecopteran, the weight of evidence suggested they formed the sister group to Diptera. However, increasing molecular and novel morphological evidence now points to a sister group relationship to a subordinate component of Mecoptera, specifically Boreidae (snow fleas). Molecular phylogenetic study of internal relationships of fleas suggests that at least 10 of 16 families may be monophyletic.

**Diptera (True Flies)** Diptera is a major order of insects, with about 150,000 described species and perhaps more than a quarter of a million species in some 150 families. Diptera are holometabolous, and readily recognized by the development of hind (metathoracic) wings as balancers, or halteres (halters), and in the larval stages by lack of true legs and the often maggot-like appearance. Venation of the fore (mesothoracic) flying wings ranges from complex to extremely simple. Mouthparts range from biting-and-sucking (e.g., house flies) to “lapping”-type with pseudotracheate labelia functioning as a sponge (e.g., biting midges and mosquitoes) to “lapping”-type with pseudotracheate labelia functioning as a sponge (e.g., house flies). Dipteran larvae lack true legs, although various kinds of locomotory apparatus range from unsegmented pseudopods to creeping welps on maggots. The larval head capsule ranges from complete, through partially undeveloped, to complete absence in a maggot head that consists only of the sclerotized mandibles (“mouth hooks”) and supporting structures.

Traditionally Diptera had two suborders, Nematocera (crane flies, midges, mosquitoes, and gnats) with a slender, multisegmented antennal flagellum, and the heavier-built Brachycera (”higher flies” including hover flies, blow flies, and dung flies) with a shorter, stouter, and fewer-segmented antenna. However, Brachycyrae is sister to only part of “Nematocera”, and thus Nematocera is paraphyletic.

Internal relationships amongst Diptera are becoming better understood, although with some notable exceptions. Ideas concerning “basal” Diptera are inconsistent: traditionally Tipulidae (or Tipulomorpha if subordinate groups are given family rank, but nonetheless undoubtedly monophyletic) is treated as a lineage arising from a basal node, particularly on evidence from the adult wing and other morphology. Such an arrangement is difficult to reconcile with the much more derived larva, in which the head capsule is variably reduced. Furthermore, some molecular evidence places the craneflies much higher in the dipteran tree as sister to the Brachycera. An alternative view based on morphology is that the relictual family Tanyderidae, with complex (“primitive”) wing venation, arises from close to the basal node of the order. Support for this view also comes from tanyderid larval morphology.

There is strong support for Culicomorpha, comprising mosquitoes (Culicidae) and their relatives (Corethrellidae, Chaoboridae, Dixaes) and their sister group the blackflies, midges, and relatives (Simuliidae, Thaumaleidae, Ceratopogonidae, Chironomidae), and for Bibionomorpha, comprising the fungus gnats (Myctophophilidae sensu lato), Bionioidea, Anisopodidae, and possibly Cecidomyioidea. However, in both groups internal relationships remain a matter of debate, which molecular evidence may help to resolve.

Monophyly of Brachycera, comprising “higher flies,” is established by features including in the larva the posterior elongation of the head into the prothorax, the divided mandible, and loss of premandible, and in the adult by the eight or fewer antennal flagellomeres, two or fewer palps segments, and separation of the male genitalia into two parts (epandrium and hypandrium). Possible relationships of Brachycera include sister to Tipulomorpha, to Psychodomorpha, or even to Culicomorpha (molecular data only), but strong support is provided for sister taxon to the Bibionomorpha or to subordinate Anisopodidae. Brachycera contains four equivalent groups with internally unresolved relationships: Tabanomorpha (with brush on larval mandible and larval head retractile); Stratiomyomorpha (with larval cuticle calcified and pupation in last larval instar exuviae); Xylophagomorpha (with distinctive elopement, conical strongly sclerotized larval head capsule, and abdomen posteriorly ending in sclerotized plate with terminal hooks); and Muscomorpha (adults with visible spars absent, flagellum with no more than four flagellomeres and female cercus single-segmented). This latter speciose group contains Nemestrinoidea (bee flies and relatives), Asiloidea (roberflies and relatives), and Eremoneura (empidoids and Cyclorrhapha). Eremoneura is a strongly supported clade based on wing venation (loss or fusion of vein M4 and closure of anal cell before margin), presence of ocellar setae, unitary palp, and several genitalic characters, plus larval feature including maxillary reduction and presence of only three instars.

Cyclorrhapha, united by their puation within a puparium formed by the last larval instar cuticle, include a heterogeneous aschizan group including Phoridae and Syrphidae (hoverflies) and the Schizophora defined by the presence of a balloon-like pituitum that everts from the frons to assist the adult escape the puparium. Higher flies include the ecologically very diverse acalyptrates, and blowflies and relatives (Callipygatae), treated here as sister groups (Fig. 8), but with alternative views suggested.

![FIGURE 8 Cladogram depicting relationships among, and inferred classification of, Diptera. Dashed line indicates paraphyly in classification.](image)

**Hymenoptera (Wasps, Bees, Ants, Sawflies, and Wood Wasps)** This order contains at least 115,000 described species of holometabolous neopterans, varying from minute (e.g., Trichogrammatidae) to large-sized (0.15–120 mm in length), and slender (e.g., many Ichneumonidae) to robust (e.g., certain bees). Hymenoptera often is treated as containing two suborders: “Symphyta” (wood wasps and sawflies; the parentheses indicate a paraphyletic group, as explained below) and “wasp-waisted” Apocrita (wasps, bees, and ants). The hymenopteran head has mouthparts...
ventrally directed to forward projecting, ranging from generalized mandibulate (in “Symphyta”) to sucking and chewing with mandibles often used for killing and handling prey, and in Apocrita in defense and nest building. The compound eyes often are large; the antennae are long, multisegmented, and often prominently held forwardly or recurved dorsally. “Symphyta” has a conventional 3-segmented thorax, but in Apocrita the propodeum, abdominal segment 1, is included with the thorax into a mesosoma, or in ants, the alitrunk. The wing venation is relatively complete in large sawflies, is reduced in Apocrita in correlation with body size, such that very small species of 1–2 mm body length have only one divided vein, or none. The hind wing has rows of hooks (hamuli) along the leading edge that couples with the hind margin of the fore wing in flight. In Apocrita, the second abdominal segment (and sometimes also third) forms a constriction, or petiole. Hymenopteran female genitalia include an ovipositor, comprising three valves and two major basal sclerites, which may be long and highly mobile allowing valves to be directed vertically between legs. The ovipositor of aculeate Hymenoptera is modified as a sting associated with a venom apparatus.

Symphytan larvae are eruciform (caterpillar-like) with three pairs of thoracic legs bearing apical claws and with some abdominal legs; most are phytophagous. Apocritan larvae are apodous, with the head capsule frequently reduced but with prominent strong mandibles; larvae may vary greatly in morphology during development (heteromorphy). Apocritan larvae have diverse feeding habits and may be parasitic, gall-inducing, or fed with prey or nectar and pollen by their parent, or, if a social species, other colony members. Adult hymenopterans mostly feed on nectar or honeydew; only a few consume other insects.

Hymenoptera is considered either to be sister to all other endopterygote orders, or sister to Amphiesmenoptera (Trichoptera + Lepidoptera) + Anthliphora (Diptera + Mecoptera/Siphonaptera). However, Apocrita appears to be sister to one family of symphytan only, the Orussidae, and thus “Symphyta” form a paraphyletic group, with the symphytan superfamily Xyeloidea sister to all other hymenopteran taxa. The monophyletic tenthredinoid (sawfly) clade in turn is sister to weakly supported [Pamphilioida (Cephoidea (possible grade Siricidae and relatives (Orussidae + Apocrita)))] (Fig. 9).

Within Apocrita, aculeate (Aculeata) and parasitic (Parasitica or terebrant) wasp groups were considered each to be monophyletic, but Parasitica evidently is rendered paraphyletic by aculeates originating from somewhere within Parasitica. Some traditional groupings also are non-monophyletic, including Proctotrupoidea, but Proctotrupomorpha comprising superfamilies Proctotrupoidea, Chalcidoidea, Platygasteroidea, and Cynipoidea appears to be monophyletic. From morphology, Ichneumonoidea were argued to be sister to Aculeata, but molecular data and re-analysis refute this. The monophyletic aculeates, defined by their distinctive ovipositor construction and loss of female cerci, comprise [Chrysidoidea (Vespoidea + Apoidea)]. Internal relationships of aculeates, including vespids (wasps), formicids (ants), and apids (bees) and the monophyly of subordinate groups are under scrutiny.

**Trichoptera** (*Caddisflies*) Trichoptera contains about 45 extant families containing some 13,000 described species, with estimates of undescribed (mostly SE Asian) species diversity some four-to fivefold higher. Trichoptera are holometabolous; the moth-like adult has reduced mouthparts lacking any proboscis, but with 3–5 segmented maxillary palps and 3-segmented labial palps. The antennae are multisegmented and filiform and often as long as the wings. The compound eyes are large, and there are two or three ocelli. The wings are haired or less often scaled, and differentiated from all but the earliest lineages of Lepidoptera by the looped anal veins in the fore wing, and absence of a discal cell. The larva is aquatic, has fully developed mouthparts, three pairs of thoracic legs (each with at least five segments), and lacks the ventral prolegs characteristic of lepidopteran larvae. The abdomen terminates in hook-bearing prolegs. The tracheal system is closed, and is associated with tracheal gills on most abdominal segments. The pupa is also aquatic, enclosed in a retreat often made of silk, and possesses functional mandibles to aid in emergence from the sealed case.

Amphiesmenoptera (Trichoptera + Lepidoptera) is now unchallenged, despite earlier suggestions that Trichoptera arose from within Lepidoptera. Proposed internal relationships within the Trichoptera range from stable and well supported, to unstable and anecdotal. Monophyly of suborder Annullipalpia in its strictest sense, comprising families Hydropsychidae, Polycentropodidae, Philopotamidae, and some close relatives, is well supported by larval and adult morphology — including presence of annulate apical segment of both adult maxillary and larval palp, absence of male phallic parameres, presence of papillae lateral to the female cerci, and in the larva by the presence of elongate anal hooks and reduced abdominal tergite 10.

The monophyly of the case-making Integripalpia (comprising families Phryganeidae, Limnephilidae, Leptoceridae, Sericostomatidae, and relatives) is supported *inter alia* by the absence of the m cross-vein, hind wings broader than forewings especially in the anal area, female lacking both segment 11 and cerci, and larval character states including the usual complete sclerotization of the mesonotum, hind legs with lateral projection, lateral and mid-dorsal humps on abdominal segment 1, and short and stout anal hooks.

Monophyly of a third putative suborder, Spicipalpia, is more contentious. Defined for the Glossosomatidae, Hydroptilidae, and Rhyacophilidae (and perhaps the Hydrobiosidae), the proposed uniting features are the spiculate apex of the adult maxillary and labial palps, ovoid second segment of maxillary palp, and eversible oviscapt (egg laying appendage). Morphological and molecular evidence fail to confirm Spicipalpia monophyly, unless at least

---

**FIGURE 9** Cladogram depicting relationships among and inferred classification of, Hymenoptera. Only major superfamilies are depicted. Dashed lines indicate uncertainty in relationships or paraphyly in classification.
Hydroptilidae is removed. All possible relationships between Annullipalpia, Integripalpia, and Spicipalpia have been proposed, often associated with scenarios concerning the evolution of case-making. An early idea that the Annullipalpia is sister to a paraphyletic Spicipalpia+non-monophyletic Integripalpia finds support from some morphological and molecular data.

**Lepidoptera (Moths and Butterflies)** Lepidoptera, with some 160,000 described species in more than 120 families, is one of the major orders of Holometabola. Adults range from very small to large, with wings always covered in scales. The head bears a long, coiled proboscis formed from greatly elongated maxillary galeae; large labial palps usually are present, but other mouthparts are absent, except mandibles are present primitively in some groups. The compound eyes are large, and ocelli frequently are present. The multisegmented antennae are often pectinate in moths and knobbed or clubbed in butterflies (Papilionoidea+Hedyloidea+Hesperioidea). The wings are completely covered with a double layer of scales (flattened modified macrotrichia), and the hind and fore wings are linked either by a frenulum, jugum, or simple overlap. Lepidopteran larvae have a sclerotized, head capsule with mandibulate mouthparts, usually six lateral ocelli, and short 3-segmented antennae. The thoracic legs are 3-segmented with single claws, and the abdomen is 10-segmented with short prolegs on some segments. Silk gland products are extruded from a characteristic spinneret at the median apex of the labial prementum. The pupa usually is contained within a silken cocoon.

The basal radiation of this large order is considered well enough resolved to serve as a test for the ability of particular molecules to recover phylogenetic signal. Although over 98% of the species of Lepidoptera belong in Ditrysia (Fig 10), the morphological diversity is concentrated in a small non-ditrysian group. Three of the four suborders are species-poor (represented by families Micropterigidae, Agathiphagidae, and Heterobathmiidae, respectively), branch sequentially at the base of the Lepidoptera, and lack the synapomorphy of the mega-diverse suborder Glossata, namely the characteristically developed coiled proboscis formed from the fused galeae. Highly specialized Glossata contains a comb-like basal series of species-poor taxa, and a subordinate clade (Neolepidoptera) defined by the possession of abdominal prolegs with muscles and apical crochets (hooklets). Much of the glossatan diversity is found in the larva (caterpillar) of abdominal prolegs with muscles and apical crochets (hooklets). The thoracic legs are 3-segmented with single claws, and the abdomen is 10-segmented with short prolegs on some segments. Silk gland products are extruded from a characteristic spinneret at the median apex of the labial prementum. The pupa usually is contained within a silken cocoon.

Hydroptilidae is removed. All possible relationships between Annullipalpia, Integripalpia, and Spicipalpia have been proposed, often associated with scenarios concerning the evolution of case-making. An early idea that the Annullipalpia is sister to a paraphyletic Spicipalpia+non-monophyletic Integripalpia finds support from some morphological and molecular data.

Physical Control of Insect Pests

Charles Vincent,
Agriculture and Agri-Food Canada, Saint-Jean-sur-Richelieu, Que., Canada

Physical control is one of the main approaches to crop protection against insect pests, the others being chemical, biological, and cultural (Table I). From theoretical and technical points of view, all of these approaches have limits that make them more or less suitable for control of a given pest. In practice, the relative merits of each approach are also weighed against numerous factors before an actual decision is made regarding the most appropriate method to be implemented. A majority of agricultural commodities are protected using chemical control but ideally, all components and technologies should be blended optimally and harmoniously into an integrated pest management (IPM) program.

Physical Control Methods

Definition, Context, and Literature

Physical control methods in crop protection comprise techniques that limit pest access to the crop/commodity, induce behavioral changes, or cause direct pest damage/death. The primary action may have a direct impact, for example, when insects are killed immediately by mechanical shock. In other instances, the desired effect is attained through stress responses.

With the rapid advances that have occurred in the physical, chemical, and biological sciences since the late 19th century, agriculture has been transformed from a strictly empirical activity, largely based on tradition and aimed primarily at staying off famine, to a quantitative form of agriculture focused on producing large quantities of food. During this transition, which has been sustained at an increasing rate over the past 50 years, physical control methods have been set aside because of the tremendous success of chemical control. It is only natural that some people should view the use of physical control methods as a step backward to those distant, ancestral practices. Without technological advances and greater precision in the implementation of such methods, physical control now has all the necessary attributes for incorporation into IPM strategies.

Use in Agricultural Production

The different methods of physical control used against crop pests have some common characteristics. Passive physical control measures (Table II) have long-lasting effects although they may require periodic renewal (trap replacement) or maintenance (physical barriers, mulching). One of the characteristics that differentiate active physical control tactics from chemical control methods is the absence of persistence; the effect of a treatment is limited to the period of application. When treatment stops, the stressor disappears immediately or dissipates quickly. From the standpoint of exercising control over the treatment and its secondary effects, the absence of a residual action is an advantage. However, this characteristic can be a drawback, because the treatment may have to be repeated every few days to control crop pests that emerge and are active for a few days or a few weeks. In such cases, persistent chemicals constitute a much more convenient approach, although they are often undesirable from an environmental standpoint.

In addition to being restricted to the time of application, the impact of a physical control method is limited spatially. Mechanical, pneumatic, electrical, and thermal energies are dissipated locally over a distance of up to a few meters from the site of application. Electromagnetic radiation, which covers considerable distances (and is subject to numerous restrictions: reserved frequency bands, maximum power, and absence of interference), is an exception. Some pesticides have the unfortunate characteristic of dispersing over considerable distances. Similarly, many biological control agents can disperse or become dispersed beyond the treatment area.

Compared with traditional chemical control, present methods of physical control are more labor intensive and often time consuming (Table I). This drawback is one of the main reasons physical control techniques have had little success in penetrating the field-crop market. Given these circumstances, crops with a high profit margin per hectare represent an obvious market for physical control methods. From the viewpoint of implementation, physical methods compare favorably with biological methods, which often entail labor-intensive field observations and may be difficult to apply in a field-crop setting.

Modes of Action and Classification

Passive methods (Table II) cause changes in the immediate environment and have a more lasting effect; although with no residual action after they are removed. For example, there are a wide variety of physical barriers in use which can be applied in the field, greenhouse or food storage area. Barriers used in the field can take several forms (trenches, exclusion nets, etc.) and can be deployed on a range of scales to protect a complete field, a crop row, or a group of plants. Passive methods should be used whenever possible, because they extend the length of the treatment. For example, plastic-lined trenches along field boundaries trap Colorado potato beetles during the whole migration period; screening windows and doors in food storage prevent flying insects from entering. Physical barriers used to keep pests out, combined with suppression techniques, are the cornerstone of the approach adopted by industrialized countries to replace methyl bromide. Other techniques such as diatomaceous earth, hydrophilic particle films, sticky traps, and oils also are also passive techniques.

Active methods (Table II) are used to destroy, injure, or induce stress in crop pests or to remove them from the environment, and can be classified according to the mode of energy use: thermal shock (heat), electromagnetic radiation (microwaves, infrared, and radiofrequency), mechanical shock, and pneumatic control (blowing or vacuuming tools).

Various applications that use thermal shock for crop protection in the field have been developed and research is in progress. This approach is based on the premise that the commodity or crop to be protected will be less sensitive than the target pest to an abrupt change in temperature. Research on thermal sensitivity thresholds and physiological reactions to short-duration thermal stresses is central to the development of control methods based on thermal shock.
Several avenues have been explored for applying the different forms of electromagnetic radiation as a tool for controlling insects. Non-ionizing electromagnetic radiation kills insects by raising their internal temperature. The utilization of radio, microwave, and infrared frequencies is based on a principle similar to that of thermal shock methods except that, with applications involving electromagnetic radiation, the transfer of energy occurs without using a heat transfer fluid. Technologies that harness electromagnetic radiation are often too expensive for use in the field. Furthermore, existing regulations restrict the available frequency bands, either for reasons of

Pneumatic control consists in using an airstream to dislodge insect pests. Insects that are removed by vacuum pressure are killed when they pass through the moving parts of the blower (mechanical shock). After being dislodged by a blowing device, individuals of some insect species are injured and die because they are unable to climb back onto the host plant. Other machines are equipped with a device for collecting the dislodged insects, which are subsequently killed. Sound knowledge of the target insect's behavior is necessary to enhance the effectiveness of this type of approach as exemplified by the management of tarnished plant bug as a pest of strawberries.

Like any pest management approach, physical methods have strengths and weaknesses, and some of them are likely to have secondary effects on no target organisms, for example, pollinators of...
strawberry. In an IPM context, the decision to use a physical control tactic must therefore be made on a case-by-case basis according to the same criteria as in decision-making regarding the appropriateness of pesticide applications: efficacy, cost-effectiveness, and undesirable effects. In addition, no physical control technique is sufficient on its own for all pest control treatments in a given crop.

**Postharvest Physical Control**

Postharvest situations offer ideal opportunities to research and implement physical control methods. In long-term storage of non-perishable agricultural commodities (seeds and grain, dried fruits, by-products, dried and dehydrated plants, spices, herbs, coffee, cocoa), the most serious losses are due to the action of insects and mites or the spoilage by certain microorganisms (e.g., fungi). Chemical control using persistent insecticides is the most commonly used approach for preventing damage to grain and seeds by insect pests. Some of the benefits of this strategy are low cost, ease of implementation, and protection that lasts for several months, until the quantity of active residues falls below the lethal threshold for the target species.

Active physical control methods (cleaning, cold, heat, ionizing radiation) are major postharvest phytosanitary treatments to prevent the spread of invasive species while permitting trade in fresh and stored commodities. Although the use of methyl bromide fumigation has been exempted for postharvest phytosanitary applications, physical methods are replacing methyl bromide in an increasing number of instances and research in this area is quite active.

Physical control applications developed for postharvest treatments in stocks of stored grain have focused on procedures for controlling physical conditions (temperature and water content), thermal or mechanical shock, the establishment of extreme conditions for insect pests (anaerobiosis, pressure, and modified atmospheres), the use of abrasive or dehydrating minerals, and the erection of physical barriers to keep insects out. Postharvest control approaches are essentially based on passive methods, with the exception of thermal and mechanical shock treatments. In postharvest situations, most physical methods are suitable solely for prevention against pests and hence cannot be compared with classical chemical control. A thorough knowledge of IPM strategies is required, since these techniques afford no protection following application, unlike persistent insecticides.

Practical use of physical control methods necessitates verification at each step, particularly in relation to secondary effects on the quality of treated products (e.g., the germinating power of malting barley or the baking quality of bread-making wheat). The use of persistent contact insecticides on processed food products (e.g., wheat, semolina, and dried fruit) is prohibited worldwide, and the prospect of registration reviews for non-persistent pesticides that are currently used in protection of foodstuffs in processing and storage facilities has revived interest in postharvest physical control. Physical methods hold promise as a complement to, and a means of moving away from, exclusive reliance on chemical control. Furthermore, the most accessible physical methods for this pest management sector, such as dry heat treatments or airtight storage using inert gases, should help to diminish the secondary risk of spoilage of raw foodstuffs by storage molds.

**GENERAL CONSIDERATIONS**

Although physical control methods are very diverse, this strategy of pest control deserves to be recognized as an area of expertise similar to the area of biological control. This recognition is bound to come in the future as the quest for alternatives to pesticides intensifies. Although physical control methods became far less important with the advent of chemically based pest control methods in the middle of the 20th century, the limitations of pesticide use, coupled with their adverse affect on implementing biological control, have created an impetus for the renewed development of physical control.

The regulatory framework for physical control differs markedly from that for agrochemical products (Table I). First, many physical techniques are subject to rules concerning their use (i.e., the registration process), which are designed to protect users and the general public. Sometimes, such as with the use of propane gas, specialized training is required. The use of electromagnetic radiation is constrained by telecommunications regulations, some of which stem from international agreements. In the case of microwave energy, for instance, only a handful of frequencies have been set aside for industrial, scientific, and medical applications. With regard to the regulatory framework for physical control technologies, it is completely defined a priori. In short, the equipment employed must meet the applicable standards (mostly related to user safety). With chemically or biologically based methods, the difficulty in anticipating secondary effects precludes the establishment of comprehensive specifications that would be known a priori. This explains the need for increasingly costly test protocols designed to evaluate pesticide safety from the standpoint of human health as well as ecotoxicology.

A number of factors tend to complicate the implementation of physical control methods, and these tactics cannot be readily compared with chemical crop protection systems. For agricultural operations the use of a tractor and agricultural sprayer to apply pesticides entails low variable costs and fixed costs. In contrast, the equipment used for physical control is often very specific: for example, microwaves and ionizing radiation for stored-product pests, vacuuming device for field pests, and so on (Table I). Very few physical control tools offer the operational versatility that would allow them to perform several types of crop protection operations. Integration efforts, such as designing multi-task burners for controlling Colorado potato beetles, killing weeds, and performing top-killing, are needed to enable physical control tools to penetrate the crop protection market.

Most physical methods of control can be used in a crop protection program incorporating chemical, biological, and cultural controls. Chemical and biological methods are sometimes incompatible; however, biological, cultural, and physical methods can be compatible. Organic produce represents a growing market segment. In short, public demand and economic and legislative incentives will provide the leverage for the use of physical control methods and secure their success as alternatives or supplements to pesticides.

Phytophagous Insects

Elizabeth A. Bernays
University of Arizona

Phytophagous insects are generally considered to be those that feed on green plants. They include species that attack roots, stems, leaves, flowers, and fruits, either as larvae or as adults or in both stages. Leaf feeders may be external (exophytic) or they may mine the tissues, sometimes even specializing on a particular cell type. Typically nectar and pollen feeders are not included. “Phytophagous” is often synonymous with “herbivorous,” although the latter term is sometimes restricted to those species feeding on herbs (i.e., herbaceous plants). Commonly, species that use only one plant genus or species are called monophagous and species that use plants within a tribe or family are called oligophagous. The term stenophagous is less commonly used and includes both of these. Polyphagous species are those that use plants in several to many plant families.

DIVERSITY

Phytophagous insects are highly diverse and the total species number is at least 500,000. This represents about 25% of known multicellular animals. There are phytophagous insect species in the majority of insect orders, including Orthoptera, Lepidoptera, Coleoptera, Heteroptera, Hymenoptera, and Diptera but there are very large differences in numbers of species in the different groups (Table I). All green plants are eaten by one or more species of phytophagous insects.

Major differences occur among orders in the ways in which hosts are selected and the life forms that use plants. Thus, grasshoppers usually lay eggs in the soil so that the nymphal stages must select the plant resource. In the Orthoptera and Hemiptera, which are hemimetabolous, the nymphal and adult stages generally have similar feeding habits. By contrast, among Lepidoptera and Hymenoptera adults commonly feed on pollen or nectar while only the larvae are phytophagous, and among Coleoptera the larvae and adults of leaf beetles have similar habits, while larvae of wood borers often have adults with different feeding habits. Thus, there is a dichotomy (with some notable exceptions) between species in which the mother chooses for her offspring and species in which all stages are independent.

The great diversity of insects feeding on plants is matched by a remarkable diversity of lifestyles, mouthparts and gut morphological adaptations to the food eaten, cuticular morphology and coloration adapted for crypsis or aposematism, and behavioral adaptations for use of particular plants and escape from natural enemies. Many of the remarkable pictures of insects in popular journals involve surprisingly effective visual and behavioral crypsis.

Insects feeding on plants had their origin early in the history of life on land, with all the major orders that feed on plants today being present 300 million years ago (with the possible exception of Lepidoptera). This means that partitioning of food resources had occurred then, because there were spore feeders, sap suckers, and gall makers as well as miners and external feeders. This can be determined from information provided by fossils of insects and damaged plants and fossilized remains of insect feces. The diversity of insect mouthparts required for the different feeding guilds was established well before the appearance of angiosperms 200mya, but diversification of families, genera, and species has continued unabated ever since. The diversification is now known to be clearly related to angiosperm diversity and believed to be related largely to the diversity of plant secondary metabolites. These chemicals provide the signals for acceptance or rejection of potential host plants.

Mouthparts and Feeding

Although each of the major phytophagous orders of insects has distinctive biting and chewing or sucking mouthparts, the structures are highly diversified to handle every type of physical problem. For example, caterpillar species feeding on different plants can often be recognized by their mandibular morphology, and species feeding on physically similar plant parts tend to have similar morphology, whether they have a common ancestry or not. Among grasshoppers (Acrididae),

those that feed only on grasses have highly specialized mandibles with incisor regions for snipping through the tough parallel veins and molar regions for grinding the tissue. These highly characteristic mandibles have evolved independently at least eight times during the evolution of grasshoppers. It is probable that the details of mouthpart structure evolve quite quickly to suit changing diet, because it has been found in certain seed-sucking bugs (e.g., Jadera) that beak length has evolved to suit different fruit sizes within the past 100 years. Such rapid evolution may reflect the need to process food efficiently to maximize growth as well as the need to ingest food very rapidly to minimize predation risk.

Unless they utilize such structures as seeds and pollen, most phytophagous insects deal with the low protein levels characteristic of much plant tissue by eating relatively large amounts, and the gut throughput rates are high, with food in some cases taking only a couple of hours to pass through the digestive system. Some supplement their diets with carnivory or use symbionts to upgrade the levels of essential amino acids. Aphids, for example, which feed on phloem, tend to be particularly short of certain essential amino acids such as tryptophan, and their symbiotic bacteria commonly have multiple copies of genes involved in making tryptophan, so that the aphid obtains its requirements with the help of the symbionts.

Unlike many vertebrate herbivores, insects that feed on plant tissues often do not make nutritional use of the cellulose, which makes up a large proportion of plant bulk. This may partly reflect the fact that for phytophagous insects, protein is more likely to be limiting than carbohydrate. As heterotherms (animals whose body temperature varies with that of the environment) they are not concerned with the use of diets that are high in calories for maintenance of body temperature. Those species that do use cellulose, such as beetles feeding on wood or termites feeding on dead and decaying plants, often have symbionts that break down the cellulose, releasing non-protein amino acids as well as sugars. It is possible that the digestion of cellulose in these cases is a mechanism for releasing nonprotein amino acids that are bound to cellulose but that can be converted to useful amino acids for the insects by the resident symbionts.

Apart from the need to obtain sufficient quantities of major nutrients such as protein, insects (like other animals) often require nutrients in suitable ratios. For example, the proportions of protein and carbohydrate required for maximal growth vary among taxa; if a particular resource is limited in one respect the balance can be improved behaviorally. Thus, individual insects with a choice of high-protein/low-carbohydrate food and low-protein/high-carbohydrate food can eat a mixture of both. Studies indicate that species in different taxonomic groups are able to select among the foods available to optimize the balance ingested. This ability depends on a variety of mechanisms, including nutrient feedbacks that influence taste receptor sensitivity to sugars and amino acids, a tendency to move away from a food that has recently proved unsuitable, and a tendency to select foods with new and different flavors following experience on an unsuitable food. In addition, it has been demonstrated that insects can learn to avoid unsuitable food and to associate particular odors with high-quality foods.

**THE IMPORTANCE OF PLANT SECONDARY METABOLITES**

The great diversity of secondary metabolites in plants profoundly affects the behavior of phytophagous insects and, thus, the evolution of that behavior. These compounds may be repellent, or deterrent after contact. In addition, the deleterious postigestive effects of them enable insects to learn to reject a plant. Such food aversion learning has been demonstrated particularly in grasshoppers.

Many plant secondary metabolites serve as relatively nonspecific attractants or feeding stimulants for insects that feed on plants, although more commonly one or several particular compounds in a plant species serve as highly specific attractants or stimulants for feeding/oviposition by insects adapted to that plant. Thus, specialist phytophagous insects generally have a genetic predisposition to accept plants with a particular chemical or suite of chemicals present, the so-called sign stimuli; indeed, the sign stimuli may act as valuable signals in the sense of improving the speed of decision-making and discrimination by these insects. Some examples of sign stimuli are shown in Table II.

Apart from Orthoptera (specifically grasshoppers), the majority of phytophagous insect species tend to be specialists. That is, they feed on just a few species, genera, or tribes of plants. It is common among Lepidoptera (moths and butterflies), for example, to find species that feed on plants in one family, one tribe, one genus, or one species of plant. It appears that the degree of specialization is related to the occurrence of one or a few chemicals that characterize that plant group. In addition, the narrower the host range, the more likely it is that non-host chemicals will repel or deter the insects at relatively low concentrations. Many of these chemicals that reduce feeding or oviposition behavior are not noxious if ingested, suggesting that their role in these cases is more as signals of non-hosts than as signals of toxicity in specifically evolved plant defenses. Nonetheless, there are situations in which plants probably evolved high concentrations of particular chemicals in response to the attack of insects. Insects, over time, would be likely to evolve countermeasures. Thus one can envisage, as many have done, that a chemical arms race between plants and phytophagous insects has occurred (and is occurring).

Diet breadth variation occurs in all phytophagous insect orders, and there is evidence from molecular and other studies that evolution of diet breadth can occur in either direction. What drives these changes has been a subject of much controversy. Included in the hypotheses are the following: arms race coevolution in which specialists are in some way more successful, sequential evolution of insects in which species benefit from the use of specific plant signals to improve behavioral efficiency, adoption of specific plant hosts from which specialists may sequester high levels of protective chemicals, and the selection pressure of parasites and predators that involve adoption of limited host-plant species as a means of better avoiding attack (e.g., by enhanced visual or chemical crypsis).

The study of host-plant selection by phytophagous insects has been important in theories of resource use and whether it should be flexible in ecological or evolutionary time. For example, a change in host use may involve a change in specificity (how many different resources are acceptable) or a change in preference (which of a limited number of available resources is ranked highest). A change in specificity could result from a simple change in gustatory or olfactory sensitivity to many plant secondary metabolites or a change in the central nervous system affecting the relative importance of negative inputs from chemoreceptors. A change in preference, however, probably involves a change in receptor conformation or proportions of receptors with different conformations, at the level of the sensillum.

**VARIATION IN HOST USE**

Advances in how evolutionary changes occur or have occurred are being studied by examining genetic variation currently seen within populations of particular species, geographic variation that occurs in host specificity or preference, and historical changes in host use together with the physiological mechanisms underlying them. Experiential change can influence host preference, in turn altering the nature of selection pressure on those individuals and their offspring.

Host shifts or increases in host range have provided models of evolutionary change including the study of sympatric speciation, whereby populations of an insect species become associated with different hosts. Because many species mate on or near their hosts, gene flow between populations using different hosts drops and speciation occurs in host specificity or preference, and historical changes in host use are being studied by examining genetic variation currently seen within populations of particular species, geographic variation that occurs in host specificity or preference, and historical changes in host use together with the physiological mechanisms underlying them. Experiential change can influence host preference, in turn altering the nature of selection pressure on those individuals and their offspring.

Host shifts or increases in host range have provided models of evolutionary change including the study of sympatric speciation, whereby populations of an insect species become associated with different hosts. Because many species mate on or near their hosts, gene flow between populations using different hosts drops and speciation becomes possible. An example of this kind of divergence is with the apple maggot *Rhagoletis pomonella* in North America. Some populations moved from the ancestral *Crataegus* to apple and, currently, populations are diverging and evolving additional differences.

The interaction of phytophagous insects and plants is greatly influenced by predators and parasites. This is because they are major mortality factors for the phytophagous insects and yet use the plants themselves for sources of nectar and places to shelter, as well as places where they find their prey and hosts. In many cases, they are attracted to the odors of plants that are being attacked by plant-feeding species. The phytophagous insects that can remain visually or chemically cryptic by being specialists, or sequester plant toxins and become warningly colored, will be selected for by these natural enemies.

**AGRICULTURE**

The study of phytophagous insects has been very important in agriculture. Probably from ancient times, humans have selected varieties of crop plants that are minimally attacked by insects, and in the last 100 years breeding programs have been important in specifically increasing plant resistance. For example, resistance in rice to the rice brown planthopper (*Nilaparvata lugens*) and resistance in wheat to the greenbug (*Schizaphis graminum*) have resulted from dedicated research effort. Today, genes that express resistance factors against particular insect pests are inserted into some crops. For example, a toxic protein from the insect disease bacterium *Bacillus thuringiensis* can be produced in plants genetically modified by introduction of the bacterial gene.

Research in all areas of the biology of phytophagous insects has found application in agriculture. For example, behavioral studies of attractants has led to the use of traps for specific pests, and the study of antifeedants has had use in development of such materials in crop protection. Plant resistance is sometimes indirect, with plants expressing characteristics that favor natural enemies of the phytophagous species. For example, some crop plant varieties have hairs distributed at such densities that the parasitoids of pest whiteflies are slowed down in their running on a plant to a speed that improves host recognition. In other crops, surfaces lacking a wax bloom enable small predators to run more easily and thus efficiently find small caterpillars.

Alexander H. Purcell

*University of California, Berkeley*

**Specialized Terms**

**Phloem** Plant vascular tissues that transport sugars and other nutrients.

**Xylem** Plant vascular tissues that transport water and nutrients from the roots upward.
The feeding of insects and mites, especially those that suck fluids from plants, can cause symptoms of distress such as yellowing (chlorosis), silverying, bronzing or necrosis of foliage, wilting or discoloration of shoots, and malformation of leaves, stems, roots, fruits, and other plant organs or tissues. These symptoms may be confused with plant diseases caused by viruses or other plant pathogens.

**DEFINITION AND IMPORTANCE**

Insects damage plants in many ways, but the most common type of damage is the removal of plant tissues, as in the familiar examples of caterpillars, beetles, and grasshoppers whose feeding creates noticeable holes or even the wholesale removal of leaves, fruits, or other plant parts. Minute arthropods such as mites and thrips remove plant parts on a smaller scale by evacuating the contents of individual plant cells by their feeding. In contrast to damage caused by the removal of plant tissue, a phytotoxemia is the reaction of a plant to a chemical toxin introduced by insect feeding. Sucking insects in the order Hemiptera, such as plant bugs, aphids, leafhoppers, and psyllids, are the best-known insects that cause phytotoxemia by their feeding (phytotoxemias). Examples of external phytotoxemias include chemical air pollutants and pesticides. Abnormal plant growths or deformities called galls can be caused by certain insects (see Gallmaking and Insects).

The symptoms or appearance of insect phytotoxemias are often very similar to symptoms caused by infections with plant viruses or other infectious microorganisms that cause plant disease. Phytotoxemias can be distinguished from diseases caused by pathogens by the following criteria: (1) the capacity of the insect to produce symptoms is characteristic of the species, not restricted to certain individuals within the species; (2) the incidence and severity of symptoms are directly related to the number of insects (even where a single insect may cause symptoms) and the amount of time spent feeding; and (3) plants recover at least partly from further development of symptoms when the insects are removed. In contrast, plant viruses transmitted by insect vectors (see Plant Diseases and Insects) are not present in all individuals in a vector species; each individual must acquire or inherit the virus. Furthermore, plants develop symptoms of viral disease as a result of infection introduced by a single vector insect that might have transmitted the virus to the plant. Finally, plants will not recover from virus diseases because of the removal of vectors from the plant.

The appearance of a phytotoxemia can be small, localized lesions of discolored or dead (necrotic) tissue, the formation of cork, scabs or pits, premature fall of leaves or fruits, curling or malformation of plant organs. These are often symptoms of plant diseases caused by pathogenic microorganisms and thus may be easily confused with symptoms caused by pathogens. Symptoms may be systemic, that is far removed from the site of insect feeding. For example, leaves may be discolored or distorted by phytotoxic feeding in roots or stems.

**EXAMPLES AND CAUSES OF INSECT PHYTOXOTOXICITY**

The causes of phytotoxemias are not well understood. Mechanical damage to plant tissues caused by sucking insects is not as easy to observe as for chewing insects because the damage occurs at the cellular level and is internal. Hopperburn is a condition caused in a variety of plants by small leafhoppers (family Cicadellidae) in the genus *Empoasca*. The most widely studied type of hopperburn is in alfalfa caused by the potato leafhopper *Empoasca fabae*. Laceration of the vascular tissues of the plant disrupts the flow of water and plant sap to leaves, but there is also evidence that chemicals within the leafhoppers’ saliva induce yellowing and necrosis typical of hopperburn. Simulation of leafhopper feeding with a fine needle causes some but not all symptoms of hopperburn. Introducing crushed salivary glands of the potato leafhopper more closely simulates hopperburn. Other species of *Empoasca* cause hopperburn in beans in South America (*E. kreameri*) and grapes in Europe and North Africa (*E. hybrida*). The phytotoxicity of the leafhopper *Sophonia rufifascia*, which became established in Hawaii in the 1980s, caused extensive damage to many native plants in Hawaii, threatening the continued survival of some rare species. Its phytotoxicity is similar in many respects to hopperburn: halted growth and necrosis in some plants, yellowing of leaf tissues, and stunting of new growth in other plants (Fig. 1).

The grape phylloxera (Daktulosphaira vitifoliae) is a devastating pest of grapevines that wrecked millions of hectares of European vineyards in the 19th century and continues to be a serious pest of vines worldwide. The aphid-like phylloxera have a complex life cycle, with some forms (gallicoles) causing galls on leaves, and other forms (radicoles) causing galls and necrosis in roots. Phylloxera damage to roots kills European vines unless they are grafted onto rootstocks of wild grape species native to North America or onto hybrids of tolerant wild species (Fig. 2). Resistant grape species may have fewer phylloxera on their roots than European grapes, but it is their tolerance of grape phylloxera infestation without damage that is the main basis of their usefulness in avoiding phylloxera phytotoxicity. Feeding damage causes small roots to develop deformities and also kills root cells just beneath the bark. Soil-inhabiting fungi that invade roots may promote the decline of phylloxera-damaged vines.

The feeding of the silverleaf whitefly (Bemisia argentifolii) causes silverying of the leaves of squash plants and reduces fruit size and color. Feeding also causes tomatoes to ripen more slowly than normal. Unidentified chemical components of whitefly saliva seem to be involved, but the plant’s reaction is genetically controlled. The potato

**FIGURE 1** The myrtle bushes on the left (normal to right) are damaged by the feeding of the leafhopper *Sophonia rufifascia* (inset). Photograph with permission of Vincent Jones, Washington State University. (Insect photographs by Walter Nagamini, Hawaii Department of Agriculture.)
Psyllid \((\text{Paratrioza cockerelli})\) causes a yellowing and stunting of potato and tomato called psyllid yellows. The immature stages rather than adults are most damaging. Because individual psyllids may vary markedly in their ability to cause damage and only a few psyllids are needed to cause symptoms, a virus was suspected to be involved in causing psyllid yellows but discounted because of the direct relationship between damage and the number of psyllids feeding on a plant and the disappearance of symptoms after removing the psyllids. However, the recent discovery of a bacterium \("\text{Candidatus Liberibacter psyllaurous}\"\) associated closely with the disease, may yet show that a pathogen is involved in causing psyllid yellows.

Other insects that cause phytotoxemias include species of aphids, mealybugs, planthoppers, treehoppers, spittlebugs, mirid bugs, coreid bugs, and stink bugs. Blister or gall mites (family Eriophyidae) are also well known for inducing abnormal growth in many uncultivated plants as well as ornamentals and some crop plants.

**Insects and mites can cause plant diseases or transport and inoculate viruses and microorganisms such as bacteria and fungi that cause plant disease. Insects are the most important vectors of plant viruses and the main or sole means of spread of many plant pathogens. Plant diseases spread by insect vectors can be crucially important to the profitable production of some crops. Insecticidal or biological control of vectors often do not control the diseases spread by some vectors, and so physiological and ecological relationships between vectors and the pathogens they transmit are important to understand.

The direct damage to plants caused by insect feeding (herbivory) generally is considered in a separate category from plant disease. However, some insect feeding causes plant responses that are very similar in appearance to plant diseases caused by microorganisms and may be difficult to distinguish from diseases caused by microbial pathogens such as viruses or fungi. See *Phytotoxicity* and *Gallmaking and Insects* for details on insects as direct causes of plant disease.

**VECTOR TRANSMISSION OF PLANT VIRUSES**

Arthropod transmission of plant viruses illustrates the complexity and variety of relationships between plant pathogens and the arthropods that transport and introduce viruses to the plants. Because plants and plant viruses cannot move by themselves, plant viruses usually have mobile vectors. Most plant virus vectors are insects, mites, or nematodes. Arthropods are not thought to be important in the spread of the smallest plant pathogens—viroids (infectious small ribonucleic acids or RNAs). Viruses consist of nucleic acid [either ribonucleic acid (RNA) or deoxyribonucleic acid (DNA) that provides the genetic information for host cells to generate new copies of...
the virus (replication). In some cases the viral coat contains lipids or glycoproteins in addition to coat proteins.

Sucking insects that feed on plants' vascular tissues (xylem and phloem) appear to be the most common vectors of plant viruses. The order Hemiptera contains the greatest number of insect vectors of plant viruses. Within the Hemiptera, aphids (Aphididae) transmit the greatest number of different plant viruses, followed by whiteflies (Aleyrodidae), leafhoppers (Cicadellidae), and plant hoppers (Fulgoroidea). Mealybugs (Pseudococcidae) and miscellaneous other hemipteran families have species that are virus vectors. Thrips (Order Thysanoptera) transmit only a few viruses, but these can be of great economic importance worldwide. Mandibulate, or chewing insects, mostly beetles (Order Coleoptera), transmit a relatively small number but varied types of plant viruses. Among the mites, the minute bud or gall mites (family Eriophyidae) are the most important virus vectors.

Vector transmission of a pathogen can be characterized with respect to vector efficiency or competence. Efficiency is usually estimated on the basis of how likely transmission is to occur during each opportunity that a vector has for transmission. Usually this is estimated by determining how many individuals of a particular species are able to transmit a pathogen to plants during a given time interval. An important aspect of transmission efficiency is that only a single insect species is known to transmit some viruses. Such viruses are said to be highly vector specific. Other viruses have less vector specificity; for example, many species of insects within a family or subfamily may be vectors. Such viruses are classified as having group specificity or low vector specificity.

Transmission efficiency often changes dramatically over time. Vectors such as the green peach aphid (Myzus persicae) transmit viruses such as potato virus Y (PVY) most efficiently within seconds after acquiring the virus from a plant. After only a few minutes or at most hours of feeding on plants, the aphids (family Aphididae) no longer transmit the virus to plants. In fact, even the aphid’s efficiency of acquiring PVY varies with time. Aphids fed only for a brief interval on the virus-infected source plant more frequently transmit virus than do aphids fed for longer intervals on the source plant. Aphid transmission of PVY is said to be non-persistent, meaning that virus transmission rapidly declines after acquisition (Fig. 1A), although airborne aphids lose transmission efficiency at much slower rates than do aphids that are feeding on plants or even probing an inert surface such as glass. Non-persistently transmitted viruses generally have low vector specificity; that is, many aphid species can transmit them. At the other extreme, the green peach aphid transmits potato leaf roll virus (PLRV) only after an interval of many hours or even days after it acquires PLRV from feeding on virus-infected plants but then continues to transmit for many days (persistent transmission). Only a few aphid species can transmit PLRV. The time required between the vector’s acquiring the virus and its successful introduction (inoculation) of the virus to a plant is called a latent period (LP).

Changes in vector transmission efficiency over time (Fig. 1) provide clues as to the nature of the relationship between the vector and the virus and help to explain how vectors transmit the virus. For example, the persistent type of transmission typified by aphid transmission of PLRV often results from the virus having to circulate within its aphid vector before it can be transmitted, explaining the delay or LP required for transmission. A plant virus, such as aphid transmission of lettuce necrotic yellows virus (LNYV), which must multiply within a vector before it can be transmitted, will typically have a median or average LP of days or even weeks. LNYV is also persistently transmitted by its aphid vectors after the LP is completed. In contrast, a non-persistently transmitted virus such as PVY seems to be carried in or on the needlelike mouthparts of its aphid vectors. Many such viruses produce a viral-encoded polypeptide or small protein “helper factor” to aid the attachment of the virus to the aphid vector’s mouthparts. The helper factor of one virus may also act as a helper factor for a different virus. Certain viruses may require the presence of another virus in the same plant to be transmitted to another plant. It is not known if the assisting virus or an extra-viral “helper factor” provided by the assisting virus is what aids transmission of the dependent virus. For example, rice tungro disease is caused by the rice tungro bacilliform virus (RTBV), which can only be transmitted by its vector, the rice green leafhopper (Nephotettix cincticeps, family Cicadellidae), along with another virus, the associated rice tungro spherical virus (RTSV). By itself, RTBV can cause tungro disease cannot be transmitted to other plants, and RTSV by itself does not cause a disease in rice. Some viruses, such as maize chlorotic dwarf virus (MCDV), persist only for hours to days in the black-faced leafhopper vector, Graminella nigrirostris, and are classified as semi-persistently transmitted. The shedding of the vector’s exoskeleton during molting from one growth stage to another helps the transmission of non-persistently and semi-persistently transmitted viruses. Because the lining of the foregut is shed during molting, PVY and MCDV are thought to be transmitted to plants from a location within the mouthparts or foregut of the vector. Electron microscopy and the labeling of viruses with fluorescently or colloidal gold-tagged antibodies that bind to specific viral proteins have been used to identify areas where viruses accumulate or attach within the foregut. The same approach can be used for viruses that circulate within the vector’s body cavity.

The circulative viruses such as luteoviruses that are transmitted by aphids, and geminiviruses that are transmitted by leafhoppers or whiteflies do not appear to multiply within their vectors, and so their transmission is thought to entail efficient methods of viral uptake and translocation within the vector’s body cavity (hemocoel). Luteoviruses appear to be taken up by a process of endocytosis, in which virus particles are engulfed in a portion of the external cell membrane of intestinal cells, transported into the cell and expelled from the cell into the body cavity. By processes that probably involve membrane-bound transporter proteins, viruses can penetrate the membranes surrounding the salivary glands of the vector. Virus particles then enter
Some of the persistently transmitted plant viruses such as the reoviruses replicate within their insect vectors. It is remarkable that the same virus can subvert the genetic and protein processing systems of both plant and animal cells for viral replication. Although vectors normally acquire viruses by feeding on virus-infected plants, some plant viruses can invade the developing eggs or embryos within a female vector insect. The rice dwarf virus (RDV) is an example of a reovirus that passes from virus-infected female rice green leafhoppers to leafhopper offspring by this route. Invariably these transovarially transmitted viruses such as RDV multiply within their vectors, yet most viruses that multiply in vectors are not transmitted transovari-ally. The tomato spotted wilt virus (TSWV) is unusual because it can only be acquired by immature stages of thrips. An adult thrip can transmit this virus only if it fed as a nymph on a plant with TSWV. Thus the vectors of TSWV have vector specificity not only for particular vector species but also for the immature stages, at least in the acquisition phase.

**ARTHROPOD VECTORS OF BACTERIAL PATHOGENS**

Unlike viruses, most bacterial diseases of plants do not require insects as vectors, relying instead on rain, wind, soil, seed dispersal or other means of transport and entry to plants. However, insect vec-
tors contribute to the spread of some bacterial pathogens of plants. Fireblight is an important bacterial disease of pome fruits such as pears and apples in which flower-visiting insects may have an important role in disseminating the causative bacterium (Erwinia amylovora) among blossoms. Insects are not essential, however, for fireblight to spread within plants once the bacteria are established, and there is little vector specificity among flower-visiting insects. Bacteria that rot potatoes (Erwinia caratovora) may be transported from infested potato tubers to uninfested tubers by flies whose maggots feed on plant roots or seeds beneath the soil. There is much greater vector specificity in corn flea beetle transmission of the bacterium (Erwinia stewartii) that causes Stewart’s wilt of corn and cucumber beetle trans-
mission of the bacterium (Erwinia tracheiphila) that causes curcurbit wilt, an important disease of melons, squash, and cucumbers. The bacteria enter feeding wounds made by the beetle vectors, but not much is known of how the beetles introduce the bacteria into plants. Overwintering adult beetles provide an important way for these bacte-
teria to survive the winter season without host plants.

Some bacterial pathogens are specialized parasites of plant vascular systems and require insect vectors for plant-to-plant move-
ment and to enter and infect plants. These bacterial pathogens are specialized for vector transmission and for living in plant vascular systems. Examples are the mollicutes (bacteria that lack a rigid cell wall) that live exclusively in the nutrient-rich phloem tissues. A few bacterial pathogens with rigid cell walls, such as the bacterium that causes citrus greening disease, also specialize in living within plant phloem sap. The citrus greening bacterium is transmitted by psyllids (superfamily Psylloidea). The mollicute plant pathogens include phytoplasmas and spiroplasmas. Most of the helical-shaped spiroplasma pathogens of plants, such as the spiroplasma that causes citrus stubborn disease (Spiroplasma citri) and the corn stunt spiroplasma (Spiroplasma kunkelii), can be cultured on artificial media. So far, none of the phytoplasma (formerly known as mycoplasma-like organ-
isim) plant pathogens have been cultured. Examples of economically important phytoplasmas are aster yellows phytoplasma in lettuce, carrot, celery, and other flower and vegetable crops and X-disease phytoplasma in stone fruits such as peach or cherry. Lethal yellowing disease of palms has been a major factor in killing coconut palms in Africa and the Caribbean region. Both phytoplasmas and spiroplasmas are more specialized for parasitizing insects rather than plants because they can successfully colonize, and more importantly, can be transmitted by only a few species of insects. The most important vectors of mollicute plant pathogens are leafhoppers and planthoppers, but psyllids are an important third group of Hemiptera that are vectors. The pear psylla (Cacopsylla pyricola) transmits the
In contrast to their high degree of vector specificity, phytoplasmas and spiroplasmas can parasitize a typically wide range of plant species if the vectors can feed successfully on the plants. Transmission appears to require that the mollicutes be taken up by vector feeding, penetrate the gut and multiply within the vector's body cavity, enter the salivary glands, and be expelled with saliva during vector feeding into functioning phloem tissues. Thus, it is not surprising that vector transmission of various phytoplasmas or spiroplasmas requires a LP ranging from 1 to over 4 weeks. The length of the LP may be very sensitive to temperature, probably because the mollicutes must multiply within the vector for transmission to occur and multiplication is temperature sensitive.

Vector-borne bacterial species that parasitize the water-conducting part of the plant's vascular system (xylem) are less numerous but cause some important plant diseases. One such pathogen is *Xylella fastidiosa*, best known as the cause of Pierce's disease of grapes, but other strains of this bacterium cause important other diseases of citrus, coffee, peach, and other crop and forest plants. Sucking insects in several families that feed primarily on xylem sap are *Xylella* vectors. This includes sharpshooter leafhoppers in the subfamily Cicadellinae of the leafhopper family Cicadellidae and spittlebugs (family Cercopidae). Vectors appear to transmit the bacterium from their foregut without any required LP, but continue to transmit for weeks or even months as adults. An immature vector (nymph) stops transmitting after molting its exoskeleton. Sumatra disease of cloves in Indonesia, caused by the xylem sap-inhabiting bacterium *Pseudomonas syzygii*, is spread by tube-building spittlebugs (family Macheerotidae), which are also xylem sap-feeders.

**ARTHROPODS AND FUNGAL PLANT DISEASES**

The fungi are the most varied, common, and important plant pathogens, but the great majority of fungal pathogens do not require mobile vectors such as insects or mites. Instead fungal pathogens disperse to plants mainly in wind, rain, or soil. A large variety of fungi colonize plant wounds, including those made by arthropod feeding. However, some fungi are specialized for transmission by insect vectors.

Dutch elm disease is the best-known example of a fungal disease of plants transmitted by an insect vector. The causal fungus, *Ophiosphaera ulmi*, grows into a spore-bearing fungal mass (mycelium) under the bark and into the water-conducting woody tissues of elms. Adult bark beetles, such as the European elm bark beetle (*Scolytus multistriatus*), are especially attracted to stressed elms or freshly cut elm logs. The adult beetles excavate a tunnel by feeding beneath the bark and deposit eggs along the tunnel. Beetle larvae hatch from the eggs, tunnel further under the bark, pupate, and then emerge as adults the following year. The Dutch elm disease fungus grows throughout brood chambers excavated by the beetles and produces sticky spores that attach to body and mouthparts of the adult beetles that bore out of the bark to exit the tree. The beetles transmit the fungal spores to wounds they infect while feeding on elm twigs. The fungus gradually spreads from the point of infection into the larger branches of the tree, then to the tree's trunk, where its action on the woody tissues eventually kills the tree. In very cold climates of North America, the native elm bark beetle (*Hylurgopinus rufipes*) is the main Dutch elm disease vector. Its transmission of fungal spores to elms leads to more rapid development of disease because it feeds principally on the trunk and large branches of the elm tree rather than small branches. Oak wilt disease, caused by the fungus *Ceratocystis fagacearum*, is spread by sap beetles (family Nitidulidae) that vector the spores from oozing cankers on diseased trees to fresh wounds on trees to which these beetles are attracted.

Some insects can create wounds which fungi can then colonize without transport by the insects. Yet even though insects in these cases are not vectors of the fungi, they can be important in determining how severe fungal infestation becomes. An example is a variety of fungi that can colonize the feeding wounds of caterpillars that feed on maize or peanuts. Some of these fungi (notably *Aspergillus* species) can produce powerful toxins, called aflatoxins, that sicken or even kill animals that are sensitive to the toxins. Preventing insect damage to grain in the field or storage is an important step in preventing high levels of aflatoxins.

**INSECTS AS VECTORS OF TRYPANOSOMES AND NEMATODES**

Plant diseases that are caused by trypanosomes are not as well understood nor as important as trypanosome diseases of animals and humans, such as malaria. Trypanosomes are protozoans of variable body shape, depending on their developmental stage and environment. Most insect-associated trypanosomes have stages that are elongated or leaf-like and are propelled by a centrally attached flagellum. Milkweed bugs (family Lygaeidae) transmit trypanosomes to milkweeds, where they harmlessly occupy the interconnected latex system. A variety of other plant-parasitic trypanosomes inhabit the phloem systems of their plant hosts, causing severe disease. Phloem necrosis disease of coffee in northern South America and heartrot of palms are spread by sucking insects in the family Pentatomidae and other related families.

Wood-boring beetles are vectors of pinewood nematodes (Bursaphelenchus xylophilus) that cause a severe disease of conifers in Asia and more recently North America. The juvenile nematodes enter the tracheae (breathing tubes) of adult long-horned beetles (family Cerambycidae), as the beetles emerge from the dead trees in which they bred. As the beetles bore into new trees, the nematodes disperse from the beetles into the tree's woody tissues, causing blockage of the water-conducting system.

**CONTROL OF DISEASES SPREAD BY ARTHROPODS**

The most obvious first step in controlling diseases caused by insect-borne pathogens might seem to be the elimination of vectors with insecticides. Although they are very effective in some situations, insecticides usually are not the best tools for control for most vector-borne pathogens of crops. The most effective approaches combine multiple methods.

Sanitation to eliminate nearby sources of the pathogen (usually diseased plants) reduces the number of infective vectors near the crop to be protected. Physical isolation to prevent disease spread may be achieved in some cases by growing susceptible crops as little as 100 m or so from infected sources, but normally much greater isolation or separation is required. Area-wide cooperation may be necessary for sanitation to control some diseases. The use of virus-free plants is probably the most widespread method of preventing virus spread. This is especially important for perennial plants such as fruit trees or plants propagated from vegetative cuttings, such as potatoes, strawberries, or sugar cane. Heat therapy or antiviral chemical treatments may be used to produce virus-free new plant growth that can be grafted or rooted to create virus-free plants for nursery
propagation. As new infections of virus appear in trees, the trees can be removed; for some diseases, such as swollen shoot disease of cacao, trees within a specified radius of a newly diseased tree are also removed. Some viruses are transmitted via seeds from infected plants, and control may be based on planting virus-free seed. Lettuce mosaic virus (LMV), for example, is best controlled by using seed with less than 1 in 10,000 seedlings infected with LMV via seed. Above this threshold, aphid spread of the non-persistently transmitted LMV will be economically damaging. The production of virus-free seed may require growing the seed crop in isolated areas otherwise free of the crop and the viruses of concern. Insuring virus-free foundation plants or seed to seed producers or nurseries is an important service usually provided by government or grower cooperatives.

Keeping one period of the year completely free of the targeted crop may reduce virus spread by breaking the transmission cycle. For example, this approach has proven effective for yellows viruses of sugar beet and celery mosaic virus, both of which are aphid transmitted. The growing of these crops for several months during the year is prohibited on an area-wide basis to prevent the carry-over of virus in crop plants from one season to another. New fast-maturing varieties of rice that allowed multiple crops per year rather than a traditional single crop introduced new problems with long-established viruses because virus-infected crops co-existed next to newly planted fields. The solution was to have a least one period of the year free of all rice crops. Peak infective periods can be avoided for some virus diseases by planting after peak vector flight periods if the late planting still produces a profitable crop.

Removing diseased plants as soon as symptoms appear is an important step in preventing further spread of Dutch elm disease. The bark beetle vectors of the fungus that causes the disease are attracted to weakened trees, so removing diseased elms reduces populations of the beetles as well as reducing the percentage of beetles carrying fungal spores. Sanitation may also limit the spread of phytomass diseases of trees, such as X-disease of stone fruits like cherry.

The effects of the crop environment on vector flight behavior or plant choice may be effective in slowing virus spread, even for non-persistently transmitted viruses. For example, reflective plastic sheeting used as a mulch (ground cover) repels aphids from landing on melon crops. The resulting delay in virus infection usually prevents the virus from reducing average fruit quality or yield. Sprays of 1% emulsions of paraffin oils on peppers or tomatoes reduces aphid transmission of non-persistently transmitted viruses. Plants must be sprayed frequently with oil sprays to cover new growth because the oil directly affects the inoculation and acquisition of virus by aphids.

Insecticides generally are most effective in controlling disease spread where vector-borne pathogens are persistently transmitted, are spread mostly within the crop (termed secondary spread) rather than being carried into the crop from outside sources (primary spread), or where the most important vectors reproduce on the crop. Insecticides are usually not effective against non-persistently transmitted viruses unless they quickly reduce or inhibit vector probing on treated plants. Examples of successful insecticidal control of vectors that achieved economic control of viruses are the persistently transmitted barley yellow dwarf luteovirus in grain crops, PLRV, and the leafhopper-transmitted beet curly top virus. These all are viruses that are acquired or inoculated into plants only during relatively long feeding probes by aphids. Insecticides also reduced the spread of the leafhopper-transmitted aster yellows phytoplasma if vector pressure was not too high.

Genetically based plant resistance to pathogens or tolerance of infection without loss of yield provides the basis for the most successful control programs for vector-borne plant pathogens. A drawback is that breeding resistant plant varieties that are commercially acceptable has proven to be difficult or impossible to achieve for some crops. Molecular methods of introducing novel genes for resistance to viruses directly into crop plants promises to provide resistance to virus diseases where no genetic resistance has yet been discovered.

**Plant–Insect Interactions**

J. Mark Scriber

*Michigan State University*

At the ecological level, the interactions of plants and their herbivores center upon the primary (nutritional) and secondary (allelochemical) composition of plants or plant parts, and the adaptations of the insect to feeding and/or living on that plant. At the evolutionary level, insect feeding patterns involve population genetics, host race formation, evolutionary divergence, speciation, and historical (phylogenetic) patterns.
ECOLOGICAL ISSUES

The fundamental limitations for insect use of plants as food involve nutrients (nitrogen/protein, water, lipids, and various minerals) as well as various classes of secondary chemical defenses (including alkaloids, cyanogenic glycosides, glucosinolates, terpenoids, phenolics, phytoecdysteroids, and polyacetates). The location (“findability”) and utilization (suitability) of plant parts as insect food may depend on phenotypic variation induced by previous herbivores and microbes, as well as a wide array of interactions involving environmental factors such as nutrient availability, light regime, water, temperature, carbon dioxide, and various pollutants. Seasonal (ontogenetic) changes in plant growth, reproduction, and chemical/physical defenses also are important. Natural declines during plant maturation in the concentration of many low-molecular-weight allelochemicals (often called qualitative defenses) are contrasted with other higher molecular weight chemicals (such as tannins, lignins, and fiber; sometimes called quantitative defenses). In leaves of plants, a general pattern of decline in the concentrations of total nitrogen, water, and many qualitative chemical defenses usually accompanies leaf maturation. The phytochemical suitability of leaves for insect herbivores (the leaf-chewing guild in particular) also has genetically based biochemical variation. Together these factors affect the physiological and ecological suitability of the plant for supporting herbivore feeding, growth, survival, and reproduction. Specialization by insects is the common theme in most insect–plant interactions, but behavioral or physiological efficiency is not often associated (but see Fig. 1).

HOST-PLANT RESISTANCE AND INSECT COUNTERADAPTATIONS

In natural terrestrial communities, approximately 10% of the annual plant production on average is consumed by herbivores, a percentage that is generally greater than the plant biomass allocated to reproduction. In addition to the well-known defensive structures of thorns, barbs, spines, trichomes, hairiness or fuzziness, and physical toughness, plants possess a large array of chemicals that defend against the herbivore and pathogen enemies. Artificial selection also has produced insect-resistant genotypes and cultivars of crop plants, which has helped reduce the reliance on broad-spectrum synthetic pesticides. Plant breeders have recently been able to use techniques of molecular biology to incorporate new arrays of biochemical or microbial “pesticides” for plant defenses that have not been previously evolved by the plants (but that may occur naturally in the plant environment or even on the leaf surface).

Insects may respond to these secondary plant products physiologically (e.g., by sequestration or enhanced excretion rates), biochemically with resistance (e.g., via target site insensitivity or enzymatic detoxification), or behaviorally (e.g., by reducing exposure or consumption by changes in feeding behavior). Many of these phytochemicals may be used by adapted herbivores that sequester the bioactive compounds in their wings or other body parts where they may serve a protective function from herbivore enemies (such as in distasteful models with aposematic or warning coloration) and often in various insect mimicry complexes.

PLANT DEFENSE AND HERBIVORE OUTBREAK THEORY

An understanding of the full array of potential insect–plant interactions is probably beyond comprehension. The geographic, altitudinal, and seasonal variation in plant chemistry in even a single plant species and the associated responses of insect herbivores (each species with its own geographical and genetic variation) make the task truly daunting. However, out of this complexity, ecologists have attempted to identify general patterns and organizing principles. The development of a series of general explanatory hypotheses or proposed models of insect herbivory, population dynamics, and plant defenses (generated since the 1970s) are not mutually exclusive and have often built upon the theories of their predecessors with details of the historical development of plant defense theory nicely summarized in 1997 by Price, with a phylogenetic/coevolutionary/cocadaptation perspective recently provided by Scriber in 2002 and Agrawal in 2006.

Climatic Release

This hypothesis suggests that bad weather, lack of food, or lack of their natural enemies (predators, parasites, or diseases) were the primary insect population regulators. The indirect effects of the climate and abiotic environment as mediated through changes in host-plant nutritional quality will likely be of increased significance in the near future, given increasing concentrations of certain atmospheric gases (e.g., carbon dioxide), acid rain, global warming, and increased pollution.

Plant Stress

This hypothesis suggests that water stress in plants may affect the availability of soluble nitrogen (especially for those in the plant-sucking or sap-feeding guilds). Nitrogen generally limits insect herbivores and population growth rates.

Plant Apparence

This hypothesis was developed following study of insect herbivores on oak trees in England and those on the cabbage family (Cruciferae) in North America. P. P. Feeny noted the divergent patterns of chemical defense used by these two plant types. The tree leaves were composed of relatively high concentrations (2.5–5% dry weight) of compounds believed to be digestibility reducers (tannins, lignins, resins, cellulose, silica). In contrast, herbaceous crucifers (forbs) had low concentrations (usually lower than 1%) of biosynthetically “less expensive” toxins (such as mustard oil glycosides or other low-molecular-weight chemicals such as alkaloids, cyanogenic glycosides, and coumaric acids).

Herbivore food was prevalent and predictable (i.e., apparent) in trees and mature plant leaves containing these convergent digestibility reducers, or quantitative defenses or hurdles to herbivores, whereas the food resources for forb-feeding herbivores seemed less predictable, with divergent, qualitative (toxic) barriers in annual plants/herbs and very early immature (i.e., unapparent) plant parts. The “bound-to-be-found” trees were late successional, frequently in pure stands, large, and long-lived, with large amounts of general chemical defenses (effective against specialists as well as generalists) that acted in a dose-dependent (i.e., quantitative) manner. In contrast, the annual plants were short-lived, hidden from enemies in space and in time (unapparent), and defended by small quantities of qualitative allelochemicals such as mustard oils that repel nonspecialized insects (but are not effective against adapted herbivores) and that are effective at very low levels (basically not dose dependent).

The explanatory value and rigor of the apparency concept has been questioned because of the difficulty in its quantification. Most plants and plant parts have a dynamic continuum of both quantitative and qualitative chemical defenses, as well as phenological changes in the nutritional quality of leaves (as indexed, e.g., by leaf water and total leaf nitrogen concentrations). Tannins were also shown not to be
the general dose-dependent, digestibility-reducing chemicals they were originally believed to be. Instead, tannins evoke a wide variety of physiological effects such as increased mortality, decreased consumption rates, histopathological effects in the gut, and elevated metabolic costs for insect herbivores. In 2005, Boege and Marquis reviewed and reemphasized these ontogenetic patterns originally described in 1981 by Scriber and Slansky.

**Induced Defenses**

This hypothesis arose with the occurrence of phytochemical induction with leaf damage as observed since the late 1970s. Plant-to-plant chemical communications and plant-to-insect parasite/predators have subsequently been included as multitrophic-level chemical synomones (plant volatiles that benefit both the sender and its receiver). Herbivore-damaged plants have been shown to provide carnivorous enemies of insect herbivores with important volatile chemical cues, detectable from a distance and aid natural enemies in locating suitable herbivore prey.

**Resource Availability and plant Vigor for defense against herbivores**

A relationship between resource availability and plant defense was noted, as reduced nitrogen availability for plants usually resulted in reduced nitrogen-based defenses (usually toxins), but not necessarily in reduced carbon-based defenses (digestibility reducers). Thus, on nutrient-poor and late-successional sites, inherently slow growth rates of plants may select for more carbon-based herbivore defenses (e.g., resins or phenolics) that could be reduced with fertilization with nitrogen (with corresponding increases in the nutritional value for herbivores). Low carbon conditions (e.g., shade and reduced photosynthesis) may result in slow growth despite high nitrogen, which could then be used for N-based defenses (e.g., alkaloids, cyanogenic glycosides). These hypotheses about the carbon-nutrient balance and resource availability for slow-growing and fast-growing plants received support from many researchers in the 1980s. In many instances, predictions of the apparency, resource availability, and growth–differentiation balance hypotheses are in agreement. For example, trends in the types of chemical defense of early successional plants and late successional plant communities are congruent. However, equally apparent plants in resource-rich and resource-poor environments suggest that the resource availability hypothesis may have greater explanatory power than the apparency concept, because the fast growers in resource-rich environments (nutrients and light) seem to support high herbivory (and may be predisposed to rapidly recyclable defenses such as alkaloids or other toxins) that can contrast with slow growers in the tropics, temperate zone, and arctic communities. A preference of herbivores for fast-growing plants has led to the suggestion that interactions may relate most simply to “plant vigor” (as a general hypothesis) to explain not only persistent differences in plant defenses between species, but also quality differences within a single plant species, genotype, or even individual. These indices of resistance can be induced by herbivory itself, as well as being constitutive.

In summary, despite the different roles of an overwhelming diversity of secondary plant chemicals, the fundamental limitations on herbivore growth rates seem to relate to the nutritional suitability of the insect food. Different leaf water and leaf nitrogen contents for different plant tissues correlate well with maximum achievable insect growth rates and efficiencies for most guilds and hundreds of different herbivore species. Many biotic and abiotic factors (and their interactions) affect the realized growth performance and fitness for insect herbivores (see below).

**Voltinism-Suitability Hypothesis**

This hypothesis was developed in 1992 by Scriber and Lederhouse, with the observations that at certain latitudes or in geographically localized cold pockets, seasonal thermal unit constraints (degree days as a resource) can determine whether an additional insect herbivore generation is feasible in any given year, depending on its selection of the most nutritional host-plant species, which varies with the timing of leaf bud break and phenological (seasonal) patterns, which differ at various locations. Thus, abiotic factors have been shown to affect host-plant choice (acceptability) and host-plant suitability for herbivores. High nitrogen and high water content generally reflect the most rapid leaf and cell growth and presumably plant vigor as well. Insect growth performance usually correlates well with these plant quality indices. The range of host plants utilized at a given latitude (or local climatic zone) may be the result of natural selection in relation to these abiotic factors. Thermal constraints for the summer growing season (as in Alaska or in similar localized cold pockets in the continental United States) contrast ecologically with thermally relaxed zones (i.e., where choice of either excellent or poor host-plant species or leaves does not influence the possibility of an extra generation per season). The difficulty in the voltinism-suitability model is that a good host typically is more than just a particular plant species and its allelochemical acceptability, nutritional suitability, and the abiotic thermal regime in which the herbivores are trying to optimize their growth and survival. The biotic community of natural enemies (e.g., enemy-free space as a resource) must also be considered as a critical determinant of the real ecological evolutionary suitability of any plant. The relative roles in plant defense played by natural enemies, weather-induced stress, herbivore-induced stress, and various abiotic factors remain complex, generating many unique and dynamic variations on the suitability hypothesis.

**SPECIALIZED VS. GENERALIZED HERBIVORES**

Among the world’s herbivorous insects, the number of feeding specialist (stenophagous) species dominates generalist species (polyphagous) for most taxa and feeding guilds (see Slansky and Rodriguez, 1987). Ecological advantages to herbivores of such stenophagy may involve efficient location and use of host plants, timing of critical life stages with budbreak and plant phenology, or enemy avoidance via cryptic matching of the herbivore eggs, larvae, pupae, or adults to plant parts. Mate finding may also be more efficient (e.g., with host races and habitat specificity). As host race populations genetically diverge, and perhaps even develop reproductive isolation, speciation may result.

The evolutionary benefits of host specialization have been presumed to be at a “cost” (e.g., tradeoffs in other performance measures; Fig. 1), but determining the existence or the amount of such evolutionary costs is as difficult as it was for the “feeding specialization/physiological efficiency” hypothesis at the ecological level (reviewed in 2005 by Scriber). Key innovations (e.g., furanocoumarin-metabolizing enzymes of the cytochrome P-450 gene families) allow circumvention of powerful antibiotic plant defenses for plants over millions of years from basal (ancient) angiosperms to current insect species (Scriber et al., 2007). It is also remarkable that one or two base pair substitutions may enable new detoxification capabilities and therefore open up new host-plant families for use by related herbivores (Mao et al., 2007).
However, not all interactions of insects and plants (herbivores or pollinators) become increasingly specialized: (1) evolutionary “reversals” have shown that specialization is not necessarily an evolutionary “dead end”; (2) homoploid recombinant hybrid speciation has recently been described in several insects, some with new host race affiliations, but some in polyphagous species (temporally isolated from parent species); (3) some taxa oscillate from specialists to generalists in their phylogenetic development; and (4) ecological specialization (strong selection with gene flow) has been recognized as an important process leading to new insect species. All of these points have recently been addressed by chapters in Tilmon.

**EVOLUTIONARY LEVEL**

Coevolutionary or reciprocal changes between plants and insects are the foundation of numerous phytochemical defense theories. However, there is surprisingly little direct evidence that insects select for plant phytochemical defenses. Most insect–plant interactions are diffuse without mutual counteradaptations. They will be, at best, a geographic mosaic with isolated and dynamic hot spots. Additional studies of different geographical populations (with and without herbivore selection pressure), plant and herbivore genetic analyses, phytochemical dynamics in relation to abiotic factors, and historical biogeography all seem to be warranted and critically needed to understand the historical patterns that produced current ones. For example, furanocoumarin cytochrome P-450 detoxification gene family may represent the “key innovation” for multihabitat phylogenetic mechanisms for processing ancient angiosperms (see Scriber et al., 2008) as well as current ecologically significant physiological induction abilities (Li et al., 2007). The ecologically enigmatic problem seems to be that our understanding of both plant resistance and insect counteradaptations ultimately depends on the identification of specific molecular pathways and an elucidation of the relative roles of genetic and environmentally induced variation between interactive populations.

**INSECT HERBIVORES CAN BENEFIT PLANTS**

It has been generally accepted that insect herbivory results in plant tissue damage that is detrimental for plant growth, survival, or reproduction; however, insect herbivory and subsequent frass fall can be beneficial for plant and ecosystem productivity. Although many crops and other plants can sustain 30–40% defoliation with little obvious impact on production, such feeding, if repeated annually or if on flowers and/or seeds, can be much more damaging. Insects provide direct nutritional benefit to some plants. Carnivorous plants that “digest” insects and use chemicals from their bodies for nutrients (especially nitrogen) are represented by many species, including pitcher plants, bladderworts, Venus flytraps, and sundews. Carnivorous plants are often found in soils that are low in available nitrogen, which may have been an important selection pressure for the evolution of these botanical life history traits.

**SUMMARY**

Insect–plant interactions involve a wide array of biotic and abiotic environmental influences as well as geographical and temporal variations built upon the diverse genetic foundations and inducible phenotypic plasticity of species, populations, and individuals. It, therefore, seems very appealing when theories arise that seem to have predictive power for these complex interactions. Such complexity is amplified when the variety of insect feeding guilds and variations in response of different plant parts and tissues are considered.

**FIGURE 1** Larva of *Papilio troilus*, a swallowtail butterfly that specializes on only 1–2 species of the Lauraceae plant family, has the highest feeding efficiency and fastest growth rates of any Lepidoptera tree feeder known (including several other specialized species; Scriber, 2005). This species grows at two to three times the efficiency and two to five times the rate of the generalist sister species, *P. glaucus* on the same spicebush (Lindera benzoin) leaves. This species, therefore, provides strong support for the “feeding specialization/physiological efficiency hypothesis,” and may exemplify the expected ecological/evolutionary “trade-offs” for specialists; it lacks the cytochrome P-450 furanocoumarin genes for metabolizing Rutaceae and other families used by the *P. glaucus* species group (Lauraceae lack furanocoumarins). Whether or not this inability represents an evolutionary loss for the specialized *P. troilus*, this species is chemically constrained (oviposition preference and larval performance); currently unable to feed on plants in any other family tested in North America and Australia, and unwilling to oviposit on anything but a few Lauracea hosts (Scriber, 2005).

The relationships between normal phenological changes in plant leaf (or part) composition throughout the growing season, carbon-nutrient stress, mineral nutrition, plant vigor, phytochemical induction of resistance in damaged/diseased leaves, increases in certain atmospheric gases, global warming, metabolism of different forms of carbon, and annual vs. perennial growth forms need coordinated biocomplexity studies. With such knowledge, the suitability of such plant tissues for insect and other herbivores (or the resistance of plants to their enemies) may become much more predictable, both in ecological and evolutionary time.

Plecoptera

(Stoneflies)

Kenneth W. Stewart
University of North Texas

Stoneflies comprise a hemimetabolous order of 16 families and more than 2000 species of aquatic insects distributed on all continents except Antarctica, and most major islands except notably Cuba, Fiji, Hawaii, and New Caledonia. They are primarily associated with running water, where nympha inhabit mineral or organic substrates of streambeds, and the winged adults rest throughout their seasonal lives in streamside microhabitats such as rocks, moss, debris, leafpacks, and riparian vegetation. A few species occur in waveswept substrates of cold alpine and boreal lakes, or in intermittent streams. Stonefly adults (Fig. 1D and 1E) are variable in size from about 5 to 50 mm, and in color from black to green or yellow, often marked with distinctive light or dark patterns. The aquatic adult of one species known from the depths of Lake Tahoe (Capnia lacustra) and a few other species are apterous (wingless), but most adults are winged. The wings of males and females of some species, or particular populations of a species, are shortened (brachypterous) and they do not fly, but the typical condition is of two pairs of wings as long or longer than the abdomen (macropterous). As the ordinal name (Plecoptera/Phlecentata: folded wing) describes, the hind wings typically have an expanded posterior (anal) lobe that folds longitudinally under the main wing (Fig. 1D).

Stoneflies are relatively slow, somewhat awkward fliers that typically fly short distances to disperse, to search for mates, or, for females to deposit eggs.

Adults (Fig. 1D) have ten abdominal segments; the genitalia of males are distinctive at the generic and species levels, and consist mainly of various external manifestations of the ninth and tenth segments such as paired hooks, lobes (paraprocts), or sclerotized styles and in some taxa a median probe (epiproct) of various shapes. During copulation, the copulatory organ (aedeagus) normally inside the abdominal cavity is everted ventrally from the genital opening on the ninth sternum. The external female genitalia consists of a flap-like subgenital plate covering the genital opening on the eighth abdominal sternum, a structure that the male grasps or holds with his hooks or lobes during copulation. The wings, 3-segmented tarsus, genitalia, and a pair of usually multi-segmented tails ( cerci),
Plecoptera

arising from the 10th abdominal segment, generally characterize stonefly adults. Nymphs (or larvae) (Fig. 1B and 1C) may or may not generally resemble their adults. They are gill-less or have diagnostic simple or branched tracheal gills arising from different parts of the body such as near mouthparts, ventral head, thorax, coxae or abdomen, and they always have multi-segmented tails ( cerci). Stubs or the basal remnants of gills are retained as vestigial structures in the adults of some taxa, and aid in their identification to family and genus. The long, multi-segmented nymphal cerci become reduced to fewer segments in some adults, or to a single segment in adult males of the families Leuctridae, Nemouridae, and some Taeniopterygidae.

TAXONOMY AND GENERAL DISTRIBUTION

The Plecoptera is divided into the two suborders Arctoperlaria and Antarctoperlaria. The Arctoperlaria are distributed in the Northern Hemisphere, except the family Notonemouridae which occurs only in southern South America, Southern Africa, Madagascar, Australia, Tasmania, and New Zealand, and some genera of Perlidae such as Anacroneuria and Neoperla that have moved south across the equator in recent times, perhaps from 15 to 30 mya. The Arctoperlaria is further divided into the Group Euholognatha (containing six families: Capniidae, Leuctridae, Nemouridae, Notonemouridae, Taeniopterygidae, and Scopuridae) and the Group Systellognatha (containing six families: Chloroperlidae, Peltoperlidae, Perlidae, Perlodidae, Pteronarcyidae, and Styloperlidae). The Euholognatha have mouthparts adapted for herbivory (scrapers, grazers, collector-gatherers, shredders, gougers, and detritivores), including molariform mandibles, and its species occur with few exceptions in streams of various sizes. The Systellognatha, except Peltoperlidae and Pteronarcyidae whose mouthparts are similar to those of Euholognatha because of convergent evolution to herbivorous food habit, have mouthparts mainly adapted for predation, including sharp-cusped mandibles and toothed lacinia for grasping and holding prey. The systellognathan families Perleidae and Peltoperlidae have very few species in arctic and subarctic streams.

The suborder Antarctoperlaria, as the name implies, is restricted in distribution to the Southern Hemisphere. In some areas, recently invading genera of Arctoperlaria, such as Anacroneuria (Perlidae) in South America and Neoperla (Perlidae) in Africa, have outcompeted them. The suborder contains four families: Asturperlidae, Diamphipnoidae, Eustheniidae, and Gripopterygidae. The Asturperlidae and Gripopterygidae live in a wide variety of habitats and the Diamphipnoidae and Eustheniidae are restricted to select populations in the southern Neotropical and Australian regions. Each of the 16 families of Plecoptera have unique combinations of wing venational, genital, gill, and other characteristics.

ECOLOGICAL IMPORTANCE

Stoneflies are integral and important food web components of most stream ecosystems throughout the world and therefore are almost exclusively beneficial insects. The various taxa have radiated to utilize virtually every type of food and substrate habitat resource available to them. The nymphs are variously detritivores, herbivores, insectivores, or omnivores, and in some species the diets of nymphs shift from detritivory or herbivory, through omnivory, to strict insectivory as development proceeds. In turn, they become food for larger insectivores and fishes, and are therefore important in the energy dynamics of stream food webs. Particular taxa are usually associated with particular stream microhabitats, such as the interspaces of loose gravel or cobble substrates, leafpacks, detritus, debris, or logs.

The nymphs of numerous species have evolved to coexist in a relatively harmonious, noncompetitive way in given stream ecosystems by partitioning their food, space, and time resources. Most stonefly species require relatively undisturbed conditions of the streams they historically inhabit and therefore are important biological indicators of stream water quality. They constitute the “P” component of one of the major biomonitoring indexes of “clean water species,” called the EPT Index (“E” for Ephemeroptera; “T” for Trichoptera), used for assessing water quality and degree of stream disturbance by humans.

LIFE HISTORY AND BEHAVIORS

Adults

Adult stoneflies (Fig. 1D and 1E) usually emerge during the night from nymphs that have crawled out of the water onto objects projecting from streams or on the stream bank, such as entrained leafpacks, logs or debris, rocks, or riparian vegetation. Some species of Euholognatha are black and emerge under ice or snow cover in winter. A light colored (teneral), clumped-winged, soft adult emerges from the last instar skin during the molt through a split in the head and dorsal thoracic segments. Males of many species emerge a day or more before females, so that they are present and searching when females appear. After some degree of hardening, both sexes become cryptic, hiding in crevices or vegetation during inactive periods, usually during the day, and becoming active in mate finding and other activities typically at night. Adults of Systellognatha have reduced mouthparts and typically do not feed, but may ingest liquids or nectar. Adults of Euholognatha feed variously on algae, lichens, flower pollen and nectar, or soft fruits. For most species of stoneflies, the details of transformation, dispersal, feeding, inactivity periods, and longevity are unknown. Generally, adults live only one to a few weeks, and are mostly actively engaged during that time in the reproductive activities of mate finding, copulation, and oviposition.

Communication, Mate Finding, and Mating

The primary method of communication for locating mates in the Northern Hemisphere stonefly suborder Arctoperlaria is vibrational signaling through substrates. The vibrations are produced by tapping or rubbing the abdomen on the substrate or by body tremulations transferred to the substrate. The signals of most insects that use this method consist of simple volleys of evenly spaced vibrations, but stoneflies have evolved a much more diverse and complex system of vibrational communication than is known for other insect groups. The currently accepted paradigm of how this behavior, generally known as drumming, evolved suggests that the ancestral method of signal production was percussion, and that signals were monophasic volleys of evenly spaced drumbeats. Natural selection favored increasingly complex signals, leading to greater efficiency of communication and mate finding among species, and possibly increased capability for sexual selection to measure reproductive fitness. An increasing complexity of particularly male call signals may have evolved through the following three behaviors: (1) more sophisticated signaling methods, sometimes associated with specialized co-evolving ventral abdominal structures, (2) rhythmic patterning of signals, and (3) possible use of selected natural substrates for signal transmission. The result has been that current species signal variously by percussion, scraping or rubbing the abdomen on the substrate (abdominal–substrate stridulation) or tremulation (vibrations produced by push-ups or rocking motions of the body without
abdominal contact with the substrate). Signal rhythms are species-specific and vary from evenly or unevenly spaced monophasic volleys to variously spaced diphasic or grouped signals.

The entire mating system of stoneflies involves communication as well as aggregation and movement behaviors of both sexes, the actual copulation, and post-mating behaviors. The typical system in Arctoperlaria involves the following complex of behaviors: (1) initial aggregation of sexes at encounter sites near streams, (2) calling by males with species-specific signals during ranging search, (3) duet establishment by virgin females answering the male call if effective vibrational communication distance from her is achieved, (4) a localized search by the male in a “triangulation” or other pattern for the now stationary female while both continue dueting, and (5) almost immediate mating after the male locates and contacts the female. Males are polygamous and presumably continue calling and searching during their short reproductive lives.

Typically, mated and unguarded females reject subsequent male advances by raising and curving their abdomens. Southern Hemisphere stoneflies of the suborder Antarctoperlaria have never been documented to drum; therefore, their communication-search system for mate finding is unknown, but they may have evolved a highly specific encounter site aggregation behavior that enables sufficient mate-locating ability without vibrational or other forms of intersexual communication.

Mating in stoneflies involves the male mounting the female, curving his abdomen around her left or right side and engaging the subgenital plate, pulling it down with his external genitalia. This effectively matches her genital opening beneath the plate with a dorsal position between his cerci where the aedeagus will project. His aedeagus is everted from beneath the ninth sternum and expands backward and upward between his cerci into the female. Sperm are usually conveyed into the female by this intromittent aedeagus, but in some species sperm are conveyed through a hollow male epiprost or are externally deposited onto the female opening to be subsequently aspirated into the bursa (vagina) by telescoping movements of her abdomen.

Eggs and Oviposition

The eggs of stoneflies (Fig. 1A) vary considerably in size, shape, and details of chorionic (egg shell) ornamentation and sculpturing. Commonly, eggs are spindle-shaped, but they also may be spherical, flattened or three-sided. Frequently, an anterior collar is present and the shell surface may be smooth or ornamented with ridges or the hexagonal pattern of impressions formed by the cells lining the ovarian chambers where the eggs are produced. Micropyles (sperm entrance holes) penetrate the chorion completely, and may have associated surface grooves or ornate projections that serve as sperm guides. Actual penetration and fertilization by sperm of the egg is, as in most insects, delayed until the eggs are being stored or passed through the oviduct just prior to oviposition. The sperm are stored in the female spermathecum between copulation and fertilization. There also may be shallow pores leading to elaborate respiratory networks within the chorion. Eggs have sticky membranous or gelatinous surface coverings, and sometimes filament-like projections with hooked tips, that swell and help the eggs attach to substrates under water close to the selectively optimal sites where females deposit them.

Eggs are deposited by females in pellets or masses, each containing numerous eggs, that the females hold on the subgenital plate. They release the egg masses either directly into the water by splashing into the surface during an oviposition flight, or by contacting shallow water while running near the shore, or by dropping eggs from the air while flying over water. Females of some Capniidae are also known to completely submerge themselves and crawl along the bottom and scrape the egg mass off onto the substrate.

In most species, embryonic development proceeds directly and is complete within 3–4 weeks. In other species, particularly those adapted to intermittent streams or streams subjected to extremes in temperature, embryonic development may be arrested for from 3 months to 1 or more years, and hatching is thus delayed until environmental conditions are favorable for nymphal survival. Such arrested development is termed diapause, and it may be manifested in both egg and nymph stages.

Nymphs

Hatchlings (Fig. 1B) emerge from the egg by pushing on the chorion with the front of their head. The shell breaks into two halves, or splits leaving a hinged cap and opening through which the first instar crawls out. The first instars are unpigmented with few body hairs, have fewer than 12 antennal and 6 cervical segments, and gills and wingpads are absent, reduced, or represented only by knobs or stubs. Little is known about the food, habitat, or behavior of hatchling and early instar stonefly nymphs. The few species that have been studied feed mainly in detritus or the microflora-fauna on the surface of decomposing leaves.

Nymphs progressively develop and grow through about 10–24 sizes (instars). Full development of particular species requires from 4 months to 3 to 4 years. During this time there is a molt between each instar, addition of antennal and cervical segments, usually addition of body hairs, a progressive increase in size of wingpads, and appearance and development of gills (if present in particular taxa) and characteristic pigment patterns. Growth of a particular species may be sustained at an even pace or seasonal, with fast and slow stages. In temperate climates growth is generally rapid during spring and fall and slowed or arrested (diapause) during extreme temperatures in summer or winter. But, interestingly, a number of euholognathan species, particularly in the families Capniidae and Taeniopterygidae, have adapted to experience their major growth in late fall and winter and emerge as adults during winter on ice or snow or in early spring during ice breakup. Completion of development and subsequent emergence as adults in temperate climates, therefore, may occur during any season, depending on altitude, latitude, and species.

Stoneflies have diversified their food habits such that different species fill about every conceivable major food niche in streams. Some species are herbivore–detritivores throughout their development, some are insectivores throughout development, and some experience an ontogenic (developmental) shift from herbivory–detritivory through omnivory and finally to carnivory. Characteristics of mandibles give a clue to food habits. The mandibles of herbivores have molariform surfaces or scraping ridges and those of carnivores sharp teeth for grasping and tearing. The food of carnivores species consists primarily of the other aquatic insects of their communities such as midge larvae (Chironomidae), mayfly nymphs (Ephemeroptera), caddisfly larvae (Trichoptera), and occasionally the smaller nymphs of other stoneflies. Nymphs may be opportunists, or in some cases are very selective for the size, behavior, and taxa of their prey. Prey are captured, grasped by the head with the lacinia and mandibles, and usually swallowed whole, head-first.

Particular species of nymphs are found in certain types or sizes of streams at particular latitudes or elevations and often in specific microhabitats. Rare and endemic species have very specific biological and physical requirements and therefore continue to exist only in pristine or little-disturbed sections of streams that in many instances are now
found only in remote areas or in, or adjacent to, protected national parks or preserves. Many species have broader requirements and are more widespread or ubiquitous over large areas of continents in a wide variety of habitats. Only a few species are tolerant of the conditions of streams disturbed by siltation, alteration of natural temperature regimes or chemical pollution. Stoneflies depend on substrates as a place in which to live. Slender species live in the interspaces of gravel, cobble, or vegetable debris such as leaf packs. Partitioning of microhabitats, and consequent microdistribution, is characteristic of most stonefly assemblages in a given stream. Most species live in the surface layers of a streambed, but a few live deep in loose mineral substrates such as glacial till, and sometimes in the water-filled spaces of such substrates for considerable distances deep and lateral from the margins of the surface stream. Nymphs are sometimes found drifting in the water column of streams. This results from being dislodged by some physical disturbance or entering the water column as a behavioral means of dispersal, using the flow of water. Drifting enables nymphs to escape predators or move to a less populated habitat where food and/or space resources are more available or of higher quality.

**Life Cycles**

With few exceptions, a full generation of the egg, nymph, and adult stages of a stonefly species requires 1–4 years. For 1-year (univoltine) cycles the nymphal growth period may be “fast,” requiring only 4–7 months, or “slow,” requiring nearly a full year. The fast type is characteristic of species that diapause for variable times up to 8 months during warm or dry periods of streams; the slow type characterizes species whose nymphal stage requires about 11 months. Species requiring more than 1 year for a generation are termed semivoltine. Those that live in intermittent streams may diapause in the egg stage during drought periods for more than a year, then have a fast-growing nymph for only 4–6 months. Semivoltine species living in cold streams may have a short egg stage, with nymphs requiring 2 or more years to develop, or a year-long diapausing egg stage, with nymphs requiring 1–3 years to develop. The life cycles and resource requirements of stoneflies are important considerations for developing stream management strategies.

**Pollination and Pollinators**

Gordon W. Frankie

*University of California, Berkeley*

Robbin W. Thorp

*University of California, Davis*

Pollination in its most basic sense is the transfer of pollen from the male sex organ (anther) to the receptive portion of the female sex organ (stigma) in flowering plants (Fig. 1). If the transfer is successful, it leads to fertilization, production of seed, and reproduction of the plant. This process often involves some sort of external vector such as wind, water, or animals. Some flowering plants may reproduce without the aid of pollen vectors, using mechanisms such as vegetative reproduction, apomixis, or automatic selfing. But our concern in this article is with animal vectors of pollen. Many kinds of animals may perform the ecological service known as pollination, including birds, bats, and some nonflying mammals. However, the dominant group of pollinators is the insects, especially bees.

*FIGURE 1* Floral parts of an almond blossom. The petals are color signals, the male stamen (anther and filament) and the female pistil (stigma, style, and ovary) are the reproductive parts. Nectar from the nectary and pollen from the anthers are food rewards to pollinators.

**ENTOMOPHILY**

Many flowering plants are adapted to insects as pollinators and provide primary rewards that attract and keep the pollen vectors returning to flowers. Rewards include nectar, pollen, lipid secretions, food bodies, scents, resins, and material for nest building. In addition to primary rewards, most insect-pollinated flowers also produce a number of cues or signals that distinguish them from other species and promote the case by which an insect can relocate a rewarding flower, thereby encouraging the insect to move pollen from flower to flower of the same species. These signals include odors, colors,
shapes, textures, and tastes. These signals are often combined into patterns that have been recognized as syndromes related to the type of pollen vector. For example, a typical butterfly-pollinated flower that would be red, have little odor, possess a landing platform, have nectar hidden at the base of a deep tube that can be reached by the long coiled butterfly proboscis, have nectar that would be high in amino acids, and have flowers that would be open during the day. In contrast, a typical hawk moth-pollinated flower would be white, have a strong sweet odor, lack a landing platform, have long stamens with freely swinging anthers, and would bloom nocturnally. Nectar position and composition would be similar to those of a butterfly flower. All these characteristics are well suited to the hovering flight and extremely long proboscis of a hawk moth (Fig. 2).

Pollinator syndromes are perhaps most readily distinguished in the tropics. However, not all flowers are easily classified in a pollinator syndrome. Many flowers are visited by guilds of visitors that include diverse taxa of insects. For these reasons some pollination biologists see little value in the use of pollination syndromes even for teaching. However, even when using a pollination syndrome approach, it is important to distinguish which taxa among the visitor guilds are actually effective pollinators of a flowering plant.

Many insect taxa visit flowers and thus are potential pollinators; however, only a few taxa are of prime importance. Minor groups include those Orthoptera that feed on pollen and some Heteroptera that visit flowers for nectar or those that use flowers as sites that attract prey items (e.g., Phymatidae, Reduviidae). Thrips (Thysanoptera) are common on flowers and often feed on pollen and other flower tissues. They may do more damage than good, but their positive contribution as pollen vectors is understudied. The major groups of insects that pollinate plants belong to the four largest orders of insects: Coleoptera (beetles), Diptera (flies), Lepidoptera (butterflies and moths), and Hymenoptera (bees, ants, and wasps).

**Coleoptera**

Beetles are often considered “mess and soil” pollinators in that while rumaging around in flowers feeding on pollen and other flower parts they pick up pollen on their bodies that is transferred to other flowers on subsequent visits. This type includes many that destroy some flowers by feeding on them (e.g., Scarabaeidae, Meloidae), but in the process others get pollinated. Some beetles are associated with pollination of some “primitive” flowers and have been considered responsible for pollination and diversification of early flowering plants (Angiospermae). Beetles of the family Nitidulidae feed on specialized food bodies on anther tips of the spice bush *Calycanthus* (Fig. 3).

**Diptera**

Diverse flies, including male mosquitoes, various midges, carriion flies, pollen-feeding Syrphidae, and long-tongued nectar feeders (e.g., Bombyliidae, Acroceridae, Nemapriinae), pollinate flowering plants. Pollination by flies is greatly understudied and underrated. Although flowers of pipevines are considered classical “trap” flowers that imprison flies with inward directed hairs until the flower has released pollen on them, flowers of the California pipevine, *Aristolochia californica*, exhibit a different mechanism involving a reward to retain flies until pollen is released. Midges of the family Mycetophilidae are the primary visitors and pollinators of *A. californica*. When flowers of *A. californica* first open, the stigma is receptive and a dark ring of glandular trichomes encircles the outer wall of the flower at the level of the stigma. Flies descend through the hooded entrance to the lower bowl and are attracted to the area of the stigma and trichomes by a light window. Flies feed on the trichome surface, contacting the stigma and depositing pollen from previous flower visits. The stigma closes, the trichomes wilt, and the anthers shed pollen into the bowl and onto the flies. Because there is no more food available, flies exit the flower and seek another, thereby pollinating the next flower.

**Lepidoptera**

Most adult butterflies and hawk moths are well-known flower visitors. Other day-flying moths (e.g., *Schinia* of the Noctuidae, *Adela*, Incurvariidae) and nocturnal moths pollinate while settling or perching on flowers during feeding or oviposition. A very specialized relationship exists between yucca moths (*Tegeticula*, Prodoxidae) and their host yucca flowers (*Yucca*, Liliaceae). Female *Tegeticula* enter *Yucca* flowers, collect pollen into a ball in specialized maxillary palps, move to the apex of the pistil where pollen is deposited on the stigma, and oviposit into the base of the pistil where seeds will develop from the pollination behavior. Larvae of the moth develop in the fruit pod,
feeding on a portion of the seeds. Thus, both insect and plant benefit from this highly mutualistic association; the plant gets pollinated and produces seed, some of which goes to producing new moths.

**Hymenoptera**

Some sawflies and parasitoid wasps feed on pollen, especially on open shallow flowers. Classical mutualism occurs with the pollination association of fig wasps (Agaonidae) and their floral hosts, figs (Ficus, Moraceae). Similar to the situation with yucca moths and yucca, a portion of seeds in fig host flowers provides nourishment for development of the pollinating wasps. The story is often more complex and involves more than one generation of wasp per year and more than one host.

Other aculeate wasps, both social and solitary, augment insect prey diets with nectar. One genus of solitary wasps, *Pseudomasaris* (Masaridini, Vespidae), is completely dependent on flowers for nectar and pollen as food for their young. Ants may visit flowers but because their metathoracic glands secrete mold inhibitors they inhibit pollen germination and are unlikely pollen vectors. Bees (superfamily Apoidea) are the single most important taxon of pollinating insects with 20,000–30,000 species worldwide. Bees are derived from wasps and highly adapted to gathering pollen as brood food and nectar for flight fuel.

**EXPLOITATION RELATIONSHIPS**

Not all pollination relationships are mutualistic, that is, beneficial for both partners. Some are based on deceit or robbery, in which only one partner benefits and the other may even be injured.

**Thievery**

Insect visitors to flowers may obtain the food items they seek without transferring pollen in the process. Some insects with mouthparts too short to reach nectar sequestered in the bottom of long tubes or spurs are able to penetrate the nectar-bearing structures with strong mandibles or maxillae. Such behavior is well documented for bumble bees called *pseudocopulation* because it relies on mating attempts by male wasps or bees. The flowers bloom during the brief time when male insects are on the wing before females of the species emerge. During this period, flowers are the only potential sources of “mates” for the male insects. Once females of the hymenopteran species emerge, the floral mimics are forsaken by males for the real female.

**CROP POLLINATION**

**Economic Value**

The most recognized benefit of pollinators to humanity is their value as pollinators of many of the crop plants that we use for food and fiber. The principal pollinator managed for crop pollination has been and currently is the honey bee, *Apis mellifera*. Although calculating the value of pollination by honey bees is far from exact, the most recent estimate of the annual value of increased production of crops contributed by honey bee colonies rented for pollination in the United States is over $14.5 billion, on average, over 1996–1998. The “free” contribution from native pollinators, especially other bee species, is even less measurable, but attempts are under way to estimate their value to sustainable agriculture farms in central California.

**Exemplar Crops**

California is perhaps the leading state in rentals of honey bee colonies for crop pollination. In large measure this is the result of the continuing increase in the acreage of almond, which has increased from about 36,000 hectares in the mid-1960s to over 200,000 hectares in 2001. At the recommended five to eight honey bee colonies per hectare, more than twice as many commercial colonies as exist in the state are required to accommodate the demand. Thus, there is a mass movement of colonies into California each year from as far as the Dakotas and Texas and beyond to pollinate the crop.

Alfalfa is another crop traditionally pollinated by honey bees that was widespread in California in the mid-1960s. However, the honey bee is not an effective pollinator of alfalfa over much of the crop's

**FIGURE 4** Female carpenter bee (*Xylocopa tabaniformis orpifex*, Apidae) robbing nectar from base of a California fuchsia (*Epilobium canum*, Onagraceae) flower.
range. When two more efficient alternative pollinators (the introduced alfalfa leafcutting bee, *Megachile rotundata*, and the native alkali bee, *Nomia melanderi*) came under management for pollination of the alfalfa seed crop, much of the production shifted to the Pacific Northwest. Only the southern areas of California continued to produce alfalfa seed solely with honey bees. Currently even some of these areas are augmented with alfalfa leafcutting bees.

**Crop Pollinators Other Than Honey Bees**

Although honey bees are readily available, easily transportable in large quantities, and generalist pollinators, they are not universal pollinators. There are some crop flowers, such as figs, that require insect pollination (specialized wasps) and cannot be pollinated by honey bees. There are other crop flowers that can be pollinated by honey bees but for which honey bees are not the most effective pollinators; these include crops such as alfalfa, squash, and greenhouse tomatoes. Another concern about excess reliance on a single pollinator for a wide variety of crops has been the widespread decimation of feral honey bees by the “vampire” mite, *Varroa*; increased cost of treating colonies to maintain healthy pollinating units; and reduction in numbers of beekeepers and colonies available for pollination. Warnings about this overdependence on honey bees and the general decline of pollinators because of factors such as loss of habitat and pesticides were issued in 1996 in a landmark publication by Buchmann and Nabhan.

One of the first insects introduced into North America specifically to pollinate a crop was the fig wasp, *Blastophaga psenes*, for production of edible Smyrna figs in southern California in 1899. Attempts to produce edible figs in California in the late 1800s failed until it was recognized that wasps from the wild ancestral caprifig, *Ficus carica*, were required. Edible figs contain predominantly pistilate flowers; pollen from male flowers of the caprifig is vectored by fig wasps. The growing of caprifi g flowers containing introduced fig wasps, harvesting the fruits with a new generation of fig wasps, and then hanging them in baskets in trees of edible figs became a common practice in southern California, a process called “caprifi cation.”

Other insects that have been used for commercial pollination on a small scale include various flies, especially for breeding hybrid seed crops in cages by seed companies. Most of these have been muscid flies, the pupae of which are readily available from insectaries. Results of large-scale open-field trials using carrion or other baits to attract flies have been equivocal for crop pollination.

Various species of non-Apis bees have been and are being studied for their management potential for pollination of crops. In the late 1950s, studies were begun to manage two bee species (*M. rotundata* and *N. melanderi*) that are more effective than honey bees as pollinators of alfalfa for seed production.

More recently mason bees in the genus *Osmia* have been studied for pollination of crops in North America and Europe. *Osmia lignaria propinqua*, referred to as the “blue orchard bee,” has been successfully managed to pollinate tree fruits in western North America. It is a cavity nester, like the alfalfa leafcutting bee, but uses mud partitions to create brood cells. Many of the management techniques were adapted from those used for *Megachile*, but modified to accommodate specific life history and behavioral attributes, including early spring activity and a single generation per year. Successes in managing other species of *Osmia* include *O. cornifrons* in Japan, *O. cornuta* in Spain, and *O. rufa* in Britain and France. In North America, *Osmia* are being studied for pollination of blueberries (*O. ribifloris*) and clovers (*O. sanrafaelae*).

In the late 1980s, major breakthroughs in year-round production of bumble bee colonies completely altered and expanded hothouse production of tomatoes. Tomato flowers require “buzz” pollination (i.e., vibration of flowers to release pollen from the apical pores of their specialized anthers) and bumble bees are much more effective at this than are honey bees or humans who hand pollinate with vibrating tools. This led to extremely large-scale movements of bumble bee colonies and queens, primarily *B. terrestris*, from central Europe, New Zealand, and Israel to many nations throughout the world. Some of this trafficking was unnecessary because closely related species were available for use at some locales. In Japan, environmental concerns have been expressed over the thousands of imported *B. terrestris* colonies and the subsequent establishment of this species outside the greenhouse environment. Males of this species will mate with queens of local species and produce viable offspring. Similar environmental concerns are being raised in other countries. In Canada and the United States, importation of *B. terrestris* was not sanctioned, but local bumble bee colonies have been successfully reared and used in hothouse tomato production. East of the 100th meridian (a line that runs from central North Dakota to central Texas), *B. impatiens* was the species of choice and west of this line, *B. occidentalis*. These bees were used in their respective areas of distribution until 1999, when a disease outbreak was reported in the western species. Since then, the eastern *B. impatiens* has been imported into all western states, again causing concern in some areas that establishment outside its normal range may produce environmental damage.

Although pollinators are generally considered beneficial insects, importations to new areas should be done with considerable care to avoid environmental risks, such as introduction of disease organisms, nectar thieving, decreased pollination of nontarget native plants, enhanced pollination of introduced weeds, and genetic contamination of and competition for food and/or nest sites with native pollinators. The local fauna should be studied and searched for candidate species that could be suitably managed before any exotic species are introduced. Rearing technology is already available for several species of cavity-nesting bees, for bumble bees, and for some soil-nesting species. These methods may be modified and applied to local species that show promise for solving difficult pollination problems.

If it is deemed necessary to introduce a new pollinator, these should be thoroughly screened for biotic enemies (e.g., parasites, disease organisms) before being introduced. They should be monitored after release in the new environment to determine their efficiency in pollinating the target crop and to detect any adverse environmental effects.

**POLLINATOR DECLINE**

Pollination biologists have worked for years studying the behavioral, ecological, and evolutionary intricacies of animal–plant pollination relationships. With the environmental movement of the early 1970s came awareness that mistreatment of the environment could also negatively affect these unique relationships. However, very few biologists sounded the alarm at that time that trouble was brewing for pollination relationships and pollinators, especially at the ecosystem or landscape level.

In the early to mid-1990s, the issue of pollination/pollinator problems was again brought to the attention of the biological community and the informed public, through the Island Press publication of The Forgotten Pollinators in 1996 by Stephen Buchmann and Gary Nabhan. Although the book contains anecdotal accounts of pollinator problems, the message was clear—everyone concerned with the pollination of plants needed to pay serious attention to what appeared to
be an emerging picture of global pollinator decline. A subsequently important publication by Allen-Wardell et al. in 1998 pointed out the potential threat of pollinator decline to the human food supply. Adding to the general concern for declining pollinators was the fact that European honey bees in the New World tropics, and several western and southwestern U.S. states, were being systematically replaced with Africanized honey bees, and that all honey bees were being attacked and significantly reduced in numbers by two species of parasitic mites. Continued careless use of pesticides and bacterial infections were also cited as factors in the decline of honey bees.

The above trends have led to many scientific conferences worldwide to address the issue of pollinator decline and its potential consequences to crop plants and to native wildland plants. The first important global conference was held in 1998 in São Paulo, Brazil, where numerous relevant issues on pollinator decline were discussed by more than 60 pollinator/pollination professionals representing several New and Old World countries. The São Paulo meetings and subsequent meetings in other parts of the world have put into motion new research directions in the field, which are listed below.

1. Documenting pollinator decline. One of the main recommendations emerging from São Paulo was to seek quantification of pollinator declines through careful case history studies. Long-term monitoring of pollinators and comparative assessments at specific study areas were recommended approaches for gathering the needed data on decline. This has proved to be quite a challenge because of natural fluctuations in pollinator populations and the lack of long-term baseline data. Where decline has been detected, loss of habitat is suggested as the main cause.

2. Causes of decline and restoration of pollinators. Habitat loss is a convenient general explanation for the cause of decline, but detailed information is needed on the precise factors causing decline. Further, specific causes of decline are not always obvious, and this becomes an important issue when considering projects to restore or establish pollinators and their required resources (often diverse) to an area.

3. More research on non-honey-bee pollinators. Honey bees can be likened to a monoculture in agriculture; overdependence on a single organism in agriculture can lead to disastrous results when natural mortality factors get out of balance. Such was the case with blight on a large portion of the U.S. corn crop several years ago. Because honey bees are now showing great vulnerability to two species of parasitic mites, more research on these parasites and on other bees (especially native solitary species) is being conducted.

4. Conservation of pollinators. Much has been written on conserving pollinators and especially bees. Unfortunately, there is little evidence to suggest that conservation recommendations, which would result in measurable increases in pollinator numbers, have been put into action. Many possibilities exist for increasing pollinators through manipulations of preferred food plants, nontropical plant products (e.g., resins), and planned efforts to increase nesting sites and other requisites such as alternate food plants for moths, beetles, wasps, flies, bats, etc.

5. Increasing awareness of pollinator services. The conservation of pollinators and calling attention to vital services provided by pollinators becomes issues of information transfer that biologists must address. They are the only professionals who know the needs and fragilities of small organisms such as bees, flies, beetles, and nocturnal organisms such as moths and bats. Pollinator/pollination professionals will need to form closer working relationships with policy-makers, land stewards, and a wide variety of government and nongovernmental organizations to realize future successes in the management of pollinators.

There are at least two courses of action that pollinator biologists could pursue now to assist declining pollinator populations. First, they can collaborate with other biologists who are also concerned about decline of their specific organisms (e.g., birds, mammals) and habitat. Building a coalition of concerned biologists with integrated management plans for habitat protection for several threatened species could be effective if land stewards, associated with the habitat, were receptive and willing to participate in some way as stakeholders in the project. Second, biologists could also work in a variety of ways toward conserving areas known to naturally harbor healthy populations of pollinators, preferably several types. Biologists are aware, through years of field experience, which areas have good diversity and abundance of, for example, bees and moths.

TROPICAL POLLINATION

The literature is filled with fascinating case histories of individual tropical plants and their pollinators. More recently, researchers have been investigating pollination systems involving groups of prominent pollinators (e.g., bees, bats, moths, hummingbirds) and their plants in major tropical life zones. A few larger, long-term studies from the New and Old World tropics have also provided the first community pollination patterns for a high percentage of the representative plant life forms. These latter studies are particularly helpful in elucidating diversity and frequency of pollination systems for conservation work, as well as for interesting comparisons with temperate environments.

In Table I, pollination systems of two lowland forest sites and one midelevation cloud forest (1200–1500 m) in Costa Rica are compared and contrasted with one lowland forest site in Malaysia. From about 40 to 70% of the surveyed plant species in each of the four sites were pollinated by bees. Although less frequent than bees, birds were important pollinators in Costa Rica’s cloud forest and wet forest and in the Malaysian forest. Beetles were important in the Costa Rican wet forest and in Malaysia; moths were important in all three Neotropical forests. The four sites had numerous plant species that were visited (and pollinated) by a variety of general insects.

The importance of animals, especially insects, as pollen vectors of tropical plants was clearly demonstrated in a classic paper by Bawa in 1974, in which he reported that most tree species in a lowland dry forest of Costa Rica were obliged to outcross. Through controlled pollinations, he demonstrated that a high percentage of the tree species tested were self-incompatible (incompatible of self-pollination) or dioecious (having separate male and female plants of a species). Until that time, many biologists believed that self-pollination was probably the rule in tropical forests. Flower-visiting animals, and especially insects, were not viewed as capable travelers between widely distributed tropical plants. Subsequent studies on interplant movements and foraging patterns of these animals have substantiated their capacities to move among flowering plant species at levels required to produce abundant fruit crops.

Some general, but limited, comparisons of tropical vs. temperate pollination systems are possible with the information available in the literature. First, the flora of many low- to midelevation temperate habitats is mostly pollinated by bees. Estimates vary widely from 70 to more than 90%, depending on locality. Flies and Lepidoptera may also be important in the pollination of temperate plants. Second, the diversity of pollination systems is comparatively lower in temperate environments because most lack, for example, the more specialized bird, bat,
beetle, and fig wasp systems. Third, when lowland tropical and temperate forests are compared, the high diversity of tropical trees and their dependence on animal pollination become immediately apparent. Temperate forests have relatively low tree species diversity and most, such as conifers, oaks, willows, elms, and maples, are wind pollinated. In contrast, wind pollination is rare in tropical forests (Table I).

### SPECIALIZED VS. GENERALIZED POLLINATION

As mentioned previously, there is ongoing controversy about specialized vs. generalized pollination systems and the associated concept of pollination syndromes that propose to characterize a plant as to a particular pollinator type. There can be little doubt that some plants have highly specialized systems that can be easily characterized by floral morphology and behavior alone, such as fig flowers and fig wasps, certain orchids and their specific bee relationships, and long, white-tubed fragrant flowers that open at night and are pollinated by long-tongued hawk moths (Fig. 2). There are, however, many instances in which flowers attract a wide variety of visitor types, making characterization of pollination syndromes difficult. For example, there are examples of “large-bee flowers” that are regularly visited by small bees, butterflies, and wasps; hawk moths that visit “bat flowers”; bees that visit both “hawk moth flowers” and “bat flowers” the morning after. Further, there are flower types that attract a wide diversity of insect visitors (Table I). Who are the pollinators and who are the visitors to these flower types? Do many or most plants have the option of being pollinated by a variety of potential vectors? The answers to these questions will be forthcoming through carefully planned experimental studies that include evaluations of all visitors and their capacity to transport pollen on their body parts, as well as between plants. Floral behavior must be studied simultaneously, especially with regard to breeding system and period of stigmatic receptivity. These case studies should take much of the speculation and guesswork out of pollinators, visitors, and pollination ecology.

### CHEMICAL ECOLOGY AND POLLINATION

Chemical communication between flowering plants and their pollinators and between conspecific pollinators in relation to floral resources is commonplace in many natural communities. Flowers release a variety of odors that attract pollinators and other visitors. Some of these are sweet and highly fragrant, as with many “moth flowers” and some “bee flowers.” Some are unpleasant to humans but highly attractive to flies and beetles. Other floral fragrances fall somewhere between fragrant and unpleasant such as musky odors associated with some flowers that attract a variety of visitor types.

In the New World tropics, chemicals are emitted from certain orchid species that attract only males of the Euglossini tribe of bees, better known as orchid bees. These orchids and “their” bees have evolved a unique relationship in which chemical substances are scratched from special regions of the orchid flowers by male bees. The compounds are collected in special leg glands that have unique apertures on the hind legs. According to theory, the scratched compounds are metabolized and transformed into chemical messages or pheromones that male bees use for attracting females for mating. Some male orchid bees form elaborate leks or mating rituals, which they use to lure females. During the process of scratching chemicals, orchids belonging to genera such as Catesetum, Cycnoches, and Stanhopea have cleverly evolved elaborate mechanisms for attaching or actually gluing a pollen packet (or pollinia) on the bee for transport to the next orchid, thereby effecting cross pollination. Each orchid species glues its pollinia on a characteristic location of the bee. Where orchid diversity is rich, it is common to see some bees with pollinia on their heads, other bees with pollinia on their thoraces or abdomens, and still other bees with pollinia on more than one body location, indicating their visits to more than one orchid species.

There is also chemical communication among members of some social and solitary bee species. Some honey bee species scent mark flowers, and this informs others of the same species of a very recently visited flower. The mark also serves to alert a bee that it has just visited

Pollution, Insect Response to

David M. Rosenberg
Freshwater Institute, Winnipeg, Canada

Vincent H. Resh
University of California, Berkeley

Pollution is essentially the wrong substance, in the wrong place, in the wrong concentration, at the wrong time. More formally, pollution can be defined as the introduction of human-made substances (or natural substances released by humans) and forms of energy into the environment that are likely to damage ecosystems or their constituents, amenities, or structures.

Insects, like other living organisms, are affected by pollution. However, insects are also used to assess the effects of pollution as surrogates or representatives of the larger assemblages of organisms in communities and ecosystems. We refer to insects in this latter role as biomonitoring agents.

Pollution can be caused by a variety of substances and activities: sewage and other organic enrichment, fertilizers (e.g., nutrients such as phosphorus), siltation (e.g., from erosion), pesticides (e.g., herbicides, fungicides, insecticides), metals (e.g., cadmium, mercury, selenium), organic compounds (polyhalogenated biphenyls, polycyclic aromatic hydrocarbons, industrial atmospheric emissions (e.g., sulfur dioxide and NOx, which are precursors to acid rain; greenhouse gases such as carbon dioxide and methane), radiation (as in the Chernobyl disaster), heat (e.g., thermal pollution from power plants), and habitat destruction (e.g., clear-cutting, stream channelization, reservoir creation). Disturbances that have consequences similar to those of human activities can also be caused by natural events such as volcanic eruptions or forest fires, but the products of these disturbances do not fit our definition because they are not deliberately introduced by humans.

POiLLUTION EFFECTS ON INSECTS

The effects of pollution on insects occur at a variety of spatial and temporal scales. For example, effects can occur at the molecular levels, affecting the physiology of the individual insect, or at the community levels, affecting the diversity and abundance of insect populations. Pollution can also affect the structure of ecosystems, altering the interactions between insects and their environment, which can lead to changes in the distribution and abundance of insect species.

Further Reading

level in fractions of seconds (i.e., biochemical effects), at the ecosystem level over several decades, and at various scales in between these extremes (Fig. 1). The most easily detected responses are at the level of the individual (as in bioassays), in which evaluation is often based on whether an insect lives or dies when exposed to a contaminant. However, population and community levels are generally used when effects are examined in nature (Fig. 1). Within a population, we can see shifts occurring in the frequency of organisms of different sizes.

For example, early instars in a population seem to be more susceptible than later instars because early instars have higher surface-to-volume ratios, they are more active, and they have thinner cuticles. Eggs, pupae, and diapausing insects are usually more resistant stages. Common community-level changes observed with the onset of pollution involve decreases in species richness (i.e., the total number of species), decreases in species evenness (i.e., the distribution of numbers of individuals among species), and alterations in species composition. Severe sewage pollution in fresh waters presents a good example of the kinds of changes that can occur. With sewage input, the total number of species decreases immediately downstream of a sewage source and species evenness decreases because the remaining tolerant organisms proliferate. Also, pollution-tolerant organisms such as dronefly maggots (*Eristalis tenax*), some species of midge (*Chironomidae*) larvae, and aquatic earthworms replace less tolerant ones, and these tolerant organisms can reach extremely high densities.

Alteration of feeding-group structure is another response to pollution. For example, the removal of a riparian zone surrounding a stream can lead to increased production of algae because of more open conditions and greater sunlight reaching the stream substrate, a decline in the leaves falling into the stream, and an increase in grazing insects (feeding on algae), which replace the insects that would normally feed on leaves.

More subtle community-level effects are also possible. For example, the suppression of parasites by air pollutants may enhance outbreaks of forest insect pests whose populations are normally held in check by the parasites. These indirect effects (Fig. 1) are often more difficult to detect than the direct effects discussed above.

Natural variability is a problem in evaluating the effects of pollution on insects. Only the accrual of long-term baseline data on insect species present and their abundances, and the use of an experimental approach to establish causation, can lead to understanding of the effects of pollutants on insects.

**USE OF INSECTS IN BIOMONITORING**

The responses of insects to pollution can be used in biomonitoring of air, land, and water quality. The most extensive biomonitoring has been developed in aquatic habitats, perhaps because aquatic insects are directly exposed to water pollution and their responses are easy to measure.

Insects present a number of advantages for biomonitoring: (1) they are ubiquitous, so they are exposed to pollution in many different habitats; (2) the large number of species offers a range of responses; (3) the sedentary nature of many insects allows spatial analysis of pollutant effects; and (4) their long life cycles allow temporal analysis of pollutant effects. Unlike relying on instantaneous measurement of physical and chemical variables, the use of living organisms, like insects, provides a temporal integration of pollutant effects over their life span.

Biomonitoring can be done at a variety of spatial and temporal scales (Fig. 1). The smallest scale is biochemical; for example, exposure of stonefly species to the pesticide fenitrothion can be measured by depression of acetylcholinesterase activity in the stonefly head. The largest scale is the ecosystem, in which measures of processes such as productivity and decomposition can indicate pollutant stress. However, biomonitoring is most commonly done at individual, population (or species assemblage), and community levels.

Common examples of biomonitoring at the individual level include the use of insects as sentinel organisms and for measuring morphological deformities. The use of morphological deformities to measure pollutant effects is more common in freshwater than in terrestrial habitats. The head capsules of midge larvae are frequently used for this purpose. Bioassays often involve exposure of individuals to potential pollutants to detect sublethal responses (e.g., diminished growth or fecundity) or lethal responses (e.g., mortality).

Biotic indices are popular ways to summarize information and assess pollution at the population or species assemblage levels. For example, indices of the trophic status of lakes have been developed...
Polyembryony

Specialized Terms

pattern formation Is the activity by which embryonic cells form ordered spatial arrangements of differentiated tissues; during insect embryogenesis, patterning begins with specification of the anterior–posterior and dorsal–ventral axes, and ends with the formation of the characteristic structures associated with each segment of the head, thorax, and abdomen.

blastosomeres The embryonic cells produced during the process of cleavage.

caste Any set of individuals in a colony that are morphologically distinct and/or that perform a specialized task.

complete (holoblastic) cleavage A coordinated series of mitotic divisions wherein the entire volume of the egg cytoplasm is divided into numerous smaller cells that are fully separated from one another and which together comprise a morula.

hemocoel The body cavity of the insect that contains blood and all internal organs.

morphogenesis The phase of embryogenesis in which specific tissues, organs and structures develop.

parasitoid An insect which is free living as an adult but which develops as a parasite in or on the body of another arthropod during its larval stage; parasitoids require only a single host to complete their immature development and almost always kill their hosts; most hosts of parasitoids are other insects, and most parasitoids are in the orders Hymenoptera and Diptera.

polar body The process of forming an oocyte (egg cell) is called oogenesis; at the beginning of oogenesis the oocyte is diploid (called a primary oocyte), but oocytes subsequently undergo two meiotic reduction divisions producing a haploid secondary oocyte that retains most of the cytoplasm and two haploid polar bodies; in most insects polar bodies degenerate soon after fertilization of the haploid oocyte by a sperm; in some endoparasitic Hymenoptera, however, the polar bodies persist and develop into a syncytial membrane that surrounds the embryo; this membrane mediates uptake of nutrients from the host and in polyembryonic wasps participates in partitioning embryonic cells to form additional embryos.

using midges, and an index of acid stress is available that uses a group of macroinvertebrate organisms, each of which has a different sensitivity to acidification.

However, biomonitoring is most frequently done at the community level, and measures vary from simple taxa richness to biotic indices that use the whole community (e.g., Family Biotic Index) to complex multivariate statistics that use the “reference condition” approach.

Bioassays are widely used in determining toxicity of industrial by-products before and after they are released into the environment and can be a valuable adjunct to field biomonitoring. They can be used to answer questions such as: (1) At what concentration does a pollutant become toxic to a certain insect species? (2) What are the physical and chemical conditions under which the pollutant is most harmful? (3) Which stage of the life cycle is most susceptible to the pollutant? (4) What are the effects of acute vs. chronic exposure? (5) Which species are most susceptible to the pollutant? Bioassays can be as simple or as complex as needed (e.g., single vs. multiple species, static or flowthrough setup, laboratory beaker vs. field mesocosm).

Biomonitoring using insects can involve volunteers as well as professionals. Work with insects is usually labor intensive, and volunteers can provide much of this labor. In fact, volunteer biomonitoring programs involving school classes and local community groups are currently very popular throughout the world.

In conclusion, although pollutants have affected living organisms, habitat destruction may be more important in determining whether organisms can recover. For example, it may be possible to clean air and water of their pollutants but recovery of ecosystems is impossible if the habitat remains impaired.

Polyembryony is a form of clonal development in which a single egg produces two or more genetically identical offspring. Many animals are sporadically polyembryonic including humans who occasionally give birth to identical twins. However, a few groups of parasites (some cestodes, trematodes, and insects), colonial aquatic invertebrates (oligochaetes, bryozoans), and mammals (armadillos) are obligately polyembryonic. Among these obligately polyembryonic animals, some species of insects produce thousands of offspring per egg. All known species of obligately polyembryonic insects reside in two orders: Hymenoptera (bees, wasps, and ants) and Strepsiptera. The biology of several polyembryonic wasps has been studied, whereas little is known about polyembryonic strepsipterans.

Polyembryonic wasps occur in selected genera from four families of Hymenoptera: Braconidae (Macrocentrus), Platygasteridae (Platygaster), Encyrtidae (Copidosoma), and Dryinidae. Polyembryony in these groups evolved from monoeembryonic ancestors that produce only a single offspring per egg, because the basal members of these large families are all monoeembryonic. The phylogenetic distance between these families also indicates that polyembryony has evolved independently multiple times in the Hymenoptera. Despite their multiple origins, all polyembryonic wasps share the common biology of being endoparasites that lay their eggs into the egg or larval (nymphal) stage of their insect hosts. After oviposition, each egg laid by a polyembryonic wasp develops into a single embryo. This embryo then clonally gives rise to additional embryos that together form an assemblage called a polyembryo or polymorula. Polyembryonic wasps in the family Encyrtidae have evolved a second novelty: a caste system in which morphologically and functionally distinct larvae develop from the same egg. Key factors regulating the development of polyembryonic wasps, caste function and determination, and the evolution of polyembryony are discussed below.

**DEVELOPMENT OF COPIDOSAMA AND OTHER POLYEMBRYONIC WASPS**

Polyembryonic wasps in the families Platygasteridae and Dryinidae parasitize selected species of Diptera and Hemiptera, respectively, whereas polyembryonic wasps in the families Braconidae and Encyrtidae parasitize Lepidoptera. All polyembryonic encyrtids oviposit into the egg stage of their host and their progeny complete the larval stage of their development in the host's final instar. The most studied polyembryonic wasp is the encyrtid *Copidosoma floridanum* which oviposits into the eggs of different plusimae moths (Noctuidae) including the common agricultural pest *Trichoplusia ni*. *C. floridanum* also produces among the largest broods of any polyembryonic wasp, with up to 3000 offspring emerging per host.

Development of *C. floridanum* and other polyembryonic wasps consists of three major phases known as early cleavage, proliferation, and morphogenesis (Fig. 1). In *C. floridanum*, early cleavage begins when the wasp oviposits a tiny, yolklless egg surrounded by a thin chorion into a host egg. The polar nucleus of the egg rapidly separates from the pronucleus which migrates to the posterior pole of the egg along with cytoplasmic germplasm (see below). The *C. floridanum* egg then initiates first cleavage that results in formation of two equal-sized daughter cells (blastomeres) from cleavage of the pronucleus and an anterior polar cell that contains the polar nucleus. Polar body nuclei are aborted in most insects but they remain viable in polyembryonic encyrtids and form a polar body cell. After first cleavage, all of the germplasm associates with one of the blastomeres. Second cleavage is unequal with the germplasm-containing blastomere dividing into a large and small daughter blastomere with the germplasm always segregating to the smaller cell. The other blastomere in contrast divides into two equal-sized daughter cells (Fig. 1, four-cell stage). Subsequent cleavages are asynchronous resulting in formation of approximately 200 blastomeres of which 4–8 contain germplasm. Concurrently, the nucleus of the polar cell divides without cytokinesis to form a syncytial compartment that migrates as an extraembryonic membrane over the dividing blastomeres. The embryo then emerges from the chorion and continues development in the host body cavity unconstrained by the eggshell. Enveloped by the extraembryonic membrane, this embryo is referred to as the primary morula; it usually implants in the prothorax of the host embryo in proximity to a major tracheal branch or the ventral nerve chord (Fig. 1).

Upon hatching of the host larva, *C. floridanum* enters the proliferation phase of development (Fig. 1, proliferative phase). This phase begins when the primary morula divides itself into two to five embryonic masses called proliferative morulae that together form a polymorula. Each proliferative morula consists of hundreds of round, seemingly nondifferentiated cells surrounded by the extraembryonic membrane. Each proliferative morula in turn becomes further subdivided by invagination of the extraembryonic membrane resulting ultimately in formation of >1000 proliferative morulae consisting of 10–30 cells each by the time the host molts to the fourth instar.

The majority of embryos then synchronously enter the third phase of development, morphogenesis, which is first recognizable by the rounded cells in proliferative morulae becoming fibrolastic and compacting. This is rapidly followed by formation of a primordium, guttulation, and segmentation. Almost all of the morulae that synchronously initiate morphogenesis in the host fourth instar develop into reproductive larvae that emerge in the host's fifth instar. These larvae morphologically have a rounded body form and small mandibles (Fig. 1, reproductive morphogenesis). Reproductive larvae rapidly consume the hemolymph and internal organs of the host, pupate within the remaining exoskeleton of the host, and subsequently emerge as adult wasps. In contrast, some proliferating morulae, initiate morphogenesis during the host's first through fourth instar and develop into the second caste, soldier larvae, that are morphologically recognized by their elongate body form and larger mandibles (Fig. 1, soldier morphogenesis). On average about 4% of the total number of larvae produced per host by *C. floridanum* are soldiers, although certain conditions result in up to 25% of larvae developing into soldiers. Soldier larvae never molt and die from desiccation after their reproductive-caste siblings consume the host. As discussed below, soldiers are also functionally distinct from reproductive larvae.

Limited comparative studies of other polyembryonic encyrtids indicate they too produce soldier and reproductive larvae that appear to develop similarly to *C. floridanum*. Studies of selected polyembryonic braconids, platygasterids, and dryinids indicate they too lay small, yolklless eggs that undergo complete cleavage to form a single embryo, followed by a proliferation stage and morphogenesis. Unlike encyrtids, however, polyembryonic wasps in these other families lack a caste system and only produce larvae that consume the host pupate and emerge as adult wasps.

**CASTE DETERMINATION**

Caste formation in social insects like ants, bees, or termites is usually a phenotypically plastic trait whereby each individual has the capacity to develop into one caste or another. Caste fate is usually mediated by the interaction between environmental factors (photoperiod, crowding, pheromones, nutrition) and endocrine physiology during the larval or nymphal stage that commits individuals to developing into one caste or
FIGURE 1  Development of the polyembryonic wasp Copidosoma floridanum in its host Trichoplusia ni. At the top of the figure is shown a wasp ovipositing into a host egg. Major host stages are illustrated on the left with duration of each stage indicated in days. The host egg hatches in 3 days followed by development of the host larva through five instars from day 3 to 15. For wasp stages, the newly laid C. floridanum egg undergoes early cleavage and formation of a primary morula during the host’s egg stage. The proliferation stage then occurs during the host’s first–fourth instar. Some embryos undergo morphogenesis during this period and develop into soldier larvae, whereas the majority of embryos synchronously initiate morphogenesis at the end of the fourth instar and develop into reproductive larvae that consume the host at the end of its fifth-instar. The polar-body derived extraembryonic membrane is shown in gray, the germ line derived from the small blastomere at the four-cell stage of early cleavage is shown in red, and presumptive somatic stem cells are shown in blue.

another as an adult. Caste formation is also associated with differential expression of a number of genes associated with metabolic functions. Polyembryonic wasps obviously differ from most caste-forming insects in that both castes arise from a single egg that develops in a seemingly identical environment (the host). Although environmental cues from the host could play a role in caste fate, several studies collectively suggest extrinsic factors from the host are not the key factors that regulate caste formation. Instead, caste fate appears to be intrinsically regulated by the asymmetric parceling of the germ line during the proliferation stage of embryogenesis. In most animals including insects, germline stem cells (GSCs) generate either more of themselves or differentiate into gametes which give rise to offspring. GSCs derive from primordial germ cells (PGCs) that are determined during embryogenesis. Phylogenetically advanced insects like Drosophila establish the germ line at the beginning of embryogenesis by inheritance of maternal determinants supplied in the form of specialized germplasm.
These maternal determinants also prepattern the embryonic axes of
*Drosophila*. *C. floridanum* and other polyembryonic wasps are relatively
closely related to *Drosophila*, yet the dramatic differences in
eye development (see above) make it unclear whether these insects
determine the germ line similarly. Using a conserved marker for germ
cells in insects and many other animals called *vasa*, studies with *C.
floridanum* indicate that germplasm is prepackaged into eggs and is
inherited specifically by the small blastomere that forms after second
cleavage (see above) (Fig. 1). This asymmetry persists in the primary
morula and during the proliferation phase suggesting that daughter
cells of the small blastomere all inherit *Vasa* protein and thus represen-
t a PGC lineage. Most proliferating morulae inherit two to eight
cells that express *Vasa*, but a smaller proportion of proliferating
morulae inherit no *Vasa*-expressing cells (Fig. 1). Upon initiation
of morphogenesis, embryos that contain *Vasa*-expressing cells always
develop into the reproductive caste. During morphogenesis, these
*Vasa*-expressing cells also localize to the posterior of the embryo
and give rise to the gonads (Fig. 2). In contrast, embryos lacking *Vasa*
expressing cells always undergo morphogenesis into soldiers (Fig. 2).
Evidence that presence and absence of the germ line is responsible
for caste fate derives from manipulative experiments in which elimi-
nation of the small *Vasa*-containing blastomere at the four-cell stage
of embryogenesis results in formation of only soldier larvae. Thus,
in addition to specifying the germ line, PGCs in *C. floridanum* also
have noncell autonomous functions that regulate caste fate. Loss of
the PGC lineage at the four-cell stage also dramatically reduces the
number of embryos produced suggesting an additional role in regulat-
ing proliferation. In contrast, the fact that soldier larvae develop
when maternal germ determinants are eliminated suggests these fac-
tors are not required for pre-patterning of embryonic axes as found in
other insects.

**CASTE FUNCTION**

The evolution of specialized castes has occurred most often in
species that live in groups comprised of closely related individuals,
and that occupy resource-rich but defensible resources. These con-
ditions exist in well-known eusocial insects like ants and termites as
well as in less studied caste-forming insects like gallmaking thrips
and aphids. These conditions also exist in polyembryonic wasps that
propagate clonally inside the nutrient-rich but defensible environ-
ment of hosts. In *Copidosoma* sp., reproductive larvae are so named
because they are the only offspring that develop into adult wasps
with reproductive functions. On the other hand, hosts parasitized
by these wasps are also commonly attacked by other parasitoids that
then compete for the same host resources. Cruz reported that one
function of soldier larvae is to recognize and kill heterospecific com-
petitors by attacking them with their mandibles. Field studies with
*C. floridanum*, further reveal that risks from intraspecific competi-
tors may be equal or even greater. Consequence with this risk,
*C. floridanum* soldiers exhibit a well-developed ability to discrimi-
nate kin from non-kin, and aggressively attack non-relatives (Fig.
2). In both hetero- and intraspecific defense, soldier larvae increase
their own fitness by assuring the survival of their reproductive sib-
lings. Because selection acts at both the level of the individual and
brood, the ratio of investment in reproductive and soldier larvae
would also be predicted to vary depending on how large or small the
threat from competitors might be. Such adaptive phenotypic
plasticity occurs in *C. floridanum* where the proportion of embryos
developing into soldiers increases greatly in hosts attacked by
competitors.

**FIGURE 2** Caste determination and function in *C. floridanum.*
(A) Lateral view of a reproductive-caste embryo during morpho-
genesis at the onset of visible segmentation. The embryo remains
coiled with the anterior and posterior extremities of the germ band
oriented to the right. Germ cells expressing *Vasa* protein (red) are
clustered in the posterior of the embryo in a location corresponding
to the future gonad (arrow). Embryonic nuclei are counter stained
with H1 histone (green). (B) Lateral view of a soldier caste embryo
lacking germ cells. Scale bar in (B) equals 25 μm. (C) Newly eclosed
reproductive larva with head oriented to the right and abdomen to
the left. (D) Newly eclosed soldier larva with same orientation. Scale
bar in (D) equals 50 μm. (E) Soldier larva attacking embryos from
a nonrelative wasp. Embryos were labeled with a vital dye (green)
while the gut of the soldier is labeled green from consuming cells of
the foreign embryos. Scale bar in (E) equals 75 μm.

A second, more complex function of soldiers in at least some spe-
cies of polyembryonic encyrtids is the killing of male siblings. Like
most Hymenoptera, all caste-forming polyembryonic wasps are
haplodiploid with male offspring developing from unfertilized eggs
and female offspring developing from fertilized eggs. In *C. floridanum*, female wasps usually lay two eggs per host (one male and one female) and as a consequence most broods are of mixed sex. However, soldier larvae develop almost exclusively from female eggs resulting in soldiers that are fully related to their sisters but not to their brothers. These female soldiers attack and kill most brother embryos but fully refrain from attacking sister embryos, resulting in a strongly female-biased sex ratio (>95%) for the adult wasps that emerge from hosts. The asymmetric production of female soldiers that kill brothers but not sisters likely arose as a consequence of genetic conflict among siblings. Under conditions of limited host resources, daughters favor a more female-biased sex ratio than the mother and sons because of higher relatedness to clonal sisters. Sons in contrast favor a less biased sex ratio than mothers or sisters, because of higher relatedness to clonal brothers. Increasing opportunities for males to obtain mates away from the host from which they emerge further increases conflict. The biased production of aggressive soldiers by females, therefore, appears to resolve this conflict in favor of daughters. Selective pressure for large brood size may also be less for brothers than sisters, because a few males almost always survive in mixed-sex broods which mate a large number of sisters before dispersing and seeking additional mates that emerge from other hosts.

**THE EVOLUTION OF POLYEMBRYONY**

Given that polyembryony occurs in several lineages of parasitic Hymenoptera and Strepsiptera, but is unknown from other insect taxa, suggests factors associated with a parasitic lifestyle are likely key to the evolution of this unusual form of development. Most hymenopterans are in the suborder Apocrita. Most free-living apocritans (pollen-nectar feeders and predators) are restricted to the Aculeata (Chrysidioidea, Vespoidae, and Apoidea), whereas the other major apocritan superfamilies are comprised almost exclusively of parasitoids. Parasitoids exhibit two developmental strategies. Many develop as ectoparasitoids that lay their eggs externally on hosts and feed as larvae by rasping a hole through the host’s cuticle, while others develop as endoparasitoids that inject their eggs into the hemocoel of the host where the larvae feed on blood or tissues. Phylogenetic analyses indicate that all apocritans likely evolved from an ectoparasitic ancestor related to contemporary orussoids. Thereafter, endoparasitism has evolved independently at least eight times from different ectoparasitic ancestors. Although polyembryony itself has evolved multiple times, all polyembryonic wasps and strepsipterans are themselves endoparasitic as are their nearest monoembryonic ancestors.

The association between endoparasitism and the evolution of polyembryony is unlikely coincidental. Free-living insects like *Drosophila*, ants, or honey bees develop in a terrestrial environment independent of the parent. Adaptations for survival include a thick chorion to protect the embryo, and an abundant yolk source to supply nutrients for development. Ectoparasitoids confront the same environmental conditions, but endoparasitoids develop in the nutrient-rich environment of another insect where protection from desiccation and preprocessing of a yolk source are no longer required. Unconstrained by the need for a prepackaged source of nutrition (yolk) and a rigid chorion, the embryos of endoparasitoids also have the potential to evolve alterations in early development as well as to increase significantly in volume and biomass during embryogenesis. If endoparasitism is an important prerequisite for the evolution of polyembryony, the loss of yolk and alterations in early development associated with polyembryonic wasp eggs should also occur in at least some lineages of monoembryonic endoparasitoids. This in fact is seen in several different families of endoparasitic Hymenoptera that produce tiny, yolk-free eggs that undergo early cleavage to produce a single embryo similar to the early phases of embryogenesis exhibited by polyembryonic species. Early cellularization by endoparasitic wasp embryos allows for spatial and temporal uncoupling of processes like germ line specification and embryo axis polarity that typically occur concurrently in *Drosophila* and other terrestrial insects. Thus, within the nutrient-rich environment provided by a host, alterations in early development combined with the evolution of cell-autonomous activity by germ cells allowed for the evolution of a novel proliferation stage during embryogenesis in which differentiation of presumptive somatic stem cells is inhibited. Thereafter, selective pressure from hetero- and/or intraspecific competitors has likely favored a second novelty: a caste system founded on asymmetric partitioning of the germ line that results in development of altruistic, sterile soldiers that protect their still proliferating reproductive-caste siblings. Additional variables such as host distribution and the mating structure of populations could then further select for different patterns of progeny allocation and sex-specific differences in soldier production.

Population Ecology

Joseph S. Elkinton
University of Massachusetts

Population ecology deals with questions related to the density or number of individuals of a species in a habitat or location. Insect population ecologists try to understand why population densities of some insects fluctuate dramatically, but others show little variation in density. They want to know why some species are rare, whereas others are common. They seek to understand the mixture of factors affecting mortality and fecundity that together determine the characteristic density of a species and whether the density will decline or increase. Applied population ecologists try to understand the conditions that allow densities of pest insects to reach damaging levels, and they seek to modify those conditions to keep the densities below those levels. To isolate the effects of particular variables from the multitude of factors influencing population growth and survival, population ecologists apply a range of tools to understand population systems, including gathering data on density, fecundity, and mortality from natural populations, construction of mathematical models of population interactions, and experimental manipulation of populations in the field.

ESTIMATING INSECT ABUNDANCE

Research on the population ecology of an insect typically begins with the development of sampling techniques to determine the abundance of the insect in the habitat under study. When the habitat has definable boundaries, we can estimate the number of individuals in the population. More frequently, we estimate density or number of individuals per unit of habitat. Sampling methods vary tremendously with habitat type. Specialized sampling techniques have been developed for insects that live in the soil, in the air, on foliage, and on vertebrate hosts. A large scientific literature exists on the methods developed for each of these habitats.

One can make several general distinctions about different methods of sampling insects. One of these is to distinguish between absolute and relative measures of density. Absolute measures quantify numbers per unit area or volume of habitat. Examples are numbers of grasshoppers per square meter in quadrat samples or numbers of Collembola per cubic centimeter of soil. Relative measures express numbers per sample unit, such as numbers of insects captured in a sweep-net sample or numbers of male moths captured in pheromone-baited traps. Relative measures may or may not reflect absolute density. They are frequently much easier to obtain than absolute measures, but they may be influenced by many factors (e.g., air temperature) that affect the activity of the insect and its likelihood of being captured. Consequently, much research is needed to be sure that relative measures give an accurate indication of differences in absolute population density. In addition, there are population indices, which are indirect measures of density, such as measures of defoliation.

Another general characteristic of sample methods is that some, such as sticky traps or pheromone-baited traps, obtain data continuously over an extended interval of time, whereas others obtain an essentially instantaneous “snapshot” of a population at a particular moment. Examples of the latter include sweep-net samples, quadrat samples, and insecticide knockdown samples. Such instantaneous samples are susceptible to the effects of time of day or weather conditions at the time of sampling, which in turn may influence the number captured. Continuous samples may also be influenced by weather conditions but, because capturing occurs over an extended interval, these effects are averaged over a range of such conditions.

Any investigator planning a sampling program must think carefully about how the samples will be selected. Consultations with statisticians with expertise in experimental design prior to collection of data is always wise, as is preliminary sampling or pilot testing to estimate the expected amount of sample variability. Most sampling schemes may be classified as random, systematic, or stratified random designs. In random sampling, the sample units are chosen or placed at randomly selected locations in the sample area. Random selection is typically done by choosing coordinate points from a table or list of random numbers. In a systematic design, sample units are placed at regular intervals across the sample universe (e.g., every 20 m or every 10th plant). Systematic samples are frequently much easier to conduct, and they ensure that the samples are distributed evenly across the sample universe. However, systematic samples violate the requirement that samples be selected independently and at random from the sample universe, imposed by most statistical analyses. Whether violation of this requirement leads to erroneous conclusions in any particular system is usually debatable. A reasonable compromise between the two approaches is a stratified random or randomized block design in which the sample universe is divided into regularly spaced subunits or blocks and samples are selected at random from each block. Differences in density between subunits caused by edge effects or density gradients across the field can be detected with appropriate statistical analysis.

Mark–recapture techniques are sometimes used to estimate insect abundance. Individuals are marked with a permanent mark that does not significantly alter the behavior of the insect or affect its survival. Marked individuals are counted and released into a population. Subsequently, a sample of individuals is collected from the population and the proportion (m/n) of marked individuals in the sample is recorded. Nearly all mark–recapture methods rest on the basic assumption that m/n of the sample is an estimate of the proportion of marked individuals in the larger population M/N. If one assumes that M, the number of marked individuals in the population, is equal to the number released, then the population size N can be calculated directly: N = M(n/m). This calculation is known as the Lincoln index or Peterson estimate. As a rule, it cannot be assumed that M is equal to the number of marked individuals released because some of them will have died or emigrated in the interval between release and recapture. Several fairly elaborate techniques involving multiple rounds of mark and recapture have been developed to estimate M when it is unknown.

Applied ecologists frequently use sequential sampling to classify populations into density categories such as high (requiring treatment) or low (requiring no treatment). The basic idea is to minimize the cost of the sampling effort by collecting only the number of samples needed to make this decision with sufficient statistical reliability. Development of a sequential sampling scheme for a particular insect and crop or habitat requires research to define the population density that forms the dividing line between the high and low categories, a definition of the degree of allowable risk for making an incorrect classification, and an estimate of the degree of lumping or patchiness that typifies the species.

POPULATION GROWTH AND LIMITS TO GROWTH

A fundamental property of the population dynamics of all species is that the number or density of individuals will grow at an ever-increasing rate when conditions are favorable. The simplest example of such growth is illustrated by the replication of single-celled organisms.
If a bacterium divides every hour, a colony that began with one individual would grow to $2, 4, 8, 16, \ldots, 2^t$, where $t$ is the number of hours or replications. With insects, the rate of replication with each generation is potentially much faster. The house fly, Musca domestica, for example, has generation time of approximately 2 weeks and lays more than 200 eggs. If half those eggs were females and all survived to maturity, the population would increase by more than a hundred fold each generation. By the end of 1 year the population would have increased to more than $10^{52}$ individuals (a mass of flies much larger than the earth). Even if mortality were much higher (e.g., only 1 fly in 10 survived to maturity), the end result would be similar but would take longer to achieve. Mathematically, we refer to this process as geometric or exponential growth, and for insects that reproduce continuously, it is typically expressed with the following equation (Fig. 1):

\[
\frac{dN}{dt} = rN
\]

Here $N$ is the population size or density, $dN/dt$ is the growth rate (the change in density per unit time), and the constant $r$ is the instantaneous per capita rate of increase. The parameter $r$ equals instantaneous per capita birthrate minus the instantaneous per capita death rate. When the rates of birth and death are equal, $r = 0$ and the population ceases to grow. When the death rate exceeds the birthrate, $r$ is negative and the population declines.

The notion of exponential population growth was first expressed in 1798 by T. R. Malthus, who observed that human populations increased exponentially, whereas food production increased in a linear fashion. As a result, Malthus predicted that mankind would be doomed forever to a life close to the edge of starvation. Malthus did not foresee the large increase in agricultural production that accompanied the Industrial Revolution, but he may yet prove to be correct. The ideas of Malthus were fundamental to the development of Darwin’s theory of evolution: all organisms must struggle to survive because all species produce more offspring than can survive.

It is obvious that no population can continue growing forever; sooner or later, it will reach a density above which individuals can no longer obtain the resources they need to survive. This density is known as the carrying capacity of the environment. For different species in different habitats, the carrying capacity will be determined by competition for particular resources. For desert plants, water is typically the limiting resource. For many animals, food supply determines the carrying capacity. As a population expands toward the carrying capacity, the rate of growth slows down. This process is typically represented by the following logistic equation (Fig. 2), which was first applied to population growth by P. F Verhulst in 1838 and independently by R. Pearl and L. J. Reed in 1920:

\[
\frac{dN}{dt} = rN - \frac{rN^2}{K}
\]

Here $K$ is the carrying capacity and $r$ and $N$ retain their earlier definitions. The first term ($rN$) represents exponential growth. The effect of the second term ($rN^2/K$), often called environmental resistance, increases as $N$ becomes large. As $N$ approaches $K$, the rate of growth ($dN/dt$) approaches zero.

There are a number of assumptions inherent in the use of the logistic equation to represent population growth. The first is that unless disturbed, population density will approach the carrying capacity ($K$) and then remain stable about it. In actuality, most populations fluctuate in density, even populations kept in the laboratory under constant environmental conditions. Another assumption is that the shape of the curve is symmetrical above and below the midpoint. In fact, few population systems, even in the laboratory, follow the trajectory predicted by the logistic equation. Rather, the importance of the equation is its contribution to theoretical ecology. It captures the most basic processes of population dynamics: exponential growth and the effects of factors that limit growth. Variations of the logistic equation have been explored by many individuals; indeed, it is the foundation of a large body of work in theoretical population ecology. A. J. Lotka in 1925 and V. Volterra in 1926 extended the logistic to describe both competition between species and predator–prey interactions. More recent applications include models of food webs and interactions between many species in a community.

### Regulation of Population Density

Although no one doubts that competition for resources confines an upper limit on the growth of all populations, it seems clear that many populations of insects persist at densities far below any obvious carrying capacity. Furthermore, the densities of most species fluctuate within a fairly narrow range of values. For a population to remain at constant density, the birthrate must equal death rate. Each individual must on average replace itself with one surviving offspring. Indeed, for any species to persist over evolutionary time, the average birthrate must equal the average death rate, although these quantities may vary considerably from year to year. Organisms that experience high mortality compensate by producing lots of young. For this fundamental

---

**FIGURE 1** (A) Exponential growth of a population yields a straight line when density ($N$) is plotted vs. time ($t$), as in (B), on a logarithmic scale.

\[
\frac{dN}{dt} = rN \quad \text{or} \quad \frac{dN}{dt} \frac{1}{N} = r
\]

reason, most population ecologists believe that most populations are stabilized by factors that are called density dependent. Such factors influence birthrates or death rates in a way that varies systematically with density, such that populations converge to densities at which rates of birth and death are equal and the density is at equilibrium. Such factors act as a negative feedback system that is analogous to the regulation of room temperature by a thermostat. If densities rise above the equilibrium value, the death rate exceeds the birthrate and the population returns to equilibrium. If densities fall below the equilibrium value, the birthrate exceeds the death rate and the population increases.

Predators, pathogens, and parasitoids usually cause mortality to insects that is density dependent. The proportion or percentage of the population killed by these factors varies systematically with density. An increase in the proportion dying with increasing density is called positive density dependence; a decrease in the proportion dying with increasing density is termed negative or inverse density dependence. A mortality factor is density independent when the proportion killed varies in ways that are unrelated to population density. Many abiotic factors, such as mortality due to subfreezing temperatures, act in ways that are density independent. Although many insect population ecologists focus on sources of mortality, density-dependent changes in fecundity may either lead to changes in density or serve to stabilize densities. Certainly, competition for resources is a density-dependent process that will stabilize a population at the carrying capacity, if other factors do not intervene at lower densities.

For more than 50 years ecologists have debated whether population densities of most species are stabilized by such density-dependent factors. L. O. Howard and W. E. Fiske in 1911 were the first to articulate the idea that populations cannot persist long unless they contain at least one density-dependent factor that causes the average fecundity to balance the average mortality. Other early proponents of this idea in the 1950s were A. J. Nicholson and D. Lack. In contrast, H. G. Andrewartha and L. C. Birch argued in 1954 that most populations are not held at equilibrium density. Rather, densities merely fluctuate. In their view, most species avoid extinction because they comprise what we now call metapopulations, that is, a series of subpopulations that are linked by dispersal but whose densities fluctuate independently of one another. Extinction of subpopulations occurs quite frequently, but these are recolonized by individuals dispersing from other subpopulations, thereby allowing the species to persist indefinitely over the entire region. In recent years metapopulation dynamics has been explored by way of computer simulations, and these have revealed that in the absence of density dependence, such systems eventually go extinct.

The debate about the ubiquity of density-dependent processes has persisted despite the efforts of various ecologists to terminate the discussion either because it was bankrupt or because they deemed that prevalence of density dependence was too obvious to deny. Many ecologists have insisted that no conclusion can be made regarding the existence of density dependence in a population system unless its action can be demonstrated statistically in data collected from the populations. This has proved difficult to achieve. Until recently, adequate methods for detecting density dependence in population systems have been lacking, and earlier methods are now known to be statistically flawed. Several new methods were proposed in the decade following 1985, most of which involved a variety of computer-based resampling procedures, such as the bootstrap.

**LIFE TABLES**

Population ecologists typically summarize their collected mortality data in life tables, which express the proportion of the insects that survive to successive instars or life stages. The proportion dying in each instar or life stage can be partitioned into components caused by different agents of mortality. Techniques for quantifying mortality in this way were pioneered in the 1960s by R. F. Morris, who worked on spruce budworm, *Choristoneura fumiferana*, in Canada, and by G. C. Varley and G. R. Gradwell in England, who studied the winter moth *Operophtera brumata*, a defoliator of oak trees in Europe. In 1960 Varley and Gradwell reported a 13-year study of winter moth survival to successive life stages at one site. They showed that predation on pupae was density dependent and was responsible for maintaining a low-density equilibrium. Their studies illustrated the benefits of collecting data on density, fecundity, and mortality from the same populations over many generations. They developed a graphical procedure known as key-factor analysis to identify the life stages or causes of mortality most responsible for observed fluctuations in density. In the winter moth system, the key factor was overwintering mortality. Subsequent work offered analytic procedures for key-factor analysis, but others, such as E. Kuno and T. Royama, noted statistical shortcomings as a result this procedure is rarely used.

Mortality from parasitoids and disease is typically measured by collecting a sample of hosts and dissecting them, or rearing them to determine the proportion that is parasitized or infected. This proportion, however, may or may not accurately reflect the total proportion of hosts attacked over a life stage or generation, since attack rates vary over time with the number of hosts available to attack and the number of adult parasitoids searching. In 1992 T. S. Bellows and colleagues reviewed the techniques that have been developed to convert proportion infected in samples to the summary values appropriate for life tables or for comparisons of parasitism between populations or treatments in a study.

**PREDATORS, PATHOGENS, AND PARASITIOIDS**

Nearly all insect species are attacked by a suite of natural enemies and, as indicated earlier, these frequently act in a density-dependent manner that serves to maintain populations at densities well below the carrying capacity determined by resource limitation. Different natural enemies will attack different life stages. Predators are mobile organisms that feed on many prey. Predators of insects include many vertebrate and invertebrate species. Parasitoids are insects whose immature stages feed on many prey. Predators or parasitoids in response to increasing prey density. The numerical response is an increase in the density or number of predator or parasitoid offspring induced by increases in prey availability, or it can arise from an aggregative response whereby predators and parasitoids are attracted to sites with high densities of prey.

The functional response is an increase in the number of prey taken per predator or parasitoid at increasing prey density. Important contributions to the understanding of the functional response were made by C. S. Holling beginning in 1959. In laboratory experiments, Holling presented individual predators with different numbers of prey. He showed that the number of prey consumed over a specified time interval increased with number of prey available, but at a decreasing rate toward an upper maximum (Fig. 3A). This effect is caused by an upper
limit in the predator’s capacity for consumption and by the increasing proportion of time devoted to handling the large number of prey at the expense of time spent searching for prey. Above this limit, further increases in prey density will not cause higher consumption. The proportion of prey consumed plotted vs. prey density steadily declines (Fig. 3B), illustrating that the functional response is inherently inverse density dependent. Without a numerical response, predators and parasitoids are unlikely to stabilize a host population. Further work by Holling showed that under some important conditions, the functional response can lead to positive density-dependent predation. Whenever increases in prey density result in some change in the foraging behavior of the predator or parasitoid, such that foraging becomes more efficient or efforts are concentrated on the particular prey species, the number taken will accelerate with increasing host density (Fig. 3C), and the proportion taken will increase (Fig. 3D) over the lowest range of prey densities. Holling termed this a type III functional response in contrast to type II, which is the continuous decline in proportion taken evident whenever there is no change in foraging behavior in response to changes in prey density (Fig. 3A and 3B). Holling demonstrated a type III response for shrews foraging for sawfly pupae. He envisioned type III responses to be characteristic of vertebrate predators, which have a relatively high capacity for learning and behavioral change. However, the type III functional response has subsequently been demonstrated in many insect predators and parasitoids.

Specialist or monophagous natural enemies are those that attack a single host species. Oligophagous natural enemies restrict their attacks to a closely related group of species. Generalist or polyphagous natural enemies attack a wide range of host species. The distinction is important because generalists and specialists typically respond very differently to changes in host density. Generalists are most likely to exhibit a numerical response to changes in density of their prey because they depend on no other food sources and their seasonal development is closely linked with that of their prey. Generalists may exhibit little or no numerical response, because they depend on many types of prey and may shift from one prey to another, depending on which species are available. In fact, it is very common for many natural enemies, especially generalists, to exhibit inverse density dependence, wherein mortality declines as prey density increases. Such mortality cannot stabilize prey densities unless accompanied by a numerical response.

Many systems exhibit complex density dependence; for example, mortality from particular natural enemies may switch from positive to negative as host density increases. Thus, bird predation on forest-dwelling caterpillars that is density dependent at the lowest density may shift to inverse density dependence as the densities exceed the capacities of the predators to respond numerically and the functional response approaches the upper limit of prey consumption. Under such conditions, the prey densities may “escape” into an outbreak phase, which is characteristic of a few species. Outbreak populations are typically subject to a different suite of density-dependent factors, such as viral diseases and starvation, which become major sources of mortality only when densities are high. These factors can maintain populations at a high-density equilibrium, but more frequently they cause the collapse of populations back down to a low-density, endemic phase. In contrast, generalist predators, which might consume the majority of prey individuals at low density, are likely to consume a tiny fraction of the population at high density even though they are attacking the same or higher numbers of prey individuals at these high densities.

In 1976 T. R. E. Southwood and H. N. Comins proposed a “synoptic model” as a general feature of insects that occasionally go into an outbreak phase (Fig. 4). Earlier expressions of this idea can be found in the writings of R. F. Morris and R. M. Campbell. The model is depicted by plotting $R_0$, the net reproductive rate, against density. At intermediate densities in the “natural enemy ravine,” density-dependent mortality caused by natural enemies maintains the population at equilibrium ($R_0 = 1$). The natural enemy ravine separates two “ridges,” one at high and one at low density, where mortality is lower and population densities increase. At very high density, other mortality factors such as starvation and disease cause the populations to collapse. At the extremes of low density, an “Allee effect” comes into play, caused primarily by the failure of individuals to find mates and reproduce. Populations in this range decline inexorably to extinction. Such low densities are infrequent in most natural populations, but they play a very important role in the establishment of invasive species.

**FIGURE 3** Number of prey consumed per predator and the corresponding proportion consumed for type II (A, B) and type III (C, D) functional responses. [Adapted from Holling, C. S. (1965). Mem. Entomol. Soc. Can. 45, 3–60.]
Many incipient invasions go extinct without human intervention because not enough individuals were established to sustain the population (for a review, see Liebhold and Tobin, 2008). Similar processes constrain the introduction of natural enemies as biological controls of invasive species. The establishment of biological control agents will fail if insufficient numbers of them are released at each release site.

**POPULATION MODELS**

Theoretical ecologists have developed numerous population models to study the effects of natural enemies on their prey. Much insight has been gained from simple mathematical expressions that relate prey density to that of changes in density of specialist predators or parasitoids. One approach, pioneered by A. J. Lotka and V. Volterra in the 1920s, entailed a simple modification to the logistic equation by adding a term that represents prey consumption on densities of both host and predator:

\[
\frac{dN}{dt} = r_1 N - k_1 PN \\
\frac{dP}{dt} = -r_2 P + k_2 PN
\]

where \( N \) and \( P \) are the respective densities of host and predator, and the rates of population growth are given by \( dN/dt \) and \( dP/dt \). In the first equation, the first term represents exponential growth of the host \( (r_1 N) \) in the absence of the predator, whereas in the second equation, the first term represents exponential decline in the predator \( (-r_2 P) \) in the absence of the host. The second term in each equation represents the effects of predation, which is determined by the encounter rate of host and predator and is proportional to \( PN \). The constant \( k_1 \) is a measure of the ability of prey to escape predators, and \( k_2 \) is a measure of the ability of predators to capture the prey. The model predicts a predator–prey oscillation (Fig. 5A). The changes in density of the predator or parasitoid lag behind those of its host. The highest rates of attack on the host occur at peak predator density, which is observed after the host population density has
absence of parasitism and annual census data. Laboratory studies of predator–prey interaction time-series analysis for detecting delayed density dependence in P. Turchin and others developed new statistical methods based on density dependence, even though the predator or parasitoid is clearly against host density would not reveal a consistent pattern of positive decline. Plotting percent mortality from the predator or parasitoid goes extinct. Other factors such as patchiness in parasite attacks have a similar effect.

The models described so far are relatively simple. They contain a small number of parameters or variables and leave out much of the known biology of the host and its natural enemies. Theoretical ecologists focus on such models because they can be analyzed by a variety of mathematical tools and can be used to address questions of general ecological significance. They hope that the models capture the essential features of the systems they represent. Applied ecologists, in contrast, are often drawn to more complex models, because they wish to understand the complex interplay of environmental and biotic variables that account for the density fluctuations of particular species of interest. With modern computers, there is virtually no limit to the complexity that can be built into such models, but this does not mean that the resulting simulations will necessarily be useful or revealing. Many highly complex models constructed in the 1970s, when high-speed computers first became widely available, were abandoned because they failed to accurately predict the behavior of the systems they represented and were too complicated to understand. Many ecologists have advocated models of intermediate complexity. A good example of a sophisticated attempt to model a very simple population system with a family of models that vary in the 1960s, M. P. Hassell, R. M. May, and colleagues began an exploration, extending over several decades, of the various factors that would stabilize host–parasitoid interactions in models of this type. These factors included mutual interference of parasitoids, patchiness of hosts or parasitoid attacks, and variation in host susceptibility. For example, Fig. 6 illustrates how an increase in the magnitude of mutual interference between parasitoids will reduce parasitoid efficiency at high host density and thus stabilize the system. When mutual interference is low (Fig. 6A and 6B), or absent altogether (m = 0, as in the original Nicholson–Bailey version), the model oscillates with increasing amplitude and both host and parasitoid go extinct. Other factors such as patchiness in parasite attacks have a similar effect.

The models described so far are relatively simple. They contain a small number of parameters or variables and leave out much of the known biology of the host and its natural enemies. Theoretical ecologists focus on such models because they can be analyzed by a variety of mathematical tools and can be used to address questions of general ecological significance. They hope that the models capture the essential features of the systems they represent. Applied ecologists, in contrast, are often drawn to more complex models, because they wish to understand the complex interplay of environmental and biotic variables that account for the density fluctuations of particular species of interest. With modern computers, there is virtually no limit to the complexity that can be built into such models, but this does not mean that the resulting simulations will necessarily be useful or revealing. Many highly complex models constructed in the 1970s, when high-speed computers first became widely available, were abandoned because they failed to accurately predict the behavior of the systems they represented and were too complicated to understand. Many ecologists have advocated models of intermediate complexity. A good example of a sophisticated attempt to model a very simple population system with a family of models that vary in IMPACT OF GLOBAL CLIMATE CHANGE

In the last decade many insect ecologists have devoted their attention to the impact of global climate change on the abundance and spread of important insect species. There are many examples of insects expanding their range to higher latitudes and altitudes as climate warms. There have been several spectacular outbreaks of important forest insects. For example, the mountain pine beetle, Dendroctonus ponderosae, has vastly expanded its range in North America northward into British Columbia and caused unprecedented tree mortality. This insect has also moved into high altitude forests in the Rocky Mountain region where it has been killing pine tree species that have not been attacked before. These phenomena have been explained by sophisticated models of temperature dependent growth of mountain pine beetle devised by J. A. Logan and colleagues.
COMPETITION AND TROPHIC INTERACTIONS

When resources are limiting, intraspecific competition prevents growth of a population beyond the carrying capacity of the habitat. Interspecific competition occurs when two or more species compete for the same resource. Ecologists have long appreciated the importance of interspecific competition in shaping community structure and the interaction between species. Models of competition developed in the 1920s by Lotka and Volterra, analogous to those for predation, predicted that when two species compete for the same resource, under most conditions one species will win out and the other will go extinct. This phenomenon, which became known as competitive exclusion, was readily demonstrated in laboratory populations by G. F. Gause in the 1930s with microorganisms, and by T. Park and associates in the 1950s with flour beetles (Triobolium spp.). Coexistence occurs only when species do not overlap completely in their use of resources. To put it another way, two species cannot coexist if they occupy the same niche. Clear examples of competitive exclusion of insects in the field are harder to come by. Most examples involve introductions of insects to regions outside their native range. For example, the Argentine ant Linepithema humile has been introduced to many regions of the world and has outcompeted and excluded many native ant species. In California around 1900, biological control introductions of Aphytis parasitoids of California red scale, Aonidiella aurantii, resulted in the establishment on citrus of Aphytis chrysomphali. After further introductions in the 1940s and 1950s, this species was displaced by A. lingnanensis, which in turn was displaced by A. melinus in the hot interior, but not the coastal, regions of southern California. The mechanism by which A. melinus out-competes A. lingnanensis has been extensively researched by R. Luck and colleagues.

In many other systems, however, different insect species coexist, even though they appear to use the same resource in the same way. For example, in 1981 J. H. Lavton and D. R. Strong examined the various coexisting herbivores of bracken fern and found no evidence for competition. A famous experiment in the rocky intertidal habitat reported by R. T. Paine in 1974 suggested a general explanation. The intertidal community consists of various species of filter feeders (e.g., barnacles) and other invertebrates that coexisted, even though they competed intensely for space on the rock surfaces. Paine removed starfish, the top predator in this system, and as a result, one species (a mussel) outcompeted and excluded all the other invertebrates and took over the site. Paine termed the starfish a keystone predator, meaning that it had dominant effect on the number of species present in the entire community. The implication was that such predators in many communities prevent competitive exclusion among their prey by maintaining densities below the level at which competition would cause one species to predominate.

Population and community ecologists frequently portray the interaction of organisms in a community in terms of trophic levels or food webs. At the bottom trophic level are the primary producers, the green plants that use photosynthesis to sequester energy from the sun. The next trophic level is occupied by herbivores that feed on the plants. Carnivores that feed on the herbivores or on other carnivores occupy higher trophic levels. A typical food web involving insects on collard plants is illustrated in Fig. 7.

An influential paper by N. G. Hairston and colleagues in 1960 proclaimed that the importance of competition for resources, as opposed to regulation by natural enemies, varies with trophic level. These authors proposed that densities of primary producers are typically governed by competition for light, nutrients, or water. Herbivores, on the other hand, are typically regulated by their natural enemies at densities well below carrying capacity, so that competition for resources is unimportant. In contrast, carnivores typically limit the densities of their prey and thus are regulated by competition for resources. Regulation of population density by natural enemies has been termed “top-down” control. Regulation by way of competition for resources or by other interactions between an animal and its food supply has been termed “bottom-up” control.

The generalizations of Hairston and colleagues were widely criticized and many obvious exceptions exist, but variations on this idea have persisted. More recent versions have included effects of several levels of carnivores and other factors such as community productivity or environmental stress. Experimental manipulations, particularly in aquatic systems, have provided support for the general idea in the form of trophic cascades. For example, in 1990 M. E. Power reported the experimental exclusion of top carnivores (large fish) from a food web in a California river. The results were a 10-fold increase in smaller fish and predatory insects that in turn caused an 80% decrease in herbivores (larval chironomid midges) and a 3- to 120-fold increase in the primary producers (algae). These results were the opposite of those predicted by Hairston and coworkers because there were four trophic levels, instead of three. Omnivores that feed simultaneously on several trophic levels complicate our understanding of most natural food webs. Research in several agricultural systems shows that predatory predation can cause counterintuitive effects of predators on herbivorous insects. For example, in 2001 W. E. Snyder and A. R. Ives showed that carabid predators in alfalfa feed on pea aphids. Since, however, they feed even more heavily on the aphid “mummies” that contain parasitoids of pea aphids, their net impact is to increase aphid densities.

The relative importance of top-down vs. bottom-up regulation of herbivores has been debated for several decades. A review of population studies by D. R. Strong and colleagues in 1984 concurred with Hairston and colleagues that competition among most insect herbivores was rare, because herbivore densities were typically kept far below carrying capacity by natural enemies. More recent reviews (e.g., by Denno et al., 1995) have challenged this view. One issue is that many plants have sophisticated chemical defenses and many plant parts, such as foliage, are nutrient poor. Many herbivores consume specialized plant parts that are either nutrient rich (e.g., seeds) or are poorly defended (e.g., new leaves). Competition for these resources may be intense. Furthermore, plants influence both the survival and fecundity of herbivores in many subtle ways. For example, all herbivores disperse and must locate suitable host plants; failure to find host plants may be a dominant source of mortality and may vary from one habitat to another. Spring-feeding foliage feeders must synchronize their emergence with that of host foliage; failure to synchronize may cause mortality or may reduce fecundity because of consumption of inadequate or poor-quality foliage. Such factors are rarely documented in life-table studies. For most insect herbivores, a mixture of top-down and bottom-up forces determines density.

TEMPORAL PATTERNS OF FLUCTUATION

Density fluctuations, whether they are large or small, may occur at erratic or at regular intervals. Simple population models of predators and prey or laboratory studies, as already discussed, often exhibit regular oscillations. Evidence, however, for regular oscillations in nature is rare. The density of most species fluctuates erratically (Fig. 8). This is not surprising because the density of most species is influenced by weather conditions in a multitude of ways. Except for obvious regularity of seasonal variation, weather conditions vary from week to week and year to year in ways that are mostly erratic.
Furthermore, most species are influenced by a large suite of natural enemies. Predator–prey oscillations, such as those that occur in simple theoretical models or simple laboratory systems, become erratic and irregular when many natural enemies are involved.

Although the density fluctuations of most species are erratic, there are a few that exhibit regular cycles of abundance, similar to what is observed in laboratory populations or in theoretical models. For many others it is not obvious whether the fluctuations are or are not regular. For example, which of the insects in Fig. 8 have a regular component in their fluctuations, and what is the cycle period? Time-series analysis provides the statistical tool to answer these questions. Perhaps the most famous example among insects of regular cycles is that of the larch budmoth, *Zeiraphera diniana*, an insect that periodically defoliates larch forests in the European Alps (Fig. 9). The defoliator reaches peak density at 8- to 9-year intervals and seems to increase or decrease exponentially in the intervals between (linear on a log scale, as in Fig. 1B). The changes in budmoth density were associated with increases in both parasitism and mortality from a virus disease in what looked like a classic case of delayed density dependence. In 1981 R. M. Anderson and R. M. May proposed a host–pathogen model for this system that has served as a template for similar models of other insect host–pathogen systems. Anderson and May believed that the pathogen alone could account for the regular cycles. Other data suggested that effects of defoliation on host-plant quality, as well as genetic variation in the budmoth itself, may also account for the density oscillations. This famous example illustrates the difficulty in distinguishing cause from effect in the confluence of bottom-up and top-down forces that account for cyclic behavior in some population systems.

Prior to the 1970s, ecologists assumed that erratic fluctuation evident in most populations was caused by erratic weather conditions or other sources of randomness. They assumed that the density fluctuations embodied in mathematical models or in simple laboratory populations would have simple dynamics. Densities of such systems would either remain at equilibrium or exhibit regular oscillations about the equilibrium value, as in all the examples given earlier (Figs. 5 and 6). The pioneering work on deterministic chaos by R. M. May in 1974 taught us otherwise. May studied the behavior of versions of the logistic equation appropriate for organisms with discrete...
or nonoverlapping generations (Fig. 10). There is a family of such models, of which the simplest is

\[ X_{t+1} = aX_t - aX_t^2 \]

where \( a \) is reproductive rate analogous to \( r \) of the continuous logistic, and \( X_t \) is density in generation \( t \) as a proportion of the carrying capacity \( K \) (i.e., \( X_t = N_t/K \)). When the reproductive rate was low (Fig. 10A), the population remains at equilibrium. At higher values of \( a \), the system alternates between high and low values, a pattern known as a 2-point cycle (Fig. 10B). As \( a \) increases further, the system shifts to 4-point (Fig. 10C), and then 8-point, \( \ldots, 2^n \) cycles. Above \( a = 3.57 \) however, an entirely new behavior, the chaotic regime, prevails, and densities fluctuate erratically without ever repeating themselves (Fig. 10D). These results had profound implications. They suggested that the erratic behavior characteristic of most natural populations (e.g., Fig. 8) might be due to the inherent mathematical properties of the interaction with natural enemies and other density-dependent effects, instead of resulting from random forces such as weather.

There ensued an effort to determine whether natural populations were indeed chaotic. Early studies concluded that most populations were not chaotic. These were based on attempts to fit natural populations to simple models and then to see whether the values of model parameters representing, for example, density dependence, time delays, or reproductive rate would elicit the expectation of chaotic behavior. The problem was that the conclusion depended on the particular model used, which was always a simplistic abstraction of the inevitably complicated dynamics of real populations. Subsequent investigators offered techniques that were more general and free of assuming particular population models. Applications of these techniques have indicated that some population systems are chaotic, but most are not.

**SPATIAL PROCESSES**

Species that are introduced into new habitats will spread from the point of introduction to surrounding areas in a pattern that frequently resembles concentric rings (Fig. 11). Theoretical population biologists, beginning with J. G. Skellam in 1951, have developed models of population spread that couple processes representing population growth with that of dispersal. Dispersal is typically modeled as a random movement process that is analogous to molecular diffusion.
Population Ecology

**FIGURE 10** Density of a hypothetical population plotted vs. time for a version of the logistic equation appropriate for insects with discrete generations under different values of the reproductive rate $a$ illustrating (A) a steady state, (B) a 2-point cycle, (C) a 4-point cycle, and (D) chaos. [Adapted from May, R. M. (1976). *Nature* 261, 459–467.]

These models typically predict that the leading edge of the infestation forms a traveling wave that moves across the landscape at a constant speed in any given direction. As illustrated in Fig. 11, speed of movement will in fact vary markedly in different directions with differences in prevailing winds or with the presence of barriers such as the Sahara Desert.

Density fluctuations of different populations of the same species frequently exhibit spatial synchrony, meaning that densities go up and down together over a large region, as illustrated by gypsy moth *Lymantria dispar*, in the northeastern United States (Fig. 12). Since there are several possible causes of spatial synchrony, including dispersal of animals between populations, increases in density in one population will produce emigrants that trigger increases in surrounding populations. By far the most common cause of spatial synchrony, however, is the Moran effect, named after the individual who studied the synchrony of lynxes and hares in boreal Canada. In 1953 P. A. P. Moran showed mathematically that the density fluctuations of two or more populations will synchronize, provided they are governed by the same factors, such as the same natural enemies and are also influenced by some common factor such as the weather, which varies from year to year in the same way on a regional spatial scale. The important point is that although variations in weather may cause spatial synchrony, we should not infer that weather is also responsible for fluctuations in density, which might typically be caused by interactions with predators, pathogens, and parasitoids.

**CONCLUSION**

Population ecology forms the theoretical foundations upon which management of insects is based. Much has been learned from the development of mathematical models of population systems, studies
of laboratory populations, analyses of data from natural populations, and experimental manipulation of populations in the field. Despite decades of research, we are still far from understanding the population dynamics of most insects, even those such as gypsy moth or spruce budworm, which have been studied by several generations of researchers. Although various individuals have proposed theories to account for the dynamics of these species and have collected supporting data, rigorous demonstrations that these theories are correct elude us. For most insect species we have neither theories nor data to account for their population dynamics. The reason for this state of affairs is that it is extremely difficult to accurately measure the density of natural populations, especially when densities are low, and even more difficult to measure the impact of various factors causing mortality or variation in fecundity. Each insect and its natural enemies are embedded in a web of interactions whose intricacies must be disentangled. To understand how these intricacies vary over time, the financial and human resources necessary to conduct such research are rarely assembled.

Predation/Predatory Insects

Ronald M. Weseloh
The Connecticut Agricultural Experiment Station

J. Daniel Hare
University of California at Riverside

Predators are animals that must consume more than one individual of another animal to complete their life cycle. Under this definition, the predatory habit occurs in a wide range of insect groups. Some orders, such as Odonata and Neuroptera, are wholly or predominately predaceous. Other orders contain large numbers of species that are predatory, such as Hemiptera, Coleoptera, Mecoptera, Diptera, and Hymenoptera. Even a few species in the orders Ephemeroptera, Orthoptera, Plecoptera, Thysanoptera, Trichoptera, and Lepidoptera are predaceous. This article emphasizes the diverse ways in which predaceous insects live.

MODES OF PREDATION

Hunting

Many insect predators carry out active hunting. The adults of tiger beetles (Cicindellidae), ground beetles (Carabidae), and many ants (Formicidae) actively run over the ground to capture prey. Many walking or crawling predators, including ladybird beetles (Coccinellidae), lacewing larvae (Chrysopidae), syrphid fly larvae (Syrphidae), and predatory bugs (Hemiptera), feed on sedentary insects such as aphids and scale insects or on eggs and young larvae of more mobile species. Other insect predators are agile flyers and actively snatch insects out of the air. Dragonflies and damselfly nymphs (Odonata) have large eyes and strong wings and feed mainly on mosquitoes and other small flying insects. Robber flies (Asilidae) also catch their prey on the wing, but will often tackle and subdue insects at least their own size, even bees and wasps. Their legs are very strong and they have piercing mouthparts to suck up prey juices. Other insects, such as many social wasps (Vespidae), pluck insects from the ground or vegetation while flying.

Many predaceous insects live in fresh water and pursue prey by swimming. The giant water bugs (Belostomatidae) are excellent swimmers and often capture and subdue small fish and tadpoles. Backswimmers (Notonectidae) hang ventral side up at the water surface and dart after aquatic organisms using powerful, oar-like hind legs. The diving water beetles (Dytiscidae) are also voracious predators that actively capture prey under water. Water striders (Gerridae) are true bugs that skim over the water surface and prey on small organisms that fall from above. Whirligig beetles (Gyrinidae) also hunt on the water film, but sometimes dive below the surface. Each eye is a double structure, with half adapted to seeing above the surface and the other half below.

Other active hunters are less visible. A large number of beetle and fly larvae, as well as immature insects from other orders, prey on small organisms by burrowing through soil, wet ground, rotting logs, or other vegetation. The immature of many horse flies and deer flies (Tabanidae), for instance, are predaceous on organisms in moist soil and water. The larvae of some common midges (Chironomidae) feed on other organisms in the mud at the bottom of ponds or along its margins, as do the larvae of some crane flies (Tipulidae). Click beetle larvae (wireworms, Elateridae) are generally plant or detritus feeders, but some are predatory in soil or rotting logs.

Stalking and Ambush

Many predaceous insects subdue active prey, but not by hunting. These are the ambush predators or slow-moving stalkers. Many have special adaptations to efficiently capture prey. Praying mantids (Mantidae) have large, grasping forelegs, superbly fitted for grasping and holding prey, and remain motionless on vegetation until an insect comes near enough that they can strike out with their forelegs. A number of the true bugs also capture prey this way, including assassin bugs (Reduviidae), Nabidae, and ambush bugs (Phymatidae). Dragonflies and damselflies are successful ambushers that live in water. Their labium, or lower lip, is modified as a grasping tool that can be rapidly shot out to impale an insect, tadpole, or small fish. Tiger beetle adults are hunters, but their larvae dig vertical burrows in the ground and wait with their heads plugging the entrance. Such larvae grab small organisms walking near the burrow. They have back spines that help anchor them so they are not pulled out. After capture, the prey is dragged to the bottom of the burrow and devoured.

Trapping

Insects that trap their food are similar to ambush predators, but go a step further and use inanimate materials to help snare their prey. The ant lions (Myrmeleontidae) are the larvae of insects in the order Neuroptera that as adults look somewhat like wasps. Larvae burrow into sand and form conical pits. Small, walking organisms, such as ants, fall into these pits and have difficulty escaping because of the loose material of the walls. In addition, the ant lion at the bottom actively toses its head to remove sand dislodged by the victim. When the prey falls to the bottom, it is grabbed in the long mandibles of the predator, dragged under, and sucked dry. Some snipe fly larvae (Rhagionidae) build similar pits and capture prey the same way.

A few larvae of fungus gnats (Mycetophilidae) capture prey by secreting webs of mucilaginous materials in moist locations, such as beneath rocks, under bark, or in caves. In New Zealand caves, individuals of Arachnocampa luminosa not only spin webs that hang from cave ceilings, but also glow to attract adults of chironomid midges that breed in the water below. The colonies of the gnats are tourist attractions, and the ceilings of the caves are covered with pinpricks of light reminiscent of starry nights.

Provisioning

Solitary wasps in the families Vespidae, Sphecidae, and related families are often provisioners—the adult females capture prey that they paralyze with a sting and place the prey in a closed cell along with an egg. The larva that hatches feeds on the enclosed prey until...
fully developed. Different provisioner species specialize on different prey and construct different kinds of cells. For instance, the mud-dauber sphecid wasp, *Scoliphas caementarium*, constructs cells out of mud and provisions these with spiders. *Amomaphila*, another sphecid, constructs cells by burrowing into the ground and stocks them with caterpillars. Others may burrow into wood or plant stems. Prey species vary from aphids to grasshoppers, true bugs, caterpillars, or spiders. Some provisioning wasps as the cicada killer, *Sphecius speciosus*, stretch the definition of predator. The female usually places one paralyzed cicada per underground cell, but sometimes she puts in two. Thus, the resulting progeny are sometimes parasitoids that can complete development on one host individual and sometimes predators that consume more than one prey.

**Host Feeding**

This is another behavior that blurs the line between parasitoids and predators. Host-feeders are female adult hymenopterous parasitoids, especially of the family Pteromalidae, that feed on host fluids oozing out of oviposition wounds. Such females host-feed to obtain protein for egg maturation. In many cases the host is parasitized as well. But some parasitoids have developed a habit of host-feeding without ovipositing, and in some cases the host (which in this case becomes the prey) may die from excessive feeding. Some parasitoids even use fast-drying fluids secreted from the base of their ovipositors to construct “feeding tubes” from a concealed prey to the surface through which host fluids can be drawn up.

**Mass Foraging**

There are many social insects, primarily wasps and ants, that actively hunt prey for food. Most of these do so as individuals, capturing small prey, and returning directly to the nest. But some ants are able to overcome vertebrate and large invertebrate prey. These are the mass foragers, the army ants and driver ants. These ants move over the ground in large swarms or columns and subdue prey, such as large scorpions and lizards, that other ants cannot. They also devour many small arthropods and deplete an area of prey so rapidly that they must frequently move from one nest site to another. The army ants of the New World tropics and the driver ants of Africa have been depicted in fiction as very dangerous predators that may even threaten humans. While it is possible that penned animals may be killed, the ants are not generally dangerous. The swarm front or hunting column moves forward only relatively slowly, and it is easy to step out of the way. In fact, a swarm of army ants removes vermin as they raid through a house and may be beneficial, so long as the ants are there.

**Deception and Predation**

Some insect predators use deceptive practices. Firefly (*Lampyridae*) adults use bioluminescence to attract mates. Each species has a set of recognition flashes that are exchanged between flying males and the sedentary and often wingless females. If the sequence is correct, a male is guided to a receptive female. However, the females of some species mimic the recognition flashes of other species and so lure fooled males to their death.

Perhaps some of the most sophisticated deceptive predation practices occur among the insects that live in or near ant nests. These “ant guests” or “myrmecophiles” may survive by stealing food from ants by soliciting, but many are also predators. To be successful they must deceive the ants into accepting or at least tolerating them. Some of these predators live on the periphery of nests and prey on foragers that they encounter. The reduviid *Acanthaspis concinna* fools ants by placing the bodies of its prey on its back. Another reduviid, *Ptilocerus ochraceus*, secretes “trickling” attractive substances from trichomes on its abdomen that apparently subdue ants long enough for the bug to kill them.

Other insects, particularly beetles of the family Staphylinidae, live in the brood chambers of ants, where, among other things, they prey on ant larvae. Most of these predators apparently use chemical subterfuge to gain entry and stay in the brood chambers. Apparently, the chemicals mimic recognition substances produced by the ant brood. In fact, ants may pay more attention to the larvae of the beetles than they do to their own larvae. Some lycaenid butterfly larvae also have this habit. Early instars of these caterpillars live on plants and secrete attractive substances that ants collect. Larger caterpillars move to the brood chambers where they prey on ant larvae.

**BEHAVIORAL ECOLoGY AND PREDATORS**

Behavioral ecology is a field in which actions and movements of individual organisms are studied in order to understand interactions and impacts between organisms and their environment. Predaceous insects are often used as subjects in behavioral ecological studies because they are numerous, generally have a limited number of responses, and are small enough to be easily manipulated and yet large enough for easy observation. For instance, numerous studies have investigated how the number of prey eaten by a predator varies as prey numbers change. These functional responses usually show an increased tendency of predators to devour more prey as the number of prey individuals increases until the predators become satiated, so that the number of prey eaten increases rapidly at first as prey numbers increase and then becomes steady. However, backswimmers (*Notonectidae*), which feed on a variety of prey, may switch from one prey type to another as the latter become more abundant. In such a case, the functional response is S-shaped, at first starting out slowly and then increasing rapidly until slowing again at high prey numbers. Such S-shaped, or sigmoid, functional responses are usually more typical of vertebrate predators than insects.

An important aspect of behavioral ecology has to do with searching by organisms in areas that contain various amounts and quality of food. Many predators, such as ladybird beetles (*Coccinellidae*), aggregate in places containing many prey. Finding the most profitable way in which a predator can divide its time between encountering prey within an area of prey abundance and searching for other concentrations of prey is an exercise in optimal foraging theory. Predators such as backswimmers (*Notonectidae*) have been found to do this rather well. The actual time they spend foraging in an area varies with prey abundance in a way that is close to optimal. Like the better-studied parasitic *Hymenoptera*, some predators can improve their foraging efficiency over time by learning to associate particular chemical cues of their host’s environment with successful foraging events. Ants have been used to investigate the kind of prey searching called center place foraging. In this situation, an organism departs and returns to a fixed location, often a nest, during a foraging session. Studies of ant foraging show that a center place forager often restricts its searching to only part of the available area, foraging in different areas at different times. Also, such foragers often do not search near the nest, but only at some distance from it. Both these characteristics may increase the efficiency of foraging by decreasing searching overlap with nest mates.
IMPACT OF PREDATORS ON POPULATIONS OF THEIR PREY

While most biological control work has involved parasitoids, some predators have been used as well. In fact, the first really successful classical biological control project was the control of the cottony cushion scale, Icerya purchasi, by the vedalia beetle (Coccinellidae), Rodolia cardinalis. Other coccinellids are important predators of aphids and nites. Ground beetles are important generalist predators, and at least one of these (Calosoma scrutator) is an effective predator of the gypsy moth. Other predators used in biological control practice include the true bugs Orius (Anthocoridae) and Geocoris (Lygaeidae), clerid beetles, green lacewings, syrphid flies, and marsh flies (Scionmyzidae). On the other hand, some robber flies are voracious predators of bees and are considered to be economically harmful. Also, because of their propensity to attack nontarget prey, generalist predators are not considered good prospects for use in programs that introduce exotic natural enemies into new areas.

Insect predators may be more important in the regulation of their prey species than is commonly thought. Because they often leave no identifiable remains after devouring prey, the extent of predation is hard to quantify. It is probably true that insect predators help keep the majority of potential pest organisms under control. Without them, the world likely would be quite different.

Prosorrhyncha

(Heteroptera and Coleorrhyncha)

Carl W. Schaefer
University of Connecticut

The Hemiptera suborder Prosorrhyncha comprises two groups, the Coleorrhyncha (family Peloridiidae) and the Heteroptera. Like all hemipterans, members of these two groups have elongated mouthparts for sucking fluids; unlike all other hemipterans, many heteropterans (true bugs) suck the fluids of animals—mostly of arthropods but in a few instances of vertebrates. Heteroptera contains 8 infraorders, 79 families, and about 38,000 described species. The families range from the very small (one species) to the very large (>10,000 species), and heteropterans as a group live in all habitable (and many apparently uninhabitable) parts of the world, from deserts to forest canopies, and on and below the sea. Heteropterans feed on all parts of plants (including on fungi and freshwater algae); some are sufficiently serious predators of pests to be biocontrol agents; and a few (bed bugs, triatomine bugs) feed on human blood. As a whole, Heteroptera is the most diverse of all hemimetabolous insect groups. Nevertheless, we know amazingly little about heteropteran biology and ecology, and the more we learn, the greater this diversity is shown to be.

CLASSIFICATION

The classification of the order Hemiptera is confused, sometimes defies the available evidence, and always arouses controversy. That there is an order Hemiptera, few doubt; moreover, that the group of true bugs, Heteroptera, is a phylogenetically valid taxon, no one doubts. Questions arise, however, concerning what had been considered the other suborder, Homoptera, a group that some (mostly homopterists) elevate to ordinal rank; indeed, some homopterists elevate groups within Homoptera to ordinal rank. However, recent work has shown that Homoptera and some of its subordinate groups are paraphyletic (and may not even be monophyletic). As a result, confusion reigns.

The order Hemiptera is characterized by being hemimetabolic (three life stages: egg, nymph, adult), having wings (with a few exceptions), and especially in possessing elongated mouthparts (“beak,” or “rostrum”) designed for the piercing of plants or animals and the sucking up of their juices. The Heteroptera differ from the majority of other hemipterans. In these other insects (mostly homopterans), the forewings are usually opaque (hence, “Homoptera”), but they are half opaque and half membranous in Heteroptera (again, hence the name). The two groups differ also in the apparent location of the mouthparts, which arise from the ventral surface of the head in both groups but, in Homoptera, arise from the back of the head (sometimes appear to arise from the thorax) and, in Heteroptera, arise from the front of the head. In addition, all homopterans, but not all heteropterans, are herbivorous. Nearly all nonheteropterans, except coleorrhynchans, have a filter chamber, which allows water ingested with the dilute plant juices to be “short-circuited” in the digestive system for rapid elimination. Heteropterans also differ from homopterans in that many feed on animal juices, a few indeed on the blood of vertebrates (including humans). It is likely that animal-feeding characterized the early heteropterans, although this view is controversial.

There is some confusion over the meaning and extent of “Hemiptera” and over just what a “bug” is. To some, “Hemiptera” refers only to Heteroptera, which is treated as an order the equivalent of Homoptera. To others, including most if not all students of Heteroptera, “Hemiptera” is an order with two suborders, Heteroptera and Homoptera. The features (i.e., synapomorphies) that the two groups share seem to be far more basic and significant than the two groups’ differences, a circumstance that is best represented by treating all members of the two groups, Heteroptera and Homoptera, whatever this latter group may in fact contain, as belonging to an order, Hemiptera.

Because the group known as “Homoptera” (=nonheteropteran) is either paraphyletic or not monophyletic, the higher classification of
Hemiptera is in flux. One consequence of the recent analysis of these relationships (based particularly on molecular evidence) has been the recognition of a small formerly homopteran group, Coleorrhyncha, as the sister group of Heteroptera. These two—Coleorrhyncha and Heteroptera—have been placed by some as a single hemipteran suborder, Prosorrhyncha. Although this idea was based on molecular evidence (and therefore likely to be discounted by some), morphological evidence also supports it. This article considers the hemipteran suborder Prosorrhyncha. Because the Coleorrhyncha is very small and of limited distribution, the focus is on Heteroptera.

**Coleorrhyncha**

The Coleorrhyncha is a group that contains the single family Peloridiidae, which had once been treated as a major homopteran group (Coleorrhyncha) and then as a group equal in taxonomic status to Heteroptera and Homoptera (*sensu antiquo*) and perhaps “bridging the evolutionary gap” between them.

The dozen or so species of Peloridiidae have a classic Gondwana distribution; they occur in southern South America, New Zealand, and Australia and are associated with southern beech trees (*Nothofagus*), where they feed probably on moss (like idiostolids, mentioned later under Pentatomomorpha). They are small (2–5 mm long) and flattened, and many have expansions on the head and/or thorax which, semitransparent, are quite beautiful.

**Heteroptera**

All insects are not bugs. Heteropterans, however, are indeed bugs, and so are often called “true bugs” (i.e., “real” bugs, not “faithful” ones). The word *bug* derives from the Middle English word *bugge*, meaning a “spirit” or “ghost.” If one awakens in the morning with red itching welts, one clearly has been visited in the night by a malevolent wraith or spirit—that is, by a bugge. This, of course, is correct: one has indeed been visited by a bug, by a bed bug (*Cimex lectularius*), which has fed and fled, leaving behind a red welt and a mystery. Bed bugs are “bugs” and so, by extension, are all their relatives—all heteropterans. (The original meaning of *bugge* is retained in English in such words as *bugbear* and *bugaboo*, and in the name of the insect—repping plant, bugbane. And the scientific name of the bed bug, *Cimex lectularius*, means “bed bug,” *cimex* being the Latin for bug, and *lectularius* describing a small couch or bed. The word “cimex,” by the way, was sometimes used by the Romans as a derogatory epithet.)

The suborder Heteroptera is perhaps the largest of the hemimetabolous groups (with about 35,000 species, and probably considerably more are undescribed), and also among the most diverse. The group’s diversity is reflected in the variety of organisms fed upon, the variety of habitats lived in, and the variety of habits; these varieties are in turn reflected in the variety of shapes, sizes, and ornamentation found among the Heteroptera. Many heteropterans are aquatic or semiaquatic, and in this feature alone they differ from other hemimetabolans. Many are predaceous (upon other arthropods) and some are hematophagous (upon vertebrate blood), and in this feature too they differ.

Like all hemipterans, heteropterans have elongated mouthparts for piercing organisms and the drawing up of those organisms’ juices; predaceous bugs reduce to juice the soft internal organs of their prey. The organisms fed upon include all terrestrial groups of plants (except perhaps algae; but Corixidae include freshwater algae in their diet), other arthropods, snails (fed upon by some giant water bugs), and of course vertebrate blood.

Heteroptera is further distinguished by having scent glands. These occur on the abdominal dorsum in immatures and on the metathoracic pleura in adults. Nymphs lack the thoracic glands, but the abdominal glands occur in adults usually as nonfunctional scars; however, considerable evidence has accumulated showing that in many heteropteran groups one or more of the abdominal glands are functional in adults as well as in nymphs. Another distinctive feature of heteropterans is the scutellum (“little shield”). This triangular structure (broad base anterior) is a modification of the mesonotum; it may be quite small relative to the body, or quite large. In a few families and in a few members of a very few other families, the scutellum is large enough to cover the wings and the entire dorsum of the abdomen.

Regarding the general account of heteropteran biology that follows, and also the more specific accounts of the different groups, it cannot be too heavily emphasized very little is known about most heteropterans: many of the generalities given here are based on small samples, and what we do not know far outweighs what we do know. The reader is urged to take all general statements, if not with a pillar, then with several grains of salt.

Predaceous bugs, and those feeding on vertebrate blood, are not particularly host specific, although some degree of specificity may be imposed upon them by their habitats: bat bugs, living in bat caves, are restricted to feeding on bats, although given the chance they may feed on other warm-blooded vertebrates; many triatomine bugs live in or with their vertebrate hosts and are perfectly restricted to them. A few predaceous bugs are more clearly host specific: the bed bug (everybody’s favorite heteropteran) lives only with humans and does poorly when fed other kinds of blood; certain minute flower bugs (*Anthocoridae*) appear to specialize on certain species of scale insects (although here the specificity may be habitat driven, not prey driven); and some predaceous mirids prefer certain species of lace bugs as prey. There are few other examples.

The host specificity of herbivorous heteropterans is in general greater than that of predaceous ones. Not all herbivorous bugs are host specific, and among those that are, the specificity is sometimes at the species—species, or species—genus level (bug—plant, but more commonly at the family group—family group level (e.g., Alydinae and Platastidae on Leguminosae; Rhopalidae: Serinethinae on Sapindaceae). Many bugs, and family-level groups of bugs, are oligo- or polyphagous. Of course, the heteropterans that compete with humans for their food and are agricultural pests are those that are either host specific on crop species or, although polyphagous, can build up large populations quickly on crops. Measuring host specificity can be impeded by the willingness of bugs to probe nonhost plants, either to test their suitability as food or merely to get water. Too many host-plant records are of this sort; the best records are those of the feeding of immatures, since immatures, being wingless, cannot go elsewhere to better their lot.

Most heteropterans (perhaps two-thirds) are herbivorous. Many pierce plants to their circulatory systems and feed on the contents of phloem or (less often) xylem; a few very small heteropterans feed on plant cell contents. These heteropterans thus feed not unlike most homopterans. However, plant sap is low in nutrients, and many heteropterans feed on reproductive tissues such as flowers, ovules, and ripe and unripe seeds, which are richer in nitrogen; another group of heteropterans (*Miridae* and some *Tingidae*) feeds on somatic tissues that, to the delectation of the bugs, mobilize nitrogen when the host is wounded. A very few heteropterans feed on bryophytes, and a few *Tingidae* are the only heteropterans to induce plant galls. Many herbivorous bugs, especially in the infraorder Pentatomomorpha, contain bacterial symbionts in gastric ceca or mycetomes; these presumably supply necessary trace nutrients.
As mentioned earlier, several heteropterans may become pests on agricultural crops. In the Old World tropics, cotton stainers (Pyrhocoridae) feed on developing cotton bolls and may allow entrance of destructive pathogens; the bugs’ excreta also stain the cotton (hence the bugs’ name). Sunn pests, species of the genera *Eurygaster* and *Aelia* (Scutelleridae and Pentatomidae), are among the most serious pests of small-grain crops (especially wheat) in a broadband of countries from eastern Europe through the Middle East into western Asia. Chinch bugs similarly afflict wheat in North America, and a close relative attacks lawn and golf course grasses in Florida. Lygus bugs (several species), a leaf-footed bug (Coreidae), and southern green stinkbugs (Pentatomidae) feed on a variety of vegetables and fruits and are pests worldwide (lygus especially in the north-temperate regions). Species of *Riptortus* and *Neomegalotomus* (Alydidae) may become pests of legume crops (Fig. 1). Several burrower bugs (Cydnidae) are pests of many crops and range grasses, upon whose roots they feed. The red pumpkin bug (*Dinidoridae*) may seriously damage cucurbit crops in Asia. There are many other major pests, and very many other minor or regionally restricted ones; nearly 1000 are discussed in a recent book by Schaefer and Panizzi. As the foregoing list suggests, most pests specialize on the plant family to which the crop belongs. A few (e.g., lygus, southern green stink bug, and the leaf-footed bug *Leptoglossus gonagra*) are exceptions, feeding on many unrelated plants and quickly achieving large destructive populations.

Only a few heteropterans are vectors of plant diseases; one important group is Piesmatidae, one of whose members transmits a serious viral disease to sugar beets. Overall, however, heteropterans are far less important than homopterans as vectors of plant diseases, perhaps because most bugs, unlike many homopterans, do not feed directly in plant cells.

The few bloodsucking bugs may cause damage by withdrawing excessive amounts of blood and thus weakening people who may, in addition, be weakened by disease, or frail in health because very old or very young. Bed bug populations may increase to the point where such damage may occur.

Of the two important groups of bloodsucking bugs, the bed and bat bugs (*Cimicidae*) do not transmit disease pathogens, although there is some slight evidence that the hepatitis B virus may be transmitted by bed bugs in southern Africa. On the other hand, triatomine bugs (*Reduviidae*, subfamily *Triatominae*) are vectors of *Trypanosoma cruzi*. *T. cruzi* causes Chagas disease, a debilitating and often fatal disease of the New World tropics and subtropics (a handful of cases reported in the United States); major international efforts are now under way to eliminate this disease by eliminating the places where the bugs hide. These efforts have been successful in many areas of South America.

Although most heteropterans having an economic impact on humans are harmful, some are beneficial. Chief among the latter are the predaceous bugs that feed on insect pests. Because predators as a rule are not host specific, there are no one-to-one relationships of predator to prey in Heteroptera or in any other group considered for biological control. Nevertheless, many groups of heteropterans have been studied for, and some successfully used in, biological control programs: asopine pentatomids (Pentatomidae, subfamily Asopinae) against many pests, especially garden pests (indeed, an artificial aggregation pheromone has been developed to “call in” these predators); certain minute flower bugs (Anthocoridae) to combat stored-product pests; some predaceous mirids on vegetable and greenhouse crops; and an array of predaceous bugs in field crops. The one exception—remarkably, considering its wide distribution, its variety and numbers of species, and the size (and presumably appetite) of its members—is the *Reduviidae*. The biological control potential of this family has been surprisingly little explored. It should also be mentioned that the value of very small predators—Anthocoridae, small mirids, early instars of other predators—is unknown; these feed on arthropod eggs and small instars, whose absence goes unnoticed because their presence was overlooked in the first place.

In 1998 Cohen showed that predaceous bugs feed differently than had been thought: instead of merely sucking up the fluids inside a prey, these bugs inject salivary enzymes that digest all soft tissue; the digested material is then sucked up. This discovery has profound implications for biological control: a single predator will be sated by a far smaller number of prey than had been believed, and will therefore be less effective in controlling pests. This realization is only slowly making its way into the biological control community.

Of less importance is the control of harmful plants, weeds, by plant-feeding heteropterans: Some tingids have been used in various parts of the world to control (not very successfully) the invasive plant lantana; cactus bugs (*Chelinidea, Coreidae*) have been tested—with small success—against invasive cactus in Australia; and several other bugs have been and are being tested for possible control of other weeds. So far, no major plant pest has been controlled by a heteropteran, but the exhaustive study of biology and ecology necessary for success in such an endeavor is only now being undertaken.

Detailed accounts of economically important heteropterans are provided in the book by Schaefer and Panizzi.
COURTSHIP, MATING, OVIPosition  Unlike feeding, the sexual lives of heteropterans show little variety. There is little courtship, although males of several species may fight (usually briefly) for the attention of a female. The sexes are brought together initially probably by sex pheromones and, in a few species, by sex-neutral aggregation pheromones; however, only a tiny handful of species, all of them land bugs, has been shown to have pheromones of both types. Mating occurs end to end or with the male directly or diagonally across the female; the position seems to vary with the family group or even the infraterrestrial of the bugs. Mating may be brief or long; if long, the larger female may move about and even feed, while the hapless male scrambles along behind, walking backward.

Mating by bed bugs and some relatives in Anthocoridae and Nabidae (and, just recently discovered, some Miridae), is (to quote from another context) nasty, brutish, and short. The male mounts the female and, with a scimitar-shaped clasper, pierces the side of her abdomen and deposits sperm; in primitive species this traumatic insemination (as it is called) may occur in various parts of the abdome, allowing sperm to enter the abdominal cavity; in more advanced species (including the bed bug itself), sperm is deposited in a special patch of tissue. Such insemination leaves small healed wounds in the female’s cuticle; counting these, the number of times an individual has been mated can be determined. Sperm then progresses to a sperm storage organ at the base of the common oviduct.

The internal reproductive structures are very conservative—that is, they resemble those of very many other insects. There is a pair of ovaries or testes, each almost always consisting of seven ovarioles or testicular follicles. Paired ducts lead from them to a common duct, sometimes more than a single egg deep. They may be deposited on surfaces (of leaves, stems or trunks, ground, stones, etc.) or placed into crevices; the crevices may in some groups be created by the female’s ovipositor. The eggs of some mirids and tingids absorb water in the spring, and thus nymphs hatch just as the plant becomes suitable for feeding.

The females of some heteropteran groups (some Tingidae, many— all?—Acanthosomatidae; a few others) guard their eggs and the early immature stages. Guarded eggs have been shown to be less heavily parasitized, and guarded nymphs less heavily preyed upon, than unguarded eggs and nymphs. A single female will lay several batches of eggs. In a few groups (some giant water bugs (Belostomatidae), at least one cored), females lay eggs on the backs of males. Belostomatid males then aerate the eggs, sweeping fresh water over them; without such aeration, the eggs might die of oxygen lack and/or of fungal infection. In some species each new batch requires a fresh mating; in bloodsucking species each new batch requires a blood meal.

Hatching occurs sometimes through areas of weakness in the egg’s chorion; not all species’ eggs have such areas. In some groups (Pentatomomidea, some Coreoidea, and others?) the new hatching (first instars) do not feed, although they may take water, and pentatomoids may suck up symbionts from the emptied eggs. Nearly all heteropterans have five immature stages (instars) (those that do not, have four; very rarely are there six), and except for blood-feeding bugs, the stimulus to molt from one instar to the next is unknown. Blood-feeding bugs require the stimulation (manifested as a distension of the abdomen) of a blood meal to molt.

As the instars grow larger at each successive molt, the wing pads develop; as these become more and more distinct, one can determine the instar by the degree of their development.

The instars (except sometimes the first one) feed for the most part on the same food as their adults. Exceptions include predaceous bugs, whose smaller instars may take smaller prey (although a group of small instars may attack a single large slow prey, like a caterpillar); and some herbivores, whose instars do not feed on the plants chosen by their adults, probably because of seasonal differences in the plants’ availability, and/or because some plants may provide nutrition to the young and others nutrients needed for reproduction to the adult.

Development (egg to egg) in temperate climes usually takes a year, the egg overwintering or sometimes a mated female (less often, other stages). In regions of less predictable or less severely contrasting seasons, there may be several—rarely, many—generations in a year. Even when there is only one annual generation, however, populations of some pest heteropterans can build up over a very few years.

A distinctive feature is the possession by some heteropterans of a pair of small (micro- or m-) chromosomes. The sex-determining mechanism is XY, although XO occurs in some groups and, in others (especially the bed bugs, Cimicidae), multiple X chromosomes may occur. The chromosomes are holocentric, and numerical doubling of the autosomal complement has occurred in several groups and, probably, reduction in others.

DISPERsal  As with all living things, dispersal is an important aspect of heteropterans’ lives, necessary for the leaving of places no longer suitable and for the discovery of places as yet unexploited; it is necessary, too, for the finding of nonsibling mates. The wingless immatures depend upon the mother to place them where resources—biotic and abiotic—are suitable for development.

Dispersal for mating appears to be far more frequent among bugs than dispersal for the discovery of new habitats, although of course it may often serve both purposes. One important exception
is the dispersal of cotton stains (Dysdercus spp., Pyrrhocoridae) from areas where high populations have depleted food to new areas, which may include cotton fields. After the move, females resorb the flight muscles, converting the products into eggs; thus such dispersal occurs but once. (Evidence suggests that not all Dysdercus spp. do this.) Another exception may be the moonlit flights of some giant water bugs (Belostomatidae) in Africa; it is not clear that these flights correspond to drying of habitat. Like other insect groups, Heteroptera contains some groups that are drawn to light traps (white or black light) and some groups that are not; no one has listed these groups, much less sought a correlation between being attracted to light and having a propensity to disperse.

Of course, for many heteropteran resources are replenished: for predators, new prey is continually being produced; and many smaller herbivores feed on annual plants that appear and disappear too rapidly for their populations to be seriously reduced. In addition, many herbivorous bugs feed on several different species and turn easily from one host to another. Thus for these bugs, dispersal may at times be necessary, but it is not a constant need.

Far better documented for far more heteropteran species is movement in response to sex pheromones, often produced by both sexes. In addition, aggregation pheromones occur in some species. This type of dispersal is of course a “pull” dispersal, not a “push” dispersal: the insect is drawn toward something rather than being driven away. Nevertheless, like the messengers in Through the Looking-Glass (one to fetch and one to carry), movement toward a conspecific may draw one also to fresher resources. The pheromone of at least one beneficial predaceous bug has been synthesized, patented, and marketed to draw these bugs into users’ gardens.

**ENEMIES AND DEFENSE** Heteropterans have the same enemies as other organisms: predators that would eat them from the outside and parasites that would eat them from the inside. The major predators—again like other insects’—are insects; vertebrates seem to be less important than they are for some other insect groups. Bugs may be protected from vertebrate predators by the secretion of their metathoracic scent glands, which also (it has been suggested) protect bugs from ants; the experimental work demonstrating these possibilities is scant and mostly anecdotal.

Many bugs are also protected from visually orienting vertebrates by being bad tasting and warningly colored. Aposomatic coloration occurs in nearly every group of land bug as an arresting contrast of black and red, yellow, orange, or white; the similarity of color and pattern has little to do with genetic or phylogenetic relatedness, and much to do with the strictures placed on color by limited metabolic pathways, as well as the limits placed on pattern and design by the strictures of small body size. Thus unrelated aposomatic bugs may resemble one another merely because the possibilities for variety are few. However, as in other groups of animals, both Batesian and Müllerian mimicry occur in Heteroptera: the edible look like the inedible (Batesian) and the inedible look like other inedibles (Müllerian). Mimetic assemblages occur, although they have been little studied. Certain cottonstainer relatives (Pyrrhocoridae) and their predators look much like certain Redniididae. It has been suggested that the reedniids can thus slip unnoticed upon their prey (“aggressive mimicry”). This seems outrageously unlikely: more probably, the group as a whole benefits from a collective aposatism, from which the pyrrhocorids benefit more than they lose from being preyed upon.

Few creatures like to eat ants, and it is not surprising that ant mimicry has arisen often in the Heteroptera. The immatures of some Alydidae resemble specific species of local ants; and as the immatures become larger, they resemble increasingly larger species of ants. One assumes that looking like ants is good; no one has tested the idea.

None of these defenses (except perhaps scent) is especially effective against other insects. More effective (guessing here) are the thickened cuticles of many heteropterans, the corrosive hemelytra, as well, perhaps, as the enlarged scutellum of several bugs.

Body shape may also play a part: the round sleek surfaces of Canopidae, Plataupidae, Megaridiidae, and a few other heteropterans offer the jaws of small predators (especially mandibulate insects) little purchase. And the many small spines of coreid nymphs (and others), and the single large spine of adult Cyrtocoridae and some Podopinae (Pentatomidae), must also prove to be unpleasant surprises to vertebrate predators.

It is difficult to know whether heteropterans are more or less parasitized than other insects. The eggs of certain species are often well parasitized by wasps, and the immatures and occasionally the adults by tachinid flies. Two indirect bits of evidence suggest that parasitizing bugs is an old and successful way of life: certain family groups of parasites have evolved that parasitize only heteropterans (Diptera: Tachinidae: Phasiinae; several genera of Hymenoptera). And parental care has evolved several times in Heteroptera, to ward off potential parasites (and predators, but these seem to be a lesser evil).

It has been carefully shown that guarding by parents (usually but not always females) protects certain lace bugs (Tingidae), coreids, and many anachthonomats from parasitism and predation; and the eggs placed upon the backs of some giant water bugs (Belostomatidae) are protected from fungal parasitism by the water currents generated by the male’s rowing movements.

**THE INFRAORDERS AND FAMILIES OF HETEROPTERA** Cladistic work on the morphology of heteropterans has resulted in a new classification into eight infraorders: Enicocephalomorpha, Dipsocoromorpha, Gerromorpha, Nepomorpha, Leptopodomorpha, Cimicomorpha, Pentatomomorpha, and Aradimorpha. In a commonly accepted (but not thoroughly tested) analysis, each of these infraorders is the sister group of those succeeding. Aradimorpha, the most recently proposed, is not universally accepted.

To some extent, these groupings correspond to earlier ones: Preceding this arrangement, for example, Heteroptera was divided into Hydrocorinae (=Nepomorpha, with some adjustments), Amphibicorinae (=Gerromorpha, with some adjustments), and Geocorinae (the remainder, with some adjustments): “water,” “ambitious,” and “terrestrial bugs,” respectively. The last was divided into Cimicomorpha and Pentatomomorpha, names retained in the new classification with the same family composition (with some adjustments in Cimicomorpha); Aradimorpha was included in the earlier Pentatomomorpha. Each morpha name is based on a genus in the infraorder.

The following treatment of infraorders and families of Heteroptera, is presented, once again, with the admonition to recognize that little is known in this area and often details are generalized to an entire family from what is known about a tiny fraction of its members.

**Enicocephalomorpha, Dipsocoromorpha** These small infraorders are the most primitive in Heteroptera. The latter is usually assumed to have arisen from the former, but there is some suggestion that each may have arisen separately from one or more related preheteropteran ancestors. Each is small: the two families of Enicocephalomorpha, Aenictopecheidae and Enicocephalidae, contain about 20 and 400 described species, respectively; however, it is probable that several thousand species remain to be described.

The same is true of the Dipsocoromorpha, whose five families are Ceratoconidae (50 described species), Dipsocoridae (30),
Schizopteridae (120), Hysiperygidae (3), and Stemocryptidae (1). As in Enicocephalomorpha, there remain to be described many hundreds, if not thousands, of diplocoromorph species.

Members of both groups are small (Enicocephalomorpha, 2–16 mm long; Diplocoromorpha, perhaps the smallest of the heteropterans, 0.4–4 mm long). They are all predaceous (as far as is known) and live in or on the soil surface, in leaf litter, or in the interstices of mosses and similar low-growing plants. Their small size, and their life in a habitat of remarkably small interest to biologists or ecologists, render them apparently rare, but actually locally abundant yet nearly wholly unknown.

This is unfortunate, because not only are these bugs of great ecological interest (as predators—and perhaps scavengers—in an ancient and poorly known habitat), but because many occur worldwide and study would yield valuable biogeographic information. Moreover, since they are the most primitive of heteropterans, careful study should reveal much about the origins of this group, as well as its relationships to certain homopteran groups: some enicocephalomorphs share some genitalic characteristics with some auchenorrhynchos homopterans; and Aenictopecheidae is defined wholly by plesiomorphies.

Some enicocephalids swarm, either in single-sex or mixed-sex swarms, and have been confused with midges! This statement sums up our knowledge of enicocephalomorphic reproductive biology!

**Gerromorpha** Members of this infraorder are the semiaquatic bugs whose members live near or on water, but never in it. Several members of several gerrphon group families live near or on the surface of the sea and are among the only heteropterans that are, if imperfectly, marine; halobatines (a subfamily of the Gerridae) may occur many kilometers from land. These gerrmorphans are *semi* aquatic bugs—they do not get wet, except occasionally; and indeed a few live not where it is wet, but where it is merely damp. Like other water-associated animals (e.g., Neponomera), gerrmorphans are usually dark above and pale below.

All are predaceous, those living on the water surface feeding on land arthropods that fall onto and are caught by the water's surface film; there is some evidence that these bugs may also feed on aquatic crustaceans that are seized upon rising to the water's surface. Prey is located by many bugs by ripples caused by its struggling. The bugs probably secrete something unpleasant because they themselves are only occasionally preyed upon by fish.

Many gerrmorphans are fully or partly winged, some are wingless, and populations of some are pterygopolymorphic (some members wingless, some winged), a phenomenon that may also vary seasonally. The hormonal and ecophysiological bases for pterygoploymorphism has been studied in a few gerrid species. This diversity, as well as variety in diapause physiology, is doubtless related to the temporary nature of the habitat, which may dry up or freeze at various locations and times of the year. In temperate regions, many gerrmorphans overwinter in debris away from, but close to, their water habitat.

Because of their ubiquity, and especially because of their tight adaptations to an unusual way of life, gerrmorphans (especially gerrids) are being used more and more to work out questions in communication and reproductive evolutionary ecology (including courtship). These efforts are helped of course by the wide interest in aquatic ecology, and by the excellent phylogenetic foundations provided by Andersen in 1982 and much recent work as well.

Being semiaquatic predators, a few gerrmorphans have been studied for their ability to control rice pests and the aquatic larvae of biting flies; in each situation, success is at best limited, probably because rice pests do not fall into the water often enough and aquatic larvae do not spend much time at the water's surface.

There are eight families: Mesovelidae (35–40 species), Hebridae (150), Paraphrynoveliidae (2), Macroveliidae (3), Hermatobatidae (8), Velidae (720), Gerridae (620), and Hydrometridae (110–115). Several of these families—or components of them—were once contained within a more exclusive Gerridae or Velidae, but the thorough phylogenetic studies just mentioned have yielded a firm and stable systematic classification.

The insects range in size from very small (1 mm long) to the aptly named *Gigantometra* (Gerridae), which is up to 36 mm long. Most gerrmorphans are at the small end of the range.

Members of the family Gerridae occur worldwide and are among the most frequently seen and frequently admired inhabitants in—or rather on—bodies of fresh water. As they skate about on the surface, their shadows are patterned dark on submerged objects in the water body. This esthetic appeal, and the bugs' ability to remain on the water, not in it, have earned them various names, such as “water bugs,” “pond skaters,” “wherrymen” (in Britain), and even “Jesus bugs.”

Their shape is characteristic and easily recognized: the head extends somewhat forward of the eyes, the abdomen is often truncate and its segments compressed, and the middle and hind legs are greatly elongated, sometimes looking as if they had been designed for a larger bug. All legs are used in moving on the water's surface, and the front legs are short, often stout, and used too for prey capture. The claws of all legs are subapical (not apical, as is usual). Probably this is an adaptation for moving on water surface films—something they do with remarkable speed and agility.

Much work has been done on communication and courtship/reproduction behavior in a few gerrid species: communication is via wave patterns of surface waves and ripples created by the bugs; these ripples apparently serve several functions, including location and courting of potential mates, defining territories, and perhaps even recognizing conspecifics for the avoidance of cannibalism. The extent to which other gerrmorphans use similar signals is unknown, although there is some evidence that a veliid does, and it seems reasonable that other surface skaters would also.

Velidae (riffle bugs, broad-shouldered bugs) is the largest family; the genus *Bhagovela* alone contains more than 200 species. Like gerrids' claws, veliids' claws are subapical; the legs are not relatively so long (not greatly surpassing the body), the abdomen is more often elongate, the pronotum is larger (covering the rest of the thoracic terga), and the middle legs' claws of some veliids are modified into a fanlike structure for pushing against the water's surface. In general, the veliids are smaller than gerrids: 1–10 mm vs. 1.5–35 mm in length.

Like gerrids, veliids for the most part occur on the surface of ponds or of the quiet stretches of moving water; also like a few gerrids, some veliids live on ocean surfaces, and others are nearly terrestrial, occurring in damp situations or intertidally, or in mangrove swamps. Veliids too feed on smaller animals trapped in the surface film.

Again like gerrids, veliids can move very quickly, and they move even faster when they secrete from the mouthparts a fluid that lowers the surface tension and causes them to “scoot” away.

Veliids may form large assemblages of very many individuals, sometimes almost seeming to cover a stretch of water. What brings and keeps the bugs together is unknown, nor is the advantage of these assemblages clear.

Members of Hebridae are the velvet water bugs, so called because of their coating of fine (presumably hydrophuge) hairs. Quite small (1.2–3.5 mm long), they are not often collected and live in damp places such as the edges of water bodies, in moss, or in and among waterside vegetation. The family occurs worldwide. Hebrids look somewhat like small veliids, both being somewhat broader and thus relatively shorter than gerrids.
As the names suggest (in English and Latinized Greek), water t breeders or marsh breeders (Hydrometridae) walk with measured tread on surfaces close to the water’s edge, and sometimes even on the surface itself. They are classic sit-and-wait predators, motionless for long periods until some small prey comes near. Hydrometridae are elongate insects, small to moderate in size (2.5–20 mm or so long); a distinctive feature is the position of the eyes about halfway along the length of the head. The genus Hydrometra, with 80–85 species, is found worldwide, but the rest of the family is tropical.

Mesoveliidae may be the most primitive family in the infraorder, possessing as it does a number of primitive character states and sharing only a few advanced states with other gerriforms; indeed, the group has at times been excluded from the infraorder, although its inclusion there is now firmly based. Like so many gerriforms, mesoveliids are small and pterygopolymorphic (some species); Mesotelia occurs worldwide, but most of the remaining genera are localized. Mesoveliids vary in their habitats; some (many Mesotelia) are active on the water surface, but others live in dump habitats some distance from water; a few are crenicolous, and a few are intertidal.

The other three families (Paraphrynoveliidae, Macroveliidae, and Hermatobatidae) are small in number of species (113 species in all) and in size (1.5–2.5, 2.5–5.5, and 2.5–4 mm long, respectively). The first has so far been found only in southern Africa; the second only in the New World; and members of the third live near coral reefs, where they remain in air bubbles during high tide and feed during low.

**Nepomorpha** Most of these are the truly aquatic bugs—that is, bugs that actually occur underwater and get wet; the group is the same as the earlier Hydrocorisae (water bugs). Most are predaceous, but corixids are, as a group, more omnivorous. Although nepomorphs live much of their lives in water, they also are active aerial dispersers. It is hard to imagine, therefore, why most of these bugs lack ocelli; even if unnecessary below the water’s surface, ocelli ought to be useful in the air (e.g., the riparian families have ocelli). Water bugs range from small (1 mm long, some Helotropididae) to huge, the largest of the Heteroptera (112 mm long, some Belostomatidae). Like gerriforms, and for the same reason, most nepomorphs are much paler ventrally than dorsally. Unlike prorhyncha, most (not all) nepomorphs are streamlined, fusiform; those that are not (Gelastocoridae, Ochteridae) are riparian, not wholly aquatic. The antennae of nepomorphs are short and often concealed; hence an earlier name, “Crypticerata” (“hidden horns”).

Living as most nepomorphs do, underwater, the problem of breathing arises and has been solved in several ways. Two families are nearly terrestrial: Gelastocoridae and Ochteridae live on the edges of streams and breathe like terrestrial bugs. Belostomatids and nepids have extrusible (belostomatids) or permanently exerted (nepids) “airtraps” or siphons, which can be thrust above the surface. Members of the other families rise to the surface periodically to trap air in hydrofuge hairs; oxygen is then taken into the body (much carbon dioxide here as in most animals is released through the body wall); in some groups and to some extent, plastron respiration occurs (i.e., as the oxygen tension in the air bubble drops, oxygen is drawn into the bubble directly from the water). Plastron respiration is so efficient in Aphelechiridae that these bugs may remain permanently submerged.

Because of these bugs’ importance as fish food (and sometimes as human food), because they occur in aquatic habitats, which have always held a fascination for ecologists, biologists, and folk in general, and because some are so large, nepomorphs have probably been better studied as a group than any other infraorder. The literature on the systematics, biology, and ecology of the group and its members is very large.

There are nine families: Corixidae (at least 600 species), Nepidae (225 species), Belostomatidae (150), Nannocorididae (nearly 500), Notonectidae (350), Plectidae (40), Helotrephidae (44–120 species; authorities differ), Ochteridae (50–55), and Gelastocoridae (100). All but the last two live below the water’s surface; Ochteridae and Gelastocoridae are riparian (ripicolous).

Corixids (family Corixidae) are the water boatmen, found commonly in ponds, lakes, and (less often) streams throughout the world. More than 600 species make this the largest nepomorphan family. Aspects of their morphology differ so greatly from those of other bugs that Corixidae has sometimes been placed in its own group, separate from other heteropterans. In particular, the labium of the mouthparts is broad and fused to the head, and the foretarsi are modified (enlarged, somewhat flattened, with an array of long setae) for food gathering. Like other nepomorphs, the hind legs are flattened and hairy, for swimming; in particular, corixids look superficially like notonectids, but corixids are flatter and swim rightside up. Under magnification, the dorsum of many corixids has many fine horizontal zigzag and anastomosing pale lines; this feature too distinguishes these bugs from notonectids and, indeed, from other bugs.

Water boatmen are 2.5–15 mm long and occur throughout the world; they live in aquatic habitats of all kinds, including the intertidal. Unlike other nepomorphs, corixids probably feed mostly on algae (and one suspects other small bits of living or dead organic matter). Some are carnivorous, however; indeed, probably many are (only a few have been studied) and are important predators in waters containing few others (e.g., acidified or saline inland waters). Excellent fliers over long distances, water boatmen are often among the first animal colonizers of new aquatic habitats and have even been captured landing on the shiny roof of an automobile in the desert far from the nearest water.

Corixids are of some small importance in feeding on aquatic larvae of noxious dipterans; they are of greater importance as food for commercially valuable fish (and in some cultures, for humans). In addition, they have been used as indicators of organic pollution.

The function of stridulation has been more thoroughly studied in Corixidae than in any other heteropteran group. (The so-called stridultrum on the male’s abdomen is not sound producing but probably aids in clasping the female.)

Superficially similar to corixids are the Notonectidae, backswimmers [wherrymen (cf. also Gerridae), boat flies] which, however, swim upside down; notonectids swim ventral side up because that is where the buoyant air bubble is. Backswimmers, like water boatmen, are fusiform and also have flattened hirsute hind legs for swimming. However, they have typically heteropteran mouthparts, which are wholly predaceous, lack modified foretarsi, and never have the pale irregular linear markings of many corixids. They range from 5 to 15 mm in length. Moreover, unlike corixids, notonectids bite viciously and painfully, as many a hydrobiologist has learned. The largest genus, Notonecta, occurs worldwide, and the other genera are more localized, although sometimes within entire continents.

Like corixids, notonectids are excellent fliers and are also early colonizers of new bodies of water. Some notonectids also may use sound in courtship and mating, but the evidence here is far more slight than that for corixids. Backswimmers inhabit nearly all types of water, although records from saline or near-saline waters are scarce.

These bugs are eager predators and they prey near the water’s surface, whence they may drive their prey, a procedure aided by the bugs’ buoyancy. They feed on other arthropods (and occasionally fish, see later), including small crustaceans and the larvae and
The giant water bugs comprise the Belostomatidae; here are the largest of Heteroptera, ranging from 9 to 112 mm in length. All are predaceous, and the largest may be important pests in fish hatcheries; one group of species feeds on snails in Africa and is of some value in suppressing populations of snails that carry bilharzia (schistosomiasis); the report of a giant water bug attacking baby ducklings vents fungal growth. 

Water scorpions do not swim actively; they are, rather, "sit-and-wait" predators, often sitting patiently on vegetation in quiet ponds until appropriate prey wanders past. They grab the prey swiftly with the forelegs, rather like aquatic preying mantids. 

Belostomatid body is broadly oval and somewhat flattened; the forelegs are modified for grasping, and one claw is reduced. The eighth abdominal tergum is modified laterally into a pair of extrusible airstraps, which can be thrust above the water's surface and through which air is moved to an air bubble below the wings. In several subfamilies, these bugs (both families) swim upside down (although they can at times swim rightside up), and they presumably get oxygen and prey in much the same way as do notonectids. Pleids occur almost exclusively in still waters, permanent or temporary; helotrephids live in almost any kind of water, still, or running, permanent or temporary, hot springs, or water seeps; one species can even wait in the desert for ephemeral waters. Members of both families may be of some small value in controlling mosquito larvae. Pleidae is wholly, and Helotrephidae mostly, tropical.

Cimicomorpha. This is by far the largest of the heteropteran infraorders, containing as it does Miridae and Reduviidae, the two largest families. Within the infraorder’s 14 families is the widest variety of foods and of habitats: primitively predaceous on other arthropods, others to feeding on plants. Habitats of various cimicomorphans range from human homes and caves to the webs of spiders, embiids, and psocids; one reduviid “fishes” for termites and another is “led” to range in length from 2 to 7.8 mm. Known as shore bugs, saldids occur in damp areas near water; they are excellent jumpers, fly readily, and are more difficult to collect than they at first appear to be. The eyes are indented medially (kidney-shaped), and the dorsum of many species is mottled dark and light. The male has a grasping structure on the side of the abdomen. Shore bugs occur mostly in temperate regions (somewhat unusual for heteropterans) and may occur at fairly high elevations or quite far north (e.g., Alaska); a few are intertidal or found in salt marshes.

Aepoephilidae and Omaniidae are wholly intertidal. Indeed, the single aepoephilid species lives below the water; breathing (like Aphelocheiridae) via plastron respiration with an air bubble permanently trapped in a dense mat of hydrofuge hairs. Omaniids seek prey on exposed rocks at low tide; at high tide they wait in crevices, probably tapping air bubbles for oxygen. Members of both families are very small (2 and 1–2 mm long, respectively), and presumably feed on even smaller intertidal invertebrates. Aepoephilids have quite small eyes, as do aphelocheirids, suggesting that a life permanently under erratically moving water is not sight based.

Aepoephilus bonnairei occurs in Europe south to coastal North Africa. Omaniids are known from the Red Sea, south to Akbar on the African coast, and east to Samoa; it seems likely that they occur on the Indian Ocean coast, and on coasts to the east.

Species of Leptopodidae are about the same size as saldids, ranging from about 2 to 7 mm in length. These bugs vary in shape, and males have a grasping organ similar to but different from that of saldids. Most species are tropical, and many occur near water, but others are in quite dry habitats. Some have been collected in ant lion pits, which suggests they may be scavengers.

Prosorrhyncha

The largest and best-known family is Saldidae, whose members range in length from 2 to 7.8 mm. Known as shore bugs, saldids occur in damp areas near water; they are excellent jumpers, fly readily, and are more difficult to collect than they at first appear to be. The eyes are indented medially (kidney-shaped), and the dorsum of many species is mottled dark and light. The male has a grasping structure on the side of the abdomen. Shore bugs occur mostly in temperate regions (somewhat unusual for heteropterans) and may occur at fairly high elevations or quite far north (e.g., Alaska); a few are intertidal or found in salt marshes.

These bugs vary in shape, and males have a grasping organ similar to but different from that of saldids. Most species are tropical, and many occur near water, but others are in quite dry habitats. Some have been collected in ant lion pits, which suggests they may be scavengers.

Cimicomorpha. This is by far largest of the heteropteran infraorders, containing as it does Miridae and Reduviidae, the two largest families. Within the infraorder’s 14 families is the widest variety of foods and of habitats: primitively predaceous on other arthropods, three major groups have moved to feeding on vertebrate blood, and others to feeding on plants. Habitats of various cimicomorphans range from human homes and caves to the webs of spiders, embiids, and psocids; one reduviid “fishes” for termites and another is “led” to its food by ants.

The group has long been recognized (before the current classification of Heteroptera) but is held together only loosely by shared advanced character states, not all of which are possessed by all members. The head usually bears some long-socketed hairs (trichobothria) and is usually prominent and extends directly forward; the forewing’s membrane usually has several closed cells, the claws usually lack pads between them; and the eggs often have a characteristic type and arrangement of microstructures. However the sperm storage organ of other heteropterans (the spermatheca) is in cimicomorphs non-functional or either greatly reduced or absent. The cimicomorph families are united by this last character. Moreover, since each family is more or less phylogenetically related to another, the first and last are joined less by their relationship to each other and more by their relationship one at time to those in between (rather like a group of people in a line holding hands).

With its 6700 species, Reduviidae is the second largest of the Heteropteran families; it is also perhaps the most diverse, as is suggested by the 25, or 22, or 21, or 29, or 23 subfamilies—and the confusion over the number! Suggested by the number is the systematic confusion at the higher taxonomic levels, a situation similar to that in the Pentatomidae (another large family) and—until recently—in the Lygaeidae (yet another).

Reduviids, also called assassin bugs, for the fierce way some attack prey, vary greatly in shape and in size, ranging in length from 3–4 mm to 40 + mm. All (or most) have a short, stubby, slightly curved beak, designed for being stabbed downward through the cuticle of arthropod prey; well-developed eyes (sight-orienting predators); fore femora often enlarged and with spines for prey capture; forewing membrane with two closed cells; glandular setae and a spongy pad on the foretibiae, presumably to help in grasping; paired first-abdominal glands (Brindley’s glands) whose secretion apparently wards off enemies (but, then, what is the function of the metathoracic scent glands?); and a stridulitrum on the prosternum whose pectrum is on the beak, also presumably to frighten would-be vertebrate predators. Not all reduviids—even not all reduviid subfamilies and tribes—have all these characters, but most species are two to four times longer than wide, with a large head, bulging eyes, and a stout beak. Most assassin bugs are easily recognized.

All reduviids are predaceous, the great majority on other arthropods. There is some degree of specialization: Ectrichidiinae (645 species) on millipedes, Peiratinae (47 species) on hard-bodied prey like grasshoppers and beetles, Harpactocorinae (2060 species) on soft-bodied prey like grubs and caterpillars, Reduviinae (980 species) on social insects, Emesinae (920 species) on flies, and other subfamilies with usually lesser degrees of specialization (but again it must be emphasized: much generalization here is based on scant data).

FIGURE 3 A triatomine, Triatoma protracta (Reduviidae), on a human host, China Lake, CA. (Photograph by G. R. Ballmer.)

One group, the subfamily Triatominae, feeds upon the blood of vertebrates (mostly warm-blooded vertebrates). These are the only bugs responsible for a human disease (Fig. 3): Chagas disease is a serious trypanosomiasis in the neotropics, costing many deaths every year. Triatomines that live near or in human dwellings are vectors of the protozoan parasite T. cruzi. An intense cooperative effort by Latin American countries and several other national and international agencies is gradually reducing the range of this disease.

Triatomines are large (50–200 mm long, 5–8 mm wide) bugs, usually brown or patterned light and dark brown. They occur throughout the New World tropics and subtropics (including well into the
United States) and the “wild” (sylvatic) ones feed on small mammals (often burrowing rodents) and (some species) on birds. Domestic triatomines live in the thatch or in litter on the floor of dwellings. One genus (Linskocostenus) occurs only in India; a species complex of Triatoma occurs in Malaysia, Indonesia, New Guinea, and surrounding areas; T. rubrofasciata is pantropical (and may be the ancestor of the species in the second group). The possibility that Triatominae is paraphyletic (or polyphyletic)—that its members are descended from several different reduviid groups and independently evolved blood-feeding—is being investigated.

Certain reduviid species and smaller groups feed rather strangely. An Indian reduvium (Acanthaspis sivara) hunts honey bees at their nests, and some neotropical apiomerines, which wait near resin sites for certain bees to arrive to harvest nest-constructing resin, may even release a kairomone to attract the bees, which are eaten; fossil evidence indicates that the latter relationship goes back at least 25 million years. The Indian harpactocorine Lophocephala guerini feeds on the juices emanating from cow feces (or perhaps on arthropods found within?) and is led to this food by ants, which in turn feed upon the bugs’ feces. Many emesines live unentangled in spider or psocid webs, and they feed on their hosts or on prey trapped therein. Salyavata variegata (Salyavatinae, neotropical) waits by crevices in termite nests and disguises itself with bits of the nest itself; it eats termites that emerge to repair the crevice and even uses the remains of fed-upon termites as bait to lure more termites out.

Most reduviids actively seek prey and seize it. Some wait where prey is sure to be found (e.g., termite or bee nests); others wait more patiently for less specific prey. Once seized, prey may be fed upon at once or, often, dragged to a secluded spot. Nymphal reduviids may engage in communal feeding: several bugs feeding on a single prey. This occurs in other predaceous heteropterans too, and probably the pooling of saliva with its digestive enzymes is of benefit to all (except the prey!). Several reduviids resemble other heteropterans (e.g., alf dids, pyrhocorids) and may be associated with them. Some have thought this a ruse to lure these others to their doom (see earlier comments on this “aggressive mimicry”).

Reduciids are abundant in most habitats. They are large and presumably eat a lot. They are aggressive predators. It is therefore surprising that their possibilities as biological control agents have been so little studied (except—recently—in southern India, as described by Ambrose).

Phymatidae is a family often included in Reduviidae, and as often treated separately. Also known as ambush bugs, phymatids lie in wait for their prey, grabbing them with ferociously enlarged forelegs. In the United States, a common ambush bug is yellowish and lurks in late-summer yellow flowers, waiting for hapless bees and other insects seeking nectar where “rosae … sera morentur” (to twist Horace a bit).

The small family Pachydominae contains 15 described species of tropical predators. They look like certain nabids and share characters with several different cimicomorphan groups; recently they have been placed as the sibling group of Reduviidae. They and another family, Velocipedeidae, are the only cimicomorphans with ventral abdominal trichothoria (long-socketed hairs, regularly arranged), a feature found more commonly in Pentatomomorpha. Pachydomini range from 3 to 15 mm in length. Nothing is known of their biology—not even the immatures (that they are predaceous is inferred from the thick curved beak).

The family Miridae [Capsidae (Britain), plant bugs], with its 10,000 species, contains nearly one-third of all heteropterans. So vast is the family and so diverse in habits and habitats, that it cannot be covered here. Luckily, Wheeler’s excellent book on the family’s biology is available.

All but one group of mirids lack ocelli (hence the German name Blindwanzen, “blind bugs”); all are relatively small (1.5–15 mm long), delicate in appearance, usually brown or greenish but often brightly and contrasting ly colored, and range in shape from elongated to round to myrmecomorphic. Many (most?) have setae on their surfaces, a “break” in the forewing where leathery part (corium) and membranous part meet, one or two closed membranal cells, and asymmetrical genitalia in the male.

The primitive groups are predaceous, reflecting the predacity of their infraorder (Cimicomorpha). Many mirids are herbivorous, however, although even many of these have reverted to predacity (secondarily predaceous”). Overall, the percentage of predaceous (and scavenging) mirids is quite high; and many others are omnivorous, supplementing a plant diet with arthropod prey, or vice versa. Moreover, many mirids are cannibalistic. In general, then, a great many mirids are opportunistic feeders and, therefore, may be crop pests under one set of circumstances and useful control agents (of weeds or pests) under other circumstances. However, mirids are small and feed on small prey (eggs, small arthropods). Thus they are rarely seen feeding, and their impact on natural ecosystems and on agroecosystems, although great, is much underestimated (this of course is true of all small predaceous arthropods).

![FIGURE 4 A mirid, Onceromopitus nigriclavus, Coachella Valley, CA. (Photograph by G. R. Ballmer.)](image)

Many mirids (Fig. 4) are somewhat host specific, at least at the bug-species to plant-genus/tribe level. The bugs feed, usually intracellularly, on the reproductive parts of plants and on new, still-growing somatic tissues. The bugs’ enzymes cause the plant to mobilize nitrogen to these feeding wounds, which the bugs suck up. Many mirids feed on annual plants, and often on plants that appear only briefly (e.g., early successional plants); the brief presence of such plants, and their great diversity, may help explain the diversity of mirids: this type of association would seem to promote speciation.

Some of the predaceous mirids also appear to be host specific, but the specificity would seem to be more one of habitat than of prey: associated with a particular habitat (rhododendron plants, tree bark), the mirids perform feed on prey found only there (cf. Anthocoridae). Members of one subfamily, Cylapinae, occur with fungi, and although they may feed on arthropods also found there, at least one species feeds directly on the fungus.
Because of their numbers and diversity, mirids occur throughout the world in all manner of habitats (except aquatic, but some are found in salt marshes). Probably a majority of plant species is fed upon by mirids, and their populations may become high locally; mirids are therefore often the most frequently collected of heteropterans.

As mentioned, the family is very large; one genus (Phytocoris) contains more than 600 species. Eight subfamilies are accepted (but not universally), but it is not surprising that there is less agreement about the number and validity of tribes. Much work is needed on cladistic analyses and higher group systematics of Miridae. And, because of the variety in food preferences, in habitats, in degrees of food and habitat specificity, and in other aspects of their biology, biological and ecological data should be used in these analyses.

Related to the mirids are the Tingidae, known as lace bugs because of the elaborate expansions of the thoraces (and sometimes heads and abdomens) of many of these bugs. Although small (1.5–10 mm long), these are among the loveliest of Heteroptera; some vaguely resemble large coleorrhynchans, but there is no phylogenetic relationship.

Because of their often bizarre shape and strange (and attractive) outgrowths, it is not easy to characterize lace bugs. The head is small or of moderate size, the body (when shorn of outgrowths) usually oval. In most tingids the expansions of the thorax conceal the scutellum and, in some, a pronotal “hood” may partly cover the head; some species are coleopteroid (forewings completely leathery or hard, and closely appressed; the bug looks beetlelike).

The family, with nearly 2000 species, is distributed worldwide; all tingids are herbivorous, even members of a small subfamily that live in ants’ nests and (probably) feed on rootlets that penetrate therein. As a group, lace bugs prefer woody plants (but there are many exceptions) and are quite host specific, either at the plant-specific or generic level. Species in one genus (Acalypta) are among the few heteropterans that feed on mosses; and members of two other genera (Copium and Paracopium) are the only heteropterans that induce gall formation in their host plants. Tingids’ preference for woody (perennial) plants sets them apart from mirids (which seem to prefer annuals) and perhaps partly explains why there are so many more of the latter.

This feeding preference of lace bugs also explains why so many are pests of ornamental and fruit-bearing shrubs and small trees, where they feed mostly on somatic tissue. Large populations can arise quickly, the buildup aided in part by various defensive mechanisms of the nymphs. These range from maternal care through several defensive phero nomes and kairomones, to an array of sharp or defensive-liquid-producing setae on the body. Another strategy is the laying of small batches of eggs in different places, a form of bet hedging (this of course occurs in many other groups). These population buildups often lead to major problems localized in time and space.

Maternal care has been carefully worked out in the genus Gargaphia, especially Gargaphia solani. In this species several females may oviposit in a single cluster, which they then communally guard, as well as the resulting nymphs. This opens up the possibility of “cheating”: a female that lays eggs in the cluster but does not help guard it can thus devote more time and resources to producing more eggs.

One other family of Cimicomorpha is herbivorous: the 19 species of Thaumastocoridae feed on a variety of plants, but many feed on palms, and the name palm bugs has been given to the family. These are small (2–5 mm long) insects, broadly to narrowly ovate, and flattened. The external genitalia are much reduced; the ovipositor is gone in females, one or both parameres are gone in males; the genital capsule is highly asymmetrical. Like tingids, these bugs feed on the cells of plants’ somatic tissues (usually leaves), leaving behind pale spots. Populations occasionally build upon ornamental plants to the point of visible damage. One such culprit is the royal palm bug, Xylocoris luteolus, which may at times cause unsightly damage to a decorative palm.

The approximately 400 species of Nabidae are about 8–12 mm in length and most are slight in appearance, which perhaps accounts for the derivation of their name, damsel bugs. All are predaceous, but some will probe plants, probably for water (some survive on plant food alone). The majority of species seem to prefer seeking prey on low vegetation or in fields, and for this reason nabids are an important component of agroecosystems. Nabids also fly readily and disperse well. As a result, several species are cosmopolitan. One genus (Arachnocoris) lives in spiderwebs, probably stealing prey.

Most nabids are brown or light brown, although a few are black and red. The males of most species have a specialized group of tibal setae which, upon being rubbed across part of the genital capsule, spread an attractant pheromone produced in rectal glands.

In many species copulation is normal, but in some a form of internal traumatic insemination (cf. Cimicidae) occurs, wherein the male aedeagus pierces the wall of the female’s genital chamber and deposits sperm in her hemocoel.

Two small cimicomorph families, Medocostidae (one species) and Velocopedidae (discussed earlier), have been placed in Nabidae from time to time. The arguments for excluding them are slightly more persuasive than the arguments for including them (more persuasive for the first than the second); and the evidence for their phylogenetic relationships is equally insecure.

The single medocostid species is about 9 mm long, elongated oval, and presumably predaceous. It has an unusually long fourth rostral (beak) segment and lives under bark in western and central Africa.

Three other small families are Plokiophilidae (a half-dozen or so species), Microphysidae (25–30 species), and Joppeicidae (one species). The first appears to be related to Anthocoridae–Cimicidae, but the relationships of the other two are not clear, their affinities with other groups consisting mostly of character-state losses. All are small (1–3 mm long) and predaceous. Of these, the most interesting are the plokiophilid bugs, which live in webs, one species in those of embiids, where they feed on eggs or dead embiids. Other species live in spiderwebs (like some nabids), where they feed alongside the spider on trapped prey. Microphysids are found on tree trunks, and the joppeicid in dry situations.

Closely related to one another are Polyceniidae (bat bugs) and Cimicidae (bed bugs, although most—like all polyctenids—are ectoparasites of bats). Both groups are well adapted as ectoparasites of vertebrates: They are wingless and flattened, the latter an adaptation both for slipping through the hair or feathers of a host and for expansion of the body during engorgement. Cimicids are temporary ectoparasites, moving onto the host only to feed.

As noted earlier, it is cimicids, the bed bugs, that have given their name to heteropterans: true bugs. The 100 or so species are temporarily ectoparasitic on bats, birds (mostly those that roost in groups), and humans. Of the human bed bugs, C. lectularius (worldwide, especially in cooler regions) and C. hemipterus (tropics), the former is among the very few arthropods associated only with humans (like the house fly and the head/body louse). C. hemipterus, the tropical bed bug, may also be found on bats, but it seems to prefer humans.

These human bed bugs are small (5 mm long), round to broadly oval, flat (except when engorged with blood), and brown; they are well known, to the extent that although no one claims to have seen one, everyone knows someone who has. Because bed bugs are secretive
and feed at night, they are not uncommon but are rarely seen, spend-}
{ing the day hidden in crevices in dwellings and in bedclothes. Despite}
{their ubiquity, they usually do little harm. They spread no pathogen}
{(although they have been implicated in transmission of hepatitis B}
{virus in southern Africa, the evidence offered is at best equivocal),}
{and for the most part they are annoying rather than harmful.}

Cimicids that feed on birds can cause harm; some feed on poultry}
{and may take enough blood to decrease egg and meat production;}
{and swallow bugs (genus Oeciacus) may cause serious damage to}
{populations of these attractive and useful birds.}

It is in the human bed bug that traumatic insemination has been}
{studied in the most detail. The male punctures the venter of the}
{female’s abdomen with his scimitar-shaped left clasper. Sperm are}
{deposited either directly into the hemocoel (more primitive cimicids,}
{some noncimicids) or into a patch of tissue specialized for their recep-
{tion. In either case, the sperm then travel (for part of their journey,}
{from cell to cell) to the base of the ovarioles, where they are stored;}
{this journey cannot occur if the sperm are not activated by an agent}
{in the seminal fluid. Eggs are fertilized as they pass the storage}
{depot. This process has not been worked out for the majority of traumati-
{cally inseminated species but is probably the same in broad outline.}

Unlike bed bugs, polyctenids live permanently on their host bats}
{and are so well adapted to this way of life that they closely resemble}
{not cimicids but bat flies (Streblidae, Nycteribiidae). They are eyeless}
{and have claws and stiff setae “designed” as in other ectoparasites}
{to catch on fur and prevent them from being captured and dragged}
{away by the host. Bat bugs have also carried further the traumatic}
{insemination of their relatives: the female is mated before molting}
{to adult, through the base of the right midcoxa into the hemocoel,}
{whence the sperm move close to the oviducts. Here (apparently)
{fertilization takes place, and here too occurs not only embryogen-
{esis but also hatching. Nymphs are then “born,” and because some}
{of these births may occur before the female is adult, they represent}
{a form of pedogenesis (i.e., reproduction by immature stages). The}
{embryos are nourished in part directly from the oviduct wall, and the}
{entire process has therefore been termed pseudoplacental viviparity,}
a phenomenon that occurs in other groups of insects (cf. the tsetse}
{fly). (It is not clear that mating must occur before molting: presum-
{ably an unmated adult female can be mated.)}

Bat bugs are 3–5 mm in length and occur in the tropics. As a group}
{they show some host specificity, and it would be interesting to com-
{pare their host associations with those of streblids and nycteribiids.}

Anthocoridae contains 500–600 species and here includes the}
{subfamilies Lycocorinae and Lasiochilinae, sometimes treated as}
{separate families. Anthocorids are sometimes called minute pirate}
{bugs, perhaps because they are predaceous and some of the more}
{common ones are picturesquely black and white (like the Jolly}
{Roger). Anthocorids’ eyes are prominent, suggesting they orient to}
{prey visually “up close”; some evidence indicates they are initially}
{attracted by the odor of the leaves on which prey are feeding. The}
{left paramere of the male is in many anthocorids modified for tra-
{umatic insemination of the female.}

Although small (1.5–6 mm long), anthocorids are efficient preda-
{tors on small arthropods and upon the eggs and early instars of larger}
{arthropods. They are also abundant in many habitats, and for these}
{reasons are quite useful in biological control. In Europe especially,}
{anthocorids are used for control of pests in such confined growing}
{areas as greenhouses. Some members of the Lycocorinae live in dry}
{areas and have proven useful in the control of stored-food pests.}

Many anthocorid species seem to be habitat specific. One impres-
sive example is Elatophilus, whose species are found on the trunks
{of north-temperate pines, where they feed on Matsucoccus scale}
insects; the specificity appears to be one of habitat, not prey. Other}
{anthocorids live on the trunks of other trees, feeding there on small}
homopterans and sometimes bark beetles.

Also known as flower bugs (again perhaps for their daintily con-
{trasting colors), a few anthocorids—most of the large and wide-
{spread genus Orius—live on annual plants; but this is not the most}
{important habitat of anthocorids. Most species (as far as is known:}
{not very far) live on tree trunks, some in leaf and other ground litter}
{and the bases of grass clumps, and some in natural accumulations of}
{seed or berries (and in the nests of rodents that have carried these}
{foods in—perhaps evolutionarily en route to living where grain is}
{stored). Because of the considerable value of these bugs in biologi-
{cal control, the literature on their biology is vast. Unfortunately,}
{the literature is concerned with relatively few species, and the biologies}
of most are wholly unknown. It is known that some species (perhaps}
{many?) supplement their diet with pollen; and at least one may be}
{entirely herbivorous.

**Pentatomomorpha** This is the second largest of the heterop-
{teran infraorders. Unlike the others, it (and Aradimorpha) is primiti-
{vely herbivorous: that is, the ancestor, or the earliest members, of}
{the infraorder, were themselves almost certainly feeders on plant}
{juices. With few exceptions, members of Pentatomomorpha feed}
{on plants. The exceptions are certain Rhyparochromidae that feed}
{on vertebrate blood; members of Geocoridae, which prey on small}
{arthropods as well as plants; a very few Pyrrhocoridae that may be}
either obligate or facultative predators (it is not always clear which),
{and Pentatomoidea of the subfamily Asopinae, all of whose members}
{are predaceous. For the most part, pentatomomorphs feed on the}
{nitrogen-rich reproductive parts of plants: flowers, ovaries, and ripe}
{and unripe seeds. Many, however, feed on plant somatic tissues.}

Pentatomomorphs range from the very small (some Lygaeoidea) to}
{the largest of the land bugs. The beak is long, extending usually at}
{least to the mesosternum and sometimes beyond the abdomen; the}
{abdomen’s venter bears a regular number of regularly arranged sock-
{eted setae. Associated with the metathoracic scent gland opening is}
one or more raised structures, and the shape is rounded to narrowly}
{oval (rarely long and thin).}

Pentatomomorpha contains five superfamilies—six if one includes}
{Aradoida. (The recent elevation of this group to infraorder level has}
{not met with universal acceptance, and in this article “Aradoidea” is}
treated as the infraorder Aradimorpha).}

The Idiotoloidea contains two families, Idiostolidae (four spe-
{cies) and Henicoridae (one species); the latter was until recently}
{considered to be a subfamily of Lygaeidae (in the broad sense, as dis-
{cussed shortly). In some features (e.g., abundance of trichobothria),}
{Idiostolidae appears to be the most primitive of the pentatomomor-
{phan superfamilies; however, in Henry’s analysis, this group is the}
sister group of the families formerly included in Lygaeidae. The}
biology of Idiotoloidea is not known, although specimens have been}
captured on the ground, not up on plants. Idiostolids are associated}
{with the moss and litter of southern beech (Nothofagus) stands, and}
{may indeed feed on mosses. The superfamily has a Gondwana dis-
tribution occurring in southern South America and in Australia (see}
{also Coleorrhyncha, earlier).}

Until recently most members of the superfamily Lygaeoidea were}
classified in the family Lygaeidae. However, it had long been recog-
{nized that the members of this family were not all closely related and that}
{indeed Lygaeidae was paraphyletic and, probably, polyphyletic: that is,}
{Lygaeidae did not include all descendents from the common ancestor,
and indeed different members of Lygaeidae were descended from several different ancestors. In 1997 T. J. Henry applied cladistic analysis to Lygaeidae, as well as to related families, and presented a new classification of the members of the former Lygaeidae. This classification, which has been generally (but not universally) accepted, is used here.

The family Lygaeidae (sensu Henry) now consists of 15 families: Artheneidae, Blissidae, Cryptorhamphidae, Cynidae, Geocoridae, Heterogastridae, Lygaeidae (sensu strictu), Ninidae, Oxyccarenidae, Pachygronthidae, Rhyparochromidae, Berytidae, Colobathristidae, Malcidae, and Piesmatidae. The last four had already been treated as separate families in the old Lygaeoidea. The superfamily contains roughly 4400 species, most of them in the former “Lygaeidae.”

Lygaeoids are relatively small heteropterans (1–20 mm long); the largest are the milkweed bugs, several of which are common in North America. Milkweed bugs are Lygaeidae (sensu strictu), and many are warningly colored because they are distasteful. Of greater importance are the chinch bugs (Blissidae); all feed on grasses, and several are serious pests of graminaceous crops (wheat, sugarcane, rangeland and lawn grasses, etc.) (Fig. 5). Several other families are of some economic importance (Geocoridae, one of the few facultatively predaceous groups in Pentatomomorpha, in biological control; some Colobathristidae on sugarcane).

Members of the largest lygaeid family, Rhyparochromidae, with nearly half the superfamily’s species, feed on fallen seeds; for this reason they are called seed bugs, a name that by extension is often applied to lygaeoids generally. Members of other lygaeoid families feed on seeds still attached to plants, and others feed directly on somatic tissues (mostly leaves, sometimes in vascular tissue, sometimes in plant cells).

Members of the rhyarochromine tribe Cleradini, and one species in the tribe Udeocorini, feed on vertebrate blood, and it has been suggested they might be able to vector T. cruzi, the pathogen of Chagas disease (see Reduviidae).

There are two families in the Pyrrhocoroidea, the Largidae and Pyrrhocoridae. The first contains about 120 species, and a few are excellent ant mimics. The Pyrrhocoridae, with one exception, occurs only in the Old World. The exception is Dysdercus (Fig. 6), with some 85 species in both the Old and New World tropics; these species are frequently pests of cotton crops. Exclusive of Dysdercus, there are about 225 species in the family. Both families are tropical or, in a few species, subtropical.

Of the five families in the superfamily Coreoidea (Coreidae, Alydidae, Rhopalidae, Stenocephalidae, and Hyocephalidae), the first is by far the largest in number of species (1800–1900) and in size; indeed, members of the neotropical coreid genus Thasus may be the largest land heteropterans known (Fig. 7); up to 40 mm in length, being exceeded in this respect only by some giant water bugs (Belostomatidae). The other families are smaller in numbers and size: Alydidae (about 250 species), Rhopalidae (somewhat more than 200), Stenocephalidae (about 30), and Hyocephalidae (3). All are phytophagous.

Members of Coreidae are sometimes called leaf-footed bugs because several species, occurring in several apparently unrelated tribes, have hind tibial expansions (and sometimes antennal expansions) as adults, as nymphs, or as both; their function is obscure, although they may serve to deflect the attacks of birds. Males of
several groups of coreids have enlarged hind femora, which are used to defend territories from other males. The nymphs of several species are gregarious, and it would be interesting to learn whether this gregariousness occurs in species whose males are territorial. The coreid head is small relative to the body (cf. Alydidae), and the bugs’ length ranges from about 6 to 40 mm.

Members of the family feed up on plants, some species on ripening seeds and other reproductive parts, and many species on the juices from vascular tissue. Varying degrees of host specialization occur in the family, from mono- through oligo- to polyphagy. Some species feed on cucurbits (hence another common name, squash bugs). Some unrelated coreid groups (Pseudophloeinae, and three coreine tribes) are among the few heteropteran family groups to have broached the defenses of the Leguminosae and to have radiated upon these plants. Several of these bugs are serious pests of legume crops (e.g., pigeon pea) in the Old World tropics.

The males of one species, *Phyllomorpha laciniata*, are heavily spined and, somewhat like some giant water bug males, carry among the dorsal spines their females’ eggs.

Alydidae—called broad-headed bugs because the head is relatively wide (it also resembles an ant’s)—comprises three groups. The subfamily Alydinae is another group specializing on legumes, upon whose ripening seeds the bugs feed. Several species are pests of legume crops (e.g., soybean, pigeon pea) in the tropics. Immature alydines mimic ants, often successfully enough to fool heteropterists; some species mimic small species of ants as early instars and other larger ant species when older (Fig. 8).

![FIGURE 8 Broad-headed bug (nymph), probably *Megalotomus quinquespinosus* (Alydidae). Note ant mimicry. (Photograph by John H. Acorn.)](image1)

Some members of the second alydid group (Micrelytrinae: Micrelytrini) mimic ants both as adults and as nymphs. The biology of this pantropical tribe is almost completely unknown, although one species may become abundant on range grasses in northern South America. It has been speculated that many micrelytrines are grass feeders (on grass seeds?), as are members of the other tribe (Leptocorisini) of Micrelytrinae.

All members of Leptocorisini feed on grasses, as far as is known. Some species (genera *Leptocorisa*, *Stenocoris*) are elongated and are often serious pests on rice in the Old World. Leptocorisines feed on the rice panicles and, when rice of the appropriate stage is not available, rice bugs feed on wild grasses found nearby. These grasses thus serve as a reservoir for the rice pests; some leptocorisines prefer these grasses to rice, however.

Members of Rhopalidae are called scentless plant bugs because all are herbivorous and the external opening of the metathoracic scent gland is small and placed more ventrally (hence harder to see) than are the openings of other bugs. Rhopalids are not scentless, however, and indeed the scents of a few species have been analyzed.

The subfamily Serinethinae (60–65 species, mostly tropical and subtropical) includes the box elder bug (Fig. 9), which in North America sometimes seeks warmth in houses in late fall. Serinethines feed on sapindalian plants and occasionally become minor pests on these ornamental plants. The 150 or so members of the subfamily Rhopalinae are more drab than the red and black Serinethinae, and far more of them occur in the Holarctic region. They feed on a variety of plants and rarely become pests even locally. At least one species has helped biologically control a weed, velvetleaf, in the United States.

![FIGURE 9 Box elder bugs (adult and nymphs), *Boisea trivittatus* (Rhopalidae: Serinethinae). (Photograph by John H. Acorn.)](image2)

Stenocephalidae occurs in the Old World tropics, with a few members in the Paleartic region; the single species on the Galapagos Islands may have been introduced by ship from Africa. Stenocephalids feed on euphorbs, as far as is known. The family is of interest because it possesses certain features of Coreoidea (many) and of Lygaeoidea (ovipositor type, egg type); the phylogenetic significance is unclear.

The three species of Hyocephalidae are all Australian. The family is related to Stenocephalidae, and both families seem to be primitive in the Coreoidea. Little is known of hyocephalid biology except that some occur under stones, where they apparently feed on fallen seeds. Both stenocephalids and hyocephalids are relatively large (8–15 mm long) and slender.

Pentatomoida is a well-defined superfamily, although there is some disagreement (not to say confusion) about the higher classification of the groups within: some heteropterists treat some groups as tribes, subfamilies, or even families, and others treat them differently. The taxonomic limits of Pentatomoida are clear and agreed upon; and there is general agreement that the various tribes, and so on, are indeed worthy of supra-generic rank; the level of that rank is sometimes argued. A forthcoming catalog of the largest family, Pentatomidae (by D. A. Rider), will help settle some of these questions.
In general, pentatomoids are larger than many other bugs. Most (but not all) have five-segmented antennae (hence the name); most other heteropterans have four. Most are also wider than many other heteropterans, and, ranging in length from about 4 to 30 mm, many pentatomoids appear somewhat "squat." Quite a few are very brightly colored. All except one subfamily (Pentatomidae: Asopinae) are herbivorous; the superfamily contains general feeders and quite host-specific ones. Within both groups are some serious pests of crops, and asopines have shown some success in biological control.

The largest family, Pentatomidae, whose approximately 4500 species make it slightly larger than Lygaeidae (in the old sense, as discussed earlier), occurs abundantly throughout the world. One species, the southern green stinkbug, Nezara viridula, is cosmopolitan, feeds on just about anything green, is a major pest in some areas and a minor one in many others, and in Asia has several striking color varieties. This species has been so widespread for so long that its place of origin remained unknown until recently: it probably arose in or near Ethiopia.

The subfamily Asopinae is predaceous, a fact easily recognized by its members' short stubby beak, well designed for stabbing into prey. Asopines are useful in biological control, and one (Perillus bioculatus) specializes on the Colorado potato beetle and related chrysomelids; the red of this bug is derived from ingested pigment of the beetle prey. However, quite a few are brightly and contrastingly colored and are presumably aposematic. Many pentatomids live on tree trunks and indeed may be the most common group of herbivorous bugs to use this habitat; it is not clear what they feed on, perhaps mosses and other epiphytes and perhaps (occasionally) these bugs can penetrate through to the tree's cambium.

Most pentatomoids are somewhat broad and flattened, but some (like the grass feeders) are more or less elongated. Some members of Podopinae are almost globose and may bear thornlike spines dorsally (see also Cyrtocoridae).

Various degrees of parental care have arisen in this family (or have been retained from parentally caring ancestors; the point is controversial) and in other pentatomoid families (and elsewhere, rarely). For the most part, this care protects eggs and early instars from parasitism and predation. In many species, however, this effort denies the female an opportunity to feed and, as a result, she produces fewer eggs or batches of eggs than her less caring sisters. The significance of this trade-off remains to be worked out for most species.

Scutelleridae contains 400–500 species in which the scutellum is greatly extended to cover the abdomen (hence the common name, shield bugs); these bugs range from 5 to 20 mm in length and are somewhat more globose than pentatomids (although some of the more spectacular ones are broadly elongate). Several species are brilliantly colored (one genus is Chlropsocoris, or golden bug), either in solid sometimes iridescent colors (blues, violets, reds) (Fig. 11) or in bold patterns of spots and stripes. These are among the most beautiful of heteropterans and, in some cultures, considered to be among the most tasty. Most however are drab brown or tan, the color sometimes patterned.

Despite their relatively large size and often striking appearance, shield bugs remain poorly known biologically, and very poorly known ecologically. The females of a few care for their young, as do those of a few other pentatomid families. All scutellerids are herbivorous, and a few are pests of several crops. One group is particularly important. Several species of Eurygaster are very serious pests of small-grain crops in a broad swath from eastern Europe through the Middle East (where they are the most serious) into eastern Asia. In the spring, these Sunn pests move from upland wild plants down to the fields with the young grain; there they feed first on the young shoots and then on seeds. In late summer or early fall, they move back into the hills and mountains, sometimes undertaking a trip of many miles. Crops may be completely destroyed over a very large expanse.
The family is represented throughout the world, but members of each of the four subfamilies are concentrated in different continents, with a few representatives in one or two other continents (the historical biogeography of the family is needed; the pretty ones are all tropical or subtropical).

Acanthosomatids (Acanthosomatidae; there is no common name) look much like pentatomids, but are somewhat larger (7–20 mm long) and more elongated. Their tarsi have only two segments, and the bugs have several other advanced features. The latest revision (1974) recognizes about 45 genera; there are about 200 species, although no one has listed or cataloged them. As far as is known, acanthosomatids feed on woody plants (trees and shrubs). Maternal care by the females of several species has been thoroughly studied; as in Pentatomidae, protection is provided eggs and early instars against predators (chiefly ants) and parasitoids; the body-jerking and wing-fanning movements are so strong that small predators may actually be hurled from the leaf.

The 250 species of Tessaratomidae are in general larger (15–26 mm long), and paleotropical (a few species in neotropics) (Fig. 12). The second abdominal spiracle is exposed, and a projection from the mesosternum extends anteriorly sometimes beyond the tip of the beak. One tessaratomid, the bronze orange bug (Musgraveia sulciventris), is a frequent pest on citrus in Australia.

Possibly related to this family is Dinidoridae, whose 85–90 members are also large (10–30 mm long) and robust, and whose distribution is roughly that of Tessaratomidae. Here too the second abdominal spiracle is exposed (although this may in both families be somewhat covered). Their smooth bodies, flattened heads, and strong forelegs are adapted to digging; so also probably is the coxal "comb" (not a "cox-trum"), an array of stout setae perhaps used for cleaning soil particles from the antennae. The foretibial spur or one subfamily (Scaptocorinae) are greatly developed for digging. There are four subfamilies: Sehirinae (60 species), Thyreocorinae (5), Corimelaeninae (200), and Parastrachininae (2). All live above ground. Females of the Sehirinae and Parastrachininae care for their eggs and early instars. The Thyreocorinae and Corimelaeninae have sometimes been grouped as a single family; and the two Parastrachia species are large and brightly red and black and have recently been elevated to family rank.

The remaining 350 species are subterranean, feeding on roots. They may at times become serious, although localized, pests of both crops and rangeland grasses.

Cydnidae may be phylogenetically close to the "base" of the Pentatomoidea and may also be related to the group of small families described next.

Within the Pentatomomorpha is a number of small families, mostly restricted to the neotropics [Cyrctocoridae (11 species), Canopidae (8), Megarididae (16), Philocoridae (3)] or to Australia [Aphylidae (2 species), and Lestoniidae (2)]. Plateaspidae (500 species, a very rough estimate) is primarily paleotropical, but a few species occur in the Palearctic region. Characteristic of many of these families are small size and a rounded globose body, with forewings and/or scutellum enlarged (and often ornamented) to cover the entire abdomen. The cyrtocorid scutellum bears a stout impressive spine. Some (all?) may be related to Cydnidae and to Scutelleridae and as, Schuh and Slater say, the phylogeny and biogeography of these groups need to be worked out. Of phylogenetic importance too is the primitive family Thaumastellidae, whose few members live in southern Africa.

**Aradimorpha** This infraorder contains two families, Aradidae (1800–2000 species, worldwide) and Termitaphididae (9 species, pantropical). These families were included in Pentatomomorpha, from which Aradimorpha probably evolved.

Aradimorphans are very flattened, and (most striking) their feeding styles are very long, very narrow, and stored coiled within the head. Termitaphidids are small (2–3 mm long), wingless, eyeless, and ovipositorless; they live in termites' nests and probably feed, like aradids, on fungal mycelia.

Most flat bugs (Aradidae) are larger (3–11 mm long) and live under the bark of dead or dying trees, a habitat to which their flat body and shortened legs and antennae fit them; other aradids live in the litter of the forest floor; and a few live in termites' nests, or vertebrates' burrows. All these places are closely confined and thus both temperature and humidity vary little, conditions conducive to the growth of fungi, within whose long tubular mycelia the flat bugs feed. This way of life is unique to aradids, which have successfully exploited it (as witness the many aradid species).

One species is an exception: Aradus cinnamomeus (actually, a three-species complex) feeds on the circulatory tissues of living pines (and occasionally Larix), and in central and eastern Europe can become a serious pest. Some other aradids also may feed on tree fluids, but the frequency of such feeding, the number of species that so feed, and the phylogenetic significance of such feeding are all unexplored.
Protura

Markus Koch
Freie Universität Berlin, Germany

The Protura are a group of minute, almost unpigmented soil arthropods (Fig. 1). With a body length of merely 0.2–2.6 mm in adult size, they inhabit moist crevices within soil, predominantly forest humus, but also leaf litter, moss, and occasionally rotting wood, where they probably feed on fungal mycelia. Apart from the eventual hardened, yellowish pigmented body parts, living specimens are nearly translucent and peristaltic movements of the gut can easily be observed. Living specimens also perform characteristic movements with the abdomen in that the small postabdomen is recurrently invaginated into the preabdomen, probably for the purpose of ventilation. These regular ventilatory movements of the postabdomen become especially rapid when the animals are stressed and attempt to escape from a threat.

Proturans are distinguished from all other hexapods by an extraordinary set of unique features. They resemble insects in their tagmosis, but each tagma shows distinctive modifications (Fig. 2A–H). The proturan head has the insect-type set of mouthparts (mandibles, first maxillae, and a labium formed by medially fused second maxillae) but with neither eyes nor antennae (Fig. 2F). The thorax is composed of three segments, each bearing one pair of walking legs, but the anerionmost pair is usually carried forwards above the head and equipped with numerous sensilla as if to replace the antennae functionally. The apparent substitution of the antennae by the forelegs correlates with a backward shift of the head onto the prothoracic segment, which therefore is hardly recognizable in at least dorsal view. Proturan locomotion is accordingly mainly “tetroaped” and usually slow although the forelegs, which are still equipped with unpaired pretarsal claws, can be used in locomotion, as when climbing through fungal mycelia or moss and escaping predatory threats. The abdomen is composed of eight large segments (preabdomen) followed by four conspicuously smaller segments (postabdomen). The 12-segmented abdomen accordingly seems to be one segment longer than in all other hexapods (Fig. 2G and 2H). The segmental nature of the ultimate abdominal segment, however, has not yet been confirmed. The alleged twelfth abdominal segment is sometimes considered to represent an unusually large nonsegmental “telson”, which in all other hexapods merely forms minute selerites (“laminae anales”) around the anus, if at all. This alternative view is supported by the postembryonic development of the abdomen, during which three penultimate segments are formed in front of the “telson” (or ultimate segment). This anamorphic development of the Protura is unique among hexapods. The same holds true for vestiges of leg-derived appendages on the first three abdominal segments (Fig. 2B and 2D), which primarily are still segmented and distally taper off into an eversible vesicle. The sternites and leg-bases of the appendicular vestiges on the first three abdominal segments remain clearly separated, whereas in the “cerci-bearing hexapods” (Cercophora, i.e., Diplura and Insecta) they consistently fuse and form so-called coxosternites.

ENVOI

Heteroptera not only comprises the most species of any hemimetabolous group (except perhaps the paraphyletic “Homoptera”) but contains the most biological, structural, and ecological diversity. It is a measure of this diversity, this evolutionary versatility, that so many ecological niches are filled by bugs. From the Alaskan cold to the webs of embiids to the bottoms of streams and the surface of the sea, and to the beds of people, heteropterans live where few other insect groups (and no other hemimetabolans) occur. Moreover, a vast number of heteropterans remain to be described, many from unusual habitats (tree canopies, leaf litter); and the biologies of most heteropterans remain to be worked out. The diversity we see, although great, is less than the diversity to be discovered. Why this group of insects should be so diverse cannot be answered here. But that it is so diverse explains the group’s great and continuing fascination.

Protura

FIGURE 2 Morphological characteristics of the Protura exemplified by Eosentomon sp. (Eosentomidae: A–B, F–H) and Acerentomon sp. (Acerentomidae: C–E). (A) Ventral view of a typical eosentomid head, showing entognathy, linea ventralis (lv), and reduced palps of the first (mxp) and second (lp) maxillae. (B) Ventral view on an eosentomid preabdomen, showing segmented vestiges of appendages (arrows) on the first three abdominal segments. (C) Ventral view of an acerentomid head, showing the labrum prolonged to a rostrum. (D) Ventral view of an acerentomid preabdomen, showing two-segmented appendicular vestiges on the first abdominal segment and short, unsegmented appendicular vestiges on second and third abdominal segment. (E) Dorsolateral view on eighth abdominal segment, showing the opening of the abdominal defensive glands (ogl) covered by a pectinate lid. (F) Lateral view on an eosentomid head and thorax (left prothoracic leg L1 removed), showing position of the cephalic pseudoculus (po) and spiracles on the laterotergites of meso- and metathorax. (G) Dorsolateral view on an eosentomid postabdomen, showing the smaller ultimate segments (t9–t11) followed by a segment-like “telson” (te). (H) Frontal view on the postabdomen, showing the transverse opening of the genital chamber (ogc) and the terminal, transverse slit forming the anus (an). Abbreviations: an, anus; L1–3, locomotory legs on thoracic segments 1–3; lv, linea ventralis; lp, labial palp; mxp, maxillary palp; ogl, orifice of genital chamber; po, pseudoculus; ro, rostrum; s1–11, sternites of abdominal segments 1–11; sp, spiracle; t8–11, tergites of abdominal segments 8–11; te, “telson.”

Thoracic leg L1 removed, showing position of the cephalic pseudoculus (po) and spiracles on the laterotergites of meso- and metathorax.

FIGURE 3 Consensus tree inferred from 52 morphological characters depicting the relationships among the ten currently recognized families of the Protura. The three main subgroups according to current classification are highlighted in gray. Numbers in brackets refer to the number of species described thus far (compiled by Andrzej Szeptycki, Institute of Systematics and Evolution of Animals, Polish Academy of Science; see http://www.isez.pan.krakow.pl). Asterisks indicate families that may not represent monophyletic groups.

The apparent primitiveness of the abdomen relative to the states in remaining hexapods forms the name-giving character of the Protura (“primitive-tails”). Their relatedness to insects, however, has repeatedly been questioned and still is doubted. Upon their discovery and first description by Filippo Silvestri in 1907, proturans were considered as intermediate forms between myriapods and insects and were therefore classified by Anton Berlese in 1909 as “Myrientomata.” Traditional phylogenetic hypotheses recognize the Protura as sister group of the Collembola (Ellipura-hypothesis) based on the shared absence of caudal appendages (name-giving character), a corresponding entognathous state of the mouthparts, and the presence of a cephalic longitudinal groove called linea ventralis (Fig. 2A and 2C), along which secretions of the salivary glands and/or labial kidney pass backwards toward the cervical region. In the light of a crustacean origin of hexapods, the Ellipura-hypothesis gains additional support from the presence of paired lateral sense organs on the head capsule (postantennal organ in Collembola, pseudoculus in Protura: Fig. 2F) that are innervated by the protocerebrum. Molecular data instead currently favor a sister group relationship between Protura and Diplura (Nonoculata-hypothesis). Apart from the absence of eyes (name-giving character), this clade is usually stated to have no unambiguous morphological support. The following correspondences of the Protura and Diplura are nevertheless remarkable: the first immature instar (hatchling) is an immobile, nonfeeding prelarva (pupoid stage); mandibles are primarily denticulate and devoid of a molar plate; the thoracic sterna primarily form Y-shaped apodemes; Malpighian (excretory) organs, when
present, are differentiated as short papillae; and the gonopores show a corresponding segmental (or intersegmental, respectively) position in both sexes. Current embryological and some ultrastructural data, in contrast, still raise doubts on whether proturans are most closely related to hexapods at all.

Proturans are distributed worldwide and seem to be lacking at the polar regions only; a faunistic overview is presented in Szüptycki (2007). About 750 proturan species have been described thus far and assigned to ten (or seven, respectively) families (Fig. 3). By far the most species-rich and abundant genus is *Eosentomon* (Eosentomidae), followed by *Acerentulus* (Berberentulidae) and *Acerentomon* (Acerentomidae).

**COMPARATIVE ANATOMY AND CLASSIFICATION**

The monophyly of the Protura is supported by plenty of unambiguous apomorphies. Apart from the absence of antennae, most noteworthy are (1) the relatively small size of the head (microcephaly) that anteriorly tapers off into a narrow, immobile labrum; (2) the enigmatic head endoskeleton (fulcro-tentorium); (3) the position of the tracheal spiracles on thoracic nota; (4) the presence of abdominal defensive glands; (5) the formation of a genital chamber housing external genitalia; and (6) the structure of the spermatozoa.

The microcephalic state of the head seems to be correlated with a sucking mode of food uptake. Although details on feedings habits are still unknown, the pipette-shaped head can be assumed to optimize the uptake of scratched-off particles or fluid food. The head endoskeleton is largely cuticular and resembles the X-shaped corpotentorium of pterygote insects. The prelarval stage demonstrates that it is formed by paired cuticular rods that arise next to the mouth opening. In subsequent stages, these rods are coalesced and form an X-shaped "fulcro-tentorium." The homology of its components to paired anterior and posterior tentorial apodemes in remaining hexapods is likely but still disputed.

Meso- and metathorax are the only body segments that primarily have one pair of spiracles each, but they are not located within the pleuron as commonly found in the cerci-bearing hexapods (Diplura and Insecta), but are located mid-laterally on the tergites (Fig. 2F). Subgroups of the Protura are characterized by the loss of the tracheal system.

Paired abdominal defensive glands of variable size are dorsally located in the preabdomen and open to the exterior via a more or less conspicuous orifice at the hind-margin of the eighth abdominal segment (Fig. 2E and 2G). These glands seem to compensate the relatively slow "tetrapod" movements by the production of repellents that efficiently act as a deterrent to at least predacious mites.

In both sexes, external genitalia, the so-called *squama genitalis* (putative copulatory organ in males, ovipositor in females), are formed within a genital chamber that opens to the exterior through a transverse slit between the eleventh abdominal sternum and the "telson" (Fig. 2H). Comparative musculature studies support the view that the proturan external genitalia are formed by the ninth abdominal segment, but their appendicular nature and homology with insect genitalia still remain unclear.

Flagellate spermatozoa show a strikingly variable axenomal pattern in proturans, but a common, distinctive feature of the axoneme is the absence of central microtubules (9 + 0 to 14 + 0-patterns). Many species show spermatozoa devoid of a flagellum, which is generally considered to be due to convergent loss.

Present uncertainties on proturan interrelationships, however, hardly permit final conclusions on character evolution within the Protura. Cladistic analyses of proturan phylogeny are still in the very beginning. Three major subgroups are currently distinguished (Fig. 3), among which the Sinentomata are particularly interesting for combining characteristics of both Eosentomata and Acerentomata.

The Sinentomata (or *Eosentomoidea*) uniquely share lens-like pseudoculi with a central foramen and are further characterized by flagellate spermatozoa and elongate maxillary glands that extend into the thorax, by defence gland orifices with inconspicuous lids (Fig. 2G), and by details of their external genitalia. Most species of the Sinomatanata maintain denticate mandibles (except *Styletoentomon* with stylet-shaped mouthparts), a tracheal system with paired spiracles on the meso- and metathorax (except the Chinese *Antellentomon*, sole genus of the Antellentomidae), complete Y-shaped apodemes on the thoracic sternum, and segmented leg-derived appendages with terminal eversible vesicles on all of the first three abdominal segments.

Among the remaining proturans, dentine mandibles and a tracheal system are only present in the East-Asian *Sinentomon* species, whereas three pairs of segmented abdominal appendages are maintained in the East-Asian *Fujientomon* species only (as well as in some *Hesperentomon* species). *Sinentomon* species are unique among the Protura in having no cephalic lineae ventralis. Based on features of the flagellate spermatozoa and the presence of striated pseudoculi, among others, the Sinomatanata and Fujientomidae were united in the Sinomatanata, but this classification is not supported in current cladistic analyses. The structure of the pretarsal claws of the walking legs and a transverse, variably striated cuticular band on both tergum and sternum of the eighth abdominal segment indicate that the Sinomatanata and Fujientomidae form a presently unresolved unit with the Acerentomata.

Molecular analyses, in contrast, retrieve the Sinomatanata as a basal grade leading to a unit composed of Eosentomata and Acerentomata.

Members of the Acerentomatida (or *Acerentomoida*) generally have pointed or stylet-shaped mouthparts and share a special type of pseudoculus with a posterior foramen, incomplete or missing sternal apodemes on the thoracic segments, unsegmented appendages devoid of eversible vesicles on at least the third (and in some subgroups also the second) abdominal segment (Fig. 2D), and conspicuous, more or less pectinate lids ("combs") roofing the orifice of the abdominal defensive glands (Fig. 2E). Compared to Eosentomata and Sinomatanata, acerentomoid proturans seem to be plesiomorphic in maintaining flagellate spermatozoa in most of the subgroups. The interrelationships among the acerentomoid subgroups still largely remain unclear, since some of the traditionally recognized families seem to have no unambiguous morphological support.

**BIOLOGY**

Information on proturan biology is still scarce, since attempts to rear proturans under laboratory conditions succeeded just a few years ago (see Machida, 2006). The insemination mode remains unclear, but a direct sperm transfer is likely as males produce no spermato- phores. The egg period (embryogenesis) of *Baculentulus densus* (Berberentulidae) was estimated to take about 2 months, but might be shorter in other species. Hatchlings (prelarvae) are in a resting stage and show depanerate mouthparts and walking legs as well as only nine abdominal segments (or eight segments plus "telson"). The subsequent postembryonic stages comprise three mobile and feeding immatures that consecutively add abdominal segments in front of the ultimate segment (or "telson"): larva I keeps 9 abdominal segments,
larva II shows a 10-segmented abdomen, and larva III (maturus junior) the full set of 12 abdominal segments as in the adult. Full maturity is generally achieved after the molt of the maturus junior except for male acrerynomids that include a short stage termed preimagno with incomplete genitalia. It is not known whether adult proturans still molt. The postembryonic development takes about 3–5 months, and some proturans accordingly show more than one generation per year. Parthenogenetic species have been recorded as well.

Proturans reared under laboratory conditions recently confirmed that fungal mycelia, especially mycorrhiza, form their main food source. In forest humus, proturans may be amazingly abundant and show population densities up to 90,000 individuals per square meter. Some species are equally abundant at depths of about 25 cm below the humus level.

**COLLECTING AND SPECIMEN PREPARATION**

The most efficient collecting technique for proturans is their extraction from soil samples by Berlese-Tullgren (or Kempson) apparatus. Because of their small size, specimens preserved in 75% ethanol need to be studied by a compound light microscope for proper species identification. The most important taxonomic characters refer to the chaetotaxy and forelegs, but the shape of the mouthparts, modifications of the maxillary gland canal (Filamento di Sostegno), the pseudoculi and abdominal appendages, as well as the female external genitalia may be likewise relevant to distinguish the species. Determination keys and diagnostic descriptions of all proturan genera known thus far were compiled by Nosék (1978). North-American genera can readily be identified with the keys provided by Copeland and Imadate (1990). An online catalogue of all known valid species, including synonyms, is regularly updated by Andrzej Szeptycki (Polish Academy of Sciences).

**Psocoptera**

( Psocids, Booklice )

Edward L. Mockford

*Illinois State University*

Psocoptera (Corrodentia, Copeognatha) constitutes an order of neopterous, exopterygote insects commonly called psocids, barklice, or booklice. Their closest relatives are the Phthiraptera or true lice. Psocids are small and soft-bodied and therefore have received little attention from collectors. Only recently, when several dozens of species have been found in stored products, and the tropical forests have proved to harbor a highly diverse fauna, has greater interest been focused on this group.

**FIGURE 1** Psocid, *Graphopsocus cruciatus*. (Photograph courtesy of Ken Gray Collection, Entomology Department, Oregon State University.)

**EXTERNAL ANATOMY**

Adult psocids range from about 1 to 10 mm in body length. Most adults are fully winged with the forewings longer and more complexly veined than their hind wings (Fig. 1). The forewings at rest generally exceed the tip of the abdomen. Antennae are long and slender, in the larger forms tending to be longer than the body. The head is rounded with compound eyes often large and bulging but sometimes greatly reduced. The postclypeus (Fig. 2) is usually swollen to accommodate the well-developed corialial pupal muscles. Often the postclypeus bears pigmented chevron marks (Fig. 2) indicating the attachment points of these muscles. Mouthparts are of the chewing type with large, well-developed mandibles. The maxilla contains an elongate, slender lacinia. The hypopharynx includes structures unique to these insects that are important in maintaining water balance. In fully winged forms the thorax is frequently reduced while the meso- and metanota are swollen to accommodate the flight muscles. Wing venation tends to be relatively simple. Legs tend to be slender, with the hind femur somewhat swollen in some forms, allowing short hops or initiation of flight by jumping. In the small booklice of the genus *Liposcelis* (Fig. 3), the greatly swollen hind femora are thought to facilitate the ability to change course rapidly and crawl backward. In many winged adult psocids, the hind coxae each bear a rasp and tympanum: the two structures together are called the coxal organ. This is thought to be a stridulatory organ, although as yet no sound has been detected from it.
slit through which it exits. Immediately it molts again, casting off the nymphal exuviae (the cast cuticle), which remain partially caught in the exit slit of the egg.

Eggs of some species undergo a winter diapause and in the Northern Hemisphere this is brought about by the mother’s perception of decreasing day length in late summer.

Nymphs undergo five to six instars, requiring 4–6 weeks to reach maturity. Adults remain teneral for a day or two prior to engaging in sexual activity. Females of some sexual species produce a sex pheromone that, at a short distance (1–2 cm), brings about immediate, rapid search behavior in mature males—invoking them running about and vibrating their wings. This reaction may be elicited by a piece of substrate on which an “advertising” female has been standing or even by the tips of a pair of forceps that have just held such a piece of substrate. Behavior after contact is tremendously varied. Frequently a male “antennates” a female, that is, touches his antennae to hers and then crawls over her back and forces himself under her body from in front. The copulatory structures then grasp together, after which the male may stay under the female or move—180° to face opposite the female (suborder Trogiomorpha) or back on top of the female (family Lachesillidae). Copulation lasts only a few seconds in many groups of the suborder Psocomorpha, although in the genus Lachesilla it generally requires some 35 min. In the suborder Trogiomorpha, it may last up to 2 h during which individual sperm pass through the slender spermathecal duct, then clump together, and become enclosed in “spermatophores” in the spermathecal sac. This is probably the sequence of events in any form in which the spermathecal duct is slender and spermatophores are seen in the spermathecal sac.

Oviposition may start within a day or 2 of copulation. Under favorable conditions, oviposition may continue over a period of 2 months.

**EVOLUTION TOWARD NEOTENY**

Although most adult psocids are fully winged, a variety of levels of wing reduction are seen throughout the order. Associated with wing reduction are reductions in several other structures: compound eyes, ocelli, paraproctal sensorium, and ctenidia (comb-based setae) of the basal hind tarsomere. The resulting adult appears nymph-like in these characters, and these changes can thus be regarded as neotenic. Several patterns of change are seen, which can be summarized as completely wingless, Liposcelis (Fig. 3); with very short scale-like or button-like wings, Trogium, Cerobassi; wing development variable in both sexes, Rhyopsocus, Lachesilla (some species); with sexual dimorphism in wing development and males wingless or nearly so, females variable in wing development, Enubidosocus, Psoquilla, Archipsocus; sexual dimorphism and males fully winged, females variable in wing development, Periposocus (some species), Valenzuela (some species); and sexual dimorphism with males fully winged, females wingless or nearly so, Camelopsocus, Mesopsocus (most species), Reuterella, Lachesilla (some species; Fig. 4). Except for the first two categories, these reductions have occurred repeatedly in the evolution of the order. Thus, they appear to offer advantages in energy conservation and keeping the organism closely associated with its habitat.

**HABITATS AND FEEDING PREFERENCES**

Psocids live in a great variety of habitats, including living leaves, especially of monocotyledonous plants and conifers; dead foliage of all plants, both hanging and in ground litter; trunks and branches of trees and shrubs (open surfaces and under bark); rock surfaces; and human dwellings. In general, psocids feed on algae, fungi, lichens,
Pterygota

Ring T. Cardé
University of California, Riverside

Vincent H. Resh
University of California, Berkeley

Pterygota is a subclass of the class Insecta of the phylum Arthropoda. It contains two divisions: the Exopterygota and the Endopterygota. Most extant orders of insects are pterygotes.

Puddling Behavior

Scott R. Smedley
Trinity College, Connecticut

Puddling is a behavior in which insects, chiefly adult lepidopterans, drink from mud puddles, moist soil, fluids of vertebrate origin (urine, excrement, blood, sweat, and tears), carrion, and even seawater. Although broadly distributed geographically, puddling is particularly spectacular in the tropics where numerous individual butterflies representing multiple species gather to imbibe from damp river banks. The behavior generally is strongly sex biased, with typically only males participating. Puddling is associated with both the insects’ nutritional ecology and their reproductive biology. In certain moths, the behavior is hereculean, as individuals imbibe several hundred times their body mass in a single drinking bout!

GENERAL BACKGROUND

Both diurnal and nocturnal, puddling is widely distributed taxonomically among the Lepidoptera (≥6 butterfly and ≥12 moth families). Puddling takes place in tropical, temperate, and boreal ecological regions. While observing butterflies puddling in Amazonia in the 1860s, the British naturalist H. W. Bates was first to note that the behavior is strikingly male biased. Subsequently, numerous studies have confirmed that this is generally true, although there are certain species in which females often exhibit the behavior. The exposed, sedentary nature of puddling leaves the drinking insects vulnerable to predation. The dilution effect achieved in large aggregations of puddling butterflies appears to lower individuals’ risk of avian predation. In addition to lepidopterans, nocturnal aggregations of leafhoppers (Homoptera: Cicadellidae), also predominately male, drink from moist soil surrounding puddles.

NUTRITIONAL ECOLOGY

Sodium and protein are substances of physiological importance that are scarce within the foliar diets of insect herbivores. By puddling, adult lepidopterans augment their herbivorous larval intake of these limited materials. Since the 1910s, beginning with the British entomologist E. B. Poulton, there was speculation that puddling
might allow lepidopterans to obtain sodium. The demonstration in the 1970s that sodium was a necessary stimulus to evoke puddling in the tiger swallowtail (*Papilio glaucus*) supported this notion. In the 1990s, it was established that puddling indeed leads to sodium uptake: while drinking from mud puddles, the notodontid moth *Gluphisia septentrionis* showed a gain of sodium, matched evenly (on a molar basis) by a loss of potassium, a plentiful mineral in the larval diet and consequently in the adult body.

Puddling, however, is not simply a means of sodium acquisition, but can further lead to uptake of nitrogenous nutrients. Drinking from moist soil laced with labeled amino acids, tiger swallowtails incorporate these compounds. For tropical butterflies, representatives of certain families (Papilionidae and Pieridae) preferentially visit sodium sources, while members of other families (Lycaenidae, Nymphalidae, and Hesperiidae) typically prefer a protein source, suggesting that nutritional needs may vary among taxa. Species-specific preferences of temperate montane butterflies for puddling substrates of varying sodium (and presumably protein) content further bolster this idea.

### REPRODUCTIVE BIOLOGY

Puddling is linked to lepidopteran reproduction and possibly other physiological activities. Through puddling, the male *G. septentrionis* sequesters nearly 20 μg of sodium, approximately half of which is converted nuptially to the female via the spermatophore. About 5 μg of the transferred sodium is incorporated into the eggs. A nuptial transfer of sodium is also known from the European skipper (*Thymelicus lineola*), another puddling species. In this butterfly, there is apparently no endowment of eggs with male-derived sodium, but access to the mineral does enhance male mating success. No studies have directly examined whether male Lepidoptera contribute puddle-derived amino acids to their mates. However, such a bestowal is quite plausible, given that males of certain non-puddling lepidopterans transfer amino acids via the spermatophore. The observed relationship between paternal consumption of an amino acid solution and increased egg viability in the tiger swallowtail may reflect such a nuptial transfer.

Beyond reproduction, other potential functions (e.g., neuromuscular activity) of puddle-derived sodium are receiving attention. A comparative study of the nymphrid genus *Charaxes* showed that certain species are attracted to sodium and puddle intently, yet produce spermatophores with relatively little sodium. A morphometric analysis of riodinid butterflies revealed a positive correlation between species' metabolic costs associated with flight and the tendency of their males to puddle.

### EXTREME PUDDLING BEHAVIOR

When puddling, a number of lepidopteran species pump fluid through the digestive tract, emitting droplets from the anus. This behavior is displayed in extreme form by the male *G. septentrionis*, which forcibly releases anal jets at approximately 3-s intervals while imbibing from puddles. In this insect’s quest for sodium, drinking often persists for hours, resulting in the passage of immense volumes that constitute over 600 times body mass (Fig. 1). Coupled to this behavior is a sexual dimorphism of the ileum (anterior hindgut). The male’s ileum is longer and wider than that of the non-puddling female. Numerous villi are present in the male ileum, but are virtually absent in the female’s. Thus the surface area of the male ileum is nearly 20 times that of the female, making this enteric region a likely site for the observed sodium absorption.

A pupa is the stage in the development of holometabolous insects between the mature larva and the adult wherein major morphological reorganization takes place. Pupation usually occurs in a protected location (in a cell or cocoon), but in some groups, such as many butterflies, the pupa (chrysalis) is suspended openly and is usually well camouflaged by its shape and color.

There are two basic kinds of pupae, exarate (Fig. 1) and obtect (Fig. 2). An exarate pupa has free appendages. An obtect pupa has the appendages adhering to the body wall. Most Lepidoptera, most lower Diptera, some chrysomelid and staphylinid beetles, and many chalcidoid Hymenoptera have obtect pupae; nearly all other pupae are exarate.

**BEHAVIORS**

Most pupae are inactive, their body movements often limited to the abdominal segments. However, pupae in some groups are capable of locomotion, and some have functional mandibles that enable them to cut their way out of the pupal cell, cocoon, or chamber. These active pupae are sometimes referred to as pharate adults because the adult is enclosed in the pupal cuticle.

**DESCRIPTION**

Pupae may have articulated mandibles (decticous) or nonarticulated mandibles (adecticous). Decticous pupae are capable of chewing their way out of cells or cocoons and may be active. They occur in the Mecoptera (scorpionflies), Megaloptera (dobsonflies and fishflies), Neuroptera (lacewings, antlions, and relatives), Raphidioptera (snakeflies), Trichoptera (caddisflies), and primitive Lepidoptera (Micropterigidae).

In the higher Diptera (Muscomorpha: Schizophora), the exarate pupa (also called a coarctate pupa) is enclosed in a delicate membrane within the hardened and barrel-shaped last (third) larval skin termed the puparium (puparia) (Fig. 3), which surrounds and protects the pupa. The adult fly emerges by forcing the end of the puparium off with the ptilinum, a membranous eversible pouch between the eyes and above the antennae that is expanded outward by blood pressure from the abdomen and thorax. After emergence, the ptilinum is withdrawn into the head, resulting in the frontal suture that arches over the antennae. If the puparium is buried in the soil, the ptilinum may also be used to help the adult fly crawl or force its way to the surface.
A prepupa is the last instar that has completed feeding. It may wander in search of a pupation site, but generally it becomes nonmobile before pupation. It is easily observed in Lepidoptera, wherein the mature larva becomes shortened and the prolegs and crochets become progressively retracted before pupation.

**FIGURE 3** Puparium of a higher fly, formed from the last larval skin, showing the larval spiracular scars and pupal spiracular prongs that anchor the exarate pupa within (dorsal). [From Peterson, A. (1948). “Larvae of Insects,” Vol. 1. With permission of Jon A. Peterson.]
The Raphidioptera is a small order of winged, holometabolous insects. Adults (Fig. 1) have an elongate pronotum and two pairs of subequal wings of about 5–20 mm in length. Females have an elongated ovipositor. Larvae (Fig. 2) are terrestrial, living under bark or in detritus, and have biting mouthparts. Pupae are decticous (with articulated mandibles).

Raphidioptera is presumed to be the sister group of Megaloptera/Neuroptera and comprises two families: the Raphidiidae with 200 described species and the Inocelliidae with 25. The Raphidioptera is distributed throughout the Holarctic region, except for the northern and eastern parts of North America; the southernmost records are from Mexico, northwest Africa, northern India, Indochina, and Taiwan. They are restricted to woodland habitats and occur in almost all Holarctic types of forests and forest-like habitats. In southern parts of their distribution, they live mainly at high altitudes, up to about 3000 m.

HISTORY OF RESEARCH

Snakeflies first appear in the literature in 1735, when Linnaeus described an insect that he called Raphidia. By 1800 only three species had been described; in the 19th century, snakeflies were known from southern Europe, Anatolia, and North America and, by the beginning of the 20th century, also from northern and central Asia and from northern Africa. By 1900, 31 species were known; in 1950, there were 60. At the beginning of the 1960s, a worldwide search for snakeflies and revision of the order was started and more than 150 species were discovered and described between 1960 and 2008. Many species were reared from the egg, so that preimaginal stages and biologies of the majority of species are documented.

CHARACTERIZATION

An extremely flexible head characterizes the adults. It is prognathous, elongate, flat, and strongly sclerotized and may be broad or tapering basally. The large compound eyes are situated laterally. Inocelliidae lack dorsal ocelli. The mouthparts are of the biting type. The prothorax is remarkably elongated, particularly in Raphidiidae, and very mobile (hence the common names snakeflies and camel-neck flies). All three pairs of legs are similar and cursorial. Both pairs of the elongate subequal wings are membraneous, and the venation is simple with few crossveins. The abdomen consists of 10 (visible) segments. Terminal sclerites constituting the external genitalia are extremely complex in males; in females they are equipped with a long ovipositor.

The larvae are elongate and flattened, with a prognathous head, biting mouthparts, and five to seven lateral stemmata. The head and the only moderately elongate prothorax are strongly sclerotized, and the 10-segmented abdomen is of soft consistency.
BIOLOGY

Adult Raphidiidae are day-active entomophagous insects, preying on soft-bodied arthropods and pollen; the natural food of Inocelliidae is virtually unknown, but in captivity they feed on artificial diets and pollen has very rarely been found in their gut. All stages of larvae of both families are entomophagous, feeding on a variety of soft-bodied arthropods; the spectrum of prey is, however, considerably different in bark-inhabiting larvae on one hand and in larvae living in the soil on the other.

There is a long courtship before mating, including a highly sophisticated cleaning behavior with legs and antennae. Two positions of copulation have been observed: a “dragging position” in Raphidiidae, in which the male hangs head first from the female and is carried by her, and a “tandem position” in Inocelliidae, in which the male crawls under the female attaching his head in fixed connection to the fifth sternite of the female. Copulation lasts from a few minutes to 1.5 hours in Raphidiidae, but up to 3 hours in Inocelliidae. Spermatophores have been observed and studied only in Raphidiidae.

The egg stage lasts a few days to 3 weeks. The number of instars varies around 10 to 11 and may reach 15 or more. The larval period lasts 1 year in a few species, in most species it is 2 or 3 years, and under experimental conditions it may be up to 6 years. The prepupal stage lasts a few days. In the majority of species, pupation takes place in spring and lasts a few days to 3 weeks. In some species pupation starts in summer or autumn and the pupal stage lasts several (up to 10) months; in a few others pupation starts in summer and adults hatch in late summer after a short pupal stage. Hibernation thus usually takes place in the last larval stage, the penultimate stage, or the pupa, but never as eggs, prepupae, or adults. The pharate adult (the active pupa) is very mobile.

Snakeflies need a period of lowered temperature (usually around ≥0°C) to induce pupation or hatching of the imago. Larvae that are continuously kept at room temperature will usually not pupate but become prothetelous, i.e., they develop pupal or imaginal characters, such as compound eyes, wingpads, and appendages on the abdomen, and may live for years.

Parasites, parasitoids, and hyperparasites are a frequent phenomenon among Raphidiidae. Hymenoptera are of considerable significance as parasitoids of larvae, and species of the genus Nemeritis (Ichneumonidae) comprise 90–95% of them; other ichneumonids, braconids, and chalcidids contribute about 1%.

Snakeflies are effective predators; all larval stages of all species of both families, and at least the adults of Raphidiidae, feed on (mainly soft-bodied) arthropods. Snakeflies are believed to be rare insects. This is true for many species and many regions, but a number of species often occur in large numbers. There have been several attempts to use snakeflies as biological control agents: an unidentifed North American species was introduced in Australia and New Zealand 100 years ago, but did not become established. The use of snakeflies for future biological control efforts is, however, hampered by the long developmental period and narrow food preference of these insects.

DISTRIBUTION AND BIOGEOGRAPHY

Extant Raphidiidae are confined to the Northern Hemisphere and almost exclusively to the Holartic region. In Central America the southernmost records are from high altitudes at the Mexican–Guatemalan border. In Africa snakeflies have been found only in arboREAL regions north of the Sahara, and in Asia the southernmost records are from altitudes above 900 m in transition areas from the Palearctic to the Oriental region in northern India, Myanmar, and northern Thailand. The northern and eastern parts of North America lack snakeflies. Almost all species are restricted to very limited areas of a refuge nature. Only three species represent a Eurosiberian type of distribution occurring throughout northern Asia to central and northern Europe, and a few Neartic species with distribution centers in the southwest have reached Canada.

SYSTEMATICS, TAXONOMY, AND FOSSILS

The order Raphidiida is a relic group of “living fossils” that comprises two extant families and 225 described species.

Taxonomy of adults has been well established. Because shape and coloration of body structures and of wing venation are highly variable, the most powerful and reliable tool is the morphology of the genital sclerites, in particular of the males. Taxonomy of larvae, mainly based on patterns and coloration of the abdomen, still remains difficult because of the similarity of related species.

The fossils lead to the conclusion that there was an enormous biodiversity of Raphidiida in the Mesozoic. The majority of species and genera (in several families) are known from Jurassic and Cretaceous deposits. The rich and diverse Raphidiida fauna of the Mesozoic died out at the end of the Cretaceous, probably due to the K/T event (that is the worldwide catastrophe resulting from an asteroid of about 10 km diameter that hit our planet) 65mya ago and its climatic consequences. In particular, all snakeflies of tropical climates disappeared and apparently only the few representatives adapted to a colder climate survived. Fossil snakeflies from Tertiary layers, as well as from Baltic amber, belong to the two extant families.

Rearing of Insects

Norman C. Leppla
University of Florida

The goal of organized insect rearing is to provide reliable, affordable sources of high-quality insects for their many important purposes. We are now able to rear literally thousands of insect species through multiple generations and many more for part of their life cycles. The greatest difficulty is to provide fresh host material or to develop a diet that is nutritionally complete and induces feeding, especially for predators or parasitoids. Precautions must be taken to start colonies with an adequate number of clean specimens and maintain them with very limited levels of mortality. These measures help to limit genetic bottlenecks caused by inbreeding, contamination with other species, and disease epizootics. As production levels and the number of species increase, rearing must be organized into systems with discrete operations or activities. These operations incorporate the rearing procedures necessary for each stage of the insect’s life cycle plus acquisition and maintenance of supplies, equipment, and facilities. Facilities must be designed and constructed to contain and maintain the insects under specified conditions. Problems encountered in established insect rearing systems invariably are caused by inattention to procedural details or lack of environmental control. For the foreseeable future, advances in insect rearing will be focused primarily on culturing new species, maintaining existing colonies more efficiently, supporting advances in research and pest management, and increasing the use of insects in people’s lives.

PURPOSES FOR REARING INSECTS

Insects are reared for many purposes that may not be obvious to the nonentomologist. Certainly, insects are aesthetically pleasing and, therefore, reared by those who appreciate their many shapes, colors, features, and behavior patterns. This appreciation may be shared by means of personal collections, static displays, insect zoos, butterfly houses, and even household pets. Many of these and similar experiences would not be possible without organized insect rearing.

Insects are reared for a wide range of primarily agricultural and public health research, esthetic, and utilitarian purposes, an increasingly popular example is the release of butterflies at social events. Chemical insecticides are developed by using laboratory colonies of insects to robotically screen massive numbers of candidates, more than 1 million insecticides per year in some instances. Similarly, plants are screened for resistance to insects or the disease organisms they transmit. Nontarget insects and plants are tested as possible hosts before nonindigenous natural enemies are released into nature. Insects have been reared, marked, and released to understand their orientation, dispersal, and migration. The cells of insects are used to study physiological processes, such as reproduction, ontogeny, growth, aging, and cold tolerance. The fruit fly, Drosophila melanogaster, is the “white rat” of geneticists and the nerves of large cockroaches are used by sensory physiologists. Students learn morphology by dissecting lubber grasshoppers, Romalea spp., and other insects reared in the laboratory. A variety of educational subjects involve insect colonies, including the process of insect identification, principles of insect taxonomy and systematics, and engineering aspects of insect flight. A somewhat gruesome but effective practice is the postoperative surgical use of the blow fly maggots, Lucilia sericata and Phormia regina, to maintain clean wounds.

The major use for laboratory-reared insects is in biologically based methods of integrated pest management. One of these methods, biological control, is the rearing and release of parasitoids, predators, and pathogens to suppress pest insects. A global industry has developed to rear and sell these natural enemies (www.anbp.org, www.dfma.ch/). Autocidal control is accomplished using the sterile-insect technique or inherited sterility. Male insects are reproducitively sterilized with gamma-irradiation or chemicals and released by the thousands per hectare to mate with wild females. This ensures that most of the wild females mate with sterile males and do not produce offspring. Inherited sterility is a variation using partially sterile males to induce sterility in subsequent generations. Genetic control takes advantage of altered genes to disrupt the insect’s physiology and behavior. In the near future, we may use mass-reared insects to widely distribute manipulated endosymbionts via paratransgenic strains.

Insects have been reared to enhance wild and domestic populations, particularly for improving their products and benefits. Silk and honey production are obvious examples but pollination and pest management are equally important. Elaborate strain development methods have been used for silkworms, honey bees, screwworms (antocidal control), parasitic wasps (biological control), and others. Field insectary populations of expensive, showy butterflies and beetles have been used to augment natural populations that have become depleted. Eventually, the use of reared insects in conservation may include protection of rare and endangered species and repopulation, as is currently practiced with birds and predators.

KINDS OF INSECTS THAT ARE REARED

Insect rearing may be partial (egg to larva or nymph and adult) or complete (egg to egg). Virtually any free-living insect can be collected as an egg, larva, or nymph and maintained through stages in metamorphoses until it becomes an adult. However, this often requires considerable knowledge about the species’ habitat and natural food. Re-creation of soil or aquatic environments, symbiotic relationships and specialized foods can make rearing difficult. Some insects undergo temperature- and photoperiod-dependent diapause or require host plant cues to terminate multivoltine cycles. Trophallactic feeding may necessitate maintenance of an entire colony, as in termites, ants, and other social insects. Because of these and other peculiar life history characteristics, the easiest insects to rear are relatively small, multivoltine (more than one generation per year), plant-feeding, terrestrial species with wide host ranges and no unusual environmental requirements. Species that infest common crops, landscape plants, or stored products are particularly suited to artificial rearing.

Complete rearing of an insect for one or more generations is often complicated by the mating and oviposition requirements of the adults. Species-specific requirements for temperature, humidity, amounts of space, light characteristics, photoperiod, population size, food, oviposition stimulants and substrates, and other environmental conditions all must be understood and provided. Insects may swarm and couple in flight, form mating aggregations on host plants, orient to each other...
by means of pheromones or auditory signals, transfer spermatothores (sperm packets), engage in postmating female guarding to protect their paternity, and perform other unimaginable actions to produce another generation. Fortunately, most of the species we rear for multiple generations have less complicated requirements; these are primarily butterflies and moths (Lepidoptera, >300 species have been reared), beetles (Coleoptera, >200 species), flies (Diptera, nearly 200 species), bugs (Heteroptera, <100 species), and bees and wasps (Hymenoptera, <100 species). Grasshoppers and katydids (Orthoptera), lacewings (Neuroptera), cockroaches (Blattodea), termites (Isoptera), and fleas (Siphonaptera) are also reared but in reduced numbers (roughly 10–20 species). Many more species undoubtedly could be reared using the techniques developed for their close relatives.

**NATURAL AND ARTIFICIAL DIETS**

Immature herbivorous (plant-feeding) insects can often be reared by feeding them clean, fresh-cut, or potted versions of the plant material on which they feed in nature. The roots, stems, leaves, flowers, or fruit must be readily available or grown in sufficient quantities. Examples are larval silkworms raised on mulberry leaves, boll weevils on cotton squares and bolls, tropical fruit fly on papaya fruit, and monarch butterflies on milkweed leaves. Similarly, medical and veterinary insects, e.g., adult mosquitoes and biting flies, are fed on their hosts or suitable surrogates, such as rodents, sheep, goats, or pigs.

Substitute plants can also be used to maintain herbivorous insects that are adaptable, usually readily available human and animal food. Green beans can be used for plant bugs, lettuce for grasshoppers, dry dog food for cockroaches, and cow manure for house flies. Rearing natural enemies of plant- or animal-feeding insects is considerably more difficult because three trophic levels must be synchronized: the plant or animal, the insect host, and the natural enemy.

Artificial diets have been developed to simplify and improve the rearing of both plant- and animal-feeding insects. Henry Richardson's development in 1932 of a bran, alfalfa meal, yeast, and diamalt formula for rearing house flies eliminated the objectionable mess and odor of cow manure. A commercial diet made of wheat bran (33.3%), alfalfa meal (26.7%), and brewer's grain (40%) is now available for rearing house fly larvae (CSMA medium; Chemical Specialties Manufacturer's Association, Rakston-Purina, St. Louis, MO). Another historical advancement was M. H. Haydak's 1936 grain flour, milk powder, honey, and glycerin diet for stored-grain insects, such as mealworms and flour moths. Gelled diets were developed for rearing insect larvae that require large quantities of contained water in their diets. The first was Pearl's 1926 diet for Drosophila spp., followed by Botger's 1942 larval medium for the European corn borer, Ostrinia nubilalis. Interestingly, these and subsequent diets have been gelled with agar, a polysaccharide derived from seaweed, that was previously developed for use in bacteriology by Robert Koch in the late 1800s. Agar remains the standard gelling agent for culturing both microorganisms and insects; however, its cost and requirement for heating have led to the development of alternative materials: polysaccharides (industrial gums, cellulose, pectin, plant starches), heteropolysaccharides (carrageenan, sodium and calcium alginate), scleroproteins (gelatins, animal albuminoids), starch polymers (polyacrylonitrile graft copolymers), crude fibrous plant products, and waxes. Ground plant fibers, such as sugarcane bagasse (pulp remaining after the sugar is extracted), corn cobs, and carrot powder are used to rear tropical fruit fly larvae, e.g., the Mediterranean fruit fly, Ceratitis capitata. The awful stench of using a mixture of dried blood, milk, and yeast in water for rearing screw-worm larvae, Cochliomyia hominivorax, was virtually eliminated by a starch polymer-gelled diet developed primarily by David Taylor of the USDA, Agricultural Research Service (ARS), in 1988. A practical artificial diet for predaceous insects has recently been perfected and patented by Allen Cohen, USDA, ARS, retired.

**INITIATION AND MAINTENANCE OF COLONIES**

Insect colonies are initiated from field-collected specimens or samples from previously established colonies. Any developmental stage can be used to start a colony, but surface-sterilized eggs are generally preferred because they are durable, easy to ship, and less likely than other stages to carry a pathogen. However, eggs may be difficult to find in nature and often larvae suffer high levels of mortality as first instars because they are not yet adapted to the laboratory. It is generally advisable to use late instars, hold them in individual containers for parasitoid and pathogen screening, combine the adults in mating cages with a suitable oviposition substrate, and collect and treat the eggs before colonization. From source, field, or insectary, the degree of success achieved over multiple generations will depend on the quality of the colonized insects and the skill with which they are reared. Many species that can be colonized and reared for multiple generations are much larger, healthier (free of malnutrition, pathogens, parasitoids, and predators), uniform in growth, and more active and fertile than those in nature. Special consideration must be given to rearing insects that are required to behave normally, particularly those destined for release to suppress wild populations. Fruit flies (ca. 1 billion per week), screwworms (ca. 500 million per week), and other species that have been mass reared for 20 or more generations in isolation may no longer interact and mate with their target populations in nature. To avoid this so-called strain deterioration, insectary populations can be recomolized or infused periodically using specimens collected from the targeted wild population. Yields will be relatively low for several generations of a new colony destined for mass production, unless a previously isolated strain has been adapted to the insectary in anticipation of its use for colonization. Infusion is accomplished best by holding field-collected larvae, obtaining adults, and combining their eggs with those of the mass-reared colony, as explained earlier. A large number of the new insects must survive to ensure that the colony has been infused. Also, genetic bottlenecks (sources of selective mortality) must be avoided because these will hasten the selection of insects that no longer behave normally.

There are several options for starting a colony from one that already exists. Colony starts can be obtained by contacting entomologists who publish on species of interest or are involved in large-scale, biologically based pest management programs. In the 1980s, the Entomological Society of America published lists of Arthropod Species in Culture and specialized directories still exist for Drosophila strains and other species. Arthropod Species in Culture listed colonies of the following taxonomic orders (number of species, colonies): Acari (41, 77), Anoplura (1, 1), Coleoptera (78, 266), Diptera (168, 301), Heteroptera (90, 206), Hymenoptera (119, 169), Lepidoptera (101, 308), Mallophaga (3, 3), Neuroptera (2, 2), Orthoptera (64, 203), Siphonaptera (2, 7), and Thysanura (4, 11). Suppliers of Beneficial Organisms in North America is maintained by Charles Hunter of the California Environmental Protection Agency (www.cdpr.ca.gov). This publication lists more than 130 species of beneficial organisms available from 142 suppliers. The most popular species offered for
sale were the green lacewing, *Chrysoperla carnea* (65 suppliers); brown lacewing, *C. rufilabris* (54); nealying destroyer, *Cryptolocanus montezuieri* (52); whitefly parasitoid, *Encarsia formosa* (54); convergent ladybeetle, *Hippodamia convergens* (56); predaceous mite, *Phytoseiulus persimilis* (54); and egg parasitoid, *Trichogramma pretiosum* (77). Peter Ebling recently established the Insect Producer Database to provide a comprehensive worldwide listing of producers who are willing to sell or donate live insects (www.insect.glc.cfs.nrcan.gc.ca/). There are many commercial sources of insects, including Carolina Biological Supply and Combined Scientific Supplies. Pioneers in supplying diets for research are BioServe and Southland Products.

**CATEGORIES OF INSECT REARING**

There are three distinct categories of insect rearing: single species, multiple species, and mass rearing. In single-species rearing, immature stages are usually fed on host plants or animals, although artificial diets may be substituted. Seminatural environments and oviposition substrates are duplicated from nature and all rearing operations can be performed by a single individual. Multiple-species rearing is usually accomplished in central facilities to support research. There is economy of scale in the rearing operations, i.e., diet preparation, egg treatment, larval rearing, harvesting of pupae, and adult colony maintenance can be combined for similar species. Multiple-species rearing is common in research laboratories, such as those used for insecticide or transgenic crop development, and is typically performed by a small staff. Mass rearing involves a single species produced for biologically based pest management that is reared in factory-like facilities with controlled environments, artificial diets and oviposition substrates, mechanized equipment, and operations performed by work units. The largest facilities are used to rear the screwworm and Mediterranean fruit fly. Although based on single-species rearing, mass rearing systems are distinct in design and implementation, not merely multiplications of scale.

**BASIC INSECT REARING OPERATIONS**

Regardless of the size of the colony, insect rearing is organized into operations based primarily on the species’ life history. At some level of complexity, insect rearing operations include inventory, acquisition, and storage of supplies; diet preparation and containerization; egg collection and treatment; larval or nymphal development; pupal or adult recovery and distribution; adult colony maintenance; quality control; and facility and equipment maintenance. Depending on the species, these operations are subdivided into procedures for which space is allocated and personnel are trained and assigned. “Traffic patterns” are established in the facility that flow from relatively clean areas to those that are potentially contaminated; i.e., diet preparation through larval development and diet disposal. Diet and eggs are usually handled more carefully until they are sealed in clean rearing containers. Isolating the larvae, pupae, and adults in containers protects them from contamination and prevents workers from being exposed to potentially harmful microorganisms and allergens. Rearing operations are performed in synchronized sequences, so they can be interfaced at the most appropriate times.

**REQUIREMENTS FOR INSECT REARING FACILITIES**

Insect rearing facilities have evolved from field insectaries with outdoor temperature and humidity to environmentally controlled laboratories that contain insects under high security. Field insectaries provide adequate environments for rearing insects under seminatural conditions on host plants or animals. However, pathogens, parasitoids, and predators are not controlled, and workers are exposed to potentially dangerous pathogens and allergens. Conversely, temperature, humidity, air quality and quantity, light quality and photoperiod, sanitation, and security are closely regulated in laboratory insectaries. Insects and supplies are carefully screened for contaminants before they are admitted and human access and exposure are limited. All openings to a laboratory insectary are sealed or filtered to prevent insects from entering or leaving, particularly in quarantine facilities. Quarantine and containment facilities have strict construction requirements and operational protocols. Laboratory insectaries must be well insulated and have highly filtered, recirculated air to be efficient and cost effective.

**PROBLEMS ENCOUNTERED IN MAINTAINING INSECT COLONIES**

Virtually all severe insect rearing problems result from failure to perform standard operating procedures or defective environmental controls. Once established, rearing operations become routine and individual procedures are easy to forget. For example, a dietary ingredient may be omitted or destroyed by overheating, eggs may be accidentally desiccated following surface sterilization (dechorionation), closely related species may be mixed unintentionally, or larval densities may be more or less than required per container. Additionally, dietary ingredients can deteriorate after prolonged storage. These kinds of problems can be detected and corrected before a colony is lost. However, temporary loss of environmental control can destroy all of the insects. Pathogens can also be devastating, although diseased insects are usually confined to certain containers that can be eliminated before others are contaminated. Parasitoids and predators must be detected and similarly discarded. Genetic deterioration from inbreeding and genetic drift has been blamed for declines in insect colonies, but this is not a typical problem in large colonies. Insect rearing is generally safe for humans unless they are hypersensitive to insect proteins, react to the physical irritation of insects or their body parts, work with insects that sting or bite, or expose themselves to toxic substances used in the operations.

**THE FUTURE OF INSECT REARING**

Insect rearing is in transition, along with the science and technology it supports. Appreciation of the natural history of insects and their rearing is increasing steadily as people enjoy ecotourism, butterfly houses and gardens, insect zoos, butterflies in ceremonies, and educational products based on insects. Insects are commonly used as baits for fishing and, in certain countries, have become popular pets. Rearing is becoming more important as field collection of insects is restricted to preserve habitat biodiversity and protect germplasm ownership. This is analogous to the collection of orchids and other showy organisms. Insects are no longer major sources of natural products, such as silk, wax, or dyes, and their use as human food is very limited. However, bird-watching and exotic pet ownership have become extremely popular in affluent countries, causing a significant increase in the use of insects as animal food. Rearing insects to produce bioactive substances remains a research support activity in the fields of biology and medicine. Living as well as dead insects are used increasingly in classroom education.

Agricultural uses for insects have expanded dramatically during the past 40–50 years in the development and support of new pest management technologies. Every major company that produces chemical...
insecticides or pest-resistant plants maintains a multispecies insect rearing facility. Although insecticides have provided effective insect control at individual farms and residences, overall losses to insects have not declined and we need new options for sustainable pest management. Large federal and state entomological research laboratories and university entomology departments also have laboratory insectaries, although the current trend is toward decentralization and outsourcing. The sterile-insect technique, pioneered by E. F. Knipling, USDA, ARS, has proven too expensive, unless used on an area-wide basis with stringent regulatory controls, as in the screwworm and Mediterranean fruit fly eradication programs. Advances in insect rearing have enabled the eradication of these species and others from vast geographical areas. As a result, area-wide approaches to pest management are increasing, along with new methods for using genetically modified organisms. Reliable, cost-effective rearing will be required for these technologies to be successful.

Major advances in insect rearing are currently being made in support of biological control. Natural enemies are reared and released to prevent rather than cure pest problems, and they rarely have unacceptable nontarget effects. Another major advantage in using natural enemies is that they do not induce the pest resistance that eventually makes insecticides ineffective. We now have efficient host-rearing systems for at least 40 parasitoids and predators. Advancements are also being made in the mechanization of rearing operations, large-scale release technology, and rearing of newly discovered natural enemies. Global markets are increasing in organic food production, ornamental and vegetable greenhouse crops, urban pest management, fly control, home gardening, and other specialized areas. Biological control will continue its expansion as insect resistance to chemical insecticides increases, worker protection and food safety regulations are enforced, people avoid real or perceived environmental contamination, and the quality and efficacy of natural enemies improves.

Insect rearing will play a critical role in the future of entomology. Insects will always be appreciated for their intrinsic value, used as a source of useful materials, and produced as food for wildlife. Moreover, they will become increasingly important for pest prevention in natural areas, crops, and buildings and in human and animal wastes. Other uses will include transgenic biological control and autocidal methods (sterile-insect technique, paratransgenesis). Insects will be reared to restore and supplement insect populations in nature; control pests over vast, low value-per-acre lands; and eliminate chemical insecticides in specialized cropping systems.

Insect rearing can be enhanced most by learning more about the natural history of insects, emphasizing their ecology, behavior, and systematics. This knowledge can be used to create artificial diets and environments that separate species from limiting factors, biotic (pathogens, parasites, and predators) and abiotic (temperature, humidity, and light). As knowledge about insects is gained, it must be published, communicated at meetings, and widely distributed to help advance the field. The Entomological Society of America and International Organization for Biological Control have been particularly helpful in disseminating insect rearing information. Insect rearing is often considered a support activity to be described in the methods sections of articles on other subjects. This makes the information difficult to retrieve and has led to relatively obscure publications on insect rearing. Another major limitation has been a general lack of formal education and training in insect rearing. However, Frank Davis conducts a popular annual workshop on the subject at Mississippi State University, Allen Cohen has a continuous educational program at Insect Diet and Rearing Research, LLC (www.insectdiets.com/), and David Dame covers the subject in his biannual FAO, International Atomic Energy Agency short course at the University of Florida. This is the best time in history to discover and disseminate insect rearing knowledge and obtain training in this essential field.

Recruitment Communication

James F. A. Traniello
Boston University

C ooperative labor defines life in the social insects. Workers receive instructions from chemical signals to travel to sites where work needs to be done. Because individual workers are relatively small, energetically rewarding food sources can be profitably harvested by groups of individuals. Nest conditions may deteriorate, and more attractive, alternate nests found. Nest emigration requires communication about the quality and location of the new nest. Territorial disputes and attacks on nests abound, and cooperative defense is the most effective way to cope with threats.

The behavior that mobilizes nestmates is termed recruitment communication, commonly used by social insects to organize and accomplish work. The mechanisms that mediate recruitment communication can be understood by analyzing the behaviors of individuals and the signals they produce. Descriptions of how pheromones and other
Recruitment Communication

signals organize cooperation are ubiquitous. Social coordination depends on these signals. Although systems as “linguistically” elaborate as the honeybee waggle dance have evolved to communicate information about the location of food sources or nest sites, it is pheromones that serve the primary signaling role in wingless social species such as ants and termites.

The majority of research on recruitment behavior concerns communication during foraging, defense, and nest emigration. Workers scouts for new food sources and patrol the territory of a colony. When food or a new nest is located or a competitor from an alien colony is identified, nestmates are recruited to perform work together. Scouts that have located food or a territorial intrusion return to the nest, laying a chemical trail and sometimes performing behavioral displays to alert nestmates, which then leave the nest and orient along the scout’s trail to the target area. Recruited nestmates, in turn, may continue the process by reinforcing the trail. Regulatory mechanisms involving pheromone evaporation turn off recruitment when the food has been harvested or the threat no longer exists.

Ecology influences the evolution of recruitment communication, and the adaptiveness of recruitment behavior can be studied in reference to patterns of food distribution, predation, and competition. Foraging behavior and space-use patterns are the result of community-level interactions such as interference competition, and recruitment communication is a behavioral mechanism that mediates interactions among sympatric species. Recruitment signals, in turn, are generally trail pheromones that “excite” nestmates and orient them to a locus of activity. The physical characteristics of a trail (e.g., how long it lasts as a signal) and the response it induces reflect the ecological function of the pheromone.

This article focuses on recruitment behavior in social insects, primarily in ants and termites, groups that frequently employ these communication systems and for which the greatest level of ethological, ecological, and evolutionary understanding has been achieved. The recruitment behaviors of honeybees, which are behaviorally more elaborate, are covered in a separate chapter.

**PHYSIOLOGY AND BEHAVIOR OF RECRUITMENT**

**Exocrine Gland Sources of Recruitment Pheromones: Trail-Laying and Trail-Following Behavior**

Recruitment pheromones are discharged from exocrine glands, which are anatomical structures often specialized for their synthesis and secretion. Since the first identification of the source of the trail pheromone in the fire ant by E. O. Wilson more than four decades ago, ants have served as excellent models for the study of the organization of recruitment. Thanks to the research of Bert Hölldobler and Hiltrud Engel-Siegel, among others, the structure of ant exocrine glands and the function of their secretions have been described in detail for many species. In ants, the accessory glands to the sting (the Dufour’s gland and the poison gland), the pygidial gland and sternal glands, the hindgut, the rectal gland, and the tibial and tarsal glands are known to produce substances that serve to recruit nestmates (Fig. 1). In ants in the subfamily Formicinae, the hindgut is the source of trail pheromone, which is emitted through the acidopore located at the tip of the gaster. In another diverse group of ants, the subfamily Myrmicinae, the poison gland and the Dufour’s gland secrete recruitment chemicals. Other ants rely on a variety of glands to produce trail substances. In termites, only one source of trail pheromones, the sternal gland, has been described. The structure

of the sternal gland, which is composed of modified epidermal cells, varies in different genera. It appears that the secretions of this gland may have first played a role in defense against microbes, as the gland's substances have antibiotic properties.

The secretions of the trail-substance-producing exocrine glands are deposited as a worker travels from a target area to the nest, or vice versa. In some ant species (e.g., myrmicine ants) the sting, serving as a conduit for the secretions of exocrine glands, is extruded and dragged over the substrate to release trail pheromones. Chemical trails may be deposited continuously or as a series of point sources between the nest and the target area, sometimes in conjunction with other secretions. The cuticle may be adapted as an applicator for the secretions of exocrine glands beneath. Some termites mark areas around the nest entrance or a food contact between sternites and the substrate to regulate pheromone deposition. Some termites mark areas around the nest entrance or a food source by dotting the tip of the abdomen and laying directional trails using the sternal gland. There is significant convergence in the trail-laying behaviors of ant and termite species, both applying chemicals as point sources or streaked or continuous trails.

The spatial processing of the information encoded in an odor trail is by tropotaxis, which is a sampling of the trail pheromone by means of the paired antennae. Antennal chemoreceptors perceive variation in pheromone concentration along the trail’s semiellipsoidal active space, the area in which the concentration of the pheromone is sufficient to elicit following behavior. Theoretically, diffusion yields a gradient of odor molecules; pheromone concentration is highest at the point of application (the centerline of the trail) and symmetrically decreases on either side, defining the boundaries of the active space. The odor gradient is sampled by the antennae as the insect travels along the trail. When lower concentrations are sensed at the lateral edges of the active space, opposing movements are made so that position within the active space is maintained.

**Determining the Source and Behavioral Effects of Trail Pheromones**

Understanding the glandular sources and chemistry of trail substances is at the heart of the study of recruitment communication. The nature of the bioassay, the behavioral test used to determine the effectiveness of different substances as recruitment or trail pheromones, is critically important. The bioassays used in trail pheromone isolation and identification must distinguish among the range of behavioral responses involved in trail communication. It must be noted that trail pheromones can have both recruitment and orientation effects. A recruitment pheromone induces nestmates to leave the nest to travel to a work site. An orientation pheromone has no such stimulatory effect, but it can serve as a chemical “guide” for worker traffic. Trail substances, if they have a recruitment effect, will stimulate nestmates to leave the nest or otherwise alter their task performance in the context of a current need. In some ants, nestmates are recruited with a motor display delivered in the nest by a recruiting worker. The trail substance in this case does not have the ability to draw ants out from the nest; rather, it is used as an orientation cue by nestmates that have contacted a recruiting ant. Some trail pheromones can alone elicit both excitation and orientation in the absence of any other behavioral display or stimulus. If an artificial trail (one prepared from a solvent extract of the appropriate exocrine gland) is drawn out from the nest entrance and ants leave the nest to follow it, a recruitment effect has been demonstrated. If the artificial trail cannot induce inactive workers to leave the nest, yet the trail is able to orient workers alerted by either a motor display or some other trail chemical that has an alerting property, an orientation effect is occurring. Careful dissection of the kinds and sequences of behaviors in the recruitment process and detailed chemical analyses have revealed that several pheromone constituents may control a number of behaviors associated with recruitment and trail following.

**TRAIL CHEMISTRY AND RECRUITMENT BEHAVIOR**

Social insects may mix the secretions of different exocrine glands to induce recruitment and trail-following behaviors, or the chemical output of a single gland may be composed of more than one substance, each having a distinct role in releasing behavior. Trail communication can therefore be a multicomponent phenomenon or a process that involves a series of chemical homologs produced in the same exocrine gland. For example, the Dufour’s gland of the fire ant is the source of a trail pheromone that induces both recruitment and orientation behaviors in workers. Dufour’s gland chemistry is varied: the constituents of this gland’s secretion regulate different behaviors, which have been called “subcategories” of trail following. These chemicals include recruitment primers, synergists, and orientation inducers. Primer and inducer substances together release recruitment and orientation behaviors. \((Z,E)-a\)-Farnesene is the principal trail orientation component isolated from the Dufour’s gland. Another chemical fraction acts together with \((Z,E)-a\)-farnesene to increase the effectiveness of the mixture in inducing trail communication. Homofarnesenes of presently unknown function and an orientation inducer present in the secretion also increase trail following. In the ant *Myrmica*, homofarnesenes in the Dufour’s gland may be added to 3-ethyl-2,5-dimethylpyrazine (EDMP), which is the poison gland trail pheromone, as part of a multicomponent trail system. Electroantennograms have been used to characterize the olfactory response to trail substance constituents.

Similar findings have been made in other ant species, and new glands and multiple sources of trail substances have been described. Pure chemicals seem to induce lower responses than gland extracts, indicating the importance of the naturally occurring chemical mixtures in trail communication. Constituents present in different ratios sometimes show synergistic effects. Artificial trails prepared from extracts of the poison gland of the harvester ant, *Pogonomyrmex badius*, have a recruitment effect lasting approximately 20 minutes, whereas artificial trails prepared from Dufour’s gland secretions and aged for longer periods of time have elicited orientation responses. In the ant *Leptogenys diminuta*, the poison gland and pygidial gland produce \(3R,4S\)-4-methyl-3-heptanol and isogeraniol, respectively, to regulate orientation and recruitment. Similarly, pheromone blends are known to mediate alarm communication, including alarm—recruitment systems involved in defense.

The sternal gland secretions of termites stimulate recruitment and may have highly durable orientation effects. Single chemicals such as \((E)-6\)-neocembrene A and dodecanetriol have been isolated from whole-body extracts, but termite sternal gland secretions probably are more elaborate mixtures of pheromones that have different functions. Researchers have described “recruitment” and “basic” trails in termites; “basic” trails have only an orientation effect. The sternal gland secretion of *Nasutitermes costalis*, for example, can induce recruitment (drawing undisturbed soldiers and workers from the nest) and can orient searching and/or homing termites. Sternal gland material collected from trails aged for more than 20 years can orient, but not recruit, termites. Although the chemical that regulates recruitment dissipates in minutes, the orientation component of the secretion is a remarkably stable pheromone.

The persistent orientation components of a trail substance can “channel” foragers away from neighboring nests to minimize aggressive confrontations and can also serve as territorial recognition cues.
or as an initial guide for naïve foragers. Some species of desert ants have trunk trail systems (a network of trails emanating from the nest entrance and arborizing at their distal portions) marked with Dufour’s gland secretions composed of durable blends of hydrocarbons that are specific for species, populations, and colonies. In other ant species, different glands may produce trail chemicals with different behavioral effects. The ecological significance of trail structure in termites is not well understood, although apparently foraging galleries divide foraging space to increase the efficiency of harvesting food. Recent comparative studies have examined the fine structure of sternal glands of pseudogates and workers.

**Trail Pheromone Specificity**

Pheromone specificity is achieved through chemical mixtures and molecular structure. Early studies in ants suggested that trail substances were highly species specific, but results of more recent work do not support such a conclusion. One striking example of this lack of specificity is that ants in as many as six different genera in the subfamily Myrmicinae use the same trail pheromone, EDMP. Dodecatrienol, a trail pheromone in the termites Reticulitermes virginicus, R. speratus, and Coptotermes formosanus, provides a nonspecific orientation cue in these species, in other species of Reticulitermes, and in a cluster of geographically and phylogenetically diverse termites. (E)-6-Cembran A, which has been isolated from whole-body extracts of the Australian Nasutitermes exitiosus, can induce orientation in African nasutitermitines, rhinotermitids, and to a lower degree in African macrotermitines (fungus-growing termites). At present, it is challenging to explain the significance of trail pheromone specificity in termites.

Metabolic end products, dietary differences, and genetics may produce variation in the chemistry of trail pheromones. In myrmicine ants, pyrazines and farnesenes are shared by different species and genera; these chemical constituents, present in small quantities and serving no function in one species, may have a prominent role in another. Biochemical variation may provide a substrate for evolution to act on in the selection of trail pheromones.

There have been many analyses of the level of specificity of trail substances, but the ecological significance of specificity is to a great extent unknown. Research on the behavioral ecology of trail pheromones indicates that chemical specificity may play a role in community structure. For example, competition may have selected for differences in the trail communication systems of sympatric species. Indeed, variations in recruitment communication systems in desert ants have been correlated with resource use and competition. Desert harvester ants forage as individuals on evenly distributed seed resources and recruit nestmates to cooperate in collecting seeds from dense patches. Different foraging strategies may be adapted to the exploitation of resources with different density distributions, serving as a mechanism of resource partitioning in granivorous ant communities. Foraging systems and their pheromonal regulatory mechanisms may also enhance food defense and retrieval, thus reducing interference competition.

The behavioral mechanisms of recruitment that are the basis for enhanced competitive ability may be associated with trail pheromone chemistry and response specificity. The harvester ants Pogonomyrmex rugosus and P. barbatus, which are very similar ecologically, have trunk trail systems that divert groups of foragers away from each other. Their trunk routes, which are composed of Dufour’s gland and are colony specific, suggest chemical differentiation resulting from competition. The specificity of the trunk routes may also give an advantage in territorial defense if fighting ability is greater when ants are on their own territory. Other ant species are known to mark trails with persistent colony-specific pheromones.

Colony specificity in the trail pheromones of termites has rarely been examined. In Trinervitermes bettonianus, workers do not discriminate their own trails from those of neighboring colonies, although their trail pheromones and the trail substances of other sympatric termites appear to be species specific. Some termites distinguish between intraspecific and interspecific competitors. Workers deposit rectal fluid and sternal gland secretions on trails, a mixture that may encode colony identity.

Surprisingly, the chemical trails of some ants may also encode information about the identity of the individual that laid the trail. Individually specific trail markings are used during nest emigration by workers of the ant Pachycondyla tessertodula. Individually specific trails, used for food recruitment, have also been described in the ant Leptoethorax affinis. Individuality in a trail pheromone could provide a finely tuned mechanism of directional discrimination and maintain the path fidelity of individual foragers.

If ants can decipher the chemical code of another species’ trail substance, they may be able to exploit information about the location of food sources. Interspecific trail-following is uncommon but is known in ants in parabiotic associations (i.e., different species of ants living together in a compound nest). In these species, foragers lay and follow their own chemical trails but are also able to interpret the trail pheromones of other species and to exploit their food discoveries.

**Regulation of Recruitment and Foraging Activity**

Trail pheromones communicate information about food quality to nestmates that have not had direct experience with a food source. Trail-laying behavior regulates pheromone concentration (i.e., the amount of pheromone deposited on a trail), which in turn controls a colony’s response. After deposition on the substrate, a trail pheromone diffuses. The chemical properties of the pheromone both determine the spatial and temporal structure of its active space and regulate foraging activity at the colony level. The concentration of trail pheromone mediates communication between groups of individuals, those that have fed and any potential foragers within the nest. In fire ants, the continuity of the sting trail, measured by causing a scout ant to walk over a smoked glass slide (removing soot from the slide where the ant’s sting is dragged) depends upon the concentration of a sugar solution offered as a food source. The more concentrated and thus rewarding the solution, the greater the extent to which the sting is extruded and dragged continuously over the substrate, and the greater the number of workers that will lay such a trail after they have contacted the food source (Fig. 2). The distance between the food source and the nest can also affect the rate at which food is retrieved, and thus the profitability of the colony’s foraging.

The regulatory mechanism underlying foraging organization is called mass communication. Foraging is initiated when scouts locate new food, determine its quality, and deposit trail pheromone according to the food’s energetic value and the colony’s nutritional needs. This trail induces recruitment in nestmates, which repeat the cycle of food quality assessment and trail pheromone deposition until the food source has been depleted or the colony satiated. The entire process is regulated by the concentration and evaporation of the trail pheromone. If the recruitment trail is not reinforced, the trail substance evaporates and foraging rate decays over time until food collection ends. Different ant and termite species show variations on the theme of mass communication that likely are associated with the foraging ecology of individual species.
DEFENSIVE RECRUITMENT AND DIVISION OF LABOR BETWEEN CASTES

Social insects can be the most important competitors and predators of other social insects. Army ants, for example, exert significant predation pressure on social wasps and ground-dwelling ant species, favoring the evolution of adaptive systems of predator recognition and response. Some responses involve a division of labor among castes. Castes are groups of individuals specialized for a given set of tasks; they may have specific functions related to foraging or colony defense, and different castes may be recruited according to their specialization. Upon encountering a particularly important competitor or predator, ants that are patrolling the territory of a colony may preempt an attack through a caste-specific alarm-recruitment system. For example, the ant species *Pheidole dentata* and *Solenopsis geminata* are sympatric (i.e., occur together) in the southeastern United States and use similar nest sites. *S. geminata*, the native fire ant, as well as *S. invicta*, the imported fire ant, may attack colonies of *P. dentata* and destroy the colony (Fig. 3). Because fire ants are fierce predators of *P. dentata*, it is important to quickly respond to a potential threat. In *P. dentata*, minor workers usually care for brood, maintain the nest, and forage, whereas major workers, which have large heads and mandibles, have a significant role in colony defense. When minor workers encounter as few as one or two fire ants, they return to the nest, laying pheromone trails to recruit minor and major workers. Major workers recognize the threat as emanating from fire ants through the odor of the predator carried on the messengers’ bodies, and together with the excitatory behavior and trail substances deposited by minor workers, are recruited to the site at which the enemy has been located (Fig. 4). Because majors are recruited to respond defensively following contact with fire ants but not other ant species, this defensive recruitment system is said to have “enemy specification.”

Species of termites that forage above the ground face a higher degree of predation than species that forage in the confines of subterranean gallery systems, and the social architecture of these ecologically different groups of species seems to have undergone adaptive modification. For example, species whose foragers harvest food above the ground have a high proportion of soldiers that use chemical defense in combating predators. Species that nest and seek food below ground have relatively low investment in soldiers, which rely
on mechanical defense and are not involved in foraging. The recruitment communication systems that organize foraging in aboveground species appear to be adapted to reduce predation during the time period between the discovery of food and the construction of covered protective galleries, when termites are exposed and are vulnerable to predation by ants. In *Nasutitermes*, for example, the most diverse genus of the higher termites, there are worker and soldier castes: the ampule-headed soldiers are highly modified for chemical defense but also have an important role in organizing foraging (Fig. 5). Soldiers of the neotropical *N. costalis* scout in groups for food sources, and upon locating food communicate its location to nestmates. Groups of soldiers search as groups along trails in different areas, but all trails generally coalesce when a food source is located; subsequently additional soldiers and then workers are recruited.

There are three phases of foraging organization in *N. costalis*, each involving recruitment communication within and between castes. First, soldiers search for and discover new food sources and communicate information about their location to other soldiers. Next, workers are recruited in large numbers. Finally, the recruitment of workers increases further and soldiers flank both sides of the foraging trail to protect the more vulnerable workers traveling between the nest and the food. This pattern of soldier and worker recruitment shows that soldiers, which themselves do not feed directly, are nevertheless scouts, which assess food quality and recruit workers that will harvest food. Soldiers first recruit other soldiers to ensure an adequate defense at the food source and then communicate with workers to begin food collection. This intercaste communication is chemical; both soldiers and workers have a sternal gland, which produces a trail pheromone that induces the recruitment of soldiers and workers depending upon the quantity of pheromone deposited. The sternal gland secretion is not caste specific, but the volume of the sternal gland varies in soldiers and workers (large workers have a significantly larger sternal gland volume than soldiers). Caste differences in pheromone perception and/or responsiveness to the sternal gland pheromone appear to regulate the prominent division of labor during foraging organization in nasute termites.

Nasute termites also have an alarm-recruitment response. When disturbed, soldiers discharge frontal gland terpenoid secretions; soldiers nearby then are recruited over short distances. Frontal gland and sternal gland secretions function in defensive recruitment and cause soldiers to remain in an area where a disturbance has been signaled. Similar foraging and defensive recruitment communication systems have been identified in other termites.

Defensive recruitment and the recognition of specific enemies occur in some termites. *N. costalis* responds defensively to the presence of a single soldier or worker of an alien conspecific colony by recruiting large third-instar workers, which attack the intruders with their mandibles. This response is not seen if other species of termites are encountered.

**THE EVOLUTION OF RECRUITMENT COMMUNICATION**

**Ethological Models**

Ethologists have long hypothesized that the origins of behavior can be traced from comparisons of similar actions in groups of closely related species. The history of recruitment behavior and chemical trail communication has been examined in ants with such an approach. The ancestral condition is thought to involve a behavior called tandem running.
In this mode of recruitment, a single nestmate is led “in tandem” from the nest to a new nest or food source: A “leader” guides a “follower” to a target area. Tandem running involves motor displays that initiate pairing (Fig. 6) and surface pheromones and other exocrine gland secretions to maintain the communicative tie while the ants move pairwise, outbound from the nest. This type of recruitment communication is considered to be basal because it commonly occurs in ponerine species, which are themselves ancestral in the evolutionary history of ants.

In chemical mass communication, excitatory and orienting information is contained in the structure of the trail substance, and no other signals are required to control recruitment activity. In tandem running, behavioral displays alert recruits to the need for their assistance; chemical signals on the body of the recruiter, as well as physical contact between the members of the tandem pair, provide directional guidance. In the most derived state of recruitment communication, all information required to regulate group action is encoded by pheromones. This type of trail communication is characteristic of many species in the majority of ant subfamilies and in the termites appears to be the only method of trail communication.

The origin of trail communication in termites has received relatively little attention. The secretions of the sternal gland are known to inhibit fungal growth; thus, the ancestral function of this gland may have been the production and deposition of antibiotics to control microbial growth in the nest. Recruitment communication became more elaborate with the separation of nesting and feeding ecology and the evolution of a sterile worker caste.

Resource Distribution and the Evolution of Recruitment Communication

Some species of ants have no recruitment communication; these species offer important insights into the role of food distribution in the evolution of recruitment behavior. The relative significance of phylogeny and ecology can be separated in some of these species because the absence of recruitment communication has been noted in ants in derived subfamilies. The ant *Cataglyphis bicolor*, a formicine species that nests in the ground and forages on the arid salt pans of North Africa, does not mobilize nestmates to food sources greater in size than what a single worker can transport. Recruitment does not occur naturally and cannot be induced experimentally. The diet of this ant is primarily composed of arthropods that have desiccated; the distribution of these prey is unpredictable in space and time, suggesting that the ecology of prey distribution has been the major selective force for individual retrieval without the possibility of recruitment.

Among the basal ponerine ants, the same point concerning food distribution and phylogeny can be made. Ponerine ants in the genus *Pachycondyla* generally show no food recruitment, employing tandem running only during nest emigration. These ants feed on randomly distributed individual prey. Yet chemical recruitment behavior occurs in species that utilize clumped food resources, such as *P. laevigata*, an obligate termite predator. *P. obscuricornis* huntresses collect prey as individuals but do not have food recruitment communication. Nest relocations involve tandem running; secretions from the pygidial gland, which is located dorsally beneath the seventh tergite on the gaster, hold the tandem pair leader and her follower together as they make their way to the new nest. In *P. laevigata*, an obligate termite predator, scout ants initiate the recruitment of nestmates after only a single termite has been found. Workers of this species apply the potent secretions of their pygidial gland to the substrate by curling the gaster forward ventrally and dragging the dorsal surface (Fig. 7). One trail-laying ant can induce the formation of a foraging column of several dozen workers. Shifts in diet in the genus therefore appear to have selected for the changes in trail-laying behavior and the chemistry of the pygidial gland secretion. Another basal ant that has well-developed recruitment communication is the ambylopine *Ongchomyrmex*, which is a specialist on large prey and has an army ant-like life cycle.

Resource distribution is associated with the use of chemical communication during foraging in desert seed-harvesting ants. *Pogonomyrmex rugosus* and *P. barbatus* occur sympatrically and feed on seed clumps. These ants have well-developed trail communication. On the other hand, *P. maricopa* collects scattered seeds, primarily through individual retrieval, and has a comparatively narrow diet breadth and a relatively weak recruitment response to seed patches.
may result in some species “specializing” on prey of a certain size while size optima. This will cause competitive ability to vary among species and each species in a community may have different thermal and prey ecological factors that can alter the way in which resources are partitioned.

FIGURE 7 The pygidial gland and trail laying. (A) The ant P. laevigata applies the pygidial gland, located dorsally, to the substrate to lay a trail. (B) Structure of the gland; AS, cuticular applicator; GC, gland cells, CH, gland channels in the intersegmental membrane. Scale bar = 2.5 mm. [Modified from Hölldobler, B., and Traniello, J. (1980). The pygidial gland and chemical recruitment communication in Pachycondyla (=Termitipone) laevigata. J. Chem. Ecol. 6, pp. 886, 887, with permission of Kluwer Academic/Plenum Publisher.]

RECRUITMENT, COMPETITION, AND COOPERATIVE RETRIEVAL Recruitment communication allows the diet of a species to be expanded to include food items greater in mass than a single forager’s load size limit. This is accomplished by recruiting nestmates to help transport prey. In this way, small-bodied ants can cooperate in prey retrieval, sometimes greatly increasing diet breadth. Recruitment communication is flexible; the number of ants in the cooperative retrieval group can be adjusted to prey size and thus allow a colony to efficiently collect resources of different sizes. There may be an energetic advantage to cooperative foraging, reflected in reduced search and retrieval costs and the caloric benefit of successfully acquiring large prey. Recruitment may also improve competitive success; workers recruited to a contested resource can enhance prey defense as well as assist in transport. Short-range recruitment, mediated by acoustical and/or chemical signals, may be used to attract nearby ants to a food find. Such is the case in the foraging organization of the desert ant, Aphaenogaster cockerelli. Following short-range recruitment, a small group of foragers will cooperatively transport the food to the nest to minimize competition with sympatric ants.

The recruitment response of a colony is influenced by a number of ecological factors that can alter the way in which resources are partitioned between species. Recruitment varies with temperature and food item size, and each species in a community may have different thermal and prey size optima. This will cause competitive ability to vary among species and may result in some species “specializing” on prey of a certain size while foraging within a given temperature range. In open-field north temperate ant communities, the small-bodied Monomorium minimum is more tolerant of higher temperatures and can use a mass recruitment pheromone from the Dufour’s gland to recruit rapidly to large prey, which workers defend with a chemical repellent originating in the poison gland. M. minimum foragers also dissect prey more rapidly than sympatric ants. Temperature preferences, recruitment, prey defense, and dissection together represent a foraging strategy that allows this ant to successfully retrieve large prey.

Although the benefit of recruitment is diet expansion, its costs lie in the time required to assemble a cooperative retrieval group. During this time, competing ant species may discover the prey and interfere with its exploitation. Indeed, the probability of interference competition from sympatric ant species can increase from 0% to 100% when prey items exceed the upper size limit for individual worker carriage. The ability to move prey is an important factor in decreasing losses to competitors.

SELF-ORGANIZATION AND RECRUITMENT BEHAVIOR

Theories of foraging strategy note the significance of time, energy, and food profitability in the evolution of feeding behavior. Social insect colonies adjust their foraging (i.e., regulate the number of workers feeding at a given food source) according to food profitability, the risk of worker loss to predation, and competition. Recruitment communication, through the physical properties of trail pheromones, allows foraging adjustments to be made adaptively. It is at the colony level that such adjustments in worker feeding behavior, or decisions, are made. The concept of self-organization has been used to explain how collective action at the level of the colony can be the result of simple rules followed by individual workers. The complex foraging activities of a colony thus result from the interactions of simple workers, whose behavior is determined by trail pheromone concentration.

Self-organization has been used to explain the foraging behavior of mass-recruiting species such as fire ants, which have large colonies composed of workers with limited behavioral repertoires. In addition, their communication systems rely almost entirely on the deposition and diffusion of trail pheromones. Computer simulations and mathematical models have been used to describe the mechanisms involved in dividing foragers between two food sources, as well as the structure of raids of army ants and the rotation of foraging columns of desert seed-harvesting ants. Self-organization theory has also attempted to explain why mass-recruiting ant species have larger colony size: the greater complexity of larger colonies and their efficiency of colony operations may be dependent upon the individual simplicity of the workers that make up these social groups. Individual simplicity may allow greater flexibility in colony-level behavior than would be possible in a social group composed of complex individuals. This reinforces the notion that social insect colonies have a decentralized rather than hierarchical system of control. It has long been known that the queen does not “hand down” orders to workers to direct colony activities.

Self-organization theory can provide useful descriptions of how efficiency is achieved through decentralization and group decision making. Studies of colony emigration in the ant Temnothorax curvispinosus have provided insight into the decision rules involved to organize recruitment. A relatively small number of ants are responsible for transporting nestmates to a new nestsite, either by discovering new sites independently or by being recruited through tandem running by successful scouts. There is much loss of information needed
to guide naive nestmates to a new site, but even unguided ants are able to locate their new home. Tandem running is infrequently used to guide nestmates to nearby nests, but it is common when nest are more distant. Scout ants appear to use a “quorum rule” to decide when to switch from using tandem running recruitment vs. physically carrying nestmates to the new site by monitoring how many nestmates have already found the nest. This can reduce the cost of recruitment.

PEST EXCLUSION
The basic premise of pest exclusion is that it is better to live without pests than to live with them. History provides numerous examples of nonnative species that have caused extensive damage when brought into new areas. Examples of invasive species that have caused damage in nonnative areas include the Formosan termite (Coptotermes formosanus) in Hawaii and Louisiana, gypsy moth (Lymantria dispar) in the eastern United States, opuntia cactus (Opuntia spp.) and rabbits (Oryctolagus cuniculus) in Australia, brown tree snake (Boiga irregularis) in the Pacific region, American cockroach (Periplaneta americana) throughout most of the world, and Colorado potato beetle (Leptinotarsa decemlineata) in Europe. Pest exclusion uses phytosanitary regulations, including quarantines and other legal actions, to prevent the immigration of quarantine pests. Quarantines prohibit the movement of the quarantine pest or plants or other items known to be infested or liable to be infested from crossing the quarantine boundaries.

Quarantines may identify specific organisms (e.g., San Jose scale, Quadraspidiotus perniciosus) or groups of organisms (e.g., fruit flies in the family Tephritidae). Pest insects attack human food, fiber, shelter, or persons; carry diseases of people or other organisms, including domestic livestock or native biota; or are pests of human or natural environments (Table I).

Plants or other regulated articles are prohibited from crossing the quarantine boundaries unless they meet compliance procedures specified in the phytosanitary regulations that render them free of the quarantine pest. Compliance agreements and permits are authorizations to move the prohibited items under conditions prescribed by the quarantine issuer. Quarantine compliance may be performed at origin, the preferred option, or at destination, which is the less preferred option. The compliance requirements vary from those designed to keep the pest out of the regulated items, such as growing nursery stock in insect-proof screenhouses or applying pesticide sprays while the plants are growing, to those designed to kill any pests associated with the regulated items prior to or during shipment, including fumigation, hot/cold treatments, or irradiation (Table II).

Permits are also used to regulate the importation and holding of live insects for exhibit or research by insect zoos, butterfly houses, public or

Regulatory Entomology
Robert V. Dowell
California Department of Food and Agriculture

Regulatory entomology is concerned with preventing the unwanted movement of insects and related invertebrates from areas where they occur to areas where they do not occur. Nonnative species have caused untold amounts of damage to our crops, homes, environments, and persons. Officials in regional, state, or national governments achieve this goal with a five-component prevention program of exclusion, detection, eradication, identification, and public awareness. Exclusion is the primary prevention level. It uses phytosanitary regulations, including quarantines and other legal actions, to prevent the introduction of the quarantine pests. Detection is the secondary prevention level, which uses visual surveys or traps to find infestations of quarantine pests that have penetrated the exclusion barriers. Identification provides the name of the invading organism and information about its biology. It also provides intelligence to assist exclusion and eradication activities. Eradication is the tertiary prevention level. Eradication is the elimination of populations of quarantine pests found by the detection program. Public awareness strives to make the citizens aware of the regulatory laws concerning the importation of quarantine pests and items and enlists their cooperation in making the prevention efforts successful. The components work together much like a ladder with exclusion, detection, and eradication being the rungs, which are held together by identification and public awareness. Working together, these components can prevent the unwanted immigration of quarantine pests.

Quarantine pest. Compliance agreements and permits are authorizations to move the prohibited items under conditions prescribed by the quarantine issuer. Quarantine compliance may be performed at origin, the preferred option, or at destination, which is the less preferred option. The compliance requirements vary from those designed to keep the pest out of the regulated items, such as growing nursery stock in insect-proof screenhouses or applying pesticide sprays while the plants are growing, to those designed to kill any pests associated with the regulated items prior to or during shipment, including fumigation, hot/cold treatments, or irradiation (Table II).
private research facilities and universities, and private citizens. The regulations that allow the insects to be held safely are specified in the permit issued to the person or entity requesting permission to import or hold live insects that are subject to regulation. Another form of pest exclusion uses the continual release of sterile insects throughout an area of high risk of invasion by that pest to preclude establishment. These sterile insects mate with wild adults as they emerge, producing infertile eggs. This preventative release approach stops the invading pest from developing infestations that may require eradication. This preventative release approach is being used against the Mexican fruit fly (Anastrepha ludens) along the Mexico–California border and against the Mediterranean fruit fly (Ceratitis capitata) in the greater Los Angeles area of California, along the Peru–Chile border, and along the Mexico–Guatemala border.

PEST DETECTION

Pest detection programs serve two purposes: to ensure that a political entity is free of the quarantine pest(s) regulated by their phytosanitary regulations and to find infestations of quarantine pests that have penetrated the exclusion barrier. There are two basic forms of pest detection: traps and visual surveys. The use of traps has many advantages and traps are the preferred method of detection of insect pests. However, not all pests respond to traps or lures. For these pests visual surveys, with their own advantages and disadvantages, are used (Table III).

Traps may be completely visual, such as yellow traps used to catch aphids and whiteflies, but most often they contain one or more chemicals attractive to the target species (Table IV). These chemical lures include sex pheromones, pheromone precursors, parapheromones (attractant not of botanical origin or a pheromone precursor that attracts males), food lures, chemicals of unknown action, and combinations of visual traps and lures.

Visual surveys can look for the pest itself, such as the white garden snail (Theba pisana); the damage the pest can cause, such as that caused by the Asian longhorn beetle (Anoplophora glabripennis); or the abode of the pest, such as the galls of the balsam gall midge (Paradiplosis tumifex). Visual surveys may use food lures to attract and hold the pest as is done with the red imported fire ant (Solenopsis invicta).

Detection efforts are concentrated in those areas where the target pest might enter and where the pest may become established. In general, large urban areas have a greater number of invading exotic species than rural or agricultural areas. This is the result of people directly bringing in exotic invertebrates in the fruit, flowers, and other items that they obtain while traveling and the importation of large volumes of goods (food, plants, etc.) that are needed to service large population centers (Table V).

If a pest is found during a detection program, a delimitation survey is used to determine whether an infestation exists and if so, its physical boundaries. Unlike detection efforts that try to uniformly cover an area, delimitation efforts strongly target the area immediately around where the pest was found, with decreasing effort as one moves away from that point. For example, Mediterranean fruit fly detection in urban areas of California deploys a uniform 4 Jackson traps baited with...

Trimedlure per square kilometer. For delimitation, 100 Trimedlure-baited Jackson traps are deployed in the 2.56 km² area (core area) centered on the site where the first fly was found. An additional 50, 25, and 20 Trimedlure-baited Jackson traps per 2.56 km² are deployed respectively in three 1.6-km-wide rings around the core area.

Delimitation surveys are conducted until an infestation is confirmed and a decision about further actions is made or until it is determined that no infestation exists. The latter requires that no more target insects be found for a time period equal to several generations, typically two to three, of the pest. At the end of the delimitation effort, a trapping or visual survey program resumes at the detection level.

Delimitation efforts using visual surveys follow the same format, with a greater effort expended in the area immediately around the site where the pest was detected and diminishing effort as one moves away from that point.

PEST IDENTIFICATION

An important part of any detection program is the rapid and accurate identification of organisms that are found. Professional scientists provide these identifications and background information on the biology of the organism, which are used to help decide what, if any actions, may be taken against the pest. These professionals also provide information used to develop phytosanitary regulations and quarantine pest detection and delimitation programs.

PEST ERADICATION

Eradication of infestations of exotic pests is the most controversial aspect of regulatory entomology. Eradication is designed to eliminate a pest from a proscribed area, usually within a given time. Eradication programs are conducted at the point where the pest is found, not necessarily where it may do the most damage. Eradication programs using pesticide sprays in urban settings often generate considerable public outcry and opposition. Programs using nonpesticidal tactics or less intrusive methods of pesticidal applications engender little to no public concern. Thus the aerial application of pesticides or the extensive use of ground applications of pesticides in urban areas is strongly contested by the public, whereas mass trapping or male annihilation programs in the same areas are ignored. In general, successful eradication programs have the following components: the organism poses a clear-cut threat, an effective detection technique is available—usually not only visual surveys, the organism is limited in its distribution in the newly invaded area, continuous natural invasion of the organism cannot occur, and effective techniques exist to reduce the target population below the point at which reproduction can occur (Table VI).

Eradication procedures are applied to the target population for several life cycles of the organism beyond the last individual found. Posttreatment monitoring at delimitation levels is conducted for at least one additional life cycle of the pest. If no further individuals of the target organism are found within the treated area, eradication is considered to have been successful.

PUBLIC OUTREACH

Public outreach is conducted in a number of venues. Among the most frequently encountered are the forms that are required to be filled out before leaving a plane that has landed at a foreign airport or crossing a border. Information flyers handed out during eradication programs, on cruise ships, and at other sites are another venue through which the public is made aware of the exclusion efforts conducted on their behalf. Regular inspections of products moving into or out of an area keep professional importers and exporters aware of the quarantine regulations of their trading partners.

The five-component pest exclusion program described earlier, with modifications for local weather, topography, target species, and so on, is used by all countries that adhere to the International Standards for Phytosanitary Standards published by the Food and Agriculture Organization of the United Nations.

Reproduction, Female

Diana E. Wheeler
University of Arizona

In female insects, reproduction generally involves producing yolky eggs, mating, and then laying fertilized eggs. Across the diversity of insects, however, different ways of reproducing illustrate an astounding variation in this simple series of events as well as divergence from it. In the most extreme examples, females can reproduce without supplying eggs with yolk, without mating, and even without laying eggs.

Female reproduction has been one of the most intensively studied aspects of insect biology in the past 50 years for two reasons. First, frequent confrontations between humans and insects in the arenas of agriculture and health make understanding insect reproduction of great practical importance. Production of the next generation of insects has several steps that are centered on the female. To reproduce, females need to make eggs or provide their embryos with nutrition in other ways. Once made, females must find an appropriate spot to deposit their eggs. For entomologists concerned with problem insects, these steps offer opportunities to disrupt reproduction and reduce the number of insects in the next generation. Second, the diversity of ways that insects reproduce provides a rich source of material for discovering the underlying rules of biology. For example, the extraordinary effectiveness of female insects in converting resources into eggs led to their use as an intensively studied model system. The process by which yolk is taken up into insect eggs serves as a model for how cells take up large molecules from the surrounding environment.

STRUCTURE OF FEMALE REPRODUCTIVE SYSTEMS

Female insects can make eggs, receive sperm, store sperm, manipulate sperm from different males, and lay eggs. Their reproductive systems are made up of a pair of ovaries, accessory glands, one or more spermathecae, and ducts connecting these parts. Ovaries make eggs, and accessory glands produce substances to help package and lay the eggs. Spermathecae store sperm for varying periods of time and, along with portions of the oviducts, can control sperm use. The ducts and spermathecae are lined with cuticle.

The ovaries are made up of a number of egg tubes, called ovarioles. The number of ovarioles varies with the type of insect, its size, and its particular life history. Clearly, the number of ovarioles and the number of eggs that can be produced by each set an upper limit to the total number of eggs, or young, an insect can produce. The rate that eggs can develop is also influenced by ovariole design. In meristic ovaries, the eggs-to-be divide repeatedly and most of the daughter cells become helper cells for a single oocyte in the cluster. In panoistic ovaries, each egg-to-be produced by stem germ cells develops into an oocyte; there are no helper cells from the germ line. Production of eggs by panoistic ovaries tends to be slower than that by meristic ovaries.

Accessory glands or glandular parts of the oviducts produce a variety of substances for sperm maintenance, transport, and fertilization, as well as for protection of eggs. They can produce glue and protective substances for coating eggs or tough coverings for a batch of eggs called ootheca.

Spermathecae are tubes or sacs in which sperm can be stored between the time of mating and the time an egg is fertilized. Paternity testing of insects has revealed that some, and probably many, female insects use the spermatheca and various ducts to control or bias sperm used in favor of some males over others.

COMMON AND DIVERSE MODES OF REPRODUCTION

The most common mode of reproduction in insects is by yolked eggs, fertilized internally, that are laid outside the body. However, other modes of reproduction are not uncommon. Insects with unusual and even unique modes of reproduction are interesting as examples of extreme biological forms and processes. Modes of reproduction vary in three important aspects: whether eggs are fertilized, whether eggs are provisioned, and where embryonic development takes place.

First, reproduction without fertilization, or parthenogenesis, is common in insects as a normal means of reproduction in addition to or instead of sexual reproduction. For example, the system of sex determination in the Hymenoptera relies on parthenogenetic production of males. Virtually the entire order produces males from unfertilized haploid eggs and female from fertilized diploid eggs. This type of sex determination, called haplodiploidy, is also found in some Sternorrhyncha, Thysanoptera, and Coleoptera.

In another common type of parthenogenesis, germ stem cells in the ovary do not go through meiosis before they start development. As a result, offspring are clones of the mothers, having a full copy of her genes. Aphids are the premier example of this type of parthenogenesis. In a third type, meiosis occurs but the diploid number of chromosomes is restored by fusion of two nuclei. This type of parthenogenesis has been particularly well studied in stick insects (Phasmatida). A fourth type requires mating, but fertilization is not completed. Sperm is necessary for development to begin, but the male’s genes are discarded. Sperm-dependent parthenogenesis is found in some bark beetles.
A second important factor that defines the mode of development is the amount of yolk material provided to the egg. Amount of yolk can vary from none to more than enough to complete development. When eggs are laid without provisioning, nutrition must be obtained from elsewhere. Females of some insects, such as aphids, can keep developing embryos in their bodies and supply them directly with needed nutrients. In contrast, some parasitic and parasitoid wasps (e.g., Trigonidae, Braconidae) and flies (Tachinidae) produce tiny eggs lacking yolk and lay them inside other insects that can provide for them.

A third important descriptor of developmental mode is the site of embryonic development. Most eggs are laid outside the mother’s body but, in ooviviparous insects, eggs can be retained inside the body of the mother where the embryos develop. At hatching, they are released to the outside world. In true viviparity, embryos also develop in the mother’s body but there is no intermediate egg stage. The site of development of parasitoids is similar to that in viviparous insects, in that it is inside another insect. Development of parasitoids, however, takes place in the bodies of host insects, rather than in the mother.

**MANAGEMENT OF NUTRIENTS FOR EGGS**

In the common mode of reproduction by yolked eggs, female insects accumulate large amounts of macronutrients, especially protein and fat. Lipids are usually derived from carbohydrates in the diet and are not generally in short supply. Amino acids, particularly essential amino acids, can be limiting. Therefore these are a particularly important part of the yolk.

Eggs may be provisioned with nutrients obtained in either the larval or the adult stage or both. Insects that do not feed as adults and have their lifetime’s egg production completed when they become adults can draw only on larval nutrients. Even insects that feed after eclosion can use excess larval nutrients to provision eggs.

Mosquitoes and other blood-feeding Diptera provide examples of the often interlocking roles of larval and adult feeding. Female mosquitoes feed on nectar and vertebrate blood to obtain nutrients for egg production. In some mosquitoes, however, food eaten during the larval stage supports the production of at least some eggs. The ability to produce eggs without blood feeding is called autogeny. Some autogenous species can mature their eggs only this way and have lost the ability to feed on hosts. Other species are more flexible and can use leftover reserves, if they are available, but can feed on blood immediately if they are not. In addition, when species occur over a broad geographical area, they can be locally adapted. The pitcherplant mosquito, *Wyeomyia smithii*, is completely autogenous in the northeastern United States, where larval densities are low and food more abundant, but must feed on blood in the southeast, where larval resources are more scarce.

Aspects of both larval and adult environments can favor autogeny. A larval environment that offers more consistent resources than the adult one will favor obligate autogeny, whereas more predictably abundant food in the adult environment will favor obligate blood feeding. In the Northern Hemisphere, autogeny becomes more autogenous in the northeastern United States, where larval densities are low and food more abundant, but must feed on blood in the southeast, where larval resources are more scarce.

**TRANSFER OF SPERM AND POSTMATING MANAGEMENT**

Fertilization of eggs is the focus of sexual selection. Natural selection biases survival toward individuals that are most successful in their environment. Sexual selection biases its rewards toward those individuals that enhance the success of their own genotype in the next generation through any aspect of mating and subsequent fertilization.

Classically, males compete with each other for access to females, and females can choose to mate with them or not. Because insects have internal fertilization, there are many possibilities for females to manipulate sperm after mating. When females mate multiple times, male competition can take place between sperm in the female reproductive tract. Overlooked for many years, it is now known that the female may also have control over which male’s sperm will fertilize her eggs. Mechanisms that females use to bias paternity include active elimination of sperm, digestion of sperm, lack of sperm transport to the spermatheca, and decreased use of some sperm batches in fertilization. Postmating female choice is often called cryptic female choice, although it is no more cryptic than postmating competition between sperm.

Females are generally believed to choose their mates based on features that indicate their quality as parents. For example, a choice can be made based on behaviors such as gifts of food or some other indicator of resources, on the amount of sperm transferred, or on the concentration of a protective chemical given to the female. In addition to features that indicate success under the rules of natural and sexual selection, females may also choose sperm or mates based on genotypes that are most complementary with their own.

Highly social insects, especially those in perennial colonies, provide an interesting variation in female reproductive strategies. For example, to produce enough worker insects, queens must have a large supply of sperm. Only a small proportion of total sperm is used to produce new queens and males; most of it is used to make more workers. In social Hymenoptera, which includes ants, bees, and wasps, males can be produced without sperm because males develop from unfertilized eggs. As far as is known, new queens mate only before starting or joining a colony and must, therefore, at that time store as much sperm as they will need for the remainder of their lives. One important factor that affects colony longevity is the amount of sperm available for fertilizing eggs. Queens of large leaf-cutting ants (*Atta*) mate many times and store as many as 250 million sperm. In contrast, termites do not have to store large amounts of sperm because termite colonies are headed by both a queen and a king, and mating takes place throughout their lives.

Ants, the most speciose of the social insects, have a wide range of colony sizes and rates of worker production. Across the group, the number of sperm stored is correlated with the number of ovarioles, which suggests that there is a cost to long-term sperm storage and that sperm storage is matched to the lifetime needs of a successful colony queen.

**OVIPOSITION**

The culmination of insect reproduction is typically the oviposition of mature, fertilized eggs in an environment that will support their development. Eggs can be placed on surfaces, in crevices, in soil, and in animal or plant tissue, and accessory glands produce secretions used to protect eggs. Females often have a structure called an ovipositor, which is made up of modified appendages on the last abdominal segments and serves as a tool for penetrating substrates. For example, many grasshoppers use their ovipositors to dig into soil, where they
lay eggs in a frothy matrix. Also, some parasitic wasps have long, needle-like ovipositors that can drill through wood to reach host insects.

Oviposition can be linked physiologically to prior events in egg maturation. For example, insects that mature eggs throughout the adult stage can often adjust their egg production based on available oviposition sites as well as on available nutrition. When oviposition sites are rare, unspawned eggs can inhibit the hormonal control network that guides egg maturation. Delayed oviposition can further slow egg production and lead to resorption of eggs, which reallocates resources away from reproduction and toward survival.

Oviposition sites also provide sensory cues that can stimulate further egg maturation. For example, egg production in newly eclosed females in the diamondback moth, *Plutella xylostella*, is accelerated by the presence of single volatile components of host cabbage plants. Ovarian response to oviposition and related cues can reduce the opportunity costs females suffer when the supply of completed eggs does not match the availability of oviposition sites.

Protection of eggs, particularly those laid in clusters, can be extended by parental care. For example, egg guarding reduces the risk of eggs being used by parasitoids or eaten by predators.

**Reproduction, Female: Hormonal Control of**

**Diana E. Wheeler**

*University of Arizona*

Female reproduction has been a major focus of entomological research for the past century, driven by the need to control populations of insect pests. The central process in female reproduction in insects, the production of eggs, is hormonally regulated. To reproduce successfully, females must coordinate egg production with other aspects of reproduction such as dispersal, the availability of resources, and selection of mates and oviposition sites. Environmental signals are effectively translated into physiological processes by networks of hormonal signals.

Egg development in insects has become a model experimental system studied to understand the general principles of stage-, sex-, and tissue-specific responses to hormones. In insects, juvenile hormone (JH) and ecdysone typically play important roles in orchestrating egg development. The development of improved analytical methods has led to the elucidation of the roles of other key hormones, particularly a variety of neurosecretory hormones. Common themes in the hormonal control of egg production are becoming clearer, as are important differences between insect groups.

**PATTERNS OF FEMALE REPRODUCTION**

To reproduce successfully, female insects must coordinate feeding, mating, and locating places to lay their eggs. Mating and egg laying almost always take place in the adult stage, but female insects vary widely in the manner in which they feed and accumulate nutrients for egg production. The accumulation of nutrients for eggs takes place during larval or nymphal development, as well as during adult life.

Eggs are generally filled with bulk nutrients to support embryonic development, and so it is not surprising that the timing of egg production is often tightly linked to the timing of feeding. The earlier the nutrients required for egg production are eaten, the earlier the egg production can begin. Starting egg production during the immature stage and completing it before eclosion allows female insects having very short adult lives to focus on mating and laying eggs. In fact, adults in many insects do not feed at all and even lack mouthparts. Mayflies are an example. At the other end of the spectrum, insects may take only sufficient nutrients during the larval stage to support their own larval or nymphal development. As adults, they must compensate for the lack of stored reserves by additional feeding. Female mosquitoes that emerge ready to find a blood meal are one example of this pattern. The relative advantages of these contrasting strategies depend on the opportunities for acquiring nutrients, as well as other ecological factors that exist in both the immature and adult habitats. When egg development is telescoped into preadult stages, hormonal signals that control larval or nymphal development and metamorphosis must be coordinated with those of ovarian and reproductive development. Not surprisingly, setting the timing of egg development to different points relative to preadult development requires different hormonal controls.

Female insects that feed as adults differ in the size and number of their meals. At one extreme, females feed fairly continuously. At the other extreme, females take very large meals and have long periods of fasting between them. In blood-feeding insects particularly, a single blood meal can supply the bulk of nutrients necessary for a batch of eggs. Hormones signal the results of feeding to ensure that egg development is matched to an adequate supply of nutrients.

Egg development begins in the germarium, when stem germ cells produce daughter cells that become oocytes. Depending on the type of egg development, oocytes occur alone or in association with sister nurse cells, and follicle cells surround either the oocyte or the oocyte–nurse cells complex. Both nurse cells and follicle cells make and transfer materials important for future embryonic development to developing oocytes. In addition, vitellogenins, fats, and carbohydrates are all taken up into the egg, mostly from the blood. Most or all of the vitellogenins is made by the fat body, a complex organ analogous to the vertebrate liver. Fat body cells release yolk proteins into the blood from which they are taken up by rapidly growing eggs.
When uptake of nutrients is complete, the follicle cells secrete egg coverings in preparation for oviposition.

Hormonal control of egg production is well understood in only a few species. Nevertheless, enough is known about a wide variety of species to infer some general patterns. Four checkpoints in ovarian development are commonly regulated by hormonal signals: (1) the formation of new oocytes by stem cells in the germarium, (2) initial growth of the oocyte, (3) vitellogenin synthesis by the fat body, and (4) vitellogenin uptake by the oocyte. The hormonal signals that break these checkpoints reflect various aspects of the external environment and internal conditions.

HORMONES

The two major hormones that control female reproduction, ecdysone and JH, also control preadult development and metamorphosis. In adult females, ecdysone is produced by ovaries, rather than by the prothoracic glands as in nymphs and larvae. JH is produced by a pair of glands called the corpora allata in both preadult and adult stages. The corpora allata are located near the brain and are connected to it by tracts of neurosecretory cells. Neurosecretory hormones made in the brain and in other parts of the central nervous system are also important controlling factors. Nerves are also part of control networks, especially in relaying sensory information to the brain cells, which affect the hormone-producing organs.

EXAMPLES OF HORMONAL CONTROL OF EGG PRODUCTION

Hemimetabolous Insects That Feed Continuously

Migratory locusts, Locusta migratoria, feed almost continuously if they can, and females produce and lay eggs in batches. The importance of JH in controlling egg production in this species has long been recognized. Shortly after eclosion, JH levels rise and stimulate synthesis of vitellogenin by the fat body. Mating and plant odors also affect JH level through neurosecretory cells in the brain. JH alone, however, is insufficient to complete a batch of eggs. An ovary-maturing parsin (OMP), which is a neurohormone, is required, in addition to JH, to stimulate sufficient vitellogenin synthesis and uptake.

In the viviparous Pacific beetle cockroach, Diploptera punctata, JH also regulates vitellogenin synthesis and uptake. Signals associated with mating and pregnancy result in increased and decreased levels of JH, respectively. Mating stimulates the release of JH through mechanical stretch of the reproductive tract. The signal is transmitted to the brain by nerves. After mating, females produce a set of eggs and retain them in a pouch off the oviduct called the brood chamber until embryonic development is complete. After the hatching and deposition of nymphs, the female can reproduce again. As in many insects, lack of sufficient nutrients causes JH levels to fall, which delays production of the next batch of eggs.

Hemimetabolous, Blood-Feeding Insects

The bloodsucking bug Rhodnius prolixus takes blood meals throughout its life. For nymphs, blood meals are required for growth and molting; for adults they are needed for egg production. In adult females, abdominal stretching associated with feeding stimulates the release of a peptide hormone from the thoracic ganglion. As a result, the corpora allata release JH, which causes vitellogenin synthesis by the fat body and vitellogenin uptake by growing oocytes. Only the terminal, largest oocyte in each ovariole develops, however. Nerves that stretch as the ovaries grow secrete a neurohormone, called an oostatic hormone, that prevents smaller oocytes from taking up vitellogenin. The result is a synchronously produced batch of eggs. As the eggs mature, the oocyte secretes ecdysone, which triggers the release from the brain of a neurohormone that stimulates contractions for laying the eggs.

Lepidoptera: Holometabolous Insects That Vary in Timing of Egg Production

Lepidoptera are holometabolous insects, which means that preadults (larvae) and adults differ greatly in form, function, and ecology. Larvae are specialized for feeding, and adults are specialized for dispersal and reproduction. Despite the tidy appearance of such discrete stages, an extensive part of egg production can occur before the adult stage. Enough Lepidoptera species have been studied to allow some appreciation of the variation in egg production patterns across the group. Development and egg production are orchestrated by the same toolbox of hormones, so it is not surprising to find that Lepidoptera in which development and egg production occur simultaneously have control networks different from those in which these processes are sequential.

At one end of the spectrum, females complete egg production before eclosion. Adults of these species do not feed; they mate immediately after eclosion and are short lived. Examples are silkworms (Bombyx mori) and gypsy moths (Lymantria dispar). JH does not stimulate egg production and can even inhibit some aspects of it. Pulses of ecdysone associated with pupal development apparently stimulate vitellogenin synthesis and uptake.

In some moths, only part of egg production is completed before eclosion. Examples include pyralid moths such as the Indian meal moth (Plodia interpunctella) and the southwestern corn borer (Diatraea grandiosella). Synthesis and uptake of vitellogenin take place before the molt to adult, and egg coverings are added afterward by the follicle cells. The portion of egg development that occurs after eclosion can be controlled by JH.

Finally, in many Lepidoptera, such as the monarch butterfly (Danaus plexippus), development and egg production are sequential and nonoverlapping, and hormones regulate egg development during the adult stage. In these insects, JH typically stimulates both vitellogenin synthesis and uptake.

Holometabolous, Blood-Feeding Insects

Hormonal control of egg production has been studied extensively in Aedes aegypti, the yellow fever mosquito, spurred by the ability of these and other mosquitoes to transmit diseases. Most mosquitoes must drink blood to obtain sufficient amino acids to make eggs. Females in a few species of mosquitoes have the ability to carry over reserves from the larval stage to make part or all of entire first batch without blood feeding.

Eclosion of female mosquitoes is usually followed closely by an increase in JH titer. The rise in JH induces target tissues to become responsive to hormonal signals that occur later. Specifically, the ovaries become sensitive to ovarian ecdysiotropic hormone (OEH), the primary oocyte grows slightly, and the fat body becomes responsive to ecdysone. The posteclosion peak of JH also causes behavioral changes: females search first for mates and then for hosts. Egg development is blocked until a blood meal can be taken. This check-point ensures that the intensive metabolic activity required for making eggs will not occur unless enough nutrients are available. When the mosquito has found a sufficiently large blood meal or series of
meals, OEH is released into the blood by neurosecretory cells in the brain. OEH stimulates the ovary to produce ecdysone, which then stimulates the fat body to synthesize vitellogenin and the ovary to take it up. The ecdysone peak also causes new, secondary oocytes to separate from germaria, the first step in preparing for the next cycle of egg production. Growth of the primary oocyte ends at about 36 h after blood feeding. JH begins to rise again, and this stimulates the secondary oocytes to grow slightly and become ready for the next round of egg production. Finally, the eggshell is produced, the eggs are laid, and the mosquito is then ready to seek another blood meal.

Stimulation of vitellogenin synthesis by ecdysone has been studied at the molecular level. Analyses of the nucleotide sequence upstream of the vitellogenin gene show several broad regions of control. First, closest to the gene, is a binding site for ecdysone bound to its receptor complex. Binding to this site is necessary for expression. Second, more distally, are binding sites for two transcription factors, E74 and E75, that are known to be expressed quickly in response to an ecdysone signal. Therefore, the regulatory region of the gene has both direct and indirect interactions with ecdysone.

Holometabolous, Feeding Continuously
In contrast to mosquitoes, the fruit fly Drosophila melanogaster feeds continuously, and eggs develop serially as resources become available. The chain of oocytes in each ovariole includes a range of developmental stages. A balance between JH and ecdysone levels controls how many eggs produced.

In D. melanogaster, yolk proteins are made not only by the fat body but also by ovarian follicle cells. JH and ecdysone stimulate synthesis in the fat body, but only JH stimulates follicle cells. JH appears to enhance egg maturation, whereas ecdysone inhibits it. The antagonism in the effects of the two hormones can be seen by manipulating the amount of food and mating. When food is withheld, JH level drops relative to ecdysone levels and oocytes on the verge of taking up yolk proteins die. In addition, formation of new oocytes is reduced as more die than progress. Providing sufficient food again increases JH levels and reduces cell death. Mating enhances oocyte progression. Sex peptide, a hormone-like substance in seminal fluid, stimulates a rise in JH. Therefore, the increase in egg production seen after mating seems to act through the same hormonal mechanism used in nutrition. In this way, a sexually mature virgin female will not produce new eggs if she lacks either food or a mate. The two points of cell death, at separation of oocytes from the germarium and at the initiation of yolk protein uptake, correspond with similar checkpoints in mosquitoes.

HORMONAL LINKS BETWEEN EGG PRODUCTION, RECEPTIVITY, OVIPOSITION, AND PARENTAL CARE
Hormonal control of egg production in insects can be linked to other activities or states related to reproduction such as receptivity to mating, feeding, oviposition, and migration. In mosquitoes and D. melanogaster, receptivity and feeding are associated with an increase in JH level, which triggers early events in the production of eggs. In other insects, however, JH can be inhibitory or have no effect.

Oviposition, too, can be under hormonal control. Oviposition by L. migratoria requires extreme extension of the abdomen. Muscles in the appropriate segments respond to JH by altering their contractile properties so that they can function when greatly extended.

Adult insects are often specialized for migration in addition to reproduction. These two functions can create a conflict between protein needs for flight muscles and eggs, and between lipid and carbohydrate needs for flight fuel and eggs. Hormonal coordination can minimize such physiological conflicts. Both the large milkweed bug, Oncopeltus fasciatus, and the boll weevil, Anthonomus grandis, use JH to stimulate egg production and long-duration flights. Stimulation of flight apparently requires low levels of hormone, whereas higher levels stimulate oogenesis but inhibit flight. High levels of JH in some insect species lead to both yolk uptake and breakdown of flight muscle.

Burying beetles (Nicrophorus orbicollis) use carcasses of small vertebrates for their own food, for an oviposition site, and as food for their offspring. Immediately after females have found a suitable dead body, their JH levels rise and egg production is stimulated. JH cannot, however, stimulate yolk uptake in the absence of a carcass, indicating that other factors are important in integrating the discovery of the food source and oviposition site with egg production. Juvenile hormone surges even higher in females when the larvae hatch. Egg production is not stimulated by this rise, which is necessary to stimulate and maintain parental care of developing larvae.

SUMMARY
Female reproduction in insects is controlled in diverse ways. The most fundamental process, egg production, is linked to other aspects of reproduction and reproductive behaviors by hormonal controls. Common themes are the central roles of JH and ecdysone, with control points modulated by neurohormones. Hormonal control of egg production is relatively well understood in a few insects because of its use as a model system for studying hormone action. The integration of hormonal controls with other aspects of reproduction is more complex and is less well understood.

Reproduction, Male

Marc J. Klowden
University of Idaho

Insect reproduction is accomplished with both enormous numbers and an elegant simplicity. In partnership with the female reproductive system, the male reproductive system of insects produces haploid gametes, the spermatozoa, that fertilize the haploid female gamete, the oocyte. Sperm develop in the testes and, when mixed with secretions from accessory glands, travel through the female genital tract when the insects mate, to be stored for later egg fertilization.

STRUCTURE OF THE MALE REPRODUCTIVE SYSTEM

The basic component of the male reproductive system is the testis (Fig. 1A), suspended in the body cavity by tracheae and fat body. The more primitive apterygote insects have a single testis, and in some lepidopterans the two maturing testes are secondarily fused into one structure during the later stages of larval development, although the ducts leading from them remain separate. However, most male insects have a pair of testes, inside of which are sperm tubes or follicles that are enclosed within a membranous sac. The follicles connect to the vas deferens by the vas efferens (Fig. 1B), and the two tubular vasa deferentia connect to a median ejaculatory duct that leads to the outside. A portion of the vas deferens is often enlarged to form the seminal vesicle, which stores the sperm before they are discharged into the female. The seminal vesicles have glandular linings that secrete nutrients for nourishment and maintenance of the sperm. The ejaculatory duct is derived from an invagination of the epidermal cells during development and, as a result, has a cuticular lining. The terminal portion of the ejaculatory duct may be sclerotized to form the intromittent organ, the aedeagus. The remainder of the male reproductive system is derived from embryonic mesoderm, except for the germ cells, or spermatogonia, which descend from the primordial pole cells very early during embryogenesis.

PRODUCTION OF SPERMATOZOA

Within the testes are numerous tubular follicles that contain the developing male gametes. These follicles are in turn enclosed by a peritoneal sheath. The follicle number varies considerably; there is only 1 follicle in some coleopterans and over 100 in some orthopterans. The follicle is formed when a stem cell divides mitotically at the anterior region of the follicle to produce a gonialblast and is surrounded by cyst cells in the stem cell niche (Fig. 2). Mitotic division of the gonialblast results in spermogonia that are enclosed by the somatic tissue that form cysts. The development of the spermatozoa occurs within these cysts, which elongate as development proceeds. As more cysts are synthesized, they move the more mature ones posteriorly so that a range of cysts that contains gametes in progressive developmental stages is produced.

A spermatogonium within its cyst divides mitotically 6–8 times, ultimately resulting in 64–256 diploid spermatocytes, each of which remains connected by cytoplasmic bridges or ring canals. Farther down the spermatocytes undergo meiotic division to become haploid spermatids. At the posterior end of the cyst, the spermatids complete a developmental transformation known as spermiogenesis to become the spermatozoa, with heads that contain the nuclear material and elongated flagella for motility. Finally, the spermatozoa break through the cyst and migrate to the seminal vesicles where

![Figure 2](A) Longitudinal section of one follicle showing the development of spermogonia from spermatogonia within cysts. (B) The stem cell niche at the anterior of the follicle, with stem cells surrounded by cyst progenitor cells and the hub dividing to give rise to a gonialblast.)
they remain as a reservoir of sperm until the insect copulates with a female.

Insect spermatozoa have elongated heads and especially long tails (Fig. 3). Within the head are the nucleus and the acrosomal complex, which contains the enzyme acrosin and is associated with the penetration of the plasma membrane of the egg for fertilization. Insect sperm are unique in that they are the only cells of these animals that bear a flagellum. Within the flagellum is an axial filament that develops from the centriole and consists of an array of microtubules in a 9+9+2 arrangement, with nine outer accessory tubules, nine inner doublets, and a pair of central tubules comprised of the dimeric protein tubulin. One member of each inner doublet also bears the protein dynein, which breaks down ATP and converts the energy released into flagellar movement.

Another feature of the reproductive tract of male insects is a pair of male accessory glands. These glands can open into either the vas deferens or the ejaculatory duct. Those arising from the vas deferens during development are mesodermal in origin, whereas in some insects in which they originate from the ejaculatory duct they have an ectodermal origin. The male accessory glands serve a variety of functions, including producing the seminal fluid that serves as a transport, activation, and nourishing medium for sperm; forms a vaginal mating plug that temporarily blocks sperm from another male from entering; and forms spermatophores, the proteinaceous secretions of the glands that enclose the sperm and protect them while they are being transferred to the female.

The male accessory glands also produce substances that affect the behavior and physiology of the female. During insemination, peptides produced by the accessory glands that are contained in the semen are transported to various sites within the female. They are frequently involved in triggering her reproductive processes, including oogenesis and oviposition, or terminating subsequent female mating behavior so as to prevent her from acquiring the sperm of another male. Male accessory gland substances are frequently responsible for monogamy in females.

**EXTERNAL GENITALIA AND MALE COURTSHIP**

The external genitalia of males show an extreme morphological divergence. Indeed, their shapes often serve as the only reliable basis for species identification in taxonomic keys. In species in which the females mate often, there may be selective pressure for males to develop genitalia that compete for more effective ways to inseminate the females. There is a selective pressure for the evolution of male genitalia that offer males the greatest success; males with genitalia that more effectively transfer sperm are more likely to have their genetic contributions remain in the gene pool. Because copulation may last for a long period, males must have a way of avoiding detachment by other males that are also attempting to mate. Male insects have thus evolved a diverse array of grasping structures that allow the male to remain attached to the female; these devices include claspers, spines on the aedeagus, and even the use of mandibles to grasp a portion of the female’s body. Structures have also evolved for the removal of existing sperm from a prior mating. For example, the aedeagus of the damselfly male scoops out the sperm present in the female before he adds his own. He thus eliminates any competition among sperm that may already be present in the female. Some male bedbugs inseminate the female by piercing her cuticle and depositing sperm directly into the body cavity.

Male reproductive behavior typically involves first searching for a female and, once she is found, precopulatory behaviors that increase her receptivity for copulation. This may include the presentation of a nuptial gift that occupies the female and increases her nutritional state. Once copulation is initiated, the actual transfer of sperm may require from a few minutes to a few hours. To protect their genetic investment, some males remain with the female for a variable interval after insemination has taken place. Male termites guard their mates for life. Some male scarab beetles gather dung for the female to lay her eggs on or help her to build a burrow and even remain inside the burrow with her for months.

Male paternal investment in offspring is highly expressed in the giant water bugs of the family Belostomatidae. Females lay their eggs on the backs of partially submerged males, interrupted only to mate repeatedly with the male. The males carry the eggs on their backs until the young hatch, actively maintaining their own position in the water in order to properly aerate the eggs.

Reproduction, Male: Hormonal Control of
Marc J. Klowden
University of Idaho

The endocrine control of reproduction in female insects has been relatively well studied, perhaps because egg production is often cyclical and the experimental manipulation of hormones at key developmental periods has a direct effect on the number of offspring the females produce. This has not been the case for the males of most insect species in which the production of sperm may begin early during the larval, nymphal, and pupal stages and often continues throughout adult life. Given the vastly different hormonal conditions that exist during the immature and adult periods, a unifying scheme for the control of male spermatogenesis has not been forthcoming. There are only a few examples of hormones controlling the reproductive processes of male insects.

PRODUCTION OF SPERM

The male gametes are produced in the follicles of the paired testes. The development of the testes during metamorphosis and their synthesis of proteins respond to the insect hormone 20-hydroxyecdysone (20HE). In the reproductively mature male, apical stem cells at the anterior end of the testes are surrounded by cyst progenitor cells and specialized non-dividing somatic cells, known the hub, that together form the stem cell niche. Signaling from the niche regulates the renewal, maintenance, and survival of the stem cells. The stem cells divide mitotically to produce a gonialblast that becomes surrounded by a follicular cyst produced by the cyst progenitor cells. The development and maturation of spermatozoa occurs within these cysts.

Both 20HE and juvenile hormone (JH) have been implicated in the regulation of spermatozoa within the testes. In the absence of prothoracic glands of the adult male, the 20HE is produced by the testes themselves in response to an ecdysiotropin produced by the neurosecretory cells of the brain. High levels of 20HE increase the rate at which the spermatogenesis undergo mitotic divisions to form spermatocytes, but this increase is abolished by high levels of JH. When spermatogenesis begins during the larval period, as in some Lepidoptera, the spermatocytes initiate their meiotic divisions but are arrested at prophase until the end of the larval period is reached. In many holometabolous insects, in which to pupate. A postwandering peak of 20HE occurs before the end of the larval period that induces the “wandering” behavior that allows the larva to find a secluded spot in which to pupate. A postwandering peak of 20HE unblocks the meiotic division of the spermatocytes and allows the cells to proceed to metaphase. In some insects, JH has also been found to accelerate spermatogenesis. The release of mature spermatozoa from the cysts has a circadian rhythmicity in some insects that is inhibited by 20HE and occurs when levels of 20HE decline.

When spermatogenesis begins during the larval stage, as it does in most Lepidoptera, it is interrupted if the insect diapaus as a larva or pupa. However, it resumes once diapause has been completed. The interruption is not caused by a pause in developmental activity but rather from the lysis of developing gametes before they become mature. The renewal of spermatogenesis when diapause has been terminated occurs when the titers of 20HE increase.

The developmental sequence in which spermatozoa develop from spermatids involves an elongation of both the nucleus and the flagellum. In Lepidoptera, the nuclear elongation is triggered by the declining concentrations of 20HE, but the elongation of the flagellum appears to be independent of any hormone.

Lepidopteran males produce two different types of sperm. Eupyrene sperm have a nucleus and fertilize the eggs, but apyrene sperm are amnulate. Both types of sperm are transferred to the female spermatheca after copulation. The function of the apyrene sperm is not well understood but they may provide nutrients required by the eupyrene sperm or aid in the migration of the eupyrene sperm within the female genital tract. The developmental pathway leading to the differentiation of apyrene sperm is regulated by a hemolymph-borne apyrene-spermatogenesis-inducing factor that is present at the time of pupation.

ACCESSORY GLANDS

The accessory glands of the male reproductive system produce semen, accessory structures such as spermatophores, and various peptides that regulate female behavior and physiology. The interaction between JH and 20-hydroxyecdysone during postembryonic development regulates the development and differentiation of the glands. Juvenile hormone alone may also control the synthesis of those specific proteins that are transferred to the female. The accumulation of some secretory peptides in the glands that are enhanced by JH may be either enhanced or inhibited by the simultaneous presence of 20HE. In the blood sucking bug, Rhodnius prolixus, protein synthesis by the glands is stimulated by brain neuropeptides. In the German cockroach, Blattella germanica, the activity of the corpora allata, which is the source of JH, declines during the formation and transfer of the spermatophore and may thus initiate a new cycle of male accessory gland maturation.

Research Tools, Insects as

Kipling W. Will
University of California, Berkeley

In addition to serving as classic experimental laboratory animals (e.g., *Drosophila* flies in genetics, *Periplaneta* cockroaches in neurophysiology, and *Manduca* moths and *Schistocerca* grasshoppers in physiology), insects have been essential to the formulation and testing of many general theorems in ecology and evolutionary biology. Scientists seek to develop general synthetic theories in biology, just as in physics and chemistry, that provide answers to questions of how and why things are as they are. Perhaps more importantly, these generalities make predictions that allow us to test what we think we know. The use of data to constantly reevaluate our theories divides empirical science from personal belief systems and popular metaphysics. The latter two are concerned with understanding the fundamental nature of all reality and often are based on abstract elements. In contrast, hypotheses in mainstream science are typically explanations of the processes that exist in nature and are tested against empirical observations.

To develop these testable hypotheses in science, a constellation of data from model systems is needed, especially in biology. Insects are used as many of these model systems. In part this is because they are so abundant and species rich that, in terms of diversity, they make up the bulk of terrestrial species and, in many habitats, the greatest number of individuals. Because of this dominance, comprehensive biological hypotheses must account for insects if the hypotheses are to be generally accepted. Insects provide the numerous observations that are essential for developing and supporting broadly applicable hypotheses explaining the diversity and distribution of life on earth.

Insects are a magnificent source of observations. The sheer number of units for study at all levels—species, populations, and individuals—provide the repeated patterns of variation that provoke questions and provide data for hypothesis testing. Also, insects usually have a relatively short life cycle, often more than one generation per year. This allows scientists to make multiple observations of all life stages of a species in a relatively short time period. Insect species can be widespread, but typically they are localized, making it easy to accumulate distributional data for at least the more conspicuous taxa. Certainly there is an important human factor as to why insects are so important in the study of biology. Insects delight us with their forms and behaviors and seem to embody all that fascinates humans about the natural world—beauty, diversity, mystery, and perhaps most of all, mystery. Wallace even suggested this may have been a common thread that helped to lead both of them to arrive independently at similar conclusions about the evolutionary origin of species. Both present colorful stories of collecting insects. Wallace wrote wonderful passages on “one good day’s work” collecting in Borneo, recalling species by species those collected and those that escaped one day, to be pursued the next. Darwin recalls with great passion his beetle collecting and the unflagging thrill of discovering rare or new species. Wallace earned much of his livelihood collecting and providing specimens to museums and private collectors. He sold thousands of specimens at about 2 cents each to fund his tropical expeditions. For both Darwin and Wallace, attention to details necessary for separating species, subspecies, and varieties of insects was fundamental to developing their ideas. The diversity of forms and sheer reproductive output of insects provided examples that cultivated in their minds the theory of natural selection.

Wallace traveled with another entomologist and great naturalist, Henry Bates. In 1842 Wallace and Bates went to the Amazon to explore and to collect insects. These explorations and Bates’ collections (Wallace’s were unfortunately lost in a ship fire) became incredibly valuable in terms of insights into natural history and evolution. For 11 years, Bates collected insects, primarily butterflies and beetles, that were and remain a source of awe and study material for students of insects and users of European museum collections. Bates readily accepted Darwin’s and Wallace’s ideas of natural selection as the mechanism of evolution and went on to develop his theory of mimicry. Known as Batesian mimicry, this concept stemmed from his experience with tropical butterflies. This theory is widely applied throughout biology as an explanation for the similar and convergent appearance of some organisms.

**THEORETICAL WORK IN THE 19TH CENTURY**

Willi Hennig is best known for developing a coherent theory for phylogenetic systematics, a field of research that investigates and presents relationships among taxa. Hennig’s theoretical works form the core of modern cladistic methods (use of shared derived characteristics to elucidate sister group relationships of taxa). Hennig was also the foremost authority on flies (Diptera) and produced many publications, including his series of publications on maggots (dipterous larvae), which became the standard work on the subject. Throughout his classic work *Phylogenetic Systematics*, he relied on insect examples. Today our ideas about how to develop hypotheses of relationships for animals in an evolutionary scheme and how to classify them are largely based on theories and methods developed with insects as models.

Biogeography is a major field of biology that strives to understand the spatial relationships of organisms and looks at both historical and contemporary questions regarding biodiversity. Darwin, Wallace, and Hennig were all prominent contributors to this field, each drawing on ample observations from the insect world. Wallace was particularly influential in developing ideas that are still important in biogeographical studies. Biogeographical regions of the earth presented by Wallace, which were modified from Philip Sclater’s previously published scheme, are still a standard part of describing the geographic distribution of animals. Most prominent is Wallace’s observation of a distinct change in fauna between Bali and Lombok in the East Indies, known as Wallace’s line. Wallace drew heavily on his knowledge of insect life histories, dispersal abilities, and distribution of some conspicuous insects (beetles and butterflies) to develop his biogeographical ideas.
Respiratory System

Jon F. Harrison
Arizona State University

The primary goals of the insect respiratory system are to deliver oxygen from the air to the tissues and to transport carbon dioxide from the tissues to the air. In contrast to many other animals, most oxygen and carbon dioxide transport occurs in the gas phase, with gases transported through the tracheal system by both diffusion and convection. However, insects do have oxygen-binding pigments that likely assist in gas exchange, with primitive insects having hemocyanin in the hemolymph and probably all insects possessing hemoglobin in certain tissues. The structures and physiological mechanisms of the respiratory system vary dramatically with phylogeny, developmental stage, and habitat. With a given tracheal structure, the ability of the tracheal system to transport gases can be modulated dramatically by varying spiracular opening, ventilation, and the fluid level in the tracheoles.

MECHANISMS OF GAS EXCHANGE

Insect gas exchange occurs in a series of steps. Oxygen molecules first enter the insect via the spiracles, then proceed down the branching tracheae to the tracheoles. The terminal tips of the tracheoles are sometimes fluid-filled, so at this point gas transport may occur in a liquid medium rather than air. Oxygen then must move across the tracheal walls, through the hemolymph, across the plasma membranes of the cells, and finally through the cytoplasm to the mitochondria. Carbon dioxide generally follows a reverse path.

Diffusion

Diffusion is the passive movement of molecules down their concentration gradient, driven by random molecular motions. Because oxygen is transported to the tissues as a gas and the diffusion rate of oxygen is much more rapid in air than in water, the insect tracheal system is capable of high rates of gas exchange by diffusion. Consumption of oxygen by the tissues lowers internal oxygen levels, creating a partial pressure gradient from air to tissues that drives diffusion of oxygen through the tracheae. The reverse occurs for carbon dioxide. The final steps of oxygen delivery, from the tracheoles to the mitochondria, may occur by diffusion in all insects, because diffusion operates rapidly over micron distances. In the initial steps of oxygen delivery (across the spiracles, through the tracheae), the importance of diffusion is more variable. Simple diffusive gas exchange through the tracheae and spiracles likely occurs in some pupae, as washout rates of inert gases are similar to those predicted from their diffusion coefficients. Diffusion is clearly the only mechanism of gas exchange in insect eggs, with the major layer providing resistance being either the crystalline chorionic layer or the wax layer of the egg shell. Unlike

Respiratory System

vertebrates, most insects can recover from exposure to anoxia; during such recovery oxygen delivery to the mitochondria seems very likely to occur by diffusion since the ventilatory muscles are paralyzed.

Convection

Convection is the bulk movement of a fluid (gas or liquid) driven by pressure. Differential air pressures can drive gas movement through the tracheae and spiracles at much higher rates and over longer distances than diffusion. Tracheal and air sac collapse and inflation can now be observed within living insects using modern imaging systems such as phase-contrast synchrotron imaging (Fig. 1).

The advantages that insects gain by using convective gas exchange are somewhat controversial. In general, the use of convective gas exchange increases with metabolic rate, suggesting that convection is necessary to allow most insects to achieve high rates of gas exchange. However, it is also plausible that the increased convection is at least also important for other functions such as reducing gradients for oxygen within the active insect or is a byproduct of hemolymph pumping.

The mechanisms by which insects achieve convective gas exchange are complex and varied. In many insects, well-coordinated actions of muscles and spiracles produce regulated convective air flow through the tracheae and spiracles. Most commonly, convection is driven by contractions of respiratory muscles attached to the body wall, which produce increases or decreases in body volume, causing compressible portions of the tracheal system to inflate or deflate.

One common mechanism by which insects accomplish convective air flow through the trachea is abdominal pumping. Expiratory muscles connect the ventral and dorsal cuticular plates and also span adjacent abdominal segments. When they contract, they pull the dorsal terga and ventral sterna together (Fig. 2) and the tip of the abdomen inward as the cuticular plates slide over the flexible pleural and intersegmental membranes. When the body volume decreases, the cuticle pushes on hemolymph and tissues, which in turn compress the collapsible air sacs. Inspiration may be passive and result from cuticular elasticity. Alternatively, contractions of inspiratory muscles attached to tall sternal apodomes and the lower edge of the terga can lift the terga relative to the sterna and expand abdominal volume and the air sacs (Fig. 2). Abdominal pumping drives hemolymph pulsations and tracheal air flow in a wide variety of adult, larval, and pupal insects.

In many of the insects that have been examined, abdominal pumping is coordinated with spiracular opening in a manner that produces directed flow through particular spiracles. In some insects, unidirectional air flow through the longitudinal tracheal trunks occurs. During inspiration, abdominal spiracles are closed and air flows in through open thoracic spiracles (Fig. 3). During expiration, air flows out open abdominal spiracles, while the thoracic spiracles are closed. There is evidence for unidirectional air flow in adult Dictyoptera, Orthoptera, Hymenoptera, Coleoptera, and Odonata. In some pupae, abdominal pumping is coordinated with the opening of one or a few “master spiracles” that exchange all gases.

Muscles that have the primary purpose of driving hemolymph circulation, such as the heart and ventral diaphragm, also play a role in creating convective ventilation. Pumping of the heart and accessory muscles

(B) and (C) Inflated (left) and deflated (right) tracheae in the mesothorax (B) and metathorax (C), red stars indicate tracheae, scale bar 200 μm; the frequency of these cycles is 10–15 min⁻¹ [Socha et al. (2008), adapted with permission from the Society for Experimental Biology].

![FIGURE 2](image2.png)

**FIGURE 2** Respiratory muscles that drive the dorso-ventral movements of the abdomen during abdominal pumping in a grasshopper.

![FIGURE 3](image3.png)

**FIGURE 3** Unidirectional airflow during abdominal pumping in a grasshopper. During inspiration, air flows in through open thoracic spiracles (sp), along the longitudinal trachea, and into the air sacs. At low metabolic rates, air flows out only through the tenth abdominal spiracles; in more active animals, air flows out all abdominal spiracles.
at the base of the wings, antennae, and legs pushes hemolymph and air into these appendages. In a variety of adult Lepidoptera, Diptera, and Hymenoptera, the heart occasionally reverses pumping direction, shifting hemolymph from the thorax to the abdomen. As the hemolymph accumulates in one body compartment, it compresses air sacs in that compartment, causing convective air flow through tracheae and spiracles.

**OXYGEN-BINDING PROTEINS AND OXYGEN SENSING**

Oxygen-binding pigments such as hemoglobin have been thought to be unimportant in gas exchange for most insects, due to the high capacity of tracheal systems. However, it is becoming apparent that oxygen-binding pigments are very important for gas exchange in a variety of insects. Both hemoglobin and hemocyanin play roles in insect gas exchange, with their distribution being at least partly related to phylogenetic history (Fig. 4).

Hemocyanin, which is the respiratory protein found in the crustacean ancestors of insects, occurs in the hemolymph of a wide variety of primitive insect orders including Collembola, Zygentoma, Plecoptera, Orthoptera, Isoptera, and Blattoidea, but not in the Eumetabola. At least in one plecopteran, hemocyanin occurs at relatively high concentrations in the hemolymph, and the oxygen affinity of the hemocyanin is consistent with a role for this protein in oxygen delivery, suggesting that the hemolymph hemocyanin may play a significant role in oxygen delivery for a variety of insects.

Hemoglobin only occurs in the hemolymph of aquatic larval and pupal chironomids. These insects possess high-affinity hemoglobins that help them extract and store oxygen from hypoxic environments. Certain other aquatic insects have specialized tissues that contain high concentrations of intracellular hemoglobin that extract and store oxygen. One example is the larvae of the botfly, *Gastrophilus intestinalis*, which parasitizes horse intestines and obtains oxygen from intermittently available bubbles swallowed by the host. Backswimmers (Hemiptera) have specialized organs, penetrated by tracheoles, that contain hemoglobin. When backswimmers dive, oxygen is transferred from the air bubble they carry to the hemoglobin, stabilizing their buoyancy, and prolonging their dive duration.

Intracellular hemoglobins have also recently been detected in the tracheoles and a variety of other tissues of a wide variety of insects including the fruit fly, *Drosophila melanogaster*, the honey bee, *Apis mellifera*, and the mosquitoes, *Aedes aegypti* and *Anopheles gambiae*. The concentration of hemoglobin in these tissues is unknown. These hemoglobins are evolutionarily similar to crustacean hemoglobins, suggesting that intracellular hemoglobins are common and primitive in insects. The functions of these hemoglobins are unknown and may include oxygen storage for use during hypoxia or burst performance, enhancement of oxygen transport within tissues, detoxification of reactive oxygen species, and oxygen signaling.

Oxygen-sensing proteins allow insects and other animals to monitor internal oxygen levels and respond appropriately. One major class of oxygen sensors are the hypoxia-inducible factors (HIF), which serve as transcription factors. The HIF signaling pathway is conserved.
from worms to humans, generally serving to increase oxygen delivery capacity and anaerobic capacities in response to hypoxia. The abundance and activity of HIF protein is inversely related to tissue oxygen levels in *Drosophila*, due to oxygen effects on HIF oxidation by prolyl hydroxylase (and subsequent degradation of HIF protein). Relatively few studies have yet examined the functional consequences of increased HIF levels in response to hypoxia, but there is evidence suggesting that increases in HIF may trigger tracheal proliferation and reduced cell (and body) size via effects on the cell cycle.

A second protein implicated in responses to hypoxia are the atypical guanyl cyclases. The product of guanyl cyclase, cyclic GMP (cGMP) is an important intracellular second messenger for many processes. Atypical guanyl cyclases are activated by hypoxia, and in *Drosophila*, cGMP levels are inversely related to oxygen partial pressures. There is evidence that increasing cGMP may mediate the rapid escape response observed when fruit fly larvae are exposed to hypoxia.

**DISCONTINUOUS GAS EXCHANGE**

For many insects, especially those that are highly active, the spiracles close for only brief periods if at all, and oxygen and carbon dioxide are exchanged relatively continuously. However, many insects exhibit discontinuous gas exchange. During discontinuous gas exchange, periods of spiracular closure (in which no or reduced gas exchange occurs) alternate with periods of spiracular opening (and greatly increased gas exchange).

Discontinuous gas exchange has been most extensively studied in ants and diapausing lepidopteran pupae. In lepidopteran pupae, spiracular openings can be separated by hours. After the burst of gas exchange, the spiracles hermically seal (closed phase). While the spiracles are closed, oxygen is consumed from within the tracheal system. The oxygen removed from the tracheal air space is not completely replaced by carbon dioxide, primarily because a large fraction of the carbon dioxide produced dissolves in the tissues and hemolymph (carbon dioxide, in contrast to oxygen, is highly soluble in biological fluids). Therefore, pressures fall below atmospheric within the tracheal system and abdominal length is reduced. When internal oxygen tensions reach a low threshold, the spiracles begin to open slightly at high frequency (flutter phase), and tracheal pressures rise to near-atmospheric levels. During the flutter phase, high-frequency, but minutely subatmospheric, air pressures allow the animal to convectively take in oxygen with minimal emission of carbon dioxide. The spiracles remain sufficiently closed so that internal oxygen levels remain low. Carbon dioxide accumulates throughout the closed and fluttering phases, eventually triggering the spiracular open phase, when tracheal oxygen levels are restored to near-atmospheric partial pressures.

Discontinuous gas exchange patterns and mechanisms are quite variable among and within species. Many insects only exhibit discontinuous gas exchange when at rest or during diapause. However, some highly active insects, such as running ants, also exchange gases discontinuously. When metabolic rates increase (at higher temperatures or during activity), the time period between spiracular phases tends to decrease. Significant carbon dioxide is lost during the flutter phase of many insects, suggesting that outward diffusion gas exchange occurs during flutter phase of these species. Another variant is the use of abdominal pumping to enhance gas exchange during the open phase.

The functional significance of discontinuous gas exchange remains controversial. A variety of cross-species comparisons suggest that insects evolved to live in warmer or more arid regions have longer and more pronounced discontinuous gas exchange cycles. However, within-species experiments have often indicated that switching in and out of discontinuous gas exchange has little effect on water loss for the insects examined. Other current, nonalternative hypotheses are that discontinuous gas exchange: (1) protects tissues from reactive oxygen species by keeping internal oxygen levels low; (2) enhances gas exchange during hypoxia, and (3) is simply a consequence of having spiracles controlled in a relatively binary fashion (open vs. closed).

**AQUATIC AND ENDOPARASITIC INSECTS**

Insects can obtain oxygen while living in fluid environments and are common in the shallows of fresh waters, brackish estuaries, and as endoparasites. Aquatic and endoparasitic insects generally retain an internal, air-filled tracheal system. The air-filled, buoyant tracheal system may inhibit insects from being able to dive deeply and avoid predators, limiting their ecological success in deep waters.

Many aquatic and endoparasitic species have anatomical features that allow them to feed underwater (or within the host) while maintaining contact with air. For example, in many aquatic dipteran larvae such as mosquitoes, the posterior spiracles are surrounded by water-repellent hairs and are kept in the air while the animals feed in a head-down position. In water scorpions (*Hemiptera: Nepidae*), spiracles are located on the end of a long tube which is extended up to the water surface. Similarly, endoparasitic insects such as chalcid (Hymenoptera) larvae and tachinid (Diptera) larvae connect to the air using posterior spiracles inserted through the host’s integument or tracheal system.

Some Coleoptera and Heteroptera use their hairs or wings to carry air bubbles adjacent to their spiracles when they dive. These air bubbles serve as oxygen stores and as temporary gas exchange structures. Oxygen is removed from the air bubble by the diving insect, causing oxygen partial pressures in the air bubble to fall below that in the surrounding water. Oxygen consumption from the bubble also causes the nitrogen partial pressure in the air bubble to rise above that in the surrounding water, so that nitrogen leaves the bubble to the water by diffusion. Eventually, when all the nitrogen leaves, the bubble disappears and the insect must return to the surface.

Many aquatic and endoparasitic insects never access air and must obtain oxygen directly from water or the blood of the host. Some aquatic insects that rarely visit the surface obtain oxygen from the water by having specialized structures called plastrons which hold a thin film of air on the outside of their body. These insects have a thick (as many as 2 million hairs per mm²) layer of short water-repellent hairs that resist wetting and do not collapse under pressure. Spiracles open directly into the air space of the plastron. Plastrons are thought to behave as gas exchange structures in a manner similar to air bubbles. However, because the dense hairs make the plastron incompressible, oxygen removal from the plastron by the insect will lower both the total pressure and the oxygen partial pressure in the air of the plastron. Thus nitrogen levels are likely to remain near to those in water, and the air and gas exchange function of the plastron can persist indefinitely.

Many aquatic or endoparasitic insects that do not access air lack spiracles, and so oxygen must be transported by diffusion from the water, across the cuticle, and then into the tracheae. A common feature of these insects is tracheal gills, leaflike structures of thin cuticle containing many tracheae and tracheoles, that increase the available surface area for obtaining oxygen from water (Fig. 5). Gills may be on the abdominal tip (Diptera, Odonata: Zygoptera), laterally along the abdomen (Ephemeroptera, Trichoptera), or within the rectum (Diptera, Odonata: Anisoptera).
As oxygen is absorbed across a gill, oxygen level in the boundary layer of water over the gill can become low, slowing diffusive influx of oxygen. To overcome this problem, muscles drive rhythmic waving of abdominal gills, forcing fresh, oxygenated water to flow over the gill, thereby reducing boundary layer thickness. For similar reasons, rectal gills are ventilated by alternate contractions and relaxations of the rectum, which drive water in and out of the anus. Such ventilatory movements are enhanced in water containing low levels of oxygen.

**PLASTICITY IN TRACHEAL STRUCTURE AND FUNCTION**

An insect's need for oxygen and production of carbon dioxide varies tremendously, as metabolic rate varies strongly with transitions from rest to flight, unfed to fed state, or from diapause to growth. When metabolic rates increase, there is an increased need for oxygen uptake and carbon dioxide removal. Insects also require a higher capacity to exchange gases when they are exposed to low-oxygen conditions such as hypoxic waters or high altitudes.

In the short-term, increased gas exchange with a set tracheal system structure can be accomplished by at least four nonexclusive mechanisms. First, insects can simply tolerate lower internal oxygen and higher internal carbon dioxide partial pressures. The increased gas partial pressure gradients will enhance gas exchange by either diffusion or convection. Secondly, insects can increase diffusive gas exchange by opening the spiracles to a greater degree or for longer time periods. Third, insects can increase convective ventilation through the spiracles and tracheal system (terrestrial insects) or over the gills (aquatic insects) by mechanisms such as abdominal pumping or gill waving. Convection in the hemolymph may also be important for insects that utilize hemolymph hemocyanin. Fourth, insects can reduce fluid levels in the tracheoles, enhancing diffusive oxygen delivery within the tissues because of the faster diffusion of oxygen through air than water. In the longer term, alterations in tracheal morphology (e.g., tracheal diameter and number of tracheoles) and perhaps the level of oxygen-binding pigments may affect gas exchange capacity.

**Locomotion**

Locomotion requires muscular activity and increased ATP turnover, which increases the organism's need for oxygen. Running insects increase their gas exchange rates by 2–10 fold relative to resting conditions. Flight is usually associated with larger increases in gas exchange, especially in insects that maintain thoracic temperatures near 40°C, such as bees and dragonflies. These insect athletes have oxygen consumption rates among the highest known in the animal kingdom, reaching levels 100 times higher than those of cold, resting insects.

Relatively little is known of the mechanisms by which insects increase gas exchange during terrestrial locomotion. In a cockroach, and a grasshopper, internal carbon dioxide levels rise while oxygen levels fall during running and hopping, respectively. In the grasshopper *Melanoplus bivittatus*, abdominal pumping rates are low during hopping, but increase relative to resting rates afterward, increasing convective and restoring tracheal gases to normal, resting levels. Even though there is no evidence for increased abdominal pumping during hopping, increased convective ventilation may occur due to pressure fluctuations associated with cuticular deformations associated with jumping.

During flight, convective gas exchange can be increased by thoracic autoventilation and abdominal pumping. Thoracic autoventilation occurs when flight muscle contractions cause compression of the air sacs within the thorax, producing strong convective ventilation. Such increases in thoracic autoventilation have been shown for grasshoppers, cerambycid, elaterid, and anthribid beetles, moths (Lepidoptera), and dragonflies (Odonata). Another method for increasing gas exchange has been shown for the gigantic cerambycid beetle (*Petrophassa gigas*) in which wind pressure generated by forward flight drives convective air flow through the major tracheal trunks. Abdominal pumping is considered the major mechanism by which convective ventilation is increased during flight in large Hymenoptera, Diptera, and scarabaeid and buprestid beetles, and abdominal pumping supplements autoventilation during flight in dragonflies and grasshoppers. In the insects studied to date (a moth and a bumblebee), oxygen partial pressures in active flight muscles are maintained at levels similar to those in resting animals, suggesting that increases in the capacity of the tracheal system to conduct gases match increased tissue needs for oxygen during flight.

**During Hypoxia**

Insects may encounter low environmental oxygen availability in a number of locations including hypoxic waters, burrows, feeding sites within large dense structures such as granaries, or at high altitude. Terrestrial insects are generally quite good at coping with hypoxia, and, usually, can maintain resting metabolic rates down to atmospheric oxygen levels of 1–5 kilopascals (normal atmospheric oxygen partial pressure is 21 kilopascals). The large safety margin for oxygen delivery of resting terrestrial insects probably reflects the fact that tracheal systems must be designed to allow the much higher rates of gas exchange during activity. In support of this hypothesis, metabolic rates during flight are generally more sensitive to hypoxia, with flight metabolism being inhibited at 8 kilopascals in hovering honey bees, at 10 kilopascals in tethered flying flies, and being stimulated by hyperoxia in a dragonfly. Growth rates are inhibited by relatively mild hypoxia (10 kilopascal), at least in larval mealworms (Coleoptera) and fruit flies (Diptera), suggesting that such moderate hypoxia limits some physiological processes even in nonlocomoting insects.

Insects respond to hypoxia by increasing tracheal gas exchange capacity. In a wide variety of insects, hypoxia induces spiracular opening. In ants and lepidopteran pupae exhibiting discontinuous ventilation, exposure to hypoxia increases the frequency and duration of spiracular opening. In adult grasshoppers, exposure to hypoxia causes a strong increase in convective ventilation, mostly accomplished by an increase in the frequency of abdominal pumping. Aquatic insects with gills generally increase convective water flow past the gills in response to hypoxia, either by increasing the frequency of
their gill-beating (Ephemeroptera), body undulations (Plecoptera), or rectal pumping (Odonata). Aquatic insects exposed to hypoxia often move to faster flowing water, to the water surface, or even into the air. Insects can exhibit changes in tracheal system structure in response to longer-term exposure to hypoxia. For example, the transverse tracheae of mealworms (Coleoptera) and fruit flies (Diptera) increase in size when reared under conditions of low oxygen availability. Tracheole growth and branching are stimulated by hypoxia in the epidermis of Rhodnius (Hemiptera) and fruit flies. Similarly, in some larval Ephemeroptera, gill area is inversely proportional to environmental oxygen levels.

**CONTROL OF RESPIRATORY FUNCTION**

The spiracular muscles are primarily controlled by nerves from the central nervous system. The motor neurons to the spiracular muscles arise from ganglia in the same segment or that immediately anterior. In dragonflies, Periplaneta cockroaches, and Schistocerca grasshoppers, the spiracular closer muscles are innervated by two motor nerves that branch from the median nerve sending an axon to each side of the animal, so that both spiracles on a segment receive similar neural input. In the prothoracic spiracle of Schistocerca, two motor nerves innervate the opener muscle from the prothoracic ganglia and one motor nerve arrives from the mesothoracic ganglia. Increasing action potential frequencies in these nerves stimulate increasing muscle activity, resulting in gradations in the magnitude and duration of spiracular closing.

Current information suggests that for spiracles with two muscles, effects of carbon dioxide or oxygen are mediated centrally. When high levels of carbon dioxide or low levels of oxygen are applied to the ventral ganglia or head, the frequency of action potentials to the closer muscles decreases and the frequency of action potentials to the opener muscles increases, increasing spiracular opening. Temperature increases or flight also affects the frequency of action potentials to these spiracular muscles.

In contrast, data for spiracles with only a closer muscle suggest that carbon dioxide acts peripherally, while oxygen acts centrally. Central application of hypoxic gases stimulates a fall in the action potential frequencies to the closer muscle, whereas carbon dioxide has little effect. However, when carbon dioxide is applied directly on the spiracular muscle, there is a fall in the muscle membrane depolarization resulting from nerve stimulation, a decrease in closer muscle tension, and increased spiracular opening. Spiracle opening is stimulated by a rise in carbon dioxide but not a decrease in extracellular pH, suggesting that the carbon dioxide effect is not mediated by pH changes.

The rhythmic abdominal pumping movements that drive convective ventilation in many insects are initiated by central pattern generators in the metathoracic ganglia or the first abdominal ganglia. These rhythmic ventilatory bursts can be demonstrated in nerve cords isolated in vitro. The motor output from these central pattern generators passes down the ventral nerve cord via interneurons and stimulates rhythmic sequences of respiratory muscle activity.

In grasshoppers (Orthoptera) and probably many other insects, the rate of abdominal pumping can be altered by sensory output from stretch receptors in the abdomen, chemosensors located in the thorax and head, and by feed-forward control. Increasing carbon dioxide or decreasing oxygen partial pressures in the tracheae stimulate the frequency of abdominal pumping. Deposition of carbon dioxide below normal levels or elevation of oxygen above normal levels inhibits abdominal pumping, indicating homeostatic regulation of internal gas levels. Feed-forward control of abdominal pumping occurs when neural centers that control flight muscles also stimulate the central pattern generators, increasing the rate of abdominal pumping.

In a series of classic experiments, V. B. Wigglesworth demonstrated that the terminal ends of the tracheoles can contain fluid which disappears in response to hypoxia or activity. Changes in the fluid levels in the tracheoles have the potential to strongly affect the ability of the tracheoles to conduct gases, which would provide a highly significant control mechanism for the tracheal system. Further experiments by Wigglesworth suggested that the withdrawal of fluid from the tracheoles could be due to elevations in hemolymph osmotic pressure.

In summary, the tracheal respiratory system of insects is a dynamic system, capable of a tremendous range of function and fine control. This light-weight, adaptable, high-capacity respiratory system is certainly one of the major traits which underlie the ecological and evolutionary success of insects.

River Blindness

Vincent H. Resh
University of California, Berkeley

Onchocerciasis, or river blindness, is a nonfatal, human disease that affects the skin and vision and can ultimately lead to blindness in infected persons. The name river blindness reflects both the place where the disease is most common and severe, and its ultimate outcome.

The disease is caused by a filarial (threadlike) worm in the fly’s gut, *Onchocerca volvulus*. The disease is found in 37 countries, 30 of which are in Africa, 6 in the Americas, and 1 in the Arabian Peninsula; however, Africa, and particularly sub-Saharan West Africa, is by far the most affected area in terms of clinical manifestations of the disease, number of affected persons, and widespread occurrence.

The worm is most commonly transmitted to humans in Africa by black flies in the *Simulium damnosum* species complex, which contains about 40 different forms, several of which are distinct species. Other species of *Simulium* are vectors in other parts of the world. Larval and pupal stages of these species occur attached to near-surface substrates in fast-flowing rivers. Because the adults are capable of long flights (>200 km), the aquatic stages are considered the most vulnerable for control.

In humans, the disease takes three progressive forms: first, skin lesions and intense, often violent, itching occur; second, painless nodules containing adult worms form where tissues are thin over bones, such as pelvis, ribs, and scalp, and these nodules are the sites of reproduction for the worms; and third, eye lesions form that can lead to blindness. The third phase can be devastating to communities; 10% of the people in vast areas can be blind, with levels of adults being blind in individual villages sometimes exceeding 30%. This disease is most prevalent among the rural villages that occur in some of the poorest areas of the poorest countries of the world. In these areas, subsistence (whether through agriculture or freshwater fishing) is difficult to achieve; the large proportion of blind adults makes the burden of the disease devastating to these communities.

The life cycle involves both humans and black flies, and there are no known animal reservoirs of this disease. First, a biting, black fly female sucks blood from a human host; if that person is infected, she may also suck up some microfilaria (which are best thought of as worm embryos) of the parasite. Interestingly, evidence indicates that the worms migrate to the skin surface during the day, when black flies are active, which increases their chance of uptake by the biting females. Second, the microfilaria move from the fly’s stomach to its thoracic muscles, where they pass through three larval stages (L1, L2, and L3), and the infective L3 larvae move into the black fly vector’s head and mouthparts. Third, in the course of biting, L3 larvae are transferred from female black flies to humans. Fourth, the larval worm matures to an adult (which can be 40–45 cm in length) and adults mate (in the nodules that form), producing millions of microfilaria (each about 3 mm in length) that can be picked up from the skin of that human by a biting black fly. The death and disintegration of microfilaria result in an inflammatory reaction, which ultimately leads to itching, visual impairment, and eventually blindness.

The control of river blindness in West Africa has been one of the success stories of public health and economic development (Fig. 1). In 1974, the Onchocerciasis Control Programme in West Africa (OCP) began, with its objective being to eliminate onchocerciasis as a disease of public health importance and as an obstacle to socioeconomic development in this region. Eleven countries participated in this program, in a geographical region ranging from Senegal in the west to Benin in the east. Under the jurisdiction of the World Health Organization, and funded through the World Bank and 20 donor countries and organizations, the strategy was to interrupt transmission of the blinding strain of the worm *O. volvulus* for a period of about 12 years, which is the life span of the adult worm. This was done by aerial application of seven different selective insecticides, weekly, to rivers infested with black flies. Because the female black fly lays batches of eggs at or near the water surface in fast-flowing water, these were the sites sprayed with insecticides. Much of the current understanding of the environmental impact of pesticides on aquatic ecosystems comes from studies conducted as part of this control effort. Beginning in the late 1980s, an ivermectin drug (a microfilaricide originally used as a veterinary product for the treatment of dog heartworm) was also distributed annually to people living in infected areas.

The success of the OCP is especially impressive when one considers the scope of the project: Onchocerciasis was eradicated in most parts of 11 different countries; at times, over 50,000 km of rivers had to be sprayed weekly for more than 10 (or sometimes 20) years; no permanent environmental damage resulted from the spraying activities because of the increased reliance on insecticides that selectively targeted the black fly vectors; the drugs were distributed to almost 7 million people by over 22,000 community volunteers; millions of children have been born that will be free of this disease; the drugs were donated to the program without charge by the producer of them, Merck; the drug distribution program has recently been expanded to cover 19 more countries (and 157 million people); and...
plans include using this same system for dispensing drugs against lymphatic filariasis (elephantiasis) and pesticide-impregnated bed nets that are effective against malaria. The OCP ended in 2002; perhaps its most significant accomplishment is not only that the disease is under control, but also that the previously abandoned valleys, now free of river blindness, grow food for 17 million people in areas inhabited by the poorest of the poor, the people truly living at the “end of the road.”

Salivary Glands

Gregory P. Walker
University of California, Riverside

Salivary glands are glands associated with the mouth or oral cavity and produce secretions (saliva) that are mixed with the food during feeding and are ingested along with the food. Among insects, there are four pairs of glands associated with the mouth or oral cavity, although all four generally are not present in the same insect. Each of these is associated with and is named after its associated mouthpart: the mandibular, maxillary, hypopharyngeal, and labial glands. The presence or absence of each of these glands varies among insect species, and in holometabolous insects, a given gland may be present in only one life stage. For example, in Lepidoptera, mandibular glands occur in the larval stage, but not in the adult. The four glands serve a variety of functions, including some non-salivary functions, and the same gland may serve different functions in different species or even in different life stages of the same species. Within a given species, one or more of these four pairs of glands usually function as salivary glands.

GLANDS ASSOCIATED WITH THE MOUTH

Mandibular glands, found in many insects, function as the main salivary glands in Lepidoptera larvae. A common function of mandibular glands in social Hymenoptera is to produce pheromones such as alarm pheromones in ants and honey bees, and the queen substance in queen honey bees. Function can vary with age. For example, the mandibular glands of older honey bee workers (which perform mostly foraging tasks) produce an alarm pheromone, whereas the mandibular glands of young workers (which perform mostly nursing tasks) produce secretions, called royal jelly, that are fed to larvae in differential quantities to control whether a given larva will develop into a queen or worker. Mandibular glands of stingless bees serve in defense and produce a burning sensation when ejected onto the victim.

Maxillary glands occur in Protura, Collembola, some Heteroptera, and some larval Neuroptera and Hymenoptera. They are believed to provide secretions to lubricate the mouthparts, and thus serve one of the salivary functions.

Hypopharyngeal glands occur in the Hymenoptera, and in honey bee workers they produce secretions that are fed to the larvae (a substance different from royal jelly). Hypopharyngeal glands are vestigial in honey bee queens and absent in males. The hypopharyngeal glands of honey bee workers also produce invertase, a common salivary enzyme that hydrolyzes sucrose, and another enzyme that oxidizes glucose to an acid, which is believed to serve as a preservative in honey.

Labial glands occur in the great majority of insect orders (an important exception is the Coleoptera), and most commonly function as salivary glands, but in the larval stage of some groups of silk-producing insects, such as Lepidoptera, Trichoptera, and Hymenoptera, labial glands are the silk-producing organs either throughout the larval stage or at its end, just before pupation. In the Psocoptera, adults have two pairs of labial glands, one pair functioning as silk glands and the other pair functioning as salivary glands. In the primitive orders Collembola and Thysanura, which lack Malpighian tubules (the usual excretory organs of insects), the labial glands function as excretory organs.

STRUCTURE AND FUNCTION OF SALIVARY GLANDS

The salivary glands of most insects are labial glands, which are the focus of this section. Labial salivary glands have been examined in detail in relatively few insect species, and there is great variation among the species examined (Fig. 1). This is not surprising, considering the great variation in mode of feeding (e.g., chewing, piercing–sucking, non-piercing–sucking, sponging, etc.) and types of food consumed by different insect species.

General Description

Several aspects of structure and function are common to most or all variations of insect labial salivary glands. The glands occur in pairs, and the ducts from each gland usually join to form a single common duct that opens to the oral cavity at a single orifice (Fig. 1). Even though the glands originate in the labial segment, the orifice usually occurs just behind or on the hypopharynx, and the glands often extend back into the thorax and even as far back as the abdomen (e.g., Fig. 1A and 1B). The glands are suspended in the hemocoel and are constantly bathed in hemolymph. The glands generally have at least two regions: a secretory region and a reabsorptive region. Generally, the lumen of the salivary duct is lined with cuticle, at least at the end closest to its opening.

The secretory region produces the primary saliva. The major component of saliva is water. Water is transported from the hemolymph across cells of the salivary gland and into the lumen of the gland. Movement of water from the blood to the gland lumen is accomplished by active transport of potassium or sodium ions from the hemolymph to the lumen, causing water to move from the hemolymph to the lumen down an osmotic gradient. Cells responsible for water transport generally have deep infoldings of the cell membrane and/or dense microvilli on the side of the cell adjacent to the lumen of the gland. This serves to greatly increase the cell's luminal surface area, and also serves to enclose very narrow extracellular spaces into which ions are pumped. The enclosed nature of the spaces helps contain the ions to keep their concentration high, thus facilitating the osmotic movement of water from the cell into the space. The infoldings and microvilli usually are associated with abundant mitochondria to provide the energy for the ion pumps. The secretory region of the gland also synthesizes proteins, such as salivary enzymes and other organic components of the saliva. Cells responsible for secretion of these components generally possess extensive endoplasmic reticulum, Golgi bodies, and secretory granules that synthesize and transport (intracellularly) the secretions. There may be one or several different types of cell in the secretory region. It should be noted that salivary components are not necessarily produced by the salivary
The hemolymph and away from the cells, thus reducing the osmotic gradient, which would cause the cells to lose water. Reabsorptive cells also have abundant mitochondria to power the active transport of ions from saliva to hemolymph.

**Acinous Salivary Glands**

The salivary glands of many insects are composed of clusters of acini, or saclike glandular structures (Fig. 1A) comprising at least two types of cell. Each acinus empties into a cuticle-lined duct, and the ducts of different acini fuse, eventually forming a common duct that leads to an opening just behind or on the hypopharynx. The anatomy of acinous salivary glands varies greatly among different insects. The acinous glands of locusts and cockroaches have been particularly well studied and are described next.

**LOCUSTS AND COCKROACHES**

The gross anatomy of locust and cockroach salivary glands is illustrated in Fig. 1A. The acini are the secretory region of the salivary gland and consist of peripheral cells and central cells. The peripheral cells have deep, microvilli-lined invaginations that are continuous with extracellular canaliculi that open into the gland’s duct. The peripheral cells transport water from the hemolymph to the canaliculi, and from there, the water empties into the duct. Additionally, in locusts, the peripheral cells seem to synthesize and secrete other salivary components. The central cells of both locusts and cockroaches synthesize salivary enzymes and other salivary components, and secrete them into the salivary duct. The walls of the salivary ducts of locusts and cockroaches are one cell thick, and the lumen is lined with a thin cuticle. The salivary duct contains the reabsorptive region of the gland, and in some cockroaches, a small part of the duct adjacent to the acinus is secretory.

**Tubular Salivary Glands**

Some groups of insects, such as Lepidoptera, Diptera, and Siphonaptera, possess tubular salivary glands. Generally, the walls of tubular salivary glands are one cell thick and the lumen is lined with thin cuticle. Tubular salivary glands are divided into several regions along the length of the gland. The number of regions and anatomical details of the regions vary among insect groups. Two examples of tubular salivary glands are described.

**BLOWFLY ADULTS**

There is a pair of tubular salivary glands, each gland with three regions (Fig. 1B). The apical region is the longest and is the secretory region; the shorter middle region is the reabsorptive region; and the short common duct at the proximal end opens to the exterior of the body on the hypopharynx. The blowfly’s secretory region comprises a long distal section located mostly in the abdomen and a shorter proximal section located in the thorax. Cells in the distal section serve a dual function: they move water from the hemolymph into the lumen of the gland, and they synthesize and secrete salivary enzymes and other salivary components. The cell surface adjacent to the lumen of the gland’s central duct encloses extensive canaliculi into which the cells secrete their products. Secretions then move from the canaliculi to the gland’s duct. Cells in the proximal section are generally similar in appearance to those in the distal section, but they do not contain secretory granules. Thus, they do not seem to secrete enzymes and probably secrete only water and ions. The reabsorptive region of the blowfly’s salivary glands consists of a single cell type that is believed to be responsible for reabsorbing ions from the saliva back to the hemolymph. Finally, the common duct of the blowfly’s salivary glands comprises highly flattened cells that seem to play no role in the secretion or reabsorption of any salivary components. This region of the salivary gland is very short and opens on the hypopharynx.
**SPHINGID MOTH** In the tobacco hornworm, *Manduca sexta*, adults have a pair of tubular salivary glands that are divided into four regions (Fig. 1C). In the apical region, proteinaceous material is synthesized in the extensive rough endoplasmic reticulum and Golgi bodies, and is stored in large vacuoles before eventual release into the lumen of the gland. The second region transports water from the hemolymph to the lumen. Cells in this region have the characteristic structure of water-secreting cells to accommodate what is believed to be the primary function of this region; but in addition, the presence of rough endoplasmic reticulum and Golgi bodies suggests that these cells secrete more than just water. The third and fourth regions, called the thin duct and bulbous duct, both seem to have a reabsorptive function, moving ions back from the saliva and into the hemolymph. Cells in these two regions differ in the structure of their surface adjacent to the lumen, but the reason for the difference is unknown. After the fourth region, the right and left glands fuse forming the common duct. Cells of the common duct are unspecialized and probably play no role in saliva production.

**Salivary Glands of Hemiptera**

The most complex insect salivary glands that have been studied occur in the Hemiptera. This complexity is undoubtedly related to the piercing–sucking mode of feeding in this taxon, where saliva is injected into the food substrate via a specialized salivary canal in the elongate maxillary stylets. In this mode of feeding, solid substrates must be pierced and then the food, which is often initially solid, must be liquefied before ingestion through the maxillary food canal. These processes depend greatly on a multitude of salivary components that serve different functions. Consequently, there are usually many distinct types of secretory cells in the same gland, each producing different salivary components. Furthermore, many phytophagous hemipterans produce two distinct types of saliva at different times in the feeding process: sheath saliva and watery saliva. Sheath saliva consists mostly of lipoprotein and is secreted incrementally as the stylets advance through the plant tissue. It gels shortly after secretion and forms a continuous solid sheath around the stylets. As a consequence, only the stylet tips come in direct contact with the plant tissue; the shaft of the stylet bundle is encased by the sheath. Watery saliva, as the name implies, is dilute and does not gel. It contains mostly water and various enzymes.

In general, salivary glands of the Hemiptera are divided into two main parts, the principal gland and the accessory gland. The principal gland is often subdivided into two or more lobes. The principal and accessory glands are served by their respective ducts, and the ducts from each lobe fuse to form a lateral salivary duct. The lateral ducts from each side fuse to form a median duct that leads to the salivary pump (described later in this article). There is considerable variation in the salivary glands among the Hemiptera, even within the same family. Two examples are described.

**BEET LEAFHOPPER** The principal salivary glands of the beet leafhopper, *Circulifer tenellus*, are divided into an anterior and posterior lobe, each served by its own duct (Fig. 1D). The ducts from each lobe fuse to form the lateral salivary duct. The accessory gland is not subdivided, and its duct joins the others near the point where they fuse to form the lateral duct. The principal glands have eight different cell types that are arranged in rings around the duct of each lobe, five in the anterior lobe and three in the posterior lobe. All eight cell types are secretory, possessing abundant endoplasmic reticulum and/or secretory granules, and all have intracellular canaliculi that come in contact with the salivary duct. Details of the cells’ fine structure and the staining properties of the secretory granules differ sufficiently to indicate that each cell type produces different components of the saliva. Accessory gland cells have some features typical of water-secreting cells but also have abundant endoplasmic reticulum, Golgi bodies, and secretory granules, suggesting that they secrete water and other salivary components.

**MILKWEED BUG** As in most hemipterans in the suborder Prosorrhyncha, the principal salivary glands of the large milkweed bug, *Oncopeltus fasciatus*, (Fig. 1E) are divided into discrete lobes that are much more compact than the lobes just described for the beet leafhopper. The lobes comprise a mass of cells with a distinct glandular lumen. The accessory glands and the three lobes of the principal glands each secrete their own salivary components. The anterior and lateral lobes secrete two different components that mix to form the salivary stylet sheath (described earlier). The lateral lobe secretes the bulk of the sheath saliva protein, including most of the components that form the hydrogen bonds that solidify the salivary sheath, while the anterior lobe secretes the components that form most of the disulfide bonds. The posterior lobe produces salivary digestive enzymes, such as amylase and esterase. The accessory gland supplies the bulk of the water in the saliva, as well as polyphenoloxidase and possibly mucoid substances.

**CONTROL OF SECRETION, INNERVATION**

Secretion of saliva generally is stimulated either by direct innervation or by neurohormonal factors that are released into the blood by secretory neurons. Innervation of the salivary glands varies considerably among different insects. Innervation can come from the subesophageal ganglion, thoracic ganglia, the stomatogastric nervous system, the median–transverse nervous system, or a combination of these.

Two neurotransmitters, serotonin and dopamine, are commonly found in neurons innervating the salivary glands, and each may stimulate different aspects of salivation. For example, in the American cockroach, serotonin induces secretion of proteinaceous saliva, whereas dopamine induces secretion of nonproteinaceous saliva. Other neurotransmitters occur in neurons innervating salivary glands, but their roles are not understood. The diversity of neurotransmitters suggests that control of salivation is a complex process.

The salivary glands of some insects such as blowflies lack direct innervation, and salivation is induced by one or more neurohormonal factors released into the blood. One of these factors seems to be serotonin.

**STRUCTURES ASSOCIATED WITH SALIVARY GLANDS**

**Salivary Reservoirs**

Some insects, such as cockroaches, have a pair of distensible salivary reservoirs for storage of saliva. In cockroaches, each reservoir has its own duct, which joins with the duct of its associated salivary gland. The combined gland/reservoir ducts from each side fuse to form the common salivary duct leading to an opening on the hypopharynx. A valve near the orifice of the common duct on the hypopharynx opens and closes as the hypopharynx is raised and lowered during feeding, thus controlling release of saliva. When the insect is not feeding, the hypopharynx is in a lowered position, closing the valve, and saliva produced by the salivary glands then backs up into the reservoirs where it is stored.
Salivary Pumps

Many insects with piercing–sucking mouthparts inject saliva into their food for various purposes. Often a pumping mechanism is used to inject the saliva through elongate hypodermic needle-like mouthparts. In many Hemiptera, the pump is a hollow chamber near the hypopharynx and is referred to as a salivary pump or salivary syringe.

FUNCTIONS OF SALIVA

General

Perhaps, the most fundamental and ubiquitous function of saliva in insects is lubrication of the mouthparts and lubrication of the food bolus to assist its transport through the foregut. Lubrication can be achieved primarily by water, the most abundant constituent in saliva. Water in the saliva also can dissolve components in the food, such as sugars, which then become detectable by chemoreceptors on the mouthparts. Thus, saliva also can aid in food recognition.

The most common class of organic constituents of saliva consists of digestive enzymes, such as amylase, invertase, various proteases, and lipases. In many insects with chewing mouthparts, salivary enzymes are mixed with the food during chewing and swallowing, and initiate digestion. However, the midgut usually is the main site of production and secretion of digestive enzymes, and salivary enzymes in these insects generally play only a secondary role in digestion. In other insects, salivary digestive enzymes provide the main digestive function. This is especially common in piercing–sucking insects, such as many Heteroptera, in which digestive enzymes are injected into the food. The enzymes then break down and liquefy the food, and the digested, liquefied food is sucked up through the mouthparts.

Predators

Predaceous insects that have piercing–sucking mouthparts often capture and eat prey that are as big or even bigger than themselves. Large prey size is not nearly as common in predators with chewing mouthparts. This is because many predators with piercing–sucking mouthparts use the mouthparts to inject a salivary toxin into the prey, which enables them to subdue prey without having to be large and strong enough to physically overpower them. Thus, in these insects, saliva assists prey capture and gives the insects a potentially larger range of prey than their chewing mouthpart counterparts. Venoms in predaceous piercing–sucking insects often are accompanied by salivary hyaluronidase, which breaks down hyaluronic acid, an important “intercellular cement” in insects. Hyaluronidase is believed to serve as a spreading agent for toxins (as well as for digestive enzymes), assisting their penetration between cells by breaking down the intercellular cement.

Blood Feeders

Salivary components of blood-feeding insects serve several functions. These have been best studied in mosquitoes, other biting flies, and kissing bugs. Blood feeding is the most dangerous time in the lives of these insects, and survival is greatly enhanced by the ability to complete the task quickly and escape before being detected by the host. Salivary enzymes help to shorten the time it takes to acquire a blood meal. Blood vessels occupy only a small volume of skin tissue, and thus locating blood with the mouthparts can take considerable time. During probing, many blood feeders damage capillaries or tiny blood vessels by random movement of the stylets, and small subcutaneous pools of blood (hematomas) form in the vicinity of the damaged vessels. This increases the volume of the blood in the skin, and thus increases the probability that the stylets will locate a blood source, reducing the time required to locate blood. Successful formation of hematomas is greatly facilitated by factors that inhibit blood clotting, and consequently, the most common salivary components in these insects are factors that inhibit clotting. Clotting comprises two general processes, platelet aggregation and coagulation. In the small vessels used by most blood-feeding insects, platelet aggregation is the more important of the two, being capable of plugging a damaged vessel in a matter of seconds. One of the compounds that initiates platelet aggregation is ADP, and the saliva of many different blood-feeding insects contains apyrase, which is an enzyme that breaks down ADP. The importance of apyrase is demonstrated in mosquitoes, where the time required to complete a blood meal is directly dependent on the amount of apyrase injected by the mosquito. In addition to salivary components that interfere with platelet aggregation, some blood-feeding insects have salivary components such as antithrombins that inhibit coagulation. Also, substances that inhibit vasconstriction occur in some blood-feeding insects, thus inhibiting the host’s attempt to restrict the flow of blood to the feeding site.

Anticlotting also serves another function: it prevents blood from clotting in the food canal. Clotting would clog the food canal and lead to starvation and death. Finally, antihistamines in the saliva of some blood feeders may act as anti-inflammatory agents and reduce the probability that the feeding insect will be detected by the host.

Herbivorous Hemipterans

Many or most phytophagous hemipterans produce two kinds of saliva, sheath saliva and watery saliva, which were described briefly earlier. Sheath saliva forms a continuous solid sheath around the stylets, and several functions for it have been proposed. One likely function is to reduce friction between the stylets and plant tissue, facilitating advancement and withdrawal of the stylets. Another function may be to shield the moving stylets from plant cells, and thus avoid triggering a defensive response by the plant that could include hypersensitive reactions or release of plant defensive chemicals. This may be especially important in sternorrhynchan hemipterans like aphids and whiteflies, which feed primarily on sap from phloem sieve elements that lie deep in plant tissue. These insects carefully weave their stylets between and around plant cells from the plant surface to the sieve elements, and successful extraction of sap from the sieve elements may be dependent on avoiding the triggering of plant defensive responses during penetration to the sieve elements. In addition to mechanically shielding the stylets from plant cells to avoid plant defenses, salivary sheaths contain the enzyme polyphenoloxidase, which has been proposed to serve the function of oxidizing plant defensive chemicals and converting them to more harmless forms.

Watery saliva contains assorted enzymes and other components that vary among species. Some, like proteases and amylases, serve a digestive function, breaking down insoluble plant constituents into soluble forms that can be ingested through the stylet food canal. Others, like pectinases, break down pectin, which is the “intercellular cement” in plants, and loosen the adhesion between adjacent cells. For hemipterans like aphids and whiteflies, whose stylets penetrate between cells until they reach their actual ingestion site (phloem sieve elements), pectinase may facilitate the penetration of stylets between cells by loosening the intercellular cement. After penetrating a phloem sieve element, aphids and whiteflies inject saliva into it. This recently has been demonstrated to prevent sieve elements from plugging up, a plant defense against sap loss, analogous to blood clotting in animals. The water component of watery saliva also can have a critical role other than simply serving as a carrier for enzymes. Many phytophagous hemipterans (especially phytophagous Heteroptera) feed by a method known as “lacerate and flush.” In this feeding method, the feeding insect rupture nearby cells with their stylets, then inject saliva into these cells, causing them to burst and release their contents. The saliva acts to liquefy the contents, facilitating their eventual uptake by the feeding insect.
method, the stylets are inserted into the plant, and a pocket of cells beneath the surface is liquefied by the combined action of digestive enzymes in the saliva and mechanical laceration by repeated thrusts of the stylets. Once the pocket of cells has been liquefied, the nutrient-rich liquid is flushed out of the pocket by copious secretion of watery saliva and sucked up through the stylet food canal.

**Gall Formers**

Plant galls are produced by several groups of phytophagous insects that occur especially, but not exclusively, in the dipteran family Cecidomyiidae and the hymenopteran family Cynipidae, as well as many species of sternorrhynchan Hemiptera and some Thysanoptera. The abnormal tissue and cell growth characteristic of plant galls is caused by secretions from the insect, usually salivary secretions, that mimic plant growth hormones or serve as molecular signals that redirect plant cell growth from its normal course to an abnormal form that serves the needs of the gall maker.

**Construction of Shelters and Webs**

Silk is produced by many insects for a variety of functions such as construction of pupal cocoons in many Lepidoptera, Hymenoptera, and Siphonaptera, and construction of larval retreats or food-gathering nets in most Trichoptera larvae and some chironomid larvae. Many Psocoptera use silk to construct sheetlike shelters under which they aggregate and also use silk to attach their eggs to the substrate. Weaver ants use silk to tie together leaves to construct their arboreal nests, but interestingly, only larvae produce silk; so to weave leaves together with silk, the workers hold the larvae in their jaws and use them as silk dispensers. Not all insects that produce silk do so with their labial glands, but all the examples just cited do, representing some of the diverse uses of these specialized salivary secretions.

Mucoid secretions are produced by the salivary glands of several groups of Diptera. Some Diptera, such as *Drosophila*, produce salivary mucopoly saccharides that glue the puparium to the substrate. In some scarids and fungus gnats (*Mycetophilidae*), mucoid secretions are used as a “slime trail” to facilitate larval locomotion, much like terrestrial snails. Larvae of some predaceous fungus gnats use these sticky mucoproteins to trap prey. The most fascinating of these are the New Zealand glow worms, which construct a silken retreat from which they dangle silk threads that are covered with sticky mucoproteins to trap prey. The larvae reside in their silken retreats, and at night, they produce light by bioluminescence to attract nocturnal flying insects to their traplines.

**Trophallaxis**

Trophallaxis is the exchange of food between two individuals. The food exchanged may be salivary secretions or regurgitated gut contents. Larvae of many ants and wasps are dependent on adults to feed them. In exchange for being given food by the adult, the larvae of many species secrete a salivary fluid that is greedily consumed by the adult that provided the food. This stimulus for adults to give up food to a larva may have played a role in the evolution of eusociality in the Hymenoptera, in which adult females readily feed larvae that are not even their own offspring.

**Others**

Larval warble flies bore their way through the subcutaneous tissues of their mammalian hosts. To facilitate movement through the host’s tissues, they secrete a salivary collagenase, which breaks down collagen, a main component of connective tissue.

The saliva of some moths contains an enzyme called cocoonase that weakens the silk cocoon. It is produced by the newly eclosed moth to assist its escape from the pupal cocoon.

**Further Reading**

from simple mechanoreception to various other functions, including defense, locomotion, prey capture, pheromone dispersal, sexual display, preening, and camouflage. Setae are often highly modified, with one common modification being that they may be flattened into a broad, plate-like scale. This article specifically examines the tremendous diversity in shape, structure, and function of setae and scales used by different insect groups and at different life stages. This diversity in setae type is then characterized according to their four major functions in the biology of the insect: mechanoreception, camouflage, defense, and pheromone dispersal.

**STRUCTURAL MORPHOLOGY**

The terminology applied to scales and setae has historically been confused, with numerous, often interchangeable, terms used by researchers to describe the various types of structures (e.g., hairs, bristles, trichiae, aculei, chetae). Each seta, or trichoid sensillum, is a multicellular protuberance with specifically differentiated cells, with the most diagnostic landmark being its socket. The term trichoid sensillum applies to chemoreceptors as well as mechanoreceptors. The term hair is incorrect when applied to insects because hairs are morphologically different from setae and are considered a characteristic of mammals and not arthropods. Trichobothria is a term occasionally used to describe large, nontapering seta often associated with the mouthparts and genitalia. Other types of cuticular protuberances not considered here include the various minute projections of the cuticle (e.g., pruinescence, velutum, pollen), collectively termed microtrichia, and large sclerotized extensions of the cuticle (e.g., spines, tubercles).

Most setae form the covering of the body surface, which in very high densities is called a pile. Usually a mechanoreceptor, a typical seta, is composed of four cells: (1) a sensory cell, which innervates the seta, is surrounded by a (2) thecogen cell, which acts as an auxiliary cell by secreting the dendrite sheath. During seta development the (3) trichogen cell secretes the tapered or scale-like protuberance, whereas the (4) tormogen cell is responsible for formation of the socket. While most setae develop as mechanoreceptors, some will become secondarily noninnervated and lose their sensory function. These setae may take on a different role (such as aerodynamics, sexual display, preening) in the functioning of the insect.

Scales are modified setae that have a flattened blade with longitudinal ridges, sometimes with serrate edges (Fig. 1A and 1B). Scales are usually inclined relative to the cuticle, overlapping each other when present in sufficient densities. Each scale has a narrow pedicel, and the enlarged blade may be either gradually attenuated to an apex or truncated.

Scales are found in most groups of insects and serve a variety of functions. In true flies (Diptera), scales are not common but in certain species can be found on the wings (e.g., mosquito, *Anopheles annulipes*—Culicidae), legs (e.g., *Trichopoda* spp.—Tachinidae), or body (e.g., *Metatrichia* spp.—Scenopinidae). Scales are also found on the elytra of various beetle (Coleoptera) families (e.g., Elateridae, Curculionidae, Buprestidae), but the function of such scales in Coleoptera and in Diptera is unknown. Scales on the body and wings of Lepidoptera have been studied in greater detail and are known to contribute to lift during flight but not to drag, thus enabling them to glide for longer periods.

Lepidopteran wing scales have a specialized structure and are divided into two types. Primitive-type scales, found in nonditrysian Lepidoptera, are solid with longitudinal ridges (Fig. 1C). Normal-type scales, found in the ditrysian Lepidoptera, are composed of superior and inferior lamellae, with an internal lumen subdivided by internal supports called trabeculae (Fig. 1D). Whereas the inferior lamella is smooth, the superior lamella is usually covered with longitudinal ridges, interconnecting transverse ridges (flutes), and/or perforations (windows). Some groups of nonditrysian Lepidoptera have a mixture of the two types, with normal-type scales layered over the primitive-type scales.

Wing color in Lepidoptera is produced by wing scales. Individual scales are usually a single color which may be generated by any one or a combination of pterins (red, yellow, white), melanins (black), flavonoids (white), carotenoids (blue, yellow), papilliochromes (cream-yellow), and ommachromes (red). Scales also produce color by diffraction; regular longitudinal ridge spacing produces various diffraction colors, whereas irregular spacing produces overlap in color spectra and is perceived as white light. Interference colors, from which light is reflected from a series of superimposed surfaces separated by distances equivalent to light wavelengths, result in selective phasing in and out of various colors. This type of color is important for producing bright color hues in adult butterflies (e.g., *Morpho* spp.) and is produced from a series of longitudinal vanes along the scale blade. Each vane is supported by a series of thickening, or mullions, which act in concert with other vanes to form a series of reflecting surfaces and produce interference colors.

**FUNCTIONAL TYPES**

The functions of setae are sensory (e.g., touch, taste, and smell), but in many insects the original sensory function of some setae has been discontinued though cell death that creates a noninnervated...
seta. These setae often have more specialized roles, sometimes with
great morphological modification. There is incredible diversity in the
shape, structure, and function of the both the seta and its morphological
derivative, the scale. A detailed examination of almost any insect will
reveal a myriad of seta or scale types, often with vastly differing roles
in the biological functioning of the organism. The following classi-
cation is clearly artificial and categorizes the diversity of setae and
scales into functional types for ease of discussion.

**Mechanical**

**LOCOMOTION** Elongate setae are used by numerous insect
groups for flight and swimming. Elongation of marginal setae is an
efficient mechanism to increase the surface area of locomotory struc-
tures (e.g., wing, leg), with only a slight increase in weight or devel-
opmental investment (Fig. 2). Such elongation of setae along wing
margins is common only in very small sized insects, as the degree of
elongation is finite and insufficient to generate adequate lift for larger
insects. Groups of insects that use this mechanism for flight include
all Thysanoptera and various microhymenopterans (e.g., Mymar—
Mymaridae), microlepidoptera (e.g., Macarostola—Gracillariidae), and
Coleoptera (e.g., Acrobatia—Ptinidae) (Fig. 2). Aquatic insects that
are active swimmers often have paddle-shaped leg segments fringed
with elongated setae for added propulsion through water. Examples
include various families of Heteroptera (e.g., Naucoridae, Corixidae,
and Notonectidae) and Coleoptera (e.g., Hygrobiidae, Halphilidae,
Dytiscidae, and Gyrinidae).

**WING COUPLING** Some insect groups use specialized setae
to couple the fore- and hind wings together, so ensuring synchro-
nous wing beats during flight. The basic pattern, which occurs in
Choristidae (Mecoptera), is composed of retinacular setae along the
jugal margin of the forewing interlocking with frenular setae along
the basicostal margin of the hind wing. More advanced forms are found
in Lepidoptera, in which the frenulum may be a single single seta or
multiple slender setae. In Trichoptera, a row of large setae is present
along the costal margin or the subcostal vein of the hind wing, which
engages either the jugal lobe or a ventral ridge in the anal field.

**DIGGING** Fossorial insects often have stout setae arranged in
rows on the leg segments for digging. A comb of long setae (pecten)
is commonly present on the foretarsi of ground-nesting aculeate wasps
(e.g., Benix—Sphecidae). Enlarged and thickened setae-like struc-
tures borne on acanthophorites are used for digging during oviposition
by females of various asiloid Diptera (e.g., Therevidae, Apioceridae).

**Camouflage Aids**

Highly modified setae are commonly used by insect larvae that cam-
ouflage themselves by carrying soil, feces, and/or trash particles on their
body. Some of the most elaborate of these may be found on the bod-
ies of myrmeleontoid Neuroptera (i.e., Ascalaphidae, Nemopteridae,
Psychopsidae, Nymphidae, and Myrmeleontidae). Other than entan-
gling camouflage materials, the biological function of these highly
modified setae, called dolichasters, is unknown. Dolichasters may be
simple, scale shaped or highly ornate, star or cup shaped or recurved
hooks (Fig. 3). Ascalaphid and nymphid lacewing larvae may also have
abdominal extensions called scoli (Fig. 4), on which rows of enlarged
scales or setae are used to entangle camouflage materials.

**PLASTRON** To extend their duration under water, some
aquatic insects use a plastron, or air bubble trapped by fine hydro-
fuge setae. The setae are used to hold a large air bubble by surface
tension. The plastron enables them to live permanently submerged
in water because oxygen passes by diffusion from the water into the
plastron. Examples of plastron use by this method include the beetle
families Elmidae and Hydrophilidae.

**FOOD GATHERING AND PREY CAPTURE** In preda-
tory insects, enlarged setae are an economical substitute for teeth or
spines for holding prey. Stiff enlarged setae are present along the inner
margin of mandibles of some larval Nymphidae and Myrmeleontidae
(Neteoptera). Similar setae on the inner margin of fore femora of adult
Leptopodidae (Heteroptera) are used for the same purpose. Aquatic
insects may use elongated rows of setae around the mouthparts as fi-
lters to trap food particles in flowing water (e.g., Coloburiscoides sp.—
Coloburiscidae: Ephemeropodera) or use setae-fringed foretarsi to seize
for prey in detrital ooze (e.g., Agraphocorix—Corixidae: Hemiptera).

**Defensive**

Lepidopteran larvae of several families (e.g., Arctiidae,
Notodontidae, Thaumetopoeidae) use specialized urticating (irritat-
ing) setae as a defense against potential predators. Urticating setae are
modified setae with a poison cell associated with the trichogen cell;
the former discharges venom when the tip of the seta is broken off.
The urticating setae may be very long and scattered over the body surface or short and positioned on the apex of a scolii. In Limacodidae, the sting setae are short and positioned at the apices of often brightly colored, eversible tufts that are extended when the individual is disturbed. Some adults and/or larvae of the coleopteran families Cleridae, Trogossitidae, and Dermestidae are often clothed in long bright tufts that are extended when the individual is disturbed. Some adults and/or larvae of the coleopteran families Cleridae, Trogossitidae, and Dermestidae are often clothed in long fine setae, which may be recurved. In addition to a sensory function, these setae may be used defensively to obstruct or entangle potential predators or parasitoids.

Secretory Substrate

Setae are commonly used by insects as a substrate of high surface area from which a pheromone is dispersed by evaporation. Adult males of some nemopterid (Neuroptera) genera use distinctive tufts of fine setae (bulla) on the hind margins of the fore- or hind wings to disperse pheromone. Males of the antion tribe Acanthoclini (Myrmeleontidae) have eversible sacs (hair pencils) covered with fine setae for a similar purpose, and many male butterflies use specialized setae (androconia) located in basal depressions along the forewing veins called androconial organs. During courtship pheromone is dispersed from the hairs, often with elaborate “calling” behavior, which can consist of hovering and diving at the prospective female and fanning pheromone in her direction.

Scorpions

Stanley C. Williams
San Francisco State University

Scorpions are among the most recognizable groups of arthropods. Their highly segmented body plan is uniquely subdivided into a leg-bearer prosoma, a broad seven-segmented preabdomen (mesosoma), and a narrow five-segmented postabdomen (metasoma) that terminates in a bulbous stinging organ, the telson. The fossil record indicates that scorpions were the first arthropods to occupy the terrestrial environment. An important member of the class Arachnida, scorpions survived periods of mass extinctions and today occupy a prominent position in arthropod communities. This gives them the distinction of being the oldest surviving group of terrestrial arthropods.

EVOLUTION

Scorpion fossils date back to the Silurian, some 400 mya. The oldest known taxon, Palaeophonus, is strikingly similar in structure to modern forms in their extensive, characteristic segmentation, appendages, and general body form. Their body was organized into four regions: a prosoma (cephalothorax), a broad mesosoma (“preabdomen” containing digestive and reproductive organs), a taillike metasoma (slender “postabdomen” composed of five ringlike segments), and a terminal postanal segment, the telson. Palaeophonus differs from modern scorpions in not having pretarsal claws on the distal ends of walking legs and in having a blunt ending of the telson. The absorptive membranes of the book lungs might have been eversible, forming a gill-like respiratory structure. This suggests that Palaeophonus might have existed in aquatic and land habitats.

The fossil record indicates that scorpions underwent rapid adaptive radiations that led to structural diversity, especially in the segmentation and morphology of the ventral prosoma, the development of pretarsal claws, the formation of a sharp venom-delivering aculeus on the terminus of the telson, and trichobothrial patterns.

MORPHOLOGICAL CHARACTERISTICS

Scorpions are readily distinguished by their unique morphology (Fig. 1). Their prosoma consists of six body segments that are covered dorsally by an unsegmented carapace. Each of these segments bears a pair of characteristic segmented appendages. The first pair, the chelicerae, is small, chelate or scisorlike, and serves as the mouthparts. The second appendages are large, conspicuous pedipalps that terminate in a strong scisorlike chela used to capture and immobilize prey. The
next four pairs of appendages are the walking legs, each of which terminates in a pair of distinctive pretarsal claws, the ungues. Along with a single pair of median ocelli, there are two groups of lateral ocelli located at the anterolateral corners of the carapace. Each group of lateral ocelli consists of zero to four facets, evidently derived from a primitive compound eye. The mesosoma is attached broadly to the prosoma, lacks appendages other than the sensory pair of comblike pectines, and houses the digestive, urinary, and reproductive organs. The four pairs of respiratory book lungs open to the outside through stigmata on mesosomal sterna two through six. Expansion of tergal–sternal and intersegmental membranes permits meal engorgement during feeding and also allows for increase in body volume to accommodate internal development of the eggs and embryos. The metasoma is composed of five narrow segments forming a freely articulating, taillike body region. A single unsegmented telson freely articulates with the metasoma and is composed of a swollen vesicle that terminates in a sharply pointed aculeus or “sting.” Paired venom glands are housed in the vesicle, and the associated aculeus injects the venom into the victim (Fig. 2).

Scorpions all over the world have the same basic body structure, which is surprising considering the antiquity of the extant families.

**ANATOMICAL ADAPTATIONS**

Scorpions demonstrate basically the same organ systems characteristic of most arachnids. These systems reflect adaptations that support their successful lifestyle as opportunistic ambush predators. The digestive system begins with a tiny mouth located below the base of the chelicerae. Its small diameter allows intake of food only in fluid form. Preoral enzymes are secreted by salivary glands directly into the body of the prey, and the liquefied, preorally digested tissues are ingested through a sucking action. This is facilitated by a pressing or grinding action of the gnathobases at the inner bases of the pedipalps.

Large, expansive midgut ceca facilitate rapid intake and storage of nutrients. Because particulate matter is not ingested with a meal, fecal wastes are minimal. Nitrogenous wastes are excreted by means of Malpighian tubules that deposit wastes, primarily in the form of crystalline guanine directly into the digestive tube for subsequent elimination. Some species have also been found to excrete nitrogenous wastes in the form of uric acid and xanthine. Scorpions have no tracheal system but instead use four pairs of book lungs to respire. Air passes through four pairs of tiny stigmata, which are opened and closed by membranous opercula in the mesosomal sterna. Inspired air then enters the lamellar spaces of the membranous book lungs. This limiting mode of oxygen uptake is correlated with the sedentary lifestyle and metabolic simplicity characteristic of most scorpions. A ventral nerve cord with highly metameric ganglia characterizes the nervous system. At the cephalic end is found the subesophageal ganglion and supraesophageal brain. The circulatory system consists of a long, pulsing muscular tube, called the dorsal vessel, and colorless blood composed of hemolymph and hemocytes.

The reproductive system has organs arranged in a somewhat segmented, fishnet-like form within the mesosoma. The male has a paraxial organ that contains a pair of hemispermatophores that fuse to form a sperm-carrying spermatophore used for indirect insemination of a female during the courtship dance. The female system is composed of a hollow tube with an inner lumen that exits the body through a ventrally located genital aperture which is covered by a valve like genital operculum adjacent to the basal plate of the pectines. Multiple oocytes in different stages of maturation may be seen...
on the surface of the reproductive tube. Fertilization is internal, and the female carries the developing embryos until birthing as larvae.

**SYSTEMATICS**

Substantial numbers of undescribed species and genera are still being discovered. This largely results from the nocturnal and secretive habits characteristic of most scorpions, which make them difficult to find. The scorpion fauna from many regions are also poorly known and largely unrepresented in scientific collections. Approximately 1300 species of living scorpions are currently recognized and are assigned to 13 families and about 160 genera (Table I). The higher classification of scorpions is the subject of current reevaluation. The trend has been to recognize more families and genera, and to base the resulting classification on phylogenetic relationships as suggested by cladistic analyses. Recently, a number of impressive regional studies have been published, and most have resulted in recognizing numerous new taxa. The numbers of extant scorpion families and species are surprisingly low considering their success as a group, their broad distribution, their diverse habitats, and their antiquity.

**DISTRIBUTION AND BIODIVERSITY**

Scorpions are conspicuously common in tropical and subtropical regions throughout the world. They also range into the more temperate regions of both the Northern and Southern Hemispheres. In North America, they range as far north as British Columbia, Alberta, and Saskatchewan, Canada (approximately 52°N). In South America, they range south into Chile and Argentina (approximately 50°S).

Scorpions show wide-ranging adaptations to different elevations. In Baja California, Mexico, scorpions are found in the intertidal habitats. In the White Mountains of California, they are established at elevations up to 3170 m (10,400 ft). Scorpion species often go unnoticed, even when abundant. They are mainly nocturnal, secretive animals and usually remain inactive, hidden in their retreats, except when feeding, mating, or disturbed. For many scorpions, such as *Hadrurus* and *Vaejovis*, adults are the stage usually encountered; juveniles tend to minimize their exposure in the environment. This pattern is most conspicuous in scorpions found in more temperate areas and at higher elevations. In other species, such as *Centruroides* spp. and some *Paruroctonus* and *Smeringurus* spp., however, juvenile instars are commonly encountered.

**BIOLOGY**

**General Life Cycle Strategy**

Scorpions often go unnoticed, even when abundant. They are mainly nocturnal, secretive animals and usually remain inactive, hidden in their retreats, except when feeding, mating, or disturbed. For many scorpions, such as *Hadrurus* and *Vaejovis*, adults are the stage usually encountered; juveniles tend to minimize their exposure in the environment. This pattern is most conspicuous in scorpions found in more temperate areas and at higher elevations. In other species, such as *Centruroides* spp. and some *Paruroctonus* and *Smeringurus* spp., however, juvenile instars are commonly encountered.

**Life Cycle**

The scorpion life cycle is a simple one consisting of an egg, a single larva stage, 2–6 nymphal instars (depending on the species), and the adult stage. The larva differs morphologically from other instars in lacking the typical unguicular claws at the tips of the walking legs, lack of a sharp aculeus or “sting,” lack of dark pigmentation and sclerotization of the exoskeleton, and lack of effective locomotor ability. Behaviorally, the larva is unique in that it usually remains on the mother’s back and does not travel alone or feed. The sedentary larva usually molts to the first nymph stage on the mother’s back at which time it shows increase in linear dimensions, has pretarsal claws and a sharp distribution. Although they are often thought of as tropical, scorpions seem to reach their highest biotic diversity in the arid regions of more temperate latitudes. Most scorpion habitats are characterized by a modest diversity ranging from one to five sympatric species. The greatest regional diversity of scorpions is reported from Baja California, where more than 61 species and 11 genera are found. The higher latitudes and higher elevations have more limited diversity, often with only one or two species represented in a given habitat.

Scorpions

aculeus, and becomes increasingly physically active. At this time, the first nymphal instar normally leaves the mother’s back, disperses from the mother’s shelter, locates a new shelter, and begins its own independent life. After periods of feeding and growth, nymphs periodically molt to their successive instars, until adulthood is reached. Adults differ from the nymphs in being sexually mature, but they often show little morphological difference except in their larger size and sometimes in the proportion of body parts such as the larger pedipalp chela and elongation of the metasoma. Adults may also show distinctive sexual dimorphism in body proportions. A few species appear capable of reaching sexual maturity during the last two life cycle instars.

Feeding

Ambush predation is the main means of prey capture. For example, some burrowing species such as Arachnidae phaiodactylus quietly wait inside their burrow entrances and ambush prey that enters or passes by their burrow. Many species of scorpions, when hungry, leave their protective shelter during nocturnal hours and take a stationary position in their environment, which may be on the substrate surface or in vegetation. Here, they will remain motionless until an unsuspecting prey ventures close, at which time it is grasped with the strong pedipalp chela and may be stung, if necessary. Other scorpions such as Centruroides spp. often range great distances from their diurnal shelters in search for prey. At such times, they may actively stalk their prey. If a scorpion is unsuccessful, it will return to its shelter and resume its predation behavior the next night, and the night after, until successful.

After successful prey capture, a scorpion draws the immobilized prey close to its oral cavity and exudes preoral digestive fluids that digest the prey’s tissues internally. During ingestion, the chelicerae also shred prey tissues. The resultant fluid is sucked into the oral region, and any remaining fluids are pressed from the prey remains by the gnathobases of the inner pedipalp coxae. Up to 97% of the body mass of a prey may be ingested. A satiated scorpion then returns to its shelter and will normally not be seen until hungry again, which may be from 2 weeks to a month or 2. Its effective mode of predation, habit of engorgement feeding, and low metabolic rate result in a lifestyle that requires minimal prey, minimal exposure of the scorpion, and survival when prey are not readily available. Scorpions in the laboratory may go for as long as 12 months between meals. However, in nature, one feeding every 2–6 weeks is probably more common. Almost any animal that a scorpion can catch and immobilize is a potential prey, so scorpions feed on a variety of insects and spiders. Predation on centipedes, other scorpions, lizards, and small snakes has also been observed.

Reproduction

The scorpions’ reproductive mode is one of the most ancient ones used by terrestrial arthropods. It involves sexual reproduction, with insemination of the female by the male following a ritualistic courtship dance. Internal fertilization is complicated by the lack of an intromittent organ in the male. Fertilization takes place indirectly by a spermatophore deposited by the male.

Pheromones bring potential mates together and initiate courtship. When two potential mates encounter each other, they grasp each other by their pedipalpal chelae and undergo a forward and backward “dancelike” behavior, the “promenade à deux,” which may be over in a few minutes or last for hours. At the end of this dance, the male emits a sclerotized spermatophore onto the substrate and draws the female over it, at which time she takes up the sperm packet in her gonopore. The two then part, and the female normally returns to her shelter. Depending on the taxa, gestation takes from approximately 2 or 3 months to nearly a year. Development is internal and results in the birth of a dozen to over a hundred larvae, which quickly ascend to the mother’s back and remain there for the remainder of their first stadium. Parturition takes from an hour to about 3 days, depending on the species and number of offsprings. Some species seem to have several birth cycles each year, whereas others seem to have only one per year. Parthenogenesis has been reported in Titus serrulatus and Liocheles australasiae. Field observations of Liocheles suggest that some natural populations might have parthenogenesis as their primary means of reproduction.

Habitats

Scorpions have been roughly categorized as “ground” vs. “bark” dwellers. Ground dwellers construct burrows in the ground, seek shelter in rocky substrate, invade the burrows of other organisms, or occupy protective spaces under or within ground surface debris. Bark dwellers are commonly found sheltered under bark, in bromeliads, in vegetation, in residential thatch, or in other plant material. They are often climbers and may primarily occupy forest canopies. During some seasons, forest-dwelling forms may migrate to the ground to seek shelter under rocks or surface debris. This group has members that invade human habitations and can be seen climbing walls and ceilings at night. They may reside in thatching and in the mortar spaces between bricks and rocks of walls. Most ground scorpions are solitary, although some bark scorpions such as Centruroides may be found in aggregations during certain times of the year. A. phaioadactylus constructs a burrow as a young nymph and occupies it throughout its life, which may last for several years. It seldom ventures far from its burrow and is intolerant of other scorpions in its burrow. Many of the ground-dwelling species probably spend most of their life in their permanent burrow. At time of courtship, however, mature males abandon their burrows or other territory and become more nomadic in search of mates. Scorpions are diurnal, seeking closely fitting shelters. The availability of suitable shelters, or home sites, is believed to limit the population size of some species.

Scorpions are found in a variety of habitats from desert to mesic, and they thrive in highly xeric environments. They are common in tropical and subtropical regions, and many species extend into the temperate latitudes. Most scorpions prefer well-drained habitats, but some species of Centruroides, for example, thrive in riparian and tropical rain forest environments, and seem to survive drowning by climbing trees during times of flooding. Some scorpions, such as species of Isometrus and Centruroides, are successful oceanic travelers, dispersing among islands on floating palm logs. Burrowers vary greatly in their choice of habitats and behavior. A. phaioadactylus requires soil with good drainage and adequate compaction to support permanent burrows; Vaejovis longiangus constructs burrows in unconsolidated soil of sand dunes; species of Serradigitus do not burrow but live in crevices, talus slopes, and rock fractures; Superstitionia donensis may occupy a burrow or may be found in a simple cell constructed under a rock, animal dung, or vegetation; Centruroides thorelli resides in bromeliads within tropical forests; Vaejovis littoralis is found in the intertidal wrack zone, where it continually migrates ahead of the changing tides; Centruroides exilicauda seeks shelter under bark of trees, but may also be found under surface debris or in rock crevices, and is a common invader of human habitations; and Uroctonus maorlax is commonly found in wet habitats, where it may reside under mosses and rotting logs, and in soil crevices. Almost any habitat that provides adequate shelter and prey is suitable for some kind of scorpion. As a result, these arthropods are globally widely distributed.
Scorpions

Predators and Parasites

Although scorpions do not have many natural enemies, they are an attractive prey for a few predators. Their rich nutrient content and numerical abundance contribute to their vulnerability as prey. Predators that hunt during the nocturnal hours are particularly effective in feeding on scorpions. Most capture scorpions while they are exposed on the substrate surface, but some, such as coyotes, will dig them up. Some 124 vertebrate and 26 invertebrate predators have been reported to feed on scorpions. Elf owls (Micrathene), burrowing owls (Speotyto), barn owls (Tyto), grasshopper mice (Onychomys), coyotes, bats, desert shrews (Notosorex), and a variety of lizards are among the most conspicuous scorpion predators. Parasitism of scorpions is not common; reported endoparasites include larvae of a tachinid fly (Spilochaetosoma californicum), mermithid nematode larvae, and the larvae of a sarcophagid fly (Sarcodexia sternodontis). About eight species of nites have been reported as ectoparasites of scorpions, but nite parasitism is not commonly observed.

VENOMS

Scorpions are universally recognized because of their venoms and conspicuous stinging apparatus. All species are venomous, but only a few are harmful to humans. The venom is produced in a pair of glands located in the vesicle of the telson and collects in the lumen of each gland, flowing through a simple duct that terminates near the sharp tip of the aculeus. The venom is delivered during a rapid thrust of the metasoma that results in the penetration of the victim’s skin by the sharp aculeus. Contraction of muscles surrounding each venom gland discharges the venom.

The venoms are complex substances composed of water, a number of low molecular weight proteins (neurotoxins), and various organic compounds such as oligopeptides, nucleotides, amino acids, mucus, and cellular debris. A common fraction of venoms function as simple irritants, often causing a sharp burning sensation. Other fractions may cause inflammatory responses resulting in edema. In highly toxic venoms, systemic components may result in neurological symptoms such as convulsion followed by death. The neurotoxic effects seem to be the result of multiple interactions of certain toxins with voltage-dependent ion channels of excitable cell membranes, such as those of neurons. Venom interactions may include membrane depolarization, repetitive firing, prolonged action potentials, and massive release of neurotransmitters, most importantly from the adrenal medulla.

The cumulative effects of a venom in envenomated animals are complex and varied. Venenation particularly may affect skeletal muscles, the cardiovascular system, lungs, visceral smooth muscle, uterus, and glands. The severe convulsions that may be associated with the sting of more toxic species (e.g., Centruroides spp.) are of particular concern. Each scorpion venom contains a number of different toxic components, which explains the varied venom reactions observed.

Scorpion venoms are toxic to a variety of organisms, including arthropods and vertebrates, but are often nontoxic to other scorpions. The hemolymph may have the capacity for neutralizing the toxic components in the venom from other scorpions.

The number of reported human deaths from scorpion stings ranges from several hundred to several thousand annually. Stings are considered to be more serious when they happen to children, the elderly, and those in poor health. The number of reported deaths has been declining because of better treatments, development of antivenins, the reduction of human contact with scorpions in critical areas, and public health awareness. Because of unreliable reporting in developing countries, however, the reported incidence of scorpion stings and mortality is probably greatly underestimated.

Venomous scorpions of concern to humans are found throughout the world, but some of the more severe problems are in the more arid regions. Of the 1300 known species, only a dozen or so cause significant health problems for humans. The species of greatest medical concern are members of the family Buthidae and belong to the genera Androctonus, Bathracus, Butulus, Centruroides, Leirus, Mesobuthus, Parabuthus, and Tityus. Regions with significant scorpion sting problems often have antivenins available at local pharmacies.

METHODS OF OBSERVATION AND STUDY

Sampling and Collecting

Scorpion assessments and collections were traditionally made by inspecting trees and by looking under rocks, trash piles, and other surface debris. The discovery that scorpions fluoresce under the ultraviolet wavelengths of black light blue (BLB) bulbs led to the use of the “ultraviolet method” of scorpion detection and study. Equipped with a portable ultraviolet light, an investigator can walk through a habitat at night, counting and observing scorpions undisturbed in their natural state. With such a lamp, a scorpion can be readily detected on a sand dune at a distance of about 15 m.

Care and Maintenance of Captive Specimens

Scorpions are easily kept in captivity and require minimal care. They may be housed in any closed container, such as a terrarium, plastic box, jar, or plastic bag. If soil is provided, a rock or other surface cover should be added for shelter because scorpions are thigmotactic and seek close-fitting shelters. A small amount of water needs to be provided periodically. Scorpions can be maintained at room temperature and should not be exposed to freezing temperatures, especially the tropical forms. Most live insects may be supplied for food, but crickets are particularly well accepted. Generally, one cricket every 2–4 weeks is adequate feeding for a moderate-sized scorpion.

As a rule, scorpions remain inactive in their shelters during the day and will show normal activity (if any) at night. Lack of physical activity is common and typical of most scorpions. Excessive activity often indicates a lack of food or water, excess light, excessive temperature, or other disturbance. Covering the rearing chamber with red cellophane readily simulates nocturnal environmental conditions. Most scorpions will live for 1–5 years in captivity.

Segmentation

Nipam H. Patel, Paul Z. Liu
University of California, Berkeley

Segmentation is the repetition of body units along the anterior–posterior axis and is a fundamental property of all insects; indeed, it is an obvious character of all arthropods. Insect segments are clearly visible as reiterated patterns visible in the exoskeleton, but repeating patterns are also present in internal structures such as muscles, neurons, and tracheae. Through genetic and molecular approaches in the dipteran fruit fly, *Drosophila melanogaster*, the mechanisms of segmentation in this insect are now understood in great detail. Recently, interest in the evolution of segmentation has inspired numerous comparative studies of the mechanisms governing segmentation in diverse insect taxa. These experiments indicate that some aspects of the *Drosophila* mechanisms are conserved in all insects, whereas others have undergone extensive evolutionary changes.

**PATTERN OF SEGMENTS**

Segments are most easily visible in the exoskeleton of the adult, where we can see the repeating pattern in the cuticle. The rigid body plates that make up the adult exoskeleton, or sclerites, are separated by membranous intersegmental grooves that lie at the boundary between segments and allow the body to flex. The segmented exoskeleton is also often endowed with reiterated patterns of pigmentation and other elaborations, such as denticles or hairs on the exoskeleton (Figs. 1 and 2).

**FIGURE 1** The pattern of segments can be easily seen on this Atlas moth (*Attacus atlas*), made even more evident by the reiterated pigmentation pattern. Note the head, thoracic, and abdominal tagma.

**FIGURE 2** The larval segments of *Drosophila*. The pattern of segments is clearly revealed by the pattern of denticles (hairlike projections) on the ventral surface of the larvae. The segments of the head are involuted inside, and the terminal abdominal segments are not visible on the surface.

Individual insect segments also show various levels of specialization in terms of morphology and function, and are grouped into three primary regions, also known as tagmata: the head, thorax, and abdomen. The head is composed of six segments, the thorax of three, and the abdomen of eleven segments. Segments of the thorax and abdomen are most easy to recognize, whereas the segments of the head and terminal regions of the abdomen are less apparent because they become fused in some insects during development. The head is composed of the antennal, ocular, intercalary, mandibular, mandibular, and labial segments (progressively from anterior to posterior), although some researchers have suggested the existence of a seventh segment at the very anterior of the head. The thorax has been specialized for locomotion and its three segments bear the six legs and the wings. The most posterior abdominal segments (A10 and A11) are fused and reduced in some species, making them difficult to recognize in adults but can usually be detected during embryogenesis.

Although segmentation is most clearly visible in the exoskeleton and in other products of the ectoderm, the pattern of segmentation is also reflected in the arrangement of internal features as well. The musculature, tracheal system, and nervous system are also segmented. The insect central nervous system is laid down in a segmental pattern and contains reiterated ganglia for almost all segments, although some degree of secondary fusion has occurred. Ganglia arise in all abdominal segments during development, but in most insects, the eighth abdominal ganglion is a condensation of the posterior ganglia and innervates the eighth and all succeeding posterior segments. In some insects, a greater level of fusion has occurred. In cyclorraphous flies and in the bedbug *Rhodnius*, for example, the entire ventral nerve cord is consolidated into a single mass of nerve tissue.

**PARASEGMENTS**

The segments that we see in the insect epidermis are so obvious that it is tempting to think that they must represent the fundamental building blocks of the insect body plan. It turns out, however, that the basic unit of segmentation is actually the "parasegment." Parasegments (*para* from the Greek, meaning "beside" or "near") are the same width as traditional segments, but are shifted slightly out of phase from them along the body axis such that a single parasegment is composed of approximately the posterior one-fourth of one segment and the anterior three-fourths of the next adjacent segment. So if traditional segments and parasegments are both the same width but merely shifted out of phase from each other, why consider parasegments at all?

The evidence for the existence of parasegments and their primacy in segmentation comes from several lines of evidence. First, the expression and mutant phenotypes of several of the homeotic...
selector genes (described below) seem to affect regions bounded by parasegmental boundaries. Second, the signaling centers established by the segment polarity genes act across parasegment boundaries. Third, during the development of several insect orders, small grooves corresponding to parasegment boundaries can be seen temporarily subdividing the ectoderm before the appearance of the deeper and permanent segmental grooves. Lastly, data from other arthropods suggests that parasegments serve a fundamental role in anterior-posterior patterning in these animals. Analysis of segmentation gene expression in a wide variety of other arthropods also strongly supports the fundamental nature of parasegments throughout the arthropods, and lineage analysis studies performed in some crustaceans has shown that single rows of ectodermal cells divide in stereotyped patterns to give rise to a single parasegment—evidence that the genealogical unit in these crustaceans is the parasegment.

MECHANISMS OF SEGMENTATION IN DROSOPHILA

Studies of insect segmentation through experimental manipulations such as ligation, ablation, centrifugation, and transplantation have a rich history and continue to provide important insights into the mechanisms of segmentation. Beginning about 25 years ago, however, our understanding of these mechanisms was rapidly accelerated by genetic mutant screens in the fruit fly, D. melanogaster. Indeed, these screens uncovered such fundamental principles of biological pattern formation that the geneticists who carried them out, Edward Lewis, Eric Wieschaus, and Christiane Nüsslein-Volhard, were awarded the Nobel Prize in Medicine and Physiology for their contributions to the genetic analysis of tagmosis and segmentation in Drosophila. The genetic analysis of segmentation was quickly supplemented with molecular and biochemical studies that have provided detailed knowledge of how segments are generated along the anterior-posterior axis during Drosophila embryogenesis. Because so much is now known about the mechanism regulating segmentation in Drosophila, it has served as a frame of reference for understanding this process in all insects.

Early mutant screens identified many genes that act to establish the pattern of segmentation, and they were grouped into several classes based on their associated mutant phenotypes. These phenotypes indicate that the segmentation genes in Drosophila act in a hierarchical manner to sequentially subdivide the embryo into progressively smaller and smaller units, ultimately establishing the pattern of segments we see in the Drosophila larva (Fig. 3).

The Maternal Effect Coordinates Genes

Studies of the maternal effect genes show that the process of segmentation actually begins during oogenesis, when specific messenger RNAs (mRNAs) are localized at either the posterior or anterior end of the developing egg. For example, bicoid mRNA is localized to the anterior end of the egg and forms a gradient of protein in the egg once it has been fertilized (with the highest concentration of bicoid protein at the anterior end). Mothers lacking functional bicoid produce embryos in which the anterior segments are missing. A reciprocal gradient of the nanos protein is also formed, and nanos mutants are missing the more posterior regions of their bodies. The formation of these gradients by simple protein diffusion is possible because the early development of Drosophila is syncytial, with no cell membranes between the nuclei of the early embryo allowing proteins to diffuse across the early embryo. These gradients of information act to control the expression of the various downstream zygotic gap genes, which are the next step in the segmentation hierarchy.

The Gap Genes

The gap genes are so named because mutations in this class of genes cause deletions of several contiguous segments causing a "gap" in the resulting larva. The gap genes read the informational gradients set up by the maternal genes and along with cross-regulatory inputs from other gap genes, become expressed in broad but well-defined domains across the early embryo that roughly correspond to the regions that are deleted in the mutants. All of the gap genes encode transcription factors that act together to regulate expression of the downstream pair-rule genes.

The Pair-Rule Genes

The expression and function of the pair-rule genes reveals the first periodic patterns in the Drosophila embryo. Like the gap genes, the pair-rule class of genes was originally defined through their loss of function phenotypes—in this case, deletions with a two-segment periodicity. Accordingly, most of the pair-rule genes go through a phase of expression consisting of seven stripes—corresponding to a two-segment periodicity—beginning at the syncitial blastoderm stage of the embryo and persisting through cellularization. When the striped pattern for one such pair-rule gene, even-skipped, was first observed, it was thought that the beautiful regularity of the pattern...
Segmentation

was due to some sort of chemical oscillation that could be modeled with reaction–diffusion equations. Instead, it turns out that stripes are specified individually by the upstream gap and maternal genes acting directly on the DNA regulatory regions that control even-skipped expression. The pair-rule genes encode transcription factors that work together to regulate the final level of the segmentation hierarchy, the segment polarity genes.

The Segment Polarity Genes

The segment polarity genes were also originally identified in genetic screens and named for their mutant phenotypes, which show defects in every segment. These genes are generally expressed in patterns of segmental stripes and include not just transcription factors, but also various receptors, ligands, and enzymes that are used in cell–cell communication, and act to maintain and further refine the pattern of segments that has been elaborated.

The Homeotic Genes

A final category of genes, the homeotic genes, do not act to produce segments, but rather give identity to the segments. Mutations in these genes result in the transformation of one or more segments to the identity of another segment. For example, certain loss of function mutations in proboscipedia cause legs to appear in the place of the adult labial palps. The homeotic genes are primarily regulated by the gap genes, although pair-rule and segment polarity genes also have an important role in defining the precise boundaries of homeotic gene expression. All the homeotic genes encode a family of closely related transcription factors and, in Drosophila, are organized into two complexes on one of the chromosomes. Interestingly, the expression of the homeotic genes along the body axis and their arrangement in the genome are roughly co-linear; homeotic genes expressed in anterior segments of the embryo are situated 3’ in the complex, while genes expressed in the posterior are 5’ in the complex. This co-linear arrangement is highly conserved throughout the bilaterian animals, but the reasons for this chromosomal arrangement are not fully understood.

Molecular Data in Short Germ Insects

The great depth of our understanding of Drosophila segmentation has led to a recent resurgence of interest in the development of other insects. The embryological differences seen in short and long germ development implies underlying changes at the molecular and genetic level. Homology of several Drosophila segmentation genes now have been studied in a wide variety of insect taxa and their expression and function show both remarkable levels of evolutionary conservation as well as surprising instances of change.

In all insects examined so far, the homologs of Drosophila segment polarity genes are expressed in stripes as in Drosophila suggesting a conserved role in maintaining parasegment boundaries across diverse insect taxa. But reflecting their short germ mode of segmentation, the stripes appear sequentially in an anterior to posterior progression as the embryos grow.

Moving up the segmentation gene hierarchy, the pair-rule genes show more evolutionary lability. In the red flour beetle, Tribolium castaneum, even-skipped is expressed in a pair-rule like pattern, but again the stripes appear sequentially over time as the embryo elongates. In the milkweed bug, Oncopeltus fasciatus, even-skipped

![FIGURE 4 Embryos of the intermediate germ band insect, Tribolium castaneum. These embryos have been stained for a gene called engrailed, which is expressed as a single stripe in each segment. Six anterior segments have been specified by the end of blastoderm stage (top left) with the remainder appearing sequentially during later stages of development. Compare the sequential appearance of segments in this insect with the progressive subdivision seen during Drosophila segmentation (Fig. 2).](image-url)
bypasses the pair-rule phase of expression entirely and the stripes appear in every segment (both *Drosophila* and *Tribolium even-skipped* goes through an early pair-rule pattern followed by a late segmental pattern). In the grasshopper, *Schistocerca americana*, *even-skipped* is not even expressed in stripes at all. These differences and differences in expression of other pair-rule homologs suggest that extensive evolutionary alterations have occurred at this step of the segmentation hierarchy, although these changes still result in a conserved output of segment polarity gene expression.

Less work has so far been performed on gap genes in other insects, but the results so far have again shown both conservation and change. Even examples of gap gene conservation are often surprising when viewed in the context of short germ development. For instance, mutations of the gap gene *Kruppel* in *Drosophila* delete the thorax and first half of the abdomen. In a short germ insect, since the abdomen is formed after the blastoderm stage, the expectation is that *Kruppel* would not act in this way in the abdomen. However, when *Kruppel* function is experimentally depleted in *Oncopeltus* embryos, this gap phenotype is largely conserved. This unexpected conservation of *Kruppel* function in a short germ insect implies that in certain cases, the differing modes of segmentation may be underpinned by similar molecular mechanisms.

The earliest steps of pattern formation seem even more labile during insect evolution. For example, it is difficult to imagine how a gradient of bicoid protein can form in grasshopper embryos, given that the entire thorax and abdomen arises as a result of cell proliferation well after the blastoderm stage. Studies suggest that the bicoid gene, a key component of the maternal gradient *Drosophila* system, only arose within the dipteran lineage. This raises the question as to what gene acts in the stead of *bicoid* in insects lacking this gene. Recent work in *Tribolium* has provided one example of how the anterior may be patterned in insects lacking *bicoid*. In *Tribolium*, another maternally supplied protein, the product of the *orthodenticle* homolog OTX1, acts together with Hunchback to carry out a role similar to the Bicoid gradient in *Drosophila*. Like *Drosophila*, *Tribolium* embryos also undergo a prolonged syncitial stage (but since they are short germ, only the anterior is specified), so it is not difficult to imagine how these gradients act to pattern the anterior segments. However, many insects such as *Schistocerca* lack any form of prolonged syncitial stage and all segments are patterned within a cellular environment. Thus, the anterior maternal gradients acting in *Drosophila* and *Tribolium* are probably not universal among the insects.

It is now clear that extensive modifications have occurred in the segmentation system in different insect lineages, and these changes may reflect adaptive changes in the speed and patterns of oogenesis and early embryogenesis in different insect groups. Nevertheless, the picture that is emerging reveals that the early steps in the *Drosophila* segmentation hierarchy seem evolutionarily labile with more conservation in the later steps. It is clear that mysteries remain; early insect embryogenesis is remarkably varied, promising still undiscovered mechanisms for generating the segmented insect body plan.

### RELATIONSHIP TO SEGMENTATION IN OTHER ANIMAL PHYLAE

Insects, while obviously holding an extraordinary fascination, represent only a small part of segmented animal diversity; segmented body plans are also a hallmark of the body plans of annelids and chordates. Remarkably, many of the genes involved in insect segmentation and regionalization are evolutionarily ancient, and are found today in multiple phyla. In some cases, conservation is found also at the level of developmental function. In particular, the homeotic genes, which control segment identity, are conserved in both structure and function between flies and vertebrates. On the other hand, homologs of *Drosophila* segment polarity and pair-rule genes are also well conserved between flies and vertebrates, and usually these proteins still play similar biochemical roles, but in different developmental contexts. For example, the segment polarity gene *hedgehog* is used in many pattern formation steps in vertebrates, such as patterning the dorsal–ventral axis of the neural tube, but it has no known function in vertebrate segmentation.

Cell–cell signaling based on the Notch pathway is involved in vertebrate segmentation, and recently, work in spiders (a chelicerate) has shown that Notch pathway genes show patterned expression in the posterior of developing spider embryos, in a pattern reminiscent seen during vertebrate segmentation. Moreover, Notch signaling is required for spider segmentation and for proper *hairy* expression, again reminiscent of its role during vertebrate segmentation. However, there is so far no evidence for a role of Notch signaling during segmentation in *Drosophila* or any other insect. Thus, there is still considerable debate about the evolutionary origins of segmentation in arthropods, annelids, and vertebrates, with some believing that segmentation is homologous between these groups and other believing that segmentation has evolved independently in these different animal lineages.

### Sericulture

Satoshi Takeda

National Institute of Agrobiological Sciences

Ibaraki, Japan

Sericulture is an industry that is characterized by a two-step process, the cultivation of mulberry trees and the rearing of silkworms on mulberry leaves to produce cocoons. A cocoon is an oval- to football-shaped object made by a mature silkworm larva.
by spinning silk proteins; the silkworm larva develops into a pupa inside it. Silkworms are monophagous insects, feeding only on mulberry leaves (Moraceae, genus Morus). Because the mulberry leaves must be fresh, it is difficult to transport them over long distances or store them for long periods. This has resulted in the rearing of silkworms and cultivation of mulberry trees generally forming a single enterprise. Mulberry tree cultivation starts with the production of mulberry seedlings, followed by mulberry tree training, cultivation, harvesting, and insect pest control. Silkworm rearing includes preservation of silkworm eggs, management of rearing rooms, handling of rearing equipment, prevention of silkworm diseases, supplying mulberry leaves, and collecting mature larvae to transfer to the cocooning frame.

ORIGINS OF SERICULTURE

It is impossible to document when sericulture began. The silkworm, Bombyx mori, now has no wild populations; it is a completely domesticated insect. The oldest written record of sericulture is the Chinese silkworm book Ca-in-jing, which states that the queen of the Huang-Di empire started silkworm rearing. The Huang-Di era was around 2560 B.C., but sericulture must have been carried out in China in even earlier times. From China, sericulture spread via the “Silk Road.” In the East, it was introduced into the Korean Peninsula and from there to Japan in about the 3rd century B.C. In the West, it spread to Central Asia and India and from India to Persia. Sericulture is thought to have reached Europe in 550 A.D., when silkworm eggs were presented to the Roman Emperor of the East. Silk was an important trade item along the Silk Road, where it was exchanged for its weight in gold. Commerce in silk along the Silk Road also made a major contribution to the exchange of Eastern and Western culture.

THE WORLD’S SERICULTURE INDUSTRY: PAST AND PRESENT

The state of cocoon production worldwide in 1997 compared to 1930 indicates that total global cocoon production, 617,910 tons in 1930 and 620,000 tons in 1997, was almost the same; the cocoon-producing countries, however, have changed considerably. In 1930, Japan ranked first, with a yield of 382,850 tons, and accounted for 62% of global production. Japan and other cocoon-producing countries, such as China and Brazil, currently account for 96% of global production. In contrast, in 1997 China had by far the greatest production, 423,000 tons, with 68.2% of global production. India ranked second with 127,000 tons (20.5%), followed by Uzbekistan, Brazil, Thailand, Vietnam, and North Korea. Cocoon production in Japan, which accounted for 62% of world production in 1930, dropped precipitously after World War II and today is 2500 tons, a mere 0.4% of the world total. The dramatic fall in cocoon production in Japan was the result of soaring labor and production costs and low cocoon prices compared with other agricultural products. Although an aging population of sericulture workers and a shortage of replacements were factors, the primary cause of the decline in recent years has been the development of large differences in cocoon prices between Japan and other cocoon-producing countries, such as China and Brazil.

CURRENT STATUS OF SERICULTURE IN DIFFERENT PARTS OF THE WORLD

From the 1980s to the 1990s the sericulture industry became concentrated in Asia. Brazil is the sole country outside Asia in which export-quality cocoons are produced. Although sericulture thrived in Europe during the first half of the 20th century, particularly in Italy and France, only a very small scale production remains in Eastern European countries, such as Bulgaria and Romania. The current status of sericulture in the principal cocoon-producing countries is briefly described below.

In China, the provinces of Szechuan, Jiangsu/Chekiang, and Guangdong are the three great sericulture regions. Cocoons of the wild Chinese oak silkworm, Antheraea pernyi, add to the production of silk from B. mori. About 50,000 tons a year of wild silkworm cocoons are produced by outdoor rearing in mountains and forests, chiefly in the northeast.

Sericulture suited to each of its regions is carried out nationwide in India, the second largest cocoon-producing country in the world, in which production has increased sharply in recent years. In the north of India, temperate-region sericulture is conducted with bivoltine varieties of silkworm, and in the south it is being carried out with polyvoltine varieties or hybrids between polyvoltine and bivoltine varieties. Many species of wild silkworm, including the Tassar silkworm (Antheraea mylitta) and the Muga silkworm (Antheraea assamensis), are used for sericulture in the northern regions of India. However, sericulture of wild silkworm species remains a manual industry from rearing to reeling, not like that of B. mori.

In Southeast Asia, traditional sericulture industries in Thailand, Vietnam, and Laos use tropical polyvoltine varieties suitable for clothing. In central Asia, Uzbekistan is the major sericulture country ranking third among cocoon-producing countries. There, univoltine silkworm varieties are used, and sericulture is conducted as a sideline industry to cotton growing. The Brazilian silk-reeling industry was started by Italian immigrants, and introduction of technology by Japanese silk-reeling companies has enabled the production of high-quality raw silk thread and silk, and Brazil is now a raw silk thread and silk exporter on par with China. In Japan, cocoon production amounts to less than 1%; however, Japan consumes about 25% of global production, ranking second to China.

MANAGEMENT OF SILKWORM EGGS

Management of silkworm eggs is one of the most important sericultural techniques. In tropical regions where the mulberry leaves are available all year, the management of silkworm eggs is not particularly important. Polyvoltine strains used in the tropics hatch year round and can be reared anytime. However, because univoltine and bivoltine silkworms are usually reared in temperate and subtropical regions, larval hatch must be coordinated with the season when mulberry leaves are available. Once the univoltine silkworms are reared, the larvae generally do not hatch from the eggs until early spring of the next year. Such eggs are called “hibernating eggs.” Artificial hibernation activates larvae to hatch by incubating hibernating eggs at about 10°C. Hydrochloric acid treatment can be used to induce hatching on demand.

SILKWORM REARING

Rearing silkworms consists of a series of tasks that includes harvesting and transporting mulberry leaves, supplying the mulberry leaf, cleaning the rearing beds, mounting the larvae so they can spin cocoons, and collecting and shipping the cocoons. The goal of silkworm
rearing is to produce many high-quality cocoons while economizing on labor and material. The temperature range in which silkworms can be reared is 7–40°C, but practical rearing occurs in the 20–30°C range. Larval period rearing is roughly divided into the young silkworm period (first to third instar) and the grown silkworm period (fourth to fifth instar), and the fundamentals of rearing of each of them are different.

**Young Silkworm Period**

The growth rate is very high during the young silkworm period, especially during the first instar, but this period is characterized by higher susceptibility to bacterial pathogens and malnutrition. The young silkworm period is also physiologically characterized by a low quantity of food ingested, but a high rate of digestion. The amount of mulberry leaves ingested by young silkworms, that is, first to third instar, is only about 2% of the amount ingested during the entire larval period. The mulberry leaves provided in this period are finely minced.

The basic principles of young silkworm rearing are to provide relatively high temperatures and high humidity. A temperature range of 26–28°C is ideal, and as the instars proceed, temperature is gradually reduced. The ideal humidity is 75–90% and is lowered as the instars progress. In advanced sericulture countries, rearing of the young silkworms is generally carried out in cooperative rearing facilities.

**Grown Silkworm Period**

During the fourth instar silkworms ingest 10% of the total amount of mulberry leaves taken, and during the fifth instar they ingest approximately 88%. Because the fifth instar is the period when the silk proteins for cocoons are actively biosynthesized, an adequate supply of mulberry leaves must be provided. When silkworms are reared in temperate regions, at high temperatures of 30°C or more, disease or failure to spin silk can occur. When fifth instars are mature they start to spin. Silkworms discharge a great deal of fluid outside their bodies with the silk proteins, in addition to that from defecation and urination, during the cocoon production, or mounting, period.

**REARING ON AN ARTIFICIAL DIET**

In 1960, an artificial diet for silkworms was developed that could successfully sustain them from the first to the fifth instar (Fig. 1). The growth of the silkworms and the cocoon size obtained, however, were considerably inferior to those of silkworms reared on mulberry leaves and therefore this diet was inadequate for actual use in sericulture. Following many improvements the use of artificial diets during the young silkworm period has become widespread, and in 1990 the rate of young silkworm rearing on artificial diets in Japan exceeded 40%. Japan is the only country in which artificial diets are used for cooperative young silkworm rearing.

**Sex Determination**

Michael F. Antolin, Adam D. Henk
Colorado State University

Sex determination depends on molecular switches that signal whether the male or the female sex-differentiating pathway will be followed during development; it can be triggered by genetic, epigenetic, or environmental cues. Insects display sexual dimorphism, in which males and females differ in form, behavior, and/or physiology. Although sex determination and developmental pathways leading to two distinct sexes are universal within insects, the primary signals that trigger sex determination are highly diverse and differ between groups. The primary signal for sex determination can entail genetic signaling, epigenetic signaling via maternally expressed genes or genomic imprinting of genes, or cytoplasmic factors like B chromosomes and bacterial infections. The primary signals can act alone or in combination. Molecular genetic details of sex determination and sex differentiation are known mainly from *Drosophila*, and these are described below. Comparison of sex determination of insects, nematode worms, and mammals points to a similar genetic mechanism that underlies sex determination: a cascade of gene expression, with alternative splicing of key genes and intermediate genes, leading to alternative splicing of a double-switch gene that ultimately controls differentiation of males and females. In insects, it appears that key genes and intermediate genes early in the cascade are unique to each group of insects, but genetic pathways for controlling sex differentiation after the double switch appear to be the same in all insects. Overall, sex determination in insects is highly variable among groups, and in some groups the mechanisms of sex determination differ between populations of a single species (e.g., the house fly *Musca* and the midge *Chironomus*).

**SEX-DETERMINING SIGNALS**

Patterns of sex determination have been explored since chromosomes were first described in the late 1800s. By the early 1900s, it
Sex Determination

was discovered that many insects have distinct chromosomes in males and females; the work is best described in the comprehensive 1973 book by M. J. D. White, *Animal Cytology and Evolution*. A generality about sex-determining mechanisms is that they are tremendously variable among insect orders, although considerable variation also can be found within genera or even within species. Regardless, some broad categories of the primary signal for sex determination can be identified.

The most common pattern of chromosomal sex determination is for females to be the homogametic sex, with two copies of one sex chromosome (XX), whereas males are the heterogametic sex, with two different sex chromosomes (XY). Some insect groups (e.g., Lepidoptera, Trichoptera) have the opposite pattern, in which males are the homogametic sex (ZZ) and females are heterogametic (ZW). Y chromosomes are usually much smaller than X and do not successfully recombine with the X. Unlike mammals, few sex-determining genes are located on Y chromosomes. Thus, the Y chromosome has been lost entirely in numerous orders of insects, leading to a system in which females are XX but males are haploid for sex chromosomes (denoted XO). A molecular genetic mechanism interacting with chromosomal sex determination has been described in *Drosophila*, and it entails a “molecular counting” mechanism that assesses the ratio of X chromosomes to autosomes early in development. Thus, chromosomal sex determination may generally depend on this type of genic balance, but whether this mechanism is a general feature of insects or is unique to *Drosophila* is unknown.

Sex chromosomes vary greatly in number and size in insects. Translocations and duplications of sex chromosomes are common and fall into two general categories. First, in groups with XO males, small parts of the X chromosomes may be duplicated and form what are called “neo-Y” chromosomes. Second, entire X and Y chromosomes may be duplicated, so that some species have sexes that are homogametic or heterogametic, but contain multiple copies of the sex chromosomes. For instance, in the oriental rat flea, *Xenopsylla cheopis*, males are X_1X_2Y, whereas females are X_1X_1X_2X_2, although in other insect groups it is not uncommon for there to be up to five copies of the X chromosome. Multiple sex chromosomes like these would change the balance between sex chromosomes and autosomes and thus bring into doubt the generality of genetic balance as a sex-determining signal.

Many insects have no identifiable sex chromosomes, but still have specific genetic loci encoding genes that act as key sex-determining signals. A common pattern is to have a dominant sex-determining factor that specifies male development for individuals with an M/+ genotype, whereas females have a +/+ genotype. In this regard, M represents a key gene in a system similar to heterogametic sex determination, but lacking sex chromosomes that differ in size. House flies (*Musca domestica*) demonstrate further variations of the same theme, in which intermediate genes change the sexual phenotype. Another dominant genetic factor, F, interacts with rare M/M genotypes to produce females with an M/M F/+ genotype. Individuals with an M/M F/+ genotype develop as males. Finally, some house fly populations have epigenetic sex determination via a maternally expressed gene. Here, a gene found in females determines whether they will produce only female or only male progeny, regardless of the genotype of their male mates.

Haplodiploidy sex determination (sometimes called arrenotoky—the production of males) is found in all Hymenoptera and Thysanoptera and in some Homoptera and Coleoptera. It provides an interesting study of combinations of epigenetic and genetic sex determination. In haplodiploidy, females arise from fertilized eggs and therefore have the diploid complement of chromosomes, whereas males parthenogenetically develop from unfertilized eggs and are haploid. Recent evidence from the wasp *Nasonia* indicates that haplodiploidy can be explained by an epigenetic switch; genomic imprinting of sex-determining factors during oogenesis. Imprinting renders some female-determining genes inactive in eggs during development. If the genomic imprint is removed after fertilization, fertilized eggs develop as females. Unfertilized eggs would still have inactive female-determining genes and would become male. Haplodiploidy represents a case of a key sex-determining signal under epigenetic, rather than purely genetic, control.

Many Hymenoptera have an additional mechanism that overlays the epigenetic control of haplodiploidy: a single-locus genetic sex-determining system called complementary sex determination (CSD). CSD is found in sawflies, and in most apocritan groups (bees, ants, vespid wasps, ichneumonid wasps, braconid wasps), but not in the Parasitica. In this system, sex is determined by an individual’s genotype at a single genetic locus, and the locus is known to have a large number of complementary alleles. As in all haplodiploids, males arise from unfertilized eggs and are haploid. If an egg is fertilized, however, it will develop as a female only if egg and sperm carry two different (complementary) alleles of the sex-determining locus. Thus, CSD of females depends upon heterozygosity at the sex locus. If egg and sperm have the same allele, the resulting diploid individual is homozygous at the sex locus and develops as a diploid male. Diploid males in Hymenoptera are usually inviable or sterile, so that inbreeding in species with CSD has severe consequences. The genetic mechanism underlying CSD remains to be discovered.

Haplodiploidy (arrhenotoky) differs from the case of paternal genome loss in some Homoptera (scale insects) that have haploid males. Under paternal genome loss, both males and females arise from fertilized eggs. However, eggs that lose the paternal complement of chromosomes early in development become male and are haploid.

Sex determination in insects also can be influenced by factors passed vertically through an egg’s cytoplasm. The most common appear to be by infection with the bacterium *Wolbachia*, an intracellular parasite that is widespread in arthropods. In many cases, *Wolbachia* infections selectively kill one sex early in development and skew sex ratios. *Wolbachia* also induce unisexual parthenogenesis (theletoky) in some Hymenoptera. One case of sex determination being modified by *Wolbachia* is known from insects, that of the Asian corn borer *Ostrinia furnacula*. Supernumerary chromosomes also can be passed via the cytoplasm. In the wasp *Nasonia vitripennis*, a B chromosome called paternal sex ratio (*psr*) causes condensation of chromosomes shortly after fertilization of eggs. Eggs fertilized by *psr* sperm develop as haploid males rather than as females, and subsequently these males continue to transmit the *psr* B chromosome to future generations.

Environmental cues affect sex determination, especially in reptiles and fish, although few cases are currently known from insects. A temperature-sensitive allele of the intermediate sex-determining gene *transformer* (see below) has been described in *Drosophila*, in which high temperature leads to development of males.

**GENE CASCADES IN SEX-DETERMINING PATHWAYS**

Despite the variety of sex-determining mechanisms described above, they have in common that both sex determination and sex differentiation ultimately depend on a hierarchical cascade of gene
expression during development, with numerous switches in pathways that eventually lead to somatic sexual differentiation and germ-line differentiation. Here we describe the hierarchy as it is known from the careful work done on Drosophila. The sex-determining “trigger” for male development (XY) is an imbalance between genes on the X chromosome and one of the autosomes (X:A for male development (XY) is an imbalance between genes on the X chromosome and one of the autosomes (X:A for male development (XY)).

A molecular counting mechanism controls early transcription of sex lethal (Sxl), the key gene in the sex-determining cascade in Drosophila that controls sex determination and dosage compensation. Intermediate genes, especially transformer (tra), interact with one another to control expression of the double-switch gene doublesex (dsx). This pathway controls somatic sexual differentiation of male and female morphology and behavior, in addition to germ-line differentiation leading to mature ovaries and testes.

In brief, the cascades work as follows (Fig. 1). In females (X:A = 1.0), the molecular counting mechanism activates the early transcription of Sxl mRNA. SXL protein produced by this mRNA regulates splicing of subsequent Sxl mRNAs to produce the active female-specific form of SXL (f) protein. Active SXL (f) protein regulates splicing of tra mRNA to produce female-specific TRA (f) protein. In turn, TRA (f) protein interacts with other proteins (not shown) to regulate the splicing of dsx mRNA, generating the DSX (f) form. DSX (f) protein negatively regulates the genes responsible for male somatic sexual differentiation, but allows genes responsible for somatic sexual differentiation to produce a morphologically female fly.

In male Drosophila (X:A = 0.5), the molecular counting mechanism prevents transcription of the Sxl gene early in development. In the next step, the absence of SXL protein results in unspliced Sxl (m) mRNA. This form includes an exon with stop codons embedded in its sequence, so that Sxl (m) transcripts make no functional protein. In turn, transcripts of the tra gene also are not spliced, again resulting in nonfunctional protein because of internal stop codons. Without TRA protein, there is no alternative splicing of dsx, and DSX (m) protein is made. This pathway is the default, because of the absence of functional proteins from key and intermediate genes early in the pathway. Without these proteins, transcription of the double-switch gene dsx results in male-specific DSX (m) protein. DSX (m) negatively regulates the genes responsible for female somatic sexual differentiation, but allows genes responsible for somatic sexual differentiation to produce a morphologically male fly.

Because male and female Drosophila have different numbers of X chromosomes (males have one X and females have two), a mechanism is required to compensate for the difference in the number of genes present in the two genotypes. This mechanism is known as dosage compensation. In male Drosophila, a group of genes collectively known as male-specific lethal (msl) genes are active and increase transcription/translation of genes on the single X chromosome. Thus, genes on the single X chromosome in males generate approximately twice the gene products, which are approximately equal to those from genes on the two X chromosomes in the female fly. In female Drosophila the SXL (f) protein prevents msl genes from acting, and there is no subsequent increase in transcription and translation of genes on the X chromosome in females.

A fairly large number of genes also control germ-line sex differentiation and the production of egg and sperm. The regulation of the genes responsible for germ-line sex differentiation is poorly understood. Although different forms of DSX protein appear to affect the morphology of the sex cells in Drosophila, which gene products comprise the “switch” that determines the fate of germ cells as either egg or sperm remain to be identified.

Insects other than Drosophila do not use exactly the same genetic pathways for sex determination. Not only are sex-determining triggers different, but for many insects that have been studied some or all of the genes described above either do not exist at all or do not perform the same function. In addition to Drosophila, the gene Sxl has been isolated from four other Diptera (the fruit fly Bactrocera, Mediterranean fruit fly Ceratitis, phorid fly Megaselia, house fly Musca), but in none of these does SXL protein differ between males and females. Thus Sxl is not involved in sex determination in these insects, and since no homolog of tra has been found in any other insects outside of Drosophila, it is unlikely that the same genetic pathway for sex determination exists in other insects. On the other hand, the gene dsx appears to be conserved in structure and function in Bactrocera, Ceratitis, Megaselia, and the silkworm Bombyx mori (Lepidoptera). Apparent homologs of dsx can also be found in the nematode Caenorhabditis (nab-3) and in mammals (DMT1), and in each they have sex-specific functions in somatic sexual differentiation and/or germ-line differentiation. The control of sex determination is highly variable in insects, but control of sex differentiation leading to somatic sexual differentiation and germ-line differentiation in males and females appears to be conserved, with the possibility that genes within pathways of sex differentiation of all metazoans have common origins.

**FIGURE 1** A simplified diagram of heterogamic (XXXY) sex determination in D. melanogaster, showing the main genes and proteins contributing to the cascade of gene expression leading to development of males and females. This is the best understood and most fully explored genetic system of sex determination in insects, but is probably unique to D. melanogaster and closely related species. Names of genes are in lowercase italics; names of proteins are in uppercase.

HISTORICAL PERSPECTIVES

Sexual Selection

Kenneth Y. Kaneshiro

University of Hawaii

Sexual selection depends on the success of certain individuals over others of the same sex, in relation to the propagation of the species; while natural selection depends on the success of both sexes, at all ages, in relation to the general conditions of life. Sexual selection is a struggle between individuals of one sex, generally the males, for the possession of the other sex. The result is not death to the unsuccessful competitor, but few or no offspring. — Charles Darwin (1859)

THEORETICAL CONSIDERATIONS

Anisogamy and Parental Investment

The evolutionary origins of differences between the male and female sexes lie in what is referred to as anisogamy, which is the difference in gamete size between the two sexes. Females generally produce a few but large gametes, whereas males produce large numbers of much smaller gametes. Furthermore, such sex bias in gamete size is also characteristic of the initial stages of the evolutionary differences in parental investment, because the production of large gametes requires greater energetic investment by the female than the smaller male gametes. In most species, the male’s investment ends with fertilization, while that of females may continue throughout the developmental period of the zygote, embryo, and other immature stages of the organism. Consequently, the limited number of gametes and the greater parental investment of the females result in an asymmetry in the degree of sexual selection between the two sexes. One might expect females to be generally less sexually selected but more selective in their choice of males (but see later), with males being under stronger sexual selection, hence attempting to mate with as many females as possible. It is thought that the males with the best territories, the most elaborate structures, the most attractive displays (i.e., secondary sexual traits), and so on will mate more frequently and therefore will leave more offspring. In terms of “investment” then, since it costs females much more to produce fewer large gametes than it does males, which produce lots of small gametes, females must “choose” mates that will produce the highest quality offspring (genetically).

Competition for Mates

It has been suggested that Darwin’s concept of sexual selection may be subdivided into two aspects: “intrasexual selection,” which involves competition between members of the same sex for individuals of the opposite sex, and “epigamic selection,” which is the preferential choice of mates by one sex relative to the other. Intrasexual selection is most evident in males and perhaps can be best illustrated in species that display lek mating behavior. In such species, males compete among themselves for territories to which receptive females are attracted (i.e., the territories do not provide other resources such as food or egg-laying substrates). In some species, a dominance hierarchy is established among the males that may be participants in a lek system and as a rule, the males able to occupy and defend the “best” territories will have access to most of the females that arrive at the lek. Epigamic selection, which is also referred to as “intersexual selection,” is primarily an attribute of females, since the female sex ultimately discriminates among males and exercises choice of mating partners. Curiously, in most lek species, even though the most dominant males are successful in defending what seem to be the best territories in the lek system (as evidenced by the number of females that arrive at the territories of such males), males nevertheless perform an elaborate courtship ritual before mating occurs. Sometimes a female indeed rejects a dominant male’s courtship and mating attempts, moves to an adjacent territory, and eventually mates with a subordinate male. Such occurrences illustrate that although fierce intrasexual selection among males can occur in competition for mating territories, epigamic selection based on female choice is the...
ultimate determinant of mating success among males, and thus intra-sexual selection is not necessarily linked or correlated with epigamic selection. That is, a dominant male that is able to occupy and defend a prime mating territory, must, nevertheless perform courtship displays, which may or may not be acceptable to receptive females.

Runaway Sexual Selection Model

Darwin himself recognized a serious gap in his ideas of sexual selection and stated: “Our difficulty in regard to sexual selection lies in understanding how it is that the males which conquer other males, or those which prove the most attractive to the females, leave a greater number of offspring to inherit their superiority than their beaten and less attractive rivals. Unless this result does follow, the characters which give to certain males an advantage over others could not be perfected and augmented through sexual selection.” Critics ridiculed Darwin’s ideas and sarcastically implied that Darwin would not be able to prove his theory.

The oftentimes sarcastic attacks against Darwin’s sexual selection theory challenged theoreticians to develop alternative hypotheses for the evolution of female preference for, and the evolution of, secondary sexual traits in males. The most notable of these hypotheses is the “runaway selection” model, according to which it was inferred that the evolution of a sexually dimorphic character in males could result in a correlated response in the female’s preference for that character. The model predicted that female choice and male characteristics influenced by sexual selection would coevolve very rapidly in an interbreeding population. The runaway selection model presumed that two forces act to counterbalance the runaway process of sexual selection. That is, female preference for a certain male character, whether morphological or behavioral, tends to select for extreme forms of that character until natural selection exerts its forces to maintain the optimum male phenotype that is best able to survive in its particular environment. In an article published in 1972, Ernst Mayr stated that “natural selection will surely come into play as soon as sexual selection leads to the production of excesses that significantly lower the fitness of the species.”

The paradox of the runaway sexual selection model is that the opposing forces of sexual selection for elaboration of conspicuous male traits and natural selection, which maintains the optimum condition for the particular environment, result in reduced genetic variation for such male characters (Fig. 1). However, without genetic variation, selection can no longer occur; and unless secondary sexual characters either are linked to or are pleiotropic effects of other components of fitness, such conspicuous characters would be energetically costly to produce, and individuals possessing such traits would be in greater danger of predation.

The Differential Selection Model

In 1989, in an attempt to provide an alternative explanation for the maintenance of secondary sexual characters observed in males, Kaneshiro proposed a model based on his research on the mating behavior of Hawaiian Drosophila species. He suggested that there is a range of male mating types segregating within an interbreeding population. That is, some males in the population are highly successful in mating and often accomplish the majority of the matings in the population. Other males are less successful and in fact may not mate at all, despite being given the opportunity to do so with several receptive females. Similarly, among females, there are those that exhibit higher levels of mating receptivity thresholds and strongly discriminate against most of the males in the population. In the same population, there are also females that exhibit lower receptivity thresholds and seem to accept the courtship overtures of most of the males in the population.

Observations of mating experiments of Hawaiian Drosophila both in the laboratory and in the field indicate that the most likely matings are between males that are most successful in satisfying the courtship requirements of females and females that are not extremely choosy in selecting mating partners. The genetic correlation between these two behavioral phenotypes in the two sexes (i.e., highly successful males and less choosy females) generates the entire range of mating types in both sexes in subsequent generations (Fig. 2). In this model then, there is differential selection for opposite ends of the mating distributions in the two sexes and therefore, sexual selection itself serves as the stabilizing force in maintaining a balanced polymorphism in the mating system of the population. Hence, it is not necessary to invoke the forces of natural selection to counterbalance the elaboration of secondary sexual characters as required in the runaway sexual selection model.
SEXUAL SELECTION IN INSECTS

Different patterns of sexual selection that have been observed can be illustrated by descriptions of sexual selection in a few insect species. This is certainly not a comprehensive review, since space constraints allow only a very few examples to be discussed. Several books present a more in-depth discussion of sexual selection systems in insects, and the reader is referred to such treatments.

Lek Behavior in Hawaiian Drosophila and Other Dipteran Species

In an article published in 1997, Shelly and Whittier list the following criteria in defining a lek species: (1) the absence of male parental care, with males contributing nothing but gametes to the female; (2) the existence of a mating arena in which most matings occur; (3) male territories that contain no resources vital to females; and (4) the opportunity for females to freely select a mate in the arena.

These authors also recognize two types of male mating aggregations involved in lek mating species: substrate-based, where males spend most of the time perched at stations or territories to which females are attracted for mating (although mating may occur in the air), and aerial aggregations or swarms, in which males are usually in continuous flight and matings are typically initiated in the air.

In the mating system of the Hawaiian Drosophilidae, males take up station either on the underside of leaves, one male to a leaf, or on branches of understory shrubs. Resident males aggressively defend territories from intruding males with fierce battles (Fig. 3), which in some species resemble sumo wrestling bouts. In the lek mating system of the Mediterranean fruit fly, Ceratitis capitata (Diptera: Tephritidae), males occupy and aggressively defend the underside of leaves of host plants as mating territories to which females are attracted solely for the purpose of mating. Once a female has arrived at the mating arena, the males of both the Mediterranean fruit fly and the drosophilids display complex courtship behaviors, which may or may not result in acceptance by the female. This means that successful aggressive behavior is not necessarily linked to or correlated with successful mating behavior. That is, a male that is successful in occupying and defending prime mating territories still must perform a courtship sequence that is acceptable by the females to ensure mating success. In some cases, the alpha male (i.e., the male that is most successful in defending a prime mating territory) is not successful in mating despite numerous visits by receptive females.

FIGURE 2  Differential sexual selection model, which shows that matings between less choosy females and successful males generate the entire range of mating types in each successive generation.

FIGURE 3  Males of the native Hawaiian Drosophila, D. heteroneura, in head-to-head, wingtip-to-wingtip posture, defending a territory to which females are attracted solely for the purpose of mating. The “hammerhead” shape of the males appears to be a result of sexual selection for this behavioral display among males in a lek mating system.

FIGURE 4  Courtship display of a native Hawaiian Drosophila, D. clavisetae. While in a “scorpion-like” posture, the male produces a pheromone bubble and wafts (a row of apically flattened bristles near the terminal end of the abdomen serves as a “fan”) the chemical stimulant toward the female by vibrating his abdomen in an up-and-down motion toward the female. The courtship “dance” also involves visual cues (striking white face and wing markings are sexually dimorphic characters), tactile cues (female “kisses” the extended proboscis of the male), as well as acoustical cues. Despite the complex courtship displays and considerable effort on the part of the male, sexual selection via female choice (i.e., epigamic selection) plays a powerful role in determining mating success.

Thus, at least for the drosophilids and tephritid fruit flies, although success in intrasexual selection among males may mean increased opportunity to encounter receptive females, the ultimate criterion for successful mating is epigamic selection based on female choice (Fig. 4).

Resource-Based Sexual Selection in the Scorpionfly

The mating system of the scorpion fly, Hylobittacus apicalis (Mecoptera: Bittacidae), provides another excellent example of intrasexual and epigamic sexual selection. Here intrasexual selection is

The courtship “dance” also involves visual cues (striking white face and wing markings are sexually dimorphic characters), tactile cues (female “kisses” the extended proboscis of the male), as well as acoustical cues. Despite the complex courtship displays and considerable effort on the part of the male, sexual selection via female choice (i.e., epigamic selection) plays a powerful role in determining mating success.

Thus, at least for the drosophilids and tephritid fruit flies, although success in intrasexual selection among males may mean increased opportunity to encounter receptive females, the ultimate criterion for successful mating is epigamic selection based on female choice (Fig. 4).

Resource-Based Sexual Selection in the Scorpionfly

The mating system of the scorpion fly, Hylobittacus apicalis (Mecoptera: Bittacidae), provides another excellent example of intrasexual and epigamic sexual selection. Here intrasexual selection is
evidenced by the competition among males for arthropod prey, which are offered to females as nuptial gifts. Males that are able to acquire such resources will have greater access to receptive females. It has also been shown that the size of the nuptial prey plays an important role in epigamic selection. Females apparently have the ability to evaluate the males based on the size of the nuptial gift, on which they feed during copulation. Females prefer males with a large prey versus males that offer smaller prey. Such preference results in an increased number of eggs oviposited as well as the survivorship of the female. Essentially, size of prey is correlated with the length of the copulation. It was shown that at least 5 min of mating is required before any sperm is transferred to the female and that copulation duration ranging between 5 and 20 min is directly correlated with the number of sperm transferred. Thus, when a male offers and the female accepts a large nuptial gift, the male is provided an opportunity to transfer a complete quantity of sperm. In some cases, if the prey is large enough, the males may end the mating with the first female to be able to use the prey as a gift for a second female. Furthermore, a male that mates for 20 min or longer introduces a substance into the female’s reproductive tract that renders the female sexually nonreceptive and stimulates oviposition. Females that mate for less than 20 min because of small prey size will continue to seek males with larger prey.

Thus, *H. apicalis* females may either reject males with small prey or mate with them for only a brief period, feeding on the prey but receiving few or no sperm. Females may then seek males that can offer larger prey, which will increase the likelihood of a sperm transfer adequate to fertilize her full complement of eggs. Such female preference for males that can offer larger, nutrient-rich prey, which influences the number of offspring produced, has clearly shaped the evolution of male behavioral components in this species. Since insect prey is a limited resource, as evidenced by the small number of males (~2-0%) that are carrying prey at any one moment, there is competition among males in securing prey. Males that are successful in securing a gift are not guaranteed to reproduce, since females discriminate against prey-bearing males that offer small prey. On the other hand, males that are able to secure sufficiently large prey may be able to mate with more than one female.

Female choice for prey-bearing males has apparently resulted in the evolution of other male behaviors. For example, it has been shown that males foraging for prey are more prone to predation and that males are 2.3 times more likely to be trapped in spider webs than females. Because hunting for prey can be hazardous, *H. apicalis* males can employ an alternative tactic of securing prey, namely, thievery. Some males fly to calling males and mimic female behavior—for example, perching next to a prey-bearing male and waiting for the gift to be presented, as if to a real female. If the ruse works, the thief will snatch the prey and use it to attract and feed a female without having to spend energy in a risky search of prey of his own. Thus, it would seem that sexual selection has played an important role not only in the evolution of nuptial gift giving in males but also in the development of female-mimicking behavior and prey stealing as an alternative strategy to minimize predation pressure.

THE ROLE OF SEXUAL SELECTION IN SPECIATION

Two decades ago, Mayr remarked: “Speciation...now appears as the key problem of evolution. It is remarkable how many problems of evolution cannot be fully understood until speciation is understood...” Over the past 20 years, there has been renewed interest in the process of speciation, initially to address arguments advanced by the proponents of the punctuated equilibrium model of macroevolution but also to revisit the definition of a species. At least two books address questions of speciation and the evolutionary processes of species as population units of biological diversity. It is not the intent of this chapter to discuss the various models of speciation. *Speciation and Its Consequences* edited by Otte and Endler, published in 1989, and *Speciation and the Recognition Concept* edited by Lanbert and Spencer, published in 1995, offer comprehensive reviews of this topic.

In 1997 Hampton Carson suggested that when demographic circumstances force populations to pass through a size bottleneck, the sexual selection system is temporarily disorganized by genetic recombination and the consequences of small population effects. As the population builds back up to restore efficient mate choice, novel genetic recombinants may be generated that in turn may lead to “novel selective change over a relatively small number of generations...” and that “the new population may thus be driven to undergo progressive genetic change under sexual selection.”

Based on results of mating experiments on Hawaiian *Drosophila* species, Kaneshiro formulated a hypothesis, that may provide an intuitive explanation for what Carson referred to as the “driver of genetic change.” Kaneshiro suggested that under conditions of drastic population reduction, there is even stronger selection for less choosy females in the population, since highly discriminant females may never encounter males that are able to satisfy their courtship requirements. If the bottleneck condition persists over a few generations, there will be a shift in the distribution of mating types in the population until a significant increase in frequency of less choosy females in the population has occurred (Fig. 5). Such a shift in the distribution of mating types may be accompanied by a corresponding shift in the gene frequencies in the population, resulting in the destabilization of the coadapted genetic systems that had evolved in the population. The resulting destabilized genetic environment thus sets the stage for genetic changes conducive to the speciation process. That is, the breakup of coadapted sets of genes allows the generation of novel genetic recombinants, some of which may be better adapted to the environmental conditions that led to population reduction. Thus, the dynamics of the sexual selection system can play an extremely important role in the speciation process as well as in the maintenance of genetic variability in the population on which the forces of natural selection can operate.

In the evolution of island biota such as that of the Hawaiian Islands, the most likely mode of speciation is what evolutionary biologists call founder event speciation. For insect groups such as the Hawaiian Drosophilidae, the most probable scenario is that a single

![Sexual selection](image-url)
fertilized female may be blown to an adjacent island, there to establish a new colony. For a number of generations, during the initial stages of colonization when the population size is small, there would be strong selection for females that are less choosy in selecting mates, once again, because females that are too choosy may never encounter males able to satisfy their courtship requirements. Therefore, within a few generations, there would be a shift in the distribution of mating types toward an increased frequency of less choosy females, resulting in a significant shift in gene frequencies followed by a destabilization of the coadapted genetic system. Genetic recombinants better adapted to the new habitat may be generated and strongly selected, especially if these genotypes are linked or correlated with the genotypes of the less choosy females. Thus, at least during the initial stages of colonization immediately following the founder event, the dynamics of sexual selection may play a significant role in generating a genetic environment in the population that is conducive to the formation of new species.

THE ROLE OF SEXUAL SELECTION AND NATURAL HYBRIDIZATION

It has been suggested that the dynamics of the sexual selection process also provides the opportunity for occasional natural hybridization and permits the “leakage” of small amounts of genetic material from a related species without destroying the integrity of the separate gene pools. When the population is small and there is a shift in the distribution of mating types toward an increase in frequency of less choosy females, such females in the population may occasionally accept males of a related species, which may be less susceptible to the environmental stress conditions. Genes that may be resistant to the conditions responsible for reducing the population size may be strongly selected, especially if such genes are linked to the genotypes of the less choosy females. Therefore, natural hybridization as permitted by the sexual selection process may do more than play an important role in replenishing genetic variability that may be lost owing to drift when population size is small; it may also provide a process by which resistant genes are transmitted between populations.

CONCLUDING REMARKS

The differential sexual selection model discussed here and its role in the processes of speciation may provide a possible explanation of how genetic variability may be not only maintained but actually enhanced. The generation of novel genetic recombinants and the selection for genotypes that are better adapted to changing environmental conditions are enhanced by the sexual selection system in the population, especially when subjected to population bottlenecks. It is suggested that sexual selection is a dynamic process, influenced by density-dependent factors, that enables populations to overcome environmental conditions that result in drastic reduction in population size. Shifts in the distribution of mating types when population sizes are small can generate a genetic environment producing novel recombinants able to respond to the environmental stress imposed on the population. Sexual selection influences the levels of genetic variability generated via novel genetic recombinants resulting from a reorganization of the genome, and via natural hybridization that is permitted by the sexual selection model. Thus, the biology of small populations and the dynamics of the sexual selection process are important aspects of evolutionary biology and the biology of insect populations in general. A better understanding of the role of sexual selection would provide important insights into the mechanisms of species formation as well as enabling us to develop more effective management programs, not only for pest populations but also for the conservation of rare and endangered insects.

detail. The silks of a dozen lepidopteran species are used commercially for the production of fabrics and to a small extent in the cosmetics and medicine.

THE MULTIPLE EVOLUTIONARY PATHWAYS OF SILK PRODUCTION IN INSECTS

Phylogenetic comparison of the silk producing hexapods suggests that silk production evolved multiple times, often only in larvae or adults, rarely in both stages (Figs. 1 and 2). In the apterygote hexapods, silk is used to aid the sperm transfer to females and some adults use silk to protect their eggs. Silk production is rare in the hemimetabolous clades, and common in Holometabola, in which it is most often used to protect the pupa. All known silk glands are of ectodermal cell lineage but specialized dermal glands, which are common in spiders, are found rarely in the insects. Insect silks are typically produced by modified parts of the digestive, excretory, and reproductive systems, respectively. In a number of cases the source of silk has not been identified with certainty.

Dermal glands dedicated to silk production evolved in the frontal tarsi of Embiidina which spend most of their lives in silky tunnels. Tarsal glands function both in the larvae and adults, particularly in the females, which employ silk to protect their eggs and young. Similar tarsal glands occur also in adult males of the Hilarinae fly family; silk is used to package prey given to the female during courting. Dermal glands also seem to occur in the cerci of adult Archaeognatha and Thysanura. The abdominal silk glands of Protura and possibly also Diplura may represent a kind of dermal glands.

The secretions of modified salivary glands, and some of the anal excretions, represent silks derived from the digestive system. Some larval and adult Gryllacridoidea (Orthoptera) produce silk in labial glands and use it to “glue” leaves, stones, and soils into protective covers of ground burrows. Silk production in the labial glands occurs in the large larvae and especially in the adults of Psocoptera and in the larvae of Hymenoptera, Trichoptera, Lepidoptera, Siphonaptera, and several families of nematocerous Diptera. The families of all these orders differ in the extent of silk production. For example, among the Psocoptera, the Psocidae cover their eggs with silks, the Elipsocidae and Philotarsidae spin webs singly or gregariously in small groups, and the Archipsocidae spin extensive webs covering trunks and branches of large trees.

Cocoon spinning at the end of larval development is the most common silk use in the Holometabola. The larvae of some Trichoptera employ silk to construct protective cases (they also occur in a few lepidopteran families) or nets for catching prey (Fig. 3), and some caterpillars spin large webs in which they hide (Fig. 4). The larvae of water midges (Chironomidae) live in individual silk tubes. Larvae of the nematoceran family Mycetophilidae catch prey with the aid of sticky silk threads. Larvae of several beetle families construct cocoons from anal excretions that are referred to as peritrophic membrane but they could represent proctodeal cuticle. Proctodeal epithelium was showed to be the source protein glues added to the surface of silk fibers produced in the Malpighian tubules in larval Neuroptera. The glue-like or silk-like anal excretions in adult Thysanoptera may also be derived from the proctodeum.

**FIGURE 1** Phylogenetic analysis of silk production by hexapod larvae. The most prolific silk producers, such as Embiidina, Psocoptera, and several orders of Holometabola, have evolved dedicated silk glands. (Reprinted, with permission from the Annual Review of Entomology, Vol. 42, © 1997, by Annual Reviews, www.annualreviews.org.)

**FIGURE 2** Silk production by hexapod adults is less common than among larvae. Most frequently, adult insects produce fibrous proteins in colleterial glands. (Reprinted, with permission, from the Annual Review of Entomology, Vol. 42, © 1997, by Annual Reviews, http://www.annualreviews.org.)

**FIGURE 3** Catching net of the caddisfly *Hydropsyche angustipennis*. The larva hides in a tube that opens at the edge of the net (upper right corner of the picture).
Silk production in the Malpighian tubules of larvae evolved in a few Ephemeroptera and Coleoptera, and is apparently plesiomorphic in Neuroptera. The rare silk of mayfly larvae is probably used as walking substrate, whereas in the coleopteran and neuropteran larvae it is used to construct cocoons. Larvae of the phylogenetically primitive neuropteroid taxa, Megaloptera and Raphidioidea, are also said to produce silks in Malpighian tubules, and the larvae of some Hymenoptera, for example of the stingless bee *Plebeia droryana* and the bumble bee *Bombus atratus*, bind silk fibers derived from the labial glands into the cocoon wall with the Malpighian tubule secretions.

At least five taxa of adult insects produce silks in the colletorial glands of the reproductive system. The males of Thysanura (the bristletails) produce protein secretions in the accessory glands and release it through a specialized spinning organ. Female mantids (Mantoidea) produce silk in the colletorial glands to protect their eggs, as do beetles in the family Hydrophilidae and the lacewings (Neuroptera). Neuroptera lay their eggs on silk stalks thereby protecting them from predatory mites and bugs crawling on the leaf surface.

**THE COMPOSITION OF SILK**

Labial silk glands of all holometabolous larvae are composed of a relatively small number of highly polyploid cells. The glands of caterpillars are differentiated into a posterior, middle, and anterior sections. The posterior section secretes a “heavy chain” fibroin (>200 kDa) that is in most species associated with two auxiliary proteins (25–31 kDa) called “light chain” fibroin and P25. The heavy chain fibroin is composed of species-specific repetitive regions that are built of simple motifs. The repeated regions, in part, determine the molecular conformation of fibroin, hence the mode of fiber formation. Stacked β-pleated sheets were detected in the preparations of different silks and are often regarded as the standard conformation of lepidopteran fibroin. However, X-ray crystallography and alternative fibroin sequences indicate more complex protein configurations in the silk of some species.

A highly concentrated protein gel produced in the posterior section is pushed into the middle silk gland section where it is enveloped by the sericin proteins. Sericin secretion occurs along the middle section according to a precise spatial and temporal pattern that determines which sericins are adjacent to the fibroin column and which are exterior. The shearing forces and dehydration of the silk dope during its passage through the anterior silk gland section cause fibroin solidification into a filament. Two filaments, one from the left and one from the right labial gland, are aligned and sealed together into a fiber by inner sericins when they pass through the common spinneret. Outer sericins remain sticky for some time after leaving the spinneret and glue consecutive fiber layers into the cocoon wall.

The term “fibroin” has been adopted for any thread-like silk protein but true silk gene homology with Lepidoptera probably applies only to their sister order Trichoptera. The silk of caddisflies contains heavy chain fibroin, light chain fibroin, sericin-like proteins, and additional, cysteine-rich proteins not found in the lepidopteran silk. The nature of repeat sequences in the fibroins of Trichoptera is distinct from the silks produced by the Lepidoptera.

The silks produced by the water mites (Chironomidae: Diptera) contain more than 15 mutually homologous proteins that fall into three size categories (from <100 to about 1000 kDa). They consist of repeats that seem unrelated to any lepidopteran silk. The composition of silk produced by fleas (Siphonaptera) is apparently unique by having high content of the glutamic acid and α-helical conformation. The few silk proteins identified in Hymenoptera are also unrelated to those of Lepidoptera. The sawflies spin silks based on the β-sheets, collagen-like proteins, or on the polyglycine II proteins, and the silks of analyzed Apocrita are either β-sheet structured or α-helical coiled coil.

The sequence, configuration, and composition of silks derived from glands other than the labial glands have been very less investigated. The only unifying feature of the silks from different insect orders is the repetitive nature of the major protein(s). Convergent evolution driven by the need of certain physical silk properties, minimal energy investment, and the scarcity of the essential amino acid yields repeated sequences rich in glycine, alanine, and serine. Similar conformations of the silk proteins are also products of convergent evolution. For example, silk derived from the larval Malpighian tubules in the beetle *Hypera postica* appears as a loosely fabricated networks of coarse brown fibers composed of proteins in cross-β conformation. Colletorial gland silks were also reported to have either a cross-β or α-helical configuration. All of the parallel-β silks are pulled (spun), in contrast to the α-helical and cross-β silks, which are deposited, secreted, or ejected. Silks produced in aerial environment apparently polymerize into fiber by weak molecular interactions but silk polymerization and stability under water in the larvae of caddisflies and chironomids may rest on the covalent bonds in the disulfide bridges.

**HUMAN USES OF SILKS**

Practical utilization of silk was discovered in China about 2700 years B.C. The domesticated silkworm, *Bombus mori*, and a few wild-living lepidopterans (mostly from the family Saturniidae) provide cocoons suitable for harvesting of silk fiber. To produce yarns, the cocoons are soaked or boiled in slightly alkaline water for several minutes to a few hours. The outer sericin layer is dissolved and the loosened fiber is pulled out and aligned (“spun”) with several other fibers into a thread that can be used to produce textiles. The sericulture industry declined with the invention of nylon and other synthetic fibers. Nevertheless, natural silk remains a source of materials for luxury textiles, cosmetics, food additives and in multiple medical treatments.
Siphonaptera

(Fleas)

Michael W. Hastriter, Michael F. Whiting
Brigham Young University

The Siphonaptera are laterally compressed, wingless, holometabolous insects. The order contains approximately 2575 species. All species are parasitic in the adult stage and possess mouthparts modified for piercing and sucking, highly modified combs and setae on their body and legs, and legs that are modified for jumping. Some species are vectors of disease, and current research is providing important insights into flea phylogeny and evolution. Krasnov (2008) has compiled a discourse on the functional ecology of fleas, and the authors would suggest that this reference is the most exhaustive ecological treatment of Siphonaptera to date.

EARLY RESEARCH ON FLEAS

Fewer than 100 species of fleas had been described prior to the end of the 19th century. In 1898, it was demonstrated that fleas were capable of transmitting plague organisms and, later, murine typhus, which stimulated a frenzy of flea studies. In the early 20th century, A. C. Oudemans, Julius Wagner, Nathan C. Rothschild, and Karl Jordan made major contributions. Karl Jordan is recognized as “the father of flea systematics.” From 1953 to 1971, G. H. E. Hopkins and M. Rothschild published a comprehensive five-volume series on flea systematics, and three additional companion volumes were published for the remaining families by Mardon in 1981; Traub, Rothschild, and Haddow in 1983; and Smit in 1987. Robert Traub described 153 flea taxa and provided critical insights into flea phylogeny, convergent evolution, and zoogeography. Today, there are only a few flea specialists with knowledge of the global flea fauna.

Fossil Record

Fossils of fleas are extremely rare. Three extinct species (Palaeopsylla baltica, Palaeopsylla dissimilis, Palaeopsylla klebsiana) have been reported from Baltic amber, and a single specimen (Pulex larinaecus) has been reported from Dominican amber. The former three species belong to an extant Palaeartic genus, whereas the latter belongs to an extant genus in which five species are confined to the Nearctic and Neotropical regions, and a sixth is cosmopolitan (Pulex irritans). Several other extinct fossil specimens representing the South American family Rhopalopsyllidae exist, but have never been adequately studied and published.

Zoogeography

Current distribution of flea families suggests an ancient origin, possibly in the Jurassic period (~140 mya). In general, families endemic to the boreal continents (North America, Europe, Asia) are predominantly Ceratophyllidae, Hystrichopsyllidae, Leptopsyllidae, Venipsyllidae (Holoarctic), Coptopsyllidae (Palaeartic), and Anistropsyllidae (Oriental), whereas families endemic to the southern continents (Australia, South America, Africa, Antarctica) include Malacopsyllidae and Rhopalopsyllidae (Neotropical), Stephanocircidae, Pygiopsyllidae, Stivaliidae, and Lycopsyllidae (Australian and Neotropical), and Xiphopsyllidae and Chimaeropsyllidae (Afrotropical). The families Ctenophilidae, Ischnopsyllidae, and Pulicidae are more broadly distributed in both the Northern and the Southern Hemispheres.

Classification

The approximately 2575 species recognized in the order belong to 244 genera. The most recent review of the order by Lewis in 1998 recognizes 15 families, while Medvedev (1998) recognizes 18 families. Medvedev separated the pulicoid family into Pulicidae and Tungidae (long disputed by numerous workers), and fragmented the Pygiopsyllidae into three distinct families: Pygiopsyllidae, Lycopsyllidae, and Stivaliidae. The superfamilial relationships of these two classification schemes conflict in many respects and require modern DNA techniques to elucidate their true phylogenetic relationships.

Phylogeny and Evolution

Traditional phylogenetic hypotheses favored an origin of fleas from the Diptera or Mecoptera, but could not pin point the actual sister group. Current research suggests that the closest living relative to the fleas is a single mecopteran family, the snow fleas (Boreidae). This relationship is supported by the presence of unusual proventricular spines, a suite of ovarirole characters (shared only by fleas and boreids), DNA sequence data, and other morphological and molecular characters (Whiting, 2001).

Phylogenetic relationships among Siphonaptera have been difficult to recover, in large part because of their extreme morphological...
specializations associated with ectoparasitism, which hamper the systematist from adequately homologizing characters across taxa. Though there have been attempts to reconstruct phylogeny across all flea groups based on morphology (Medvedev, 1994), these efforts have not relied upon modern phylogenetic methods and consequently lack a clear connection between character information and phylogeny. A recent molecular phylogenetic analysis based on multiple loci for 100+ flea taxa provides a more comprehensive view of flea phylogeny (Whiting et al., 2008). A summary tree is presented as Fig. 1. From the superfamilial standpoint (Medvedev, 1994), these data support the monophyly of Pygiopsyllomorpha and Ceratophyllomorpha, but do not support Medvedev’s arrangement of the superfamilies Puliciformes and Hystrichopsyllidae. Of the 16 flea families examined in this analyses of Whiting et al., 2010 are clearly monophyletic: Tungidae, Lycopsyllidae, Pygiopsyllidae, Stivaliidae, Stephanoecircidae, Rhopalopsyllidae, Chimaeropsyllidae, Pulicidae, Ischnopsyllidae, and Ceratophyllidae. The families Leptopsyllidae, Hystrichopsyllidae, and Ctenophthalmidae are grossly paraphyletic. It is rather interesting that the neosomic Tungidae is placed as the most basal flea lineage and sister group to the remainder of the extant fleas. Overall, molecular data suggest that while the classification of fleas at the level of tribe and genus mostly reflect phylogeny, the higher classification of fleas is in need of serious revision to better reflect flea evolution.

**MEDICAL AND VETERINARY SIGNIFICANCE**

Fleas are capable of transmitting disease organisms to humans, including plague (*Yersinia pestis*) and murine typhus (*Rickettsia typhi*). They have also been implicated in the transmission of Q fever (*Coxiella burnetti*), tularemia (*Francisella tularensis*), listeriosis (*Listeria monocytogenes*), salmonellosis, cat scratch fever (*Bartonella henselae*), and possibly Carrión’s disease (*Bartonella bacilliformis*). Several tapeworms occasionally infect humans who accidentally ingest fleas containing the intermediate stage (cysticercoid) of the tapeworms, including the double-pored dog tapeworm (*Dipylidium caninum*) and several tapeworms of rats (*Hymenolepis diminuta, H. nana*). Fleas also transmit a protozoan blood parasite (*Trypansomoma lewisi*) among rodents and a filarial worm (*Dipetalonema reconditum*) among dogs. Fleas are notorious for their biting and burrowing habits that cause intense itching and annoyance.

**BIOLOGY**

Detailed bionomic studies are available for only a small number of known flea taxa, so the following concepts are based on generalities found within the order.

**Life Cycle**

Fleas display four stadia (egg, larva, pupa, and adult) (Fig. 2A–D). The number and size of eggs and where they are laid differ from species to species, as does the time interval the larvae require to hatch. There are generally three instars. The exceptional neosomic *Tunga monositus* has only two larval stages. Larvae are ca. 1.5–10 mm in length, vermiform (worm-like), eyeless, legless, and without prominent features. Prior to pupation, the third instar ceases feeding and clears its gut contents by defecation. Silk glands present in this last instar are used to spin a cocoon prior to transformation into a quiescent exarate (appendages not “glued” to the body) pupa. The emergence of adults from the cocoon requires specific stimuli (e.g., temperature, vibrations) dependent on the adaptations of the individual species. Fleas may be univoltine or multivoltine. The optimum interval for development from egg to adult ranges from 3 weeks to more than a year. Adults may live for only a few weeks to more than 3 years.

**Reproduction**

Males are smaller than females, have longer antennae, frequently have a dorsal groove on the occipital area of head, have less reticular sculpturing on sternum II, and possess an elaborate aedeagus and modified terminal segments. The interantennal groove or falk

frequently divides the preantennal and postantennal areas of the head in males, while this division is often absent in females of the same species. The details of copulation are understood in only a few species of fleas. In general, the male assumes a position under the female, clasps the ventral sternites of the female with his antennae (equipped with suction cup-like organs), then clasps the female terminal segments (sternum VII) with the tergum IX (clasper), inserts the aedeagus, and transfers sperm by extrusion of long paired penis rods that penetrate the bursa copulatrix and duct of the spermatheca into the spermatheca. Spermatozoa may be stored for long periods of time in the bulga (head) of the spermatheca. The hilla (tail) of the spermatheca of many species has an external muscle extended from its apex to the bulga. When an egg passes through the oviduct, the muscle contracts, pumping the sperm from the bulga through the duct of the spermatheca to the oviduct, where fertilization occurs through a micropyle in the surface of the egg. Depending on the species, the eggs may be laid on the host, in the nest, or randomly in the environment. The reproductive cycles of Cediosylla and Spilopsyllus are linked to the hormonal estrous cycle of their rabbit hosts. Other species, such as Glaciopsyllus antarcticus, have their cycle synchronized with the seasonal migratory and nesting patterns of their avian hosts.

**Host Specificity**

Mammals harbor about 95% of the known flea species, with the remaining species living on birds. The seasonal and geographical distribution and host specificity of fleas are largely determined by specific requirements of the larvae. Each species has evolved a narrow range of tolerance for temperature and humidity, enabling exploitation of virtually every environment on the globe where avian or mammalian hosts flourish. These include the Antarctic (Glaciopsyllus); extreme xeric conditions of the world’s greatest deserts (Nosopsyllus, Hopkinopsylla, Xenopsylla spp.); altitudinal extremes of the Andean, Himalayan, and Rocky mountains (Anaphillus, Ctenopsylla, Geusibia, Ochotonobius, Cnemopsylla, Plocopsylla, Cheopsylla, Stephanocircus); tropical rainforests (Polygenis, Rhopalopsyllus, Pygiopsyllidae); and coastal marine environments (Notiopsylla, Parapsyllus). Although many species are catholic in their host preferences, the larval development is usually limited by the microenvironment of the individual host’s nest. Those demonstrating the least host specificity include those free-living taxa whose immature stages can tolerate wide ranges of temperature, humidity, and nutritional requirements (Ctenocephalides, Pulex).

**Nutritional Requirements**

Most flea species require a blood meal prior to oogenesis and spermatogenesis. With the exception of some species whose reproductive cycle is synchronized with that of their host, there are few studies on the nutritional requirements of adult fleas. Although the larvae of several fleas have been noted to burrow into dead host tissues, those of Uropysylla tasmanica are the only truly parasitic flea larvae that burrow into and feed on the tissues of their live hosts. Some larvae have been documented to feed directly on fresh blood as it is excreted from the anus of feeding adult fleas, but most scavenge on the dried blood residues or animal dandruff and excreta. A few species are predaceous on other small organisms within the nest.

**Neosomy**

Neosomy is the formation or enlargement of a morphological structure from secretion of new cuticle during an active stadium of a group that normally changes form by molting. Additional cuticle forms in neosomes, accommodating expansion during enlargement (1000-fold) of gravid females that are capable of laying more than 1000 eggs. Neosomy occurs only among females because the male’s principal function is to mate with embedded females in situ. Neosomatic growth occurs in the burrowing fleas Neotunga euroidea and all species of Tunga (Pulicidae). Fleas that do not become embedded, but attach for long periods of time, and also display neosomatic growth include members of Chaeopsylla, Doreudel, Verminpsylla (Verminpsyllidae), Malacopsylla (Malacopsyllidae), and Hectoropsylla (Pulicidae). Neosomatic fleas attach only once and do not feed repeatedly.

**Preservation of Fleas**

Study of morphological structures with the aid of a compound microscope requires mounting of fleas on glass microscope slides. Traditional techniques include puncturing the area of abdominal sterna II and III with a minuten pin, soaking for 24 h in 10% potassium hydroxide, transferring to distilled water and gently compressing the flea’s abdomen to evaluate dissolved soft tissues, dehydrating in a series of ethanol solutions (70%, 80%, 95%, absolute) for 30 min each, clarifying the chitin for 15–20 min in methyl salicylate, transferring to xylene for a minimum of 1 h, and mounting in Canada balsam using a coverslip (No. 1 thickness). Fleas should be arranged with their heads to the right and their legs away from the technician. Thus, when viewed with a compound microscope, specimens will appear in an acceptable anatomical position with head to the left and legs toward the observer. Dissections are frequently required to permit observation of otherwise hidden structures.

**Morphological Diversity among Fleas**

For a general treatise of the morphology of adult fleas, refer to Hastreiter and Whiting (2003), and the glossary of terms published in 1971 by Rothchild and Traub. As fleas co-evolved with a diverse number of avian/mammalian hosts, their morphology adapted accordingly and became equally diverse. This is well demonstrated in the ctenidia (combs), spines, setae, and general morphology of fleas. These morphological entities have evolved to accommodate travel through a variety of host feathers and hairs. The lateral thickness of the head and shape of the frontal area (frons) also deviates greatly among the taxa. The head and thorax are used here to demonstrate the extreme morphological diversity among only four representative families of the 18 recognized families (Fig. 3A–L). The myriad of existing varieties in families not illustrated is beyond the scope of this treatise; however, their diversity of adaptive morphological features place this insect order among the most intriguing, ornate, and bizarre creatures in the insect world.

There have been several theories proposing the purpose and function of broad combs that occur in some flea genera. A most extreme example is that of Barreropsylla excelsa (Fig. 3F and 3L). Undoubtedly, combs afford some protection for the two adjoining segments. These may be present on the head and nota of the thorax and abdominal tergites. The protective armor and combs are best demonstrated in the combs and lateral plate of the pronotum of Corypsylla ornata (Fig. 3C and 3D). Anomopsyllus amphibolus (Fig. 3A and 3G) is an example of a flea with limited setae and no combs, or ornate vestiges. Since the flea’s main motility is through the feathers or fur of its host, the rearward directed combs prevent reverse travel and prevents the flea from being easily dislodged by a host during preening activities. It has even been suggested that these specialized combs have the ability to clasp hairs or barbules,
Siphonaptera

although this theory has never been proven. The wedging effect of combs arranged in parallel may have some advantage to affix the flea in place when pulled back through the fur or feathers by a preening host, or when the flea attempts to feed, head combs may provide some advantage in wedging the head against the host skin while the flea pierces the host during feeding. The latter is noteworthy in bat fleas (Ischnopsyllidae) that have two spatulate combs at the oral angle of the head (Fig. 3D and 3J) and Stephanocircus dasyuri (Stephanocircidae). Lateral view of head and thorax: (G) Anomopsyllus amphibolus (Ctenophthalmidae), (H) Hoplopsyllus anomalus (Pulicidae), (I) Corypsylla ornata (Ctenophthalmidae), (J) Myodopsylla trisellis (Ischnopsyllidae), (K) Stephanocircus dasyuri (Stephanocircidae), (L) Barreropsylla excelsa (Sephanocircidae).

Lateral view of head and thorax: (G) Anomopsyllus amphibolus (Ctenophthalmidae), (H) Hoplopsyllus anomalus (Pulicidae), (I) Corypsylla ornata (Ctenophthalmidae), (J) Myodopsylla trisellis (Ischnopsyllidae), (K) Stephanocircus dasyuri (Stephanocircidae), (L) Barreropsylla excelsa (Stephanocircidae).

ANATOMY OF LARVAE

The diversity of morphological characters parallels those of adult fleas. Important structures include the shape of the egg tooth (first instars only); chaetotaxy and sensory structures of the head capsule, antenna, and antennal mound; cuticular sensilla of the dorsal plates of the thorax and abdomen; number and length of body setae; sculpturing of the integument; and arrangement of the anal comb and other setae on the 10th abdominal segment.

CONTROL OF FLEAS

Control is often necessary when fleas parasitize livestock and pets, become potential vectors of disease, or are biting people. Household sanitation such as thorough vacuuming of indoor areas and washing of pet bedding removes many of the immature stages (eggs, larvae, and pupae). Insect growth regulators (methoprene and pyriproxyfen) that inhibit the development of immature stages are used in conjunction with organophosphates (chlorpyrifos and diazinon) to interrupt the developmental cycle. Dog and cat flea collars and the use of systemic insecticides add additional preventive measures. Control of potential plague vectors in rural or sylvatic environments requires more drastic measures. Wild mammals such as rats, prairie dogs, ground squirrels, and chipmunks must be controlled around human habitations and recreation sites frequented by people. In such situations, it is necessary to apply Carbamates (carbaryl) to burrows and rodent harborage prior to control of animal populations. Failure to control fleas prior to implementing animal control endangers humans that may come into contact with these potentially disease-infected fleas.

Sociality is a life history strategy that has evolved multiple times within and among diverse and distantly related insect taxa. Because of large population sizes, social insects collectively consume more energy and biomass than vertebrate animals. In tropical ecosystems, ants and termites play a major role in nutrient cycling and soil turnover. In 1990 B. Hölldobler and Wilson noted that in tropical and temperate habitats, the amount of soil turnover attributable to ants and termites far outweighs the cycling done by earthworms. In the region of the Brazilian Amazon, ants release a significant quantity of atmospheric formic acid, which contributes to natural acidification of rainwater and weathering of limestone-based rock formations.

In eusocial insects, the ability to reproduce has been lost in worker and guard castes. Sterile workers care for the brood, provide nourishment, maintain environmental conditions (e.g., by thermoregulation) inside the nest, and remove waste. The female reproductives or gyne generally outlive several generations of the offspring and are protected and tended by workers in the confines of the nest. The presence of reproductive division of labor is vividly portrayed in social insects, with reproduction restricted to the queen, and nest or colony support being provided by the sterile worker and guard castes. With these three characteristics operating, an insect society is a highly organized, cooperative group of organisms that functions like a superorganism. Social and physiological homeostasis of the insect society is maintained through the integration of caste members through pheromone, tactile, auditory, and sometimes visual communication.

The evolutionary patterns within the Hymenoptera are complex, and eusociality has evolved over eight times within the social bees. The Isoptera (termites) is the only insect order that is exclusively eusocial. Eusociality is rare but present in some aphids (Heteroptera: Aphididae), one group of sphecoid wasps (Crabroninae), vespoid wasps (Vespidae, Masaridae, and Eumenidae), and the Apoidea or social bees (Apidae: Bombinae, Apinae, Meliponinae, and Euglossinae).

**DIVERSITY IN INSECT SOCIALITY**

In 1923 W. M. Wheeler published one of the first contemporary treatments of insect sociality. In the 1960s and 1970s, usable classification schemes for insect sociality evolved from the works of C. D. Michener and E. O. Wilson. Wilson’s 1971 treatment of the social insects streamlined and established a standard vocabulary for describing the degrees of insect sociality, ranging from solitary to eusocial, with several different grades or intermediate forms (Table I).
Presocial Insects: Subsociality

Most insects lead solitary lives, with many species forming simple aggregations during mating or at commonly used food sources. Sociality appears in insects as a departure from a solitary life history strategy. Presocial insects have one to two characteristics of sociality. One subgroup of presocial insects includes insects that provide limited parental care to their offspring. Labeled as subsocial, these species protect or shelter their eggs, nymphs, or larvae; eggs and larvae may be given parental care in an enclosed nest.

Most subsocial insects provide care of offspring in the absence of a nest or shelter. Many examples of subsociality are known from the true bugs (Heteroptera). For example, in some belostomatid genera (Belostoma, Abedus) the female lays her eggs on the male’s back, and the male carries the eggs until nymphs hatch. Males of the belostomatid Lethocerus americanus assist the female with active guarding of the eggs that are laid on aquatic vegetation. Parental care of eggs is also known in water striders (Gerridae) and leaf-footed bugs (Coreidae). Active guarding of eggs and newly hatched nymphs is known in the Acanthosomatidae, Pentatomidae, Tingidae, Reduviidae, and Scutellaridae. Usually, the female guards the clutch and covers the first instars when a predator approaches. The nymphs often orient themselves toward the parent to facilitate concealment.

More examples of behaviorally advanced stages of offspring care can be found in the orders Heteroptera and Coleoptera. Treehoppers (Heteroptera, suborder Auchenorrhyncha; Membracidae) also exhibit parental behaviors toward early instars. R. Coe, for example, observed female thornbugs (Unbonia vrasiesi) straddling egg clutches to prevent parasitism and creating feeding slits on plant stems for hatching. Additionally, the mother actively herds wandering nymphs to keep them near or around the feeding slits and emits alarm calls to alert offspring to a predator’s presence.

Within the Coleoptera, highly developed forms of parental behavior and nest making have been discovered in the Silphidae and in the dung-feeding Scarabaeidae. Known as burying beetles, species of Necrophorus (Coleoptera: Silphidae) provide provisions and actively feed newly hatched offspring through regurgitation. After discovering a small animal carcass, Necrophorus parents process the carcass into a congealed ball of putrefying flesh. After burying the provision, the female chews a shallow depression into the mass, where she deposits her eggs. To solicit parental feeding, the larvae raise the anterior portions of their bodies and wave their thoracic legs. The female parent then regurgitates a small droplet of food material, which is devoured by a larva. In some Necrophorus species, males also participate in larval feeding but less frequently than the female. Parental feeding in Necrophorus is essential for development of the young; removal of the female parent inhibits metamorphosis to the adult.

G. Eickwort and Wilson categorize most bark and ambrosia beetles as subsocial or colonial insects. Members of the Scolytidae and Curculionidae (Platypodinae) have elaborate life history strategies that enable them to evade a host tree’s defense mechanism. The scolytid beetle Xyleborus produces communal brood chambers where all life stages reside. In similar manner to Hymenoptera, these xyleborines also have haplodiploid sex determination. Another similarity between xyleborines and eusocial Hymenoptera is the presence of a biased sex ratio in favor of females. Female offspring assist in cultivating ambrosia fungi, which provide the cellulase necessary for digestion of wood fibers.

Parasocial Insects: Communal Societies

“Parasocial” refers to species that exhibit communal, quasi-social, and semisocial behavioral patterns with some form of generation interaction between generations. Communal species include insects of the same generation that share a nest site without any form of collective offspring care. A communal life history strategy is not just an aggregation; it may involve complex forms of communication and offer some distinct advantages over a solitary life history strategy. Communal aggregations enhance accessibility to food materials that are difficult to process, facilitate thermoregulation, and offer protection from predation. Examples of communal social behavior in bees can be found in the Andrenidae, Megachilidae, and several subfamilies of the Halictidae. Multiple females construct a large, composite nest, but each female tends only to her own nest cells. This produces a nest having a single nest opening that is more easily defended by multiple female bees. Many different species of beetles have communal life history strategies. Some species of scolytid bark beetles are exemplary communal insects.

Communal behaviors in larval insects can be found in tent-making caterpillars (Lepidoptera: Lasiocampidae) and some of the sulfur butterflies (Lepidoptera: Pieridae), silkworms (Lepidoptera: Saturniidae), nymphalid butterflies (Lepidoptera: Nymphalidae), and tussock moths (Lepidoptera: Lymantriidae). Batch laying of eggs predisposes some larval insects for communal life history strategies, but other species disperse from a common oviposition site to lead solitary lives. Although complex social interactions between group members are limited in many species of caterpillars, some species utilize central-place foraging that requires an extensive communication network within the caterpillar community. Central-place foraging is not tied universally to web-making, but instead is scattered throughout the lineages of Lepidoptera. In 1925 F. Balfour-Brown described a model for the evolution of elaborate caterpillar web dwellings from a mat of silk threads or carpet web. This model suggests that carpet webs, the ancestral condition, further evolved with caterpillars that used feeding webs and later to those that used domiciles or home webs.

In the jack pine sawfly, Neodiprion pratti banksinae (Hymenoptera: Neodipridiidae), communal feeding facilitates the procurement of nutrients from tough waxy pine needles. The collective efforts of many larvae chewing over the same area on a pine needle reduces the amount of time needed to break through the cuticle. Other species of larval sawflies and Lepidoptera use group defense postures in which the aggregation moves in a synchronized manner to thwart a predator. The sawflies Neodiprion sertifer and Diprion pini use synchronized head jerking and twitching to repel both egg-laying ichneumonid wasps and birds. To be effective, these protective behaviors require a coordinated group response. Similar defense strategies are also known in the woolly or eriosomatid aphids in which a coordinated waving of waxy filaments may intimidate predators.

Parasocial Insects: Quasi-Social Societies

Unlike communal insects, quasi-social insects have some cooperative brood care while sharing a common nest site. Female quasi-social bees participate in nest guarding and assist with building and stocking nest cells with provisions. In 1967, R. B. Roberts and C. H. Dodson discovered that multiple female orchid bees (Apidae: Euglossinae) often occupy a shared nest site, with the number of females present usually exceeding the cells available for egg laying. This finding suggests that euglossine bee societies have a form of cooperative brood care. Temporary quasi-sociality is also known in a few species of polistine wasps with age polyethism. Young females begin their adult lives as foragers and assist with nest provisioning. Later on, these individuals become egg layers in the common nest site.
Parasocial Insects: Semisocial Societies

C. D. Michener has stated that semisocial insects have an additional characteristic of sociality over the quasi-social species in that the former also have some form of reproductive caste that is cared for by a worker caste. Variation in ovary maturation in spring halictine bee populations suggests that the semisocial condition can arise spontaneously within a mixed assemblage of reproductives of different stages of maturity. Similar patterns of seasonal semisocial behavior occur in some Polistes wasps.

Eusocial Insects

The fundamental difference between semisocial and eusocial insects is that eusocial insects have overlapping generations that feature cooperative brood care by the offspring. Eusociality has evolved multiple times within insects and first appeared in the termites. Eusociality in lower termites (Hodotermitidae, Termopsidae, Kalotermitidae, Mastotermitidae, Rhinotermitidae) is associated with trophallaxis and enables all individuals of the nest to be inoculated with gut symbionts necessary for the digestion of cellulose. Trophallaxis also serves to transfer chemical communication in lower and higher termites. Higher termites such as the Termitidae consume sources of cellulose other than wood, lack flagellate endosymbionts, and use anal trophallaxis for transferring chemical cues.

N. Lin and C. D. Michener proposed two distinct pathways of character evolution in social insects. Most bees are believed to have evolved eusociality through a parasocial sequence. Ancient social bees used a communal social strategy with cooperative nest construction. Later generations switched from a communal to a quasi-social strategy incorporating cooperative brood care within an annual life cycle. The semi-social stage followed the quasi-social stage, with a well-defined worker caste providing cooperative brood care. Fully evolved eusocial species then acquired the characteristic of overlapping generations.

Ants, termites, vespid wasps, and some social bees are believed to have used a subsocial sequence for the evolution of eusociality. The subsocial sequence for the evolution of eusociality is based primarily on the degree of brood care by the female with respect to the age of the offspring. In basal or ancestral taxa, brood care was given only to early instar offspring, with the mother abandoning the young well before maturity. In stage two, brood care is extended to the time during which the young reach maturity. In the final sequence of events, some of the brood become permanent, sterile workers and provide cooperative brood care to the female parent.

Eusociality has also evolved in some gall-forming thrips and aphids. These insects have recently been classified as eusocial because of the presence of a sterile guard caste. However, this form of restricted eusociality differs in important ways from the eusocial condition of Hymenoptera. The guard caste is the only nonreproductive caste in aphid and thrips societies, and the guards do not care for the young. In aphids, this is partly because aphid offspring are precocious like small versions of the adult, they are motile and able to feed themselves.

B. Crespi discovered eusociality in several species of phalaenoptini gall-forming thrips. In these eusocial thrips, the first generations of adults develop into sterile soldiers and are used for defending the gall against invasive species such as ants. These Australian thrips reside in Acacia leaf galls or leaf mines and utilize social behaviors for defense of the domicile. The guards also assist with domicile construction. Morphological specialization associated with the guard caste in eusocial thrips includes enlarged prothoracic legs that are used to attack invaders. The prothoracic femora may be expanded and adorned with robust spines. Mortality in the soldier caste is high.

S. Aoki along with Y. Ito have shown that soldier castes are also present in the Cerataphidini or bamboo aphids (Hormaphididae) and in the gall-forming penaphid aphids. Ito found that some of the Cerataphidini produce a sterile guard caste that defends the offspring. In Ceratovacuna and Pseudoregma, members of the soldier caste are adorned with sharply pointed spines on the head and are used for colony defense on secondary hosts. In Penaphis obsangiaphyae, sterile guards are also used for protecting the domicile. The guards are larger than the nymphs and kick at invading predators with their long legs. In social aphids, the guard caste never assists with brood care but serves only to protect the colony from predation. Parthenogenesis is a reproductive mode employed by aphids, but how the soldier caste is determined is unknown.

In 1992 D. S. Kent and J. A. Simpson discovered a eusocial ambrosia beetle (Coleoptera: Curculionidae). A member of the Platypodinae, Austroplatypus incompertus lives within heartwood galleries of Eucalyptus. Platypodine beetles like A. incompertus feed on ambrosia fungi, and nonreproductive females tend the galleries and process fungal mycelia. Kent and Simpson found that established colonies older than 2 years were composed of a single fertilized female, and up to five unfertilized females, which helped maintain the gallery structure and provide protection from predators. The presence of overlapping generations, reproductive/nonreproductive castes, and cooperative brood care within a shared domicile provide evidence for eusociality in these ambrosia beetles.

Within the Hymenoptera, eusociality is found in all ants (Formicidae), vespid wasps (Vespidae), and some bees (Apidae). Members of the subfamilies Bombinae, Meliponinae, and Apinae are eusocial. Sex determination in Hymenoptera follows Dzierzon’s rule, first shown by J. Dzierzon in 1845 with honey bees and now termed haplodiploidy. Male progeny are produced from unfertilized eggs through a process called arthrotokyo. In many species of social Hymenoptera, males can be produced at the appropriate time from unmated females within the colony. Workers will sometimes undergo facultative thelytoky to produce diploid eggs. Autonistic parthenogenesis produces the diploid eggs in queenless hives of A. mellifera capensis. This form of thelytoky is uncommon and is restricted to certain subspecies of the honey bee.

COLONY SIZE AND LONGEVITY IN EUSOCIAL INSECTS

Insect societies may range in size from fewer than 10 to over 3 million adults. Some species of termites (families Termitidae, Mastotermitidae, and Rhinotermitidae) have colonies with millions of members. Colonies of vespid wasps can have 100 to over 5000 members; colonies of the Allegheny mound ant, Formica exsectoides, can exceed 40,000; and nests of A. mellifera usually contain between 20,000 and 80,000 individuals.

Species that build nests located on or in the ground tend to have more colony members than species that use more restrictive nests. Ground-nesting vespid wasps, for example, usually have larger colony sizes than wasps that build arboreal carton nests. Species that have a large colony size generally tend to have more complex social behaviors than species with small colonies. The correlation of increased colony size with highly evolved social behavior suggests that complex behavioral integration is necessary for colony survival. Although most data gathered on longevity have been derived from laboratory populations, the female reproductive or queen of some eusocial insects can live for more than 10 years. Well-protected inside the nest, most queens are tended by a court of workers and insulated.
from the hazards of everyday life. Workers have significantly shorter life spans and are quickly replaced with newer offspring. Attrition is high among workers, and approximately 1% of the worker caste of the army ant *Eciton hamatum* is lost daily. Unlike the queen, workers are exposed to many hazards, and activity outside the nest contributes greatly to worker mortality.

**ROLE OF ALTRUISM IN INSECT SOCIALITY**

Kim selection is the form of natural selection essential for explaining how the characteristics of eusociality evolved. In 1964 W. D. Hamilton published a mathematical model explaining the economic basis for self-sacrifice as a result of altruism. Hamilton’s rule, \( C/B < r \), suggests that the ratio of the cost \( C \) of sacrifice between two closely related individuals to the benefit \( B \) of the receiver \( r \) must be smaller than the degree of relatedness between the two individuals. Thus, the inclusive fitness of a group of related individuals is the amount of individual and kin selection. The application of Hamilton’s rule to social Hymenoptera, which follow Dzierzon’s rule with haploid males and diploid females, is illustrated by the following example. A female offspring inherits 50% of its genome from its father and 25% of its genome from its mother. Hamilton’s rule predicts that sisters produced from the same mating should tend to sacrifice themselves for each other because they share 75% of their genetic material with each other and 50% of their genetic material with their mother. Thus, the benefit for an altruistic behavior does not have to be high to spread throughout a population.

In 1977 H. E. Evans proposed that selection factors other than kin selection could explain the evolution of altruism and social behaviors in Hymenoptera. Extrinsic factors such as nest parasitism are just as plausible as kin selection for the evolution of altruism. Evans noted that in general, polygynous (multiple queens per nest) wasp species are more common than monogynous (single egg-laying queen per nest) species. Evans hypothesizes that polygynous nesting strategies are ubiquitous because they are necessary for protecting the progeny and provisions of the extended family group from nest parasitism. Likewise, polygynous nests can provide many foragers for provisioning the nest as well.

Although altruism can be detrimental to the individual, advantages to the group or colony are many. Most social insects utilize group defensive strategies when the nest or colony is under attack. Aggressive defense strategies observed in social Hymenoptera, social aphids, and termites demonstrate that defensive behaviors are usually detrimental to the defenders but facilitate survival of the reproducitives and brood within the nest. Self-sacrifice occurs frequently in social insects. In honey bees, for example, the barbed sting of the worker bee eviscerates and kills the worker after stinging, suggesting that the cost of altruism to the individual is high but trivial to the entire colony. In termites, guards will position themselves closest to the source of danger when provoked, whereas other colony stimuli are generally ignored.

Although queen adoption is most often associated with colony multiplication, Wilson believes that the genetic advantages for this strategy are clear. Increasing the number of queens in an isolated colony serves to increase the effective population size while incorporating more altruistic traits into the colony. However, polynygy in ants is not restricted to rare, isolated populations, but can also be found among ubiquitous ant populations as well.

**CASTES IN SOCIAL INSECTS**

The caste system and polyethism determine the division of labor in insect societies. Castes divide colony members into distinct functional roles within the insect society. Specialized caste members conduct such tasks as defense, brood care, nest construction, thermoregulation, provisioning, and egg laying. Morphological specialization or caste polyethism is a key feature of caste structure. The role of a caste member may also change with age (age polyethism).

Morphological specialization associated with caste polyethism is often the result of allometry and usually is tightly coupled with behavioral changes. Allometry or differential growth rates can provide dramatic changes in morphology with simple change in relative growth rates (Fig. 1). Allometric growth provides termite or ant guard castes with hypertrophied mandibles that are used for defense. The head capsule, which may also be enlarged relative to other body parts, accommodates the mandibular muscles used for biting and dismembering enemies.

**FIGURE 1** Cranial morphological differences in worker and soldier or guard termite castes. In *Reticulotermes flavipes*, workers (A) have short chewing mandibles concealed beneath the clypeus and soldiers (B) have an elongated, enlarged head with prominent mandibles.

Overall change in body size also can be important in defining the queen caste. In most eusocial insects, the queen is larger than nonreproductive. The abdomen, which houses the ovaries, may be grotesquely enlarged in mated termite queens and some ant queens. Such enlargement (physogastry) also is known in replete ants, which gather and store honeydew in the crop.

The castes of typical social insects can be categorized according to the following classification scheme. Within social Hymenoptera, guards serve as nest defenders and are equipped with well-developed mandibles and potent stings. Workers, the most ubiquitous caste, help with nest construction and repair, thermoregulation, provisioning, and brood and queen care. The queen makes up the reproductive caste, and her egg-laying activity provides the fecundity for maintaining the colony. Most of the members of an insect society are workers, and high numbers of this caste are necessary for maintaining the physiological homeostasis of the domicile.

Many differences are evident between the caste system of termites and social Hymenoptera. In lower termites, the second instars function
like workers and are actively involved in nest maintenance. Because, at least in part, of their hemimetabolous development, larval termites are active and also take care of themselves as well. Unless destined to become guards, most apterous termite larvae remain as workers throughout their lives. Termite castes differ from social Hymenoptera castes in that they contain both sexes, with reproduction restricted to the fertilized queen (Table II). Once established, termite colonies can replenish reproductives from several distinct supplementary reproductive castes. Within the Termitidae, adultoid reproductives can become functional reproductives and replace lost reproductives. Nymphoid reproductives (larvae that possess short wing pads) can become fully functional supplementary reproductives. Ergatoid reproductives are neotenic, apterous individuals with pigmented exoskeletons. Inhibitory pheromones released by functional reproductives prevent the supplementary reproductives from attaining functionality.

In honey bees, morphological and behavioral differences in castes are regulated by endocrine control of development, dietary differences of larval workers and queens, and queen pheromonal control. Hormonal developmental control is associated with the activity of juvenile hormone (JH) on target tissue sensitivity to ecdysteroids. This modulates or controls reproductive tissue differentiation in developing larvae. In addition, JH may inhibit the release of ecdysteroid and determine the duration of the last instar feeding stage. In developing queens, JH may inhibit ovariole cell death, a feature common in developing workers. Other hormones also influence ovariole development in larval queens. Makisterone A, an ecdysteroid secreted by the prothoracic glands, promotes ovariole differentiation.

Dietary differences are correlated with reproductive caste development in honey bees. Honey bee worker larvae are fed pollen and honey, whereas queen larvae are fed royal jelly. The hypopharyngeal and mandibular glands of workers produce royal jelly. The production and feeding of royal jelly to select larvae is associated with lowered amounts of queen substance, reduced queen vitality, or queen death; the construction of queen cells is also debilitating to the queen. Different proportions of proteins, lipids, carbohydrates, and trace compounds are apparent in honey and royal jelly, but the active ingredient in royal jelly responsible for queen development is still unknown.

Pheromonal control is also evident in caste formation in honey bees. Queen mandibular gland secretion reduces the amount of JH in developing worker larvae, stimulates worker foraging, promotes queen tending, and inhibits swarming behavior. Through modulation of JH titers in developing workers, queen substance inhibits ovariole development.

Examples of age polyethism are frequent in social Hymenoptera. In worker honey bees and ants, temporal changes in maintenance behaviors are associated with age. Young workers take care of the queen and feed the larvae, whereas older workers conduct most of their activities outside the nest. Behavioral changes in honey bees also correlate with the thickness of the mandibular, hypopharyngeal, postcerebral, wax, and thoracic glands. The nursing period of worker bees coincides with the maximum development of mandibular and hypopharyngeal glands at between 5 and 10 days of age.

### COMMUNICATION IN EUSOCIAL INSECTS

The functional integrity of an insect society is established through complex forms of communication. Communication pathways, either chemical, visual, or acoustic, can be used to convey alarm, simple and multiple attraction for assembly, recruitment to a new domicile or food source, grooming, trophallaxis and exchange of food material, facilitation or inhibition of group or colony effects, nestmate recognition, and caste determination. Trophallaxis and exchange of food material also function as mechanisms for the transfer of chemical information between members of a eusocial insect colony. Sensory cues of many different types are used for communication in social insects, and chemical and acoustic cues have been discovered in termites and social Hymenoptera. Visual communication is limited but, according to Karl von Frisch, plays an important role in the waggle dance of honey bees, in which the bees indicate the location of a food resource through a series of stereotypical movements. Chemical communication is believed to be important for maintaining caste structure, nestmate recognition, and establishment of the queen in an insect society. Chemical signals have an immediate effect that typically ends immediately after the chemical has diffused away from the sensory receptors. Some chemical and acoustic cues have also been implicated for initiating defensive and flight behaviors in social insects.

### Queen Dominance and Pheromones

Queen dominance in higher social insects is essential for controlling nestmates and is maintained with a variety of chemical cues in social Hymenoptera. In honey bees such as *A. mellifera*, the mandibular glands and Koschevnikov’s gland produce the components of queen substance. In *A. mellifera*, mandibular gland secretion is a pheromone blend composed mostly of 8-hydroxyoctanoic, (E)-9-oxo-2-decanolic

<sup>a</sup> Immature termites known as larvae are further grouped by the presence or absence of distinct wing pads.

<sup>b</sup> Primary reproductives become dealate reproductives after shedding their wings.
Queen odors are genetic factors that are believed to be a major component of colony odor. M. D. Breed provided some evidence to support this hypothesis. In 1981 Breed published some research findings suggesting that small groups of worker honey bees are more likely to accept a sister queen over an unrelated queen. Further research has demonstrated that resident bees are able to detect and recognize foreign queens raised under the same environmental conditions. This provides additional support for the presence of queen odor as a component of colony odor.

Colony Odor

Nest odor is believed to be important for nestmate recognition in social insects. Sources of nest odor are not clearly defined, but a combination of genetic and environmental factors may be important sources of colony odor. Environmental odors from shared foods like nectar or pollen may contribute to the uniqueness of an individual colony’s odor. Likewise, food transfer in honey bees may facilitate the spread of environmental odors to all members of the hive or nest. The waxy cuticle of honey bees may also trap environmental odors from the atmosphere of the nest. Cuticular hydrocarbons have been implicated as a means for nestmate recognition in Polistes wasps (Hymenoptera: Vespidae).

Queen odors are genetic factors that are believed to be a major component of colony odor. M. D. Breed provided some evidence to support this hypothesis. In 1981 Breed published some research findings suggesting that small groups of worker honey bees are more likely to accept a sister queen over an unrelated queen. Further research has demonstrated that resident bees are able to detect and recognize foreign queens raised under the same environmental conditions. This provides additional support for the presence of queen odor as a component of colony odor.

Trail Pheromones

Trail pheromones are used for recruitment, for marking pathways to resources, and for indicating resource richness. Often released with alarm pheromones, trail pheromones enable guards to aggregate around a nest invader. Furthermore, short-lived and persistent trail pheromones are known. In ants, trail pheromones are produced in the hindgut, Dufour’s gland, the venom gland, and the tibial, tarsal, and abdominal glands. In some myrmecines and ponerine ants, the venom gland is the source of trail odors. Odor trails produced by termites originate from the abdominal sternal glands. In Zootermopsis nevadensis, sternal gland secretions deposited on a trail from a breached or damaged nest wall to the interior of the nest draws workers toward the area for nest repair.

Odor trails emitted by forest-inhabiting bees provide three-dimensional information on resource location. Some large stingless bees of the genus *Trigona* produce strong odor chemicals from enlarged mandibular glands. *Trigona* forage in tropical forests and utilize mandibular gland secretions to cue in other foragers to nectar sources. Foraging *Trigona* will release more trail pheromone near a food source, thus indicating proximity to the food source for other foragers. The trail pheromone components of *T. subterranea* include both E- and Z-citral. Differences in pheromone composition between species may reduce inter-specific trail following in stingless bees.

Alarm Pheromones

Alarm pheromones are volatile organic molecules of low molecular weight that diffuse rapidly, forming a concentration gradient away from the signal source. Alarm pheromones initiate arousal, defensive, and assembly behaviors. Alarm pheromones are often not species specific in social Hymenoptera and termites, but the same pheromone often initiates different behaviors in different species. For example, the mandibular gland secretion 4-methyl-3-heptanone is associated with digging behavior in *Pogonomyrmex* species, but in high concentration causes repelling behaviors in the Texas leafcutting ant *Atta texana*.

Contextual responses to alarm pheromones are correlated with the proximity of the nest to the signal source. Flight occurs when alarm pheromones are perceived from the nearest nest opening. These substances are released near the nest, colony members become defensive. Aggregation, defensive postures, and frenzied excitement are often observed in agitated social insects.

Alarm pheromones are often coupled with other glandular secretions such as trail pheromones. Most alarm pheromones originate from the exocrine mandibular gland. Mandibular gland secretions produce a variety of responses that include excitement, attraction, and threat posturing in different species of ants. Other glands associated with alarm signals in ants include Dufour’s gland and the anal gland. In honey bees, isoamyl acetate is secreted by the lining of the sting pouch and generates attraction and investigation behaviors. After stinging, honey bees leave the sting and associated glandular components in the adversary’s skin, which releases more volatile alarm pheromones for attracting more defenders to the vicinity. The mandibular gland in honey bees secretes 2-heptanone, which initiates alarm behaviors.

The cephalic gland secretions found in termite soldiers are believed to initiate aggressive excitement behaviors in other soldiers and alarm in nonsoldier nest members. Known organic compounds produced by termite cephalic glands include limonene, terpinolene, and α- and β-pinenes.

Acoustic Communication

Termites and ants also use some acoustic alarm signals, and some vespid wasps employ sound to alert offspring to the presence of provisions. Acoustic communication in social insects is conveyed through the substrate, not through the air. Acousticoensey organs present on the legs of social insects detect vibrations transmitted through the substrate.

Ants use subgenual organs and campaniform sensilla located on the legs to detect acoustic signals. Among carpenter ants, the subgenual organ is sensitive to frequencies ranging from 1.5 to 3 kHz. In the leafcutting ant, *Atta cephalotes*, campaniform sensilla function as a sound-detecting organ. Sensilla campaniformae are located near the distal end of the trochanter in *A. cephalotes*. The sensitivity of campaniform sensilla to sound waves varies from the anterior to posterior legs, with the anterior legs being the most sensitive to vibration.

Acoustic signals in ants are generated by stridulation or by tapping the gastral segments on the substrate. Stridulatory files are found universally in pseudomyrmecines, in over 80% of all studied myrmecines, and in nearly half of all studied ponerine ants. Stridulatory files when
S

the sounds produced by leg tapping are loud and audible to humans to signal the presence of provisions to hungry larvae. In this species, nest. In tergal tapping when disturbed. Response to these alarm cues depends on the state of arousal in the signal receiver. In some cases, the tapping behavior causes some ants to lie motionless, presumably to make them less visible to predators, while more agitated ants orient toward the source of the signal and approach it. Outside the nest, tapping enhances the stimuli associated with disturbance and functions as a danger alarm.

Similar tapping behaviors have also evolved in some vespid wasps but not as an alarm cue. Gastral vibration is believed to signal food but not foraging for food. Ants of the genus Camponotus (carpenter ants) use a combination of mandibular and gastral tapping to signal food presence or provision. The abdomen or gaster is rapidly tapped on the surface of the comb when provisions are brought into the nest. In Vespa tropicalis, foundresses tap their legs on the nest comb to signal the presence of provisions to hungry larvae. In this species, the sounds produced by leg tapping are loud and audible to humans standing at least 1 m from the nest.

In termites, sounds are generated by rapidly tapping the head or abdomen against the substrate. Head banging in Zootermopsis is audible as a rustling sound and is believed to function either as a substrate-transmitted alarm call or as a defensive behavior meant to scare intruders away from the nest. Research on the response of termite subgennal organs to the vibrations generated by head tapping behavior (1 kHz) suggests that these acoustic sensory organs are highly sensitive to that frequency.

INQUILINES AND NEST PARASITES OF SOCIAL INSECTS

Eusocial insect nests often harbor guests that take advantage of the food resources and microclimates inside the nest chambers. Arthropod ectosymbions of social insects are numerous and include some species of mites, spiders, millipedes, isopods, and insects. Most orders of insects contain some ectosymbiotic species. Some nest invaders, such as wax moths (Lepidoptera: Pyralidae), feed on the nest structure of honey bees, whereas others may feed on the young, stored provisions, or scavenge from the debris.

Some nest owners receive a benefit (mutualism) for harboring another species. Trophobionts like aphids (Heteroptera: Aphiidae), scale insects (Heteroptera: Cocidae), and mealybugs (Heteroptera: Pseudococcidae) are often protected and sheltered by ants. In return, ants receive from these insects honeydew, a sugary fluid, while providing protection and shelter to these guests. Some have suggested that the posterior morphology of aphids mimics the head region of an ant, with honeydew secretion simulating the transfer of food between ant workers.

A diverse group of guests is usually encountered with army ant colonies. R. D. Akre and C. W. Rettenmeyer studied the association between ectosymbiotic staphylinid beetles and army ants. These beetles have evolved two distinct behavioral strategies to gain access to the resources provided by army ant colonies. Specialized species such as Eciton morpho and Ecitonus are mimetic forms that live within the bivouacs of army ants. They are highly integrated into army ant societies and die if removed from the confines of the colony. Often associated with the larvae or brood, these staphylinid beetles tend to move together within an emigrating column of ants. Phoresy is common, with army ant workers transporting and moving these staphylinids to new bivouacs. Microdonia uses a generalized strategy for exploiting army ants. The association between generalists and their host ants is less integrated than specialized species. They usually frequent the periphery of an army ant colony and will often attack wounded or dying ants. The ants will sometimes attack and attempt to drive these insects away from the nest area.

Evolved mechanisms that enable symbiotic associations between sympylales and their hosts may include behavioral and chemical mimicry. Many sympylales can attract hosts and through appeasement gain access to the nest. B. Hölldobler was one of the first researchers to discover that scents are important for attraction of worker ants to larval Staphylinidae. Some researchers believe that trichome secretions have an intoxicating effect and cause disorientation in host species. The reduviid bug Ptilocerus ochraceus, an ant predator, uses a similarly acting substance to attract and paralyze Dolichoderus ants. This bug presents its abdominal trichomes to an ant, which begins to lick the trichome hairs leading to intoxication.

The variety of interactions between different species of ants is extensive. Interactions range from coexistence to true parasitic relationships. In plesiobiosis, distantly related ant species can coexist with minimal interactions between closely neighboring nests. Some ant species rely on kleptobiosis or thievery to acquire food or refuse from nests of ants of other species. Cleptobiotic species reside in separate domiciles from their hosts. Lestobiosis differs from kleptobiosis in that one species will actually invade the host's nest to prey on the young or food cache. For example, ants of the genus Carebara nest within the walls of termite nests and are believed to prey on termites.

Mixed species colonies usually involve some form of social parasitism. Temporary social parasites were first recognized by Wheeler in 1904. Ants in the Formica microgyna group utilize this type of life history strategy. A newly fertilized queen enters a host colony and coerces the host workers to take over the nest through assimilation of the host queen. Gradually, the parasitic queen's offspring replace the host workers through attrition.

Slave-making ants invade a host nest and steal pupae for incorporation in their own nests. After eclosion, the slaves work as foragers and as nest constructors, and conduct brood care for the slave makers. Slave makers parasitize other ant species that are close relatives. Some species of Polyergus use Formica species for slaves, Formica species of the sanguinea group typically use other Formica species as slaves.

Permanent parasitism or inquilinism occurs entirely inside the host's nest. In some species, workers are present but have limited behavioral roles within the host's nest. For example, Teleutomyrmex schneideri no longer has a worker caste and represents a highly refined form of inquilinism. T. schneideri lives its entire life within the nest of Tetramorium caespitum, a close relative of T. schneideri. The queens of T. schneideri are smaller than the queens of T. caespitum and are morphologically patterned to ride on the backs of the host queen. Teleutomyrmex queens release attractants, from cuticular glands of the thorax and petiole and are eagerly tended by the host's workers.

**Soil Habitats**

Patricia J. Vittum

University of Massachusetts

Many basic and applied studies in insect ecology have considered responses of insect populations to their physical or chemical environment. For insects that live above ground, the mechanisms of behavioral responses to environmental factors often are directly observable. However, behavioral responses of soil-inhabiting insects are much more difficult to observe and quantify. Soil texture and structure can have a direct impact on arthropod behavior and adaptations. Field studies of soil insects often quantify the consequences of behavior, whereas the actual behaviors are only inferred. There have been studies of ecological and physiological adaptations of several soil arthropods that are not considered to be agricultural pests but have certain life history features that make them amenable to investigation. However, most insects that are agricultural pests as soil-inhabiting immature forms (e.g., wireworms or rootworms in corn, scarab grubs in turf grass) often have been studied in detail only in their more accessible, or observable, adult form.

This is in part because of the logistical challenge of observing the movements and other behaviors of the soil-bound larvae.

**CHARACTERIZATION OF THE SOIL ENVIRONMENT**

**Soil Solids**

Most soils have a complex structure, consisting of solids, liquids, and atmospheric gases. The solid components (e.g., sand or clay) constitute much of the soil matrix in bulk. Inorganic, or mineral, particles range in size from clays (<0.002 mm in diameter) to sands (0.002–0.05 mm) to sands (0.05–2 mm) to pieces of gravel (>2 mm). The proportion of different sized particles, or soil texture, determines to a large extent the physical properties and appearance of a soil, as well as its ability to supply chemical nutrients to plants. The soil texture also has an impact on the soil arthropod population. For example, small soil arthropods sometimes find it difficult to move in heavy clay or tightly compacted soils.

Soil organic matter consists of an accumulation of partially disintegrated and decomposed plant and animal residues that have been broken down and resynthesized by microorganisms in the soil. Although organic matter usually does not constitute more than 6% by weight in topsoil (and even less in subsoils), it binds mineral particles into slightly larger granules that produce loose, crumbly soils that can hold more water than their mineral counterparts. Organic matter also is a primary source of energy for a variety of soil organisms, including many arthropods.

**Pore Spaces**

A typical loam soil will consist of roughly 50% soil solids (a combination of sand, silt, and clay) and 50% pore spaces and water. The size and distribution of pore spaces will depend on the size and shape of the mineral particles, as well as the activity of microorganisms. A predominantly clay soil will usually have very small pore spaces because the clay particles are very small and can pack together effectively. A sandy soil will tend to have much larger pore spaces because the sand grains are more irregular in shape and do not compact as readily. Atmospheric gases (most notably, oxygen and carbon dioxide) also occupy pore spaces and can move passively through the soil profile, depending on surface conditions.

Pore spaces are further characterized as micropores (<0.06 mm) and macropores (>0.06 mm). Macropores tend to allow movement of air and percolating water very readily, whereas micropores are the first to be filled with water in a moist field soil and do not permit much air movement into or out of the pores.

Convection can enhance the exchange of gases within a soil or between a soil and the atmosphere above. Aeration (movement of oxygen and other gases) near the surface of a soil occurs most readily in the presence of large, interconnected pore networks or channels. The rate of aeration is influenced by changes in barometric pressure, temperature gradients, and wind gusts. Temperature, relative humidity, surface texture, and continuity of soil pores affect the diffusion of gases into and out of soil.

**Soil Water**

Water (and dissolved minerals) accumulates in pore spaces and moves vertically through the soil profile if the surface input (e.g., rain or irrigation) exceeds the rate at which any vegetation absorbs the water. Water moves most readily through soils that have well-spaced,
interconnecting macropores, but it also fills many of the micropores closest to the surface. Since water displaces air in the pore spaces, soils that are saturated with water cannot retain atmospheric gases that are critical to plant growth.

Soil moisture tension determines how much water remains in the soil at equilibrium and is a function of the sizes and volumes of pore spaces (matric potential), the presence of solutes in the soil (osmotic potential), and gravity. When the surface of a soil dries following an extended period of dry weather (further enhanced by low humidity or steady winds), water can also be drawn back toward the surface through capillary action.

The relative concentrations of oxygen, carbon dioxide, and water vapor often are considerably different in soil pore spaces (soil atmosphere) and in the open air. Oxygen concentrations tend to be lower or steady winds), water can also be drawn back toward the surface through capillary action.

The relative concentrations of oxygen, carbon dioxide, and water vapor often are considerably different in soil pore spaces (soil atmosphere) and in the open air. Oxygen concentrations tend to be lower and CO₂ concentrations tend to be higher in the soil atmosphere as a result of plant and animal respiration and biochemical soil processes. Relative humidity tends to be relatively high, particularly in soils used to produce agricultural crops.

**Soil Temperature**

Surface temperatures of soils often fluctuate at least as much as ambient air temperatures, but the difference between the daily maximum and minimum temperature decreases as depth in the soil increases. There is a delay of maximum and minimum soil temperatures compared with the overlying surface temperatures, correlated with depth. Seasonally the maximum and minimum temperatures occur in the warmest and coolest seasons, respectively, in the upper soil layers. In contrast, the highest temperatures occur in early winter and the lowest temperatures occur in midsummer, at 7 m depth. Soil insects and other arthropods often move vertically in direct response to soil temperature, moving downward in late autumn to avoid freezing temperatures on the surface and returning to the surface in the spring to resume feeding.

**FORMS OF LIFE IN THE SOIL**

A vertical cross section of a soil profile reveals several distinct layers. The lowest layer, or horizon, is the C horizon, which consists of unweathered rock. The B horizon contains weathered, rough mineral soil with small deposits of humus. The A horizon normally has fine mineral soil interspersed with organic matter. The O horizon is a layer of plant debris lying on the surface of the mineral soil. The thickness of this layer depends on the amount of vegetation that is deposited seasonally and annually, and on the amount of degradation that occurs as a result of soil organisms. Within the O horizon are several layers, including (from the top) leaf litter, a fermentation layer, and a humus layer. The humus layer often merges into humus-enriched topsoil.

Soils and the overlying organic layer are not homogeneous, but rather are stratified. Similarly, the arthropods that live in these regions are grouped into different life-forms that have adapted to the various conditions that exist in the soil.

**Euedaphons**

Euedaphic soil arthropods inhabit the lowest soil layers, generally moving within the soil pore system. These arthropods usually are small and are characterized by a round or wormlike body form. The body size corresponds to that of the pore system, and extremities are often reduced. Because they cannot escape predators, many euedaphons generate and release toxic or defensive substances. Most euedaphons are photophobic and either lack eyes or have eyes that have degenerated considerably. They tend to have well-developed mechanos- or chemosensitive organs, which compensate for their poor or nonexistent vision. Arthropods occurring in the euedaphon include several species of proturans, diplurans, and symphylans, as well as a few oribatid mites.

**Epedaphons**

Epedaphic arthropods live on the soil surface and in leaf litter. They are not well adapted to the conditions found in the soil pore system (e.g., high relative humidity, restricted gas exchange, restricted mobility). They are represented by many different body forms, usually are strongly pigmented, and often are dorsoventrally flattened. They have well-developed sensory organs and are highly mobile. Arthropods occurring in the epedaphon include oribatid mites (Oribatei), springtails (Collembola), ectobiid cockroaches, several cricket species, and several predatory beetles, including rove beetles (Staphylinidae) and ground beetles (Carabidae).

**Hemiedaphons**

The hemiedaphon group represents a transitory form of life, enabling some epedaphic or atmobiotic arthropods to occupy burrows in the soil. Hemiedaphic arthropods have the ability to excavate through soil by means of modified mouthparts or fossorial legs, and often they can enlarge existing cracks and pores. Several insect taxa have adopted a hemiedaphic life for a variety of reasons: to dig channels and then wait for surface prey to fall into the pit, to burrow through the soil hunting for small epedaphic arthropods, to avoid temperature or moisture extremes on the surface, or to feed on roots of plants. Hemiedaphic arthropods include earwigs (Dermaptera), field crickets and mole crickets, tiger beetles (Cicindelidae), and white grubs (Scarabaeidae).

**ADAPTIVE STRATEGIES OF SOIL ARTHROPODS**

**Response to Soil Texture**

Organisms in the soil (and leaf litter) community play very different roles, based in part on their size. Organisms (e.g., protozoa, bacteria, and some nematodes) that exist in water films, often in soil micropores, have resource requirements and defense needs that differ from those of organisms able to move in and out of soil pores independently. Similarly, a soil macroarthropod, as it grows, will perceive the soil matrix differently (Fig. 1). A neonate exists functionally as a microarthropod, able to move only within existing pores in the

**FIGURE 1** Schematic representation of the impact of soil particle size on movement of a soil insect. Japanese beetle larvae (neonate, late first instar, mid second instar, and mid third instar) shown in a square centimeter of typical loamy sand soil. [Drawing by Stephen L. Thomas, University of Massachusetts, adapted from Villani, M. G., and Wright, R. J. (1990). Environmental influences on soil macroarthropod behavior in agricultural systems. Annu. Rev. Entomol. 35, 249–269.]
soil. Thus its ability to move is a function of the porosity of the soil (including the size of the pores and their continuity). As the arthropod grows, less of the pore space is available for free movement. At this point pore space is less important in impeding movement than gross soil structure (impacting insect movement among soil aggregates) and aggregate density (movement through the aggregates). Plant root activity, surface cover, traffic and other sources of compaction, and density of soil organisms all impact aggregate formation. As the insect grows, less of the soil pore space is available to the insect for free movement, but it may take advantage of preexisting soil channels created by soil macrofauna such as earthworms, other arthropods, or small vertebrates. Water-filled soil pores can inhibit movement.

**Response to Temperature**

Several soil insect species demonstrate a seasonal pattern of vertical movement associated with soil temperature. In temperate climates, many soil macroarthropods move downward in late autumn to avoid freezing and return to the upper soil layers in spring. Some species move away from the soil surface in the middle of summer, in part to avoid high soil temperatures. Species-specific responses to soil temperatures influence periods of feeding activity and may enable similar species to occupy slightly different niches (e.g., wireworms, scarab grubs).

**Response to Moisture**

Some hemiedaphic arthropods have developmental stages that cannot tolerate extremes in moisture, and many of those stages are very sensitive to soil moisture levels. For example, grubs of several scarab species that had been held in dry soils moved upward almost immediately after moisture was applied to the surface. Several macroarthropods, including some wireworm species, alter the soil environment by creating semipermanent earthen cells. These temporary cavities enable the insects to create nearly saturated chambers in the soil, greatly reducing moisture loss from evaporation. Numerous desert arthropods create earthen cells in which they can aestivate when soil moisture is extremely low (or temperature is extremely high). Usually, eggs and pupae of insects are most resistant to moisture loss and least able to escape undesirable conditions. Larvae and adults are often mobile stages and may be able to move away or alter their behavior to minimize the impact of adverse moisture extremes. For example, scarab larvae can move downward in the soil profile to seek moister (and cooler) conditions during periods of heat or drought stress. Heavily sclerotized soil arthropods may be less vulnerable to cuticular moisture loss than are less sclerotized forms, such as grubs or maggots.

**Locomotion**

Edaphic arthropods move through soil to locate food, to escape predators, or to escape unfavorable abiotic conditions. Adaptations for movement in soil depend on soil type, particle size, pore size, and soil density, among other things. Although many epedaphic species use their bodies as wedges, euedaphic species tend to dig through soil, using their legs and mandibles as shovels. Legs of edaphic insects often are highly modified to facilitate digging or burrowing through soil. At least one leg segment is likely to be enlarged, specially shaped, and edged with spines or lobes to create functional spades. Expanded tibiae or femora provide increased surface area, providing improved leverage when the insect is moving soil. For example, mole crickets (Orthoptera: Gryllotalpidae) use their greatly enhanced fossorial forelegs to burrow through soils very rapidly.

Many euedaphic arthropods lack obvious modifications for digging, but are able to move through soil by fitting between particles or by moving in existing burrows or crevices. Body shapes may be flattened or cylindrical, but in general antennae and legs tend to be reduced or absent. Millipedes serve as an example of the variety of adaptations that have arisen over time. Some species act as bulldozers with long bodies, many legs (for purchase against soil particles), and broad heads; other species have shorter bodies, fewer but longer legs, and tapered heads that allow the millipedes to wedge through small spaces in the leaf litter or upper layers of soil. Still other species of millipedes have very tapered anterior and compressible bodies that can be used to widen crevices. The heavily sclerotized elytra and terga on adult beetles can provide a very effective protective shield when an insect is pushing aside soil particles or layers of leaf litter.

**Host Finding**

Much of the behavioral research that has been conducted over the past 50 years has centered on atmobiotic insects, in part because until recently it was virtually impossible to observe soil insects in situ without disturbing them. Destructive sampling techniques enabled researchers to make quantitative assessments but revealed very little information about how or why soil insects exhibited certain behaviors.

For many hemiedaphic insects, host finding begins with choices made by the mobile adult female as she seeks oviposition sites. For example, a female corn rootworm beetle (*Diabrotica*) may oviposit in a field where corn is growing, but if the field is planted to a different (nonhost) crop the following growing season, the neonates that emerge in the spring may have to move relatively large distances to reach a suitable host. Similarly, emerging scarab larvae must locate suitable roots and begin feeding within 24–48 h of eclosion, and overwintering grubs must relocate to suitable host plants when returning to the upper soil layers in the spring.

There are many plant-derived chemicals that elicit responses in insects in general, including host plant extracts that initiate host-searching behaviors or avoidance mechanisms. Many of the most intensively studied phytochemicals are produced in leaves or stems, but soil insects are more likely to respond to chemicals produced in the root zone. Some of these compounds are quite specific and elicit responses (e.g., host seeking) from limited taxa. Others, like carbon dioxide, are not species-specific and influence a wide range of soil insects. Chemicals produced in the soil (typically as root extracts) may diffuse over relatively large distances, but the diffusion rate depends on soil moisture, texture, and compaction.

**Defensive Adaptations**

Edaphic arthropods produce a variety of compounds that can function as contact toxins, repellents, or irritants. Many different taxa use similar biosynthetic pathways to produce closely related compounds. For example, several soil arthropod groups, including some millipedes and centipedes, as well as some chrysomelid larvae, produce hydrogen cyanide. The glands that produce this nonselective toxin apparently are not homologous, suggesting that the capability has evolved more than once.

Some edaphic arthropods have developed chemical defenses against deep-soil predators that use mechanoreceptors and chemoreceptors to provide cues to locate their prey. Others evade predators by running or jumping. Epedaphic Collombola (springtails) that live in leaf litter are cryptically colored and have a highly evolved mechanism that enables the insect to jump away from a disturbance virtually instantaneously. In contrast, Collombola that live wholly within
the soil (and thus are constrained by soil particles) tend to be smaller and paler, and to have less well-developed jumping mechanisms than euedaphic species. Instead, the euedaphic springtails secrete noxious fluids that protect them against many predators.

**Interactions of Soil Insects with Chemical Control Agents**

Edaphic insects that are considered to be pests in production agriculture or the green industry are often much more difficult to “control” than their atmbiotic counterparts. One of the greatest challenges is achieving adequate contact of an insecticide with the target insect. Many insecticides dissipate or degrade relatively quickly (before they reach the soil) or are adsorbed to soil particles. Most soil insecticides (and other pesticides) remain in the top 5–10 cm of the soil, where they are subject to microbial degradation. Soil factors such as pH, organic matter, moisture, temperature, and microbial community diversity will have a direct impact on the mobility and persistence of a soil insecticide. Insecticides that are highly mobile in soil may be ineffective because they move beyond the target zone too rapidly.

Many soil insects can detect the presence of insecticides and other chemicals and will initiate avoidance behavior (e.g., moving away from the soil zone in which the chemical is detected). Abiotic factors, such as soil moisture or temperature, that induce a target insect to move as little as 1 cm further into the soil profile may place target insects beyond the effective “range” of some chemical control agents. Often the manipulation of irrigation apparatus or the use of application equipment that incorporates a control agent directly into the soil at the desired depth can enhance the efficacy of a soil insecticide.

**IMPACT OF SOIL ON PATHOGENS, PREDATORS, AND PARASITOIDs**

**Pathogens**

The upper layers of most soils, as well as leaf litter, support active microbial communities. Many of these organisms are natural decomposers, breaking down plant and animal tissues that ultimately become part of the organic matter in the underlying soil. Interestingly, many edaphic arthropod populations are nearly free of disease. Several studies have demonstrated that secretions from many different edaphic arthropods inhibit vegetative growth or suppress the germination of pathogenic organisms.

Edaphic arthropods that are highly susceptible to pathogenic organisms in laboratory tests are rarely infected in the field, suggesting that there may be a critical behavioral component. For example, several soil insects, including earwigs (Dermaptera), mole crickets, and ants, tend and lick eggs. This behavior may remove fungal spores or bacteria or inhibit their germination. In addition, some laboratory studies utilize artificially dense populations of the target arthropod, which may enhance the spread of pathogens from one organism to another.

Nevertheless, several insect pathogens occur naturally in soils. For these pathogens to induce an epizootic, three conditions must be met. A susceptible host must be present, with host susceptibility being governed by population density, species composition, presence or absence of other stress factors, and behavioral responses to the pathogen. A pathogen must be present, with a suitable level of virulence and persistence. Finally, the environment must support both the host and the pathogen. Soil conditions, such as low temperature or high moisture levels, may stress the target insect population, predisposing individuals to infection and ultimately leading to population declines.

Several microbial insecticides were identified and developed during the last half of the 20th century. All were found in naturally occurring epizootics in the soil and were subsequently commercialized. Microbial insecticides are passively mobile because an insect that comes in contact with the microbial product may move some distance from the initial point of contact before it dies. The behavior of the target insect can be important to the spread of the pathogen, particularly when normal (or pathogen-induced) behaviors result in movement of individuals beyond their normal range. Most microbial insecticides are able to replicate within the host.

In some instances, edaphic arthropods are able to detect and avoid fungal pathogens in soil. In 1994 Villani et al. conducted a series of microcosm studies proving that when incorporated into soil, mycelial formulations of *Metarhizium anisopliae*, a naturally occurring soil fungus, repel third-instar Japanese beetle (*Popillia japonica*) grubs for as long as 3 weeks. Similar responses have been observed with tawny mole crickets and subterranean termites.

Examples of microbial insect pathogens include bacteria (e.g., *Bacillus popilliae*, *B. thuringiensis*, *Serratia marcescens*, *S. entomophila*), fungi (e.g., *M. anisopliae*, *Beauceria bassiana*, *Fusarium spp.*, *Penicillium spp.*, and *Aspergillus spp.*), protozoa (e.g., *Oocystida populillae*), and various rickettsia (bacteria-like) organisms. Many of these have been developed commercially, with varying degrees of success.

External factors relating to soil condition may modify arthropod behavior. Localized flooding may force edaphic insects to move to unsaturated soils, whereas after several weeks without rain these insects may seek moister (usually lower) ground. These localized migrations may result in contacts between populations of edaphic insects and pockets of pathogen activity that otherwise might not have occurred. Disruptions in social behavior may increase or decrease infection rates. For example, studies have demonstrated that applications of sublethal rates of certain soil insecticides, such as imidacloprid, greatly increase the pathogenicity of some pathogens, including *B. bassiana* and some entomopathogenic nematodes (see next section). Apparently the sublethal exposure of the insecticide disrupts normal social behavior in the termite colony, including grooming, trophallaxis (food exchange), and construction of tunnels.

**Predators and Parasitoids**

Insect predators are mobile and self-replicating. Their effectiveness depends on the interaction of the soil environment with both the agent and the host. The initial contact and subsequent spread through the population depend on temporal and spatial overlap. The predator must be well adapted to the soil conditions. In particular, the predator must be able to move through the soil and to respond to host cues. Some predators are edaphic arthropods, such as predatory beetles or spiders.

Entomopathogenic nematodes can also be considered to be predators, since they move through the soil in search of host insects. Some species move actively, whereas others are more passive, ambushing prey as it moves nearby. Entomopathogenic nematodes enter the host through natural openings, such as the mouth, spiracles, or anus. Nematodes in the genera *Heterorhabditis* and *Steinernema* carry a pathogenic bacterium, which is released in the body cavity of the host. The bacteria multiply within the host and produce toxins that kill the host rapidly. Although several nematode species are available commercially, their efficacy in field conditions has been inconsistent, in part because the nematodes are extremely sensitive to temperature and soil moisture levels.

Several insects have evolved as parasitoids of edaphic arthropods. Host finding is presumed to be much more complex than
for atmoiotic hosts because any host volatiles must move through the soil matrix. The parasitoid also must be able to move through the soil structure to reach the host. Studies attempting to evaluate the specific host-finding behaviors of these parasitoids must include consideration of soil texture, moisture, and temperature, as well as root zone exudates and sensitivity to movement-induced vibrations.

**SAMPLING TECHNIQUES FOR SOIL INSECTS**

One of the greatest challenges facing soil insect ecologists is the need to develop techniques of following insect movement and feeding behavior in situ while minimizing disturbance of the soil system. Until recently, researchers relied on the “snapshot” approach of collecting soil samples and sampling destructively, to determine how many soil insects might be present in the sample. This approach provided limited quantitative assessments but could not provide information over an extended period of time.

One technique that seems to be ideally suited to observing soil insect behavior is radiography, which has been used to trace the movement of scarab grubs and mole crickets in turfgrass, wireworms in corn, and onion maggots in onions, among other arenas. Plastic boxes of varying dimensions are filled with soil, and virtually any edaphic arthropod can be introduced to the microcosm and observed without disturbance. The technique has been expanded since Villani and Wright first described some of the applications in 1988. It has been used to investigate the response of soil insects to the presence of pathogenic nematodes. Studies attempting to evaluate the movement and survival of two different species in a confined space, and to conduct preliminary basic observations of species behavior in soil. Understanding of insect movement in soil has expanded tremendously as a result of radiographic observations.

**Spermatheca**

Marc J. Klowden

University of Idaho

The spermatheca is a special pouch in the female in which spermatozoa are stored and maintained after mating. In more advanced insects, the male deposits seminal fluid or a spermatophore into the bursa copulatrix, and the sperm then move from the bursa into the spermatheca. The sperm often remain viable within the female’s spermatheca for her entire life, which may be as long as 3–4 years for social insects such as the honey bee queen. The sperm are released from the spermatheca only when eggs pass down the oviduct, so fertilization may occur just before the eggs are laid.

**SPERMATHECAL STRUCTURE**

A female insect typically has only one spermatheca, but some coleopterans have two, and there are three spermathecae in some dipteras. These multiple storage organs may allow the female to segregate and manipulate the sperm. The spermatheca vary considerably in their overall structure from insect to insect, but as outgrowths of the median oviduct, they are all ectodermal in origin and produce a cuticular lining. They generally arise from the median oviduct near or on the genital chamber (Fig. 1). The spermathecal sac (or receptaculum seminis) is connected to the genital chamber by a secretory duct (or ductus seminalis) through which the sperm are discharged. There also may be specialized secretory cells associated with the capsule that produce secretions that maintain the viability

of the sperm and activate them. The sperm move quite actively within the spermathecal sac, and the secretions of the secretary cells are assumed to provide nourishment to them. Antioxidative enzymes in the spermathecae may protect the sperm from oxidative damage. Secretions of the spermatheca may also be directed into the hemocoel. In the blood-sucking bug, *Rhodnius prolixus*, a factor produced by the sperm-filled spermatheca is responsible for the increased rate of egg development that is associated with mating.

**UTILIZATION OF SPERM**

The spermatheca may be innervated by nerves that branch from the terminal abdominal ganglion and control the release of sperm. When sensory receptors on the oviduct are activated by the presence of an egg, a reflex arc through the terminal abdominal ganglion activates a motor neuron that triggers the contraction of muscles surrounding the spermathecal sac. Sperm are squeezed through the spermathecal duct to the oviduct, where the egg is fertilized before it passes out of the body.

There may not always be a random utilization of sperm present in the female spermatheca. When sequential matings occur, although the sperm from different males may be mixed within the storage organ, the sperm from one mating may be used preferentially. Most often there is precedence in the utilization of sperm so that the last sperm to enter are the first ones to leave, increasing the probability that a second mating will be used to fertilize the eggs. To ensure paternity in second matings to an even greater degree, male insects have evolved some novel mechanisms of sperm displacement. For example, the male of the damselfly, *Calopteryx maculata*, uses its scopelike penis both to transfer its own sperm to the female and also to remove from the spermatheca sperm from a previous mating. An unusual method of insemination and sperm storage occurs in some members of the heteropteran superfamily Cimicoida, which includes the bedbugs. Males puncture the cuticle of the female, injecting the sperm into a specialized tissue mass there. The sperm may then move to the ovaries or remain within the tissue mass for storage, as if in a spermatheca.

male and female is followed by the insertion of the spermatophore into the female genital tract and the attachment of its long tube to the female’s ovipositor. The sperm travel into the spermatheca of the female, and after 30–40 min, the flasklike spermatophore is dislodged.

In the more advanced pterygotes, the males form the spermatophore in a more recently evolved structure in the female genital tract, the bursa copulatrix, and the sperm then move to the spermatheca(e) of the female for ultimate storage and utilization. In some Lepidoptera, the bursa contains spines that rupture the spermatophore and allow the sperm to escape. Once the sperm have escaped, the spermatophore may be digested by enzymes secreted into the bursa, and its raw materials exploited by the female for egg production. Male Anopheles mosquitoes produce a modified spermatophore that serves as a mating plug to temporarily block the genital tract and prevent the female from mating with other males.

The metabolic costs of synthesizing a spermatophore may be one reason for its ultimate disappearance in many of the higher insect orders. Accompanying the loss of the spermatophore has often been the development of a male intromittent organ that is capable of placing the sperm directly into the bursa copulatrix or the spermatheca(e), making the spermatophore unnecessary.

Spiders

Rosemary G. Gillespie, Joseph C. Spagna
University of California, Berkeley

For many, spiders are a cause of fear and a source of revulsion. Even to entomologists, spiders have often been thought of as a mere annoyance, filling nets and pitfall traps meant for insect quarry. It is therefore surprising to learn that spiders have held a prominent role in traditional cultures for centuries. Indeed, the terms “arachnid” and “arachnology” come from Greek mythology: A young maiden, Arachne, dared to challenge the great goddess Athena to a spinning contest. Athena wove a remarkable tapestry, yet that spun by Arachne was far superior in its intricacy and perfection. Infuriated that a mere mortal could spin such a masterpiece, Athena turned Arachne into a spider, condemned to a life of perpetual spinning. In native American culture, it was a spider that brought fire to the Cherokee people; the Navajo told of Spider Woman (Na ashi’ii’ Asdzáá), who came from the “first world” and taught the women how to weave; according to Pueblo legend, Spider Woman was at the core of creation; and the Sioux Indians use the “dream catcher,” spun by a spider, to capture the good dreams of life. Spiders are also prominent in African culture, as illustrated in the well-known stories of “Anansi, the Trickster.” Rather more recently, Scottish legend tells of King Robert the Bruce, whose observations of a spider inspired him to persevere, going on to conquer the English. The reasoning behind some of the tales can be obscure. For example, in the far-flung Micronesian island of Palau, the ability of women to perform natural childbirth is attributed to a spider. With such a diversity of lore, it is clear that spiders have been held in high regard across a global spectrum of cultures and for a very long time.

Spiders, like insects, belong to the phylum Arthropoda, but they are in the class Arachnida, which includes the orders Acari (ticks and mites), Scorpiones, Pseudoscorpiones, Opiliones (harvestmen or daddy-long-legs), and several less common orders. Arachnids are only distantly related to the other major terrestrial arthropod group, the insects, and represent a separate evolutionary transition from marine to terrestrial living, because their closest living relatives are thought to be the marine horseshoe crabs (xiphosurans) and sea spiders (pycnogonids). Together, these marine and terrestrial orders are called the chelicerae orders based on the structure of their mouthparts, in contrast to the orders to which insects and crustaceans belong. Recent molecular and morphological evidence points to the Amblypygi, or tailless whip scorpions, as the group sharing the most recent common ancestor with spiders, with the other arachnid orders more distantly related. Spiders can easily be distinguished from other arachnids by their lack of visible segmentation and the marked constriction between the prosoma and the opisthosoma, dividing the body into cephalothorax and abdomen, respectively.

Although much less diverse than insects in habits and morphology, spiders, which are in the order Araneae, nonetheless occupy nearly all terrestrial environments and can be found wherever there are other terrestrial arthropods to prey upon. Research into spider biology, particularly the diversity of silks, webs, and venoms, together with the associated ecology and behaviors, has increased greatly in recent decades. Moreover, phylogenetic advances are beginning to provide the context for comparisons between spider taxa and between spiders, other arachnids, and other terrestrial arthropods.

EXTERNAL ANATOMY

The body of all arachnids is divided into an anterior prosoma and posterior opisthosoma, and in spiders these major divisions are referred to as the cephalothorax and abdomen (Fig. 1). These are connected by a narrow stalk, the pedicel. The cephalothorax is covered dorsally by the carapace and ventrally by the sternum and labium. Unlike in insects and most other arachnids, the segmentation of the spider body is not visible externally (except in two primitive lineages) and the cuticle is relatively soft, particularly on the abdomen.

At the front end of the carapace are the simple eyes, or ocelli, usually in four pairs, but in some groups one or more pairs may be reduced or absent. The eight simple eyes are usually arranged in two rows of four, though each of these rows may be curved in such a way that individual eye pairs seem to form their own rows, and in some species one, two, three, or even all four pairs of eyes may be lost. The anterior eye row is closer to the chelicerae, whereas the
posterior eye row is farther back on the cephalothorax. Each eye row consists of median and lateral eye pairs, so that each pair can be identified both by row and by position within that row. For example, the anterior median eyes (AMEs) are the central pair, closest to the chelicerae. Below the front margin of the ocular area is the clypeus, from which the two chelicerae extend downward. Each chelicera consists of a stout basal section, from the outer corner of which articulates a narrower distal section, the fang. Behind the mouth ventrally is a second pair of mouthparts, leg-like in appearance, the pedipalps. In mature males, these are modified for secondary sperm transfer and appear swollen, facilitating recognition of the spider’s sex.

Extending laterally from the ventral cephalothorax are four pairs of legs, each consisting of seven segments: coxa, trochanter, femur, patella, tibia, metatarsus, and tarsus. The legs are generally covered with hairs and often have a great diversity of spines, bristles, and scales. These outgrowths serve a variety of functions, including mechanical and chemical sensory functions (see below). Each leg terminates in two or three tarsal claws. In three-clawed spiders, there are usually two larger paired claws and a smaller unpaired median claw, whereas in two-clawed spiders, the median claw is often replaced by a tuft of dense, stiff hairs, called the claw tuft.

A spider’s abdomen is carried behind the cephalothorax. The abdomen may be globular or elongate in appearance and is sometimes covered in hairs or scales similar to those found on the legs. The respiratory book lungs (one or two pairs) open at the anterior end of the abdominal venter. They can be seen externally as patches of hairless cuticle on the ventral of the spider, adjacent to the genital opening. In mature female spiders, the genital area is found nestled between the book lungs, the form varying from a simple slit or pair of holes to a complex sclerotized copulatory plate, the epigynum.

At the posterior end of the abdomen are the spinnerets—usually in three pairs, the anterior, posterior, and median pairs—and the anal tube. The median spinneret pair is often obscured by the larger anterior and posterior pairs, and the entire complex of spinnerets may be surrounded by a sclerotized ring. Each spinneret pair has its own complement of silk spigots that extrude silks for specific functions. In addition, many spiders have a cribellum, or spinning plate, found adjacent to the standard spinneret complement that they use to produce an ultrafine looped silk for prey capture. In others, the cribellum has been reduced to a small vestigial lobe, called the colulus, or lost completely.

The sex organs of male spiders are the palps (Fig. 2A–2G). The cymbium, or modified tarsus of the mature male palp, is hollowed out to contain the copulatory organ. The basal appendage of the cymbium is called the paracymbium. The bulb of the male’s palp opens through a spineshaped apparatus, which ends in a fine tube, the embolus. The male palp is generally less complex in primitive spiders (haplogyneae) relative to more advanced spiders (entelegynes). More complex palps have hard sclerotized parts (sclerites, which include the conductor, embolus, tegulum, etc.) and soft parts (hematodochae), both of which can carry promiscuities, or apophyses. At rest, most structures are folded away, with the delicate sclerites protected. During mating, the hematodochae are filled using hydraulic pressure and the sclerites extended, as the male inserts his palp into the female epigynum. The intromittent portion of the palp must navigate through the complex ducts of the female to achieve sperm transfer, while other sclerotized projections on the palp help to lever the embolus into position during copulation. The actual copulation has been referred to as a “lock and key” mechanism because of the often complementary species-specific form of the genital structures.

The female genitalia (Fig. 2H–2N) of primitive spiders comprise a ventral fold within which a hidden opening leads into a single duct, or egg tube. This tube serves for sperm insemination and egg laying. In more advanced spiders (entelegynes), there are two openings, the egg tube and the genital tube, both hidden by an external structure, the epigynum. The epigynum is sclerotized and becomes visible upon maturity. The complex structures on the female epigynum guide the male palpal bulb through a convoluted set of internal ducts into the female’s genital tube, which leads to the sperm pocket where the sperm is stored.

**INTERNAL ANATOMY**

The central nervous system of the spider is located in the cephalothorax and consists of two main ganglia, the larger subsesophageal ganglion and the smaller, more anterior supnasophagal ganglion, sometimes
Paired venom glands occupy the upper portion of the chelicera in all spiders except the Uloboridae and, in many spiders, extend well into the cephalothorax about midway between the eyes and the supraesophageal ganglion. The digestive tract consists of a pharynx, esophagus, sucking stomach, and the beginning of the midgut in the cephalothorax, with the rest of the midgut, hindgut, and anus located in the abdomen.

The major respiratory organs are in the lower abdomen and are called “book lungs” because they resemble stacked sheets of paper. More primitive spiders have two pairs of book lungs, others have one pair and may also have a set of tubular tracheae. Within spiders, there has been a sequence of replacement of book lungs by tracheae, apparently in response to problems of circulation, with more active spiders having variably elaborate tracheal systems (Table I). The heart is a tube-like organ, suspended by muscles and ligaments along the dorsal

#### PHYSIOLOGY

**Feeding and Venoms**

Upon capture, a spider sinks its fangs into the body of its prey. At this point, the spider must paralyze, or otherwise restrict the movement, of the prey rapidly before it can eat it. Nearly all spiders use venom to incapacitate their prey. When envenomating prey, muscles surrounding the venom glands contract, forcing venom out of the glands and through ducts that carry the venom to the tips of the fangs and into the prey. Spider venoms are toxic cocktails of polypeptides and proteolytic enzymes that are quite effective for paralyzing the spider's (usually insect) prey. Because most of the polypeptides have evolved to act on nervous systems of arthropods, which use glutamate as a neurotransmitter, most spider venoms have little effect on vertebrates, but there are exceptions. Some venoms, like those of the widow spiders (*Latrodectus*), contain components that broadly affect vertebrate nervous systems. In humans, a black widow bite, which may go unnoticed when it happens, can result in several days of pain, muscle spasms, abdominal cramping, and weakness. More serious symptoms may include respiratory difficulty and hypertension. Deaths are rare, however, and antivenins are available in emergency situations. Other species, such as the brown recluse spider (*Loxosceles reclusa*), produce venoms that cause tissue death (necrosis) at the site of the wound. While these may not cause systemic effects like the black widow toxins, the wounds produced may take weeks or months to heal, and infection is a serious risk.

**Digestion and Excretion**

Spider digestion begins outside its body. Once the spider has disabled its prey with venom, silk, or both, it extrudes digestive enzymes into the prey and then, using negative pressure from its sucking stomach, reingests the soup of digestive enzymes and partially digested food. This is repeated until all of the prey’s soft tissue has been consumed. Once the liquefied food has passed through the sucking stomach, it enters the midgut where nutrient absorption takes place, with secretory cells producing digestive enzymes and resorptive cells absorbing food into vacuoles.

**Circulation and Respiration**

Although spiders have well-defined blood vessels, they lack capillaries and have few veins; thus, their circulatory system is basically open. The heart is suspended in the pericardial sinus, and blood enters the heart through paired slits called ostia, which open when the heart is at rest. The heart primarily pumps hemolymph from the abdomen forward through the aorta into the cephalothorax, supplying oxygen to the central nervous system and the skeletal muscles. Once depleted of oxygen, the fluid passes into two sinuses, which lead to the base of the abdomen where the fluid is reoxygenated by the book lungs and (if present) by tubular tracheae before pressure pulls it through pulmonary veins back into the pericardial sinus.

Unlike most insects, spider hemolymph has an oxygen-carrying pigment, hemocyanin. Hemocyanin is structurally similar to hemoglobin, but instead of iron it uses copper as its oxygen-binding metal, which can make spider hemolymph appear bluish green. Compared to hemoglobin, hemocyanin is less efficient (~5%) in oxygen transportation and is not concentrated in specialized cells.

**NEUROBIOLOGY**

The detection of touch and sound, mediated by vibrations, is the primary sense of spiders, although other senses may be well developed in some groups. These senses are discussed in detail in a 1985 book by F. G. Barth.

**Touch and Sound**

Spiders are notably hairy, and most of the various hairs on their bodies function as mechanoreceptors, sensing movement and vibrations from both the spider’s substrate (which may be the web, the ground, or vegetation on which the spider is situated) and the surrounding air. They also serve as touch receptors. The many stout hairs on the legs, cephalothorax, and abdomen, as well as the finer, more upright trichobothria, found only on the legs, are triply innervated and are involved in the localization and identification of potential prey. Additional mechanoreceptors are the slit sensilla and a variety of other proprioceptors, which respond to stresses in the exoskeleton caused by external vibration or by the spider’s own movements. The slit sensilla are found all over the exoskeleton, but may be arranged in groups to form “lyriform organs.” Together with the trichobothria, the slit sensilla/lyriform organs may be the functional equivalent of spider “ears.” Other proprioceptors include internal ganglia at leg joints and hairs that respond to joint movement.

**Taste and Smell**

Chemoreceptive hairs are localized mainly on the tarsi of the front legs, and in the palps, although some chemoreception may take place at the mouthparts. The hairs involved in chemoreception resemble tactile hairs, but are open-ended and S-shaped. Spiders respond to sex pheromones of conspecifics, and it is also likely that they use chemoreception to identify potential prey, enemies, and environmental change.
Sight

The “simple” eyes, or ocelli, have a single cuticular lens. The back of the eye contains the retina, which consists of visual cells (including the light-sensitive rhabdomeres) and pigment cells. The main eyes (always the AMEs) consist of a lens, vitreous body, and retina (which contains the visual cells), while the secondary eyes may also have a light-reflecting surface, the tapetum, behind the retina, which causes the well-known eye shine of spiders at night. The visual acuity of spiders depends on the shape of the lens and the number of rhabdomeres. For most species vision is poorly developed. Most web-building species rely almost exclusively on touch, with vision used to detect light and dark and (in a few species) direction of polarized light. However, vision is well developed in jumping spiders, with the AMEs having high visual acuity (acting like the fovea of the human eye), the remaining eyes having lower acuity but a broader field of vision and functioning for peripheral vision. In addition, jumping spiders have been shown to be sensitive to ultraviolet light. Some species show striking color dimorphism in ultraviolet light, suggesting a role in intraspecific sexual communication.

SILKS AND SPIDER WEBS

Spiders are unique among arthropods in their use of silks at all stages of their lives. Silks are produced in the abdomen in specialized silk glands, each of which yields a different kind of silk. The general structure of a silk gland is a tail area that secretes the liquid silk proteins into a sac-like lumen, or storage area. The lumen empties into a duct leading out to the spinneret spigots. The ducts are important in silk production because their tapered shape helps to orient the molecules relative to the axis of the thread to maximize strength, whereas the cells surrounding the duct draw off water from the oriented protein and turn them into solid silk fibers. The ducts of the different silk glands terminate at specific spigots in the spinnerets (Table II).

The various silks produced by spiders show different combinations of remarkable material properties, including high tensile strength, extensibility reminiscent of rubber, and resistance to decay. These properties have led to research in the pursuit of silk genes and techniques for spinning the translated products of these genes; genetically engineered spider silk may soon be found in parachutes, bulletproof vests, car bumpers, artificial ligaments, etc. At the molecular level, spider silks are a family of proteins made up primarily of a subset of amino acids (alanine, glycine, serine, proline, glutamine, and tyrosine) make up over 75% of the composition of characterized spider silks) arranged in a highly repetitive manner. The smallest repeating units of two to six amino acids are strung together into larger “tandem repeats.” This arrangement is thought to form secondary structures that determine the kind of silk produced. The overall structure can be compared to a composite material with stiff, stress-resistant crystals interspersed in an extensible, energy-absorbing matrix.

The most obvious use of spider silk is in web construction, but it is employed for many other purposes in the life of a spider, including the following.

Ballooning

Spiders are capable of producing silk as soon as they emerge from the egg, and two behaviors, the manufacture of a brood web and ballooning, are characteristic of newly hatched juveniles, or spiderlings. A brood web is made by some spiderlings upon emergence and for the earliest instars can serve as a communal nest for the young to catch prey together. Ballooning generally occurs once dispersal in the spiderlings has been initiated by developmental or environmental cues. The spiderlings let out a silk thread, which produces enough drag to catch the wind and carry the spider off, sometimes for great distances.

Dragline

Nearly all spiders trail a dragline behind them during locomotion. The dragline is extruded from the ampullate glands as the spider walks along or moves in its web, stopping occasionally to anchor the line with an attachment disc secreted by the piriform glands. The jumping spiders (Salticidae) may make seemingly reckless jumps, but are almost invariably anchored with a dragline, so a missed leap is seldom fatal. Dragline diameters vary from several hundred nanometers to several micrometers, depending on the size of the animal being supported. Draglines are stronger than any other known natural fiber, with the added ability to stretch 15–30% beyond their original length before breaking.

Egg Sac

All spiders use silk to protect their eggs. The silk covering of the egg mass may range from a few strands to a thick covering with multiple silks. The resulting silken cocoon can take on a huge variety of forms depending on the spider and the habitat.

Sperm Web

Silk is also used to make the male sperm web. Shortly after the final molt to maturity, a male spider makes a small web (sometimes just one or a few strands of silk), upon which he deposits sperm from the abdomen. He then places the tip of his palp into the sperm, which is drawn through the palp’s opening into the sperm duct, where it is stored.

Capture Web

The most remarkable use of spider silk is in the construction of snares for catching prey. In webs, silks can function both directly as a mechanical trap, to stop or slow potential prey, and indirectly as an extension of the spider’s sensory apparatus, alerting it to the trapped prey. A number of spiders can produce sticky capture webs, which come in two forms. The “hackedle” or woolly silk of cribellate spiders is sticky (akin to Velcro) because of its fine fibers. The silk is formed by rapid combing (by the calamistrum on the rear leg) of a silk produced from the cribellum, a field of fine openings in front of the spinnerets. In contrast, the web silk of ecribellate spiders usually has sticky globules, secreted by the aggregate glands, arranged along its length.

The type of web that spiders produce is often characteristic of a family, with forms including the two-dimensional orb, tangle (cobweb), sheet, and funnel webs (Fig. 4). Each of these webs has its variants as well; for example, orb webs can be oriented either vertically or horizontally or may be reduced, sometimes to a single section of a complete orb. The impressive body of literature on the form, function, and evolution of spider webs was reviewed by Eberhard in 1990.

Despite the fact that all webs serve the same basic function and despite the common characterization of spiders as generalist predators, the form of the silk of certain webs can be specialized for capture of a small subset of potential prey types. For example, many comb-footed spiders (family Theridiidae) make tangle webs with viscid threads extended to the substrate below, the last centimeter or two of which are coated with a sticky substance (“gum-foot lines”) and serve to snare cursorial prey. More specialized is the bolas spider,

an orb weaver whose “web” consists of a single strand of silk with a sticky droplet (bolas) at the end, which it uses to catch moths. In addition to these differences in silk form between web types, silks often have different functions within webs. For example, silk from the flagelliform glands makes up the core fibers of the capture spiral in orb webs and has properties quite different from those of the silks that form the web frame and radial elements. The remarkable property of this capture-spiral silk is its ability to stretch; it may more than double its length while absorbing the kinetic energy of a flying insect. In addition, the capture spiral recovers tension slowly, which prevents prey items from being flung back out of the web.

Web Decorations

One of the most conspicuous features of the webs of some orb spinners is the presence of a stabilimentum, a prominent silk line, cross, and/or spiral, at the center of the orb. The function of the stabilimentum is not clear, though it may serve to camouflage the spider, startle predators, or protect the integrity of the web from accidental damage.

RELATIONSHIPS AND TAXONOMY

Understanding of the relationships among different spider groups and between spiders and other arthropods has increased dramatically in the past two decades. Some portions of the spider tree remain unresolved, and additional morphological and molecular study will be needed to settle these uncertainties. Statements of phylogenetic relatedness between spider groups are based on a review of morphological data by Coddington and Levi in 1991, and all groups mentioned can be found on the summary cladogram (Fig. 5), unless otherwise noted.

Spiders are divided into three suborders, the Mesothelae, Mygalomorphae, and Araneomorphae, and 106 families. The Mesothelae (1 family, Liphistiidae, 2 genera, 40 species) are considered the most primitive of all living spiders, based on their external visible segmentation and location and number of spinnerets (all four pairs present, without a cribellum). The Mygalomorphae, recognized by the articulation of the chelicerae parallel to the body (paraxial), are also considered primitive; they are generally stouter-bodied and include the trap-door spiders and the impressively large tarantulas (family Theraphosidae) among their 15 families. Araneomorphs, the “true” spiders, represent over 90% of spider diversity. They can be distinguished from the more primitive spiders by the sideways (diaxial) articulation of their chelicerae. Paraxial and diaxial cheliceral orientations are also referred to as orthognath and labidognath, respectively. The most basal lineage of the Araneomorphae is the Paleocribellatae, consisting of one family, the Hypochilidae, in which the body plan is a mosaic of primitive and derived characters.

The rest of the araneomorphs belong to one of two clades, the haplogyneae and the entelegyneae, distinguished on the basis of the complexity of the female genitalia (Fig. 2). In the haplogyneae, the smaller group, the external female genitalia consist of a simple opening, or gonopore, tucked between the book lungs, with a single duct serving both the copulatory and the fertilization functions. Two well-known haplogyneae families are the spindly-legged Pholcidae (or daddy-long-legs spiders), common around and inside houses, and the Sicariidae, which may also occur in and around houses, and include the much-feared brown recluse spiders (Loxosceles reclusa), whose venom may cause necrotic wounds in humans. In the entelegyneae, the female genitalia are more elaborate, with separate fertilization and copulatory ducts and sclerotized epigynum. The most diverse and well-known entelegyneae spider families belong to the RTA clade, so named because of a retrolateral tibial apophysis on the male’s palp, and the oribicularia, which includes the orb-web builders and their relatives. The RTA clade is a huge, ecologically diverse group of spiders and includes about one-third of all described spider species. Many are web builders, for example the funnel-web spiders (Agelenidae). However, some of the most successful lineages have shifted to non-web-building hunting strategies, including the jumping spiders (Salticidae), in which the median tarsal claw is replaced by a tuft of tarsal hairs that facilitates a cursorial lifestyle. Salticidae also have greatly enlarged AME’s, giving them the best vision of all spiders. They use this vision to track prey and carry out unique jumping attacks with great accuracy and in mate choice when faced with flamboyant courtship displays. The crab spiders ( Thomisidae) are another family of two-clawed spiders with an interesting variation on the typical spider sit-and-wait game. Thomisids hide in the petals of...
flowers, where their bright colors often disguise them, and use their raptorial forelegs to capture visiting pollinators. Wolf spiders and their relatives (Lycosoidae) are also cursorial hunters, though they retain all three tarsal claws.

The Orbicularia includes some of the best known web spinners. In particular, the orb web is often considered to be the “classic” spiderweb—a two-dimensional sphere consisting of a frame, with radii projecting outward, and a spiral of sticky silk wrapped surrounding the center. There are three families primarily responsible for these orb webs, the cribellate Uloboridae and the Araneidae and Tetragnathidae, which have lost the cribellum. The orb design, once thought to be the “pinnacle” of web evolution, is now thought to have served as a point of departure for some successful groups (the “higher araneoids”) that make webs of quite different designs. The comb-footed spiders (Theridiidae) make seemingly disorganized cobwebs, often with viscid gum-foot lines as mentioned above. On the other hand, “bowl-and-doily” or money spiders (Linyphiidae) make dome-like sheets from which they hang on the lower surface; the viscid silk in these spiders dries up after being produced and serves to cement together the different layers of the sheet.

COURTSHIP, REPRODUCTIVE BEHAVIOR, AND GROWTH

Courtship

The first step in courtship involves maturation of the male spider, at which stage the palps have become modified and swollen for sperm storage and transfer. Once the palps are charged with sperm, the male sets out to find a receptive female. However, spiders are astute predators, and the male must overcome this propensity of the female if he is to mate. There is a huge array of courtship strategies that allow the male to approach. Most spiders employ some kind of vibratory communication during courtship. Among web-building spiders, the male often locates himself on the edge of the female’s web and gently plucks. It often takes hours, even days, until the female becomes receptive. Wolf spiders (Lycosoidae), although they do not have webs, make use of vibrational cues during courtship. Vibrations generated from stridulating organs are usually transmitted through the leaf litter. Visual cues, although used by wolf spiders, are most complex among jumping spiders (Salticidae). Male jumping spiders generally communicate courtship by performing a variably elaborate dance for the female, waving their often brightly colored legs and body to show off iridescent plumes. If successful, the male can extend his forelegs to touch the female before climbing on top of her.

In a number of species the female must adopt a state of complete immobility before the male can initiate copulation. In other species, the male waits until the final molt and can mate with the female immediately. In certain species the female is very much larger than the male and appears hardly to notice that the male is either approaching or copulating with her. Other males secure the female by wrapping her in silk prior to copulation. Species in the genus Tetragnatha have an unusual way of mating whereby the cheliceral fang of the female becomes wedged against a dorsal notch on the cheliceral surface of the male. The male then locks the female in place by closing his fangs over hers.

Copulation

Copulation involves the injection of sperm from the male’s palps into the seminal receptacles of the female, with the palps being inserted alternately into the epigynum. In some species, the palp breaks off and seals the epigynum. Once copulation has been completed, the male must escape from the female before her brief period of receptivity ends. If the male fails to escape in time, he can be caught and consumed by the female, although more commonly he escapes to mate again. However, the life span of a mature male is generally short, and many do not eat at all. Female spiders, on the other hand, are able to store sperm.
and so can produce fertile eggs long after copulation. Accordingly, females may survive for some time before egg laying is complete, and in many species they survive longer, to care for their offspring.

Egg Sac

Some time after mating, the female will deposit an egg sac. The eggs are always laid within a cocoon of silk. However, like courtship, there is a diverse array of egg sac types and behaviors that spiders use to protect their eggs. In most spiders, the female spins a layer of silk into which she deposits her eggs. She then covers the eggs with more silk. The covering may be scant, as in the daddy-long-legs spiders (Pholcidae). In other spiders the sac is very thick, with multiple silks, soft inside but tough and water resistant outside, as in many spiders of the family Theridiidae (e.g., *Latrodectus*). Egg sacs are also produced in a variety of colors, from white to yellow, green, or black, in pastel or vivid shades. Textures may vary from papery smooth to tufted and furry and shapes from flat to round or angular, with connections to the substrate ranging from a tight fixture to loosely suspended or pendulous. These colors and shades generally match the network of the egg sac. For example, it can be plastered on a twig (e.g., *Tetragnatha*), placed under a leaf or stone, wrapped in a leaf, or suspended in the web or retreat, either with a stalk (e.g., *Argyrodes*) or without. However, extended parental care has been documented in a number of spiders and has broad implications with regard to the origin of social behavior.

EGG SAC DEFENSE A number of female spiders guard their eggs closely until (or after) hatching. Such guarding is common among jumping, crab, sac, and ground spiders, and a variety of others, and can be critical for egg survival in, for example, the green lynx spider *Peucetia viridans* (Oxyopidae) and the Hawaiian happy face spider *Theridion grallator* (Theridiidae). In several groups of spiders, the females carry their eggs with them wherever they go. In particular, wolf spiders (Lycosidae) carry their egg sac attached to their spinnerets; fishing (Pisauridae) and giant crab (Heteropodidae) spiders carry their egg sac under the sternum; daddy-long-legs spiders (Pholcidae) carry their egg sac held in the chelicerae.

CARE OF SPIDERLINGS Maternal care in spiders, when present, often terminates after hatching, and the young disperse. However, female wolf spiders carry their young on their abdomen once they have hatched from the egg sac; fishing spiders build a “nursery web,” a large tent-like structure in which the spiderlings live while the mother stands guard. Among a few comb-footed and other spiders, care of the emergent spiderlings can develop to an extraordinary degree. This is true of the communal comb-footed spiders *Theridion saxatile*, *T. sisyphium*, and *T. grallator*, and *Anelesinus studiosus*. Females of the latter two species defend the egg sac aggressively and then capture prey for, and even feed, the young, which are unable to capture prey on their own. Providing the young with food appears to be the primary function of brood care once the spiderlings emerge from the egg sac. In addition to simply securing prey, a mother may feed her offspring by regurgitation or by laying “trophic eggs.” In some species she may even feed herself to her offspring, a process known as “matriphagy,” and in at least one species, *Amaurobius ferox*, the mother is known to expedite this process herself.

Dispersal

One of the most intriguing aspects of spiders is their dispersal. When spiderlings hatch, they are generally aggregated. However, on the first day with suitable wind speeds, they will frequently move up to the highest point they can find (e.g., the tip of a grass stalk) and let out silk which catches in the wind. As the spider lets out more silk, the pull of the wind on the silk becomes sufficient to allow the spiderlings to become airborne. Spiderlings can travel tremendous distances by ballooning and are frequently the dominant component of aerial plankton, although the family groups represented vary with locality. Linyphiidae comprise much of the fauna above land areas that have been examined, whereas Tetragnathidae dominate over oceanic areas. Because of their capacity to balloon, spiders are often the first to colonize unoccupied landmasses, whether cleared land or new islands in the middle of the ocean.

Growth

Spiders, like insects, have a rigid exoskeleton and must molt to grow; with three to nine instars (stages between molts) before reaching maturity. Spiders do not metamorphose: A first-instar spiderling looks similar to, though smaller than, an adult. Most spiders live for about a year, though mygalomorphs may live for 30 years.

SOCIALITY

Although most spiders are solitary and highly intolerant of others, there are several species that exhibit some form of social behavior, ranging from aggregations at a certain life stage to prolonged maternal care and even quasisociality or true sociality. Considerable controversy surrounds the origins of quasisocial and true social behavior in spiders, discussed in chapters of a book by Choe and Crespi published in 1997. It may have evolved through coloniality and the development of aggregations around an abundant resource. Alternatively, it may have arisen through extension of brood care into later instars. Many studies have examined the biology of social theridiids, including the formation of colonies and sex ratios in true social species.

Colonial Spiders

Some spiders (e.g., several species in the families Araneidae, Uloboridae, and Tetragnathidae) live in colonies, usually around an abundant food source. The benefits from such behavior include sharing silk support lines for prey capture, sharing prey that is not overall in short supply, and communication.

Subsocial Spiders

In subsocial spiders, there is both maternal brood care beyond the first few developmental instars that is typical of most spider species and an extended phase of tolerance among young within the maternal nest. However, these species live solitarily as adults. True sociality in spiders is thought to have evolved via the “subsocial pathway” by a prolongation of an early tolerance phase without dispersal. The subsocial route to sociality entails decreasing the genetic variance within breeding groups as a result of families staying in proximity.

True Sociality

True sociality appears to have arisen independently multiple times in spiders. Social spiders, unlike eusocial insects, have no castes that
Spiders are morphologically different or sterile and most individuals within colonies reproduce. In addition, social spiders show a female-biased sex ratio and high population turnover and inbreeding. Their breeding colonies are closed and new colonies are formed by splitting an existing colony, by a swarm of related females, or by single gravid females. High levels of inbreeding and relatedness among females bias the sex ratio toward the dispersing sex. So, unlike most spiders, males do not appear to disperse large distances in social species. Gene flow between established colonies is rare, and colonies show a high degree of genetic structure. It seems likely that sociality may be maintained by behavioral preadaptations that lead to tolerance and cooperation among colony members on the one hand and population structure on the other.

**CAMOUFLAGE AND MIMICRY**

**Crypsis**

Spiders have many enemies. In addition to other spiders, perhaps the most important predators are birds and spider-hunting wasps, both of which possess high visual acuity and color vision. Spiders can have specific adaptations for matching background colors (crypsis) such as flowers/leaves, grass/twigs, bark, underleaf surfaces, and the ground. In some spiders, the crypsis is extraordinarily close and can vary between individuals on different backgrounds. There are, for example, several species that are variable in color but always seem to match the bark on which they are living. Selection for crypsis in similar types of habitat has led to the repeated evolution of similar colorations in unrelated species. For example, spiders that live under leaves in the tropics are generally translucent yellow, often with dark leg joints that disrupt the outline of the legs. During the day these spiders lie flat against the underside of the leaf, thereby reducing shadows and becoming highly cryptic against the light transmitted through the leaf. Five unrelated spider species living in the same Hawaiian forests exhibit these adaptations for underleaf crypsis, as do at least four species from the forests of Panama. Within a single lineage, repeated evolution of similar cryptic coloration in different species has been found in a radiation of *Tetragnatha* spiders in Hawaii.

**Disruptive Coloration**

In some spiders the characteristic shape of the body is concealed, for example by bold, juxtaposed colors. These kinds of colors tend to be found where the propensity to wander over different backgrounds while searching for prey might preclude true crypsis. Crypsis *per se* may also be difficult in diurnal orb-spinning spiders. Some of these have developed mimetic resemblances to dead leaves and sticks but others have apparently adopted disruptive coloration.

**Mimicry**

Most studies of mimicry in spiders have been concerned with the imitation of ants, thought to be a form of Batesian mimicry. The spiders may gain some protection from predators through their resemblance to aggressive or unpalatable ants. The topic of ant mimicry has recently been reviewed by Cushing, in 1997. Spiders may also mimic a range of other organisms, alive or dead, and inanimate objects. For example, many *Cyclosa* spp. (Araneidae) build vertical “sticks” of prey remains within the web but leave a gap in the center, which is filled by the spider itself. Crab spiders (Thomisidae) mimic the color of flower heads very precisely and prey on pollinators that approach. Some spiders resemble bird droppings, which are attractive to insects. In the garden spider *Argiope argentata*, the visibility of both the contrastingly colored ventral and the UV-reflecting dorsal side of the opisthosoma may increase insect prey caught in the web.

**Apostatic Coloration**

At least some predators can develop search images, concentrating their search effort on more common forms of individuals of any species. This can result in polymorphism within a prey species. One of the best examples of this is found in *Theridion grallator* (Theridiidae) (Fig. 6). Within this species, there is a remarkable diversity of color forms, yet the frequency of color forms is similar in different populations, apparently maintained by bird predation.

**FIGURE 6** Some representative color morphs of the Hawaiian happy face spider *Theridion grallator*.

**HABITAT SELECTION**

How do spiders select a site in which to live? Many studies have demonstrated that there are clear associations between spider abundance and the structural diversity of the habitat, climatic regime, and prey availability. Most spiders are considered to be sit-and-wait predators, spending much time in locating a suitable site in which to wait and remaining there until its quality deteriorates. The time they remain at a site depends on their investment at the site. For species that do not spin webs, the investment is only the time spent finding the site.
Ecribellate orb-web spiders can regain most of their resource investment at a site by ingesting the web before abandoning the site. Among other web-building spiders, however, the investment at a site cannot be regained; it can only be decreased through reduction in web size. Movement from a site may be dictated by disturbance or web destruction, microclimate change, growth of the spider relative to structural requirements for web construction, and/or prey capture success.

In selecting a site, it is often not clear what aspect of the environment it is to which the spider is responding. It is possible for hunting spiders to move directly to their feeding site, at least when they can perceive air- or substrate-borne vibrations. Web-building spiders are generally confined to their web for prey detection so that movement from a web site is generally not directed, and to select a site they must “sample” a location by building a web. However, the main vibration receptors of web spiders (trichobothria) are basically the same as those of wandering spiders. Accordingly, web-building spiders may also be capable of perceiving vibrations mediated by the air or the substrate.

**PREDATION**

**Prey Capture**

For web-building spiders, prey are usually captured upon being trapped in the sticky threads. The spider will generally respond to the vibration of an insect caught in the threads by shaking the web, causing the insect to become more firmly stuck and allowing the spider to locate the position of the insect. The spider may then approach the insect, often doing so very rapidly, and wrap it in silk of various amounts depending on the size and strength of the insect. This approach and attack behavior varies, with some web-building species leaping upon and biting the prey even before it becomes firmly secured in the web. More specialized strategies have evolved in a number of web builders. For example, the ogre-faced spider (*Deinops*) holds its cribellate web, orb-like in form, between the two front pairs of legs; it uses the web much like a net, hurling it over prey that come close. Comb-footed spiders may use their gumfoot lines to catch crawling prey; the unsuspecting prey may either dislodge the tense lines, which springs them into the tangle of the web, or they get reeled in by the alerted spider.

For spiders that do not build webs, prey may be detected by air- or substrate-borne vibrational cues or, alternatively, at least in the case of jumping spiders, by visual cues. Cursorial spiders often jump on their prey without wrapping it in silk. However, certain groups have elaborate mechanisms for securing their prey. In particular, the spitting spiders (*Sycotidae*) have a high-domed cephalothorax, which contains venom glands connected to a posterior gland that secretes a sticky silk. The spider creeps up on its prey and, by rapid contractions of the muscles in the prosoma, ejects sticky silk and venom over the prey, which is then immobilized. One species of long-jawed spider in Hawaii has long tarsal claws that it uses to impale insects directly from the air. Other specialized mechanisms of prey capture are discussed below.

**Diet**

Spiders are exclusively carnivorous, although they are usually regarded as generalist predators, taking prey as they are encountered. However, their diet is dictated by the habitat in which they select to live, and habitat specialization can greatly restrict the dietary repertoire of many species. Even within a given habitat, species may specialize on prey, either through choice or because they exhibit specialized predatory behaviors. For example, species in the genera *Dipoena* and *Euryopis* (Theridiidae) are specialized for feeding on ants, while those in *Dysdera* (Dysderidae) appear to specialize on isopods, and pirate spiders (Mimetidae) and some *Argyrodes* (Theridiidae) feed on other spiders.

**Kleptoparasitism**

Kleptoparasitic spiders steal food from the webs of other, unrelated and usually larger web-building, spiders, which are also potential predators. They may form groups of up to 50 individuals around the web of a “host” spider and glean small insects from the periphery of the host spider’s web, eat the host’s silk, steal food bundles previously wrapped and left in the web by the hosts, or even approach a feeding host spider and then feed, undetected, next to the host spider. The most diverse collection of obligate kleptoparasites is found in the spider genus *Argyrodes* (Theridiidae), which contains at least 200 species, about 100 kleptoparasitic.

**Aggressive Mimicry**

Aggressive mimicry is mimicry that enhances the access of spiders to their prey. Perhaps the most interesting case of aggressive mimicry is shown by certain jumping spiders that can mimic the vibratory signals of a fly by plucking with their legs and palps on the web of other spiders. This may attract the occupant to the jumping spider close enough to be attacked. The best-studied species in this regard is *Portia fimбриata* (Salticidae) from Queensland. This spider preys on web builders with poor eyesight, which allows the araneophagous *Portia* to drum out a pattern of signals on the web that imitates the vibrations of the normal prey of the web spider. In contrast to the vibrational mimicry of *Portia*, the bolas spider (*Araneidae*) emits odors that mimic the pheromone of female moths to attract male moths to the vicinity. As soon as a moth flies within range, the spider launches its sticky bolas on a silk thread; if successful, the bolas hits and sticks to the moth, and the spider reaps in its prey.

**DIVERSITY AND CONSERVATION**

There are about 40,000 described species of spiders, though the actual number of species has been estimated at around 170,000. In common with insects, species diversity is highest in tropical regions, where knowledge of the biota is least. Also like other arthropod groups, spiders exhibit spectacular examples of adaptive radiation and local endemism in isolated situations, for example, the genus *Habronattus* (Salticidae) on the North American mountaintop “sky islands” and the genus *Tetragnatha* (Tetragnathidae) in the Hawaiian Islands. Studies of the Hawaiian *Tetragnatha* have shown how similar sets of distinct ecological types, or ecomorphs (“green” which sits on leaves; “maroon,” which is mostly on moss; “small brown,” among twigs; and “large brown,” on tree bark) occur on each island, and have arisen independently through convergent evolution. These island studies show how biodiversity arises in communities over evolutionary time. However, in almost every ecosystem, the number and diversity of spiders make them important in the management of ecosystems, whether natural or disturbed, agricultural or urban.

**Importance and Conservation in Agricultural Systems**

Spiders have been known to be important agents of insect pest control for hundreds of years. It is also well known now that chemical pesticides kill not only the insect pests, but also their major predators, in particular spiders. A review by Riechert and Lockley in 1984...
brought attention to spiders as potential agents of biological pest control. Manipulations of habitat structure have resulted in increased spider densities and concomitant decrease in insect pests. The effectiveness of spiders is often enhanced by the ability of the web to kill prey even in the absence of the spider and because many species practice wasteful killing (i.e., they kill more insects than they consume). Control of insect pests by spiders appears to be achieved most efficiently by using an assemblage of spiders (rather than specific species) and incorporating natural refuges in and around the crops. The particular methods that are best for enhancing the role of spiders in pest control in agriculture are: (i) conservation tillage and retention of stubble, preserving weeds and mulching; (ii) intercropping, provision of native vegetation within crops; and (iii) agroforestry, planting a combination of trees and food crops.

Importance and Conservation in Natural Ecosystems

We have little understanding of the precise role that spiders play in a given ecosystem. However, we do know that spiders are the dominant invertebrate predator in most terrestrial ecosystems and are also important as a food resource for other predators. Accordingly, they must inevitably play a key role in community dynamics. Studies on birds in natural areas have shown that spiders can comprise a significant proportion of the diet of many species, including a number of endangered birds. Spiders also have utilitarian value and have been used as model organisms for research in ecology, behavior, and communication. Moreover, there has been much recent attention on their potential for providing silk for materials science and supplying venom for medical and insecticide research.

Clearly, there is a huge need to augment taxonomic information on spiders, particularly in tropical areas, and to understand patterns of biodiversity. Pursuing this knowledge is imperative as we recognize the obvious importance of spiders in ecosystems, both as prey and as predators. Moreover, given the intrigue that spiders have long held in human society, such an undertaking can only lead to greater heights of fascination.

Stamps, Insects and

One of the major recent developments in philately (stamp collecting) is the popularity of “topical” or “thematic” collecting. The collector looks for anything that relates to the chosen theme. Popular examples are flowers, railroads, birds, sports, stamps-on-stamps, space, and insects. In a recent survey, butterflies and other insects on stamps ranked as the sixth most popular topic.

As of 1991, over 5000 stamps were issued by over 300 countries depicting over 1300 insect species (Fig. 1). Therefore specialization in types of insect being collected might be desirable, as it is with insect collecting itself. Subsets that could be selected as a specialty include butterflies and/or moths, apiculture, sericulture, malaria and other aspects of medical entomology, applied entomology, and noninsect arthropods. A “taxonomic” collection (in which the insect is the only real design) might be restricted to identifiable and named insects. Some, however, prefer to collect stamps with fanciful depictions, such as butterfly carnival costumes, a butterfly in the movie Bambi (on Bambi’s nose), or a “fly speck” insect in the beak of a bird. Still other philatelists specialize in mint (unused) stamps or canceled (used) ones, including “CTOs,” or stamps “canceled to order.” The CTOs are stamps with neat cancellations applied before the stamps are released, and the cancels are normally in one corner to avoid obscuring much of the
Stamps, Insects and

Stamps, Insects and

Philately consists of a number of “elements” (a term used in exhibiting). Mint stamps, used stamps, and CTOs are just the beginning. Other related postal items that can be collected and exhibited are as follows:

- **Cancel** The marking applied in the post office to show the stamp has been used.
- **Cover** An envelope with stamps and cancel attached.
- **First-day cover (FDC)** Cover canceled on the first day of the stamp’s issue, often with special cancels and a cachet (or illustration on envelope created to enhance interest and value) (Fig. 2).
- **Favor cancel** Cancel applied for a collector, not to carry mail.
- **Piece** Fragment of a cover, especially a large one such as from a package, but including stamp and cancel.
- **Meter cancel** A machine-applied indication of postage paid, often accompanied to the left by a picture or slogan and used in place of stamps.
- **Proof** A special impression of the stamp’s design used to check quality of design and color, with die proofs usually one color and often signed by the artist.
- **Essay** Original artwork submitted to the stamp-issuing authority for consideration for adoption (these are rare and usually unique; essays for designs that were never printed as stamps are especially rare).
- **Block** Symmetrical grouping of stamps, still attached to each other, with a block of four being the most common.
- **Plate block** Block with the selvedge (unprinted border) containing a plate serial number printed in the original pane of stamps.
- **Revenues** Stamps issued for fiscal purposes (postage stamps are sometimes applied to receipts in place of revenue stamps—an uncommon element to find).

**GETTING STARTED**

The first thing a beginner should do is get some help from someone who has experience in collecting stamps. The rudiments of philately, however, do not take long to learn. Knowledge of the terms just defined, and how to handle the different items is a good starting place. There are books and periodicals available as well. In North America, *Linn’s Stamp News*, a weekly newspaper, has pages of ads as well as columns on how to “do” philately. People at a local stamp club and/or stamp shop also can be helpful.

Knowledge about stamps and other postal subjects can be found in specialized books. Stamp values (mint and used) in North America usually follow the *Scott Standard Postage Stamp Catalog*, illustrated and revised yearly.

The American Philatelic Society (APS), which publishes a monthly magazine, *American Philatelist*, has departments including library and expertization services. The American Topical Association (ATA) is for thematic collectors and publishes the bimonthly *Topical Time*. This organization is divided into specialty groups. The Biology Unit, which publishes a newsletter called “Biophilately,” serves, among others, insect philatelists. The Philatelic Lepidopterists’ Association publishes a newsletter called “The Philatelic Aurelian” (an aurelian is a butterfly collector), which features updates on new butterfly and moth issues (identifiable ones only). Finally, by using key words “stamps” or “philately,” one can find many sources of material and information via any search engine on the World Wide Web.

A collector of insect stamps might wish to subscribe to a new issues service run by a dealer who mails new issues to subscribers each month. Such services are listed in the ad section of *Linn’s*, and many philatelists are glad to recommend their favorites. New issue dealers

**FIGURE 1** This pane of 20 different 33-cent stamps showing U.S. insects and spiders was issued on October 1, 1999 (Scott Catalog item 3351a-1).

**FIGURE 2** First-day cover for U.S. 4-cent malaria eradication stamp issued on March 30, 1962. Design of envelope (cachet) and special first-day cancel make the “FDC” a favorite collectible (Scott Catalog item 1194).
very likely can supply older stamps from their stocks of previous issues. There are many stamp club shows and occasional bourses (shows without exhibits, with dealers only), where collectors can fill checklists from dealers’ stocks and buy supplies—and meet with other philatelists.

Insect philately keeps alive the thrill of the hunt and the love of the beauty and order of an insect collection. However, for many participants this kind of collection takes less storage space, needs no fumigating, and can keep giving enjoyment when entomologists’ more active years of insect collecting are behind them.

Sterile Insect Technique
Jorge Hendrichs, Alan Robinson
Joint Food and Agriculture Organization/International Atomic Energy Agency Programme, Vienna, Austria

The sterile insect technique (SIT) is a biologically based method for the control of key insect pests. Wild female insects inseminated by released, radiation-sterilized males do not reproduce, and repeated releases of the sterilized insects lead to a reduction in pest population numbers. Effective control using sterile insects is achieved when they are used systematically as part of area-wide integrated pest management (AW-IPM) programs. SIT is species-specific, nonpolluting, and resistance-free. Since the original concept was developed in the United States in the 1940s, SIT has been used successfully for screwworm flies, tsetse flies, fruit flies, and moths. Technical progress in behavioral ecology, mass rearing, strain improvement, global information, positioning and monitoring systems, and aerial release, combined with economies of scale and a growing demand for pest-free and low-pesticide agricultural products in local and international trade, have increased the use of SIT in AW-IPM programs. These programs, by decreasing insecticide use, have also facilitated the use of biological control agents against secondary insect pests.

HISTORY OF SIT
In the 1940s E. F. Knipping, working with Cochliomyia hominivorax, a screwworm fly causing myasis in livestock and humans, developed the concept of using insects to control themselves (i.e., autocidal control) by reducing their reproductive capacity. Two developments helped to translate this concept into reality: the development of mass rearing procedures for this insect and the identification of an efficient method to sterilize insects. In 1946 H. J. Muller was awarded the Nobel Prize for his discovery of induced mutagenesis, showing that Drosophila fruit flies could be sexually sterilized by radiation-induced dominant lethal mutations. Knipping and colleagues confirmed that screwworm flies could be sterilized by radiation without significant damage to their mating ability or diminishing their longevity. The first decisive test that confirmed the feasibility of SIT was implemented in 1954 on the island of Curaçao, close to Venezuela. This success so impressed the cattle industry in Florida that in 1957 ranchers persuaded the U.S. Congress to fund a statewide eradication program. A rearering facility, with a capacity to produce 75 million sterile flies per week was established in 1958 at Sebring, FL, and, following an AW-IPM program, the last endemic screwworm case was recorded in Florida in 1959. Subsequently, the program was expanded, with new rearing facilities at Mission, TX, and eventually in Tuxtla Gutierrez, Chiapas, Mexico. Release of sterile screwworms as part of an AW-IPM approach eradicated this pest from North and Central America (Fig. 1). Currently, a permanent “sterile fly barrier” consisting of the aerial release of 40 million sterile flies per week in eastern Panama protects Central and North America from reinvasion.

PRINCIPLE OF SIT
The SIT involves industrial-scale mass production of insects in large biofactories (Fig. 2). Insects for release are sterilized by ν-radiation with a dose that induces sterility but which does not significantly impair the ability of the sterile males to fly, mate, and transfer sperm to wild females. The sterile insects are released on a sustained and area-wide basis to target the total pest population in the defined area and in sufficient numbers to achieve appropriate sterile-to-wild insect overflooding ratios. This leads to a reduction in the proportion of fertile matings in the wild population and results in its decline. The success of the SIT relies on the ability of the released sterile males to transfer to the wild females functional sperm that succeeds in fertilizing the eggs. The number of times a female mates is not important, providing that the sperm from the sterile male is competitive with the sperm from the wild male. Knipping devised a simple mathematical model to describe the SIT and, despite some limitations, it provides a valuable set of equations to demonstrate the principles of SIT. As the wild population declines and the number of released insects remains constant, both the proportion of sterile matings and the rate of suppression increase, that is, the efficiency of SIT is inversely density dependent, and once a wild population begins to decline, the rate at which this occurs increases with time. Also, compared with classical biological control, SIT is: (1) species-specific, (2) no exotic species are introduced, and (3) because of sterility no new strains of the target pest can become established.

Requirements for SIT Application
Not Stand-Alone Technology

Using any single technique in isolation is unlikely to be successful for managing insect populations and integrated approaches are needed. This caveat applies especially to the use of sterile insects, because wild insect populations are often of such magnitude that it is impractical to consider releasing sufficient sterile insects to cause the initial population decline. The strength of the SIT is at low population densities and to be effective it relies on a variety of suppression

**FIGURE 2** Mediterranean fruit fly mass rearing facility at El Pino, Guatemala.
measures, depending on the particular insect species targeted. A frequently used strategy is to initiate the application of the SIT when the natural population is at low density due to adverse climatic conditions.

Area-Wide Approach

The effectiveness of integrating compatible control methods is increased by coordinated implementation over contiguous agricultural and nonagricultural areas that targets the total pest population rather than just the protection of individual crops or animal herds. This approach is critical because already-mated females that move into an area under release are largely unaffected by the presence of sterile males. The area-wide concept has to be seen not just in terms of the agricultural community, but in terms of the whole ecosystem, including human activity, in the target area.

Selection of Target Species

Most insect pest species are sexually reproducing and therefore, in theory, are amenable to the SIT. However, in reality the technique has to be used selectively. Probably the first criterion is the status of key pest in a particular ecosystem. It also makes very little sense to develop the SIT for a species for which effective, acceptable controls are available. As the technique relies on the release of large numbers of adult sterile insects, it is important that this stage is not damaging one, for example, house flies or cockroaches.

Knowledge of Population Dynamics, Ecology, and Mating System

It is very important to understand population dynamics in terms of density dependence and life-table parameters, to define the spatial and temporal ecological parameters of the target population, and to estimate population size. It is also essential that the natural mating system is well understood, so that the mating behavior of the released males can be monitored to ensure that no significant changes accumulate during mass rearing.

Colonization, Mass Rearing, and Sterilization

An efficient, economical, and biologically acceptable method for the mass production of competitive insects is essential. Mass rearing insects for many generations in large biofactories imposes major selection and adaptation forces on all aspects of insect biology. These forces inevitably reduce the competitiveness of the insect in the field. The art of mass rearing is to find an acceptable compromise between the efficiency of mass production and the overall quality of the insects. Beyond a certain point it is not possible to compensate for the poor insect quality by releasing more insects. Radiation sterilization procedures must be subject to stringent quality control procedures to ensure that all the released insects are irradiated with the required dose.

Quality Control

As in any industrial system, quality control in terms of production (diet ingredients and equipment), process (mass rearing procedures and conditions) and product (sterile insects) plays a major role in determining success. For most programs a detailed set of standard operating procedures is in place, which provide some confidence as to the quality of the insects being produced. The use of mating tests under seminatural conditions to assess sexual competitiveness and continued compatibility of released insects with the wild population is essential.

STRATEGIC APPLICATIONS OF SIT

Eradication

The SIT has the unique capability of eradicating pest populations providing that certain ecological and regulatory conditions are met. The inverse density-dependent action of the SIT is very effective in removing the last individuals of the target population. Eradication is often assumed not to be an option if the target population is not isolated. However in some cases, isolation can be created by making use of natural barriers to pest distribution and by applying the technique on an area-wide basis. The screwworm eradication program relied on this “rolling carpet” approach (Fig. 1). The maintenance of the pest-free areas requires adequate quarantine measures and continued surveillance. The SIT is also one of the most powerful tools to eliminate incipient outbreaks of exotic invasive species.

Prevention

Sterile insects can be released into an area on a continuous basis to avoid the establishment of an exotic invasive pest. As the release of sterile insects is environmentally benign, this can be done in almost any situation. It is generally carried out where the risk of invasion is high and quarantine activities are not sufficient to prevent invasion.

Containment

Containment programs use barriers of sterile insects to prevent the spread of exotic invasive pests that have become established. Some of these programs become permanent and stationary but others advance, or retreat and eventually disappear.

Suppression

The concept of using sterile insects within integrated suppression programs to replace the use of insecticides is gaining increasing acceptance as the cost of sterile insects is decreasing and concerns about environmental and food safety are increasing. Integrating the SIT for suppression removes the need for expensive and difficult to maintain quarantine systems and the continuous nature of a suppression program is stimulating the commercialization of the SIT.

OPERATIONAL PROGRAMS

In the past decades, SIT has been applied in over 20 countries on 5 continents to control some 15 insect species that account for an important part of agricultural losses worldwide. Table I provides an overview of the mass rearing facilities currently in operation in support of SIT programs against fruit flies, screwworms, tsetse, and moths.

Fruit Flies

Few pests have a greater impact on world trade in agricultural products than tephritid fruit flies. Maintaining or achieving a low pest prevalence or even pest-free status has therefore been the goal of many large operational programs. The Mediterranean fruit fly, Ceratitis capitata (“medfly”), was removed from invaded areas in southern Mexico, and for 30 years a sterile fly barrier across Guatemala has maintained Mexico and the USA medfly-free. Similarly, Chile eliminated medfly from northern Chile, Argentina from Patagonia, and Peru from its two southernmost valleys. The melon fly, Bactrocera cucurbitae, was eradicated from southern Japan, the Queensland fruit fly, B. tryoni, from Western Australia, and some Anastrepha species from northern Mexico. Rather than having to eradicate outbreaks of exotic medflies, often on an annual basis, California and Florida maintain permanent...
Sterile Insect Technique

Screwworms

In addition to the current sterile insect barrier against *C. hominivorax* across the Darien region in eastern Panama (Fig. 1), an eradication project is under way in Jamaica, and others are under assessment for Cuba, Hispaniola, and areas of South America. As part of an Australian contingency planning to maintain Australia free of the Old World screwworm (OWS), *Chrysomya bezziana*, a pilot mass rearing facility was established in Malaysia.

Moths

Field programs have been in operation since the 1960s for prevention or suppression of pink bollworm, *Pectinophora gossypiella*, in various cotton areas in California and currently this pest is being targeted for eradication from all cotton areas in the southwestern USA and northwestern Mexico. There is also a successful program for codling moth, *Cydia pomonella*, suppression in apple production areas in British Columbia, Canada, and other countries, for example, Argentina, Brazil, and South Africa are planning programs against this pest. New Zealand recently eradicated outbreaks of the Australian painted apple moth, *Teia anartoides*, and programs are under way to suppress the false codling moth, *Thaumatotibia leucotreta*, in South Africa and to contain the advancing cactus moth, *Cactoblastis cactorum* along the Gulf of Mexico coast of the USA.

For moth pests there is considerable potential for expanded implementation of inherited sterility, involving the release of sterile female moths and substerile male moths which induce sterile offspring in subsequent generations. This approach has shown a significant synergistic interaction with conventional biological control agents.

Tsetse

Tsetse flies and the diseases they transmit (sleeping sickness in humans and Nagana or animal trypanosomiasis in livestock) severely limit sustainable agriculture in many areas in sub-Saharan Africa. Following SIT pilot projects in Burkina Faso and Nigeria, and breakthroughs in mass rearing and aerial release technology, an area-wide program succeeded in 1996 in eradicating *Glossina austeni* from the island of Zanzibar. This success galvanized the political environment and under the auspices of the African Union, a Pan-African Tsetse and Trypanosomiasis Eradication Campaign (PATTEC) was planned.

</table>

The most advanced program is located in the Southern Rift Valley in Ethiopia. A large rearing facility has been constructed which will produce 1 million sterile males/week when completed. Field suppression activities have started and trial releases were initiated in 2009.

ECONOMIC BENEFITS

Direct benefits of screwworm eradication to the North and Central American livestock industries are estimated to be over $1.5 billion/year, compared with a total investment over half a century of close to $1 billion. Mexico protects a fruit and vegetable export market of over $3 billion/year through an annual investment of ca. $25 million, and medfly-free status has been estimated to have opened markets for Chile’s fruit exports of up to $500 million. Eradication of tsetse has resulted in major socio-economic benefits for Zanzibar. When implemented on an area-wide basis and with economies of scale in the mass rearing process, the use of SIT for suppression is cost competitive with conventional control, in addition to its environmental benefits.

FUTURE TRENDS

Increasing constraints to the use of insecticides will enhance the need for alternative control strategies for both native and exotic pest insects. SIT can be an increasingly important component of these strategies especially when used in area-wide suppression programs that will also open the door to commercialization. However, this will depend on expanding the technique to other pest insects and improving its efficiency, requiring substantial investment in research and development related to all components of the technology. This could range from customers simply purchasing sterile flies and developing their own release and monitoring systems to the purchase of a complete SIT package. For the medfly, there are now commercial companies operating in Israel and South Africa. Along with commercialization, harmonization of quality control procedures for production, process and the product will need to be reinforced, in particular international protocols to measure the mating success of the sterile males with wild females in the field. SIT programs will also benefit tremendously if genetic methods can be developed that enable only male insects to be reared as has already been shown for the medfly (Table 1). Also more appropriate artificial diets for larvae, and hormonal, nutritional, microbiological, and semiochemical treatments for adults, could make major contributions through improved economy and insect quality.

In many insect species, transgenic technology has been developed with the aim of improving the SIT. A first application could be to replace fluorescent dye markers with a transgenic marker; these are available and are currently undergoing evaluation. A second application is to develop molecular methods for genetic sexing. A caveat to the field use of transgenic insects will be regulatory approval; however, recently the North American Plant Protection Organization has developed a standard which provides a framework for the release of sterile transgenic insects for plant protection.

DIR-SIT Database [http://www-ididas.iaea.org/IDIDAS/default.htm].
around the stylets. Other hemipterans mostly probe intracellularly, may or may not secrete salivary sheaths, and ingest from a wider variety of plant or animal tissues. Most sternorrhynchan are phloem feeders, and thus have a diet rich in carbohydrates (sugars) and deficient in amino acids and other nitrogenous compounds. Generally, there is an intimate association with intracellular bacteria, called endosymbionts, which are housed in special tissue (bacteriomes or mycetomes) and contribute nutrition to the insect host.

Sternorrhynchan excreta is a sticky, sugary liquid called honeydew that may contaminate foliage; it serves as a substrate for the growth of black sooty mold fungi that can impede photosynthesis and reduce plant vigor. Honeydew often attracts ants that may protect the sternorrhynchans from their natural enemies, especially predatory and parasitic insects.

Adult jumping plant-lice, adult whiteflies, and many adult aphids have two pairs of wings. All adult female scale insects and most adult female aphids are wingless (apterous). Adult male scale insects usually resemble small flies (order Diptera) in having the hind wings reduced to small balancers (halteres), although sometimes the halteres are absent; in a few scale insect species males are apterous. The absence of wings in adult females of scale insects and many aphids means that the immature stages (nymphs) of these groups can be difficult to distinguish from their adults.

Evolutionary interpretations of morphology have suggested either that whiteflies are sister to aphids + scale insects with psylloids sister to all three, or that whiteflies + psylloids are sister to aphids + scale insects. Phylogenetic analysis of nucleotide sequences (of small subunit rDNA, also called 18S rDNA) supports the former hypothesis that Psylloidea is the sister group to the other sternorrhynchans. Some of the morphological traits shared by Aleyrodoidea and Psylloidea are ancestral features (plesiomorphies) such as two, similar-sized, tarsal segments (the first tarsal segment is reduced or absent in aphids and coccoids) and good jumping ability. Also both groups have pedunculate eggs, that is, one end of the egg has a short stalk or narrow extension (Fig. 1). Whiteflies, aphids, and scale insects all have Malpighian tubules (filamentous excretory organs) reduced in number or absent and their gut often has a well-developed filter chamber that allows most of the water in ingested sap to bypass the absorptive part of the midgut. In contrast, psylloids have four Malpighian tubules (an ancestral feature found in other Hemiptera) and possess only a rudimentary filter chamber.

**PSYLOIDEA (JUMPING PLANT-LICE)**

Worldwide, there are only about 2500 species of psylloids or jumping plant-lice, often collectively called psyllids despite there being 6 included families. The greatest abundance and species richness of psylloids are found in tropical and south temperate regions, where many new species await discovery. In the Northern Hemisphere, however, fewer than 100 species occur in Britain and only about 300 species are known from North America. Adult psylloids are small, ranging in length from 2 to 8 mm, and superficially resemble miniature cicadas or small leafhoppers, but are distinguished by their multi-segmented antennae. Their common name derives from the ability of adults to jump backwards when disturbed. All psyllids feed by sucking sap, mostly of woody dicotyledonous plants. They ingest sap from a variety of tissue sources, including phloem, xylem, and mesophyll parenchyma, and thus are not phloem-specialists like most other sternorrhynchans. Psylloid nymphs are either free-living, gall-inducing, or lerp-forming (Figs. 2–4); lerps are manufactured sugary and starchy covers or scales under which the nymphs live. Some species of jumping plant-lice are pests of cultivated plants, with damage resulting from loss of plant sap, toxins in the saliva, and/or disease caused by transmitted microorganisms.
Evolution and Classification

Historically, the classification of psyllids was based on the well known, but relatively species-poor, Holarctic fauna. Expanding knowledge of the diverse tropical and south temperate faunas has led to better understanding of relationships and hence a more natural classification. The system used here is based on that of White and Hodkinson, presented in 1985, with emendations suggested by D. Burchardt and D. Hollis. In this system, 6 families of extant psyllid species are recognized (with each of the first 4 families listed here having 10 or fewer genera): Calophyidae, Carsidaridae, Homotomidae, Phacopteronidae, Psyllidae (includes the Aphalaridae, Liviidae, and Spondyliaspididae, recognized by some authors; about 120 genera), and Triozidae (over 40 genera).

Many species of the predominantly Neotropical and tropical/subtropical Asian family Calophyidae feed on plants in the Anacardiaceae. Carsidaridae is almost entirely pantropical in distribution and is restricted to the related plant families Bombacaceae, Malvaceae, and Sterculiaceae. The Homotomidae is predominantly from the Old World tropics and feeds almost exclusively on figs (Moraceae: Ficus). The Phacopteronidae occurs in tropical Asia, Africa, and the Americas and many species feed on plants in the Meliaceae. The Psyllidae is the largest family, but it is heterogeneous morphologically. A large number of Psyllidae are associated with legumes (Fabaceae), although the speciose subfamily Spondyliaspidinae specializes on Eucalyptus (Myrtaceae). Many species of Spondyliaspidinae produce lerps or induce leaf galls that they plug with lerp substance. The Triozidae is cosmopolitan and has wide-ranging host preferences. The fossil record of at least stem group Psylloidea extends back into the Permian (>270 mya) and the extant families probably diversified in the Cretaceous. Relationships among psyllid higher groups (families and subfamilies) are largely unresolved.

Life History

Reproduction is always sexual. There are seven life stages (Fig. 1); the egg, which is stalked; five nymphal instars; and the adult, with the males and females in about equal numbers. Eggs are either completely inserted into plant tissue or inserted by just the stalk (peduncle) through which water is absorbed. Depending on species, each female may lay as few as 20 to more than a thousand eggs. In cold temperate regions, psylloids frequently have only a single generation per year (univoltine). In warmer climates, development continues year round, often with several to many generations per year. Species with multiple generations per year (polyvoltine) are more likely to have population outbreaks than univoltine or bivoltine species.

Morphology

Identification is based primarily on adult characteristics, with males being most important for species-level determinations, although features of the female terminalia are sometimes used. The fifth-instar nymph can materially aid identification in many groups. Adult males and females are morphologically similar, except that males are often smaller, have different genitalia, and thus different abdominal shapes. In a few species the sexes are color dimorphic, and there is often a seasonal color dimorphism. Body coloration or the pattern of markings can be diagnostic of species. The size and shape of the head and its appendages provide useful taxonomic characters. Immature psylloids are usually characterized by flattened dorsoventrally and many secrete wax.

Behavior and Ecology

Adult psylloids disperse over short distances by jumping or flying, but many species may travel long distances on air currents. The adults of a number of species are naked (Fig. 2), although often covered in waxy body secretions, and live exposed on the shoots of their host plant. Others induce galls of various complexity from simple pits in leaves to round or elongate structures that totally enclose the nymphs (Fig. 3). Some lerp-formers also (e.g., Glycaspis) produce copious honeydew, whereas others (e.g., Cardiaspina spp.) produce very little or none.

Most species are specialist feeders as nymphs, with many species restricted to one plant genus or even a single species, and often to particular host structures (leaves, new shoots, etc.) or growth stages (either young or mature foliage). Most psylloids develop on dicots, a few on monocots or conifers, but none on ferns. In cool-temperate climates, some species overwinter as adults on evergreens, returning to their true hosts in spring, when eggs are laid. Host selection appears to involve taste rather than olfaction. Adults frequently are less discriminating than nymphs and thus host plants are defined as those on which nymphs can complete their development to adulthood. Nymphal feeding frequently damages the host plant (e.g., premature leaf senescence), whereas adult feeding usually causes little injury. Many psyllid species have a mutualistic association with honeydew-seeking ants.
Some species of jumping plant-lice have become pests of plantation trees (e.g., *Ctenarytaina* spp., *Glycaspis brimblecombei*, *Eucalyptolyma maideni* and *Blastopsylla occidentalis* on *Eucalyptus* spp., all now established in California). Two of the world’s most serious citrus pests are the Asian citrus psylla, *Diaphorina citri* (Psyllidae), and the African citrus psylla, *Trioza erytreae* (Triozidae). Other than the citrus pests, the most economically important psylloids of temperate and subtropical areas feed on cultivated apple and pear trees (e.g., *Cacopsylla mali*, *C. pyricola*, and related species of Psyllidae). Members of the Triozidae occur as pests on persimmons, cultivated fig, carrots, potatoes, tomatoes, and other Solanaceae. The leucaena louse, *Heteropsylla cubana* (Psyllidae), a Caribbean native, has become a pest of the tropical leguminous tree *Leucaena leucocephala* in several parts of the world where it is planted for a range of purposes. Recorded parasitoids are mostly psylloid specialists, but there is little evidence of parasitoid-host specificity. Worldwide a number of wasp species, especially from the families Encrytidae (e.g., *Psyllaephagus* spp.) and Eulophidae (e.g., *Tamarixia* spp.), are parasitic on psylloids. In Europe, cecidomyiid flies (*Endopsylla*) are parasitic on some adult psyllid pests (e.g., *Cacopsylla* spp.).

**ALEYRODOIDEA (WHITEFLIES)**

Members of the Aleyrodoidea derive their common name from the powdery, white waxy secretion preened over the body and wings of most adults. The Greek root “aleuro,” found in many whitefly names, means “flour.” Adults of both sexes are tiny, delicate, and free flying. They have a wingspan of up to 11 mm, but usually about 2 mm, and resemble minute moths. They are a familiar sight to many home gardeners because, when infestations are heavy, the adults will fly up en masse if disturbed from the foliage of favored host plants. The group occurs worldwide although few whiteflies occur in the cooler temperate regions. About 1560 species have been described, with perhaps two or three times as many species awaiting collection and formal taxonomic study. All adults and nymphs feed by ingesting phloem sap and several species are serious plant pests.

**Evolution and Classification**

All whitefly species belong to one family, Aleyrodidae, which is divided into just two accepted subfamilies, the Aleurodicinae and Aleyrodinae. The Aleurodicinae contains 20 genera and 130 described species, mostly from Central and South America, and the Caribbean. All other species (in around 140 genera) belong to the Aleyrodinae, which has a mostly pantropical and warm-temperate distribution. The two subfamilies are defined on both adult and nymphal features, whereas species and genera are diagnosed mainly or entirely on characters of the fourth-stage nymph, usually known as a puparium. The Aleurodicinae generally have larger adults (the largest is a centimeter long) with more complex wing venation than those of the Aleyrodinae. Whiteflies are rarely fossilized because they have small and delicate bodies. The known fossils are preserved mostly in Cretaceous and Tertiary amber with one record from the Upper Jurassic. The two modern subfamilies probably diverged during the Cretaceous.

**Life History**

Reproduction is usually sexual with fertilized eggs producing females and unfertilized eggs producing males (arrhenotoky or arrenotokous parthenogenesis); unmated females lay only haploid eggs. A few species produce only females (thelotoky or thelotokous parthenogenesis). There are six life stages (Fig. 5): the egg stage; the first instar, in which the nymph is often called a crawler; the second and third instars, in which...
the nymphs are sessile; the fourth instar or last nymphal stage at the end of which the insect is usually referred to as a “pupa,” or a “puparium,” although it is not a true pupa as seen in holometabolous insects as there is no molt to a totally non-feeding, “resting” stage; and, finally, the adult (or imaginal) stage (Figs. 6 and 7). After the emergence of the adult, the molted cuticle (exuviae) is often called a “pupal case.”

Whitefly eggs are usually attached to the underside of leaves by a short stalk, the pedicel, through which water is absorbed from the plant. Eggs are often laid in circles or arcs (Figs. 6 and 7), and egg batches are frequently conspicuous because of a dusting of white wax. First-instar nymphs usually settle adjacent to the eggs from which they hatch. In most species, development occurs on the underside of leaves. After the first molt, the nymphs become immobile and cannot move to a new site if food quality deteriorates. During the fourth instar, feeding ceases and the insect transforms into the winged adult.

Species such as the greenhouse whitely (Trialeurodes vaporariorum) can breed continuously in greenhouses or indoors. Those whitefly species that have economic impact have several to many generations per year, but many other species have only one or two generations annually.

**Morphology**

Historically, puparial rather than adult characteristics have been used to recognize species and genera, although adults do display many taxonomically useful characteristics. Seasonal dimorphism, as seen in many aphid species, is uncommon but occurs in the puparia of a few temperate species. Male and female whiteflies are similar in appearance except for their genitalia, but males are often smaller than females of their own species. The body and wings are dusted with powdery wax emanating from large, paired wax plates on the underside of the abdomen and thus adults most commonly appear whitish or grayish even if the body color is yellow, brown, red, or if they are darkly sclerotized. The male genitalia (the claspers or parascapes and the intrumittent organ or aedeagus) are more informative taxonomically than the female terminalia (ovipositor and associated structures), especially in the Aleurodicinae.

Nymphs of all stages (Fig. 5) superficially resemble scale insects (Coccoidea) and frequently have ornate wax secretions in later instars. The anus of all life stages opens in a special dorsal pit, near the posterior end of the abdomen, called a vasiform orifice which comprises a depression, a dorsal flap (the operculum), and a tongue-shaped lingula that is used to flick away each droplet of anal excreta (honeydew) before it can accumulate. The lingula is the only mobile body part in instars II–IV.

Puparia are mostly oval or elongate-oval, 0.5–2 mm long, their color varying from transparent to white, brown, or black (Fig. 8). Waxes contribute to puparial protection and may be invisible or highly ornate, white or grayish, but mechanical color (iridescence) may be beautiful blue, turquoise, bottle-green, or pearly-white. Visible wax may form dorsally and/or as a marginal fringe.

**Behavior and Ecology**

Adult males of a few whitefly species, especially *Bemisia tabaci* and *T. vaporariorum*, have been observed to display courtship behavior prior to mating, including abdominal oscillations that result in acoustic signals caused by substrate-borne vibrations. Females may produce sex pheromones to attract males. Adult whiteflies will fly short distances if disturbed from their host plant. They also undertake

longer migratory flights, which are air-current dependent because whiteflies are weak fliers. They have complex host-finding and host-orientation behaviors, at least involving attraction to particular colors, especially yellow or yellow-green.

Whiteflies feed from plant vascular tissue and all feeding stages produce copious quantities of honeydew; yet few species are ant-attended. Most whitefly species appear to be oligophagous, with few known to be monophagous; however, polyphagous species are the most documented because they are most likely to be pests. Whitefly host plants are almost entirely flowering plants (angiosperms), especially woody dicots; relatively few species of whiteflies are found on herbs, grasses, ferns, or palms, upon which plant groups they do appear to specialize.

The morphology of the puparia of some species has been shown to vary depending on the species of plant that is acting as host, probably because of differences in the nature of the plant surfaces. For example, in B. tabaci the size, number, and position of setae of the puparia can be correlated with leaf hairiness. These phenotypes of the same species often look very different from each other and this phenomenon can confound identification. This variation is especially a problem among polyphagous species in the genera Bemisia and Trialeurodes.

**Notable Pest Species and Their Control**

The feeding activity of many whiteflies damages their host plants and some species are known or believed to transmit diseases, especially those caused by viruses. The most serious aleyrodid pests are those of orchards (especially citrus), greenhouse crops, and some ornamentals such as orchids and aroids, and a few pest species are almost cosmopolitan in distribution. The past two decades have seen an increase in the pest status of certain whiteflies, probably because of the development of aggressive strains that are more fecund, more efficient virus vectors, and/or have broader host ranges. Successful whitefly control depends upon an appropriate integrated pest management program (IPM) in which natural enemies are protected or augmented. A number of groups of parasitic wasps (particularly Eulophidae and Aphelinidae) specialize on whiteflies and useful predators include some ladybird beetles (Coccinellidae). Whiteflies also are attacked by pathogenic fungi, especially Aschersonia species.

One of the most important pests is the polyphagous tobacco or sweet potato whitefly, B. tabaci, which occurs predominantly in tropical and subtropical regions and on protected crops elsewhere. It feeds on numerous fiber, food, and ornamental plants, and damage is exacerbated by its ability to vector more than 70 different viruses. B. tabaci exists in many biotypes or strains, and one virulent form is known as biotype B or the silverleaf whitefly.

Other important whitefly pests include the cosmopolitan and polyphagous greenhouse whitefly, T. vaporariorum, the spiralling and giant whiteflies (Aleurodus dispersus and A. dugesi, both Neotropical natives), Siphoninus phillyreae (perhaps of Middle Eastern origin), Parabemisia myricae (originally from Japan), the Indian grass-feeding species Vásárdípus (formerly Aleurocytobus) indicus, the citrus woolly whitefly (Aleurothrixus floccosus, endemic to the Americas but now established in Africa and south-east Asia), and Trialeurodes citri and Singhiella (formerly Dieuleurodes) citrifolii (widespread pests of citrus).

**Evolution and Classification**

The Aphidoidea contains about 75 species, in eight genera, divided between two tribes. The Phylloxerini has seven genera, feeding mostly on oaks (Fagaceae: Quercus), or hickory and pecans (juglandaceae: Carya), but with one pest species on grape vines (Vitaceae: Vitis). The Phylloxerini has a single genus associated with the willow family (Salicaceae). The Phylloxeridae is probably the oldest extant family, although only one fossil (Palaeophylloxera from the Lower Miocene) is known. Many phylloxerid species induce galls on their host plants; only a few species are host alternating.

Conifer woolly aphids, the Adelgidae, comprise 2 genera and about 50 species and are entirely Holarctic in distribution. Adelgids induce galls on their primary host, spruce (Picea), and move to other conifers as alternate hosts.

The largest family, Aphididae, has been divided into a number of subfamilies and tribes, but different authors frequently use different classifications. The 10 subfamilies listed here are those recognized in the monographs by Blackman and Eastop: Anoeciinae (34 species), Aphidinae (over 2700 species), Calaphidinae (including the Drepanosiphinae, Thelaxininae, and several other groups treated as subfamilies by some other authors, 400 species), Chaitophorinae (164 species), Eriostomatinae (formerly Pemphiginae, 319 species), Greenideinae (151 species), Hormaphidinae (176 species), Lachninae (355 species), Mindarininae (5 species), and Phloeomyzinae (1 species).

The oldest aphid fossils are from the Triassic (at 220–210 mya) but aphids may have originated in the Permian. Phylogenetic analysis of molecular data suggests that aphids underwent a rapid radiation into the current tribes after transferring from gymnosperms to angiosperms some time during the Upper Cretaceous. Furthermore, the ancestral aphid probably had a simple life cycle with host alternation evolving independently in each of the families and perhaps several times within the Aphidoidea.

**Life History**

There are six stages in the life history of an individual aphid: the egg or embryonic stage, four nymphal instars, and the adult. Aphids have evolved a range of annual or biennial life cycles and other adaptive strategies that often vary within as well as among species. This complexity can complicate the study of aphid biology. Furthermore, aphidologists have developed a special nomenclature for the different life stages and types. Life cycles are called holocyclic (Fig. 9) if a sexually
Host alternation may occur as part of a 1-year (annual) life cycle, as in many Aphididae, or as a 2-year (biennial) life cycle, as in Adelgidae. In the Aphididae, in temperate climes, alternation is frequently obligate, overcoming the twin problems of poor sap flow in woody primary hosts in summer, and the death of many herbs in winter.

Morphology

Aphids are highly polymorphic, with most species occurring in several different forms, or morphs. In individuals destined to be winged as adults, the wing buds are usually apparent after the second nymphal molt. Most common aphid species are soft-bodied and green in color, but dark and brightly colored species and a few hard-bodied species also occur. Nymphs superficially resemble a pterous adult except that they are smaller in size and never have wings. Aphids usually have two prominent, tube-like structures on the posterior dorsum of the abdomen, called siphunculi or cornicles, which can discharge defensive lipids and alarm pheromones. In some species, these structures are reduced to pores, or are absent. Another structure unique to the aphids is a posterior projection on the tip of the abdomen called the cauda, equivalent to the lingula in whiteflies. Protective wax secretions are common.

Behavior and Ecology

Both adults and nymphs can disperse short distances by walking, but migration of alatae occurs by both active flight and passive long-distance movement on air currents. Apterous and nymphs frequently

---

are transported by attendant ants. In sexual morphs, males are attracted to females by sex pheromones released from glands on the female’s legs. Altruistic behavior has been reported in the few aphid species that have a sterile soldier “caste,” which is a special kind of first- or second-instar nymph that defends the family group against competitors and natural enemies.

Aphids generally live in aggregations (Fig. 11) on the buds, stems, and/or leaves of their host plants. Some species induce galls and a few others live underground on roots. Almost all aphids are phloem feeders, producing copious quantities of honeydew, and thus often are attended by ants. Some aphids feed from both phloem and parenchyma tissue, and adelgids are largely parenchyma feeders. In general, monoecious aphids are quite host specific, with each genus being associated with a particular host-plant family and each species with one genus or species of host plant or at least closely related plant genera. In host-alternating species, however, the primary and secondary hosts are usually unrelated and the specificity to the primary host is generally higher than to the secondary host(s). Pest aphids, especially those of agricultural crops, often feed on plants in a number of unrelated families.

**Notable Pest Species and Their Control**

Infestations of aphids can grow rapidly to enormous size and cause plant debilitation through nutrient deprivation, but even small numbers of aphids can transmit viruses to uninfected plants. Pest aphids often are more polyphagous than non-pest species and frequently are species exotic to the area where they are of most economic concern. Cosmopolitan pest species are frequently anholocyclic, that is, reproducing continuously by parthenogenesis on their crop hosts, and thus are particular pests in the tropics.

One of the most notorious aphidoid pests is the grape phylloxera, *Daktulosphaira vitifoliae* (Phylloxeridae), which induces galls on *Vitis* species, including the viticulturally important *V. vinifera*. The main method of control is the use of resistant grape rootstocks.

Genera of Aphididae that contain significant pests of crops include *Aphis*, *Brachycyrtus*, *Brevicoryne* (Fig. 11), *Dysaphis*, *Macrosiphum* (Fig. 10), *Myzus*, and *Rhopalosiphum*. The species listed below all transmit plant viruses. There are a number of serious *Aphis* pest species, including *A. craccivora*, *A. fabae*, and *A. gossypii*. Other pests include *B. brassicae* (Brassicaceae), *M. euphorbiae*, *M. ascalonicus*, *M. cerasi*, *M. persicae* (whose secondary hosts include a range of economically important plants), *R. maidis* (a worldwide pest of cereal crops), *Pineus* species (Adelgidae, on pines), *Cerataphis fransseni* (Hormaphidinae, on coconut and other palms), *Cinara* species (Lachninae, on conifers), and *Eriosoma lanigerum* (Eriosomatinae, on apple branches and trunks).

The most common aphidophagous predators are ladybird beetles (Coccinellidae), lacewings (Neuroptera), some hoverflies (Syrphidae), a few gall midges (Cecidomyiidae, especially the widespread *Aphidoletes aphidimyza*), and certain predatory bugs (Anthocoridae). Wasps of the large family Aphidiidae and several genera of Aphelinidae are endophagous parasitoids of Aphididae; Adelgidae and Phylloxeridae are not parasitized.

**COCCOIDEA (SCALE INSECTS)**

The scale insects (also called coccoids) occur worldwide. They are mostly small (less than 5 mm long) and often cryptic in habit although others are highly visible (Fig. 12). There are estimated to be almost 8000 species. Many scale insects are economically important pests of agriculture, horticulture, and forestry. Male scale insects display complete metamorphosis, whereas female development is paedomorphic (adults resemble nymphs). A number of taxa display remarkable diversity in their genetic systems (e.g., parthenogenesis, hermaphroditism, and paternal genome elimination) as well as in chromosome number, sperm structure, and types of endosymbioses.

**FIGURE 11** An aggregation of *Brevicoryne brassicae* (Aphididae) on cabbage flower shoot, England. (Photograph by J. H. Martin.)

**FIGURE 12** Hermaphroditic adult of the cottony cushion scale, *Icerya purchasi* (Monophlebidae), on *Grevillea juniperina*, New South Wales, Australia; note the long, fluted ovisac emanating from the ventral abdomen of the insect. (Photograph by P. J. Gullan.)
The name “scale insects” derives both from the frequent presence of a protective covering or “scale” and from the appearance of many of the female insects themselves. Most species produce a waxy secretion that covers the body either as a structure detached from the body (a scale or test) or as a secretion that adheres to the body surface. Some coccoid species have been used as sources of candle wax, lacquers such as shellac, or dyes. Scale insects are more diverse in terms of major evolutionary lineages (families), species richness, and morphology than any of the other sternorrhynchan groups.

**Evolution and Classification**

Scale insects have been assigned variously to 20 or more families, but the family-level classification is controversial. Often the Coccoidea is divided into two major, informal groups, the archaeococcoids (or archaeococcids) and the neococcoids (or neococcids). The extant archaeococcoids comprise the Margarodidae *sensu lato* (with about 440 species and now treated as 11 families including Margarodidae *sensu stricto*, Matsucoccidae, Monophlebidae, and Xylococcidae), Ortheziidae (ensign scales; almost 200 species), Putoidae (about 60 species of *Puto*), Carayonemidae (4 species), and Phenacoleachiidae (2 species). Collectively, the above 15 archaeococcoid families only number approximately 100 genera and 700 species. Some of the morphological features that define the archaeococcoids occur more widely in the Hemiptera and monophyly of archaeococcoids is uncertain.

The neococcoids, which comprise all of the other extant families (usually 17 are recognized) and most of the species of scale insects (about 7000), are a monophyletic group characterized by derived features, including a chromosome system involving paternal genome elimination, and loss of abdominal spiracles. Among neococcoids, most families (except the Eriococcidae) are well characterized morphologically. In contrast, relationships among families are largely unknown or not supported well by available data. The three largest families of neococcoids, in order of size, are the Diaspididae (armored scales; about 2400 species; Fig. 13), Pseudococcidae (mealybugs; about 2200 species; Fig. 14), and Coccidae (soft scales; about 1150 species; Fig. 15). The other neococcoid families are the Eriococcidae (felt scales; ca. 360 species), the three pit scale families—Asterolecaniidae, Lecanodiaspididae, and Cerococcidae—totaling about 350 spp., Kerriidae (=Tachardiidae, lac insects; about 90 species), Kerresidae (gall-like scales; about 90 species), Aclerdidae (about 60 species), and 7 smaller families, in order of size—Conchaspididae, Halimococcidae, Stictococcidae, Beesoniiidae, Dactylopiidae (cochineal insects), Micrococcidae, and Phoenicococcidae—totaling about 100 species.

The oldest described fossil scale insects are from the Lower Cretaceous but the group is at least of Triassic and probably of Permian age. Archaeococcoids comprised the earliest lineages with the neococcoids apparently diversifying in conjunction with flowering plants.

**Life History**

The reproductive repertoire of scale insects includes hermaphroditism, several kinds of parthenogenesis, and six major types of sexual chromosome systems. In the vast majority of coccoid species, the males are functionally (because of inactivation or elimination of paternal chromosomes), and sometimes actually, haploid.
Each individual female scale insect has four or five growth stages (Fig. 16): the egg, two or three immature (nymphal) instars, and the adult (imaginal stage). The female either lays eggs (oviparous) in a cavity under her body or in a waxy covering (ovisacs; Fig. 12) that may be attached to her body; or she retains the eggs in her reproductive tract until they are ready to hatch (ovoviviparous). The mobile first-instar nymphs, called crawlers, are the main dispersal agents for Coccoidea; other immature instars generally are sessile. Adult females may live for an extended period (months to several years).

After hatching from the egg, male scale insects have a total of four immature or pre-imaginal instars including their own specially derived form of a complete metamorphosis (holometaboly) involving one or two pupa-like stages (Fig. 16). These are called the prepupa and pupa, and develop either under a scale cover or test or inside a waxy cocoon or test that is produced by the second-instar nymph. Neither the pupa-like instars nor the adult males feed; adult males are short-lived (at most a few days) and have limited time to seek out female and male and identification is based almost entirely on the long-lived adult female. Adult females (Figs. 12, 14–16) are sac-like without a well-defined head, thorax, or abdomen, and they are paedomorphic, perhaps due to neoteny, that is, the adult resembles an immature individual. Adult females are wingless, may or may not have legs, but usually have well-developed mouthparts. The anus opens posteriorly and usually is surrounded by a chitinized ring and often anal plates (Fig. 15) or anal lobes flank the opening. Species that have a scale cover (e.g., armored scales; Fig. 13) usually incorporate in it the dorsal part of the cast-off cuticle from the previous growth stage. If the body wax is of the adhering type, then it may vary from a thin translucent sheet (many soft scales) to a thick, wet mass (e.g., wax scales), a cottony secretion (e.g., some monophlebids; Fig. 12) or a powdery, white dusting (many mealybugs; Fig. 14). Species that produce waxy tests (e.g., felt scales) often also have a dusting of powdery body wax. Wax is produced by epidermal glands and is exuded from a great variety of cuticular pores and ducts, and sometimes also from glandular setae. Typically the body also is covered in setae that may be hair-like, spine-like, or other shapes, often with several types present on each species.

Adult males resemble small, delicate flies (Fig. 16) and have a distinct head, thorax, and abdomen. Most have a pair of membranous fore wings and a pair of vestigial hind wings (balancers or halteres), although adult males of some species are wingless. The mouthparts of the prepupa, pupa, and adult males are reduced or absent. Crawlers (Fig. 16) are usually ovoid or elongate-ovoid and flattened dorsoventrally. Their antennae, legs, and mouthparts are well developed and various kinds of pores, ducts, and setae are present on the body and its appendages; often a fringe of setae surrounds the body margin.

**Behavior and Ecology**

The first-instar nymphs either seek suitable feeding sites on the natal host plant or disperse on the wind; some crawlers display behaviors that increase their chances of becoming airborne. Adult males probably locate their sessile conspecific females using sex pheromones but the presence of these chemicals has been demonstrated experimentally for very few species.

Scale insects primarily feed from either the phloem or parenchyma, and their host associations range from monophagous to polyphagous. Sap removal is the main cause of plant damage, but a few species (especially of mealybugs and armored scales) also transmit plant pathogens and/or toxins that may further reduce plant vigor and eventually kill the host. Furthermore, most scale insects (except armored scales and a few others) produce honeydew and are ant-attended; associations are usually facultative but a number of obligate ant–coccoid relationships have been described.

Curiously, cochineal scales (*Dactylopius* spp.) and certain mealybugs and lac insects have been used as biological control agents for particular noxious weeds; for example, cochineal insects can assist with the control of prickly pear cacti, *Opuntia* species.

**Notable Pest Species and Their Control**

Some scale insects are serious plant pests, especially of perennial agricultural plants. They can cause damage to nut and fruit trees, forest or plantation trees, glasshouse plants, woodyamentals, houseplants, and sometimes to sugarcane and even grass in lawns. Pests are usually either polyphagous or oligophagous. The cryptic habits and small size of most scale insects means that they may not be detected until plant damage is substantial. Also, if populations on plants are low, they can be notoriously difficult to detect during quarantine inspections. Most pest scales belong to the Diaspididae, Coccoidae, and Pseudococcidae, but a few significant pests belong to other families, such as the Monophlebidae (especially polyphagous *Icerya* species; Fig. 12), Eriococcidae, and Asterolecaniidae.
The most important predators of scale insects are ladybird beetles (Coccinellidae; especially species of Rodolia, Chilocorus, and Cryptolaemus). The main parasitoids of scale insects are chalcidoid wasps, especially species of Aphelinidae (e.g., species of Aphytis, Encarsia, and Cocophagus) and Encyrtidae (e.g., species of Anagyrus, Leptomastix, and Metaphycus), although some scale insects are attacked by flies that may be either parasitic (e.g., Cryptochetidae) or egg predators (e.g., a few Cecidomyiidae).

### Stored Products as Habitats

Rudy Plarre
Federal German Institute for Materials Research and Testing

Wendell E. Burkholder
University of Wisconsin

The protection of stored food against attack by insects and molds has been a necessity since the dawn of agriculture, or perhaps since humans began to manufacture primitive clothing and tools for daily use from plant or animal material. Protection of stored products, thus, has a tradition of tens of thousands of years and is documented in the earliest records of history.

Stored food and other products of plant or animal origin provide a habitat with shelter, food, and breeding sites for insects (Fig. 1). Worldwide losses from these postharvest insects and other food pests are estimated to be from a few percent in developed countries to 20% in an average year in some developing countries. Under certain storage conditions, 50–100% of food is lost.

![FIGURE 1 Traditional storage facility for grain in China.](image)

Several hundred insect species are associated with stored products. Most are beetles (Coleoptera) or moths (Lepidoptera), with their parasitoids being wasps (Hymenoptera). However, there are only about 100 species of economic importance. These can be divided into two main categories: species infesting dry botanicals, mainly but not exclusively grain seeds and their products, and scavenger species infesting animal products (meat, furs, wool, feathers, etc.). Very few pest insects can feed and breed successfully on both plant and animal material.

**ECOLOGY OF STORED-PRODUCT INSECTS**

The storage environment can be regarded as a human-made, simply structured, unstable ecosystem. All trophic levels of a typical ecosystem are represented. However, the system is not self-sustaining, and there is a unidirectional flow of energy and biomass.

**Trophic Levels in a Storage Environment**

The harvested and stored parts of the plants or the processed material are regarded as the producers (or the first trophic level) and contain the energy that was captured by the crops in the field. The primary consumers of the second trophic level in stored cereals are insects that infest the intact grain kernel. Most numerically dominant are the grain weevils of the genus Sitophilus (Curculionidae) (Fig. 2), the grain borers Rhyzopertha dominica (Fig. 3) and Prostephanus truncatus (Bostrichidae), and the grain moth Sitotroga cerealella (Gelechiidae). Primary consumers provide routes of entry for secondary consumers, such as Tribolium spp., that feed on the waste...
stored products as habitats

products or on debris, the frass, provided by the primary consumers. However, because damaged grain and grain dust are always present, secondary consumers can also exist without primary consumers.

The oxidation processes of the stored commodity and the respiratory activity of primary and secondary consumers generate heat and moisture that affect the microclimate. “Hot spots” may occur, which favor microbial growth. Certain microbial fungi further enhance conditions favorable to primary and secondary consumers. At this stage secondary and tertiary consumers become difficult to separate. Finally, the way is paved for the third trophic level of decomposing fungi, yeasts, and bacteria.

Predators and parasitoids of stored product insects are frequently encountered in highly infested commodities. Some of them are very closely associated with prey or host. Others are less specific: most parasitic wasps, for example, parasitize a number of different host species.

Carnivorous or scavenger species are typically found on stored commodities of animal origin such as dry meat or fish, wool, hair, and furs or products made out of these such as clothing or carpets. For example, dermestid beetles of the genera Dermestes, Anthrenus, Attagenus, or Trogoderma and the tineid moths Tineola bisselliella and Tinea pellionella are the most common insects in households. Scavengers feed on dead insect parts as well, which is why they are often found in stored products of plant origin that are infested with phytophagous insects.

Because of the weblike interactions of the different trophic levels, it is difficult to place insect species in specific categories. Their roles may be granivore, carnivore, fungivore, predator, parasite, and scavenger. These roles, together with the microflora and the environmental factors temperature and humidity, result in ongoing fluctuations of physical parameters, species succession, changes in population densities, and continuous degradation of the stored commodity.

Feeding Habits and Damage

Primary and secondary insect pests of stored foodstuff are polyphagous, with a general preference for either dry plant material or material of animal origin. Under a different perspective, these pests can also be classified into internal and external feeders. Internal feeders are species that penetrate the intact outer coating of seeds either as feeding or ovipositing adults or as freshly hatched larvae. External feeders graze on the surface of stored foodstuff, on already damaged material, and on debris. Nevertheless, they almost all have a cryptic feeding habit that is probably a result of their negative phototaxis. The larvae of the Indian meal moth, Plodia interpunctella, the most common stored-product moth worldwide and also frequently encountered in households, prefers undisturbed and darker places wherever suitable food is available.

The most obvious damage caused by stored-product insects is the destruction of food destined for human consumption. In addition to their capability to cause tremendous losses, insects contaminate the commodity with frass, feces, exuviae, and corpses. The accumulation of filth may lead to the rejection of the stored material. Except for some tenebrionid grain beetles infected with a certain tapeworm, stored-product insects have not been shown to transmit human pathogens or diseases. However, some of their by-products can be highly allergenic to humans.

Environmental Factors

Temperature and relative humidity usually determine the limits of insect infestations in stored products. The range of temperature in which stored-product insects are active lies between 8 and 41°C. Reproduction and larval development above or below these limits are not possible, and the individuals can survive extremes only in diapausing or hibernation stages. Some species are more cold-hardy or heat tolerant than others. Relative humidity also is important because it directly influences the moisture content of the foodstuff. The relative humidities to which pest insects have adapted range from near 0 to close to 100%, with typical optimal conditions being from 60 to 75%. Temperature and relative humidity of the microclimate can be actively influenced through the metabolic activity of aggregated individuals. Light is less important than temperature and humidity as a factor influencing the survival of stored-product
BEHAVIOR OF STORED-PRODUCT INSECTS

In addition to physical parameters, the behavior of stored-product insects is greatly influenced by semiochemicals. Living organisms, grain, microflora, insects, and mites, as well as decaying matter, produce an array of volatiles that combine with the oxygen, nitrogen, and carbon dioxide of the system. For example, enzymatic reactions in stored seeds produce unsaturated fatty acids that are highly attractive to a number of pests. Catabolism of decaying plant and animal matter enables pest insects to locate suitable feeding and breeding sites. Fungi have a distinct odor that is attractive to fungivorous species but repellent to others at high concentrations.

Intra- and interspecific communication is directed by a number of pheromones and allelochemicals. For example, spacing and oviposition pheromones are found among bruchids marking already infested seeds. These compounds are repellent to conspecifics. Spacing pheromones of certain species not only act on conspecifics but also repel nonconspecifics and thus act as allomones.

Sex pheromones, nearly always produced by the female, attract mates. These pheromones comprise specific compounds or a highly specific combination of compounds. Aggregation pheromones, typically found in species with long-lived adults, are produced by males and attract conspecifics of both sexes. Certain compounds of some aggregation pheromones are not species specific, and there is cross-attraction, especially among closely related species. In most cases, foods synergize the effect of aggregation pheromones. Although aggregation pheromones increase the likelihood that an individual will find a mate among aggregated conspecifics, the role of these substances as mating pheromones is not necessarily obvious.

Several parasitoids and predators make use of volatiles to locate hosts and/or prey, and under certain circumstances pheromone components may act as allelochemicals. Specialists that parasitize or prey on a single host species, a very narrow range of related host species, or specific developmental stages are attracted to specific kairomones emitted by their host or prey.

ORIGIN OF STORED-PRODUCT INSECTS

The origin of stored-product insects can be examined from three viewpoints: first, from a practical or physical point of view, asking for the natural reservoirs from which the insects spread into the storage system and seeking to learn how they invade a particular commodity; second, from a phylogenetic point of view, examining the ecological and behavioral preadaptations that made it possible for insects to shift from an original or primary habitat to a relatively recent, human-made habitat; and finally, from a historical point of view, searching for the geographic origins of the various insect species that infest stored commodities, which today are considered to be distributed worldwide.

Preadaptations and Natural Habitats

Insect species capable of surviving in stored commodities generally have some biological strategies in common. Species infesting stored products are not monophagous; rather, stored-product insects are food opportunists. For example, the cigarette beetle, Lasioderma serricorne, and the drugstore beetle, Stegobium panicenum, are perhaps the most ubiquitous of all stored-product pests, but all others also feed and breed on a variety of products. Almost all species found in human-made storage systems also can be found outdoors.

Natural breeding sites of stored-product insects can be sheltered niches where seeds and nesting material were gathered by rodents, birds, or other insects. Dermestids, ptinids (spider beetles), and teneids (clothes moths) are frequently found in empty rodent or bird nests where they feed on hairs, feathers, feces, pellets regurgitated by birds of prey, and food debris brought in or left by the previous occupants. Carrion is a food source as well for some species.

Stored-product insects typically have the ability to survive a long time without food. When environmental conditions are favorable and resources are available, stored-product insects reproduce over prolonged periods and have a rapid population growth rate, exploiting resources maximally. Dispersal is regulated by population density, and most stored-product insects are good fliers, which is essential for locating patchily distributed food and breeding habitats. Therefore, the following preadaptations help insect species to exploit the resources of stored-product systems: a range of natural reservoirs, a range of food habits, ability to survive in the absence of food, a wide range of tolerance for physical factors in the environment, and a high reproductive rate at optimal conditions.

Additionally important for consumers of dry foodstuffs is the ability to conserve water. Pest insects have to be either tolerant of low humidity and moisture content, able to recycle metabolic water, or able to influence and alter microclimatic conditions. Several species, in which the adults feed, tend to aggregate at spots suitable for feeding and breeding. Such aggregation is not incidental but a result of male-produced pheromones that are attractive to conspecific males and females. This behavior raises the question of the evolutionary advantage for males producing pheromone that attracts not only potential mates (conspecific females) but also potential competitors (conspecific males). It is thought that male-produced aggregation pheromones originally served to attract a mate. If this is correct, the use of the pheromone by other males of the same species then evolved secondarily, presumably allowing them to locate resources and assembled females. This would result in a fitness gain only for the intruding males.

An alternative explanation for the production of aggregation pheromones could be that the primary role of the male-produced aggregation pheromone was to attract and congregate conspecifics to overcome host defenses or unsuitable climatic conditions. Because males and females can serve equally well in this respect, the pheromone emitter benefits from attracting beetles of either sex.

To infest dry foodstuffs or stored commodities successfully, stored-product beetles certainly do not have to overcome host defense systems. However, in natural habitats, such as under bark or in wood, stored-product beetles most likely benefit from, and rely on, aggregation pheromones to weaken the host and make the habitat more suitable. This behavior can be observed in non-stored-product species closely related to postharvest pests in the Tenebrionidae, Curculionidae, and Bostrichidae, which partly feed and breed on physiologically active host plant parts. Where seeds and other harvested products are usually stored under low temperatures and rather dry conditions, the aggregation pheromones may serve to congregate groups that alter the microclimate. Such areas of higher temperatures and humidity may provide favorable conditions for insect development.

Not all insects that infest dry foodstuff have aggregation pheromones. In those that do not, there is a tendency of the larvae to aggregate. For many species, development is maximized at an optimal density of individuals. Individual fitness declines as the population shrinks or enlarges. For example, the eggs of many bruchids are deposited in clutches. Ovipositing females in the pyralids are guided to breeding sites by mandibular gland secretions produced by conspecific larvae. (A larval pheromone from mandibular glands is responsible for...
an optimal spacing, thus regulating population density.) Many aggregation pheromones also serve as guides to ovipositing females.

**Temporary Changes in Habitats**

The evolutionary origin of most stored-product insects remains speculative. However, autecological studies indicate a more or less xylophilous origin, under bark or in decaying wood, for most species. Omnivorous and partly predatory feeding habits could have allowed those species to invade animal nests in the same habitat or close by. These nests and the materials within could have provided good sources of otherwise scarce carbohydrate- and protein-enriched resources. In the same way, at the beginning of agriculture more than 10,000 years ago, insects could have gained access to storage bins in granaries constructed of infested timber. This kind of behavior can be observed in *Prostephanus truncatus*, the larger grain borer, which can survive in a variety of wooden building materials often used for simple granaries in tropical and subtropical countries. When the new harvest is brought in, this beetle readily invades the stored commodity, returning to its xylophilous habit when the alternative enriched food source declines. Other insect pests associated with stored products also frequently commute between the stored commodity and their cryptic life in cracks and crevices of the storage facility, where they feed on debris.

**Geographic Origin and Worldwide Distribution**

Today most stored-product insects are worldwide in distribution, and it is difficult to trace species to specific geographic origins with certainty. Global trade of food and other commodities, and the past lack of quarantine regulations, dispersed most storage pests with the products they had infested. Despite their cosmopolitan distribution, not all storage insects are established worldwide or occur outside warehouses or granaries. This is especially true in the colder parts of the world. *Callosobruchus maculatus*, for example, does not survive winters in the Northern Hemisphere unless inside heated storage facilities. For some species it is impossible for climatic reasons to successfully survive as nonsynanthropic populations.

The association of certain insects with humans most likely began in prehistoric times, probably contemporaneous with intensified agriculture and the domestication of animals. Phylogenetic, ecological, and historical evidence suggests that the majority of stored-product insects originated in the tropical and subtropical parts of the world. These centers of origin were also the centers of Neolithic agriculture.

**PROTECTING STORED PRODUCTS AGAINST PEST INSECTS**

Some of the most modern approaches to keeping stored food from spoiling are based on historical and traditional methods modified by today's technology. The storage of commodities under low oxygen atmospheres, to slow down the biological decay mechanisms, was in principle already used in ancient underground and hermetically sealed storage facilities of the Old World. The same effect occurs in modern grain facilities that are fumigated with modified atmospheres enriched with nitrogen and carbon dioxide. The ancient Egyptians intermixed ash with grain, which acted as abrasives on insects' cuticle, causing desiccation. Today, inert dusts on a base of diatoms are used, and by a slightly different mode of action these additives cause the insects to desiccate. The Egyptians added specific herbs and spices to the commodities to repel pest insects. Sulfur was one of the first fumigants for stored product protection. The insecticidal property of burning sulfur was known in the New Kingdom around 1000 B.C. Toxic fumigants have the great advantage over contact insecticides of fully penetrating the commodity and therefore also killing internal infestations. However, the application of fumigants and pesticides is not risk free. Environmental concerns and the potential danger to human health have led to a steady reduction of registered fumigants and contact insecticides. Incorrect handling of pesticides can lead to control failures and resistance.

In the past, eradication of pests was the primary objective, and increasingly high food quality standards allow no, or only little, contamination of stored commodities. On the other hand, consumers demand foodstuff that is free of chemical residues. A zero pest tolerance, however, can rarely be achieved without the application of insecticides. Today's pest control programs must therefore address health-related, ecological, and economic concerns. Modern pest control strategies in stored product protection focus on integrated pest management (IPM). The concept of IPM is based on using threshold levels to make control decisions and on the combination of physical, biological, and chemical pest control measures. One threshold level, the economic injury level, is defined as the pest infestation level at which the loss due to pests is equal to the costs of available control measures. The threshold is not a fixed parameter, but varies with the control options, the infested commodity, and the infesting pest species. Fundamental requirements for a successful application of an IPM program are detailed understanding of the mode of action of any control measure and specific knowledge of the pest's biology.

**Strepsiptera**

Michael F. Whiting  
*Brigham Young University*

Strepsiptera (twisted-winged parasites) is a cosmopolitan order of small insects (males, 1–7 mm; females, 2–30 mm) that are obligate insect endoparasites. The order comprises ~600 species placed within 10 extant and 2 extinct families. Strepsiptera derive their common name from the male front wing, which is haltere-like, and early workers considered it to be twisted in appearance when dried specimens were examined. All members of this group spend the majority of their life cycle as internal parasites of other insects and consequently have a highly specialized morphology, extreme sexual dimorphism, and a unique biology.

**BIOLOGY**

The adult male strepsipteran is free living and winged, whereas the adult female is entirely parasitic within the host, with the exception of one family (Mengenillidae) in which the female last instar leaves the host to pupate externally. Strepsiptera parasitize species from seven insect orders: Zygentoma, Orthoptera, Blattodea, Mantodea, Hemiptera, Hymenoptera, and Diptera. In one family (Myrmecolacidae), the males are known to parasitize ant hosts, whereas the females are parasites of Orthoptera and Mantodea. The life cycle of most strepsipteran species is unknown, and only a few species have been studied in detail.

The first instar is free living, emerges from the female brood canal, and disperses to the surrounding vegetation in search of a new insect host. In some species, the larvae have long abdominal setae that are used to propel them on to a new host. These larvae may be carried back to the nest of a social host to begin parasitizing the host's larvae or may simply spring onto the early instars of a nonholometabolous host. In *Styllops pacificus*, the abdominal setae are short and the larva are transported to the nest inside of the crop of the bee *Andrena complex*, where it will begin parasitizing a single egg of the bee.

Once a first instar enters a new host, it molts into an apodous larva and feeds transcutaneously from the host's hemolymph. *Elenchus tenicornis* undergoes two additional molts prior to pupation; apolysis is not followed by ecdysis in strepsipteran larvae, such that the cuticle of the second to the fourth instar forms the puparium. In *Mengenillidae*, both sexes leave the insect host to pupate externally. The remaining Strepsiptera pupate in the host with a portion of the head and thorax extruded from the host's cuticle (Fig. 1C).

Males will emerge from the puparium and seek out a female for mating. Virgin females release a pheromone to attract males, and in Styllopida, the male copulates by rupturing the female's brood canal opening between her head and prothorax in a process referred to as hypodermic insemination. Adult males live only a few hours, which makes them difficult to collect, although they are occasionally found at lights or may be lured to a virgin female kept in a cage in the field. Adult males do not feed and their mouthparts are partly modified into sensory structures. After insemination, females may live for a few weeks to a few months. In *Xenos peckii*, the female is typically inseminated in the fall and she remains in the wasp host until spring, when the planidial larvae emerge. The female may be an enormous endoparasite relative to the size of its host. For example, *X. peckii* may fill up to 90% of the abdominal cavity of the wasp host. It is relatively common to find a host that has been parasitized by multiple males and/or females.

**MORPHOLOGY**

First instars bear stemmata (simple, single-lens eyes), mandibles, maxillae, and a labium. Antennae are absent. Abdominal tergites are typically smooth, the abdominal sternites are serrate, and the legs are filiform with slender tarsi (Fig. 1A). In Mengenillidae, the pupae are free living and have legs, mouth, and a segmented abdomen. In the remaining Strepsiptera, the puparium is tanned and male pupae possess compound eyes, abdominal and thoracic segmentation, and developing wings, legs, and antennae (Fig. 1B).

The adult male has large compound eyes, with ommatidia separated by cuticle and/or setae, giving the eye a blackberry appearance. Antennae are filiform and the mandibles are conical, except in Corioxenidae, which entirely lack mandibles (Fig. 1F). The first pair of wings is reduced, clubbed, and morphologically similar to the halteres of Diptera. The hind wings are enlarged and venation is reduced, and these wings are used for flight (Fig. 1G). The prothorax is small and saddle shaped, and the metathorax is large and bears the principal flight muscles. The trochanter is fused with the femora in the fore- and middle legs, the hind legs lack free coxae, and the tarsi have two to five segments and may lack a tarsal claw (Fig. 1H).

The adult female lacks wings, legs, and external genitalia, and only rudiments of the mouthparts, antennae, and eyes remain (Figs. 1D and 1E). The thorax and head are fused to form a heavily sclerotized...
cephalothorax, and this is the portion of the female that is extruded from between the abdominal segments of its host. The abdomen is large, segmentation is reduced, and the cuticle is un sclerotized, which allows nutrients to pass from the host to the developing embryos. The tracheation and the nervous system are reduced, and the reproductive system is highly modified, allowing the production of vast quantities of eggs that are freely distributed throughout the abdominal cavity.

CLASSIFICATION

A recent comprehensive morphological analysis has provided new insights into strepsipteran phylogeny. At the root of the strepsipteran tree are three distinct lineages represented only by fossils: the Baltic amber fossil *Protoxenos* (Protoxeniidae), the Burmese amber fossil *Cretostyllops*, and the Baltic amber fossil *Mengea* (Mengeiidae). The most basal extant family is *Mengeiidae*, a primitive strepsipteran group with females that are free living, bearing rudimentary legs, antennae, and a single genital opening, and the males have robust mandibles and a hind wing with an elongated and sturdy MA vein. The majority of species belong to the group Stylpidiida, the monophyly of which is supported by the fact that females are found in the host, the male has multiple genital openings, and the hind wing in the male has only residues of the MA1 vein. There are nine families that belong in Stylpidiida and are arranged in the following order from the base to the apex of a comlike tree: Coroxeniidae, Bohartillidae, Halictophagidae, Elenchidae, Protoelenchidae, Myrnecolacidae, Callipharaxeniidae, Xenidae, and Stylpidiidae.

PHYLGENY AND EVOLUTION

The phylogenetic position of Strepsiptera relative to other insect orders has been one of the most contentious issues in insect systematics, and controversy still exists as to their phylogenetic affinity. There have been four phylogenetic hypotheses presented: (1) placement as a group somewhere within Coleoptera, as suggested by the superficial similarities in their parasitic lifestyle and morphology with certain beetle groups; (2) placement as sister group to Coleoptera, as suggested by the powering of flight via the hind wing; (3) placement outside of Holometabola, as suggested by the presence of larval stemmata; and (4) placement as sister group to Diptera, as suggested by DNA sequence data and other homologies. The latter hypothesis has been the most controversial and different interpretations of the molecular data have been presented, though the most recent sequence data continue to support this hypothesis. If Strepsiptera are indeed sister group to Diptera, then this gives rise to some intriguing possibilities in insect evolution. Functionally, the halteres of Diptera and Strepsiptera appear identical, both highly specialized to serve as a gyroscopic balancing mechanism during flight. Therefore, it is possible that the mesothoracic halteres of Strepsiptera were derived via a specialized mutation in the genes controlling the development of the metathoracic halteres in Diptera, essentially causing the wings of the dipteran to switch positions to produce the type of wings as observed in Strepsiptera.

Swimming, Lake Insects

Werner Nachtigall

*Universität der Saarlandes*

Insects of many types, such as beetles (Coleoptera), true bugs (Heteroptera), and fly larvae (Diptera), can be observed swimming in ponds and lakes. Of these, the water beetles in the family Dytiscidae are reputed to be the best swimmers. The trunks of their bodies are well adapted to flow, and they generate thrust by executing synchronous power strokes with their flattened rear legs, which bear two rows of “swimming” hairs.

FLOW ADAPTATION

Measurements on flow adaptation have been carried out on trunks of several Dytiscidae, especially with the large European water beetle *Dytiscus marginalis*.

The technical term coefficient of drag, or $c_d$, is used as an indicator of flow adaptation. A small coefficient indicates that a beetle with a given frontal area and at a given swimming speed generates little drag; that is, it is well adapted to flow. However, one cannot readily compare the drag created by objects moving at different speeds because the coefficient of drag is a function of the Reynolds number (i.e., of its swimming speed in water and its body length). For certain ranges of Reynolds numbers, there are sufficient data available, ranging from the most streamlined bodies (e.g., drop-shaped trunks; lowest $c_d$ values) to the objects that produce the greatest drag (e.g., parachute forms; highest $c_d$ values). Figure 1A shows the trunks of four *Dytiscus* species viewed from above, from the side, and from the front (the front projection shows the frontal area A). Figure 1B shows the measured $c_d$ within the spectrum of coefficients that are possible for the range of Reynolds number ($Re$) obtained from swimming water beetles ($10^4 < Re < 10^6$). The coefficients of the beetle fluctuate between 0.38 for *D. latissimus* and 0.43 for *D. pisanus*, with
the smallest possible value being 0.2 or slightly less, and the highest possible value approximately 1.4. Compared with the possible spectrum, the beetles' trunks seem to be well adapted to flow, although they do not reach the extreme values technically possible. Low-drag technical constructions are unstable; in the presence of oblique flow they turn immediately broadside, and stabilizing surfaces preventing this behavior would increase drag. Enlarged prothoracic and elytra edges in large Dytiscus beetles (extreme in \textit{D. latissimus}) serve as stabilizing surfaces for swimming by damping oscillations around the longitudinal and lateral axes and by creating stabilizing moments. If one reduces these stabilizing surfaces along the edges, drag at almost all angles of attack between trunk and flow is perceptibly reduced. But the trunk then is distinctly unstable. These two contradictory demands have led to the evolution of an optimal shape with good swimming stability and good flow adaption.

Geometrically similar, 10-times-enlarged models of large \textit{Dytiscus} beetles have been used to measure the pressure distribution along the dorsal midline of these trunks, with numerous pressure holes. A positive pressure dent appears on the head–prothoracic region (and also on the abdomen), whereas the remaining upper abdominal side is under negative pressure (Fig. 2). Thus, a \textit{Dytiscus} trunk is very similar to a small-span wing profile and should therefore create a certain dynamic lift during fast swimming.

Because the drag coefficient of bodies increases with smaller Reynolds numbers, one may expect that the smallest, most slowly moving Dytiscidae (e.g., \textit{Hyphydrus}, \textit{Bidessus}) are characterized by relatively high drag coefficient values. Thus, they seem to be less well adapted to flow simply by their smallness (i.e., by their low Reynolds numbers). From flow mechanics, we know that streamlining is less effective at lower Reynolds numbers. Indeed, these small beetles are characterized by blunt body forms that may have biological advantages (more effective space for the organs). Because these beetles are energetically better equipped, this inherent physically disadvantage may not be of primary importance.
FUNCTIONAL MORPHOLOGY
Leg Flattening and Position of Swimming Appendages

The functional formation of a swimming leg is easy to understand because of the simple mechanical demands made upon it. A swimming leg should produce strong thrust (i.e., a force component in the swimming direction) during a rowing stroke (i.e., a power stroke), and little counterthrust while being drawn forward (i.e., a recovery stroke). This action is aided by morphological and kinematic adaptations.

At a given speed the hydrodynamic drag force $F_d$ is proportional to the leg surface $A$. Therefore, $A$ must be as large as possible during rowing stroke, and as small as possible when drawn forward. This is achieved by flattening the leg segments and by means of thrust-inducing processes such as swimming hairs (e.g., Dytiscus, Corixa) or swimming platelets (Gyrinus). During the rowing stroke, the flat broadside of the leg is brought perpendicular to flow, and the hairs and platelets spread out automatically under the pressure of flow, thus increasing the rowing surface. When the leg is drawn forward, it is turned so that the flattened surface lies parallel to flow, and the rowing appendages are folded together and pressed against the leg by the flow; their additional surface disappears completely (Fig. 3).

FIGURE 3 Stroke phases of the hind legs of A. sulcatus during power stroke and recovery stroke. [After Nachtigall, W. (1986).]

Leg oscillation is an angular movement. Therefore, the drag, which is created by an element of surface, is proportional to the square of its rotating radius $r$, or its distance from the coxa–trochanter joint. A component of the counterforce of this drag, parallel to the median, is the thrust force. The thrust-creating area during a rowing stroke should lie as far out as possible ($r$ large) during the power stroke, and as far in as possible ($r$ small) during the recovery stroke. Thus, the broad area and its hairs can be called a thrust-creating area. This is achieved principally because the distal leg segments, the tibia and the tarsus, are greatly enlarged and carry thrust-creating swimming hairs or swimming platelets, and because the legs are outstretched during stroke and then bent and drawn forward as close as possible to the median.

Stroke Areas and Radii of Rotation

The leg segments in Gyrinus have been flattened so extensively that their surface area is approximately five times that of a round leg; because of the simultaneously increasing coefficient of drag, a hydrodynamic force roughly eight times larger is created. During the power stroke, the leg segments spread out like playing cards, thus increasing their size by roughly 1.6 times over their projection area when not spread. The supplementary surface areas of the swimming platelets increase the stroke surface in Gyrinus even more: by roughly 230% in the tibia and roughly 130% in the tarsus.

In Acilius, the flattened tarsus positioned very distally occupies 80% of the total stroke area. Its mean rotational radius is also roughly 80% of the leg length. In Gyrinus, the corresponding values are approximately 40 and 80% for the tarsus and approximately 50 and 60% for the tibia.

During the recovery stroke, Acilius tilts the broad side of its leg parallel to the flow and presents the narrow edge of its leg to the flow. At the same time, the swimming hairs and swimming platelets are flattened and lie close to the leg. Because the exterior leg sections lie more or less parallel to the median during the first phase of drawing forward, its area of projection in the direction of flow is smaller yet. In Gyrinus, this projection area in proportion to the area of the power stroke is reduced to 1/13 for the middle legs and 1/16 for the hind legs. The tarsus from Gyrinus collapses completely and disappears partly into a groove in the tibia, which, in turn slips partly into a hollow in the femur, so that the leg surface area is dramatically reduced by roughly 70% of the leg surface during the recovery stroke.

By folding the legs when they are drawn forward nestled against the body, Gyrinus reduces the mean rotational distance relative to that of the power stroke from 60% to approximately 35% of total leg length. The values for the tarsus alone are 80 and 50%.

Two additional phenomena should augment swimming efficiency, although their precise contribution remains to be measured. First, pressure drag is created mainly during the power stroke, and frictional drag is probably more important when the legs are drawn forward. Second, the leg segments, insofar as they nestle against the ventral surface with their broad side when drawn forward, move within the boundary layer of the trunk, thus creating less drag than when moving through free water.

During steady swimming, the relations are more complicated because the leg interferes with flowing water so that the speed of the leg’s rowing surface relative to the surrounding water changes.

Newer investigations (Nachtigall, 2008) have revealed that the drag coefficient of water beetle trunks is markedly reduced at higher flow speeds (higher Reynolds numbers) that exceed the biological range. So an equalized trunk of Dytiscus pisanus (body length 3.0cm) revealed a drag coefficient of only 0.14 at $Re = 6.8 \times 10^4$. Compared to the unchanged trunk at physiological flow speeds (drag coefficient 0.43 at $Re = 4.5 \times 10^4$), this means a reduction of 67%.

It seems therefore likely that bigger models at even higher Reynolds numbers reach extraordinarily good flow adaptation exceeding that of existing submarines. To test this a 10-to-1-model of an equalized Dytiscus-trunk was built (Fig. 4) that is now analyzed in wind- and water tunnels.

Swimming and Other Movements, Stream Insects

Bernhard Statzner
CNRS–Université Lyon 1, France

The physical world of an insect living in water or air is ruled by the fluid velocity relative to its body. Thus, swimming fast in still water or slowly against a current of flowing water can be physically similar for an insect. However, flow in streams is physically harsh and often constraining the movements of stream insects. Imagine a mountain stream with its typical current velocity of \( 50 \, \text{cm/s} \), and a 1-cm-long mayfly larva swimming upstream. To move relative to the stream bottom, this larva must propel itself at more than 50 body lengths \( s^{-1} \), which is a difficult accomplishment. Therefore, stream insects rarely swim and live predominantly at or in the surface layer of the stream bottom, where friction between the moving water and the solid bottom material generates extremely complex flow patterns. As a consequence, the aquatic stages of stream insects move in a physical world that is much more complicated than that of lake insects.

LIFE IN FLOW NEAR THE STREAM BOTTOM

Streams offer a mosaic of flow conditions, including areas with (almost) still water. Where a stream runs over a rough (e.g., stony) bottom, flow can be laminar or turbulent (or transitional between these two). The difference between the laminar and the turbulent flow regime is easily understood by watching the smoke released by a cigarette in a calm place. Close to the tip, the ascending smoke travels in an orderly manner on a narrow path as a laminar flow; until suddenly the flow becomes turbulent and travels whirling on a wider path. The physical formulas for these regimes are quite different; thus, these two flow regimes constitute different physical worlds.

The Reynolds number \( Re \) indicates the flow regime for a particular flow situation through \( Re = \frac{I \times U}{\nu} \), where \( I \) is a length dimension (e.g., the body length of an insect), \( U \) is the relative velocity to the insect body, and \( \nu \) is the kinematic viscosity of the water. Low \( Re \) indicates laminar and high \( Re \) indicates turbulent regime. Therefore, in general, small and slow (relative to the flow) stream insects (having a low \( I \times U \)) experience laminar flow in which viscous forces matter, whereas large and fast ones experience turbulent flow, where inertial forces predominate.

However, near the bottom of a stream, things are a bit more complicated. When water runs over a stone, the water in contact with the stone surface does not slip relative to the surface (the no-slip condition), and a velocity gradient develops above the surface (e.g., as in Fig. 1C). Near to the surface, the flow can be laminar (‘laminar sublayer’). If the stone is embedded among other stones of similar size (Fig. 1A) and the water is shallow relative to the stone size, turbulent eddies may extend to the stone surface and disrupt the formation of the laminar sublayer. As a consequence, velocity varies tremendously over short periods near the stone surface (Fig. 1B), as well as around insects living at that surface. To maneuver in that type of flow, a 1-cm-long insect must deal with velocity changes from 5 to more than 40 body lengths \( s^{-1} \), and this within a fraction of a second. The body vibrations of black flies or elongated caddisflies staying at the surface of a stone in a shallow stream nicely illustrate that these insects have a very ‘shaky’ life.

In natural streams, isolated larger bottom elements that rise far into the water column (Fig. 1A) are often very abundant. Above the surfaces of these elements, the no-slip condition produces a steep velocity gradient (Fig. 1C). Flow is generally laminar nearest to the surface (low standard deviation of the velocity in the laminar sublayer: Fig. 1C), whereas it is turbulent in the remaining part of the steep velocity gradient (elevated standard deviation in Fig. 1C). At a given location, the geometry (e.g., the thickness of the laminar sublayer) of this steep gradient changes with changing flow. That is, discharge variation in a stream causes temporal variability of the physical conditions at that location. At a given flow, the geometry of this gradient varies spatially along the slightly curved bottom element. The changes of the isovel (line of equal velocity) pattern along the curvature (Fig. 1D) demonstrate considerable spatial variability of the physical conditions over the distance of a few millimeters. As a consequence of these temporal and spatial patterns, a relatively sessile black fly larva must deal with temporal physical variation caused by changing stream discharge, whereas a relatively mobile mayfly larva must deal with spatial physical variation when moving at the bottom surface.

Whether sessile or mobile, stream insects living in steep velocity gradients can modify the flow patterns to a considerable extent (cf. Fig. 1D–G). Frequently, these stream insects are so large (e.g., in Fig. 1F and 1G) that their lower part is in the laminar flow, their intermediate part is in the layer of elevated turbulence, and their upper part extends beyond the steep velocity gradient. These insects live with different body parts in three different physical “worlds,” and the relative importance of these different worlds experienced by their bodies changes when the insects move. Thus, the flow conditions
near larger bottom elements are also physically harsh for stream insects because they variably affect factors of physiological relevance for the insects (e.g., facility of respiration, drag, or lift force).

**MOVEMENTS IN THE STREAM ENVIRONMENT**

The surface of the stream bottom provides essential resources (e.g., food, oxygen-rich water). To exploit these resources, insects have developed many different strategies that relate to movements at and in the stream bottom, or in the free-flowing water column.

**Movements at and in the Stream Bottom**

A strategy frequently used to deal with the physical harshness at the stream bottom is temporal avoidance. Particularly, mayfly and stonefly larvae move vertically among the interstices of the stream bottom, to the top of the bottom surface and back into deeper bottom layers that offer shelter from the surface flow. Such movement produces daily and/or seasonal patterns in the presence of these larvae at the bottom surface. However, the dissolved oxygen concentration of the water interferes with the use of interstitial flow shelters. If the oxygen in the interstices drops below a species-specific critical value, the physiological means of regulatory oxygen consumption (gill movements or
Swimming and Other Movements, Stream Insects

Moving in the Drift of Stream Insects

Drifting downstream with the flow is the typical movement of stream insects in the water column. Physically, a passively drifting insect barely moves because the water velocity relative to its body is almost zero. However, relative to the stream bottom, it travels at the speed of the flow.

The drift of stream insects is perhaps one of the most frequently studied topics in stream ecology. Given that both the diversity of stream insects and the diversity of running water conditions across the continents are very high, there is evidence for almost any conceivable drift response. For example, the following factors may increase, decrease, or have no effect on the natural drift of stream insects: sunlight or moonlight; current velocity; stream discharge; type of the bottom substrate; turbidity, oxygen concentration, ion concentration, or temperature of the water; organic matter; food; predators; microbial pathogens; larger parasites; molting process; benthic density; and age or behavior of the drifting species. Thus, it is difficult to identify clear patterns in the drift of stream insects.

Typically, stream insects drift at night. This drift may be caused by accidental dislodgement of the insects through the current or by deliberate, active entries into the drift. Active entries occur when a habitat patch is overcrowded and resources (e.g., food, space, preferred flow conditions) are lacking. Approximately 10–30% of the insect population of a stream reach may drift during one night, and they may travel between 2 and 20 m during one drift movement. However, caddisfly larvae that build heavy cases from gravel typically have distinctly lower drift rates and shorter drift distances. Insects that produce silk may also have shorter drift distances. Hydropsychid and polycentropodid caddisfly larvae, and black fly larvae, can fix a silk thread to the stream bottom, actively enter into the drift and, prolonging the thread by spinning, rope themselves downstream over several centimeters until they resettie at the bottom. Polycentropodid caddis larvae that have lost contact with the bottom often spin “anchor” threads of 30 cm in length. When such a thread adheres to the stream bottom, the larva is able to return to the bottom by climbing down along the thread. Another means of affecting drift distance is used by drifting larvae of mayflies, stoneflies, and caseless caddisflies. They modify their body posture, thereby either decreasing or increasing their sinking speed, and thus the distance traveled in the water column.

A giant water bug living in desert streams has a successful response to flooding. During periods of heavy rainfall that often precede flash floods in these streams, adult and juvenile water bugs move toward the banks, leave the stream, and crawl up to about 20 m over land toward sheltered areas (from where they return to the stream after 24h). Some studies report that stream insects burrow deeper into the humid sediments to avoid effects of drying, whereas other studies do not confirm such movements. With sinking water level in a stream, insects may also crawl away over land (adult beetles), or they crawl up- or downstream to places where water remains. The speed of insects during such movements can be rather high. For example, the larvae of a caseless limnephilid caddisfly crawl downstream at about 12 m h⁻¹.

Finally, the aerial females of a few species of stream insects crawl down on solid objects through the water surface and fix their eggs on the submerged surface of the object, or they oviposit in an aquatic host insect. The first behavior has been primarily observed in mayflies, caddisflies, and black flies; the second in parasitic wasps.
Symbionts Aiding Digestion

Andreas Brune
Max Planck Institute for Terrestrial Microbiology, Marburg, Germany

The interactions of insects with microorganisms range from the cultivation of fungus gardens to intimate associations with bacteria housed within special organs (mycetomes) or dedicated cells (bacterioocytes) of the fat body. Many of these associations have nutritional implications; this article will focus on microbial symbionts that colonize the intestinal tract and are directly involved in digestion.

Although insects produce a wide variety of digestive enzymes, many species harbor an intestinal microbiota that converts a substantial portion of the dietary components to fermentation products before they are resorbed by the intestinal epithelia. The occurrence of such associations is always correlated with a dietary specialization, which indicates that the symbiosis provides metabolic capacities that are normally not available to the host.

Digestive symbioses are most common among insects feeding on wood or other lignified plant materials. The most prominent example is that of wood-feeding termites (Isoptera), which represent the only group of insects whose interactions with intestinal microorganisms has been studied in detail. Here, they serve to illustrate principles that most likely govern also other cases of symbiotic associations in which detailed information on the gut microbiota and its function in digestion is lacking.

BIOCHEMICAL BASIS OF LIGNOCELLULOSE DIGESTION

Why would an insect need help in digesting its food, and which benefits would be gained from sharing this resource with an intestinal microbiota? For xylephagous (wood-feeding) insects, the answers are found in the chemical structure and composition of their fiber-rich, low-nutrient diet.

Structure and Composition of Lignocellulose

The major components of plant cell walls are cellulose and hemicelluloses. Although the glycosidic linkages between the sugar subunits of these structural polysaccharides are relatively easy to hydrolyze, the sheer size of the molecules, their primary and secondary structures, and the intimate physical contact of the different components, especially in lignified cell walls, impart a considerable recalcitrance to enzymatic digestion.

Further Reading

The intensity of everyday drift events usually varies across seasons, either because of seasonal changes in factors affecting the insect drift or because of the seasonal occurrence of a particular developmental stage that drifts more than other stages. A typical example for the first cause is the seasonal change of temperature in temperate streams and the related effects on the insect drift. A typical example for the second cause is found in hydropsychid caddisflies that may have newly hatched first instars that drift at much higher rates than later instars.

Occasional natural events such as floods and droughts, or unnatural ones such as pesticide or pollution spills, also increase drift. During such events and in contrast to the everyday drift, insects also drift during the daytime, and the distances traveled are longer. When discharge increases, and thus near-bottom velocity, many stream insects are dislodged. Among the sessile forms that fix themselves firmly to the stream bottom, those sitting on submerged wood or leaf litter may travel extremely far downstream on dislodged litter pieces that drift for long distances. In contrast, when discharge and thus near-bottom velocity decreases during a drought, many insects release their grasp on the stream bottom and swim upward until they are caught and transported by the free flow in the water column.

Another cause for massive upward swimming of insects from the bottom is relatively low oxygen concentration in the water, a condition typical of streams with organic pollution. Drifting insects may swim, either to avoid sinking so that they stay longer in the water column or to return faster to the stream bottom. Finally, some mayfly larvae swim over short distances when they encounter predators or aggressive conspecífics. These larvae are such good swimmers that they can travel against the current just above the stream bottom, where the velocity is reduced. The larvae of most insect groups swim by body undulations.

An exceptional type of movement among the stream insects is the diving of aerial females to reach submerged oviposition sites. Female black flies can dive through thin water layers flowing over rocks to get foothold at the rock surface, where they affix the eggs. Similarly, female caddisflies dive vertically and swim to oviposition sites below inclined submerged stones.

BIOCHEMICAL BASIS OF LIGNOCELLULOSE DIGESTION

Why would an insect need help in digesting its food, and which benefits would be gained from sharing this resource with an intestinal microbiota? For xylephagous (wood-feeding) insects, the answers are found in the chemical structure and composition of their fiber-rich, low-nutrient diet.

Structure and Composition of Lignocellulose

The major components of plant cell walls are cellulose and hemicelluloses. Although the glycosidic linkages between the sugar subunits of these structural polysaccharides are relatively easy to hydrolyze, the sheer size of the molecules, their primary and secondary structures, and the intimate physical contact of the different components, especially in lignified cell walls, impart a considerable recalcitrance to enzymatic digestion.
In cellulose, the linear 1-4-linked polyglucose chains are arranged in microfibrils with a highly ordered, mostly crystalline structure. Cellulose depolymerization is catalyzed by endoglucanases (endo-β-1,4-glucanases), which cleave randomly within the extremely long polyglucose chains, and by exoglucanases (exo-β-1,4-cellulohydrolases and β-glucosidases), which require free nonreducing ends for their catalytic activity. Because native cellulose contains only one nonreducing end per many thousand glucose units, and because the action of endoglucanases is restricted to the amorphous regions of the microfibrils, an efficient cellulolytic system requires the synergistic action of both types of enzymes.

Enzymatic activity of cellulases is further impeded by the insolvibility of cellulose, and depolymerization is usually the kinetically limiting step even in the digestion of pure cellulose. In the cell wall, the cellulose fibrils are intimately associated with hemicelluloses, which comprise a wide variety of homopolymers and heteropolymers of different sugars and sugar acids. Hemicellulose chains are often branched and lack the highly ordered structure of cellulose. The variety of primary structures requires an equal variety of digestive enzymes, and it is not astonishing that the ability to degrade hemicelluloses is a prerequisite for an efficient cellulose degradation.

Sound wood is most difficult to digest because, through lignification, the polysaccharides of the secondary plant cell wall are embedded in an amorphous resin of phenolic polymers that provide an efficient barrier to enzymatic attack of the polysaccharides. The lignin macromolecule itself is extremely recalcitrant to degradation since most bonds between the subunits are extremely stable and cannot be hydrolyzed.

**Roles of Symbionts in Digestion**

For the reasons outlined above, the degradation of plant cell walls requires the synergistic action of many different enzymes and, in the case of lignified substrates, also a mechanism to break up the lignocellulose complex. The most efficient cellulose and hemicellulose degraders in nature are microorganisms, i.e., bacteria, protozoa, and fungi. Fungi and certain filamentous bacteria (actinomycetes) are also the only organisms that have developed a strategy for the chemical breakdown of lignin. Not surprisingly, insects and other animals have made use of these capacities by using microorganisms as symbionts in the digestion of lignocellulosic food.

In addition to being difficult to degrade, lignocellulose is an extremely nutrient-poor substrate. The C-to-N ratio of sound wood is up to 100-fold higher than that of the insect body. Moreover, a lignocellulosic diet typically lacks most of the essential nutrients required by the animal, such as amino acids, vitamins, and sterols.

In contrast to higher animals, many microorganisms are capable of fixing dinitrogen, assimilating nitrate and ammonia, and synthesizing those amino acids and vitamins essential for the host. Many animals, including insects, have developed means of exploiting these biosynthetic capacities of microorganisms, which include—in the simplest case—the digestion of the intestinal symbionts.

**LIGNOCELLULOSE Digestion in Termites**

The symbiotic digestion of lignocellulose by termites is a complex series of events involving both the host and its gut microbiota, which comprises prokaryotic symbionts (bacteria and archaea) and, at least in lower termites, also protozoa and possibly fungi (yeasts). Although the events in foregut and midgut are mainly the result of host activities, the digestive processes in the hindgut are largely controlled by the symbionts (Fig. 1). Many aspects of lignocellulose digestion are common to all termite species, yet there are several noteworthy differences between the phylogenetically lower and higher taxa.

**Host-Related Processes**

One of the key contributions of the termite to wood digestion is the action of the mandibles and proventriculus, which grinds

---

**FIGURE 1** Major events in the symbiotic digestion of lignocellulose by wood-feeding lower termites. The bold lines show the path of the insoluble material, the lignin-rich residues of which are released as feces, whereas the thinner lines represent soluble degradation products that are eventually resorbed by the host. The dashed lines indicate the cycling of nitrogenous compounds. Hollow arrows mark the sites where cellulolytic enzymes are secreted. Lowercase letters refer to the different groups of bacteria, which are either endobionts (A) or epibionts (B) of the protozoa, suspended in the gut lumen (C), or attached to the gut wall (D). The scheme has been simplified for the sake of clarity; not all possible interactions are shown. Further details are given in the text. L, lignocellulose; C, carbohydrates; N, nitrogenous compounds; F, fecal matter; G, gut lumen; P, protozoa; 1, mandibles; 2, salivary glands; 3, proventriculus; 4, midgut epithelium; 5, Malpighian tubules; 6, phagosomes; 7, proctodeal feeding.
the wood particles down to a microscopic size. This mechanically destroys many lignin–carbohydrate complexes and creates an enormous surface area for the digestive enzymes provided by host and symbionts, thereby relieving much of the kinetic limitations of cellulose digestion. In lower termites, comminution is also a prerequisite for the ingestion (phagocytosis) of the wood particles by symbiotic protozoa.

In all insects, the digesta are exposed to a variety of digestive enzymes secreted by the salivary glands and the midgut epithelium. The persisting dogma that higher animals do not produce cellulases has been unequivocally refuted by the demonstration of endoglucanase genes in the genomes of termites and many other related insects (Dictyoptera). Moreover, all termites investigated express endoglucanases capable of hydrolyzing amorphous cellulose in the cells of the salivary glands or the midgut epithelium (see below). Although systematic studies are lacking, one can safely assume that—as in other insects—most of the easily digestible material has been mobilized and resorbed at the end of the midgut.

Insects lacking a pronounced gut microbiota usually have a short hindgut that serves mainly in recovering water and useful electrolytes from the residual material before the feces are voided. The digestive tract of termites, however, is characterized by one or more proctodeal enlargements and may reach enormous dimensions in length and volume (Fig. 2A). The dilatations increase the residence time of the digesta, thereby prolonging the exposure to the activities of the intestinal microbiota. Moreover, the increased diameter also affects the oxygen status of the “fermentation chambers” because it reduces the proportion of the gut volume rendered oxic by the diffusion of oxygen into the periphery, thus providing a favorable environment for the oxygen-sensitive microbiota and reducing the inevitable loss of fermentation products to aerobic processes (see below).

**Fiber-Digesting Symbionts**

In lower termites, the solid food particles entering the hindgut are immediately phagocytized by the intestinal protozoa (Fig. 3A).
These oxygen-sensitive flagellates, which make up a large fraction of the hindgut volume, are essential for wood digestion and represent a major source of cellulolytic and xylanolytic activities in the hindgut. It appears that the different flagellate species are nutritionally specialized and each species might fill a specific niche in symbiotic digestion. The consecutive action of the host endoglucanases secreted in the salivary glands and the full complement of endoglucanases and exo-cellobiohydrolases of their eukaryotic symbionts forms the so-called “dual cellulolytic system.”

In phylogenetically higher termites (family Termitidae), the site of secretion of host endoglucanases shifted from the salivary glands to the midgut epithelium. Although all families of lower termites sport a hindgut packed with flagellates, the higher termites contain a largely prokaryotic microbiota. Apparently, other symbionts took over the cellulolytic function of the protozoa in the course of termite evolution. In the case of the fungus-cultivating termites (subfamily Macrotermitinae), which cultivate basidiomycete fungi (*Termitomyces* spp.) on predigested food in “fungus gardens” located within their nests, the key activities of the symbiotic partner are extensive delignification and conversion of lignocellulose to fungal biomass in the fungus combs. It has been proposed that fungal cellulases ingested together with the comb material are essential for cellulose digestion in the gut of fungus-cultivating termites, but this “acquired enzyme hypothesis” is controversial. Moreover, evidence is accumulating that fungal biomass became an important nutritional basis for certain species.

In all other higher termites cellulolytic activities in the hindgut are probably produced by symbiotic bacteria. Two major bacterial lineages (Fibrobacteres and Spirochetes) seem to be involved in this process. While the former are related to an important group of fiber-degrading bacteria in the cow rumen, the exact role of the latter is still enigmatic.

**Noncellulolytic Microbiota**

The advent of cultivation-independent methods revealed that the prokaryotic microbiota of termite guts is highly diverse. Most of these symbionts do not take part directly in fiber degradation but seem to play other important roles in digestion and in the nitrogen metabolism of the hindgut. In the lower termites, the majority of prokaryotes is intimately associated with the flagellates, whose large surfaces and biovolume represent an excellent habitat for ectobiotic and endocytophobic symbionts.

**METABOLIC INTERACTIONS** The original concept of the hindgut metabolism in lower termites assumed that the anaerobic flagellates depolymerize the polysaccharides to sugar units, which are then fermented to acetate, hydrogen, and CO₂ as the major products. Recent results indicate that the spectrum of fermentation products released by the diverse protozoa is much wider, giving rise to a variety of intermediates that form the substrates of the endobiotic or epibiotic bacteria colonizing the protozoa. Metabolites released by the protozoa or originating directly from the midgut also support numerous bacteria located in the lumen or attached to the wall of the hindgut. All metabolites are eventually converted to a range of short-chain fatty acids (mostly acetate, propionate, butyrate) that accumulate in the hindgut fluid and that are eventually resorbed by the hindgut epithelium (Fig. 1).

Although it is still difficult to assign functions to individual members of the gut microbial community and to localize the microbial populations involved in these reactions, the major roles of different functional groups are beginning to take shape (Fig. 4). At least two metabolically different groups of prokaryotes are involved in the oxidation of the hydrogen or one-carbon compounds produced in the microbial fermentations: (1) methanogenic archaea, which reduce CO₂ to methane, and (2) homoacetogenic bacteria, which reduce CO₂ to acetate.

Methanogenesis and reductive acetogenesis occur in the hindgut of all termites, although in wood-feeding species, reductive acetogenesis prevails over methanogenesis as a hydrogen sink and substantially increases the pool of short-chain fatty acids available to the host. Reductive acetogenesis in termite guts is apparently catalyzed by Spirochaetes—a unique feature encountered only in termite hindgut ecosystems. Methanogenesis—as in many other anoxic system the domain of archaea—may amount to a considerable portion of the total respiratory activity in fungus-cultivating and soil-feeding termites. Although methane production is of little use for the host, methane emission acquires global significance owing to the enormous biomass of these groups in tropical rainforests and savannahs.

**THE ROLE OF OXYGEN** The steep gradient of oxygen between gut epithelium and gut contents drives a continuous influx of oxygen into the gut. Microsensor measurements have shown that oxygen may penetrate 50–200 μm into the periphery of the hindgut, leaving only the central portion of the dilated compartments...
anoxic. The small insect guts have an enormous surface-to-volume ratio, which lends much greater importance to all surface-related processes than in larger animals. Because oxygen removal in the gut periphery is fueled by the fermentative processes in the hindgut lumen, the maintenance of anoxia is not a trivial issue, and there must be a lower size limit for arthropods with a symbiotic digestion.

The bacteria and protozoa colonizing the gut periphery, especially those directly associated with the gut epithelium (Fig. 3B and 3C), have to be specifically adapted to the presence of oxygen at low levels and may even use oxygen as an electron acceptor. The high fluxes of oxygen into the gut and its efficient removal by anaerobic and microaerobic members of the hindgut microbiota significantly influence the metabolic processes in the hindgut (Fig. 4).

Nitrogen Economy of Termites

Wood-feeding termites have developed several adaptations that help to compensate for the low nitrogen content of their diet, all of which involve the biochemical capacities of their gut microbiota. The most important strategy is a combination of conservation and recycling and is reminiscent of the application of organic fertilizers in agriculture.

Like in any other insect, uric acid and urea, the waste products of nucleic acid and protein metabolism, are secreted into the digesta via the Malpighian tubules at the midgut–hindgut junction. However, they are not voided with the feces, but are readily mineralized by the hindgut microbiota. The resulting ammonia is assimilated into microbial biomass; it remains to be clarified whether the intestinal protozoa can also assimilate ammonia directly or acquire combined nitrogen by phagocytosis and digestion of other microbial symbionts.

The nitrogen cycle is closed by the digestion of microbial cells. Because termites cannot access the microbes in the hindgut directly, worker larvae solicit hindgut contents from their nestmates. This behavior, which has been termed proctodeal trophallaxis and is unique to this group of social insects, increases in frequency with the level of nitrogen limitation. Digestion of the hindgut contents and resorption of the nitrogenous products probably take place in the foregut and midgut (Fig. 1). The efficiency of nitrogen conservation within the colony is increased further by the consumption of exuviae and dead individuals by nestmates.

While nitrogen recycling creates high ammonia concentrations in the hindgut, which allow the maintenance of an active gut microbiota and thus ensure high rates of carbon mineralization, the low nitrogen content of the food still limits the growth of a termite colony severely. However, the presence of bacteria among the hindgut microbiota capable of fixing atmospheric nitrogen may contribute considerably to increasing the nitrogen pool. It has been estimated that the nitrogenase activity in certain Nasutitermes termites would be sufficient to double the nitrogen content of a colony within a few years, and stable isotope analysis has revealed that 30–60% of the nitrogen in Neotermes koshunensis workers is derived via this pathway.

Although most lower termites are strictly xylophagous, higher termites (Termitidae) show an enormously successful dietary diversification. The fungus-cultivating termites (subfamily Macrotermitinae), which are specialized on degradation of nitrogen-poor plant litter, probably recycle nitrogen within the colony by exploiting the ammonium-assimilating capacities of the fungus. In other subfamilies (Nasutitermitinae, Termitinae, and Apicotermitinae), the diet ranges from sound wood to lignocellulosic plant materials in different stages of humification, including soil and animal dung. Since the C-to-N ratio of the diet decreases with increasing humification, microbial biomass and nitrogenous components of soil organic matter form a potential source of nutrition. The extreme alkalinity (pH 12) in the anterior hindgut of soil-feeding Termitinae appears to be the key to the exploitation of their nitrogen-rich but recalcitrant diet. During gut passage, alkaline pH and digestive enzymes, probably originating both from the host and the gut microbiota, release fermentable substrates from the ingested lumens that are protected from microbial degradation in soil. The transformation and mineralization of nitrogenous soil components in the guts of soil-feeding termites gives rise to high ammonia concentration in their feces and may be an important factor in nitrogen cycling in tropical soils.

DIGESTIVE SYMBIOSES IN OTHER INSECTS

The occurrence of a specific, autochthonous gut microbiota among insects remains to be systematically studied, but sufficient evidence for the presence of a digestive symbiosis has accumulated for representatives of several insect orders.

Phytophagous insects feeding on protein-rich plant material (e.g., caterpillars) usually have a relatively undifferentiated intestinal tract and, because of the rapid gut passage, digest little or no cellulose. Many xylophagous, detritivorous, and huminorous insect larvae, however, possess hindgut dilations that are missing in closely related species with a different feeding habit. The most prominent examples are among the Coleoptera (e.g., Scarabaeidae) and among the Diptera (e.g., Tipulidae) (Fig. 2B and 2C).

Scarabaeids and tipulids have an actively fermenting gut microbiota, including cellulolytic and hemicellulolytic bacteria and, in the former, also methanogenic archaea, which are attached to brush-like cuticular structures. Also, the guts of omnivorous cockroaches contain a largely prokaryotic microbiota of bacteria and methanogenic archaea, especially when maintained on a fiber-rich diet; many species also harbor anaerobic ciliates with methanogenic endosymbionts in their hindguts. Fiber-degrading protozoa, however, which are so prominent among the Isoptera, are found elsewhere only in Cryptocercus punctulatus (Cryptocercidae), which is not astonishing because these wood-feeding cockroaches share a common ancestor with the termites.

Reports on the Orthoptera are somewhat contradictory. The bacteria in the gut of locusts (family Acrididae) have been considered commensals because their absence in germ-free cultures had no obvious effect on the host, although key components of the pheromone responsible for aggregation of Schistocerca gregaria are produced by its gut microbiota. The situation is different in crickets (Gryllidae), which benefit from the presence of a gut microbiota when raised on a fiber-rich diet. In the hindgut of Acheta domestica, the density of microorganisms is even higher than that in termites, and there are brush-like supports for the attachment of bacteria that resemble those in scarab beetle larvae.

It is very likely that insects other than termites access protein and recycle nitrogen via digestion by microbial symbionts. Proctodeal feeding is a form of social behavior that is restricted to the termites and the wood-feeding cockroach, C. punctulatus, but theoretically any consumption of feces would also allow access to the microbial protein. A special adaptation to digestion by symbionts seems to be present in Scarabaeidae, in which a reflux of hindgut contents into the alkaline midgut has been observed. Extreme gut alkalinity is encountered also in the midguts of many huminorous, detritivorous, and coprophagous dipteran and coleopteran larvae. The principle of lumens digestion in tropical rose chafer larvae (Pachnoda species) bears many similarities to that of soil-feeding termites and may represent a case of convergent evolution.
Freshly hatched insect larvae do not possess a gut microbiota and all instars have to be reincubated after each molting because hindgut intima and contents are shed in this process. In principle, this is not difficult because many insect larvae eat their exuviae directly after molting, and first instars may pick up their intestinal symbionts together with the food from their environment. However, establishment and maintenance of a specific gut microbiota, as evidenced in the case of termites by many instances of co-speciation between host and symbionts, is facilitated by vertical transfer among parent and offspring. In contrast to the symbioses between insects and their intracellular bacteria, this is probably not accomplished by ovarial transmission, but by coprophagy or proctodeal trophallaxis. Since transfer of fresh hindgut content is crucial especially in lower termites because of the oxygen sensitivity of their gut flagellates, the evolution of sociality and symbiotic digestion in termites might have proceeded hand in hand.

**MUTUALISTS VS. COMMENSALS**

In the symbiosis between lower termites and fiber-digesting flagellates, both partners are indispensable and the mutual advantage is obvious. However, there are many symbionts in the guts of termites and other insects whose presence—to the best of our knowledge—appears to be of no obvious advantage to the host. When the benefit of the association is unidirectional, a symbiont is classified as a commensal, and the host might even benefit from its elimination.

However, it is also not unlikely that in such cases we are merely lacking insight into the symbiont's role in the symbiosis. An example might be the methanogenic archaea, which are regularly encountered in the hindguts of termites, scarab beetle larvae, and many cockroaches. Although methane, their sole metabolic product, cannot be utilized by the host, methanogenic archaea seem to be an integral part of the gut microbiota. They colonize the hindgut intima or the intestinal protozoa and are often attached to cuticular spines, which apparently represent specific attachment sites for methanogenic symbionts.

Unfortunately, it is often impossible to eliminate a specific member of the intestinal microbial community selectively, and even when possible, it is difficult to distinguish between the direct and the indirect consequences of their elimination. It might also be worth speculating on the problems that would be created by a general absence of specific gut symbionts and on the efforts involved in keeping a gut sterile. Microorganisms are continuously incorporated with the food, and while a rapid passage of the digesta controls microbial growth by washout (as long as attachment is prevented), a slow gut passage allows the uncontrolled proliferation of foreign microorganisms. Perhaps the promotion of specific symbionts excludes colonization by potential pathogens.

In this context, it is important to realize that the energy expenditure for any microbial symbionts remains relatively small as long as the access of oxygen to the dilated hindgut compartments is limited. A fermentative degradation of carbohydrates to acetate releases only a fraction of the free energy contained in the substrates, which is returned as nutritionally valuable microbial biomass. Together with the added benefit of metabolic properties like nitrogen fixation, ammonia assimilation, and the provision of vitamins, the advantages for the host may be well worth the investment.

**CONCLUSION**

The digestive symbioses of insects with their intestinal microbiota allow the insects to overcome the severe kinetic limitation of lignocellulose digestion and the nutritional restrictions imposed by this nitrogen-poor diet. Although the situation is somewhat reminiscent of the digestive symbiosis encountered in ruminants, it is important to consider the small size of insects, which affects especially the oxygen status of the gut. From a microbiological point of view, insect guts are not simply anoxic fermentors, but axially and radially structured environments with physicochemically distinct microhabitats. Termites have served as an excellent model for studying symbiotic digestion and the complex interactions within the intestinal microbial community. Recently, they are receiving great interest also because of the biotechnological potential of their gut microbiota for the conversion of lignocellulosic wastes to hydrogen and other valuable chemicals. Further efforts targeted at identifying the microbial symbionts and their metabolic capacities in this and other, hitherto understudied, groups of insects are sorely needed.

**Symbionts, Bacterial**

Michael E.N. Majerus†

University of Cambridge

Many species of insect are host to symbiotic microorganisms. These symbionts have traditionally been classified as mutualists (beneficial), parasitic (harmful), or commensal (neutral).

†Deceased January 27, 2009
A variety of microorganisms among these symbionts are vertically transmitted, that is, they are inherited. The survival of these heritable symbionts is almost totally dependent on the success of their host. It follows that these symbionts should evolve characteristics that increase host survival. However, some so-called “ultraselfish” symbionts manipulate their hosts to the symbiont’s benefit, even when this is to the detriment of the host. The strategies used by such microorganisms include sterilization of noncarriers, feminization of genetic males, induction of asexual reproduction, and biasing host sex ratios in favor of females by killing male hosts. The most common of these reproductive parasites are the ultraselfish bacteria.

**ULTRASELFISH, MATERNALLY INHERITED BACTERIA**

Inherited bacteria that live in the cytoplasm of host cells are transmitted to subsequent generations through the female line. This is because female gametes are heavily resourced with cytoplasm, whereas sperm contain negligible amounts. A maternally inherited bacterium can thus increase its prevalence, either by increasing the fitness of infected compared with uninfected hosts or by biasing the sex ratio in favor of females. The phenomenon of cytoplasmic incompatibility (CI), which involves the sterilization of noncarriers, follows the first of these options. Three other strategies, feminization, partihenogenesis induction (PI), and male-killing (M-k), skew populations in favor of females.

**CYTOPLASMIC INCOMPATIBILITY**

CI was first noted when some crosses between *Culex pipiens* mosquitoes from European, Asian, and American populations failed to produce offspring or produced offspring only when the crosses were carried out in one direction. Observed patterns of reproductive successes and failures demonstrated maternal inheritance (usually 95–100% efficiency), indicating the possible involvement of some cytoplasmic factor, hence the name given to the phenomenon. A bacterium of the genus *Wolbachia* was found to be responsible. Subsequently, CI has been reported from many insect orders. CI occurs when a male carrying a CI agent mates with a female that does not bear the same agent. The bacterium allegedly secretes a chemical into the sperm of their host that kills zygotes formed within the female parent if they do not bear the same bacteria. In essence then, an uninfected female that mates with an infected male is rendered sterile thereafter. Other mating combinations are not affected.

CI bacteria can give rise to two patterns of reproductive failure. If one host population has the symbiont, whereas the other lacks it, matings fail in only one direction; that is, the incompatibility is unidirectional. If, however, each population harbors a different strain of CI bacterium, matings fail in both directions and the incompatibility is said to be bidirectional. For example, in the fruit fly *Drosophila simulans*, both unidirectional and bidirectional incompatibility have been recorded. Indeed, some CI host species carry more than one strain of CI *Wolbachia*, with individuals in some populations hosting two strains concurrently.

**Host Range and Identity of the Agents Causing CI**

CI is commonly reported when crosses of insects from geographically distinct populations are made. It has been reported most often from species of Diptera. However, Coleoptera, Heteroptera, Lepidoptera, Hymenoptera, and Orthoptera have also been found to exhibit the phenomenon and other orders will certainly be added to the list.

The CI phenotype can be cured by treatment with antibiotics or by exposing infected strains to high temperatures (≈37°C) for several days. This suggests that the agents responsible for CI are bacteria. Most CI agents that have been identified belong to the *Wolbachia pipientis* complex, the exception being *Cardinium* species from the phylum Bacteroidetes that cause CI in some *Encarsia* wasps. The *Wolbachia* complex represents a widespread group of α-Proteobacteria, whose members are known to infect hosts from all the major orders of insects as well as some other arthropods (mites, spiders, isopods) and phyla (nematodes). Not all *Wolbachia* infections result in CI. *Wolbachia* is known to manipulate hosts in a variety of other ways and some appear to have no overt effect on their hosts, whereas some are beneficial. Estimates from molecular surveys using *Wolbachia*-specific probes suggest that between 20% and 25% of insect species harbor this bacterium.

Phylogenetic analysis has shown that *Wolbachia* in taxonomically very different hosts are more similar to one another than *Wolbachia* in very closely related hosts, indicating that *Wolbachia* can transfer between host species.

**Mechanisms of Incompatibility**

The precise mechanics of incompatibility are not well understood, partly because the mechanism of incompatibility appears to vary between host species. Various lines of evidence suggest that CI *Wolbachia* modify host paternal chromosomes during spermatogenesis. In *C. pipiens*, incompatibility results from failure of sperm bearing CI *Wolbachia* to fuse correctly with female gametes that lack the same agent. In fruit flies (*Drosophila*) and moths (*Ephesia kuehniella*), embryo development appears to be suppressed at an early stage, suggesting loss of mitotic synchrony. In the jewel wasp, *Nasonia vitripennis*, *Wolbachia* interferes with condensation of the paternal chromosome set during the first mitotic cell division of the embryo so that the paternal chromosome set is lost. All progeny that get the *Wolbachia* thus carry just the maternal chromosome set, are thus haploid, and develop as males. Here, CI results in a male-biased sex ratio.

**The Population Dynamics of CI**

Bacteria that cause CI spread through host populations because infected females have an advantage over uninfected females, which are rendered sterile once they have mated with an infected male. The precise dynamics of CI are influenced by several factors, including (1) the vertical transmission of the bacterium, (2) the fitness costs or benefits it imposes on its host, (3) any horizontal transmission, and (4) host suppression systems.

In general, the prevalence levels of CI bacteria in infected populations are high and often approach 100%. Few studies of the population dynamics of CI have been conducted. The most intensive studies involve drosophilid hosts. For example, in *D. simulans* in California, rapid spread of a CI strain of *Wolbachia was monitored during the 1980s and the 1990s. A theoretical model, based upon the levels of incompatibility, the vertical transmission efficiency of the bacterium, and the assumption that bearing the symbiont had no direct fitness effect on its bearer, produced theoretical predictions close to the observed rates of increase.

**FEMINIZATION**

**Microbes and Sex Determination**

Microorganisms of three types are known to cause feminization of their hosts. One type, microsporidians and other simple protists,
as yet are known to infect only crustaceans. The other types are both bacteria, with Wolbachia, causing feminization in crustaceans and insects, and Cardinium causing feminization in mites. In essence, what these microorganisms do is turn genetic males into females.

The best-studied cases of feminization involve crustaceans, such as the woodlouse, Armadillium vulgare. However, many aspects of the feminization system in crustaceans are probably similar to those in insects, of which two species of moth, Ostrinia furnacalis and Ostrinia scapulalis, harbor feminizing Wolbachia.

Sex determination in the Lepidoptera is normally based upon sex chromosomes; females are the heterogametic sex, carrying two different sex chromosomes (WZ), and males are homogametic (ZZ). In O. furnacalis, all-female strains were first reported in 1998. Antibiotic treatment showed the female bias to be tetracycline sensitive, and molecular analysis revealed a Wolbachia that is taxonomically similar to that causing feminization in A. vulgare.

In parallel to A. vulgare, cure of feminizer lines with antibiotics led to a strong male bias in progeny of cured females. These moths are ancestrally female heterogametic, with the result that feminized ZZ males, when cured of the bacterium and mated by normal (ZZ) males, can produce only male offspring. It is perhaps no coincidence that in almost all examples of symbiont-induced feminization, the host is ancestrally female heterogametic, and further similar instances in the Lepidoptera and other taxa with heterogametic females are likely to be discovered in the future.

Feminization in the mite Brevipalpus phoenicis is extraordinary because this mite can live and reproduce entirely in the haploid state. This species reproduces by thelytokous parthenogenesis. When infected with a feminizing Cardinium, haploid individuals develop as females, rather than males, and these infected females are able to produce haploid female offspring.

**Mechanism of Feminization**

The mechanism of feminization in the two lepidopteran examples has not been determined. However, in A. vulgare, the difference between developing into a male and developing into a female appears to depend on the activity of a single gene that blocks the expression of one or more genes that cause the differentiation of the androgenic gland.

**PARTHENOGENESIS INDUCERS**

**Microbe-Induced Parthenogenesis in the Hymenoptera**

Much of the biotic world indulges in sexual reproduction. However, some organisms reproduce asexually, either ancestrally or secondarily when asexuality has evolved from sexuality. Secondary asexual reproduction, or parthenogenesis, occurs with new individuals arising from unfertilized eggs.

Various types of parthenogenesis exist. Normal haplodiploid species, in which females result from fertilized eggs and males from unfertilized eggs, are called arrhenotokous. In deuterothoty, both males and females arise from unfertilized eggs, whereas thelytoky involves the production of only female offspring without fertilization. The production of only female offspring, without the need for males, raises the possible involvement of cytoplasmic symbionts whose interests are favored by female hosts, which can vertically transmit them. This involvement is realized in a number of haplodiploid Hymenoptera and Thysanoptera, as well as some mites.

The first report of bacterially induced thelytoky was in the parasitoid hymenopteran Trichogramma pretiosum. Here, administration of various antibiotics or of high temperatures to thelytokous females led to the production of males among the offspring. This led to the deduction that some sort of cytoplasmic microorganism, probably a bacterium, caused thelytoky in this species. Microscopic examination revealed a bacterium present in eggs of some thelytokous lines, but not in antibiotic-treated, temperature-treated, or arrhenotokous lines. Molecular genetic analysis revealed the presence of a Wolbachia.

Evidence of microbe-induced parthenogenesis has been revealed subsequently in over 50 species of parasitoid wasp, in the predatory thrip Franklinthrips vespiformis, and in the collombolan Fokomia candida, as well as in some species of mite (Bryobia and Brevipalpus spp.). The microbe involved is usually Wolbachia, although bacteria of the genera Cardinium and Rickettsia cause PI in a few cases. The bacteria involved do not form single taxonomic groups within their genera, but are intermixed with bacteria that affect hosts in other ways (e.g., CI and male-killing), suggesting that PI has evolved independently several times. Alternatively, the genes that cause PI may be horizontally transferred between bacterial taxa, through DNA exchange involving virus-like particles or plasmids. A third possibility is that the same bacterium causes different effects in different hosts, for example, parthenogenesis in haplodiploids and CI or male-killing in diploids. Phylogenetic analysis of a number of PI Wolbachia, particularly in the genus Trichogramma, has provided evidence for interspecific horizontal transmission of the symbiont.

**Mechanism of Parthenogenesis Induction**

Investigations of parthenogenetic organisms have shown variation in the way in which diploid offspring can result from unfertilized eggs. This diversity can be divided into two basic groups: either meiosis is modified with the diploid number of chromosomes being retained or, following meiosis, the diploid chromosome number is restored after the formation of a single pronucleus, usually by the fusion of two haploid mitotic products. In the examples of Wolbachia-induced parthenogenesis that have been studied microscopically, the latter of these two routes applies. In infected females, either both sets of chromosomes migrate to the same pole during the first mitotic division of the meiotic product (e.g., T. pretiosum) or, following the first mitotic division, the two mitotic nuclei fuse (e.g., Diplolepis rosae). The ways in which Wolbachia affect the behavior of host chromosomes during the first mitotic division are currently not known.

**Dynamics of Wolbachia Infection**

In most Hymenoptera with PI Wolbachia, thelytoky has been fixed. However, in many Trichogramma species, both thelytokous and arrhenotokous individuals occur together. The reasons for polymorphism in some species and monomorphism in others are not clear, but incomplete vertical transmission, levels of horizontal transmission, negative–fitness effects of the symbionts on their hosts, and suppressor genes may all have an influence.

**MALE-KILLERS**

**Types of Male-Killers**

Male-killing is perhaps the least sophisticated of the mechanisms of sex ratio distortion practiced by inherited symbionts. The basic mechanism involved is for the symbiont to kill male but not female
hosts. Among arthropods, M-k has been reported from five orders of insects (Hemiptera, Coleoptera, Lepidoptera, Hymenoptera, and Diptera) and two species of mite. In addition, perhaps because M-k is easily evolved, M-k's themselves are taxonomically diverse, with α- and γ-Proteobacteria, Mycoplasma, Flavobacteria, and Microsporidia being recorded. Two M-k strategies have been reported. The first strategy, which involves killing male hosts late in their development (typically in the final larval instar), allows symbionts to replicate within their host, so that large numbers of individuals are released from the host's corpse. Here, the population dynamics of the M-k depend on both horizontal and vertical transmission. Reported late, M-k's are confined to Microsporidia infecting mosquitoes.

The second strategy involves killing males early in their development, typically during embryogenesis. In killing its host, the M-k dies, but in doing so, it increases the fitness of copies of itself in female hosts. The death of the M-k in male hosts means that early M-k does not involve significant levels of horizontal transmission. The increase in the fitness of infected females resulting from M-k is called fitness compensation, because for a M-k to invade a host population, infected females must have higher fitness than uninfected females to compensate for the death of the infected males. The nature of cytoplasmic bacterial reproduction means that many or all progeny of an infected mother will carry copies of the symbiont that are virtually identical by descent. If by killing male hosts the symbiont thereby increases the fitness of the dead males' sisters, a fitness benefit will also accrue to "exact" copies of the male-killer within these females.

Two advantages of M-k have been identified. First, the probability of mating with close relatives, specifically brothers, will be reduced, thus avoiding the harmful effects of inbreeding. An infected female whose brothers have been killed has no siblings to mate with. The second advantage involves resource reallocation. If the resources that would have been consumed by males of an infected female become available specifically to female siblings, these females will benefit.

Early M-k has been recorded from many insect hosts, and to date, all confirmed early M-k's are bacteria. A diverse array of bacteria is involved, suggesting that M-k has evolved independently many times. The distribution of M-k's among insects is not random. Certain groups have behavioral traits and ecologies that provide a context in which high resource benefits are obtained by daughters of infected females specifically as a result of the death of males. In these instances, the resources made available to females from the death of males become preferentially available to infected compared with uninfected females. Hot spots for male-killing are known in the milkweed bugs (Hemiptera), nymphalid butterflies (particularly of the genus Acraea), and ladybug beetles (Coccinellidae).

**Early Male-Killing in Ladybugs**

Female-biased sex ratios were first reported in some families of the ladybug *Adalia bipunctata* in Russia in 1947. The female-biased sex ratio trait was shown to be maternally inherited. More recent work has demonstrated that the trait is curable with both antibiotics and heat treatment, suggesting that a bacterial agent is responsible. Male-killers have been discovered in 13 other species of ladybug. In each case, the female sex ratio bias is associated with the death of approximately 50% of eggs before they hatch (Fig. 1). This leads to the interpretation that the eggs of infected females have a normal sex ratio at fertilization, but that the secondary sex ratio is biased toward females because male embryos die before hatching.

![An egg clutch laid by a male-killer-infected female *Harmonia axyridis*. Approximately half of the larvae (the females) have hatched and the neonates have begun consuming the soma of the dead male eggs.](image)

Experimental work has shown that female larvae from mothers bearing a M-k gain a considerable nutritional advantage from consuming the contents of their dead brothers' eggs. This means that they are larger when they disperse from their egg clutch than larvae from uninfected mothers, and they have longer to find and subdue their first prey before dying of starvation.

Detailed examination of resource reallocation in coccinellids has provided a set of criteria that are predicted to allow the invasion of M-k's. The ladybug must feed on an ephemeral and often limited food, such as aphids. Neonate larval mortality from starvation must be significant. The ladybug must also lay eggs in clutches, and neonate larvae must consume unhatched eggs in their clutch. Lack of one or more of these criteria should make a ladybug reflective to M-k invasion. All ladybugs known to harbor M-k's possess all the relevant criteria.

**The Mechanism of Male-Killing**

The mechanism by which bacteria discriminate between male and female hosts and kill only the former has only been elucidated in *Drosophila melanogaster* artificially infected with the M-k *Spiroplasma poulsonii*. Here, the M-k failed to kill males with mutations in any of the five protein-coding genes in the dosage compensation complex. However, as sex determination systems of species that host M-k's vary (*Drosophila* and ladybugs have XX females and XY males, butterflies have ZZ males andZW females, and the hymenopteran parasitoid *N. vitripennis* has typically arrenotokous haplodzioid sex determination), it is unlikely that the various M-k's all detect that they are in males in the same manner.

**Consequences of Population Sex Ratio Distortion**

Rather more is known about the evolutionary effects of M-k's on their hosts. The prevalence of M-k's varies from less than 5% to over 95% in different insect groups. In the ladybug *Harmonia axyridis*, the prevalence of a male-killing *Spiroplasma* is closely correlated to the population sex ratio. At low prevalence, the population sex ratio deviates little from 50% of each sex. However, at high prevalence (50% of females infected), over two-thirds of the population are female. Similarly, female-biased populations of *A. bipunctata* have been reported. More spectacularly, in the butterflies *Acraea eceledon*, *Acraea encedana* and *Hypolimnas bolina*, some populations
are 95% females. Such highly biased sex ratios have the potential to impact on the evolution of reproductive strategies. This potential may be the cause of a number of unusual features of the courtship and copulatory behavior of these species.

First, both *A. bipunctata* and *H. axyridis* exhibit a variety of genetically determined mate choice patterns, including, unusually, weak male choice of females. Furthermore, in *A. bipunctata*, the investment that a male makes in an individual copulation decreases as the ratio of females to males increases. Male *A. bipunctata* may transfer one, two, or three spermatophores (sperm packages) during a single copulation. In populations with a 1:1 sex ratio, males transfer, on average, just under two spermatophores. Conversely, in populations approaching two females for each male, males rarely transfer more than a single spermatophore (average 1.2).

In highly female-biased populations of the butterflies *A. encedon* and *A. encedana*, many females die without mating. This suggests that males are limiting. The result has been the evolution of sex-role-reversed behaviors. The most striking of these is of female lekking behavior. Male leks, which are resource-lacking arenas where males congregate and compete for mates, are known in many taxa. In *A. encedon* and *A. encedana*, it is virgin females that congregate at resource-lacking sites. Within these arenas, females compete for matings.

**IMPLICATIONS AND APPLICATIONS**

Ultraselfish inherited bacteria adopt a strategy of harming their host to aid their own persistence and spread. Early reports of such symbionts, which caused abnormalities in host sex ratios or reproductive patterns, were long thought of as evolutionary oddities. Over the past two decades, that view has been changed as advances in molecular genetics have revealed that many insects are host to these reproductive manipulators. Surveys have shown that 20–25% of insect species harbor bacteria of a single genus, *Wolbachia*. It is likely that similar surveys directed toward other clades of inherited bacteria will lead to the conclusion that species of insects that host antagonist bacteria are in the majority.

Invasion by ultraselfish inherited bacteria can have far-reaching effects on the evolution of hosts. It has already been shown that the selection pressures imposed by these cytoplasmic symbionts have led to the evolution of nuclear suppressor genes in some insects (e.g., *H. bolina* and *Menochilus sexmaculatus*). Such genes provide evidence of the intragenomic conflict that results from the maternal inheritance of these microbes. Invasion and spread of any maternally inherited symbiont through a host population will also cause an immediate decrease in the diversity of host cytoplasmic organelles, such as mitochondria, for they are inherited together. The spread of a symbiont, therefore, pulls the organelles of its original female host through the host population with it. Further effects of CI, PI, feminizing, and M-k bacteria undoubtedly await discovery. Given the antagonistic interactions between deleterious symbionts and their hosts, it is difficult to believe that a complete understanding of the biology of any insect species can be achieved without consideration of the symbionts it carries.

Deleterious inherited bacteria, such as *Wolbachia*, currently have a high scientific profile. This is at least partly because they may have a future role in pest control. Several strategies of use can be envisaged. Endosymbionts that cause female biases in host species that are already used as biological control agents, such as parasitoid wasps or aphidophagous coccinellids, may be used to increase the impact of the control agent or reduce costs of a control program. Alternatively, mass release of CI agents could be used to cause sterility in recipient populations, much as mass releases of males sterilized by radiation have been used to control *Cochliomyia hominivorax*. A third strategy would be to use these bacteria to transfer genes. If a symbiont bearing “useful” genes were likely to spread through a target population to fixation, as is likely of a CI agent, the useful genes need to be introduced by only a relatively small initial release. Finally, *Wolbachia* could be used to affect gene expression in arthropod or nematode hosts if a gene transformation system could be developed for this bacterium.

The study of ultraselfish inherited bacteria in insects has blossomed over the past decade. The focus on this group of extraordinary parasites is likely to increase, as the breadth of their influence on host evolution becomes more clearly understood.

**Systematics**

*see Nomenclature and Classification*
In recent years, two changes in social attitudes have strongly affected entomological teaching. First, globalization, especially through the internet, has allowed people to pursue their interests at any time and place, with consequent opportunities to compare information and to communicate on a global stage. Second, localization has also occurred, at least in the sense of a surge in pride in the natural features and biodiversity that can be found in one's own backyard. One might argue that this is a bit of a reaction to globalization as well. The combination of these two seemingly contradictory movements has meant that a deluge of information and resources are available and relevant at varying scales. However, this information needs to be filtered carefully, because much of what is available now, especially through the internet, is often not peer-reviewed or generated by trained entomologists.

### WEBSITES

Websites are the most important recent development in entomological teaching, and take various forms, such as clearinghouses to other sites, museum databases, exercises for instruction at various levels, and taxon-based compilations and/or species accounts. The following list of websites offers a general overview of what is available, as well as providing links to other sites. Keep in mind, however, that the web is an ever-changing thing, and that sites come and go, as well as changing addresses. In general, institutionally affiliated websites provide the most reliable information, but this is not always so. Luckily, entomological websites as a group have been less affected by pseudoscience and the fringe element than have many other areas in cyberspace.

- Entomology Index of Internet Resources: [http://www.entiastate.edu/List/](http://www.entiastate.edu/List/). The hub of the virtual entomological wheel, with links to other sites on just about every entomological topic imaginable.
- Introduction to the Odonata: [http://www.ucmp.berkeley.edu/arthropoda/odonatoida.html](http://www.ucmp.berkeley.edu/arthropoda/odonatoida.html). A fine starting place for resources on damselflies and dragonflies.
- Orthoptera Species File Online: [http://osf2.orthoptera.org/HomePage.aspx](http://osf2.orthoptera.org/HomePage.aspx). This site is “a taxonomic database of the world’s orthopteroid insects.”
- Crickets in the Classroom: [http://www.telusplanet.net/public/ecade/CricketsInTheClassroom/cricketsintheclassroom.html](http://www.telusplanet.net/public/ecade/CricketsInTheClassroom/cricketsintheclassroom.html). A good site for those who would like to use crickets to demonstrate various biological principles.
- Ant Base: [http://antbase.org/](http://antbase.org/). Formerly Social Insects Web, a starting point for resources on social hymenopterans, with emphasis on the ants.
- The Tree Of Life: [http://tolweb.org/tree/phylogeny.html](http://tolweb.org/tree/phylogeny.html). A superb site that not only provides information on as many types of living things as possible, but also places this information in an evolutionary context through an explicitly phylogenetic structure. Insects are particularly well covered here.
- UF Book of Insect Records: [http://entnem.ufl.edu/walker/ufbir/](http://entnem.ufl.edu/walker/ufbir/). A fascinating compilation of subject matter, from “fastest flier” to “least specific sucker of vertebrate blood.”

### ELECTRONIC MAILING LISTS

Posting a question to a mailing list, or a listserve, is often the quickest way to answer an obscure question. Keep in mind, however, that experts on the list may resent the implication that they are being used to do your work for you. Therefore, before posting a question,
make a serious attempt to find the answer in the standard sources first. You may have to subscribe to the list in order to post a question, or you can have a current subscriber post the question on your behalf. Your posting may also be archived, and as a result you may be quoted some time later on. Professionalism is, therefore, a wise path to follow. A good way to learn how to ask questions appropriately is to visit the Insect Question Page at http://www.ent.tastate.edu/mail- inglist/bugnet/question.html. See also Entomological Societies.

OUTREACH PROJECTS

A number of outreach projects have entomological themes. A good example is Monarch Watch, a program of the University of Kansas that calls upon schools to help in the monitoring of monarch butterflies (Danaus plexippus) which in return provides educational materials. Other such examples of “citizen science” include Cornell University’s Lost Ladybug project, which may be explored at http://instruct1.cit.cornell.edu/courses/icb344/Lost_Ladybugs.htm.

Various institutions and organizations combine a web presence with an opportunity for school visits. The website of the Entomological Foundation provides details on a number of such projects at http://www.entfdn.org/education_links.php. Many universities also have the equivalent of insect hotlines, or extension entomologists whose duties include answering agricultural and urban entomology questions.

BOOKS AND LIBRARIES

The internet is a wonderful tool, but the library is still the right-ful place for scholarly information in entomology. Books and journals are for the most part much more carefully written, reviewed, and designed than their web-based counterparts, and therefore they are the guardians of mainstream entomological knowledge.

Here we will not cite particular faunal guides, but it is worth noting that there are interesting trends apparent in recently published works. For some groups, formerly obsolete treatments are being updated or replaced on a broad geographic scale. An example is Dragonflies of North America by J. G. Needham, Michael L. May, and Minter J. Westfall (2000, Scientific Publishers). In other instances, local faunas are being treated separately and in greater detail, often for the first time (for example, The Butterflies of West Virginia and Their Caterpillars, Thomas J. Allen, 1997, University of Pittsburgh Press). Still other books are the results of citizen science survey projects, such as The Millennium Atlas of Butterflies in Britain and Ireland (2001, James Asher, Martin Warren, Richard Fox, Paul Harding, Gail Jeffcoate, and Stephen Jeffercoate, Oxford University Press). One faunal treatment, The Insects of Australia (listed later), goes beyond geography and has become a classic of entomology in general.

For the study of most groups of insects, the traditional methods of collecting and preserving specimens are promoted, but for some, and especially for butterflies, many recent books advocate either a hands-off approach to insect study, or catching and releasing the insects one finds. This trend seems directly related to geography—dense populations of more or less urbanized people, sensitive to conservation issues, are likely to support “non-consumptive” entomology, despite a lack of evidence that this is a legitimate conservation concern, especially compared to the effects of habitat loss and introduced species.

The following is a list of 25 books, written in English, that are clearly entomological classics. Some are impressive summaries of one aspect of entomological science, and some are masterfully written explorations of particular topics. With them, an instructor should be able to quickly answer most entomological questions. A good entomology library will contain most of them, but the odds are that every entomologist has at least a few of these volumes close at hand.

TELEVISION AND VIDEO

A number of excellent television programs, as well as regular series, have featured insects as their subject matter. Some of these
are available on videotape or DVD. In general, video narration is not peer-reviewed, and is notorious for inaccuracies. Nonetheless, the value of video in education is difficult to overestimate, and sometimes a game of “spot the mistakes” can be a learning experience in itself, especially when watching “B movies.”

In terms of television series, Insectia is a 13-part, half-hour series hosted by Georges Brossard, the founder of the Montreal Insectarium, and it features many exotic locations and extra-large insects. Alien Empire is a three-part series of one-hour programs produced by the Public Broadcasting System in the United States. It is especially memorable for the use of miniature cameras and close-focusing wide-angle optics that are able to literally track alongside running and flying insects. Acorn the Nature Nut is a 91-part, half-hour series, with 26 episodes having entomological themes. It is hosted by Canadian entomologist John Acorn (coauthor of this article), and combines humor, music, and reliable entomological information.

Microcosmos, is a well-received film on insects by Claude Nuridsany and Marie Pérénoù. It features superb cinematography of the insects of southern France, and has a companion book by the same name (1997. Stewart, Tabori, and Chang). A more recent major insect video production is David Attenborough’s Life in the Undergrowth, which is equally outstanding.

SUPPLIERS

The following suppliers are keenly aware of the needs of entomology teaching. Although they deal with a mix of research customers, hobbyists and teachers, their catalogs provide a good overview of the sorts of materials available for sale in an entomological context. Field equipment can enhance field trip experience, whereas models, charts, and properly designed lab apparatus can greatly improve the quality of teaching in the laboratory. This list is incomplete, but the following suppliers have a long history and good reputation in the field.

- Bio Quip Products. 17503 La Salle Avenue, Gardena, California, 90248-3602, USA. Phone: (310) 324 0620, fax: (310) 324 7931, e-mail: bqinfo@bioquip.com website: http://www.bioquip.com. Bio Quip has been the main supplier of entomological equipment and books in North America for over 55 years. Their selection of educational items is very good.
- Watkins & Doncaster. P. O. Box 5, Cranbrook, Kent, TN18 5EZ, England. Phone: 01580 753133, fax: 01580 754054, e-mail: sales@wadton.com website: http://www.wadton.com. The British equivalent of Bio Quip, with similar items in the catalog, and a history dating back to 1874.
- Acorn Naturalists. 17821 East 17th Street, No. 103 Tustin, California, USA. Phone: (800) 422 8886 (Canada and USA), (714) 838 4888 (International), fax: (800) 452 2802 (Canada and USA), (714) 838 5869 (International), e-mail: EMailAcorn@aol.com website: http://www.acornnaturalists.com. Good selection of educational materials, especially for grade school teaching.
- Pemberley Books. 18 Bathurst Walk, Richings Park, Iver, Bucks, SL0 9AZ, England. Phone: +44(0)1753 631 114, fax: +44(0)1753 631 115, e-mail: ij@pemberley.co.uk website: http://www.merlischop.co.uk/pemberley/. An excellent selection of entomology books, both in print and used.
- Carolina Biological Supply. 2700 York Road, Burlington, NC 27215-3398, USA. Phone: (800) 334 5551 (USA only), (800) 387 2474 (Canada only), (336) 584 0381 (International), fax: (800) 222 7112 (USA only), (800) 374 6714 (Canada only), e-mail: carolina@carolina.com website: http://www.carolina.com. Long-established general source for science and technology teaching materials.
- Ward’s Natural Science Establishment. U.S. address: 5100 West Henrietta Road, P. O. Box 92912, Rochester, New York, 14692-9012, USA. Canadian address: 397 Vansickle Road, St Catherine’s Ontario, L2S 3T5. Temperature, Effects on Development and Growth

Oldřich Nedvěd
University of South Bohemia, and Institute of Entomology, Czech Republic

The body temperature of most insects is linked to changes in ambient temperature. Insects are ectothermic and heterothermic (poikilothermic) organisms, in contrast to endothermic and homeothermic birds and mammals. Large dragonflies, hairy bees, and moths generate and maintain a high and stable thoracic temperature during flight.

Temperature fluctuations are small in environments such as the tropical rainforest, caves, and large streams and water bodies. In most terrestrial habitats, the seasonal and diurnal temperature oscillations are considerable. The body temperature of insects can change rapidly by 10°C or more when shade and direct sunlight alternate. Insects heat up by sunlight through basking behavior and thermal melanism.

Preference for living at high temperatures (in warm regions or on a warm-blooded host) is called thermophily, whereas inclination to low temperatures is psychrophily (usually soil and aquatic arthropods). Temperature within the species-specific physiological range determines the rates of metabolism, growth and development, and often exerts other physiological effects.

METABOLIC RATE

The metabolic rate (mr) reflects the velocity of biochemical processes and can be measured as oxygen consumption, carbon dioxide production, or heat generation. Metabolic increase is exponential, usually two- to threefold with temperature increase by 10°C (so-called Q10): mr = eα+KT. Metabolic rate gradually decreases with decreasing temperature even in immobile insects in a cold stupor.

Weight-specific metabolic rate (in ml O2 or CO2 g-1 h-1) is higher in smaller individuals, and in insects acclimated to lower temperatures.
Active metabolic suppression mediated, for example, by downregulation of important enzymes enables survival for long periods in a dormant state without feeding, even at relatively high temperatures. The effect of temperature on metabolism of poikilotherms may explain its effects on growth rate and developmental time.

**GROWTH RATE AND BODY SIZE**

Three factors control the size that insect larva attains: (1) the growth rate of the last instar larva, which determines how much weight an individual can gain in a given time period, and which is strongly positively temperature dependent; (2) the critical weight, which is the mass at which juvenile hormone secretion stops and which is temperature independent; and (3) the interval to cessation of growth (ICG) after the critical weight is attained (the larva may double its weight during this period) decreases with increasing temperature.

The function that describes the dependence of a phenotype (such as body size) on a particular environmental variable (such as temperature) is called a reaction norm. The relationship between growth rate and temperature is often linear over the range of physiologically suitable temperatures and can be expressed as: \( gr = aT - b \). The ratio \( b/a \) is the threshold temperature \( T_0 \), the hypothetical temperature at which the growth rate would be zero (Fig. 1).

Adult insects generally are of smaller body size when larvae are reared at higher temperatures. For example, females of *Bicyclus* butterflies reared at 20°C were larger than those reared at 27°C. Moreover, females laid larger eggs when they were reared or acclimatized for 10 days at the lower temperature compared to the higher temperature.

Regulation of body size can be partially explained through mechanisms that control cell size and cell number. However, size regulation also requires mechanisms that take information on a scale related to the regulated organ. In insects, this mechanism controls the secretion of ecdysone, which terminates the growth phase of development. The regulation of the size of the entire body must either respond to information produced all over the body, or it must be sensitive to the size of a particular “indicative” body parts.

Relative proportions of body parts are almost constant with changing absolute body size related to developmental temperature (isometric growth). Insulin signaling pathway affects the growth of body parts in a proportional fashion. Spatial changes in tissue receptor activities may account for the variability of body proportions and allometry (e.g., in males of stag beetles, Lucanidae).

Robertson found that genetic differences in wing size in different strains of *Drosophila melanogaster* were mainly due to genetic differences in cell number and cell size remaining almost constant. By contrast, in a given strain of *Drosophila*, the increase in the size of body parts at lower rearing temperatures was consistently due to a change in cell size and not in cell number.

**DEVELOPMENT RATE**

Development time (dt) is the time required to complete specified stage or instar and can be described as \( dt = \frac{SET}{T-T_0} \). SET is the sum of effective temperatures or “thermal constant,” expressed as the number of degree days. \( T_0 \) is the lower developmental threshold (LDT, or base temperature \( T_b \)), the hypothetical temperature at which developmental time would be infinite or developmental rate would be zero. The product of developmental time and the amount to which ambient temperature is above the threshold was found to be constant (=SET), that is, development will take a fixed number of degree days essentially independent of the temperature at which the animal is reared. The thermal parameters are determined in defined conditions (set of constant temperatures, suitable nutrition).

For example, a SET value of 100 degree days means that development at 5°C above LDT lasts 20 days and at 10°C above LDT has 10 days. When the insect develops at fluctuating temperatures, the average temperature above LDT and the length of time when the temperature surpasses LDT are considered for each day, and the number of degree days established in this way is summed. Developmental stage (instar) is completed when the summation reaches SET value.

A temporal drop in temperature below LDT is associated with developmental block and is counted as zero. Usually, there is no
“negative developmental rate” at temperatures below LDT, that is, no delay of development is observed after transfer to an effective temperature. Natural temperature fluctuations, however, may have a signaling effect and influence the SET value in some species, and this possibility needs to be checked experimentally.

The LDT and SET values are population-specific characteristics. The LDT values are similar for all developmental stages of a given population, even when they develop in diverse seasons and experience disparate temperature fluctuations. The stability of LDT is manifested as developmental rate isometry, that is, the percentage of time spent in a particular stage at any constant physiological temperature is a stable fraction of the entire developmental time.

The LDT and SET values established in the laboratory enable prediction of the course of development in the field. On the basis of daily temperature measurements, we can predict the time of the first egg laying and of larvae hatching, and thus appropriate timing of insecticide spray against the particular pest.

Both LDT and, especially, SET may vary between geographically populations because of adjustments to local climatic conditions. There is a trade-off between LDT and the thermal constant (SET) that enables each species to adapt to its thermal environment. Tropical species have higher values of LDT than temperate ones. SET decreases as LDT increases. Insects that have spread to temperate areas because of adjustments to local climatic conditions. Special set of effects of temperature on development is connected with developmental arrest. The state of easily reversible, quiescent, behavior, and a cryptic wing underside, whereas high temperatures produce a generation of adults with delayed reproduction, quiescent plastome. Acclimation to low temperature can cause reversible changes in body coloration, lacewings and pentatomid bugs turn from green to yellow or reddish brown.

**DORMANCY AND PHENOTYPIC PLASTICITY**

Special set of effects of temperature on development is connected with developmental arrest. The state of easily reversible, temperature-dependent developmental arrest is known as quiescence. It is typical of insects adapted to relatively short periods of unfavorable, nonlethal circumstances. Insects that will be exposed to harsh conditions lasting for many months enter a programmed developmental arrest, diapause. Diapause is induced by environmental signals (typically photoperiod) acting before coming of the adverse conditions. Low temperature may increase incidence of diapause induced by short photoperiod. For example, 50% of caterpillars of *Acronycta rumicis* are induced to enter pupal diapause at a daylength of 19h at 15°C, but at 16h at 25°C.

Larvae of the wax moth, *Galleria mellonella* (Lepidoptera, Pyralidae), normally develop at high constant temperature about 30°C in the beehive. If exposed to suboptimal temperature of 18°C, a developmental arrest occurs as the consequence of low ecdysteroid titer. It was described as facultative larval diapause, although transfer back to the optimal 30°C results in the immediate resumption of development.

Daily fluctuations of temperature, the thermoperiod, can induce diapause in a few species kept in constant darkness. Once induced, diapause requires a set time, typically months, during which neurohormonal regulations return to the pattern supporting development and reproduction. In the overwintering insects, diapause is often shortest at temperatures around +5°C. Due to exposure to low temperatures in late fall, the overwintering insect terminates diapause in early winter, and the resumption of its development or reproduction is then halted only by a direct effect of low temperature: diapause turns into quiescence.

Predictable habitats permit fixed life cycles: for example, development in summer and diapause in winter. However, in many species from unpredictable habitats, individuals can follow alternative life-cycle pathways, resulting, for example, in cohort splitting.

Changes in the number of molts have been noted in many insects. Larvae of the mealworm, *Tenebrio molitor*, develop in 11–15 instars at 25°C and in 15–23 instars at 30°C. Chilling stress (short exposure to 0°C in *Galleria mellonella* causes supernumerary moltings induced by persistent increase in the juvenile hormone titer.

Some insect species occur in more than one form and their alternation depends on temperature. Development of caterpillars of *Colias eurytheme* at 18°C leads to mainly yellow butterflies, whereas development at 27–32°C produces orange adults. Progressively declining temperatures during larval development of the *Bicyclus* butterflies produce a generation of adults with delayed reproduction, quiescent behavior, and a cryptic wing underside, whereas high temperatures produce active, fast reproducing adults with an aposematic eye pattern. Acclimation to low temperature can cause reversible changes in body coloration – lacewings and pentatomid bugs turn from green to yellow or reddish brown.

**EXTREME TEMPERATURES**

A general response of insects to temperatures just below their LDT or above their UDT is the cessation of development and reproduction while the insects remain active and feed. The larvae may slowly grow and the adults accumulate reserves. These processes are terminated at more extreme temperatures.

During cooling, motility gradually decreases. At certain temperature, the neural and muscular activities are impaired and the insect lapses into cold stupor (chill coma). The stupor point is as high as 12°C in tropical insects including stored product pests, and in honey bees, around 5°C in many temperate species, near 0°C in most overwintering insects, and even below the freezing point in species living in very cold areas.

Desiccation and nutrient depletion during the cold-induced starvation are certainly incompatible with long-term survival, but death usually occurs earlier and is probably the result of damaging effects at cellular level. The loss of cell membrane fluidity and imperfect protein functions (enzymatic activity, transport, etc.) causes metabolic disorders. The ion pumps in the cell membrane become inefficient and sodium concentration in cytoplasm increases, while the potassium ions flow out into the hemolymph.

Gradual warming above UDT, which is for many species around 35°C but is never sharply delimited, increases the metabolic rate, loss of water, and motility. Around 40°C, the water loss increases sharply: the spiracles are wide open and the melting of cuticular
Thermoregulation

Bernd Heinrich
University of Vermont

In insects, as in other animals, body temperature strongly affects the rate of energy expenditure, the rate at which food can be located and harvested, growth, the facility with which mates can be acquired and predators avoided, and sometimes also the susceptibility to disease organisms. Thermoregulation refers to the ability to regulate that body temperature which best serves survival and reproduction, and it encompasses numerous conflicting constraints and selective pressures. In insects, major considerations involve body mass and access to either external or internal heat. Thermoregulation operates through behavior, physiology, and morphology. For the most part, insects are too small to be able to appreciably elevate, or regulate, their body temperature by internal heat production, although some are large enough and that, coupled with their high flight metabolism, could easily cause them to overheat. In numerous insects, elaborate mechanisms of thermoregulation have evolved both for heating and for cooling the body that possibly rival those of the typically endothermic vertebrates.

ENDOTHERMY IN FLYING INSECTS

Insects arose on earth at least 350 mya in the Devonian Period of the Paleozoic Era. Little is known about the earliest forms, except that originally they must have been crawlers, not flyers, and their bodies assumed approximately the temperature of the immediate surroundings to which they adapted. This holds true even when the immediate surroundings are quite frigid. The adult form of a flightless midge (Dianuesa sp.) walks on glacier ice even when its body temperature is chilled to −16°C. It is so sensitive to heat that, when taken from its natural environment and held in one’s hand, it is killed by the warmth of one’s skin. However, there are insects that maintain quite specific and high body temperatures. Some species of sphinx moths, for example, have thick insulating fur and normally maintain a thoracic temperature near 46°C during flight over a wide range of ambient temperatures. To these moths, our own normal body temperature of 37°C is almost cool. An insect’s head and abdominal temperatures are for the most part unregulated.

In the same way that the motor heats up when a car burns fuel, heat is released as an inevitable by-product of cellular metabolism whenever muscle contracts. Close to 94% of the energy expended by muscles during contraction is degraded to heat, while approximately 6% appears as mechanical force on the wings. Insect flight is one of the most energetically demanding activities known, and thus most insects produce more heat per unit muscle mass when they fly than almost any organism on earth. Most insects exist under conditions somewhere in between the cold-blooded crawler and the hot-blooded flyer, but these extremes show us what is possible, and they thus offer us a remarkable window into thermal adaptation from an evolutionary perspective.

The ability of birds and mammals to regulate body temperature at one set point, specifically 37–41°C, has long been considered proof of sophistication and phylogenetic advancement relative to animals whose body temperature varies with that of their environment. Deviation of body temperature from the set point of 37–41°C is, in birds and mammals, often associated with illness and was once

Thermosensitive proteins are typically expressed during mild, high-temperature exposure, protecting the organism at even higher temperatures. It is believed that they are chaperones enabling or protecting functional protein conformations.

Further Reading

thought to be caused by a failure of the thermoregulatory system. We now know that both increases and decreases in body temperature can be and often are adaptive responses. Both responses are often sophisticated physiological mechanisms that involve more thermoregulation rather than less, albeit the body is kept at a more appropriate temperature for specific conditions.

Small insects have much lower body temperatures in flight than large insects, not because they produce less heat—in fact, they may have higher rates of heat production than larger insects, but because they have much greater conductance because of their large relative surface area. In bees, for example, only the large species heat up in flight and generate an appreciable elevation of body temperature even though metabolic cost of flight per unit weight declines approximately 230% for a 10-fold increase in mass. A mosquito in flight maintains only a tiny (<1°C) gradient between thoracic and ambient temperature, despite prodigious amounts of heat production. A blow fly (Calliphora vicina) may heat up 5°C, and a honey bee heats up its thorax about 15°C. Having a much larger thorax, and hence a smaller relative surface area, means that the internally generated heat during flight is not lost by convection at the same rate that it is produced until a much higher temperature gradient has been generated.

Large insects—those that inevitably generate a high body temperature during continuous flight—must be biochemically adapted to operate their flight muscles at the high temperatures experienced. Temperature is important for mechanical efficiency; at low muscle temperature, there is partial overlap in contractions of the up- and downstroke muscles, the dorsoventral and dorsal longitudinal muscles; the two sets of muscles then work against each other rather than working to move the wings.

Numerous other moths such as most microlepidoptera and geometrids (inchworms) and some ctenuchids and arctids—are small or weak flyers that do not heat up but fly at low air temperature. They fly at muscle temperatures much lower even than those at which the large-bodied, small-winged (and hot-blooded) sphinx moths generate zero power. Evolution has acted strongly to tailor the flight motor's capacity for maximum power output for much lower ranges of operating temperatures. For example, the geometrid Operophtera bruceata can gain sufficient power to fly at 0°C. (Nevertheless, its capacity to do so is only partially the result of muscle physiology.)

The basis for the evolution of differences between species arising from a common ancestor is variation among individuals. Variation was present in the past, and for many traits, variation is maintained even now. For example, in Colias (sulphur) butterflies, the gene locus for phosphoglucose isomerase, one of the enzymes involved in energy metabolism in these butterflies, changes in allele frequency with season and habitat temperature. This suggests that natural selection is occurring even over very short (i.e., seasonal) time spans. The different enzyme alleles have different thermal stabilities, and heterozygotes are thought to have an advantage in an environment of rapidly fluctuating temperatures inasmuch as the individuals heterozygotic for this locus fly over a range of temperatures broader than that of individuals of other genotypes.

When a seasonally changing temperature environment, which is the rule, can select for heterozygosity, then one might expect that an environment of constantly high or low temperature, which is the exception, should lead to the fixation of an appropriate genotype. Hence, selection in terms of gene-frequency changes would not normally be present for our inspection in more constant environments, in which appropriate genotypes would already have been selected long ago to adapt to the average temperature. The specific thoracic temperature that is maintained by regulation is "chosen" by evolution, probably, because it is the temperature most readily regulated for maximum activity over a range of prevailing environmental conditions.

**WARM-UP BY SHIVERING**

During his classic studies of honey bee communication, Karl von Frisch noted that bees often interrupted flight for a few minutes when they were returning to the hive heavily laden with nectar. He presumed they stopped "to rest," but we now know they were stopping to work: to raise their thoracic temperature. They most likely stopped flight because it was a cold day and they had cooled convectively. Bees are able to raise their thoracic temperature by shivering, which can work their flight muscles harder than flight itself does. Von Frisch could not have known any of this, because shivering and thermoregulation by individual insects was unknown in the 1960s, nor is shivering externally visible in bees even if one looks very closely.

Like the maintenance of an elevated body temperature by internal heat production in flight, physiological warm-up is found in all large, active flyers among the dragonflies (Odonata), moths and butterflies (Lepidoptera), katydids (Orthoptera), cicadas (Clyperorrhyncha or Homoptera), flies (Diptera), beetles (Coleoptera), and wasps and bees (Hymenoptera). That is, it is found from some of the earliest forms, the Odonata, to the most evolutionarily highly derived, the Diptera, Coleoptera, and Hymenoptera. It is not found in the small and therefore, nonendothermic members of the same groups. Because no insects shiver except those that then also heat up from flight metabolism, it seems reasonable to conclude that the evolution of shivering behaviors is related to the evolution of flight but is unrelated to the insect's place on the phylogenetic tree.

During preflight warm-up, there are synchronous contractions of groups of muscles that normally contract alternately in flight. That is, the main wing-depressor muscles, the dorsoventral longitudinal muscles, are excited simultaneously—in other words, in synchrony—with the dorsoventral wing elevator muscles. The neural activation pattern of thoracic flight muscles needs to be and is already very labile for flight control, and to add shivering when flight behavior has already evolved is probably a very minor evolutionary step. Physiological warm-up in its most basic form is like the idling of an engine; the engine "evolved" to propel the car, not to warm it up. Once present, the heat-producing flight-muscle system required only a slight modification of neuronal activation patterns and, in the more sophisticated models, also the addition of the biological equivalent of a clutch—a mechanism to disengage the wings in the same way that an automotive clutch disengages the car's wheels. Some insects, such as dragonflies and moths, do have visible external wing vibrations that were originally called "wing whirring"; these were once thought to pump air into the animal before the true function was elucidated.

The zenith of the shivering response of any hot-blooded animal (vertebrate as well as invertebrate) belongs to some bees. Honey bees and bumble bees have a physiological sophistication either not existing or not yet observed in other insects, and they exploit shivering behavior to an unprecedented extent and in a variety of ways. Like flies and beetles, bees are "myogenic" flyers in which the wing-beat cycle runs in part on automatic; as the downstroke muscles contract they stretch the upstroke muscles. This stretching by itself causes the upstroke muscles to contract. The downstroke of the wing therefore automatically causes the upstroke muscles to contract and vice versa, in a repeating cycle that is sparked by neural commands that are at a much lower frequency than the wing beats and are no longer specific to a single wing beat. (This system permits some of the smallest insects, such as midges, to achieve the unprecedented
Thermoregulation

coordinate required for wing-stroke cycles of over 1000 beats per second.) But the stretching of opposing muscle groups that maintains the myogenic contraction cycle can occur only if the wings are actually beating—namely, during flight. When the wings are not in use, as when they are folded back dorsally and the clutch-like wing hinge is engaged, then the muscle groups are in near tetanus. That is the reason for the bees’ shivering.

Very vigorous shivering in bees is physically dampened even more by yet another mechanism. One of the two sets of opposite-acting muscles is activated (and hence contracted) slightly more than the other. Because the opposing muscles act like weights forcing down each side of a seesaw, the added force on one set of muscles prevents the “seesaw” from working (and the wings from “vibrating” back and forth).

WARM-UP BY BASKING

Like warm-up by shivering, warm-up by basking occurs in all major orders of insects that have fast flyers large enough to heat up from their flight metabolism. In its simplest form, behavioral warm-up is merely heat-seeking. A basking insect usually takes specific postures that simultaneously maximize solar input and minimize convective heat loss. Heat input is maximized by exposing the maximum surface area to the sun, while convective heat loss is minimized by using body parts (such as the spread wings) as baffles to retard air movement around the body. Orienting the body parallel to the air stream (as a wingless insect might do) would reduce the effect of convective cooling, but orienting the body perpendicularly to the sun’s rays to facilitate heating should take precedence, because no heat loss can be minimized until heat is first gained. Grasshoppers, beetles, and flies use these basking methods. For some dragonflies and butterflies, the wings are especially important during warm-up in their role of reducing convective cooling.

Behaviorally distinct types of basking have been described in butterflies, although some (tropical) butterflies do not bask at all. In one type, called “lateral basking,” the butterfly closes its wings dorsally and then tilts to present either the right or the left wing and body surface to the sun. The lower portions of the wings wrap around the body and touch it, and warming the lower wing portions in sunshine then causes heat to be conducted directly through them and into the body.

Many species of small-bodied butterflies, primarily pierids and some lycaenids (which commonly fly in breezy mountain meadows) bask by opening their wings partially in a V so that the body is directly available to the sun’s rays at the bottom of the V. The wings then serve as convection baffles to reduce cooling in the breezy environment. “Dorsal baskers” hug a solid substrate, such as the ground, and pull their wings down around them. They, thereby, expose the dorsal body surface to the sun while simultaneously capturing heat from the sun-heated substrate.

HEAT LOSS MECHANISMS

Insects near the size of a honey bee (approximately 200 mg) or larger may experience body temperatures during forced flight exercise that are potentially lethal to them. Alternately, metabolic heating may inhibit continuous flight at relatively modest ambient thermal conditions (of air temperature and solar radiation), unless one or more of the following mechanisms for heat loss are activated.

Harnessing Convection

The rate of convective heat loss from a body is determined by the conductance of the body, that is, its intrinsic rate of heat loss (which is a function of body size, shape, and insulation). Conductance, in turn, is a function of the wind speed (a hot body cools more quickly in wind than in still air—meteorologists call this the “wind-chill factor”). However, no convective heat loss is possible, regardless of conductance, if body and ambient temperatures are equal, and at any one conductance and wind speed, the amount of heat loss is directly proportional to the temperature difference between the body and the ambient surroundings.

Small insects that are endothermic in flight are sufficiently air-cooled such that they almost never reach the potentially dangerous high-temperature ceiling of near 45°C that is common to most animal tissues at normal atmospheric pressures. These small insects thus have no need of a specialized cooling system: they lose sufficient heat passively. Theoretically, larger insects could cool themselves by increasing flight speed and thus increasing convective heat loss, but flying faster would generally increase metabolic heat production, which would cancel out the increased heat loss, unless the internally generated heat is redistributed.

Heat Radiators

A radiator is a device that increases the surface area of a body or object so that more heat can be transmitted to the surrounding environment by convection. In some radiators, a fluid with a high heat capacity (like water, blood, or other liquid) circulates by means of a pump and transfers heat from its source to the radiator site for the heat loss. That is how a car engine is cooled.

Radiators are utilized by many large insects from the very diverse orders Lepidoptera, Odonata, Diptera, and Hymenoptera. The animals have a fluid-transfer cooling mechanism that dissipates heat through an abdominal radiator, while small members of the same groups that are not strong or continuous flyers lack the heat-transfer response. When humans exercise in the heat, blood is pumped to the skin or extremities to facilitate heat loss, but this is done at the expense of pumping blood and oxygen to the muscles instead. Therefore, work capacity is compromised. Insects, on the other hand, do not need to compromise aerobic work capacity at higher air temperatures because of thermoregulation. In insects, the total separation of respiratory and heat-transfer functions makes it possible for them to continue working, even when the fluid flow is interrupted.

The “radiator tube” that conducts the hemolymph to the abdominal heat radiator in insects also serves as a pump, which operates by peristaltic contractions along its entire length. Although sphinx moths in whom surgery has rendered its “heart” inoperative (by tying it shut) can still fly until reaching near-lethal thoracic temperatures, removal of their insulating layer of thoracic scales makes continuous flight possible again.

Evaporative Cooling

One of the extraordinary examples of an evaporative cooling mechanism specifically for thermoregulation is that found in the workers of honey bees, Apis mellifera, and yellowjackets, Vespula spp. These insects use the head as a radiator, but they do so with a difference. Nectar-gathering honey bees normally fly with flight motor temperatures near 15°C above air temperature. They are capable of the astounding feat of flying even at ambient temperatures near 45°C while maintaining the thorax at the same or only slightly lower temperature. They do so by regurgitating nectar from the honeycrop, and while the nectar is held on the mouthparts and the head, water evaporates from it. Because of the physical contact between
the head and the thorax, thermoregulation of one effectively results in thermoregulation of the other. Thus, the head is cooled by evaporation of water until there is a large temperature difference between the head and the metabolically heated thorax, at which point heat from the thorax follows the temperature gradient and is transmitted to the head. Head temperature is actively regulated, with thoracic temperature passively following, because artificial heating of the thorax alone does not result in the heat-dissipation response so long as head temperature remains low. However, artificial heating of the head (as with a narrow beam of light from a heat lamp) almost immediately results in nectar regurgitation and evaporative cooling, even while thoracic temperature is still (momentarily) low.

Some insects cool evaporatively from the back. In the hot Australian deserts, the larvae of the sawfly *Perga dorsalis*, in response to solar heat stress, first raise their abdomen to the sun to shade the body and to increase convective heat loss. In an emergency, when this response is insufficient, they also emit rectal fluid and spread it over their ventral surface to cool themselves evaporatively.

*Diceroprocta apache* of the Sonoran desert of the southwestern United States employs a third evaporative cooling mechanism—the one analogous to sweating. These cicadas are plant-sap feeders, and despite living in a dry environment, they have access to a large fluid supply by inserting their sucking mouthparts into the xylem of deep-rooted shrubs, such as mesquite. They thus indirectly tap water from deep underground stores. Cicadas sing when ambient temperatures in the shade reach 40°C, and the repetitive contractions of their tymbal muscles result in internal heat production that adds to the already considerable external heat load.

Body temperature during this exercise in the heat is reduced to tolerable levels by evaporative cooling from fluid shed through large pores distributed over their dorsal body surfaces. The release of this fluid, and the consequent evaporative cooling, occurs only in response to very high body temperature. Most insects, especially those of desert environments, are instead highly resistant to water loss when alive, and upon death, there results an immediate increase in water loss as the spiracles are no longer actively maintained shut. Killing of the cicada, in contrast, immediately stops the sweating response, therefore, showing that it is under metabolic control. The cooling response is mediated, ironically enough, by aspirin-like substances produced in their bodies in response to heat stress.

**Thermoregulation**

 Aside from physiology, various aspects of insects’ morphology come into play in their thermoregulating responses.

**Insulation**

Many hot-blooded insects that regulate their body temperature have, like their endothermic vertebrate counterparts, bodies wholly or at least partially covered with insulation. One type of insulation is derived from air sacs. Insects already have air sacs used for breathing, and still air is, next to vacuum, the best possible insulator. Many insects of various orders have air sacs between the thorax and the abdomen that greatly retard the leakage of heat into the abdomen. But large-bodied dragonflies have gone one step further: their air sacs surround the thoracic flight motor. The other two types of insulation are derived from exterior cuticular structures.

Lepidopterans are covered with a layer of thin overlapping scales, which are especially noticeable in coloring the wings. Rather than remaining flat and colorful for visual signaling as in butterflies, they have become long and thin to form a thick insulating body (thoracic) pile or fur coat in many moths. This coating of pile is so effective as insulation; it more than halves the rate of heat loss, or doubles the temperature excess, hence permitting flight at much lower air temperatures. Endothermic insects with pile now fly in many northern areas and at times of the year at which they would otherwise be excluded. Conversely, insects from tropical environments have no or only sparse pile covering.

A covering of setae, small hair-like projections from the cuticle, is the third source of insect insulation. Setae have various functions and numerous independent evolutionary origins. Within the Hymenoptera, only the northernmost large bees, the bumble bees, have a heavily insulated flight motor. However, even honey bees have a layer of short insulating pile on the thorax, which aids them on cool mornings and at high elevations. Bees inhabiting the tropics and hot deserts do not have a covering of pile dense enough to provide appreciable insulation. But even tropical bees cannot get along totally without setae, because they use these projections to trap pollen from flowers. Some wasps, in contrast, live in the same northern areas that bumble bees do, but they do not rely on pollen for protein. Instead, many are predators on fast-flying insects, and they are glabrous. Perhaps an advantage of fuel economy in flight, or perhaps the necessity for fast flight, has assumed more importance than drag-inducing insulation for thermoregulatory control.

**Color**

In a few instances, an insect’s color has a functional significance in thermal balance during basking. For example, lateral-basking sulphur butterflies (*Colias* spp., usually yellow or white) found in cool environments (such as mountaintops or high latitudes) or seasons (early spring) tend to have dark wing undersides. These darker individuals are able to heat up the thorax slightly faster than lighter congeners, which buys them additional flight time when basking is needed to prepare for flight.

Although, color can have a slight thermal advantage, it is more often subservient to other needs, such as the need to evade predators. Not surprisingly, insects that inhabit open ground often match their background in color and thus are highly camouflaged.

**Stilts and Parasols**

A beetle walking on hot desert sand might experience temperatures that could kill it in a minute or less. Just a few millimeters above the ground, however, the hot, ground-hugging air layer is disrupted and mixed with cooler air from above. If we were shrunk to Lilliputian size and forced to live where a few millimeters’ difference in elevation could mean the difference between life and death, we would find some way to lift ourselves above the searing heat. Numerous ground-dwelling beetles living on hot sands do just that. Tiger beetles (*Cicindelidae*) begin to stand tall when sand temperatures exceed 40°C. Aside from extending their jointed legs to stand taller, some beetles, like *Stenocara phalangetum* (Tenebrionidae) from the Namib Desert of southern Africa, have evolved very long stilt-like legs that allow them to avoid overheating by both avoiding the heat at ground level and losing some of the solar heat by convection through fast running.

Another option is to use one body part to shade another. For example, some beetles reduce their absorption of external heat from direct solar radiation by having an air space beneath the elytra that insulates the abdomen from direct solar radiation.
**Countercurrent and Alternating-Current Heat Exchanges**

At low air temperatures, when the abdomen is cool, the flight motor could cool precipitously if the hemolymph carried heat away from the thorax to be dissipated from the abdomen. Two mechanisms, however, normally prevent this potential problem of thoracic cooling. The first is a temporary reduction or elimination of the circulation: to retard heat loss.

Another mechanism, one more subtle than cardiac arrest, helps some insects prevent heat leakage from thorax to abdomen. Proof of that is seen in honey bee workers and Cuculliinae winter moths, which never show appreciable increases in abdominal temperature, even as the flight motor stays hot. An examination of their circulatory anatomy explains the mystery: they harness countercurrent heat transfer.

A countercurrent implies two separate currents flowing next to each other but in opposite directions, as through the petiole between thorax and abdomen in insects. If the fluid in one current is of a higher temperature than that of the other, then heat (which is not confined by the vessel walls) will passively flow “downhill,” from high to low temperature, across these walls. Thus, if the hot blood leaving the thorax flows around the vessel in close proximity to cool blood entering it from the abdomen, as in most bees, then heat exchange is inevitable. At least some of the heat from the thorax will be recycled back into the thorax, because the incoming blood is heated by the outgoing blood. In honey bees and winter moths, countercurrent heat exchange is greatly enhanced by prolonging the area for that potential heat exchange to occur, as the aorta in the petiole is lengthened and (in honey bees) convoluted into loops.

Bumble bees and northern vespine wasps have a very much different and seemingly less efficient countercurrent heat exchange circulatory anatomy than honey bees and winter moths (Fig. 1).

**FIGURE 1** Anatomy of a bumble bee (Bombus) relevant to thermoregulation. The thorax is insulated with pile that reduces the rate of convective heat loss. The ventor of the abdomen is lightly insulated or uninsulated when the bee presses her abdomen onto brood to be heated. Hemolymph (blood) is pumped anteriorly by the heart, from the abdomen into the thorax. When dissipating heat from the working muscles in the thorax, the blood enters the aorta from the heart in pulses. Each pulse of cool blood from the abdominal heart into the thoracic aorta alternates with a pulse of warm blood entering the abdomen to the thermal window. In this way, countercurrent heat flow (into blood returning to the thorax) is minimized and heat flow (into the abdomen) is maximized. [Reproduced by permission of Oxford University Press from B. Heinrich (1976), *J. Exp. Biol.*** 64, 561–583.]

This situation may seem counterintuitive because they live in cold climates, some species even inhabiting the High Arctic. They might thus be expected to have even better countercurrent heat exchangers than honey bees, which are of temperate and tropical origin. Instead of having more loops for countercurrent heat exchange, they have none! Nevertheless, their anatomy can also be understood in terms of thermal strategy, but as it relates to their social system.

Bumble bee and wasp queens start their colonies very early in the spring; each new queen attempts this task alone, as an individual. To this individual bee or wasp, time is of the essence, for she must complete the whole colony cycle within a single growing season. A queen’s first priority, then, is to rear a group of helpers. Temperatures when and where she builds her nest may be near 0°C, and if the brood were left at that temperature, it might take years for them to develop to adults—provided they could withstand the freezing temperature. Even in the High Arctic, however, the queens of *Bombus polaris* can produce a batch of workers in about 2 weeks, as can other bumble bees and *Vespula* wasps. Both bees and wasps accomplish these feats by incubating the brood from the egg to the pupal stage. The queens perch upon their brood clump—consisting of eggs, larvae, and/or pupae—and they press their abdomen upon the brood, much as a hen incubates her eggs with her belly. The abdomen provides a smooth surface for contact, but only the thorax produces heat by way of intense shivering by the flight muscles. No incubation, and hence social life, would be possible for these insects in a cold environment if, like honey bees, they were incapable of transferring heat from the source of its production into the abdomen that provides the smooth tight contact with the brood.

The bumble bee’s aorta is long enough to permit moderate heat exchange and hence retention of heat in the thorax, but it is short and straight enough, so that a physiological mechanism can be activated that shunts the fluid and heat through effectively eliminating countercurrent heat exchange.

Countercurrent heat exchangers in vertebrate animals can be bypassed by rerouting the blood into an alternate (generally external) channel. That is why our own veins seem to pop out when we are active in the heat. Such rerouting of the blood from internal to external channels is not possible, however, in insects with open circulatory systems lacking veins and capillaries. Instead, in bumble bees there is a physiological solution for heat loss in the presence of a countercurrent heat exchange anatomy that serves the same purpose as an alternate blood channel. In the bumble bee, this consists of an *alternating-current* flow of blood. To shunt heat past the heat exchanger and into the abdomen, the bee lifts a small valve that allows a pulse of warm blood to enter the abdomen, and in the fraction of a second after the warm blood enters the abdomen, she then squirts a bolus of cool blood into the thorax. And so, it goes back and forth, hot and cold pulses of hemolymph passing alternately through the heat exchange area in the bee’s waist. The essential point is that although the blood is not rerouted into a different channel, it is instead temporarily “chopped” into alternating pulses in the same channels. This is the opposite of countercurrent flow because instead of recovering heat from the thorax, the system acts to remove it, in this case into the abdomen.

The pumping of hemolymph by the heart and the ventral diaphragm is also aided by in–out pumping movements of the whole abdomen, which otherwise function only for moving gas in and out of the thorax; the in–out telescoping movements of the abdomen are synchronous with the heart beats and the ventral diaphragm beats, and they cause pressure changes that facilitate hemolymph flow in precise alternating currents.
THERMAL ARMS RACES
Against Predators

On a summer day in the Sahara Desert in Algeria, as the sun rises and begins to heat the sands that have been cold at night, an abundance of insect life is forced to retreat to cool underground refuge. Those unfortunate ones caught out in the heat become disoriented and, moving frantically, they heat up even more, then they die. The sun keeps rising, and sand temperatures begin to exceed 46°C. The desert lizards, *Acanthodactylus dumerilii*, continue to hunt the incapacitated prey and any ants they can find. But they now dash quickly across the sand, and when they stop and stand, they alternately lift their feet to prevent burning them. Meanwhile, long-legged silver ants, *Cataglyphis bombycina*, avoid the lizards by remaining in their burrows under the sand. However, they are poised to leave, waiting for the sand temperatures to heat up even more, until it reaches about 60°C, when the temperature of the air at ant height is about 46.5°C. Temperature “testers” among them lurk at the nest entrance. At the right moment, they signal the time to come out by releasing pheromones from their mandibular secretions. The rest of the colony then rushes out into the field to forage safely, until they too must retire back to their underground shelters—when they experience air temperatures of 53.6°C, which is just a fraction of a degree below their thermal death point.

In the southwestern deserts of the United States near Phoenix, Arizona, the desert or Apache cicada, *D. apache*, also engages in a thermal arms race against vertebrate predators. These cicadas are active at the hottest time of the year, and even then they wait until the high midday temperatures of 44°C (in the shade) near noon to be most active, when the cicada-killing wasps and birds are forced to retire from the heat.

In the deserts of southern California, the grasshopper, *Trimerotropis pallidipennis*, endures heat rather than regulating heat loss like the sweating cicada. By blending in with the background of the desert floor, it hides to escape bird and lizard predators. Normally grasshoppers that inhabit the ground still high above that substrate when it begins to heat up very high temperatures in sunshine. But to remain camouflaged, it is imperative for *T. pallidipennis* to crouch down onto the scaring hot ground. When that ground heats to near 60°C in sunshine, the duration of time that a grasshopper can remain hidden is limited by how high a body temperature it can tolerate. *T. pallidipennis* has evolved to tolerate the extraordinary high body temperature of 50°C and can thus escape into the sanctuary of sunlight, where a predator such as a lizard or bird cannot hunt.

It is probably rare that insects escape predators by seeking out low temperatures. Possibly the best candidates are the Cuculliinae, a subfamily of the generally endothermic Noctuidae or owlet moths. The Cuculliinae are a northern circumpolar group of moths, and in northern New England they may fly during any month of the winter when temperatures reach 0–10°C and when most of their bat and bird predators have left. During flight, cuculliines have flight-motor temperatures near 30–35°C, as do other moths of their size and wing loading. Unlike all other moths, however, the cuculliines can begin to shiver at the extraordinarily low muscle temperature of 0°C, and they continue shivering to warm up all the way to 35°C.

The giant hornets, *Vespa mandarinia*, attack honey bee colonies. During a typical giant hornet attack, a lone hornet forager first captures bees at the periphery of the bees’ nest. After several successful foraging trips to the beehive, the hornet deposits a marking pheromone at the hive entrance from the van der Vecht gland at the tip of the abdomen. This pheromone attracts other hornets from the home nest, and then the slaughter phase of the hornet attack begins: 30,000 bees can be killed in 3 h by a group of 30–40 hornets. Subsequently the hornets may occupy the hive itself, and then they carry off the bees’ larvae and pupae to feed to their own young.

The above happens when hornets attack colonies of the introduced European honey bee, *A. mellifera*, but the Japanese honey bee, *A. cerana*, has evolved an effective counterstrategy to the hornets’ mass invasion. With the latter, those unfortunate hornets that are recruited by the pheromone, then try to enter the hive and are met and killed by heat as hundreds of bees envelop each wasp into a tight ball. The interior of these bee balls quickly rises to 47°C, killing the hornet but not the bees, whose upper lethal temperature is 48–50°C.

Against Competitors

Contest competition or fighting over food is rare in insects, but at least two species of African dung beetles, *Scarabaeus laevistriatus* and *Kheper nigroaeneus*, engage in combat over dung balls that they make to feed on and/or to serve as sexual attractants. An elevated thoracic temperature plays a crucial role in these contests on the ground. The more a beetle shivers to keep warm (with its flight muscles), the higher the temperature of the leg muscles adjacent to the flight muscles in the thorax and the faster its legs can move and construct the dung into balls and roll it away. Endothermy thus aids in the scramble competition for food, and it reduces the duration of exposure to predators. Additionally, hot beetles have the edge in contest competitions over dung balls made by other beetles; in fights over dung balls, hot beetles almost invariably defeat cooler ones, often despite a large size disadvantage.

Mate Competition

For large insects, endothermic heat production is a requisite for flight, and it is during flight that other activities, including foraging, oviposition, and predator escape, as opportunity and necessity dictate, may occur. Hence, to find a direct effect of body temperature on mating success specifically, one must examine a mating behavior that is not already tightly linked with some other temperature-dependent activity. Singing in some species is a good candidate. Singing is one activity that serves only for mate attraction, and in katydids and cicadas, only the males sing and the females remain silent. The vigor of this singing activity is associated with and dependent on thermoregulation. Katydids, *Neoconocephalus robustus*, warm up for their ear-shattering mating concerts by shivering, bringing flight-muscle temperatures above 30°C. Males of the Malaysian green bush cricket, *Hemecerinus unicolor*, sing from dusk until well into the night, and before they sing, they prepare themselves by shivering to achieve thoracic temperatures near 37°C. At thoracic temperatures of 37–38°C, the males are able to achieve the extraordinarily fast wing movements of up to about 400 vibrations per second.

The dragonfly *Libellula pulchella* demonstrates both the importance of body temperature for mating success and the trade-offs required for maximizing power output as an insect matures. The young, nonreproductive adults of this species are sit-and-wait predators that typically fly with relatively low thoracic temperature. Their flight-muscle performance does not peak at any one temperature; instead, performance is uniformly spread over a wide range of low thoracic temperatures. In contrast, sexually mature males engage in nearly continuous flight in intense territorial contests. At such times, they generate a very high thoracic temperature, and they regulate that thoracic temperature precisely and within only 2.5°C from their upper lethal temperature. Thus, muscle performance of the sexually
mature males is narrowly specialized relative to that of young adults that do not engage in strenuous battle.

SOCIAL THERMOREGULATION

Many of the social insects regulate the temperature of their nests in coordinated behavioral and physiological responses involving the adult nest inhabitants. Nest temperature regulation functions primarily to maintain activity and to keep the otherwise thermally labile larvae at the proper temperature for rapid growth. Thermoregulation allows social insects to rapidly build up large nest populations and to inhabit environments where they could not otherwise exist.

Nest Site

One of the first requirements for effective nest temperature regulation is the choice of an appropriate nest site. Typically, northern ants nest in the open, often under solar-heated rocks, or they make solar-heated mounds; many termites also nest to maximize exposure to solar radiation. Honey bees that live in northern temperate climates require enclosed nest sites such as tree cavities, whereas a variety of other more tropical bees have open and exposed nests.

Nest Construction

Northern vespine wasps enclose their nests in multiple layers of paper that insulate the nest contents. Some termites and ants construct nests so located and constructed as to maximize solar heating in the morning and evening and to minimize overheating at noon. Nests may be constructed so that air circulation and heat transfer are enhanced for thermoregulation.

Behavior and Physiology

Ants regulate the temperature of their brood by carrying it to those parts of the nest with suitable temperatures. Both honey bees and vespine wasps regulate the temperature of the nest, especially near the brood. They fan to circulate and carry off heat when nest overheating is imminent, and if temperatures continue to increase, they carry in water and sprinkle it on the combs for evaporative cooling results. At low temperatures, such as during winter and in swarm clusters outside the hive, the bees crowd together tightly as air temperatures drop, thereby trapping heat inside. As air temperatures rise, the bees on the cluster start to disperse, the cluster booms, and heat from the interior is released. In hives containing both honeycomb and comb with brood, the bees preferentially cluster around the brood. Brood temperature is maintained near 36°C in hives that may be subjected to air temperatures as low as –50°C and as high as 50°C, provided the bees have access to honey, as an energy source for heat production in heating is imminent, and if temperatures continue to increase, they carry in water and sprinkle it on the combs for evaporative cooling. As air temperatures rise, the bees on the cluster start to disperse, the cluster booms, and heat from the interior is released. In hives containing both honeycomb and comb with brood, the bees preferentially cluster around the brood. Brood temperature is maintained near 36°C in hives that may be subjected to air temperatures as low as –50°C and as high as 50°C, provided the bees have access to honey, as an energy source for heat production in the cold, and for water for evaporative cooling in the heat.

Thysanoptera

1000

injected into sockets that are figure-8-shaped. When at rest, the wings lie parallel to each other on the abdomen, with the cilia of the posterior margins in the midline, but the wing-holding mechanisms vary considerably between species. The 10th abdominal segment of Terebrantia species is incomplete ventrally, and the ovipositor comprises four saw-like blades that are used to insert an egg into plant tissue.

FAMILY CLASSIFICATION

Species, or groups of species, with particularly unusual structures are sometimes segregated into smaller families in both suborders. Despite this, the suborder Tubulifera is usually considered to include a single family, the Phlaeothripidae, with 3500 species. The Terebrantia are more diverse in structure, and eight families are currently recognized for the 2400 species.

Phlaeothripidae

Two subfamilies of Phlaeothripidae are recognized with about 600 species that feed by ingesting whole fungus spores comprising the Idolothripinae. These include some of the largest thrips with body sizes up to 15 mm. Males are often considerably larger than females, with prominent tubercles and large foretarsal teeth. Moreover, these large thrips commonly exhibit patterns of allometry, such that the largest males differ considerably in structure and appearance from the smallest in the same population, and these size differences reflect fighting behaviors.

The larger subfamily, the Phlaeothripinae, comprises three ill-defined lineages. The Haplothrips lineage, or Tribe Haplothripini, is common in the north-temperate zone in the flowers of Asteraceae and Poaceae, including cereal crops, and is widespread across the Old World tropics. The Liothrips lineage occurs worldwide, particularly in warmer areas, and the species feed on the leaves of shrubs and trees, commonly causing them to distort, to roll, or to form discrete galls. The Phlaeothrips lineage occurs worldwide, and comprises species that feed on fungal hyphae on dead branches or in leaf litter. Many of these exhibit complex allometry in males, form colonies, and are subsocial. Species recognition and generic classification within the Phlaeothripidae is unsatisfactory, because of the lack of studies on biology and structural variation within and between colonies. Isolated individuals can often not be identified.

Thripidae

This is the largest of the eight families of Terebrantia. Adults of all 2000 species have slender, emergent, simple or forked, sensoria located on the third and fourth antennal segments. The greenhouse thrips, Heliothrips haemorrhoidalis, is placed in the subfamily Panchaethripinae, together with about 130 related species that have a body and legs strongly reticulate. Similar small numbers of species are placed in two further subfamilies, Dendrothripinae and Sericothripinae, but most thripids are placed in the Thripinae. This subfamily includes most of those flower-living insects that are commonly recognized as thrips, particularly the 450 members of the two genera Thrips and Frankliniella, many of which are important crop pests (Fig. 1D).

Acloothripidae

The 200 species in this family all have nine-segmented antennae with at least the last three segments closely joined, and the sensilla on the third and fourth segments are almost always linear.

FIGURE 1 Thysanoptera diversity. (A) Lichanothrips pulchra female, which creates a domicile by gluing together pairs of Acacia leaves. (B) Kladothrips waterhousei foundress, which induces leaf gall on Acacia. (C) K. waterhousei first-generation female, which functions as a soldier to defend a gall. (D) Western flower thrips (Frankliniella occidentalis), one of the world's major insect pests.

veins, and the fringing cilia insert directly into the wing membrane. When at rest, the wings lie flat on top of each other on the abdominal tergites, held in place by one or two pairs of sigmoid setae. Moreover, the 10th abdominal segment is tubular, with the anus terminal but the genital opening at the base of the tube, the female’s ovipositor being an eversible, chute-like structure.

In adult Terebrantia, the forewing surface is covered in microtrichia, two longitudinal veins are visible, and the fringing cilia are
along these segments. Aeolothripids are relatively large thrips, with the forewings broadly rounded at the apex and commonly banded black and white. Although they are probably mainly predatory on other arthropods, the common flower-feeding members of the genus *Aeolothrips* also feed on plant tissue, the only obligate predators being tropical species in the genera *Franklinothrips*, *Mynarothrips*, and *Stonatothrips*.

**Melanthripidae**

The 75 species in this family are all flower feeders. In contrast to aeolothripids, all nine antennal segments are distinct and bear transverse rows of microtrichia, and the sensoria on the third and fourth segments are continuous around the apex. Moreover, on the abdomen, remnants of an eighth sternite are visible, as in Merothripidae.

**Heterothripidae**

The 70 species recognized in this family are found only in the New World. The adults all have antennae with nine segments, and the sensoria on the third and fourth segments are continuous around the apex. One Brazilian species is ectoparasitic on a species of plant hopper (Fig. 2A), but the other species probably all breed in flowers, some being host-specific.

**FIGURE 2** Thysanoptera diversity. (A) *Aulacothrips dictyotus* larvae, ectoparasitic on *Aethalson* in Brazil. (B) *Adrothrips intermedius* adult from *Casuarina* in Australia.

**Minor Families**

Scarcely 1% of Terebrantia species comprise the remaining four families. A single, widespread, tropical species is placed in the Uzelothripidae. This is presumed to be fungus-feeding and has a remarkable whip-like terminal antennal segment. The Adheterothripidae includes two species from the western United States and four species from the flowers of date palms between the eastern Mediterranean and India. The Fauriellidae includes one species from California, two from southeastern Africa, and two from southern Europe. The family Merothripidae includes about 20 species, mostly from South America, all of which feed on fungus on dead twigs and leaves. These are minute thrips, but they retain structural character states that are presumed to be closest to the ancestral states of all Thysanoptera.

**LIFE HISTORY**

Reproduction in thrips is haplodiploid, which involves males developing from unfertilized eggs and having one-half the number of chromosomes of females. Despite this, several thrips species can produce females from unfertilized eggs, a process known as thelytoky. In a few common and widespread species, such as the greenhouse thrips *H. haemorroidalis*, males are rare or, as in the North American basswood thrips, *Thrips calceatus*, unknown. Larvae usually hatch within a few days, but in some of the larger Idolothripinae eggs develop while still in the abdomen of a female and larvae hatch soon after the eggs are laid.

There are two larval stages, both of which feed actively for about 2–5 days. In Terebrantia there are then two pupal stages with the antennal segmentation reduced or absent and the mouthparts non-functional. Wing rudiments can be seen in the first, the propupa, but are much longer in the second, the pupa. Trabulifera species are even more remarkable in that they have three pupal stages.

Some Thripidae and Phlaeothripidae pupate on leaves in association with their larvae, but more commonly pupae are found in the leaf litter or on the trunks of trees. The second instar larvae of Aeolothripidae, Heterothripidae, and even a few Thripidae spin a pupal cocoon. Larvae in some species have stout tubercles near the posterior end of the abdomen that presumably assist burrowing into the soil to pupate.

Species that are host-specific within the flowers of particular plants are usually univoltine. Related polyphagous species often breed continuously as long as conditions remain suitable. Overwintering stages are usually pupae, or adults, but the citrus thrips, *Scirtothrips citri*, overwinters as eggs in leaves and shoots.

**FEEDING**

The feeding stylets of phytophagous, predatory, and fungus-feeding thrips are essentially similar. The two maxillary stylets fit together along their length with a tongue-and-groove system, and their apices are linked with slender finger-like projections around a subapical feeding aperture. Only in the spore-feeding Idolothripinae are the stylets clearly adapted to the food consumed, being exceptionally broad to facilitate the ingestion of whole spores.

The only obvious difference in stylets between species is their length. Among the Terebrantia, the maxillary stylets are short and restricted to the mouth cone, but in many Phlaeothripidae, the stylets are deeply retracted into the head, sometimes as far as the eyes, and lie close together along the midline. In a few species feeding on *Casuarina* trees in Australia, the stylets are longer than the total body length and are coiled within the head (Fig. 2B).

When feeding, a thrips initially makes a hole by extruding the solid needle-like mandible. This is then withdrawn, and the maxillary stylets are inserted into the food source through the hole, saliva being pumped into the tissues and the resultant fluid pumped back into the thrips’ crop. In those thrips species in which adults transmit tospovirus diseases to plants, the virus is acquired only by a first, or early second, instar. The virus is taken up from an infected cell when a larva feeds. The virus passes through the wall of the fore gut into the salivary glands, from where it is reinjected into a plant by the adult thrips. Although an adult may take a tospovirus into its gut, the virus is not able to reach the salivary glands, so that no adult can acquire and then transmit a tospovirus.

**HOST RELATIONSHIPS**

The precise host relationships of most thrips species remain unknown. For example, of the 43 endemic North American species of genus *Thrips*, the larval host is not recorded for any one species. A major reason for this lack of basic biological information lies in the dispersive activity of thrips, adults sometimes being found in very large numbers on plants on which they cannot breed. Despite this, some host-plant relationships are well established. The Paleartic species...
of Odontothrips and the Old World tropical species of Megalurothrips breed only in flowers of the family Fabaceae. Similarly, Dichromothrips species live on Orchidaceae in the Old World; Projectothrips species live only in the flowers of Pandanus, the screw pines of the Old World tropics; and all four species of the adheterothripid genus Holarthrithrips live only in the flowers of the date palm, Phoenix dactylifera. The Poaceae has a particularly rich fauna of Thripidae, with Aptinothrips and Linothrips being specific to grasses in the Paleartic; Stencaetothrips, Fulmekiota, and Bregmatothrips specific to grasses in the tropics; and Chirothrips and Arvorthrips breeding in grass flowers in many parts of the world.

In contrast to these host associations at genus level, some thrips genera show a different pattern of host exploitation, with each species using as host some unrelated plant. In the New World genus Echinothriops, one species lives on a species of Selaginella (Lycopsida), another lives on the needles of Tsuga (Pinaceae), a third lives on various soft-leaved plants in Euphorbiaceae and Balsaminaceae, and a fourth is polyphagous with no clear host associations. In Australia, most Odontothripella species breed in the flowers or Fabaceae, but at least one breeds in the flowers of native Poaceae.

Biological data are particularly weak in the Phlaeothripinae, with many species being known only from single samples. In Australia, one suite of about 200 species of Phlaeothripinae is associated only with Acacia, and this suite of species appears to represent a single evolutionary lineage. This contrasts with the complete absence of Phlaeothripinae from the leaves of any of the 900 species of Eucalyptus and also contrasts with the host shifting to unrelated plant families among Australian gall-inducing Leuconea species.

Almost nothing is known of host specificity in fungus-feeding thrips. In Europe, certain species of the phlaeothripine genus Hoplothrips are associated with Stereum fungi on dead branches of trees. The tropical species of Idolothripinae that have exceptionally broad stylets presumably feed on larger fungal spores than related species with slightly less broad stylets, but such details of thrips natural history continue to be little studied.

**BEHAVIOR**

In Terebrantia, males are usually much smaller than females, whereas in Tubulifera males are commonly much larger than females. These differences are related to different patterns of sexual behavior. In fungus-feeding phlaeothripids, a male will defend a female and her egg mass or alternatively will defend a single egg mass to which various females contribute after first mating with him. These strategies lead to competitive behavior between males, involving flicking with the abdomen to displace a rival or stabbing with the abdomen to displace a rival or stabbing him. These strategies lead to competitive behavior between males, mass to which various females contribute after first mating with them. Many species then actively jump into the air, and before take off, winged Thripidae comb the marginal cilia of their wings from a parked position parallel to the wing margin into a flight position at right angles to the wing. However, even wingless individuals are dispersed by the wind. Wingless species from the mountains of southeastern Australia can reach the northern part of South Island, New Zealand, a sea crossing of more than 1600 km. Such dispersal is probably not merely fortuitous, but is a function of the behavior of particular thrips species. Some, such as Frankliniella schultzei in Australia, seem to be particularly prone to long-distance migration, whereas the extensive dispersal of the western flower thrips, Frankliniella occidentalis, is primarily due to the horticultural trade.

**FLIGHT AND DISTRIBUTION PATTERNS**

In warm humid weather, adult thrips often climb to the tops of plants or dead twigs, from where they are easily dispersed by air currents. Many species then actively jump into the air, and before take off, winged Thripidae comb the marginal cilia of their wings from a parked position parallel to the wing margin into a flight position at right angles to the wing. However, even wingless individuals are dispersed by the wind. Wingless species from the mountains of southeastern Australia can reach the northern part of South Island, New Zealand, a sea crossing of more than 1600 km. Such dispersal is probably not merely fortuitous, but is a function of the behavior of particular thrips species. Some, such as Frankliniella schultzei in Australia, seem to be particularly prone to long-distance migration, whereas the extensive dispersal of the western flower thrips, Frankliniella occidentalis, is primarily due to the horticultural trade.

The worldwide distributions of many thrips species result from our trading patterns. For example, Chirothrips species pupate within the glumes of grass florets and are widely distributed in commercial grass seed. Other grass thrips were distributed in hay on sailing ships during the period of colonial expansion, and species of the European genera Aptinothrips and Linothrips can now be found in temperate zones all over the world. Similarly, orchids, bananas, and sugarcane, all...
of which are transported and planted from plant parts, not seeds, have been accompanied around the world by their pest thrips species. The vast increase in the use of air transport by the horticultural trade since 1980 continues to expand the world distributions of pest thrips.

Some distribution patterns are clearly natural. The family Heterothripidae is confined to the New World, and most species of Merothripidae are also restricted to that area. In contrast, the genus Thrips, with 285 species worldwide, has no species native to the Americas south of Mexico, and the genus Frankliniella, with 220 species, includes very few that have a natural distribution anywhere outside the New World. Presumably these two advanced genera of Thripinae evolved at about the time that the American continent separated from Europe.

Within the Melanthripidae, the genus Dorythrips has three species in southern South America and two in Western Australia and Cramothrips has one species in South Africa and several in Australia. Among the more advanced Aeolothripidae, the two genera Aeolothrips and Desmorthrips are ecological and morphological counterparts of each other, the first restricted to the Holarctic, the second to Australia.

Geographical distribution patterns are less clear among the Phlaeothripidae. The leaf-feeding members of the large genus Liothrips are found throughout the tropics, including the Pacific region, but species of the closely related genus Gynaikothrips are Asian in origin. The large thrips of the genus Elaphrothrips, all of which feed on fungal spores, are found widely throughout the tropics, but east of Wallace’s Line they are replaced by members of the genus Mecynothrips.

**POLLINATION**

Thrips are sometimes abundant in flowers, and they can fly actively between flowers. However, their function as pollinators is frequently overlooked; no less than Charles Darwin complained of thrips interfering with his experiments on larger pollinators! Although a single thrips may carry only 10–50 pollen grains, the large number of thrips in each flower can deliver sufficient pollen to stigmatic surfaces. Thrips have been demonstrated to be pollinators in a wide range of flowers: heather plants in the north of the Northern Hemisphere, dipterocarp trees in Malaysia, a rain forest tree in eastern Australia—Wilkiea huegeliana (Monimiaceae), the Panama rubber tree—Castilla elastica (Moraceae), several Macrozamia cycad species in Australia, and Antiaropsis decipiens—the sister group to Ficus (Moraceae) in New Guinea.

**PEST SPECIES**

In general, it is only pest thrips that are noticed by nonspecialists. Phlaeothripidae species are rarely pests, although in central Europe cereal crops are sometimes damaged by one species, and other species cause leaf damage in the warmer parts of the world on decorative Ficus trees, black pepper vines, and olives. Most pest thrips, and all the tospovirus vectors that cause such serious economic losses, are members of the Thripidae. Financial losses in California and Southern African citrus production can be severe, due to the skins of fruit being scarred by thrips feeding. Similarly, the value of a nectarine can be seriously reduced through a single thrips larva feeding on the fruit when it is young. Cucumbers, capsicums, and strawberries are badly distorted at times because of the feeding activity of thrips. Roses, carnations, and chrysanthemum flowers can all be devalued through thrips feeding damage, and table grapes burst and become fungal-infected through thrips oviposition scars.

Worldwide, there are four species of thrips that are particularly significant as pests: the onion thrips (Thrips tabaci), the melon thrips (Thrips palmi), the tomato thrips (Frankliniella schultzei), and the western flower thrips (F. occidentalis). Although feeding damage by these can be severe, the tospoviruses that each of them transmits are a greater problem. More than 12 of these viruses have been described, and although they cause damage only to plants it is evident from their molecular structure that they are members of the animal virus family Bunyaviridae. The origin of the plant infections remains unknown, but each tospovirus is dependent for its continued existence on being transmitted from one plant to another by one or more of 10 thrips species.

**Ticks**

Daniel E. Sonenshine

Old Dominion University

Ticks comprise a distinct group of exclusively blood-feeding ectoparasites familiar to most people in virtually all regions of the world. Ticks transmit a greater variety of disease-causing pathogenic agents than any group of arthropods, including protozoan, viral, bacterial, and even fungal pathogens. An example is Lyme disease (LD), which is now the most important vector-borne disease of humans in the United States, Europe, and Asia. In numerous countries in tropical and subtropical regions of the world, tick-borne diseases of livestock such as babesiosis, theileriosis, and heartwater have made it difficult or impossible to raise domestic animals for food or animal products. Ticks can also cause irritating or even fatal injury to humans and animals because of paralysis, toxicity, or severe allergic reactions to their bites.

**BODY STRUCTURE**

The tick body is organized into two major body regions, the anterior capitulum, bearing the mouthparts, and the idiosoma, bearing the four pairs of walking legs (Figs. 1 and 2). There is no head, and
the highly fused body is not divided into a thorax and an abdomen. The capitulum contains the toothed hypostome, which embeds the tick into the host’s skin and also contains the food canal for blood imbition, the chelicerae, delicate paired appendages that cut into the skin, and the four-segmented paired palps that provide important sensory information for host identification. In argasid ticks, the capitulum is recessed under an anterior extension of the body. The remainder of the body contains the genital pore, anus, and spiracles, which are visible on the ventral surface. In ixodid ticks (so-called hard ticks), a prominent platelike scutum is found on the dorsal surface. Argasid ticks (so-called soft ticks) are similar to the ixodid ticks but lack a scutum, and the body cuticle is leathery.

The interior of the tick body is a simple, open cavity called the hemocoel that is filled with a circulating fluid, the hemolymph, which bathes the internal organs. In ticks, as in other terrestrial arthropods, there is no hemoglobin, and the hemolymph does not function in oxygen transport. Most of the body interior is occupied by the mid-gut, the largest internal organ of the tick body, which consists of a central saclike stomach and several lateral diverticuli. Other prominent internal organs are the paired salivary glands, which appear as white grapelike clusters, and the reproductive organs. In females, these are the ovary, paired oviducts, uterus, and seminal receptacle, and the vagina that connects the system to the genital pore. During feeding, the ovary enlarges and becomes distended with large, brown or amber-colored eggs. In males, the reproductive system consists of the testis, vasa deferentia, and seminal vesicle, and the ejaculatory duct, which is connected to the genital pore. Much of the system is obscured by the large, white multilobed accessory gland. This gland provides the components for the saclike spermatophore that the male tick uses to transfer its sperm to the female. Also present are numerous tracheal tubes, connected to the marginal spiracles, that provide the respiratory system, and the Malpighian tubules and rectal sac, connected to the anal pore, for waste elimination. Argasid ticks have a pair of coxal glands that excrete via the coxal pores excess water and salts accumulated during feeding. The fused central nervous system, the synganglion, is located in the body above the genital pore.

**SYSTEMATIC RELATIONSHIPS**

Ticks are classified with the class Arachnida, the group that contains the familiar spiders and scorpions. Arachnids have chelicerae, which are appendages with pincerlike or scissorlike cutting edges, instead of mandibles. There is no head or thorax such as occurs in insects. There are no antennae. Ticks are grouped together with the mites in the subclass Acari. Ticks constitute a distinct suborder, the Ixodida, within the acarine order Parasitiformes. The Ixodida contains three families—the Ixodidae, Argasidae, and Nuttalliellidae. The Ixodidae or hard ticks are by far the largest of the different families of ticks, with approximately 650 species. Ixodid ticks have three active life stages, including a single nymphal stage. Hard ticks contain most of the important disease vectors and pest species that plague livestock and wildlife. The Ixodidae are further subdivided into the Prostriata, represented by the single genus *Ixodes*, which is easily recognized by the anterior anal groove, and the Metastriata, which include the remaining 13 genera, in which the anal groove is posterior to the anal aperture. The Ixodidae include the ticks that transmit the agents of LD, Rocky Mountain spotted fever (RMSF), boutonneuse fever, babesiosis and theileriosis of livestock, and most of the other tick-borne disease-causing agents.

The Argasidae comprise the soft ticks, with their leathery, highly flexible cuticle. There are approximately 170 species divided into five genera (four according to some authorities). Soft ticks also have three active life stages, but most species have multiple nymphal stages before they develop into adults. Ticks of the genus *Ornithodoros (>100 species)* have a leathery cuticle with innumerable small elevations known as mammillae and a rounded body margin. Ticks of the genus *Argas (~58 species)* have a flattened lateral margin marked by a sutural line. The leathery cuticle bears small ridges and folds in a rectangular pattern, each with a pit at the center of these buttonlike enlosures. Except for species that transmit the spirochetes that cause relapsing fever, most soft ticks are not important in the transmission of disease.

The third family of ticks is the monospecific family Nuttalliellidae, represented by only one species, *Nuttalliella namaqua*, in southern Africa. It contains structures characteristic of both other tick families. Its highly wrinkled cuticle with pits and elevations resembles the cuticle of argasid ticks, but its dorsal pseudoscutum resembles the scutum of the ixodid ticks.

Ticks are an ancient group of specialized acarines that were already well developed during the Mesozoic era (i.e., the era of the
dinosaurs). A larval tick found in amber in New Jersey was dated between 90 and 94 mya (i.e., during the Upper Cretaceous period). Although exhibiting some unusual characteristics in its setal arrangements, the tick was readily characterized as a member of the genus *Carios*, a genus that exists today. This finding suggests that this genus at least (and perhaps other argasid ticks) has not changed very much in many millions of years.

**TICK BIOLOGY: LIFE CYCLES, FEEDING BEHAVIOR, DEVELOPMENT, AND REPRODUCTION**

The tick life cycle comprises the egg and three active stages, namely, larva, nymph, and adult. There is only a single nymphal instar in the ixodid tick life cycle, but varying numbers of nymphal stages may occur in the argasid tick life cycles. All ticks feed on blood during some or all stages. Most species are three-host ticks; that is, each stage attacks hosts, feeds, and detaches before developing into the next life cycle stage. Adult ticks seek hosts, feed, and, in the case of engorged females, drop off to lay their eggs. Ticks can survive for long periods between blood meals. Consequently, when feeding is delayed, the life cycle may be extended for years or, in the case of some argasids, for a decade or longer. There are major differences between the life cycles of the Ixodidae and the Argasidae, as discussed in the following sections.

**Life Cycles of Ixodid Ticks**

The ixodid ticks feed slowly, from several days to as long as 2 weeks. Immature and adult ticks each take a blood meal, except for the nonfeeding males of some species. After crawling onto their hosts, these ticks embed their mouthparts into the host skin and secrete cement from their salivary glands into and around the wound site to anchor themselves. The cement binds the ticks firmly in place and makes them very difficult to remove. During blood feeding, the ticks secrete potent anticoagulants and anti-inflammatory agents, which suppress host wound healing and facilitate blood flow. As the ticks feed, new cuticle is synthesized to accommodate the enormous blood meals the animals consume, often 10–100 times their original body weight. Females feed only once. Mating occurs during feeding, although ticks of the genus *Ixodes* may also mate prior to host attachment. In the metastriate Ixodidae (i.e., ixodids other than ticks of the genus *Ixodes*), mating occurs within a few days after the commencement of feeding and is regulated by sex pheromones, including the volatile 2,6-dichlorophenol and the nonvolatile cholesterol esters on the body surface. Following mating, females seek blood rapidly (24–48 h) and swell enormously, whereupon the repelled females drop from their hosts, find a sheltered location, and lay thousands of eggs. An example is the American dog tick, *Dermacentor variabilis*, which typically lays more than 5000 eggs. Following oviposition, the female dies. In contrast to the females, males swell only slightly during feeding. However, they can mate many times, feeding between matings. In certain species of *Ixodes*, mating may occur either on or off the host (e.g., the blacklegged tick, *Ixodes scapularis*, or the sheep tick, *I. ricinus*). In some nest-inhabiting species, the males have vestigial hypostomes. These ticks always mate off the host.

Once oviposition has been completed, the larvae hatch in the thousands and begin host-seeking activity. Except for the nest-inhabiting species, the larvae disperse into the vegetation, where they come in contact with passing animals. Once they have attached to a host, the larvae embed themselves into the host skin, form a feeding pool, and engorge in the manner already described. Feeding usually takes 2–4 days, whereupon the engorged larvae drop from their hosts to molt on the ground. Moltling usually occurs in some sheltered microhabitat such as soil or leaf litter, or in host nests. After molting, nymphal and adult ticks must seek another host and feed. However, more than 90% of the life cycle is spent off the host. When host seeking and feeding occur in all three parasitic stages, the pattern is termed a three-host life cycle.

A few ixodid species exhibit a two-host or one-host life cycle. For example, in the camel tick *Boophilus annulatus*, both larvae and nymphs feed on the same host (two-host life cycle), and in the cattle tick *Boophilus microplus*, all stages feed, molt, and even mate on the same host (one-host life cycle).

**Life Cycles of Argasid Ticks**

Feeding is very rapid among the argasid ticks. Once they have crawled onto a host, the ticks embed their mouthparts in the same manner as their ixodid relatives, but without secreting cement. Bloodsucking commences quickly and, as feeding progresses, the bloated ticks excrete copious quantities of a clear, colorless coxal fluid (sometimes this occurs soon after feeding). By eliminating excess water and salts via the coxal fluid, the ticks can concentrate their blood meals and adjust their internal water balance. The ticks expand to about 5–10 times their original body weight, depending on the ability of the cuticle to stretch. Following feeding, often completed within as little as 30–60 min, the replete ticks drop off to molt or, if female, to lay eggs. Argasid females take repeated small blood meals and lay small batches of eggs (typically <500 eggs in a batch) after each feeding (multiple gonotrophic cycles). The interval between feedings is typically several months but may be up to several years, depending on host availability. Mating usually occurs off the host. Because of the multiple nymphal instars (six or even seven in some species), argasid ticks often live for many years. In addition, these ticks are highly resistant to starvation, an advantage that can extend their longevity even further. As a result, the entire life cycle may take from 10 to 20 years.

Following oviposition and hatching, most argasid tick larvae seek hosts, feed rapidly, and molt to the first nymphal instar. These nymphs seek hosts again, feed rapidly, and molt to the second nymphal instar. Subsequently, the life cycle varies considerably, leading to additional nymphal instars or proceeding directly to the adult stage. As a rule, males emerge earlier than females and have fewer nymphal stages. In some argasids, especially bat parasites, the larvae remain attached to their hosts for many days, feeding slowly, just like their ixodid tick relatives, and then molt twice without additional feeding. Thereafter, the life cycle resembles the typical argasid pattern. Another unusual species is *Otoobius megnini*, which has only a single nymphal stage. Neither the males nor the females feed, and the females lay eggs without having had a blood meal (i.e., autogenous).

**ECOLOGY**

Most ticks are exophiles (i.e., nonnidicolous, living exposed in the open environment rather than in shelters). Most ticks live in forests, savannahs, brush, grassy meadows, or under stones, crevices, or even in sand in semidesert environments. Others, however, are nidicolous, surviving in caves, burrows, houses, cracks, and crevices where their hosts obtain shelter. This habit is characteristic of most argasids and many species of the genus *Ixodes*.
Ticks

Seasonal Activity and Host-Seeking Behavior

Exophilous ticks are active during certain periods of the year when climatic conditions are suitable for development and reproduction. During this seasonal activity period, they attack and feed on suitable animals. This is known as host-seeking behavior. At other times, ticks remain in diapause (i.e., a state of reduced metabolic activity). In temperate and subpolar regions, the seasonal activity period is regulated by ambient temperature, changing photoperiod, and incident solar energy. Tick seasonal activity usually commences with the onset of warmer weather and increasing daylength. In what is termed the ambush strategy, hungry ticks climb on the vegetation to varying heights, depending on life stage (e.g., adults climb the highest) and cling to any passing animals. In some species, the ticks emerge from their shelters and run toward their hosts when they detect animal odors (or, rarely, noise) from animals nearby. This so-called hunter strategy is useful in arid habitats, where there is little vegetation or source of other moist, protective covering. Argasid ticks normally do not exhibit seasonal activity, since they live in proximity to their hosts in nests, burrows, or other shelters. However, in some species specific for migratory birds or bats, host-seeking activity is synchronized with the period of the year when these hosts return to roecupy their nests.

For many ixodid ticks that occur in temperate or subarctic regions, seasonal activity begins in the spring. In *D. variabilis*, for example, larvae that survived the winter begin to feed on small mammals. Activity accelerates rapidly as increasing numbers of larvae, stimulated by rising soil temperatures and lengthening photoperiods, emerge to attack these animals, reaching the seasonal peak within a few weeks. Feeding by nymphal and adult ticks follows soon afterward, with the adult peak in early summer. In the southern parts of its range, the tick’s entire life cycle, from eggs to ovipositing females, is completed in 1 year. In the northern parts of the *D. variabilis* range, larval emergence is delayed until late spring. Moreover, the cooler soil temperatures and shorter daylengths delay molting of fed ticks. As a result, adults emerge from fed nymphs in late summer or early fall, when soil temperatures and incident solar radiation are declining, and this results in a 2-year life cycle. Thus, both a 1-year and a 2-year life cycle can occur because of variations in climatic conditions within this wide-ranging species.

In *I. scapularis*, larvae and nymphs feed in the spring and summer, as in *D. variabilis*, whereas adults are active in the fall and early spring. However, the order of larval and nymphal feeding is the opposite of the dog tick. Nymphal ticks emerge from their overwintering diapause in spring or early summer, depending on the region of the United States where they occur. Larvae appear next, typically a month or two after the nymphal peak. Meanwhile, fed nymphs molt over the summer, but the newly emerged adults delay host-seeking activity until the cooler months of the fall or early winter. This life cycle pattern enables nymphs infected with *Borrelia burgdorferi* to infect mice, providing thereby a reservoir of infected hosts to infect the next generation of larval ticks. The implications of these different tick life cycle patterns for the survival and transmission of zoonotic diseases are discussed further in the sections on specific diseases.

Occasionally, ticks are active only during the winter months. An example is the winter tick, *D. albipictus*, a one-host tick that feeds on horses, deer, elk, moose, and other large ungulates. In this case, larvae commence host-seeking activity in late summer or early fall. Larvae and nymphs feed and molt on the same hosts and the resulting adults reattach, feed, and mate. Feeding and development require many weeks for completion, even though these activities occur on the same host and, as a result, the adults are often found on their ungulate hosts in winter or early spring. In *D. albipictus*, declining photoperiod stimulates feeding activity, just the opposite of the pattern seen in *D. variabilis*.

Host Specificity

Host-seeking activity is strongly influenced by the availability of hosts and host selection behavior. All ticks species exhibit varying degrees of host specificity; most (>85%) exhibit relatively strict host specificity. At one extreme are the argasid ticks that feed exclusively on bats (e.g., ticks of the genus *Antricola* and certain species of *Ornithodoros*). For example, during his graduate student years, Sonenshine colonized the bat tick, *Ornithodoros kelleyi*, in the laboratory. To feed the ticks, he had to maintain a colony of bats collected from limestone caves or attics of old buildings. No other hosts would do. Similarly, the cattle ticks *Boophilus microplus* and *B. annulatus* feed solely on cattle and, when available, on white-tailed deer. Other species exhibit limited host specificity (e.g., *D. variabilis*). Larvae and nymphs of *D. variabilis* feed on a wide range of small mammals (e.g., white-footed mice and meadow voles), but never on carnivores, ungulates, humans, or other large mammals. In contrast, adults of this species feed on medium-sized and large mammals, including humans (although they can be induced to feed on rodents when confined in capsules). Finally, at the opposite extreme of the specificity spectrum are the opportunistic species that feed on hosts of virtually all types (e.g., *I. scapularis* and *I. ricinus*). Immatures feed on lizards, birds, and small, medium-sized, and large mammals, including deer and humans. Adults feed on medium-sized and large mammals, including humans. Although the range of confirmed hosts is astounding, these opportunistic ticks have preferred hosts (e.g., mice for the immatures; deer, sheep, and other mammals for the adults). Host specificity is also strongly influenced by ecological adaptations, so that ticks adapted to a particular habitat in a given region of the world will encounter only vertebrates adapted to the same habitat.

As tick–host associations evolved, ticks gradually developed the ability to facilitate long-term feeding by evading or suppressing host homeostatic systems. For example, *I. scapularis* saliva contains pharmacologically active compounds that suppress edema and inflammation in their hosts while enhancing vasodilation. This leads to greater blood flow into the wound site without the pain and intense itching sensation so characteristic of the bites of mosquitoes or biting flies. These adaptations are most effective for the hosts encountered most frequently by each tick species, so-called preferred hosts, but less effective for uncommon hosts.

Survival between Blood Meals

One of the most remarkable aspects of tick biology is the ability to survive for long periods between blood meals. The tick’s midgut serves as a storage organ where the blood meal is digested slowly over long periods. Among the argasids, individuals may survive for several years without feeding while waiting for the occasional wandering hosts that enter their secluded shelters. Among the exophilous ixodids, survival periods are much shorter, but even these ticks may survive for up to 1 year between blood meals. According to a study by Needham and Teel in 1991, ticks spend more than 90% of their life history off the host.

Ticks must also conserve body water to survive while they wait for hosts. While questing (i.e., perching for attack) on short stems, blades of grass, or other vegetation, ticks are exposed to dessicating conditions that can become life threatening within a few days or
weeks, depending on the species. Among the desiccation-intolerant *I. scapularis* and *I. ricinus*, which are adapted to cool, humid forest habitats, desiccated individuals retreat to the forest floor or rotting vegetation at the base of a meadow. In these nearly saturated humid microenvironments, they can restore their water balance by a process known as atmospheric sorption, in which the partially desiccated ticks salivate salt-rich secretions onto their hypostomes. This hygroscopic secretion collects moisture, which is sucked back into the body. Since, however, the process demands a considerable expenditure of energy, the number of cycles of desiccation and sorption is limited as the tick’s age. Other species, such as the relatively desiccation-tolerant *Hyalomma asiaticum*, can survive for long periods in the semidesert habitats in central Asia, where it waits for passing camels and other large ungulates. Nidicolous ticks, sheltering in caves, burrows, or other protected microenvironments, are subject to less stressful conditions during the long wait between hosts. These ticks exhibit behavioral patterns that restrict their distribution to these sheltered locations.

**REPRESENTATIVE TICK-BORNE DISEASES**

In view of the exceptionally large variety of diseases caused by tick-borne pathogens and injurious substances, this section is limited to a brief description of several representative examples, with primary emphasis on development of the infection in the tick and tick vector ecology. For a more extensive review, the reader may wish to consult books by Sonenshine and Strickland, or review articles, for information on the specific diseases. Table I lists some representative tick-borne diseases affecting humans and animals.

**Lyme Disease**

The most common tick-borne disease affecting human health in the world today, LD, occurs throughout most of the United States and southern Canada, Europe, and northern Asia. The disease is caused by *B. burgdorferi* (*sensu lato*), a type of bacterium known as a spirochete. *B. burgdorferi* is the causative agent of LD in most of the United States. A second genospecies, *B. lonesi*, was isolated from lone star ticks in the southeastern United States, but the relationship of these spirochetes to LD in humans is uncertain. In Europe, LD is caused by *B. afzelii* and *B. garinii* as well as *B. burgdorferi*.

In humans, LD results from the bite of an infected tick, either a nymph or adult of the genus *Ixodes*. The tick must have remained attached for several days to allow for the bacteria to travel from the tick’s midgut to its salivary glands and into the wound site. Symptoms begin several days to several weeks later. Onset of illness is characterized by mild, flu-like fever and, in most patients, a reddish skin rash, known as the erythema migrans (EM). The typical EM rash is a gradually expanding circular or elliptical lesion with a red margin and clear center, at least 5 cm or more in diameter, and often near the site of the tick bite. Some patients show multiple EM rashes. If left untreated in this early stage, the fever abates, the rash fades, and the patient may recover without any further symptoms. Often, however, the bacteria remain in people’s bodies and spread into the nervous system and joints, where they cause the long-lasting secondary symptoms of chronic LD. Late manifestations include arthritis, especially in the knee joints, which frequently spreads to different joints (polyarticular polyarthritis). Damage to the synovial membranes is a distinctive feature of this type of arthritis because of invasion of the synovial fluid by the spirochetes. Neurological symptoms include nerve pain (peripheral neuropathy), various types of palsy caused by nerve damage (e.g., Bell’s palsy), and central nervous system disorders. Many patients suffering from some or all of these symptoms simultaneously also complain of severe fatigue. In Europe, another chronic feature of late LD is acrodermatitis chronica atrophicans, a condition in which the skin atrophies and peels. Chronic LD is greatly feared in regions where it is endemic because, among other reasons, it can persist for many years despite treatment with antibiotics.

Only a limited variety of ticks of the genus *Ixodes* are competent vectors of LD spirochetes. Other biting arthropods may acquire these bacteria, but they cannot transmit the bacteria when they feed again. In the eastern and central United States, the only proven vector to humans is *I. scapularis*. In the western part of the country the vector is the western blacklegged tick *I. pacificus*. However, other species of the so-called *I. ricinus* complex that feed solely on wildlife contribute to maintaining the disease in nature; examples include *I. spinipalpis* (*I. neotomae*) in the west and *I. dentatus* in the east. The sheep tick, *I. ricinus*, is the primary vector in Europe and western Asia, while the taiga tick, *I. persulcatus*, is the primary vector from eastern Europe across most of northern Asia. Other species of the *I. ricinus* complex (e.g., *I. ovatus*) also serve as efficient enzootic vectors.

The cycle of *B. burgdorferi* development in the tick begins with ingestion of an infectious blood meal by the larva as they feed on a mouse or other reservoir host. Spirochetes survive in the midgut diverticula but are not disseminated until the tick molts to the nymphal stage and feeds again. Following the influx of fresh host blood, the spirochetes surviving in the midgut pass between the cells of the gut wall and disseminate to the salivary glands and other internal organs. However, in females, spirochetal invasion of the ovary damages the developing oocytes, which prevents efficient transovarial transmission. As a result, transmission is by the transstadial route. As the tick feeds, spirochetes escape with the saliva and are introduced to the wound site of the new host. Transmission from nymph to adult is also common.

In the eastern United States, the risk of acquiring LD is greatest in the late spring or early summer because of the peculiar nature of the LD cycle in nature. Nymphal ticks infected with *B. burgdorferi* emerge from their overwintering diapause to attack hosts, especially white-footed mice and other small mammals, as well as humans. This feeding pattern ensures the presence soon afterward of numerous infected hosts when the larvae emerge, spreading the *B. burgdorferi* infection to vast numbers of these tiny ticks. Fed larvae molt in late summer or early fall, but the resultant nymphs disperse rather than commence feeding. Thus, the infection is perpetuated from one year to the next. Meanwhile, adults that emerge from fed nymphs delay feeding until the fall, whereupon they seek white-tailed deer and other large mammals (including humans). This pattern results in a 2-year cycle throughout most of the tick’s geographic range.

Although the vector ticks are opportunistic feeders and will attack most vertebrates, only a limited variety of hosts are competent reservoirs of *B. burgdorferi*. Only competent reservoirs, animals capable of maintaining spirochetes within their tissues for prolonged periods, can infect ticks that feed on them. Examples of competent reservoirs include the white-footed mouse, the dusky-footed wood rat, the California kangaroo rat, and several other rodents in North America, and such animals as the common shrew, bank vole, wood mouse, yellow-necked field mouse, and hares and pheasants in Europe. Several species of birds are also reservoir competent and play an important enzootic role by dispersing infected ticks over considerable distances, thereby establishing new foci of infection. In contrast, some of the animals that are excellent hosts of vector ticks, such as white-tailed deer and western fence lizards, destroy invading spirochetes and, therefore, are not reservoirs. Such animals serve as amplifying...

</table>
hosts and are critically important for the expansion and spread of the tick populations, but they play no direct role in the perpetuation of the infection.

In the United States, LD has increased more than 1.7 times since it was first designated a reportable disease in 1991. By 1999, 16,273 cases that met the U.S. Centers for Disease Control and Prevention definition had been reported, for an overall incidence of 6.0 per 100,000. Most cases were reported from the northeastern, mid-Atlantic, and north central United States. Other important foci are in northern Wisconsin, northern Minnesota, and northern California. In Europe, important foci occur in the Scandinavian countries and in Germany, Poland, the Czech Republic, and Russia.

Domestic animals are also susceptible to infection with *Borrelia* pathogens. Dogs, cats, cattle, horses, and possibly other livestock and companion animals were found to be infected with *B. burgdorferi*. High seroprevalence rates occur in hyperendemic areas such as the northeastern United States, where many dogs show typical symptoms of chronic LD, especially lameness in one or more legs, fever, and fatigue.

**Rocky Mountain Spotted Fever**

RMSF occurs throughout almost the entire United States, southern Canada, and Mexico and, to a lesser extent, in South America. This disease is caused by a tiny intracellular bacterium, the rickettsia *Rickettsia rickettsii*. People become ill with RMSF following the bite of an infected adult tick. Once in the human host, the rickettsia multiply profusely in the epithelial linings of the capillaries, arterioles, and venules. Vessels hemorrhage which in the dermis of the skin leads to the characteristic red spots. These innumerable reddish lesions, raised above the skin surface (maculopapular rash), coalesce to form the characteristic spotted rash. Patients also develop high fever, severe headaches, nausea, joint and muscle pain, photophobia, and other symptoms. Unless treated with antibiotics, some patients die and others suffer irreversible injury.

In the United States and southern Canada, the primary vectors of RMSF are the Rocky Mountain wood tick, *Dermacentor andersoni*, in the west and *D. variabilis* in the east. Adult ticks of these tick species readily attack humans. Other tick species (e.g., the rabbit ticks *Haemaphysalis leporispalustris* and *Ixodes dentatus*) transmit the rickettsia when they feed on rabbits and birds, thereby contributing to the maintenance of the zoonosis in nature, but these latter species do not bite humans. The disease survives in the natural environment in overwintering (i.e., diapausing) ticks but not in the reservoir hosts. When rickettsia-infected larvae emerge from diapause in the spring, they infect mice and other susceptible rodents on which they feed. Other, uninfected larval feeding on the rickettsemic animals acquire the infection, and the disease spreads rapidly in the tick population. Nymphal ticks spread the infection further as they feed again on other small mammals. Adult ticks seek larger animals (e.g., dogs and raccoons) as well as humans. Rickettsia are passed to subsequent generations of ticks by transovarial transmission. Ticks also harbor nonpathogenic species such as *R. montana*, *R. belli*, *R. rhipicephali*, *R. parkeri*, and other as yet unnamed rickettsia, complicating attempts to measure the incidence of RMSF in nature.

In the United States, about 600–800 cases of RMSF have been reported yearly since 1985, with an estimated annual incidence between 0.24 and 0.32 per 100,000 population. Most cases now occur east of the Mississippi River, with the highest concentration in the south-central and southeastern states, especially along the Atlantic coast. Cases tend to occur in foci in rural areas and suburban communities near major population centers. Since RMSF is a seasonal disease, the frequency of cases follows the seasonal activity pattern of the adults, with highest frequency in July and August in the southern United States but greater frequency in May and June in the northeastern part of the country.

A closely related disease, boutonneuse fever (Mediterranean spotted fever), caused by *R. conorii*, occurs in southern Europe, North Africa, and Asia. These rickettsia are transmitted to humans by the bite of the brown dog tick, *Rhipicephalus sanguineus*. Although generally similar in its symptoms to RMSF, this illness is distinguished by the formation of a black ulcer, the eschar, at the wound site where the infected tick had attached.

**Ehrlichiosis**

Another rickettsial disease that has emerged into increasing prominence in recent years is ehrlichiosis. The causative agents are known as ehrlichiae, tiny obligate intracellular organisms that invade the white blood cells of humans and animals. Ehrlichiae develop within cytoplasmic vacuoles in different blood cell types such as monocytes, granulocytes, lymphocytes, or even platelets, depending on the species. Patients develop an acute illness with high fever and severe headaches, as well as aching muscles and joints. In contrast to RMSF, a rash is not common (20–30% of patients) and usually does not involve the palms or soles. Although severe cases can occur and may result in death, most cases are relatively mild. In the southeastern United States, most cases are caused by *Ehrlichia chaffeensis*, which invades the monocyte leukocytes and causes leukopenia (abnormal loss of white blood cells) among other symptoms. This disease is now known as human mononcytic ehrlichiosis (HME). The primary vector for *E. chaffeensis* is the lone star tick, *Amblyomma americanum*. These ehrlichiae develop primarily in the monocytes. Some cases are caused by *E. ewingii*, also transmitted by lone star ticks. In the northern and western United States, the disease is caused by a related ehrlichia, *E. phagocytophila* (*E. equi*), which also causes illness in livestock. However, like *E. ewingii*, these ehrlichiae prefer the granulocytic leukocytes and, for this reason, the disease is known as human granulocytic ehrlichiosis (HGE). The primary vector in the northern United States is *I. scapularis*. In California, the primary vector for humans is *I. pacificus*. In Europe, the pathogen is transmitted to humans by the bites of the *I. ricinus*. *E. phagocytophila*, believed to be the most widespread of the various human-infecting ehrlichiae, has been reported in many countries of Europe and northern Asia. Ehrlichiosis also affects dogs, sheep, and other animals, being caused by different ehrlichiae.

**Tick-Borne Encephalitis**

Tick-borne encephalitis (TBE) is caused by viruses of the family Flaviviridae. In Europe and northern Asia, the illness in humans is manifested by high, often biphasic, fever and headache, followed soon afterward by inflammation of the brain (encephalitis) and meninges (meningitis). Some patients develop muscle weakness or paralysis, especially in the right shoulder muscles. In the Far East, case fatality rates are relatively high (up to 54%), whereas the disease in Europe is considerably milder. In Europe and the Far East, TBE viruses are transmitted by *I. ricinus* and by the taiga tick, *I. persulcatus*. Other tick species that feed on wild animals may amplify viral infection. Rodents and insectivores are the chief reservoir hosts. The disease is endemic in central, northern, and eastern Europe, where thousands of cases are reported each year. In India, a similar disease known as Kyasanur forest disease has been responsible for numerous cases of human illness. In North America, a *Flavivirus* of the TBE complex causes a disease known as Powassan encephalitis, a serious
T

illness that has caused death in some patients and permanent nerve damage in others. The primary vector to humans in the east is a little-known tick, *I. cookei*, a common parasite of woodchucks, foxes, and raccoons; in the west, it is transmitted by the *D. andersonii*.

**Babesiosis and Theileriosis**

Two genera of tick-borne protozoa, *Babesia* and *Theileria*, cause severe illness and even death in domestic livestock and wildlife throughout most of the world. Tick-borne babesiosis can also cause illness in humans. *B. bigemina*, *B. bovis*, and *B. divergens* are examples of tick-borne protozoans that can cause babesiosis, a serious and often fatal illness in cattle prevalent in Mexico, parts of South America, Africa, and elsewhere. The clinical course of the disease is characterized by high fever and dehydration. Sick animals stop feeding, become lethargic, and show labored breathing. Anemia and bloody urine (so-called redwater fever) is a consequence of the massive destruction of red blood cells. Although some animals recover naturally, most of the diseased individuals gradually become comatose and die. Mortality estimates for infections with *B. bigemina* are 30–80%, with *B. bovis* are 70–80%. The causative agents, which are introduced by the bites of infected ticks, develop as meronts in the erythrocytes and multiply by multiple fission or, in the case of *B. bigemina*, by binary fission. Subsequently, huge numbers of erythrocytes are destroyed, leading to the symptoms noted. Eventually, some parasites invade leukocytes, where they are transformed into piroplasms, the stage that will infect ticks. Piroplasms remain in an arrested state of development until ingested by a suitable tick vector. In the tick’s digestive tract, the erythrocytes and leukocytes of the host blood are lysed, releasing the parasites. The meronts are destroyed, but the piroplasms develop into ray-shaped gamonts (strahlenkörpers) that fuse with other, similar gamonts to form the diploid zygotes. These parasites are transformed into cell-penetrating ookinetes that traverse the tick’s midgut epithelium and seek out the ovaries. In female *Boophilus* ticks, numerous oocytes are invaded by these ookinetes. When the ticks mate and lay eggs, the ookinetes proliferate in the developing embryos. Eventually, as the embryos mature, the ookinetes move to the salivary glands of the young larvae, where they form the invasive stage known as sporozoites, ready to infect cattle. Thus, a single blood meal in a female tick can result in thousands of disease-infected larval progeny, a phenomenon known as transovarial transmission. As a result, numerous animals or even an entire herd of cattle can be infected in a single tick generation.

Human babesiosis is a malaria-like illness caused by *B. microti*, *B. gibsoni*, *B. major*, or *B. divergens*. In the northeastern and midwestern United States, the dominant pathogen afflicting humans is *B. microti*, transmitted by the bite of *I. scapularis*. In Europe, human babesiosis may be caused by *B. microti*, or *B. divergens*, transmitted by *I. ricinus* and/or other ixodids. Although the life cycle in the human body is similar to that of the bovine babesias, development in the tick is quite different. When blood infected with *B. microti* is ingested by immature deer ticks, the invasive stages of the parasite transform into cell-penetrating sporokinetes, which, aided by a cell-piercing arrowhead organelle, traverse the midgut epithelium and find their way to the salivary glands. When the fed ticks molt to the next feeding stage and attack new human or animal hosts, the sporozoites are injected with the tick’s saliva.

Babesiosis also afflicts other animals. In dogs, *B. canis*, transmitted by the bites of the *R. sanguineus*, causes severe illness and may be fatal. Other babesias cause illness in horses, sheep, and other animals.

Protozoan parasites closely related to the babesias, *Theileria parva* and *T. annulata*, cause serious or fatal illness in cattle and other ungulates. *T. parva*, transmitted by the bites of the African brown ear tick, *Rhipicephalus appendiculatus*, causes a disease in southern Africa known as East Coast fever. *T. annulata*, transmitted by the bites of ticks of the genus *Hyalomma*, causes a disease known as tropical theileriosis. It is much more widespread, ranging from North Africa across western and central Asia to the Indian subcontinent. The life cycle of both protozoan parasites is generally similar to that of the babesias but with several notable exceptions. *Theileria* parasites multiply in the leukocytes instead of the erythrocytes. Following destruction of the host cells, the *Theileria* progeny infect other leukocytes, thereby damaging the host’s immune system, while others invade erythrocytes to form piroplasms. The latter are the stage that will infect ticks. These piroplasms remain in an arrested state of development until ingested by the tick vector. When vector-compotent ticks feed on *Theileria*-infected cattle, the piroplasms are released from the disintegrating erythrocytes and transform into gamonts similar to those seen in the babesias. Following gamont fusion and fertilization, the zygotes develop into motile kinetes that cross the midgut epithelium and travel to the salivary glands. Because only the salivary glands are infected, pathogen transmission occurs only when the infected larval or nymphal ticks molt and feed again in the next life stage on susceptible hosts (transstadial transmission).

**Tick Paralysis and Tick Bite Allergies**

In addition to transmission of infectious microbes, ticks may cause paralysis, allergies, and severe toxic reactions in their hosts. In humans, this affliction is manifested by a gradually ascending paralysis, beginning with the loss of sensation and motor coordination in the legs, abdominal muscles, back muscles, and, eventually, the diaphragm and intercostal muscles. Unless the tick responsible for these symptoms is found and removed, the patient will undergo respiratory failure and die. Most patients recover rapidly after tick removal, but those with advanced symptoms may require several weeks for complete recovery.

Tick paralysis also affects animals, especially large ungulates. In Australia, a single *Ixodes holocyclus* female may be sufficient to cause the death of a full-grown cow or bull. Thousands of cattle died in the western United States and Canada because of paralysis induced by the bites of *D. andersonii*. Other than finding and removing all the feeding female ticks, there is no known cure. Some ticks also cause severe allergic and toxic reactions. A notable example is the African tampan *Ornithodoros savignyi*, the bite of which may cause cattle to salivate, tremble, gnash their teeth, become disoriented, and even die. A similar condition, known as sweating sickness, is caused by ticks of the genus *Hyalomma*, especially *H. truncatatum*. The illness is characterized by fever, loss of appetite, sweating, lachrymation, salivation, and, usually, death. However, there is no paralysis.

**CONTROL**

Although difficult to estimate in precise monetary figures, the economic importance of ticks is enormous. This is primarily because of losses caused by tick-transmitted diseases affecting livestock. In addition, ticks cause injury from severe blood loss, reduced milk production, and damage to the hides. Worldwide, losses to the cattle industry alone were estimated to be more than $7 billion. Perhaps the most important economically are the cattle ticks, especially *Boophilus annulatus*, *B. decoloratus*, and *B. microplus*, because of the disease agents they transmit (*Babesia spp.*). Other economically important species are the bont ticks, *Amblyomma variegatum* and *A. hebraeum*, which are vectors of the causative agent of heartwater, *Cowdria ruminantium*. 
Tick control is done almost exclusively with acaricides: poisonous compounds such as chlorinated hydrocarbons (e.g., DDT), organophosphorus compounds (e.g., diazinon), carbamates (e.g., carbaryl), and pyrethroids (e.g., permethrin and fenmethrin). Animals are treated with acaricides by either bathing or spraying them with mixtures of liquids containing the specific toxicant. Acaricides can also be delivered as pour-ons or spot-ons, highly concentrated mixtures containing surfactants (i.e., spreading agents) that enable the product to disperse naturally throughout the animal's hair coat or as dusts, consisting of mixtures of tale and the acaricide. For long-lasting effects, acaricides are incorporated into plastic collars, ear tags, or even tail tags, which gradually emit the toxic chemicals over a long period of time. Also promising is the tick decoy in which tail tags are impregnated with the tick's natural pheromone as well as the acaricide. These “tick decoys” demonstrated excellent efficacy (>95%) for up to 3 months when applied to cattle in Zimbabwe. Other promising innovations for treating tick-infested animals include self-medicating devices, such as the “four-poster” developed by the U.S. Department of Agriculture for treating white-tailed deer, and antitick vaccines. Self-medicating applicators release an acaricide from a reservoir when host animals insert their heads into the device to retrieve corn or other bait. This is perhaps the first practical method that has been developed for controlling ticks on wild animals without killing or injuring them. Antitick vaccines work by immunizing livestock animals such as beef cattle against proteins in the tick's digestive tract, thereby killing the ticks as they attempt to feed. Further scientific advances may make it possible to reduce the current dependence on toxic chemicals to control ticks on domestic animals, pets, and even wildlife.

Hikers, campers, and other people entering tick-infested habitats should take appropriate precautions to avoid ticks and the risk of acquiring tick-borne diseases. Each person should wear long trousers, tuck the trouser ends into boots or shoes, and draw the socks over the trousers. The protective barrier should be secured with tape and treated with a repellent—for example, one of the many products that contain diethyl toluamide (DEET). Upon returning from the trip, each person should decontaminate the field clothes and carefully inspect skin and hair for ticks that may have attached unnoticed. Early detection and removal of attached ticks will minimize the risk of transmission of disease-causing agents. Unattached ticks, if any, may be destroyed and discarded. However, attached ticks should be removed carefully with tweezers (forceps) and retained intact if needed for future examination in case of illness.

**Tracheal System**

**Jon F. Harrison**  
*Arizona State University*

Insects have a tracheal respiratory system in which oxygen and carbon dioxide travel primarily through air-filled tubes called tracheae. Usually the tracheal system penetrates the cuticle via closeable valves called spiracles and ends near or within the tissues in tiny tubes called tracheoles (Fig. 1). The tracheae primarily serve as pipes that transport gases between the spiracles and the tracheoles, whereas the thin-walled tracheoles are thought to be the main sites of gas exchange with the tissues. However, in many insects, the tracheae are compressible, and dilations of the tracheae form thin-walled air sacs that together serve as bellows for enhancing the flow of gases through the tracheal system. The organization of the tracheal system varies dramatically among insects, with spiral number ranging from 0 to 20 and with tracheal branching patterns varying widely across species, between body regions, and during the developmental stages of holometabolous insects.

**SPIRACLES**

Spiracles are the openings of the tracheal system on the integument of the insect. Some apyergote and larval insects lack valves in their spiracles and therefore have trachea that are always open to the environment, although these are often covered with sieve-like plates. However, most spiracles have valve-like structures that allow them to close (Fig. 2). Spiracles range tremendously from 27 μm² in area for the second spiracle of the giant *Petrognathus* beetle to only a few microns

---

**Touch**

*see Mechanoreception*
square. Often the outside of the spiracle is fringed with hairs or covered with a filter to help resist entry of dust, water, or parasites.

The valve that closes the spiracle takes various forms but can appear as two lips of cuticle or as a bar of cuticle that pinches the trachea shut (Fig. 2). The movement of the valve usually depends on the action of muscles that insert on or near it, and elastic elements in the cuticle. Some thoracic spiracles have only a closer muscle, and elastic elements tend to open the spiracular valve (Fig. 2A). Often the valve is recessed behind the atrium, an enclosed space behind the external opening (Fig. 2B). The most common situation (true for all abdominal spiracles studied to date) is for the spiracle to be recessed behind an atrium and to have both opener and closer muscles (Fig. 2B).

**TRACHEAE**

Tracheae, the largest tubes of the tracheal system, range in diameter from a few millimeters to about 1 μm. The tracheal wall (Fig. 3A) contains an epithelial cell layer that secretes a basement membrane that forms the outermost layer of the tracheal wall. Internally, the tracheal cells secrete the intima, which contains protein and chitin fibers. The intima forms spiral folds known as taenidia. In general, it is thought that the taenidia prevent the trachea from collapsing inward, much like the rings of a vacuum hose, yet allow the trachea to flex. However, in the tracheae of some insects, the taenidia are widely spaced within the tracheal wall, and the intima is quite flexible so that the tracheae are compressible. Because tracheal walls are relatively thick, oxygen is not believed to pass out of the larger trachea in appreciable amounts. Thus, the primary function of the trachea is to transport gases between the tracheoles and the spiracles. However, because carbon dioxide can diffuse more easily through tissue than oxygen, it is possible that a significant portion of the carbon dioxide emitted may pass through the tracheal walls.

**TRACHEOLES**

Tracheoles, the small tubes that form the terminal endings of the tracheal system, range from 1 to 0.1 μm in diameter. Tracheoles are formed within single tracheolar cells (Fig. 3B). These tracheolar cells have many branching processes, some of which contain an air-filled channel (the tracheole) that connects to the air-filled lumen of the trachea (Fig. 3B). Tracheole walls are capable of transporting oxygen at high rates by diffusion because they are thin (usually <0.1 μm) and have a very large surface area to volume ratio. Thus, the tracheoles are likely the major site of gas exchange between the tissues and the tracheal system.

Tracheoles are particularly dense in metabolically active tissues such as flight muscle (Fig. 4). Most tracheoles occur outside of the cells of the insect’s body, but sometimes in histological sections they appear to be within cells, particularly in flight muscle. These tracheoles are believed to enter the flight muscle via infoldings of the muscle plasma membrane, and so they are actually extracellular. Most tracheoles extend parallel to the muscle fibers. The high tracheolar densities and penetration of flight muscle cells by tracheoles allow flying insects to achieve oxygen consumption rates that are among the highest in the animal kingdom.

**AIR SACS, AERIFEROUS TRACHEA, AND TRACHEAL LUNGS**

In active insects, particularly those with a rigid cuticle, portions of the tracheal system are enlarged to form thin-walled air sacs. These
Tracheal System

Air sacs lack taenidia and, so, collapse and expand with variation in hemolymph pressure. Air sacs are common in adult flying insects of many orders including Diptera, Hymenoptera, Lepidoptera, Odonata, and Orthoptera. These air sacs serve as bellows to enhance the movement of air through the tracheal system. For insects that have them, air sacs often account for the majority of the volume of the tracheal system. Of insects that lack air sacs (such as cockroaches, tenebrionid or carabid beetles or Dictyoptera), many have compressible tracheae that may also function as bellows.

Tracheal lungs, or aeriferous tracheae, are similar to air sacs in that they are thin-walled expansions of the tracheal system with few taenidia that float freely in the hemolymph. Their primary function is believed to be oxygen delivery to tissues that lack tracheoles, such as hematocytes and some ovaries and Malpighian tubules. In this case, the oxygen must diffuse through the thin wall of the tracheal lung, through the hemolymph, and to the tissues. These tracheal lungs have been reported for lepidopteran larvae, which apparently lack hemocyanin in the hemolymph; it would be interesting to look for such structures in the insects that utilize respiratory pigments in the blood.

DEVELOPMENT

The development of the tracheal system has been well studied in Drosophila melanogaster, and is serving as model for the development of the cardiovascular and respiratory systems of vertebrates. In flies, the tracheal system develops embryonically from epithelial sacs of only 80 cells per segment into its branching structure of tracheae and tracheoles without mitosis or cell death. Primary branching of the tracheae is induced by secretion of a local chemoattractant termed fibroblast growth factor (the gene is named Branchless) secreted by local tissues. The primary branches are formed of 3–20 cells organized into tubes. Some cells become terminal cells and ramify in response to fibroblast growth factor to become tracheae, with densities of tracheoles modulated by local oxygen levels.

In general, the size of the tracheal system increases with age in order to support the increased gas exchange needs of the larger insect. During the molts, the cuticular lining of the trachea is drawn out of the spiracle with the old integument. Major changes in tracheal structure, including changes in spiracle number and tracheal system organization, can occur at each molt and during the pupal period for endopterygote insects. In Drosophila, the adult tracheal system is formed from both imaginal disc cells and larval tracheal cells that activate and proliferate.

Changes in tracheal system structure are not limited to molting periods, because the tracheoles can change structure within an instar. In the event of injury or oxygen-deprivation, local tracheoles grow and increase in branching. If no undamaged tracheoles are nearby, damaged tissues produce cytoplasmic threads that extend toward and attach to healthy tracheoles. These threads then contract, dragging the tracheole and its respective trachea to the region of oxygen-deficient tissue.

Both tracheoles and trachea are fluid-filled in newly hatched insects, and fluid fills the space between the old and new trachea at each molt.

FIGURE 3 (A) Structure of a trachea. The basement membrane which encircles the tracheal epithelia has been omitted. (B) A tracheolar cell connected to a trachea.

FIGURE 4 Confocal image of tracheae branching into tracheoles supplying oxygen to the flight muscles of a fruit fly, Drosophila melanogaster (photo credit: James Waters). Scale bar: 50 μm.
Usually, this fluid is replaced with gas shortly after hatching or molting. In some cases, the spiracles must be open to the air for gas-filling of the tracheae to occur, suggesting that gas-filling occurs as fluid is actively absorbed by the tracheal and tracheole epithelia, with air entering through the spiracle to replace the absorbed fluid. However, in aquatic insects that lack spiracles, the tracheae also become gas-filled, indicating that this gas can be generated by the tissues or hemolymph.

**ORGANIZATION**

The organization of the tracheal system varies substantially among insects, at least partially in correlation with species ecology. One obvious variant is spiracle number. Some aquatic insects lack spiracles, which prevents water entry to the tracheae. Many dipteran larvae have only one pair of spiracles on their abdominal tip, which they extend into the air as they feed head-down in water. In contrast, many terrestrial insects have a full 10 pairs of spiracles. Insects also vary in the number of air sacs, the location and size of tracheal branches, and the number of longitudinal trachea.

A glimpse of the cross-species variety can be gained by comparing the organization of the major tracheae in the sixth abdominal segment of an adult grasshopper and a larval fruit fly (Fig. 5). Grasshoppers have a spiralce on every segment, whereas fly larvae have only functional spiracles on the head and abdominal tip. In the grasshopper, transverse tracheae lead from the spiracles to longitudinal tracheae that run along the heart, ventral nerve cord, and several positions on the gut. Air sacs are prominent. In contrast, in flies, two large dorsal longitudinal trunks connect the two functional spiracles on each side, with branches extending from the dorsal trunk to the tissues and one other longitudinal trachea. Air sacs are absent.

Tracheal organization also varies with location within the insect. In most insects, the head segments lack spiracles, and so tracheae usually extend forward from the prothoracic spiracles to supply the tissues in the head; similar elaborations of the tracheae occur in the posterior direction in the 10th segment. Structures that extend away from the main body of the insect, such as legs, antennae, and wings, also lack spiracles and usually have long tracheae extending from the spiracle of the local body segment. Antennae, legs, and wings all are known to have accessory pulsatile structures that pump hemolymph and help circulate air through their long trachea. The tracheal organization in the thorax of flying insects is very different from that in the abdomen, as the thoraxes often contain extensive air sacs associated with the flight muscles.

Tracheal organization can also be strongly modified by developmental stage, especially in holometabolous insects. For example, many dipterans transform from aquatic larvae with one or two pairs of spiracles and no air sacs to adults with 10 pairs of spiracles and extensive air sacs, a transition that enables high oxygen delivery and flight. Clearly, flexibility in tracheal structure and function is a key trait in the success, adaptability, and diversity of insects.

As insects increase in size, it appears that they must invest proportionally more of their body in tracheal structures. This trend has been observed in growing grasshoppers and across species of beetles. It is not clear why this is true, but it may be as simple as the need for increased diffusing area to overcome the longer diffusion distances down the longer tracheae in bigger insects. At least in beetles, this trend is particularly true in the leg coxae, with larger beetles having proportionally more of the coxal lumen filled with tracheae. Extrapolation of this trend suggests that the largest extant beetles may begin to experience spatial limitations with the tracheae filling nearly 90% of the coxal lumen, suggesting that insect maximal body size may be limited by the need of larger insects for proportionally more tracheae.

Trichoptera, or caddisflies, are holometabolous insects closely related to Lepidoptera, or moths. However, unlike most moths, their eggs, larvae, and pupae are usually found in or very near freshwater, and adults are aerial, usually not far from their aquatic habitats (Fig. 1). The Trichoptera include more species than any of the other primarily aquatic orders of insects. This high species diversity is correlated with an unusual broad range of ecological specialization. Immature caddisflies occur in almost every type of freshwater habitat and on every continent except Antarctica; they are often one of the most abundant insect orders in streams and ponds. Larvae of many species use silk to construct portable cases of various shapes and materials to serve as physical protection, camouflage, or aids in respiration. Others make stationary retreats of silk for similar purposes or to serve as food-gathering structures. The variety of feeding strategies employed by caddisflies is as great as for the highly diverse freshwater Diptera, or true flies (Table I). Because of their diversity and density in most clean, freshwater ecosystems, the significance of caddisflies for processing nutrients and transferring energy is often great. Their importance as food for ecosystems, the significance of caddisflies for processing nutrients and transferring energy is often great. Their importance as food for predators such as fish is emphasized by fly-fishing enthusiasts who imitate them with artificial lures. The different caddisfly species are variously sensitive to changes in environmental conditions, such that the diversity of the order is commonly used in part as a measure of pollution.

DIVERSITY AND PHYLOGENETIC RELATIONSHIPS OF TRICHOPTERA

Nearly 13,000 species of caddisflies have been described globally (Table I), with more than 1300 reported for America north of Mexico. The world species are in 613 genera in 46 families.

FIGURE 1 Caddisfly larvae, pupal, imagines, cases, and eggs: (A) dorsal view of larva of Molanna cinerea, ×4; (B) lateral view of larva of M. cinerea, ×5; (C) lateral view of the pupa of M. cinerea, ×4.5; (D) dorsal view of imago of M. cinerea, ×4; (E) accustomed resting position of the imago of M. cinerea; (F) ventral view of the flat larval case of M. cinerea, ×2; (G) lateral view of larva of Phlycentropus lucidus, showing the very long anal prolegs and the absence of gill filaments, ×5; (H) lateral view of pupa of P. lucidus, ×6; (I) dorsal view of imago of P. lucidus, ×3.5; (J) larval case of P. lucidus, tube composed of sand and silk, two-layered, enlargement near the end containing the pupa; (K) eggs laid by P. lucidus female on a stick protruding from the water in a breeding cage. [From Betten, C. (1901). Order Trichoptera, caddisflies. “Aquatic Insects of the Adirondacks: A Study Conducted at the Entomologic Field Station, Saranac Inn, N.Y. under the Direction of Ephraim Porter Felt D.Sc. State Entomologist” (J. G. Needham and C. Betten, eds.) pp. 561–573 and plates 13, 15, 30–34. Bull. N.Y. State Mus. 47, 383–612, plates 1–36.]
The most species have been described in the microcaddisfly family, Hydropsychidae, with over 1900 species. Other well-represented families globally include the long-horned caddisflies (Leptoceridae, >1800 species), the common netspinner caddisflies (Hydropsychidae, >1600 species), and the northern caddisflies (Limnephilidae, almost 900 species). The highest known species diversity and the greatest density of species occur in the Oriental biogeographical region (>4000 species, with 1.6 species per kilohectare).

The total number of these known species and subspecies is 12,868.
The Trichoptera and Lepidoptera are generally considered to be sister orders, together constituting the Amphiesmenoptera, with earliest fossils dating from the Permian. The families of tube-case-making caddisflies are generally considered to constitute a monophyletic suborder Integripalpia and the net-spinning caddisfly families a monophyletic suborder Annullipalpia (Fig. 2). The relationships of the remaining caddisfly families (Glossosomatidae, Hydrobiosidae, Hydroptilidae, and Rhyacophilidae, collectively the “Spicipalpia”) are yet unknown but are apparently near the base of the caddisfly phylogeny. The phylogenetic relationships among genera and species of caddisflies have been studied for most extant families, mostly with morphological characters visible with a light microscope. These hypothetical relationships have proven useful in numerous comparative studies, suggesting hypotheses for research of case- and retreat-making behaviors, feeding strategies, historical biogeography, mating behaviors, and other aspects of caddisfly biology.

Triassic fossils of species of Philopotamidae, Prorhychiopodidae, and Necrotauliidae are thought to represent the oldest known Trichoptera. The family Philopotamidae includes modern species, but the other two families are extinct.

**LIFE HISTORIES OF TRICHOPTERA**

**Life Cycles**

Among the relatively few species of caddisflies for which life histories are known, most exhibit a univoltine, or 1-year, life cycle, with some species having more than one generation per year and some with one generation every 2 or 3 years. In general, longer life cycles are found in the higher latitudes and shorter life cycles closer to the equator. A few species have been shown to have more than one cohort in the same locality, with different segments of the same population having their life cycles synchronized apart from the synchrony of one or more other segments. The time of the year during which particular phases of the life cycle occur is distinctive for the species, with most species reaching adulthood in temperate regions during the warmer months of the year.

**Eggs**

Eggs are embedded in a sticky, gelatinous polysaccharide called spumalin, forming an egg mass. Round or elliptical eggs are generally laid in egg masses of particular shapes with 12–636 eggs reported per egg mass and with a single female depositing one to several egg masses. Egg masses may be spherical, pyramidal, butterfly shaped, or some other configuration, or they may be arranged in a flat spiral or as a string of beads. Because of the spumalin, little is known about the surface structure of caddisfly eggs. Eggs may diapause for several months before larvae hatch, especially during winter, but larvae generally hatch within a few days depending on temperature. If the egg mass is out of water, the first instars of some species may remain in the spumalin matrix until it is inundated; for other species whose egg masses are laid on plants or rocks overhanging the water, young larvae drip out of the spumalin into the water.

**Larvae**

Larvae usually undergo five instars before pupation, although a few species have a generally indeterminate number of instars greater than five. The larval stage usually is the longest stage of the life cycle, with development completed during a period of 2 months to nearly 2 years. The shape of the larva differs usually with the family or genus and depends in part on the habits and feeding strategy peculiar to that taxon. Eruciform larvae, typical of the Integripalpia, are cylindrical, with hypognathous mouthparts oriented at a right angle with the body axis and with the posterior end of the abdomen blunt and having thick anal prolegs fused with segment IX; these live in portable tubular cases. Larvae of microcaddisflies (family Hydroptilidae) typically undergo hypermetamorphosis, with the first four instars campodeiform and free-living and the fifth instar with a much-enlarged abdomen and living in a purse case.
Pupae

The last instar builds a shelter or modifies the larval case to serve as a shelter. Modification of a larval case usually means simply sealing the ends with silk closure membranes that are perforated to allow movement of water through the shelter. Larvae may then line the shelter with silk; a few families (Glossosomatidae, Hydrobiosidae, Rhyacophilidae) spin a semipermeable cocoon inside the shelter. The larva may then diapause for a few months as a prepupa inside the shelter, but usually it proceeds immediately to molt into the pupal stage, usually retaining the exuviae of the last instar inside the shelter. The pupal appendages are not fused with the body, as they are in some Lepidoptera and Diptera, but are merely folded against the body, with the wings and antennae wrapped around the sides and venter of the body.

Special structures of the pupa include long mandibles for keeping debris from blocking posterior closure membrane perforations and for cutting the closure membrane or cocoon at the time of emergence, setose caudal processes for keeping debris from blocking posterior closure membrane perforations, and small plates of hooks dorsally on the abdomen for maneuvering the pupa inside the silk-lined shelter or cocoon. Respiration is assisted by undulating movements of the pupa, forcing water through the shelter and cocoon from anterior to posterior ends. The pupa usually completes development to the adult stage in 2 or 3 weeks.

Emergence

When the pupa is ready to transform to the adult stage, it uses its long mandibles to cut through the shelter’s anterior closure membrane, swims to the water surface, and emerges from the pupal exuviae at the surface in open water or on some emergent object. In the molt from pupa to adult, the period between apolysis and ecdysis is unusually long, allowing body sclerites to complete much of their sclerotization before the adult emerges. In this way, the adult caddisfly is able to fly quickly from the surface of the water, away from predatory fish, usually completing the escape from the shelter and the water surface in less than a minute. The tenial adult then rests on shore-side vegetation or rock until sclerotization is complete.

Adult

Nearly all adult caddisflies are capable of flight, with only a few species having short, flightless wings. They are secretive, hiding among shore-side vegetation or rocks most of the time, with periods of activity in the day or night specific for the different species. Adults of different species live for a few days to several months. Those that have long adult lives have an especially well-developed haustellum for ingesting liquids; apparently they ingest water or nectar for sustenance. Mating behavior for some species is mediated by sexual pheromones, with females emitting odors that attract males. Males of some day-flying species also exhibit distinctive flight patterns or swarms that attract females. Mating is accomplished while standing on shore-side substrate in an end-to-end orientation with tips of the wings overlapping; the male inferior appendages, or “claspers,” hold the end of the female abdomen while he inserts his phallus and releases a spermatoaphore into her spermatheca. The female then lays her egg mass. It may be laid on a rock or vegetation overhanging the water, from which first instars may drift into the water upon hatching. It may be laid on underwater substrates by a female that crawls or swims beneath the water surface. A few species may lay an egg mass in a protected spot in a dry depression that will later be filled with water.

HABITATS AND DISTRIBUTION OF TRICHOPTERA

Habitats

Immature stages of caddisflies may live in a wide range of habitats with fast to slow current speed or in standing water, but the habitat preferences of the individual caddisfly species usually are quite restricted. Most species require relatively clean, cool water with high concentration of dissolved oxygen. In these habitats, larvae may be found in accumulations of dead leaves and sticks, on or in woody debris, on the tops or bottoms or sides of stones, burrowing in sand or silt, in the crevices among gravel, on submerged or floating parts of living plants, or on other relatively stable debris. A few species complete their entire life cycles away from water, with immature stages crawling among leaves on the forest floor or clinging to vertical rock faces. Immature stages of a few species develop in brackish water, and those of species of the family Chathamiidae apparently all develop only in ocean surf on the shores of New Zealand, at least one of them in a complex mutualistic relationship with starfish.

Distribution

Caddisflies are distributed throughout the world, with species known from every continent except Antarctica. The greatest known species diversity is in the Oriental biogeographic region, where the density of species per hectare is nearly twice that of the next most diverse region.

CASE AND RETREAT MAKING BY TRICHOPTERA

Case Making

Caddisfly larvae have long been appreciated for the beautiful and complex cases that many of them build. These usually are not attached to a substrate but are carried by the larva as it crawls or swims in its habitat. Larvae build cases from a wide range of mineral and plant materials, with the type of material and the shape of the case often recognizable in the field for the genus or even for the species. Mineral building materials may include sand grains or small stones, which may be all of one size or may be of two or more sizes organized in a species- or genus-specific pattern, for example with larger “ballast” stones laterally. The larva selects a mineral particle of preferred size and shape and applies it to the anterior edge of the case with silk extruded from the spinneret in its mouth. Examples of plant building materials include living or dead pieces of leaves or wood that have been shaped by the larva before their attachment to the anterior edge of the case with silk. The preferred plant material may be very specific, such as algae, mosses, liverworts, or rootlets or leaves of particular vascular plants growing in the water, or pine needles, sticks, or leaves that fall from shore-side vegetation. These materials may be oriented longitudinally or horizontally; longitudinal materials may be organized in rings or in a spiral; horizontal materials may be interlocked at corners of a two-, three-, or four-sided case or may be wrapped in a cylindrical case. The larvae of a few species make their cases by hollowing the axis from a stick or piece of wood. Some cases are made entirely from silk or may incorporate pieces of freshwater sponge or abandoned shells of freshwater mollusks. At least one marine species builds its case with bits of coral.

The cases of caddisflies are often classified as tube cases (most Integripalpia), saddle cases or tortoise cases (Glossosomatidae), or purse cases (Hydroptilidae). A tube case is more or less cylindrical,
surrounding the larva at approximately the same distance from all sides, although the shape of the case, especially externally, may vary greatly from one species to another. Thus, a tube case may be externally cylindrical or four-sided or three-sided or flattened; it may have lateral and/or anterodorsal flanges; or it may be straight or curved or coiled into a tight spiral like a snail shell. A tube case almost always has recognizable anterior and posterior ends. Pupation occurs within the tube case after it has been fastened to stationary substrate and the ends have been sealed with silk membranes (except for holes left for water circulation).

A saddle case is more or less domelike, oval on its flat side, always of mineral materials, sometimes with larger stones laterally. A transverse strap of fine sand grains connects the longer sides of the oval ventrally, beneath the larva, leaving anterior and posterior openings on the ventral side from which the head and anus of the larva protrude interchangeably. This ventral strap is removed and the dome is fastened to stable substrate by the larva as it prepares to pupate under the dome.

A purse case typically consists of two flat sheets of silk (often including sand or algae) that have been sewn together at their edges, leaving the ends open for the head and anus to protrude interchangeably. Purse cases sometimes are cemented to the substrate. Pupation occurs within the purse case after the case has been fastened to stationary substrate and the ends have been sealed with silk membranes.

Retreat Making
About half the species of caddisflies do not build cases, but instead spin silken retreats that are stationary, fastened to the substrate. These retreats often are modified to assist with capturing food, usually by filtering it from moving water. The shape of a retreat usually is characteristic of a family or genus and may appear on wood or stone substrate—for example, as a flat sheet over a shallow depression on the substrate; a long, sinuate tunnel or a short covering that incorporates bits of mineral or plant material; a fingerlike net on the underrims of stones; or a bag of silk suspended from substrate in the current. Some species construct a silk-lined vertical tube in sandy soil. Pupation occurs either in the silken retreat or in a special pupation chamber constructed of silk and plant or mineral substrate by the larva.

Free-Living Larvae
Larvae of species of Rhyacophilidae and Hydrobiosidae are free-living predators, roaming about the substrate in search of prey. Pupation occurs under a domelike pupation chamber constructed of silk and plant or mineral substrate by the larva.

FEEDING STRATEGIES OF TRICHOPTERA
Although some long-lived adults may imbibe water or nectar, most nutrients are acquired by larvae. Larvae feed in a variety of ways, with a greater diversity of feeding strategies than any other group of insects having a comparable number of species. Early instars of most species and late instars of many species are collector-gatherers, picking small bits of loose organic material from the substrate. Many other species are collector-filterers, using silken nets (usually) or hairy legs to strain small bits of organic matter from moving water. Shredding herbivores chew pieces of leaves of living plants, often using some of the same leaves in their cases. Shredding detrivores gouge rotting wood or cut pieces of dead leaves that have been “conditioned” by fungi and bacteria, getting most of their nutrition from digestion of the fungi and bacteria. Scrapers graze on the algae, fungi, and associated organic material (“periphyton”) that is attached to the surfaces of stones and plant material exposed to sunlight. Predators either chase their prey or lie in wait for it to wander nearby; prey items typically include other insects, microcrustaceans, and annelids; the predators either swallow their prey whole or they chew them in bits. Some caddisfly larvae may eat the flesh of dead animals, such as dead fish, as these become available. Some species of long-horned caddisflies feed facultatively or obligatorily on freshwater sponge, ingesting whole pieces of the sponge, including the spicules, which accumulate in the gut.

IMPACT OF TRICHOPTERA
Caddisflies are one of the major groups of macroinvertebrates in freshwater ecosystems both in terms of species diversity and of density, especially in relatively unpolluted waterways. For this reason, they are significant contributors in the processing of nutrients. On one hand, collecting-gathering and collecting-filtering and scraping caddisflies help concentrate the nutrients of fine particulate organic matter into their own bodies, making the nutrients available to invertebrate and vertebrate predators in the food web. On the other hand, shredding herbivores and shredding detrivores and predators help to break coarse organic materials into small particles, including feces, that can then be used by many animals that are able to ingest only fine bits of organic material.

Food Resources
Because of the many different feeding strategies and habitat preferences of this diverse order, nearly every conceivable food resource is processed by caddisflies. Because their populations are so large, they process significant amounts of these resources for the benefit of the other animals in the ecosystem. There is even evidence that scraping caddisflies help to increase the production rate of the attached algae on which they feed, much as mowing the grass in a lawn or pruning new growth of fruit trees stimulates increased growth and production in those plants. The role of caddisflies in the food web is appreciated very well by sport fishing enthusiasts, who tie imitations of larval, pupal, and adult caddisflies on hooks to entice their game fish to bite a hook. The more those who fish learn about the species diversity, behavior, and biology of caddisflies, the more likely they are to succeed in tricking the fish to take the hook.

Pollution Tolerance
Although caddisflies generally will not tolerate even moderate levels of pollution, the range of tolerances is wide among the various species of caddisflies. For this reason and because of the usual high species diversity and density of caddisflies in unpolluted surface waters, communities of Trichoptera and other macroinvertebrates are often used to detect the presence of pollution. The occurrence of several of the less-tolerant species and high densities of large numbers of species of caddisflies suggest that the water is relatively unpolluted. Pollution may be detected with this technique more reliably and more cheaply than with chemical analyses. Once it has been established that a given waterway is polluted, follow-up analyses may then be attempted to discover the specific polluting substances or microorganisms and their concentrations. Finally, equipped with those data, land managers, engineers, economists, politicians, and other responsible decision makers may be better able to determine appropriate mitigating measures to reduce or eliminate the pollution.
Tsetse Fly

Stephen G.A. Leak
International Trypanotolerance Centre, The Gambia

Tsetse flies belong to the single genus Glossina, in the family Glossinidae of the order Diptera. They are found only in sub-Saharan Africa, Yemen, and Saudi Arabia, infesting 38 countries and occupying about 11 million square kilometers. As cyclical vectors of protozoan parasites of the genus Trypanosoma, they are of major economic and biological importance. Trypanosomiasis (sleeping sickness in humans) is a major constraint to livestock production and is a threat to millions of people in Africa. Within the genus, 31 species and subspecies of tsetse have been identified. Fossil Glossina, found in Florissant shales in Colorado, date back to the Oligocene, indicating a wider original distribution.

The genus is split into three subgenera or groups: Austenina (fusca group), Nènorhina (palpalis group), and Glossina (morsitans group). The forest-dwelling fusca group are the most primitive. Classification is based largely on morphology of the genitalia; however, the three groups also differ ecologically. Differences in the cuticular alkanes of their sex pheromones can also be used for classification and for estimating “genetic” distance between species.

LIFE CYCLE AND REPRODUCTION

An adult female produces one egg at a time, from which a first instar hatches in the uterus, where it is supplied with nutrients. After a period of development and molting in the uterus, a third instar is deposited on the ground. One full-grown larva is produced every 9 or 10 days, which then pupates in light or sandy soil. The adult emerges after a puparial period of around 30 days, depending on the ambient temperature. This process, termed adenotrophic viviparity, results in a very low rate of reproduction (Fig. 1).

Spermatogenesis occurs during the puparial stage of males and ceases after eclosion; maturation of adult males takes approximately 3 days. Substances synthesized in the male accessory glands are transferred to the female hemolymph during copulation and stimulate receptivity of female tsetse. Unfed females are unwilling to copulate, and receptivity declines with age or after mating. Most female tsetse are successfully inseminated even at very low population densities and need to mate only once in their lifetime, although multiple mating does occur. Male flies seem to rely on visual attraction to find mates (Fig. 2).

Larval Nutrition and Development

In pregnant females, proteins synthesized by highly efficient “milk” glands provide nourishment to the developing larva. Milk is secreted cyclically, with a peak in early pregnancy, which continues from the time of larval hatch until parturition. Some components of the milk probably originate from fat-body secretions, and the milk contains relatively constant proportions of protein and lipid plus phospholipids, cholesterol, triglycerides, and tyrosine. The latter may be necessary for tanning larval and adult cuticles. At eclosion of the first instar, the milk is rich in acidic lipids, which are later replaced by proteins.

The anterodorsal mouth of the first instar is blocked by a chitinized median tooth. This “egg-tooth,” lost with the skin of the first instar, is used to puncture the eggshell (chorion), which then splits along the dorsal side, allowing the first instar to hatch.

Larviposition and Pupariation

Unlike most dipteran larva, which commit to metamorphosis early in the third instar, the third instar tsetse may pupariate only when fully grown. Shortly after larviposition, larvae exhibit a strong photonegative response and attempt to burrow. Uric acid from the

pollution, insect response to
Tsetse Fly

Upon then spreads over the larva and may protect it from predation. Periodicity of larviposition is affected by temperature, and the tsetse may respond to seasonal temperature cycles such that larviposition occurs in the most favorable conditions. The female fly becomes very active a few hours before parturition, presumably while searching for a suitable larviposition site. Both tactile and visual responses have a role in breeding site location. Females tend to choose darker resting sites as pregnancy progresses and when temperatures increase. The interlarval period depends on maternal nutrition and temperature conditions and varies according to species, localities, and seasons, from 20 to 90 days. Survival of puparia is dependent on relative humidity, which, together with temperature, influences selection of breeding and larviposition sites. Survival of emerging adults depends on the existence of sufficient fat reserves to support them until their first blood meal.

The adult emerges from the puparium using the "ptilinum," a saclike structure folded in a frontal cavity of the head. Rhythmic contractions of thoracic and abdominal muscles help the adult to break out of the puparium and reach the soil surface. Females emerge 1–2 days before males. Immediately after eclosion, the wings, abdomen, and thorax are highly compressed, although the legs are already full sized. The newly emerged fly has to expand by about 90%, using the cibarial pump to suck air into the gut and must then feed to complete growth of the flight muscles and endocuticle.

BLOOD MEAL DIGESTION AND UTILIZATION

During feeding, tsetse discharge saliva containing a powerful anticoagulant antithrombin enzyme. The quantity of saliva secreted increases as tsetse become hungrier and may contain trypanosomes in infected flies. Two platelet aggregation inhibitors identified in saliva may also have immunosuppressive, anti-inflammatory properties. Digestion of blood proteins takes place in the posterior section of the midgut and involves six enzymes, which convert proteins to peptides and free amino acids.

Water Balance and Excretion

After feeding, the increased weight of the fly hampers flight and increases vulnerability to predators. There is therefore a rapid reduction of the water content of the blood meal from 79% to about 55% within 3h after feeding. A blood meal in early pregnancy provides females with nutrients that are stored for larval development in late pregnancy.

Pheromones and Hormones

Sex recognition pheromones of tsetse are saturated, methyl-branched hydrocarbons found in cuticular waxes and are apparently unique to each tsetse species. They trigger mating behavior in males at ultraclose range or upon contact with baited decoys. The pheromone is released from the cuticle via unicellular glands on the legs and spreads over the external body surface by diffusion and grooming behavior. It is present on the pharate adult female about 2 days before emergence from the puparium and remains throughout life. A larval pheromone may be released from the anal orifice of tsetse larvae. The pheromone seems to affect choice of larviposition site, resulting in aggregation of larvae in breeding sites.

Flight Metabolism

The energy required for flight is produced from proline and is sustained by utilization of lipid reserves. Proline is depleted during flight and cannot rapidly be replenished; therefore, tsetse are limited to short periods of high-speed flight, at between 6.5 and 7.5 m sec⁻¹ (0.4 km min⁻¹) in open country. Proline is synthesized from lipids in fat bodies and oxidized to alanine in the muscles under hormonal control. Daily flight duration in male flies is about 15 min in the hot season and more than twice as long in the cold season. If fat reserves fall to about 6% of total dry body mass, the fly may die of starvation; such nutritional stress also results in production of small puparia.

Vision and Sense Organs

The compound eyes of both sexes are similar, with a specialized zone of greater visual acuity in the forward-pointing region. Males, however, have a wider region of binocular overlap, which may enhance detection of females. The visual function is consistent with fast flight, detection of drift due to low wind speeds, mating chases, and discrimination of cryptic hosts at high light intensities.

For mating behavior to be initiated, both mechano- and chemoreceptors must be stimulated. The chemoreceptors are thought to be basiconic sensilla on the tibiae and tarsi. Other hair-shaped chemo- and mechanoreceptor sensilla are found on the front side of the wings.

DISTRIBUTION AND HABITATS

The general distribution of tsetse flies, determined principally by climate, is influenced by altitude, vegetation, and the presence of suitable host animals. The limit of distribution is closely correlated with the “tropical savanna (summer rain) climate,” which follows the >508 mm annual rainfall line, whereas the “tropical rain forest
(equatorial) climate" controls the habitats of the *fusca* and *palpalis* groups. The surrounding savannas are the habitat of the *morsitans* group. The southern limits of Glossina distribution in Africa lie north of a line drawn from Benguela, in Angola, to Durban, in South Africa. The northern limits are roughly a line from Dakar in Senegal across to Ethiopia and Mogadishu in Somalia on the east coast.

The distribution and abundance of *morsitans* group tsetse often correspond to those of wild animals. In West Africa, *G. longipalpis* inhabits forest islands with plenty of shade and moves to forested areas only during seasons of high rainfall. *G. austeni* is confined to the coastal zone of East Africa, from Somalia to South Africa, including the island of Zanzibar until it was eradicated from the island in 1997.

Species of the *palpalis* group occur in drainage systems leading to the Atlantic Ocean or to the Mediterranean, not those draining into the Indian Ocean. *G. palpalis* is found close to water, in gallery forests, and it cannot tolerate the wide range of climatic conditions occurring in the savanna belt, where it is restricted to watercourses or "forest islands."

Species of the *fusca* group are mostly found in forests of West and central Africa. Humans are likely to have an adverse effect on *fusca* group tsetse populations through forest clearing and hunting.

Human activity has an important influence on tsetse distribution and abundance; humans can scare away or kill potential hosts, or destroy the vegetation forming the flies’ habitat through agricultural or other development. Most African countries, particularly those in tsetse-infested areas, have low human population densities; however, Nigeria, Africa’s most densely populated country, has a population of 89–100 million, equivalent to 108 people km⁻². Nigeria developed rapidly, and as a result, up to two-thirds of the potential *G. m. submorsitans* population of Nigeria may have been suppressed. *G. m. submorsitans* occurs in areas with human population densities ranging from 0 to 15 km⁻², occasionally in areas of 15–40 km⁻², but never when the population exceeds 40 km⁻². Most sub-Saharan African countries have densities below 40 km⁻². Flies of the *palpalis* group, particularly *G. tachinoides*, are much less affected by human settlement, possibly because they are able to adapt from a preference for feeding on wild mammals and reptiles, to feeding mainly on humans and their domestic animals. Tsetse flies can adapt to peridomestic habitats, and *G. tachinoides* commonly follows domestic pigs in villages and utilizes human-made larviposition sites such as clumps of oil palm, cola nut, and banana trees.

**HOSTS AND FEEDING BEHAVIOR**

Potential hosts are recognized from visual and olfactory stimuli, which, together with mechanical stimulation, activate tsetse and initiate host-oriented responses. Approach to a stationary host is by upwind flight, modulated by olfactory stimuli, flight speed significantly reduced when a fly enters an odor plume. Final orientation toward the host is visual. Heat stimulation after a fly has landed on the host may then cause a probing response and subsequent feeding. Both endogenous and exogenous factors influence host-seeking behavior. Endogenous factors include a circadian rhythm of activity, as well as the level of starvation, age, sex, and pregnancy status of the flies. Exogenous factors include temperature, vapor pressure deficit, and visual, mechanical, and olfactory stimuli.

**Olfactory Stimuli**

Odor attractants are of three types: (1) those associated with animal breath, such as acetone, octenol, and CO₂; (2) those associated with urine, such as the phenols; and (3) those associated with skin secretions, such as sebum.

**Feeding Process**

As a tsetse fly lands on a host, the labium is enclosed between the palps. Heat is the prime stimulus leading to probing and subsequent feeding by tsetse. Responsiveness increases with hunger until the final stages of starvation. As the fly starts to probe, the labium moves from the palps to an angle of 90° to the skin. While the labella rests on the skin, the teeth on the inner surface are everted and penetrate it. At the same time, saliva is excreted from the hypopharynx. Normally, the labellar teeth lacerate capillaries, resulting in a hemorrhage, which is sucked into the labrum. When the fly stops sucking, a small pool of blood forms. If blood is not found, the fly withdraws the labium partially and makes a new penetration. Unmated female tsetse take smaller meals than mated ones, because either the gut cannot be distended to the same extent or of lower metabolic demands.

**Host Effects and Preferences**

Nonrandom feeding patterns may result from responses of hosts to tsetse attack, such as tail-fllicking or skin-rippling reactions. Although normally unable to discriminate between potential hosts at long range, the upright habit of humans, and lactic acid secretions in the skin, result in visual and olfactory repellency, including inhibited landing responses. Zebras may be protected from being fed on by biting flies, including tsetse, by their striped pattern. Tsetse are less attracted to stripes than to solid colors and seem to avoid horizontally striped objects. Zebras usually have a combination of vertical and horizontal stripes, but the horizontal stripes are on the lower part of the animal, where tsetse normally feeds.

**Natural Hosts**

There is a close correspondence between ecological niches of common hosts and tsetse habitats, and overlapping habitats are important in determining feeding patterns, in addition to behavioral characteristics of the host.

Tsetse will change to alternate hosts if their usual host(s) become unavailable. For example, *G. longipennis*, which once fed mainly on rhinoceros, adapted to feeding on other large animals as rhinoceros became scarce. Tsetse select host species rather than simply feeding on the most common available host.

Wild pigs (Suidae), particularly warthogs, are important hosts for *morsitans* group tsetse; however, the feeding efficiency of tsetse visiting a single warthog could be as low as 12–18%. Between 26% and 31% of tsetse landed on the head region of live adult warthogs, apparently because of a visual response to a dark patch produced by the preorbital glands of mature warthogs. In East Africa, Suidae can form about half the food supply of *morsitans* group tsetse in areas with wildlife. Most other feeds are from ruminants, particularly bushbuck.

The *palpalis* group, generally inhabiting riverine or lacustrine vegetation, have a close ecological association with important hosts such as crocodiles and monitor lizards. They are, however, opportunistic feeders, and many mammals, including humans and reptiles, that enter their habitat may be fed upon. In peridomestic situations in the Guinean “forest savanna mosaic” region of West Africa, domestic pigs are an important source of blood meals for *G. palpalis* and *G. tachinoides*; wild Suidae, humans, and small ruminants are the next most common hosts. In the forest zone of Côte d’Ivoire, the
feeding habits of G. palpalis vary with the availability of wild hosts and activities of humans. Around villages, nearly all feeds are from domestic pigs, whereas in plantations, more feeds are from humans. In human trypanosomosis foci outside the edges of villages, palpalis group flies may feed equally on humans and antelopes, especially bushbuck. G. tachinoides can survive in close association with humans in the virtual absence of wild mammals and reptiles. It will readily feed on domestic pigs or cattle, but feeds have rarely been identified from domestic sheep and goats even when these were common.

RESTING BEHAVIOR

Tsetse rest for most of the day, making use of sites that provide protection from extreme temperatures and from predators. The sites may also provide vantage points from which to seek hosts, and their location can change according to time of day, season, and hunger stage of the fly. Recently engorged tsetse fly poorly and rest low down on tree trunks; the height above ground level of the resting site increases in relation to the fly’s nutritional state.

During the daytime, high temperatures of exposed resting sites result in tsetse moving to rest in sites such as the boles of large trees, where they squeeze into the fissures of the bark, at heights generally less than 0.3 m from the ground. Otherwise, flies hide in rot holes, often quite high up, in big tree trunks.

At dusk, tsetse flies generally move upward, to spend the night on leaves or small twigs, possibly to avoid predators. The choice of nocturnal resting sites is influenced by seasonal effects on the physical condition of the vegetation, such as leaf fall. A reverse migration seems to take place about an hour after sunrise, possibly in response to light intensity falling below a critical level. This rapid migration may occur at different temperatures in different seasons.

Activity

The diurnal pattern of tsetse activity may differ between species and according to sex, hunger, pregnancy, and nutritional state of the population. The pattern may also differ for the same species of tsetse in different localities. Natural activity of tsetse flies can be environmentally stimulated or spontaneous, but it has an underlying endogenous circadian rhythm modified by temperature. Intensive activity occurs for periods of less than a minute. The morsitans group tsetse are mostly active early in the morning and/or late in the afternoon.

DEVELOPMENT OF TRYPANOSOMES IN TSETSE

Fly species differ in their capacity to transmit trypanosomes, and individual fly genotypes also vary and affect susceptibility to trypanosome infection. For example, salmon mutants of G. m. morsitans appear to be better vectors of trypanosomes, perhaps owing the metabolism of tryptophan, which is essential for trypanosomes. Metabolism in salmon mutants is affected so that tryptophan accumulates, predisposing the fly to trypanosome infection. Flies of the morsitans group are mostly good vectors of all trypanosome species. Species of the palpalis group seem to be poor vectors of Trypanosoma congolense but efficient vectors of some stocks of T. vivax and can be important vectors of human infective trypanosomes. Species of the fusca group can be effective vectors of T. congolense and T. vivax but poor vectors of Trypanozoon trypanosomes. Trypanosome infection rates in tsetse are generally low and can depend on the age of the fly at the time of the infective feed. Wild male tsetse can achieve a life span of almost 5 months, but this is probably unusual. Teneral flies taking an infective blood meal on the first day of life, or soon after emergence, are the most easily infected. The prevalence of mature infections appears to increase with age for Nannomonas and Duttonella group trypanosomes in many tsetse species. Susceptibility to trypanosome infection may be age dependent, but the actual age is less critical than whether the fly has taken a previous, uninfected feed.

SLEEPING SICKNESS

Trypanosomes were first known to infect humans after being detected in the blood of a steamboat captain in the Gambia in 1901. The parasite was identified and named Trypanosoma gambiense. Sleeping sickness currently occurs in about 200 distinct disease foci in Africa. These foci place between 35 and 55 million people at risk, although only about 3 million of them are under surveillance and relatively few new cases are diagnosed annually. Human sleeping sickness was largely under control in the 1960s, but its incidence then increased, and in 1994 it was estimated that there were 150,000 cases in the Democratic Republic of the Congo. Other estimates suggest that around 300,000 people are infected in Africa, many of whom will die because of lack of treatment (Fig. 3).

![Distribution of human sleeping sickness foci in Africa. Dashed line indicates boundary between foci of T. b. gambiense (west) and T. b. rhodesiense (east). Arrows denote the probable direction of spread of the two types.](image)

Identity and Origins of the Parasite

The two parasites causing human sleeping sickness, T. brucei gambiense and T. b. rhodesiense, are morphologically indistinguishable, and early diagnosis was based on clinical signs of the disease.
Sleeping sickness caused by *T. b. rhodesiense* is an acute disease, with death occurring after only a few months, whereas with *T. b. gambiense*, death may not occur for several years. *T. b. gambiense* occurs in West and central Africa and is transmitted predominantly by *palpalis* group tsetse, while *T. b. rhodesiense* occurs in southern and East Africa and is transmitted by *morsitans* group flies.

Although generally accepted that sleeping sickness trypanosomes are derived from *T. b. brucei* (infecting wild and domestic animals and morphologically indistinguishable from the human infective parasites), there are several theories on the evolution of species infecting humans. First, the two types of sleeping sickness may be caused by the same parasite, the disease simply being more acute when the trypanosome becomes adapted to certain species of wild animals. Chronic disease occurs when the trypanosome is adapted to humans as its principal host. Second, *T. b. rhodesiense* may have evolved in the late Miocene or Pliocene, when hominids were exposed to Trypanozoon trypanosomes in their savanna habitat. Subsequently, *T. b. gambiense* may have evolved from *T. b. rhodesiense* when hominids invaded forests and became hosts of *palpalis* group tsetse. Third, the two subspecies may have evolved independently from *T. b. brucei* or a common ancestral species. A fourth theory is that after *T. b. gambiense* spread to savanna areas of southeast Africa, *T. b. rhodesiense* evolved from it and subsequently spread northward. An alternative theory is that *T. b. brucei* gave rise first to *T. b. rhodesiense* and then to *T. b. gambiense* and that the two diseases evolved in humans from an animal infection to an anthropozoogenesis (*T. b. rhodesiense*), and then to a pure anthroponosis (*T. b. gambiense*).

Molecular characterization of *T. b. rhodesiense* suggests that it had polyphyletic origins. It is widely accepted that *T. b. gambiense* sleeping sickness spreading from West to central Africa. Areas of West Africa where sleeping sickness occurred and the Nile basin are ecologically similar, with a continuous corridor of Sudano-Guinean climate and vegetation. *T. b. rhodesiense* then would have spread northward either from Central Africa through East Africa or from the Zambezi valley in Zambia, increasing in virulence the further north it progressed. Contradictory evidence from biochemical and molecular characterizations suggests that strains of *T. b. rhodesiense* from Zambia, Kenya, and Uganda have independent origins.

**Reservoir Hosts**

Until recently, one of the difficulties in proving the existence of reservoir hosts for *T. b. rhodesiense* and *T. b. gambiense* arose from problems in subspecies identification. It is now possible to use molecular genetic and biochemical methods to identify human infective forms. Consequently, there is now evidence of a range of wild and domestic animal host reservoirs. The latter are likely to be less important in the epidemiology of sleeping sickness due to *T. b. gambiense* than for *T. b. rhodesiense*. Many animals can be experimentally infected with either subspecies, and wild and domestic animals can maintain the “rhodesiense” disease endemically.

Urban Habitats
Michael K. Rust
University of California, Riverside

Urban environments are created from natural or agricultural ecosystems that have been disturbed by human activities, typically by the construction of towns and cities. The urban biotic environment can be divided into plant and animal communities that surround houses and buildings, occur indoors or in close contact with humans, or directly affect the structure. Human activities give rise to special conditions and environments that are frequently exploited by a select group of insects and arthropods. For example, about 25 species of the some 3500 known cockroaches are considered to be domiciliary pests. Of these 25 species, only about 5 are considered to be serious urban pests. Similarly, of the approximately 550 species of ants found in the United States, only 30 species commonly infest homes, and only 10 of these are of major importance. Urban landscapes are truly special ecological environments and niches.

Urban environments are similar in developing and developed countries worldwide in that natural systems have been disturbed by human activities. The rate at which urbanization is occurring in undeveloped areas of Africa, South America, and Asia is almost incomprehensible. By the year 2025, 6.3–8 billion people will inhabit less developed regions of the world compared with 1.2–1.5 billion people that will inhabit the developed regions. Between 1960 and 1990, the number of cities in China, Indonesia, and Brazil with more than 500,000 residents doubled; in India, the number tripled. By the year 2010, about 57% of the world's population will be living in urban centers, and in Brazil, it will be close to 89%. Because of the rapid growth of urban cities in developing countries with tropical climates, urban insect pests, especially those that vector human and animal disease pathogens, are a critically important emerging problem.

DEVELOPMENT OF MEGACITIES

A newly emerging feature of countries with large population centers is the development of mega urban cities. Megacities typically incorporate two or more large urban centers linked by transportation. Rural zones between such megacenters are characterized by commercialization of agriculture, expansion of transport systems, and employment shift from farming to other activities, accompanied by migration to the cities. The number and size of these megacities in developing countries will continue to grow, and by 2015 it is projected that there will be some 23 megacities with more than 10 million inhabitants (Table 1). Tremendous amounts of resources and commerce will be necessary to support the large populations and the waste and garbage they will produce. It is these conditions that are conducive to insect pest problems such as mosquitoes, flies, cockroaches, fleas, termites, and wood-destroying pests. In addition, crowding and waste lead to vertebrate pest problems such as rats, mice, and pigeons.

Urban centers require the movement of goods and food to maintain their large human populations. Human movement and transportation of commerce provide a unique and rapid dissemination of insects and arthropods between centers. At the turn of the 20th century, it took over a week for ships to sail from Europe to North America. Today aircraft make the same journey in less than 7 h. The potential exists for rapidly spreading insects and the diseases they vector from one continent to another. Three recent examples of urban invasive species spread by commerce are presented.

URBAN INVASIVE SPECIES

Asian Tiger Mosquito

It is thought that the Asian tiger mosquito, Aedes albopictus, entered the United States in Houston, Texas, in 1985 in used automobile tires imported from northern Asia. A. albopictus is a major human-biting pest species throughout its range. In addition, it has been experimentally shown to be a competent vector of a number of viruses including Western equine encephalitis, dengue, Japanese encephalitis, and yellow fever. To highlight the impact of commerce on the potential movement of insect pests, over 11 million used tires from 58 different countries entered the United States from 1978 to 1985. A. albopictus also shows the importance of local transport and the interstate highways. In 1987, of the 92 counties infested with this species, 64 were on an interstate highway, nearly twice the number that would be expected if their spread were not related to these road systems.

Since its introduction, this mosquito has spread to 25 states, mostly throughout the southeastern United States but as far north as Iowa, Illinois, and Ohio (Fig. 1). The female’s propensity to lay eggs in bottles, cans, tires, rain gutters, flower pots, watering cans, children’s swimming pools, and containers makes this mosquito ideally suited for urban environments.

Formosan Subterranean Termite

The Formosan subterranean termite, Coptotermes formosanus, has spread by marine commerce to semitropical and tropical seaports throughout the world. Once ashore, railroad ties provide a rapid method of moving and establishing large colonies of termites. In the 1960s, C. formosanus was discovered in Texas, Louisiana, and South Carolina. By 2000, it had spread to nine other southern states, and to California and Hawaii. C. formosanus is characterized by extremely large populations of aggressive foragers that can do extensive damage to structures. It is the most import urban pest in Hawaii and has been estimated to cause about $300 million damage a year in New Orleans, threatening nearly all the buildings of the historic French Quarter.
The Asian long-horned beetle, *Anoplophora glabripennis* (Fig. 2), has the potential of becoming a serious pest of ornamental trees found in urban landscapes. Infestations of Asian long-horned beetle were first discovered in 1996 in Brooklyn. Another infestation was found in Chicago in 1998. It is believed that the beetle entered the United States in solid wood packing material from China. The beetle has been found in warehouses in some 26 locations throughout the United States. This beetle poses a serious threat to many different hardwood trees that are common in urban landscapes, including sugar, silver and red maple, birch, poplar, willow, ash, and black locust. The cost of suppressing the beetle in New York has already reached $4 million.

**ADDITIONAL URBAN PESTS**

The vast majority of insects, however, are not capable of adapting to the artificial and unnatural conditions created by humans in urban environments. A few pests such as the German cockroach, cat flea, and house fly have readily adapted, have been able to survive in close proximity to humans, and now are cosmopolitan. Many urban insect pests such as the German cockroach, oriental cockroach, confused flour beetle, and granary weevil have lost their ability to fly and rely on human activities for their dispersal. Other species such
as the Argentine ant and the pharaoh ant do not swarm and rely on budding for reproduction and commerce for transport. Many of the indoor pests of food and fabric have continuous development and do not require special dormancy or hibernation to complete development. These insects thrive at temperatures ranging from 18 to 35°C and relative humidity (RH) ranging from 50 to 90%, which are ranges typically found within human dwellings.

In addition to human occupants, domesticated pets may be a source of pests such as fleas, ticks, and mites. The cat flea, *Ctenocephalides felis*, is the most important ectoparasite of domesticated cats and dogs worldwide. From its probable origin in Africa, the cat flea has spread worldwide. In most urban environments, the larval development requirements of *C. felis* (RH > 75%, 21–32°C) are found in restricted microhabitats such as crawl spaces under homes, pet houses and bedding, utility rooms, and bedrooms. Interestingly, surveys of feral animals such as opossums indicate that *C. felis* is encountered only on animals frequenting urban settings.

**NEED FOR URBAN PEST MANAGEMENT**

The need for urban pest management in and around structures can be directly attributed to the dislike of insects and arthropods by humans. Some pests such as cockroaches, fleas, flies, and mosquitoes represent potential health risks. Others such as termites and wood-destroying pests can cause serious economic damage to structures. Pantry and fabric pests cause damage to foods, fabrics, and items made with furs, skins, and feathers. Many pests such as earwigs (Dermaptera), crickets (Orthoptera), pillbugs (Isopoda), sowbugs (Isopoda), and millipedes (class: Diplopoda) are occasional intruders, but their suppression often requires remedial action. The control of urban pests has created a large and important industry in the United States and Europe; in the United States alone about 1 million structures are treated each year for termite damage, repairs, and treatments at a cost of about $520 million.

The costs of treatment and repair by the pest control industry in the United States are estimated at about $2 billion. Consumers’ annual expenditures on over-the-counter pest control remedies probably are at least as much. In developing countries, there will be an increasing need for pest control to protect the health and welfare of the inhabitants. With the increasing levels of international trade and tourism, urban pest management will take on special importance in the 21st century.

**Further Reading**

Venoms are biologically active liquids delivered into or onto another organism through a piercing structure such as a mouthpart or sting apparatus and often resulting in pain, tissue damage, paralysis, or death in the target organism. Insects contain more venomous species than all other groups of terrestrial animals combined. Within insects, venoms evolved numerous times to occupy positions in groups as diverse as ants and wasps to biting bugs, robber flies, and stinging caterpillars. Venoms empower insects with unique properties that enable them to achieve far greater effects or impacts on target organisms than would be expected for such small animals. A tiny wasp weighing far less than a milligram can rapidly paralyze a caterpillar hundreds of times its own size, and a single attacking honey bee can send a million times larger human into panicked flight.

Venoms provide the biological means for insects to break free from many ecological restraints, thereby expanding their opportunities to exploit the world around them. One could argue that the omnipresence of ants in today’s world is the result of venom combined with a social structure in ancestral ant lineages. Parasitic braconid and ichneumonid wasps, whose species number more than 100,000, with probably several times that number undescribed, owe their successful speciation, in part, to the ability of their venoms to facilitate the use of a variety of host organisms. Honey bees (Apis spp.) have become dominant pollinators throughout much of the world, in large part because their venomous stings have enabled them to defend against a multitude of large, often intelligent predators. Without their effective defensive venoms, honey bees could not prevent the plunder of their large stores of honey and pollen, which they must maintain to overcome long seasonal periods of harsh conditions. The biological roles, operation, and properties of insect venoms provide dazzling illustrations of the successful adaptation of insects to their environment.

**BIOLOGICAL ROLES OF VENOMS**

Venoms serve two primary roles—defense and prey capture. In most lineages, the ancestral role was the use of venom for prey capture. The venoms of many taxa retain primary roles of prey capture. Examples are numerous and include many families or superfamilies of bugs, beetles, flies, neuropterans, and especially parasitoid and solitary aculeate wasps. Many successful insects have taken venom use another step—to defend against predators. The mere fact that insects such as honey bees, yellowjackets, and hornets are so universally familiar attests to the effectiveness of their defensive venoms. Defensive venoms are present in all social wasps, many ant species (including fire and harvester ants), some solitary bees and wasps, a few bugs, and a variety of spiny caterpillars. In many of the hymenopterans, the role of venom for prey capture has been entirely replaced by a role in defense. Some wasps and ants retain both roles, with the spider wasps (Pompilidae) and fire ants (Solenopsis spp.) as conspicuous examples. In caterpillars, which never used venom for prey capture, the defensive role evolved independently.

**EVOLUTION OF VENOMS**

Most venoms evolved from preexisting digestive or reproductive systems. Exceptions are the lepidopteran caterpillars, for which the origin of their venomous spines is unclear. The venoms of all other non-hymenopteran insects evolved from salivary or gastric secretions associated with the mouthparts and digestion. In some taxa, the venom toxins are salivary secretions injected into the prey. In others, the toxins are regurgitated from the gut into the prey through piercing mouthparts. Asilid flies use the latter form of venom delivery.

The Hymenoptera evolved an entirely different venom system. In Hymenoptera, the stinger evolved through modification of the female ovipositor, and venom evolved from the accessory reproductive glands (Figs. 1 and 2). Consequently, only female Hymenoptera can sting. The lack of ability to sting and defend a colony against large predators is considered a primary reason for the failure of males, often called drones, of honey bees and social Hymenoptera to meaningfully defend their colonies against predatory assaults or to help the colony via foraging.

VENOMS USED FOR PREY CAPTURE

Two basic types of venom are used for prey capture: those that kill outright and those that only paralyze or alter prey physiologically. Prey paralysis is important for many insects that provide prey for their young. Prey that is paralyzed but still living does not spoil rapidly, giving larvae time to feed and grow. Insects that kill their prey with venom tend to consume it immediately, though exceptions to this rule exist. Wasps that use their venoms to provide a living host for their larvae and oviposit one or more eggs in or on the host are often called parasitoids. The venoms of parasitoids span a paralysis range from no paralysis to temporary paralysis to permanent paralysis. Venoms causing no paralysis, or short-acting paralysis, are found in many species of wasps in which the parasitized host continues feeding and growing until just before it dies, all the while harboring and protecting the parasitoid larvae from environmental and predatory risks. The venoms of these wasps often contain mutalistic viruses and other components that not only help protect the oviposited eggs from host encapsulation and immune defenses, but also alter the hormone balance inside the host to prevent molting to the next stage of development. If the host is in a protected environment, as exists for wax moth larvae in combs of a dead honey bee colony, an extremely potent venom that causes total and permanent paralysis, like that of a parasitoid wasp such as Bracon hebetor, can be beneficial.

Hunting wasps are another group of solitary wasps that use venom for prey capture. These wasps include familiar sphecid, eumenid, and spider wasps plus a variety of other families of aculeate wasps. Like classical parasitoid wasps, hunting wasps possess venoms with a large activity span. For example, the sphecid Larra analis uses venom to paralyze its mole cricket hosts temporarily. At the other extreme, represented by the beeewolf Philanthus triangulum and tarantula hawks (Pepsis spp.), the hunting wasps paralyze the honey bee and tarantula prey permanently. No evidence for injection of viruses or factors altering the host's endocrine or immune systems exists for hunting wasps. The majority of parasitoid and hunting wasp venoms are of little value for defense against predators. In many groups, the wasps cannot, or do not, even attempt to sting predators; in others, the pain and activity of the venom, at least to humans, is trivial. Some exceptions exist: most pompilid and mutillid wasps; some eumenid, tiphiid, and bethylid wasps; and a very few sphecid wasps can deliver painful stings; however, none of these venoms is meaningfully toxic to mammals.

DEFENSIVE VENOMS

Because of the extreme size difference between vertebrates and insects, insects are vulnerable to attack by vertebrate predators. Once such a small creature is captured by a large predator, typical defenses such as kicking, scratching, and biting are all but useless. A very few defenses, particularly potent venomous stings and allomones, can neutralize the predator's size advantage and blunt attacks. A key feature promoting the efficacy of defensive venoms is the ability of the sting apparatus to bypass the predator's skin and external defensive barriers and inject venom directly into sensitive tissues. Venoms function as defenses in several ways. First, they cause pain. Second, they can cause body or tissue damage, or death. Beyond these primary activities, venom can have defensive value based on its nasty taste, and, possibly, on its ability to induce allergic reactions. Honey bee venom illustrates the value of a repugnant taste of a venom: birds and other vertebrates were presumed to reject worker bees while readily devouring drones because of the ability of workers to sting. For example, Western Kingbirds selectively prey on drone honey bees, which they manipulate entirely with their hard bill until the prey can be quickly swallowed, head first. The handling and speed of consumption suggested to the author that a kingbird could consume worker bees without being stung. Why then were workers rejected? A suspected, but unconfirmed, explanation was revealed upon consumption of whole frozen drone honey bees and abdomens of workers. Drones were generally palatable. In contrast, worker abdomens were noisome, possessing a bitter and “hydrolytic” taste, a taste confirmed by sampling of an isolated venom sac to be venom.

No direct evidence confirms a defensive value for venom allergy. However, three lines of reasoning suggest that such a value might exist. First, the 1 to 4% incidence of allergic reaction to insect stings in the general human population is disproportionately high compared with allergy to other proteinaceous substances. Second, observations of social interactions among human groups in which one individual experiences an allergic reaction to a sting reveal that fear of the culprit stinging insect is shared among the whole group. Primates and other intelligent social mammals, major potential predators of social insects, likely also learn to avoid the stinging insects by observation of the plight of a group member. Third, an allergic reaction impairs an individual’s ability to avoid its own predators, to obtain food, and to reproduce as effectively as if no reaction had occurred. Consequently, the genes from an individual that attacks stinging insects and suffers a reaction are not as likely to be passed to future generations. Such “genetic learning” would be a consequence of allergic reactions.

Pain, the most notorious property of an insect sting, is key for the instant defensive value of venom. Pain is the biological signal that indicates to an organism that bodily damage has occurred, is occurring, or is about to occur (Fig. 3). Consequently, pain is a signal that must be heeded and acted upon if an animal is to enhance its own survival and fitness. Pain acts to stop an attacking predator and to cause it at least momentarily to assess its own risk situation. In the meantime, the stinging insect gains valuable time for escape or further defense. Because pain cannot be measured easily or precisely, exact values to

FIGURE 3 Painful local reaction illustrating central tissue damage and surrounding inflammation induced by a honey bee sting. (Photograph courtesy of J. O. Schmidt.)
use for comparing the effects of different venoms on potential predators are unobtainable. To provide a means for comparison, a pain index was developed, based on a scale of 0 to 4. Zero indicates that the sting- ing insect is too small or otherwise unable to pierce the human skin; 2 is the central value, as represented by the pain of a honey bee sting; and 4, the top of the scale, is typically described as causing immediate, excruciating, totally debilitating pain that completely eliminates the ability of the stung individual to continue to act in a normal fashion. Table I lists pain values for some common insects.

TABLE 1

Pain Rating and Lethality of Common Insect Venoms

Insect venoms have played an enormous role in ecology and evolution. For parasitic and hunting wasps, venoms have provided the means to expand the menu of hosts as food sources. This in turn allowed, and continues to allow, isolation of breeding populations and rapid speciation of the wasps. Via their increased impact, wasps alter the foraging and defensive behaviors of their host species, with a ripple effect insofar as other predators and parasites are influenced. The influence of defensive venoms is even greater. The defensive potency of venoms provided venomous insects the freedom to enhance further their defensive strengths through the evolution of secondary defenses of aposematism and mimicry. Warning colors, sounds, or chemical signals used in conjunction with the honest threats of damage from the sting provide venomous insects with the ability not only to defend against potential predators, but also to reduce risks of being attacked. After one or a few species develop aposematic signals, other venomous insects can become Müllerian mimics of the signals. The system opens to “cheaters”—which are not noxious—to become Batesian mimics of the venomous models. For most species, freedom from one or more predators, or reduced predatory pressure, provides wonderful behavioral and evolutionary opportunities. Secretive species may expand their niches into more conspicuous environments or to increased periods of time, thereby reaping the benefits of increased quantity and variety of resources. Examples of this are brightly colored bumble bees, social wasps, and spider wasps that can forage during daylight hours in open environments, free from most threats from predatory birds and lizards. Likewise, venomous ants can exploit daylight periods, open areas, or conspicuous areas in the vegetation.

All other effects of venoms pale in comparison to their impact on the evolution and maintenance of sociality in Hymenoptera. Social wasps, bees, and ants account for a huge percentage of the individuals and biomass of most ecosystems, especially tropical systems. Social wasps are important predators of other arthropods, social bees are responsible for much of the pollination of plants, and ants are major predators and influences on other animals. Insect sociality evolved partly through kin selection in which related presocial individuals that cooperated had higher inclusive fitness (the successful passing on of their genes to the next generation) than did individuals that did not cooperate. In Hymenoptera, the evolution of sociality, and its maintenance, was possible, in large part, because of defensive venoms. Social insects and their nests brimming with defenseless brood and/or food stores represent bonanzas for predators capable of exploiting them. As colony size increases, larger and more determined predators will attempt to exploit a colony’s brood or food cache. Venoms provided the means, both proximate and ultimate, for colony defense against destruction. Once established, sociality in Hymenoptera could progress from small simple social structure to highly organized structures via the evolution of increasingly potent venoms and other defenses. Populous, highly organized social species dominate and rule most environments.
Veterinary Entomology

Bradley A. Mullens
University of California, Riverside

Veterinary entomology deals with arthropod pests and vectors of disease agents to livestock, poultry, pets, and wildlife. It is allied with the fields of medical entomology, parasitology, animal sciences, veterinary medicine, and epidemiology. The main pests of veterinary concern are sucking and biting lice, biting flies, nonbiting muscoid flies, bot flies, fleas, and Acari (mites and ticks).

**ARTHROPOD GROUPS**

Arthropods that affect animals can be categorized by the intimacy of their host association, and these range from permanent ectoparasites to pests that contact the vertebrate only briefly once every few days.

**Permanent Ectoparasites**

Some arthropods, such as lice and many parasitic mites, complete their entire life cycle on the host. All stages of sucking lice (Phthiraptera, suborder Anoplura) are mammal parasites and feed on blood. Biting lice (suborders Anylcyrena and Ischnocera) use either mammal or bird hosts. They feed mostly on skin, hair, and feather debris, but sometimes feed on blood as well. Lice tend to be abundant in cool weather or on animals stressed by poor nutrition or overcrowding. Many lice are specific to one or a few closely related hosts and cannot survive more than one to a few days away from the host. Transmission from host to host is mostly by direct contact.

Parasitic mites (Acari, suborders Mesostigmata, Acaridida, and Actinedida) are found on most groups of birds and mammals. Like lice, most are specific to one host species or a small group of related species. Several genera comprise what are commonly known as "mange mites." Sarcoptes scabei, which causes sarcoptic mange, burrows at the surface of the dermis and exists in a number of races that generally are host specific to swine, dogs, and so on. Demodex mites, causing demodectic mange, live in follicles and can be important especially in immuno compromised hosts. Chorioptes and Psoroptes, causing chorioptic and psoroptic mange, include species of considerable importance for cattle, and wild and domestic sheep. The latter mites complete their development at the skin surface and do not actually burrow in the skin, although mites often are covered by scabs and are frequently called scab mites. Ornithonyssus mites are blood feeders and are especially important for wild and domestic birds, where populations may reach many thousands per host (Fig. 1). They occupy fur and feathers, traveling to the skin surface to feed regularly.
Some of the more advanced flies are also permanent parasites, and a number of species in three families hardly resemble flies at all because they have secondarily lost their wings (apterous). Members of the dipteran families Streblidae and Nycteribiidae live on bats, whereas members of the Hippoboscidae parasitize various birds and mammals. Some hippoboscids are economically important, such as the sheep ked, *Mallophagus ovinus*. In all these families, the adult female nurtures a single larva within her body until it is mature; this is a very unusual pattern for insects. After the mature larva exits the female, it promptly pupates on the host or nearby.

**Semipermanent Ectoparasites**

The semipermanent ectoparasitic arthropods do not complete the entire life cycle on the host, but they do spend at least several days at a time on a vertebrate. The hard ticks (Ixodidae) attach to feed for several days in each of the life stages. Although some, like the cattle tick *B. microplus*, complete the entire life cycle on a single host, the most abundant and widespread species tend to use a separate host for each stage. In this case, the engorged tick falls off, molts, and then finds a new host by crawling up on vegetation and waiting for a passing vertebrate to which it attaches. This activity is known as questing. Often the larva hatches from an egg and attaches to a small host such as a rodent, whereas the nymph (the stage after the larval molt) or adult may attach to a larger host such as a deer. An example is the American dog tick *Dermacentor variabilis*. Adult female hard ticks take a large blood meal, produce a single large batch of eggs (typically several thousand), and then die.

Fleas (Siphonaptera) generally are on a host for most or all of the adult stage, and feed on blood. About 94% of flea species live on mammals, and the rest on birds. Flea eggs fall from the host pelage into a nest environment, where the larvae feed on organic debris and sometimes on excess blood produced by the adults. Fleas thus are often lacking on hosts that do not return to long-term bedding areas or nests.

Bot flies include important species in the dipteran families Oestridae, Gasterophilidae, and Cuterebridae. They spend nearly the entire year as immatures within the vertebrate’s body. Eggs, often laid on hairs, hatch and enter the host body.

Horse bot larvae (*Gasterophilus*) attach to the wall of the gastrointestinal tract for several months before they pass from the host with feces to pupate in soil. Cattle grubs (*Hypoderma*) migrate through the lining of the esophagus or spinal cord, depending on the species, and eventually form a cyst in the back. After a final period of maturation, larvae exit the cyst and fall into the soil to pupate. Bot fly adults lack functional mouthparts and depend entirely on reserves from the larval stage to sustain them for several days; in this brief time they must find mates and hosts. The invasion of vertebrate tissues by fly larvae is known as nyiasis.

Certain other flies also are semipermanent parasites. Among muscid Diptera, the horn fly, *Haematobia irritans*, is on cattle most of its adult life, where adults of both sexes take many small blood meals each day. This distinguishes them from the vast majority of blood-feeding flies, which feed far less often. Horn flies leave the host to disperse and to lay eggs in very fresh dung, and then return to the host.

**Occasional Parasites**

The broad category of occasional parasites includes a range of arthropods. The most intimate host associations in this group include the soft ticks (Argasidae) and some blood-feeding mites such as the bird parasite *Dermanyssus gallinae*. In both cases, nymphs or adults hide in or near nest areas, sheltered in cracks and crevices or under debris; thus, they are closely associated with animals, although they contact them only periodically. They leave the hiding places, often at night, to feed for periods of 5–30 min, returning to the nest to digest the blood meal. Some soft ticks can withstand dry conditions and years without feeding.

Many serious biting fly pests spend the immature period away from the host, exploiting an entirely different resource base. It is common for larvae to feed on detritus in wet habitats, whereas the adults use plant nectar for energy and blood for egg development. For example, larvae of stable flies live in rotting vegetation, black flies in running water, horse flies and biting midges in swampy mud, or mosquitoes in ponded or slowly moving water. When the adults emerge, they take blood meals at intervals of 1–4 days, but they typically are in contact with the host for only a few minutes at a time. They leave the host to digest the blood in some sheltered resting location. For the higher Diptera (Cyclorrhapha), such as stable flies (Fig. 2) or tsetse flies, both sexes feed on blood, and multiple blood meals usually are needed to develop a batch of eggs (or, for tsetse, a single mature larva). In the lower Diptera (basal Brachycera and Nematocera) such as horse flies, blackflies, or mosquitoes, only females take blood, and most species require only a single large blood meal to develop an entire batch of eggs numbering 50–300. Some other pests in this general category do not feed on blood but visit the host to take meals of tears or other protein-rich secretions that are also used to develop eggs. A good example is the face fly, *Musca autumnalis*.

**Figure 2** The stable fly, *Stomoxys calcitrans*, may attack animals in high numbers: there are approximately 200 flies feeding on the front leg of this bull. This species is illustrative of the occasional parasites because the adult flies blood-feed for only a few minutes every day or two, and larvae are in rotting vegetation away from the host animal.

**How Arthropods Cause Damage to Animals**

There are several basic ways in which arthropods cause damage to animals, and the different mechanisms interact to impact agricultural production. Arthropod damage to plant crops often is evident to consumers, who react with disgust to cabbage leaves damaged by loopers, corn earworm larvae on an ear of corn, or scale insects on citrus fruit.
In contrast, arthropod damage to animal production tends to be hidden from the consumer because the product is purchased in the form of jugs of milk or wrapped packages of butchered meat. Nevertheless, losses are serious for producers, and costs are passed on to consumers.

Loss of Blood and Tissue Fluids

Many arthropods ingest blood, usually for egg development. Impact of blood loss on the animal reflects the style of feeding and the number of arthropods. Mosquitoes may cumulate a vessel, and hosts generally lose only the blood mosquitoes ingest. In contrast, some biting flies macerate the capillary beds of the skin to feed from blood pools. They not only tend to inflict more painful bites, but the bites themselves also lead to a larger quantity of blood loss per feeding insect. For example, horse flies (Tabanidae) may directly remove over 200 ml day \(^{-1}\) from a host in a pasture, but blood continues to run from the wound for a period of time, often being fed on by other flies. Many hard ticks (Ixodidae) increase in weight by 100-fold or so as they feed for 7–10 days. Females of very large species of ticks may contain over a milliliter of blood at a time, and hundreds may be attached

Impact of blood loss on the animal reflects the style of feeding and the number of arthropods.

Product Damage

Arthropods sometimes cause direct damage to parts of the animal desired by people. For example, cattle grubs (Hypoderma) larvae form large cysts in the backs of cattle. They cut a hole in the skin to breathe, and this skin is the thickest on the animal. Although the holes heal after the larva exits, the scarred skin is less valuable for leather. The presence of larvae also can affect the quality of the meat in this area of the animal, which is the part where the best steaks come from, and damaged meat sometimes must be trimmed at the slaughterhouse. Mites such as Psoroptes and Sarcoptes, as well as many lice, often result in irritation, rubbing, and gross loss or damage to hair and wool.

Cosmetic damage, including rashes or minor hair loss, can be predictably serious to the owner of a pet or a show animal. However, cosmetic damage also can cause losses in animal agriculture out of proportion to actual damage. An example of this is the condition “gotch ear” in cattle caused by the Gulf Coast tick Anahyoma maculatum in the southern United States. Damaged ear cartilage is cosmetic, but causes the animals to be placed in an “odd lot,” with per-pound prices less than those of undamaged cattle.

Restricted Trade

Many pests have distinctive distributions, and preventing movement or dispersal into new areas is of paramount importance. Cattle ticks (Boophilus) and screwworms (Cochliomyia hominivorax) were eradicated from the southern United States in the 20th century, but the ticks inhabit Mexico and countries south of it, and screwworms persist on some Caribbean islands and South America. The U.S. habitat obviously is still suitable. Without complex systems of animal quarantine,
Vibrational Communication

Andrej Čokl, Meta Virant-Doberlet
National Institute of Biology, Slovenia

Many insects communicate by mechanical signals propagating through a medium as near- or far-field airborne sound, substrate vibrations, underwater sound, and/or water surface vibration. Vibrational signaling through substrate is most commonly used whether counted by species, family or phylogenetic distribution (Fig. 1). Over 195,000 species communicate with substrate-borne signals alone or together with other forms of mechanical signaling and about 150,000 species use vibrational signaling exclusively. Insects emit vibratory signals in connection with aggression, distress, calling, courtship, rivalry, and other specific behaviors. Among many tasks, substrate-borne signaling enables mate location and recognition. This article presents vibratory mechanisms, structures, and signals in relation to behavior.

MECHANISMS OF VIBRATION PRODUCTION

Insects produce vibratory signals by percussion, vibration of the body or its part, tymbal mechanisms, or stridulation. Percussion is common because of the hard exoskeleton, which enables either percussion of two body parts or striking against a substrate. The percussive structures are in most cases relatively simple. Book lice (Psocoptera) and stoneflies (Plecoptera) tap their abdomens against the substrate, Orthoptera use their legs, and termites and beetles drum with their heads. Tremulatory signals are produced by an insect with legs kept firmly on the substrate and jerky movement of the whole body without touching the substrate. In meadow katydids, larger males produce tremulatory signals with shorter inter-pulse intervals; females prefer sequences with shorter inter-pulse intervals indicating that tremulatory signals encode information on body size. Low-frequency signals can be emitted also by vibration of some body parts. For example, male and female chloropid flies Lipara communicate over distances of more than 2 m on a reed with signals produced by vibration of the abdomen. Lacewings (Chrysopidae) oscillate the abdomen without touching the substrate, and in this way shake the stem or leaf on which they are standing. In such a way, they produce the low-frequency tremulatory component of the broad signal used for communication. Abdominal muscles are involved in song production also in the Hawaiian fly Drosophila sylestris. Bees produce vibratory signals by thorax vibrations; “begging” signals are transmitted to the substrate through the legs, and “tooting” and “quacking” signals directly by pressing the thorax to the substrate.

Tymbal-like mechanisms are used to produce vibratory signals in leaffoppers, planthoppers, treehoppers, spittle bugs and cicadas. Because there are no special resonant air sacs behind the tymbal, the carrier frequency of emitted sound remains low and suitable

**Diseases**

A number of serious animal disease agents are transmitted by arthropods. The worst of these are tropical, and they cause death and heavy production losses in the affected countries. African trypanosomiasis causes a wasting-type disease known as nagana in animals and sleeping sickness in humans, and Theileria parva, called East Coast fever, can cause 90–100% mortality in affected cattle in eastern Africa. People in developed countries tend to underestimate the true value of animals in the developing world. Animals are vital there not only for protein-rich food, but for draft and transportation purposes, and as wealth. They are the basis of many pastoral peoples’ economies, and the economic impact of some of these animal diseases can exceed even the impact of similar, serious human pathogens.

Temperate zones also have some rather important arthropod-transmitted animal disease agents, including Anaplasm, dog heartworm, and equine infectious anemia virus. In the United States and Europe, the direct effects of arthropods on animal production generally exceed losses caused by arthropod-transmitted diseases. However, the role of wild animals as natural reservoirs of pathogens that incidentally infect people is very important in both temperate and tropical zones. Diseases that cycle naturally in animal populations and occasionally infect people are called zoonoses. Zoonoses comprise some of the more notorious arthropod-related human health problems. They include plague (maintained in rodents and transmitted by fleas), Lyme disease (maintained in rodents and transmitted by ticks), and St. Louis encephalitis (maintained in birds and transmitted by mosquitoes). Previously unknown tick-borne ehrlichioses (caused by intracellular bacteria-like organisms in the genus Ehrlichia) have been recently discovered infecting humans in the United States. They are zoonotic in origin and typify a category of “emerging” human diseases that is now of great interest in the medical community.

**Further Reading**

for transmission through a substrate. Many insects produce vibratory signals by stridulation as friction of two body parts moved one across another. For example, ants stridulate by means of a file on the dorsal surface of the first abdominal segment and a plectrum on the posterior edge of the metathorax or postpetiole. The substrate-borne component of the audible signal is used for communication. Burrower bugs (Cydnidae) communicate with substrate-borne signals produced with the tergal plate, which functions simultaneously as tymbal, as a file with its laterofrontal surface, or as a plectrum for the alary stridulantum on the postcubital vein.

Vibratory signals are produced by different insect activities. An insect singing on or close to a substrate produces signals with airborne and substrate-borne components, and many of them use both simultaneously or alternatively. Fruit flies communicate with near-field sound radiated from wings and with substrate-borne signals, which are simultaneously produced by muscles driving the wings. Soil buzz vibrations and sounds produced by solitary bees and wasps are used as cues for localization.

**TRANSMISSION OF VIBRATIONS**

An insect standing on a substrate may be represented by a model of a mass on six springs. The bodies of treehoppers, spiders, and even fiddler crabs respond to substrate vibration with resonance at lower frequencies and attenuation at higher frequencies. Legs transmit body vibrations to the substrate and are the seat of most sensitive vibrational receptors. Transmission over the legs depends on their stiffness, and the response properties of the body—legs oscillating system vary in different species with the change in posture. Signal amplitude decreases during transmission to the substrate, mainly because the body vibrates during singing also in a horizontal plane.

Green plants represent the most common substrate on which insects feed and mate. They communicate through them by bending waves which are characterized by particle motion in a plane perpendicular to the direction of wave propagation and to the surface with stresses and strains in the longitudinal direction. Insects use dispersive or nondispersive bending waves; the latter are characteristic for communication with high-frequency signals through larger stems. The propagation velocity of bending waves varies little with the structure’s mechanical properties and is proportional to the square root of the structure’s radius and the square root of the frequency. A point on a stem surface moves in an ellipse when viewed relative to a cross-sectional plane; at any frequency, the ellipse’s major axis corresponds to the maximum amplitude of vibration. Vibratory signals travel through green plants with low attenuation, reflect mainly at the root and top of the plant and may travel back and forth several times creating standing wave conditions in rodlike structures such as stems, stalks and side branches. The green host plants act as low pass filter.
with resonant properties tuned within the range of the fundamental frequency and higher harmonics of signals of most insects communicating through plants. Lowest attenuation with the distance is characteristic for about 100 Hz signals transmitted through green plants. Most insects adapt spectra of their vibratory signals with mechanical properties of transmission medium to optimize the range of substrate-borne communication. Vibratory signal spectra of the southern green stink bug, Nezara viridula, and until now all investigated species of the subfamily Pentatominae have a narrow fundamental and dominant frequency peak between 80 and 160 Hz (Fig. 2). Burrower bugs emit broadband signals composed of the stridulatory and low-frequency components produced by body vibration; the latter unit contains most of the emitted energy. Carpenter ants, Camponotus herculaneum, live in tree trunks from which the soft spring wood has been eaten out, leaving thin, lignified lamellae. The alarm signals, produced by drumming the head and gaster against the substrate, are particularly suited for transmission through the nest but not through to the outside. “Begging signals,” emitted by bees following a dancer, are used to solicit food samples. The 1-μm peak amplitude of the signals lies slightly above the threshold for the bee “freezing response,” and the signal dominant frequency around 320 Hz lies in the range of the best signal-to-noise ratio of the bee comb.

Investigations of other transmission media for insect vibratory signals are rare. The European pit-building antlions, Euroleon nostras, uses sand to detect prey. Sand particle size and the frequency of prey signals influence their propagation properties: damping is inversely proportional to the size of sand particles and is positively correlated with the frequency. The reaction distance is shorter compared with green plants and ranges from a few centimeters in the finest sand to about 12 cm in coarser one.

**RECEPTOR MECHANISMS**

The most sensitive and specialized receptor for substrate vibrations, the subgenual organ, is derived evolutionarily from chordotonal organs in the body and appendage joints. It has been found in all Pterygote insects, except Coleoptera and Diptera. The organ lies in insects in all the six legs close to the main tracheal trunk and almost completely occludes the dorsal blood sinus of the proximal tibia. The organ is supported proximally by the nerves and distally by accessory cells that form a ligament attached most often to the cuticle of the leg. The structural unit of the organ is the scolopidium, each of which is composed of one or more bipolar sensory cell(s) and two accessory cells, the scolopale and the cap (attachment) cell. The hemolymph dampens the movement of freely suspended neuron side of the scolopale, while no such dampening occurs at the side anchored to the cuticle.

In Orthoptera, the subgenual organ is accompanied by other scolopal organs of which the crista acustica, supported by sound-transmitting structures, represents a very sensitive receptor for airborne sound. In the American cockroach, Periplaneta americana, the subgenual and the neighboring Nebenorgan (Fig. 3) are most sensitive to substrate vibrations. The distal organ, which surrounds the hemolymph, responds to variations in hemolymph pressure. Scolopidia of the subgenual organ are organized in a fan-shaped manner and converge radially toward a single insertion point so that vibrations of the substrate cause tension changes. The organ is most sensitive in the frequency range between 1000 and 5000 Hz, with threshold amplitudes around 0.1 nm. Scolopidia of the Nebenorgan are stretched perpendicular to the long axis of the tibia so that the organ reacts to tension changes within the scolopale caused by vibration of the cuticular walls.

Subgenual organs of different morphology have been described in different insect groups. In the southern green stinkbug, the subgenual organ is proximally attached to the epithelium of the tibial wall, whereas the two scolopidia with the cilia and the flat and thin ligament are stretched out in the hemolymph of the blood channel. The subgenual organ in the legs of the lacewing Chrysoperla carnea (Fig. 4) is composed of only three scolopidia. The cell bodies of the three cap cells form a lenslike part of the organ, the velum, which distally divides the blood channel into two separate parts. Scolopidia are attached to the middle of the velum and extend to the dorsal leg wall. The hollow cone-shaped bee subgenual organ with approximately 40 scolopidia is connected at two points to the cuticle and at two points to the membrane bag surrounding the organ and the membrane lining the tracheal wall. The organ oscillates with the hemolymph, and the sensory cells respond to displacements of the organ relative to the leg.

The complex tibial organ of bushcrickets is composed of the subgenual organ, intermediate organ and crista acustica. The latter and the distal part of the intermediate organ function as the most sensitive auditory organ only in forelegs; the same organs in mid- and hind legs respond to vibratory stimuli like in forelegs, but unspecifically to airborne sound. The functions of the middle and distal parts of crista acustica in mid- and hind legs have not been described.

Mechanoreceptors such as campaniform sensilla, joint chordotonal organs, and Johnston’s organ respond to substrate vibrations with lower sensitivity, preferentially in the frequency range below 100 Hz.
Compared with processing of auditory information, less data are available about morphology and function of higher order neurons responding to stimulation of vibrational receptors. In the stinkbug, *N. viridula*, two receptor neurons of the subgenual organ in each leg together with low-frequency receptor neurons of the joint chordotonal organs and campaniform sensilla give rise to more than 20 different interneurons at different levels of the ventral cord. Most of them are tuned to frequencies below 400 Hz, which is the characteristic frequency range of pentatomine vibratory signals. Some of these interneurons discriminate between signals coming from different directions by analyzing the time pattern of different legs’ stimulation. Similar morphology of several interneurons in Orthoptera groups with or without crista acoustica indicates that hearing developed in insects through the evolution of the sense of vibration. In Orthopteran families Acrididae and Tettigoniidae, the auditory and vibratory information received from the tympanic and vibrational receptor organs converges to the same interneurons which are classified according to relative sensitivity to each modality as predominantly sound, vibration or sound, and vibration neurons. Simultaneous processing of the auditory and vibratory information within bimodal interneurons in many circumstances optimizes signal resolution.

**VIBRATORY SIGNALS AND INSECT BEHAVIOR**

Insects emit vibratory signals in connection with aggression, distress, calling, courtship, rivalry, and many other behaviors. In dense vegetation wind, local air currents, distance and plant architecture prevent reliable communication with signals other than those transmitted through a plant. Social insects such as bees, ants, and termites live in nests where the possibility of communication by signals of other modalities (other than airborne chemicals) is limited. Insects, whose small body size does not allow efficient low-frequency sound radiation, can use vibrational communication without attracting predators or parasites as they would by singing. Many insects use the vibratory component of the emitted airborne signals to improve signal discrimination and recognition. Emission of vibratory signals can help herbivores to avoid predation. When a predator approaches, for example, treehopper nymphs, the nearest one produces a brief vibrational signal which triggers emission by others in the group as a chain reaction. This longer and louder group signal attracts the mother to move into the offspring aggregation to defend her young. Vibratory signals of Riodinidae butterfly larvae in concert with chemical signals attract mutualistic ants which provide protection from predators.

Vibrational communication through plants is disturbed by environmental factors such as wind and raindrops. For example, wind induces low-frequency vibrations that are accompanied in apple leaves with broadband vibrations of spectra up to 25 kHz. Raindrops falling on banana leaves produce vibrations up to 1000 Hz; those on apple leaves cause vibrations composed of an irregular high-frequency and a regular low-frequency phase. Signal-to-noise ratio is enhanced by the highly ordered temporal structure of songs with narrower spectra with
dominant frequencies, usually above the low-frequency noise level, as well as by band-pass filtering properties of the subgenual organ.

The time pattern of a vibration pulse series usually carries more information about signal specificity than its spectral structure. Generally, a rapid signal divergence occurs in sympatric taxa, and song similarity is expected only in allopatric or allochronic species. In Chrysoperla, tremulation songs represent the best cue for species identification within the carnea group. Within the same region, the songs of different cryptic species differ structurally and functionally more than in pairs of species from North America and Eurasia. The vibratory song repertoire of sympatric Californian species N. viridula and Aceroternum hilare differ, and interspecific mating has not been observed. In Japan, however, the sympatric species N. viridula and N. antennata mate although their songs differ.

Vibratory signals are used by insects also as cues for mate, prey, or enemy localization. In N. viridula, male directional movement on a plant results from female calling song signals. Leaf-cutting ant, Atta cephalotes, workers stridulate when they cut leaves, and nearby ants respond by orienting toward the source of the vibrations and join in the leaf cutting. The response of the heteropteran predator Podisus maculicentris to vibrational signals produced by a common prey species demonstrates that these predators are capable of using substrate-borne vibrations as cues for prey location. The male katydid, Conocephalus nigropleureutum, shakes its body to produce vibratory signals that attract females during courtship and mating.

Central nervous resolution of stimulation time differences and amplitude gradients, which occur when vibration travels through a substrate from one leg to another, is the mechanism that enables directionality in larger insects. For example, the response of the body of the treehopper Umbonia crassicornis relative to the substrate reveals resonance at lower frequencies and attenuation at higher frequencies. The transfer functions measured on the body differ substantially depending on whether the stimulus originates in front or behind, indicating that directional information is available in the mechanical response of the body to substrate vibration. Comparison of signal amplitudes between receptors of the front and back legs might enable vibration localization in smaller insects.

Vinegaroons

Justin O. Schmidt
Southwestern Biological Institute, Tucson

First human–vinegaroon encounters evoke a natural human response: “what a bizarre animal,” “is this thing real, or did someone cobble together various parts from nature?” “Is it from outer space?” No, vinegaroons are real, live, arthropods, and not extraterrestrial, albeit extremely ancient. They were around during the Carboniferous era, about 350 mya, and have remained little changed “living fossils” since then. Their origin long predated that of mammals, birds, reptiles, or modern amphibians or sharks. Vinegaroons are large, squat arachnids sporting massive pedipalp “pinchers” on the front and a tail, often longer than the body, sprouting from the other end. As if this were insufficient, vinegaroons also possess a pair of long sensory legs frequently appearing to probe randomly the environment around them. Vinegaroons are also called whipscorpions, or whiptail scorpions, monikers originating from their close phylogenetic relationship to scorpions plus their long flagellar tail that “whips” around when they are excited. Although accurate scientifically, these common names are unfortunate because they wrongly imply that these creatures can sting or are venomous. They do not have venom, cannot sting, and do not even pinch. Vinegaroons’ true fame lies in their ability to spray a potent allophone which renders memorable first agonistic human encounters with vinegaroons. The whole environment instantly becomes redolent with the smell of vinegar, a result of discharge of highly concentrated acetic acid, plus a few other acids, from the pygidial glands. This cocktail contains the highest concentration of acid found in any known chemical defensive secretion, having an acetic acid concentration about 15 times that of vinegar. Is it any wonder that these animals were called vinegaroons and have become subjects of folklore throughout many areas? The acid blend is contained in a pair of glands located in the posterior of the animal and can be discharged in a well-aimed spray leaving a mobile turret where the tail joins the body.

TAXONOMY AND BIOGEOGRAPHY

Vinegaroons comprise a small arachnid (spiders, scorpions and their kin) order, the Uropygi, containing around 115 species in 16 genera. They caught the attention of Linnaeus, but were first described as a separate order by Latreille in 1802. Mainly tropical in distribution with the majority of species in Indonesia and Southeast Asia to India, uropygids have a smaller species concentration in the New World, especially around northeastern South America. Not surprisingly because of
Vinegaroons

their antiquity that long preceded the breakup of Pangaea and their apparent resistance to extinction, vinegaroons are found on all continents except Australia. They are also found in some unexpected places including Fiji and the Solomon Islands. Most species live in moist habitats, though several, notably *Mastigoproctus giganteus*, the largest of the species, live in arid regions, albeit they are active only during the wet part of the summer season and days and times within the season.

**BIOLOGY AND LIFE HISTORY STRATEGIES**

Even experienced biologists rarely encounter vinegaroons in nature, something that leads to a general perception that these animals are rare. Vinegaroons are strictly nocturnal, with no hint of being crepuscular even to the extent of taking advantage of the last dying glimmers of light on the horizon. During 15 years and 1000+ hours in the field, I have only once observed a vinegaroon during the day—and that was just before sunset on a cloud-blanketed, rainy day. Additional factors rending vinegaroons effectively invisible are their dark, often dust covered, black color, their slow infrequent movement while active, their lack of attraction to visible or UV light, and their lack of UV fluorescence so conspicuous in their near relatives, the scorpions. When these factors are combined, is it any surprise that vinegaroons are absent in the everyday human experience?

For more than two centuries, the inapparentness of vinegarous handcapped our knowledge. Other than a few relatively recent brief descriptions of their courtship behavior and chemistry, almost nothing was known of their biology. Fundamental information addressing life span, number of eggs produced per female brood, hunting behavior and prey captured, and predators was lacking. We now know that for *M. giganteus*, the average life span from egg through completion of the adult cycle is 7 years with a potential limit of 11 years. The life cycle consists of egg, phoretic larva, four free-living larval instars, and adult. Unlike tarantulas, in which adult females continue to molt over their long adult life span, adult vinegaroons cannot molt again and both sexes generally live three summer seasons. In Arizona, each immature instar requires a minimum of one year of development before molting, with individuals having the ability to overwinter if necessary in the same instar to continue foraging a second year for sufficient prey to enable molting. This plasticity in instar length is an ideal adaptation for an animal living in an unpredictable arid environment sometimes experiencing a scarcity of available prey subsequent to little or no rainfall during the summer.

Most of their lives, *Mastigoproctus giganteus* reside in cells they excavate in the soil or under rocks. When the soil permits, adult cells are 30–50 cm below the surface, an environment with higher humidity and a moderate temperature during both summer and freezing winter. Vinegaroons are ambush predators, spending much of their active time in a sit-and-wait position or slowly walking and ready for any hapless small animal to come nearby. Despite their lethargic, sluggish appearance, they are acutely aware of their surrounding environment, something that becomes frustrating to humans standing several meters away and hoping to obtain a glimpse of their natural habitat. This awareness is primarily through detection of substrate vibration via an assortment of sensory sensilla, including long delicate trichobothrial hairs located at the distal end of the tibia of both sensory and walking legs. These fine trichobothrial detect even the most subtle of air movement caused by an insect moving nearby. Olfaction and detection of surface chemicals undoubtedly also play key roles in vinegaroon environmental monitoring, but detailed examination has not occurred. When an organism of suitable size comes within range, the vinegaroon springs into action with a lightning fast rush and grabs the prey. Captured animals are securely held with the pedipalps while knife-like and crushing chelicerae cut through the toughest of prey cuticle or integument. Prey include virtually anything within an acceptable size range. Common prey include scarab and other beetles, crickets and grasshoppers, spiders, scorpions, solifugids, and even the occasional ant. Small vertebrates including newly metamorphosed spadefoot toads are also taken. One might wonder how they overcome spiders, scorpions and solifugids. The key appears to be their surprise factor and the ability of the large pedipalps to hold potentially dangerous prey distant from nonarmored sensitive body areas. Prey chemical defenses, sequestered toxins, and stings have minimal deterrence value—for example, they eat *Calosoma* beetles, blister beetles, honey bees, and scorpions—although some extremely well defended species including stink beetles (*Eleodes* spp.) and giant velvet mites (*Dinothrombium* sp.) are rejected.

One might imagine that a large, juicy, slow vinegaroon might have numerous predators. The opposite is the case. Over years of experimentation in which *M. giganteus* has been challenged by numerous and varied vertebrate and invertebrate potential predators, no examples of successful predatory species that normally encounter adults or fourth instar immatures have emerged. A reason for this paucity of meaningful predation is rooted in the exceptional deterrence of the vinegary allomone discharged by threatened individuals. Rodents, lizards, toads, spiders, centipedes, large carabid beetles, and solifugids flee and rub affected body parts in the soil when struck with the chemical discharge. Even voracious and determined grasshopper mice (*Onychomys* spp.) are unlikely to be serious predators because when sprayed they flee and plow their mouths through the sand, giving the vinegaroon ample time to escape. Even if the mouse is strongly hunger driven and can relocate the vinegaroon after an encounter, the vinegaroon can discharge its defense 10 or so times, each time giving it an opportunity to escape once again (Fig. 1).

This a good point to digress slightly to address the commonly asked question “why does a vinegaroon have a long tail?” Defensive encounters provide the apparent answer. Vinegaroons are built much like an
army tank towing food wagon behind. The front cephalothorax (pro-
soma) of the vinegaroon is heavily sclerotized, armored, and nearly
impenetrable. The posterior opisthosoma, however, is soft, delicate,
and easily penetrated. Any predator which successfully attacks and
punctures the opisthosoma will inflict a mortal wound to the vinega-
roon. The mobile lashing tail gives an extra body-length margin of
safety around the vulnerable posterior by detecting intruders before
they can attack. Additionally, it provides an expendable decoy to be
attacked first. Because the defensive spray emanates from the tip of
the last three segments of the mobile turret at the end of the opisthosoma
near where the tail is attached, it can be deployed instantly in a pre-
cision blast when the tail is attacked. Solifugids exemplify the system.
Attacking solifugids easily outmaneuver vinegaroons, usually resulting
in a posterior attack involving the tail. They become beneficiaries of a
thorough spraying, immediately terminating the attack and usually pre-
venting future attacks. In such attacks, the tail is frequently injured or
lost, something that does not cause serious harm or prevent future use
of defensive spray. The tail is also regenerated upon molting. The decay
value of the tail is supported by the frequency of field observation of
animals’ missing part or all of their tails or sporting regenerated tails.

**Ecology**

In good habitats, vinegaroons appear to be the most important top
predators of arthropods. In a good year, in one ideal habitat of sandy-
loam soil in Southeast Arizona, USA, 1748 vinegaroons were located
by mark-recapture methods in a 2.56 ha plot. Their combined weight
was 5420 g. These figures translate into 68,300 vinegaroons per square
km for a weight of 212 kg/km². In this habitat during the summer, is
it any wonder that relatively few arthropods are observed on the soil
surface, yet insects are in abundance resting on vegetation and coming
to UV black lights? No other predator of medium and large arthropods
in a posterior attack of the female. They become benefi ciaries of a

**DEFENSIVE CHEMISTRY**

Vinegaroons were among the fi rst animals to help usher in the era of
chemical ecology. Acetic and octanoic acids were identifi ed by derivati-

dation, crystallization, and infrared spectroscopy in an elegant chemical
analysis. Nearly 40 years later, using newer microtechniques, the secret-
tions of individuals of the four larval instars and adult males and females
were reinvestigated in search of minor components and hints of subtle
biological roles for the secretion. Enriching the major components of
acetic and octanoic acid are trace amounts of hexanoic, heptanoic, cis-
and trans-5-octenoic, and decanoic acids, plus the ketone 2-nonanone.
The secretions of females, males, and all immatures are nearly identi-
cal, essentially excluding pheromonal roles (except perhaps aggregation
pheromone; and vinegaroons are entirely solitary animals at all times
 except mating and maternal care of young). All eight analyzed other
pheromone; and vinegaroons are entirely solitary animals at all times
of defensive spray. The tail is also regenerated upon molting. The decay
value of the tail is supported by the frequency of field observation of
animals’ missing part or all of their tails or sporting regenerated tails.

**COURTSHIP AND REPRODUCTIVE BEHAVIOR**

**Courtship**

The vinegaroon courtship ritual is remarkably complex. Courtship is
initiated by males during the summer-active season, although females
are far from placid in this process, with virgin females likely remain-
ing active on the soil surface more than mated females. Overall,
courtship lasts an average of 13 hours and goes through four phases.
Phase 1, “Chase and Grapple,” occurs when a roving male contacts
a female. The result sometimes appears to be a “fight to the death”
in which the male rushes the female, engages her with his mas-
sive pedipalps and the two wrestle, push, and shove, often lift-
ing one another off the ground. This is a testing period in which
the female is assessing the male for fitness (female choice). But
the male, too, is testing. A particularly lethargic, or old, female can
be rejected by a male. The Chase and Grapple phase lasts from
1 minute to several hours, sometimes ending when the female escapes
and terminates the courtship. If she is receptive, and the male is accep-
table, frequently she will “present” the tips of her sensory legs to the
male. She does this by rapidly quivering them in front near his cheli-
cerae. If he accepts her offer, he manipulates her sensory legs with his
pedipalps and transfers their tips to his chelicerae, marking the second
stage of courtship. The Chase and Grapple phase can be complete in
as little as 1 minute after initial contact. Many times the female is not
immediately receptive and grapples, sometimes vigorously, with the
male. In this situation, she holds her sensory legs far back and away
from the male’s reach. Meanwhile, the male attempts to reach over her
to grab her sensory legs, often near their base, with his pedipalps. If she
ultimately accepts him, she will cease resisting and allow the male to
hold her delicate sensory legs in his grasping jaws. She can signal rejec-
tion by executing tiny rapid fl icking of her sensory legs along with the
rest of her body, often resulting in termination of courtship (Fig. 2).

Phase 2 of courtship is called “Dancing.” In this phase, the male
is face-to-face with the female, and while still holding the female’s
sensory legs in his chelicerae, he manipulates them with his pedi-
palps and tows her forward and back. The female usually passively
follows the male’s lead. The purpose of this phase which lasts 2.9
hours (range 1.25–6.25) appears to be to provide further opportunity
for the male and female to evaluate each other, but it likely is also
a means for the pair to move to a secure place, such as the female’s
nest or a rodent burrow, to continue the courtship.

Phase 3 of courtship is energetically costly for the male and is the
most consistent in duration. This phase, called “Generation,” starts
when the male, still holding the female’s sensory legs in his chelicerae,
rotates from being face-to-face with the female to being in front and
on top of her with his opisthosoma elevated over her cephalothorax.
The receptive female then gently holds his opisthosoma at segments
6 and 7 with her pedipalps. After a brief period of adjusting posi-
tion slightly, the pair remains quiescent for 4.6 hours (range 3.5–6.0).
During this phase, the male is forming a sperm packet inside his
reproductive system. Near the end of the generation phase, he
touches his gonopore to the substrate and deposits the spermatophore
consisting of a stand holding two sperm packets. He next carefully and
slowly walks forward, pulling the female to the exact spot where her
gonopore is directly over his spermatophore. She then dips down and
grasps the two sperm packets of the spermatophore in her gonopore,
leaving the stand attached to the substrate. She now signals the male
by slowly opening her pedipalps. He then slowly rotates, all the while
still holding her sensory legs in his chelicerae, to face her again and
advances over her top, finally releasing her sensory legs as his cheli-
cerae pass over her anterior cephalothorax. Once the sensory legs are
released, he often makes a quick rush to wrap his pedipalps around
her opisthosoma. This release terminates the generation phase.

Phase 4 of courtship, “Pressing,” consists of the male above the
female with his pedipalps wrapped around her opisthosoma and pedi-
palp tips gently stroking the sperm packets for several hours (mean 4.8,
range 2.0–7.0 hours). Such stroking is presumed to facilitate move-
ment of the sperm from the packets into the female’s reproductive track.
Courtship is completed when the pair separates after an unknown
signal and goes their separate ways. Neither partner is injured during
courtship, and post-courship cannibalism never occurs.
Fecundity, Embryogenesis, and Maternal Care

At the end of the summer foraging, vinegaroons retire to overwintering cells which they seal from the surface with a soil barrier. They do not hibernate during this period of waiting until the next summer and remain alert and active if disturbed. In the spring about 2.5–3.0 months before the next summer, mated females generate an enormous clear nursery sac attached to their gonopore and fill it with large white round eggs. The number of eggs is \( \frac{52.5 \pm 8.3}{100} \) SD, range 35–68 (n = 20). Embryos develop inside the eggs within the nursery sac for about a month, then molt to white, plump phoretic larvae that leave the sac to climb onto the dorsal cephalothorax and sometimes opisthosoma of their mother. Here they attach permanently and continue developing for about another month. The phoretic larvae molt into first instar free-living larvae and crawl off their mother to distribute within the overwintering cell. At this stage, they look nearly identical to adults except their pedipalps, and appendages are pink and their sensory legs and tails are relatively longer compared to their bodies than in adults. They also have a full complement of vinegary allomone. Mother and babies remain in the cell until all young are completely sclerotized and hardened and the summer rains have arrived. The rather thin mother then digs to the surface and begins foraging. Her first instars remain in or near the maternal burrow. Although not documented in the field, mothers in the laboratory capture prey and share it with the young. This maternal care continues throughout much of the foraging season, at which time the young disperse and dig their own individual overwintering cells. Mothers do not eat their young barring exceptional hunger or situations, although they eat their own young the next year once they have molted to second instars. Mothers mate during their maternal care summer, overwinter again and can rear another set of young the next year.

fat body, its transport to the oocyte, its sequestration by receptor-mediated endocytosis, and the developmental and hormonal mechanisms that control these processes.

**VITELLOGENIN SECRETION BY THE FAT BODY**

Before vitellogenesis can begin, the female fat body must transform from a tissue that supports molting, metamorphosis, and intermolt metabolism to one that can secrete vitellogenin and other yolk precursors. When the fat body has reached a requisite stage of maturity and hormonal stimulation, vitellogenin genes are transcribed that encode a polypeptide chain whose molecular weight in many insects is over 200,000. During transport through the endoplasmic reticulum and Golgi bodies, this polypeptide is clipped by endoproteases that remove a secretory signal from its N-terminal end and divide it into shorter polypeptide subunits. The latter differ in number from one in some Hymenoptera to nine in some Hemimetabola. As it moves through the secretory pathway, the complex of subunits is conjugated at sequence-specific sites with high-mannose oligosaccharides, phosphate, and lipids.

Amino acid sequences determined for vitellogenins from at least seven orders of insects are sufficiently similar to indicate a common ancestry. They are members of a protein superfamily that also includes the yolk proteins of vertebrates and nematodes, lipid transport proteins in the blood of both vertebrates and insects, and receptor proteins involved in the endocytosis of lipoproteins.

The yolk proteins of cyclorrhaphan Diptera are exceptional in that their amino acid sequences resemble those of a family of digestive enzymes, the vertebrate lipases. They nevertheless behave like conventional vitellogenins in being synthesized and conjugated in the female fat body, and deposited in cytoplasmic vesicles by the oocyte after endocytosis. A notable difference from conventional vitellogenins is that the several yolk polypeptides in a species are encoded by separate genes, rather than being proteolytic fragments of one gene product.

Other fat body products may supplement vitellogenin in the yolk. The eggs of several Lepidoptera contain lipophorin, a hemolymph protein whose functions include the delivery of lipids from the fat body, and deposited in cytoplasmic vesicles by the oocyte after endocytosis. A notable difference from conventional vitellogenins is the fact that several yolk polypeptides in a species are encoded by separate genes, rather than being proteolytic fragments of one gene product.

**FIGURE 1** Reflected light micrograph of a vitellogenic ovariole from the saturniid moth *H. cecropia*. The largest 36 follicles are vitellogenic. The yellow mass in each follicle is a yolk-filled oocyte, whose opacity is due to light scattering by yolk particles. The yellow color is due to carotenoids carried by vitellogenin and lipophorin, the two most abundant yolk proteins in saturniids. Nurse cells form a transparent cap at one end of each follicle. The epithelium of follicle cells surrounding each oocyte and its nurse cells is too thin to be readily visible, except where it forms a connection between successive follicles. Scale: largest follicle is about 1.9 mm long.

**Vitelligenic Functions in Ovarian Follicles**

In the ovaries, the morphological unit of vitellogenesis is a follicle—a single oocyte surrounded by an epithelium of somatic cells (the follicle cells) and associated in many insects with a set of modified germ cells (the nurse cells) (Fig. 1). All three cell types are necessary for vitellogenesis, but they contribute to it in very different ways.

Follicles begin to form during or shortly after metamorphosis. They are produced in linear chains termed ovarioles. Within each ovariole is a developmental gradient of follicles (Fig. 1), with the most mature one lying close to the beginning of the oviduct. A common pattern among cyclic egg producers is for only one follicle at a time in each ovariole to form yolk. The penultimate follicle is retarded in its development until the next reproductive cycle. In noncyclic insects, many follicles in each ovariole may simultaneously form yolk (Fig. 1).

**Follicle Cells, Patency, and Secondary Yolk Proteins**

At the onset of vitellogenesis, the follicle cells develop a system of intercellular spaces that give proteins from the hemolymph access to the surface of the oocyte. In the bug *Rhodnius prolixus*, patency has been attributed to cellular protrusions whose cytoskeletal elongation pushes neighboring follicle cells apart. In the cecropia moth, *Hyalophora cecropia*, osmotic shrinkage of the follicle cells is crucial. Whichever mechanism applies, the intercellular spaces are under tight developmental control: they arise at the onset of vitellogenesis and close when it terminates.

In addition, the follicle cells of many insects secrete proteins that are endocytosed by the oocyte along with vitellogenin. These products may resemble vitellogenin in size, antigenicity, and amino acid sequence; examples occur in Thysanura, Heteroptera, and Coleoptera. A similar relationship holds for the yolk proteins of the cyclorrhaphan Diptera. In Lepidoptera, follicle cell products are instead lipase-like sequences reminiscent of the yolk proteins of the Cyclorrhapha. A few exceptions are known in which either fat body or follicle cells but not both secrete precursors for the protein yolk.

Finally, the follicle cells connect to the oocyte during vitellogenesis via gap junctions that permit direct cytoplasm-to-cytoplasm transfer of ion currents and small organic molecules. These junctions have the potential to function in intercellular exchange of signaling substances such as cyclic nucleotides and calcium ions.

**Nurse Cells and the Origin of Egg Cytoplasm**

In all holometabolous and a few hemimetabolous orders, the oocytes connect via cytoplasmic bridges to nurse cells (Fig. 1). The bridges are wide enough to permit passage of ribosomes and membranous organelles such as mitochondria. Once believed to be the site of yolk production, nurse cells are now known to be the primary source of egg cytoplasm. They support vitellogenesis by providing the oocyte with the ribosomes, transcripts, and metabolic machinery needed to synthesize the receptors, structural proteins, and enzymes necessary for yolk deposition. In Orthoptera, Blattodea, and other
Hemimetabola that lack nurse cells, the requisite transcripts are produced instead within the oocyte’s own nucleus by amplified nuclei and lampbrush chromosomes.

**Receptor-Mediated Endocytosis in the Oocyte**

The surface of the vitellogenic oocyte contains receptors that can selectively bind vitellogenin and other yolk precursors after they have penetrated the spaces between the follicle cells. The receptors form transmembrane associations with clathrin lattices on the cytoplasmic side of the membrane. The membranes containing these complexes then fold inward to form endocytotic vesicles (Fig. 2). In subsequent processing steps, vitellogenin dissociates from its receptors within the vesicles, and the clathrin is released from the lattices on the outside. The denuded vesicles transfer their cargo of yolk precursors to neighboring yolk bodies by membrane fusion. Receptors, clathrin lattices, and extra membrane are recycled to the oocyte surface for more rounds of endocytosis. In some insects, vitellogenin is later modified in the yolk to a less soluble storage form known as vitellin.

**CONTROL BY JUVENILE HORMONE AND ECDYSONE**

In many insects, juvenile hormone secreted by the corpora allata stimulates the fat body of adult females to initiate the synthesis of vitellogenin. It may also promote patency of the follicle cells, hence making vitellogenin in the hemolymph available to the oocyte for endocytosis. Juvenile hormone, whose power as an inhibitor of metamorphosis requires that its secretion be reduced during pupation and adult development, has thus evolved new kinds of role in adults: it has become an effector of the neuroendocrine networks that synchronize vitellogenesis with feeding, the photoperiod, and mating.

Variations occur on this theme. In species such as stick insects, and native and domestic species of silk moths that complete egg formation during adult development, juvenile hormone is not required for vitellogenesis. In its classical role as an inhibitor of metamorphosis, the hormone may even prevent the fat body and ovaries from completing their essential previtellogenic development.

Another kind of variation occurs among Diptera, whose yolk protein synthesis by fat body is triggered by ecdysone. Juvenile hormone may still be required, but here it promotes posteclosion development of the fat body to a stage capable of responding to ecdysone. In the yellow fever mosquito, the ovaries themselves were shown to secrete ecdysone in response to EDNH (egg development neurosecretory hormone), a brain hormone released from the corpora cardiaca following a blood meal.

Walking and Jumping

Roy E. Ritzmann

Sasha N. Zill  
Marshall University

The agility of insects certainly contributes to their reign as the most successful creatures in the animal kingdom. Few if any forms of terrain present an insurmountable barrier to all insects. By evolving variations on a basic body plan, they have achieved remarkable dexterity in a wide range of environmental niches. We find insects that walk slowly over floors, scurry under rocks, climb up walls and over ceilings, or jump over barriers. To understand how an insect can walk on a horizontal surface. But the aspects of walking in insects that are truly remarkable, and attract them to robotics engineers, are the abilities to run over and around obstacles, climb up walls, and jump over barriers. Often these adaptations occur through subtle changes in the basic pattern of locomotory behavior.

LEG MOVEMENTS

The walking movements of insects were accurately described in 1887 by Morgan, who in an era in which galloping of horses held the public attention wrote a letter to Nature entitled “The Beetle in Motion” that recounted the coordination seen in a tripod gait. In more detailed accounts in the mid-20th century, Hughes and Wilson noted that insects walk by moving their six legs in reproducible patterns. Each leg alternates between a stance phase, when the tarsus (foot) is on the ground and the animal is pushed forward, and a swing phase, when the tarsus is moved forward through the air. At slow speeds, the legs follow a metachronal pattern, moving from the hind legs to the middle and then to the front legs on either side. However, to move more rapidly, some legs must be moved at the same time; therefore, the insect shifts into a modification of the metachronal pattern called the tripod gait. Here the front and rear legs on one side of the animal move as a unit with the middle leg on the opposite side (Fig. 1A and 1B). This tripod alternates between swing and stance with the tripod made up of the remaining legs. The tripod gait is very stable, because at most speeds, the animal’s center of mass (CoM) remains within the base of support. However, at very high speeds, many insects make dynamic postural adjustments to stay upright. Remarkably, at exceptionally high speeds, the American cockroach *Periplaneta americana* has been seen to rise up on its hind legs and run with a bipedal gait. This gait is not statically stable (the cockroach would fall if it stopped), but represents a balance of forces that produces dynamic stability.

Each leg is made up of segments that are similar from leg to leg but differ in dimensions. From the most proximal to distal location, the leg segments are the coxa, trochanter, femur, and tibia, and a series of tarsal segments ending in a retractable claw (Fig. 1C). In the cockroach, the most important joints for walking are the coxa-trochanter (CTr) joint and the femur-tibia (FTi) joint. The CTr joint actually moves the femur relative to the coxa because the trochanter-femur (TrF) joint makes only small movements. Although flexion of the TrF joint can effectively rotate the tarsus, during many movements it acts mechanically as a fused joint. In other insects, relative proportions of these leg segments are changed to match the needs of specialized forms of locomotion. Thus, the hind leg of a locust has a very short coxa and a long muscular femur, making a powerful jumping leg.

Although the legs within a tripod move their feet as a unit, the joint movements and resulting forces are unique for each pair of legs. In cockroaches, the hind legs are specialized to propel the animal forward in walking. To accomplish this, the CTr joint and the FTi joint move in near synchrony (Fig. 1A). This action allows these rotary joints to direct the movements of the tarsi (feet) in a line nearly parallel to the long axis of the animal’s body. The middle legs make similar movements, but with smaller joint (CTr) excursions. The orientation of this leg causes it to first brake and then accelerate forward movements of the animal.

The front legs make very different movements. Unlike the other two pairs of legs, the front legs make much greater use of the thorax-coxa (ThC) joint, which attaches the leg to the thorax. This joint has three degrees of freedom, similar to the ball-and-socket joint in a human shoulder. Movement of the ThC joint swings the front legs far forward much like an extending human arm. The CTr and FTi
joints then move out of phase with each other as the foot is drawn back toward the body and then is pushed backward. The resulting ground reaction forces slow the forward movement of the body and keep the animal from losing control. Clearly, the neural control of this leg is much different from the control of the other two pairs of legs. Nevertheless, the sum of the ground reaction forces of all three pairs of legs is similar to that seen in the bipedal leg movements of a human.

Cockroaches can run extremely rapidly (up to 25 steps per second), ranking them as the fastest terrestrial animal (in steps per second). Running, which follows wind stimulation of the cerci (abdominal appendages) or tactile stimulation of antennae or body cuticle, is used to escape from predators. Although fast running shows a number of similarities to walking, it occurs so rapidly that it may actually be a separate behavior. Passive elastic structures in the legs can play an important role in generating such rapid locomotion, prompting cockroach running to be modeled as a mass on a spring.

**MOTOR CONTROL OF LEG MUSCLE**

The muscular anatomy of insect legs follows a proximal-to-distal arrangement that makes very good biomechanical sense. The largest and most powerful muscles are proximal or closer to the body. The muscles are smaller in more distal segments of the leg. With the most powerful muscles placed near the body, inertial effects in the distal part of the limb are reduced, allowing for more controlled movement. Also, the movements of the proximal joints act on the tarsus or foot through the relatively large lever arm of the intervening leg segments to the tarsus or foot. Thus, for example, relatively small movements at the ThC joint can greatly alter the orientation of the tarsal end point.

The most distal segment, the tarsus, is actually made up of a series of segments ending in a retractable claw that have again remarkable mobility. However, as with human fingers, the muscle for these segments is found in more proximal segments and imparts its movements via a long apodeme that serves the role of a tendon. Indeed, although the claw can be engaged by this muscle, there is no antagonistic muscle. Rather, the claw is disengaged and lifted from the substrate by a remarkably efficient elastic protein (resilin) found in the joints of the tarsal segments. The resilin acting like a spring on a screen door, is stretched when the claw is engaged, and causes the tarsus to be lifted automatically when the muscle is relaxed.

**NEUROMUSCULAR SYSTEM**

The neuromuscular arrangement of insects provides distinct advantages for motor analysis. Unlike vertebrate systems in which muscle cells fire action potentials, in insects most muscle fibers produce graded potentials when motor neurons fire action potentials. Variation in tension in a vertebrate muscle requires recruitment of more or fewer motor neurons. However, in arthropods, simply altering the frequency of action potentials in a single motor neuron can control tension. Furthermore, insect muscles are innervated by very few motor neurons. Often, especially in stance phase muscles (the muscles that extend the leg while the tarsus contacts the ground), there are only two motor neurons serving a range of muscles. These can be readily distinguished as either fast or slow motor neurons depending on the types of muscle contraction they produce. Slow motor neurons need a series of action potentials to generate significant movement, whereas fast motor neurons generate a reasonable twitch with a single action potential. Typically, extracellular recordings indicate that fast motor neurons generate...
larger action potentials. This neuromuscular arrangement allows one to use electromyogram (EMG) electrodes to record muscle activity extracellularly and often to know exactly which motor neuron is observed.

The leg movements that occur during walking on a horizontal surface are associated with typical patterns of motor activity. In both the middle and hind legs of cockroaches, CTr extension is generated by a burst of activity in the slow depressor motor neuron (Ds). At faster speeds, one or more muscle potentials from the fast depressor motor neuron (DF) occur at specific times in the leg cycle. These actions generate the stance phase of the leg cycle and alternate with activity from several flexor motor neurons that produce the swing phase. The simultaneous extension at the FTi joint is generated by the slow extensor of the tibia (SETi) motor neuron and the fast extensor of the tibia (FETi), and is again opposed by activity in several flexor motor neurons that generate the swing phase of that joint. As expected, the motor patterns of the front legs are more complicated, matching the joint movements described earlier.

The cockroach controls the speed of walking by altering the frequency of motor action potentials. Motor frequency is positively correlated with stepping frequency and joint velocity. Thus, the animal can move faster by increasing the frequency of Ds and SETi in each leg. It can turn by increasing frequency in one or more legs of the tripod while decreasing the frequency in the leg or legs located on the opposite side. This change creates stronger forces on the outer leg of the turn and weaker lateral forces on the inner leg, thereby turning the animal.

**PATTERN GENERATION**

Although both stance and swing phase motor neurons increase burst duration with increasing walking speed, the change in stance phase motor activity is much greater. This observation led to a model for insect walking referred to as the flexor burst generator. In this model, a set of interneurons within the central nervous system called a central pattern generator controls the flexor motor neurons directly and the stance phase motor neurons indirectly through inhibition from swing phase interneurons.

Investigators have recorded traces from oscillatory neurons in cockroaches and stick insects that could be part of such a central pattern generation circuit. For example, in the cockroach, neurons have been found that undergo membrane potential oscillations in time with levator activity. Moreover, stimulation of these cells activates the flexor motor neurons. Thus, these cells could be part of the flexor burst pattern generator. However, they by no means represent the entire circuit.

Observations in stick insects strongly suggest that there are separate burst generators that activate motor neurons for each joint in the leg. Patterned activity can be recorded in motor neurons for each joint of a single leg even after removing all sensory inputs. However, the timing of oscillations is not correlated between joints. Hence, the notion of separate controls. How then are these separate oscillators coordinated during walking, when, as noted above, CTr and FTi joints often move in perfect harmony? To answer this question, we must first understand something about the contribution of leg sensors to walking patterns.

**LEG SENSORS**

Even where central pattern generation circuits contribute to the control of locomotion, sensory systems still play important roles in generating behaviorally meaningful motor activity. This concept was particularly well demonstrated in the locust flight system. Locust preparations that have been isolated from sensory structures in the periphery (deafferented) are capable of generating bursts of activity that could move the wings in an appropriate manner. However, the frequency of the “wingbeat” cycle is much lower than normal and the pattern quickly dies out, whereas in the intact animal, flight can go on for very long periods of time. If appropriately timed activity from wing stretch receptors is added in, a more normal flight pattern occurs that is maintained for long periods of time. Thus, the central circuits are capable of generating part of the cyclical pattern but not a complete, behaviorally relevant one.

Similarly, normal walking behaviors in all insects that have been studied require input from sensory structures on the legs. However, in rapid running movements associated with escape, feedback from sensory inputs probably is too slow to influence walking within a single step, and the animal may be running “on autopilot.”

The sensors that play an important role in walking provide precise bits of feedback information to the walking system through structures that are most often found in the same locations in all three pairs of legs (Fig. 2). Internal sensors such as the chordotonal organs span the joints and monitor joint angle. Hair plates (HP) are positioned near joints where adjacent segments will touch during maximal flexion. Campaniform sensilla (CS) are located in strategic locations near joints and muscle insertions and detect strain in

![FIGURE 2](image-url)
the cuticle. These structures are made up of sensory nerve endings positioned in sockets with a flexible dome. As strain increases in the surrounding cuticle, the dome is deformed and activates the sensory neuron. There are groups of campaniform sensilla near each of the leg joints, including the segments of the tarsus.

Each peripheral sensor provides information that is used at discrete phases of the step cycle as the insect walks. Some sensory inputs in walking are essential in making transitions between the stance and swing phases while others adapt muscle activities to reach levels needed for support and propulsion. The effects of leg sense organs are demonstrated particularly well in a computer simulation that was developed by Ekeberg, Bümel, and Büschges for stick insect walking. The simulation is controlled by calculations similar to those done by the nervous system. Signals from chordotonal organs that monitor joint angles are used to determine the times of transition from swing to stance, when the leg is first placed on the ground. Inputs from campaniform sensilla that detect load aid in generating extensor muscle activities in a self-regenerating loop known as positive feedback. Extensor activities continue until chordotonal inputs trigger the start of swing.

Beyond helping to set the normal locomotor pattern, these sensors are, of course, readily available to make rapid adjustments to the motor pattern as the animal moves away from horizontal surfaces and climbs inclines or vertical surfaces, or even walks on ceilings and negotiates obstacles in its path. Recent experiments have shown that the tibial campaniform sensilla can aid in this process by detecting the proportion of body weight that is supported by a leg. In these studies, load was varied by using magnets attached to the body and an electrical coil under the floor on which the insect stood. Some campaniform sensilla discharged when the load was increased while others fired when the body load was decreased. Those signals could be important in detecting when a leg slips.

Arrays of neurons with diverse properties receive sensory inputs and could mediate appropriate effects. Within each thoracic ganglion, the sensory neurons from these leg sensors project to populations of spiking local interneurons (interneurons that are isolated to a single ganglion). The projections of many receptors follow a topographic pattern that reflects the location of the sensors in the leg. The spiking interneurons project both to motor neurons and to another set of local interneurons called nonspiking interneurons. These interneurons never generate action potentials. Rather, they act through graded potentials to control and coordinate motor activity to various leg muscles within a thoracic segment. Coordination among joints of each leg (intraleg coordination) occurs through interactions in these local circuits.

Finally, spiking interganglionic interneurons project between thoracic ganglia, influencing local circuits for adjacent legs. Through these circuits, the sensory activity directs appropriate adjustments in individual muscles, coordinates segments within a single leg, and influences the coordination between legs.

The notion of feedback circuits influencing timing of leg movements suggests a solution to coupling of joint pattern generators alluded to earlier. Leg sensors influence timing of extension both in the motor neurons that control the joint that is monitored and in motor neurons serving adjacent joints. These weaker connections provide coupling for the joint pattern generators. Moreover, that coupling can be altered to provide for considerable flexibility. In this way, the joint pattern generators that produce walking could also be used in other rhythmic behaviors, such as righting (when an animal falls over and uses its legs to regain an upright posture), turning, or grooming, by changing the coupling between the oscillators. Indeed, in the cockroach, reflex effects in adjacent leg joints can be reversed by altering signals descending from the brain.

In stick insects, the influences of some sense organs are changed when the direction of walking is reversed. Stick insects readily walk forward or backward, as is needed when negotiating branches of trees. However, backward walking involves changing the activities of leg muscles. For example, protractor muscles are active in swing in forward walking but fire during stance when the animal walks backward. The effects of load-detecting sense organs on motor activities also change when the animal reverses direction. Trochanteral sensilla that excite the retractor in forward walking instead activate the retractor when the animal walks backward. The nervous system, therefore, changes the effects of the sense organs so that they counter the perturbation in the direction in which the animal is walking.

**INTERLEG COORDINATION**

To generate an effective tripod gait, insects must coordinate movements of joints not only within a single leg but also between legs. This interleg coordination on the surface appears to be a daunting task. The tarsi of the three legs that make up an effective tripod must move in synchrony. However, as described earlier, the legs of each segment make different movements. The patterns of the motor neurons that control those movements also differ in each leg. Thus, the animal must coordinate the tarsi through joint movements and neural activities that are specific to each pair of legs.

Observations on stick insects suggest that these potentially complex connections can be functionally formulated as a set of fairly straightforward rules indicating that events in one leg that are readily detected by leg sensors influence the actions of other legs in discrete ways. For example, one rule is that when one leg is in swing, the adjacent anterior leg cannot enter into swing phase. Alternatively, the start of the stance phase promotes the start of swing in adjacent anterior legs and in the contralateral leg of the same segment. More subtle influences also exist to account for transient changes. For example, an increased load on one leg prolongs the power stroke on the contralateral leg of the same segment. This would result in coactivation of legs when the animal is encountering increased resistance, such as during climbing. The specific neural connections that underlie these rules are the focus of an exciting new area of research.

**NEGOTIATING OBSTACLES**

The remarkable agility that attracts interest from roboticists is seen when insects face an obstacle. Most insects effortlessly negotiate barriers that would pose considerable control problems in robots. This problem is only now beginning to be investigated, because climbing over obstacles is a more transient event than horizontal walking, and there is considerable variability in the strategies used. However, some common themes are evident. In climbing over a block, for example, insects must move their CoM upward to surmount the obstacle. For cockroaches, the strategies used to accomplish this task vary with the size of the obstacle and the speed that the insect is moving at when the block is encountered. The front legs are normally lifted up fairly high during normal walking. If the block that is encountered is lower than the normal front leg trajectory, the insect hardly needs to change its movement at all. The front leg will be placed on top of the obstacle and pushed down to move the animal’s CoM upward as a natural consequence of the encounter with the block. Somewhat larger
barriers can be negotiated in this way when the insect is moving at faster speeds.

Larger blocks, especially at slower speeds, require a redirection of leg movements that now push the body upward upon joint extension. This rearing movement allows the front legs to be readily placed on top of the block so that climbing can commence.

These redirected leg movements often require intervention from descending activity originating in the brain. Lesion of a region of the brain called the central complex (CC) compromises the cockroach’s ability to negotiate barriers. Although little is known regarding how the CC generates appropriate descending commands, neurons in this region receive sensory inputs from a variety of structures including mechanoreceptors on the antennae and visual systems.

For very large obstacles, the insect must actually climb up the front face of the object. Here the insect must attach itself as if the face of the block were a wall. This problem is solved by a combination of claws and pads that adhere to various substrates. Cockroach claws are normally held up during horizontal walking, like the claws of a cat. However, when a cockroach is walking up a vertical surface, the claw is pulled down by a muscle in the tibia, which attaches to the base of the block so that climbing can commence.

This rearing movement allows the front legs to be readily placed on top of the block so that climbing can commence. The isometric force has been achieved. The isometric force is used to generate the jumping movement. Orthopterans such as grasshoppers and locusts have very large hind legs that can generate powerful jumping movements. However, even the large femur extensor muscles of these jumping legs cannot generate the quick extension necessary for an efficient jump without some mechanical modification within the leg structure for storing energy. In locusts, the tendon of the tibia releases locking mechanisms and produces a very rapid and powerful extension that propels the animal upward. The timing of these events is critical, and neural circuits have been identified in association with kicking movements that provide the appropriate control.

Fleas generate remarkable jumps relative to their tiny size. Again, a proportionally very large hind leg is used to generate the jumping movement, with a hook on the hind leg preventing movement until a large isometric force has been achieved. The isometric force is stored in strategically located resilin ligaments and released during the jump.

One of the most remarkable jumping strategies in insects does not even involve legs. Click beetles can jump from a standstill to four times their body length by rapidly accelerating the joint between the prothoracic and mesothoracic segments of the body. Here again a mechanical stop prevents movement until a large isometric force has been achieved, this time in thoracic muscles, and then is released suddenly to shoot the animal upward.

**ROBOTIC DEVICES INSPIRED BY INSECT WALKING**

The efficiency and agility of walking insects as well as specialized strategies such as jumping have not been lost on robotics engineers. Insects have provided popular models for legged robots because the hexapod gait is statically stable. That is, the CoM remains within the base of support of at least one tripod at all times. Thus, the control for a robot need not actively maintain balance during horizontal walking. However, to capture the agility of the insects, postural adjustments, reflexes, efficient leg design, and sensors must be incorporated into the robotic designs. This realization has generated collaborations between engineers and biologists to study insects and then incorporate newly discovered control and mechanical properties into more efficient robots. The efforts to develop and control these new robots in turn provide new insights into how the insect controls its own movements.

**Further Reading**

Few entomological words evoke more vivid imagery and response than “wasp.” Wasps live on all continents inhabited by people, and nearly everyone is familiar with their colorful presence and habits. The root of their name is the word “webh” (Low German)—to weave, a reference to the nests constructed by these insects. In entomological literature, “wasp” is often applied to all members of the Apocrita suborder of Hymenoptera except ants and bees. However, in popular usage a wasp is any social species in the family Vespidae, especially in the genera *Vespula*, *Dolichovespula*, and *Vespa*, which are often viewed as affronteries to life, plus a few conspicuous solitary hunting wasps. In this article, emphasis is accorded popular usage.

**TAXONOMY**

Broadly speaking, wasps encompass a prodigious number of parasitic species in the Ichneumonidae, Braconidae, Chalcidoidea, and many other families, plus solitary or hunting wasps, exemplified by the sphecids wasps (Sphecidae), spider wasps (Pompilidae), potter wasps (Vespidae: Enumeninae), scoliid wasps (Scoliidae), velvet ants (Mutillidae), and a myriad of others. In terms of sheer numbers of species, these groups far outnumber those of the social wasps. In terms of success, however, social wasps have earned due respect as major influences and elements of most ecosystems.

Social wasps originated more than 65 mybp in the Late Cretaceous, with a variety of more recent specimens entrapped and preserved in amber formed during the Tertiary (Fig. 1). The total number of living species of social wasps in the world surpasses 900 divided into three subfamilies: the Stenogastrinae, or hover wasps; the Polistinae, or paper wasps; and the Vespinae, or wasps, hornets, and yellowjackets (Fig. 2). Stenogastrines live in the South Indo-Pacific region, and comprise over 50 species of long slender adults in seven genera; their small, cryptic nests often are attached to roots or twigs under overhangs of banks or cave entrances. They provide their larvae with insects, often snatched from the webs of spiders, hence, the term “hover wasp.” The Polistinae have explosively radiated and are the most speciose of the three groups of social wasps. Their numbers exceed 800 species in 26 genera and they have a cosmopolitan distribution except for the colder regions of Eurasia and North and South America. The Vespinae contains over 60 species in four genera. *Vespa*, the true hornets, inhabit temperate and tropical Eurasia and northern Africa, number about 23 species, are the largest of the wasps, and are the world’s largest stinging insects. *Vespula*, called yellowjackets or the true wasps, are a Northern Hemisphere genus of approximately 22 species that are present from the Arctic to the northwestern fringe of Africa, to India, and into Central America. The 15 species of *Dolichovespula*, sometimes called aerial yellowjackets because many species construct round paper nests above ground, occupy a range similar to *Vespula* but are absent in extreme Southeastern Asia and Central America plus most of Mexico. The smallest genus of vespsines, *Provespa*, consists of three pale nocturnal species limited to forested areas in tropical Southeast Asia.
BIOLOGY AND LIFE HISTORY STRATEGIES

Social wasps are hunters and scavengers that prey on a variety of arthropod and animal protein sources. They are well equipped for this role, possessing large, powerful cutting mandibles for capturing, subduing, and processing prey, large eyes for detecting potential prey, and the ability to fly and hover in pursuit of food. Although well known for their stinging ability, wasps do not capture or subdue prey with the sting. Their venom is used entirely for defense, primarily against vertebrate potential predators. Indeed, all investigated wasp venoms are toxic, painful, and effective against vertebrates, but are rather weakly active and slow in affecting insects unless the sting is delivered near a ganglionic center of the nervous system. Moreover, wasps have little need to sting prey because they are equipped with powerful mandibles that are used to chew wood fibers from dead trees and can cut through tough insect nets in a matter of minutes.

Prey of wasps is varied. Paper wasps (Polistes) are specialists on caterpillars, which they locate by visually and olfactorily searching vegetation likely to harbor them. Once located, the prey is quickly subdued, cut into manageable pieces that are chewed into a “meatball,” and carried back to the nest to be fed to the larvae. Yellowjackets and hornets tend to have a broader diet than paper wasps and will capture a variety of arthropod prey including flies, spiders, caterpillars, and an assortment of other groups. House flies (Musca domestica) and other flies comprise major prey items of some species. Some species also scavenge for prey, removing insects captured in spider webs, carving flesh from dead animals such as rodents, and even removing insects freshly smashed on radiators and grilles of cars. The scavenging habits of some species have earned them the distinction of being considered to be pests at picnics, outdoor events, and around garbage cans.

Prey of the swarm-founding epiponine wasps in the subfamily Polistinae are less well characterized than prey of other wasps. Like other wasps, the epiponines often remove wings, legs, and the head of prey and chew it into a pulp before returning to the nest. Epiponines take a variety of prey, including flies, caterpillars, leafhoppers, and other insects, and many species are likely to specialize on certain taxa, or to prefer particular parts of the habitat, such as open areas, forest canopies, or thick vegetation. Some species in the genus Agelaia are well known for removing pieces of flesh from large dead animals and have been given the common name of “vulture wasps.”

Adult wasps usually obtain energy for flight and general metabolism from sugar sources. Nectar from flowers, honeydew from aphids and other homopterous insects, and sweet fluids from fruit all can be food sources. In most species, these sugars are supplemented by the sugary trophallactic secretions produced by larvae in response to solicitation by adults.

All wasps construct multicell nests from plant fibers (Fig. 3). The most common materials for making nests are wood fibers scraped from the weathered dead wood of trees or twigs, but other materials including rotten wood and fibers from living plant leaves and stems are sometimes used. In most cases, these fibers are strengthened with salivary secretions during preparation and application to the nest. After application of the fibers, abdominal secretions may be added to further strengthen the material and help repel ants.

Wasp life cycles consist of colony initiation, growth and expansion, production of reproductives, reproductive dispersal, and colony

WASPS AND PEOPLE

Nuisance

The general public does not appreciate the enormous beneficial role wasps play in controlling the populations of flies, caterpillars, and other often unwanted insects. It could be argued that even wasp scavenging on dead animals might provide competition for flies. These beneficial aspects of wasps are overshadowed by the view that they are nuisances, pests, and threats. Only a few species of Vespula, particularly V. germanica and V. vulgaris wherever they are present, and additionally V. maculifrons, V. squamosa, and V. pensylvanica in North America, and V. flaviceps in Asia, are attracted to human food and activities. In the fall, these species readily forage around outdoor dining areas, areas where food is processed or openly available, or where garbage is present. Some Vespula species will also attack and damage ripe fruit. During all their activities, the bright yellow-or white-on-black color patterns make wasps conspicuous, as does their buzzing and foraging action. At least in many western cultures, an innate swatting or flapping reflex is exhibited by people when they detect a buzzing insect, irrespective of whether the insect is a fly or a wasp. The origin of this reaction is uncertain: Is it fear of wasp stings, dislike of flies, or a general dislike of any insect that approaches one’s body? In any event, wasps, by their very nature, are perhaps the insect world’s masters at stimulating human aversive swatting, in the process gaining the questionably enviable reputation for being an irritating nuisance.

Wasp nests themselves are often viewed as an encroachment on human space and aesthetics. Were it not for the habit of many species of Polistes to build their exposed comb nests under eaves or inside man-made structures, their presence would rarely be noticed. These nests with their exposed adult wasps, especially when near entrances to buildings, tend to generate fear and dislike on the part of the humans passing through the area. This often results in an unfortunate consequence for the wasps—the destruction of their nests and sometimes the adults. Aerial yellowjackets, especially Dolichovespula arenaria and D. maculata in North America and D. media and D. saxonica in Europe, build large conspicuous gray, nearly spherical nests attached under eaves or to the sides of buildings. Their large size and busy activities tend to elicit an even less favorable human reaction than for Polistes.

The mere existence of wasps is seen as a nuisance by much of the human populace. As long as neither the wasps nor their nests are apparent, they do not come into conflict with people. However, should a hidden Polistes nest in vegetation, or a Vespula, Dolichovespula, or Vespula nest in the ground, a tree, or within a building be discovered, the nest is either avoided or destroyed. Such discoveries are usually beneficial neither to the wasps nor to the people involved.

Tramp and Pest Status

Tramp species are those species that tend to be able to disperse via the intentional or inadvertent help of humans to areas where they are not native, and to establish large successful populations in the new areas. Numerous examples can be found among the cockroaches, flies, rodents, domestic animals, and others. Among the wasps, only a relatively few species are successful tramps—most notably, the German yellowjacket (Vespula germanica), the common wasp (Vespula vulgaris), the western yellowjacket (Vespula pensylvanica), and the European paper wasp Polistes dominulus. Vespula crabro, a European hornet, has also been introduced into eastern North America, but it seems to be neither particularly abundant nor a pest in its new location. The others, once released from many of the controlling constraints placed on their populations by predators, competitors, parasites, pathogens, and diseases, tended to expand their populations to enormous numbers and become pests.

The German yellowjacket is classic in this regard: it is successfully established in North America, New Zealand, Australia, South Africa, and several other locations. In New Zealand, where no other social
wasps previously existed, it expanded its niche and population to such densities that it constitutes a major pest and threat to much of the native fauna of the country. In addition to its dense populations, V. germanica evolved secondary polygyny in which some colonies do not disintegrate at the end of the season, but instead many mated queens establish in the nest and the brood rearing cycle resumes—although this time the colony can become huge, with many tens of thousands of individuals. In North America, V. germanica rapidly expanded its population and range to include most of the northern part of the United States and the populated areas of California. Its success at the apparent expense of some native species of Vespolla is likely a result of its aggressive foraging behavior and its affinity for nesting in human structures. The walls of buildings provide many benefits for the wasps: warmth during the late fall and early winter, shelter from moisture and many predators, and proximity to garbage and other food sources. This proximity to people and their food allows colonies to remain active longer during the year, to grow larger, and to produce more reproductives. It also brings them into direct conflict with people and makes them a major pest in some areas.

P. dominulus, unlike V. germanica, is not particularly defensive to people near its nest and tends to be less threatening in appearance. In recent years, it successfully expanded its range in North America to most of the United States including the Midwest, where it can be present in enormous numbers. Also, its tendency to be less choosy in nest site locations causes annoyance beyond what was traditionally elicited by a Polistes species.

Stings, Venom, and Medical Risks

At the sight or the mention of a wasp, simultaneous thoughts enter the minds of many people—dislike and sting. The immediate human association of wasp with “sting” demonstrates the success of the wasp sting as a defense against large predators. Wasp stings hurt; and wasp stings provide reinforcement to the pain in the form of local swelling, redness, itching, and tenderness. Social wasps, like many other social insects, live in immobile colonies with many edible and nutritious young, offering an incentive for large predators to attempt to overpower the wasps and consume the brood. The sting with its associated venom is a nearly perfect defensive system to counter attacks by large predators: the sting can penetrate the tough skin of the predator, and the venom is then delivered into richly innervated living tissue, where it causes immediate pain and tissue damage. The consequence of wasps possessing their venomous sting is that few vertebrate predators can successfully attack wasp nests: the exceptions are a few specialists that have secondarily evolved means to exploit wasps and their nests. The effectiveness of wasp stings is not lost on people and forms much of the basis for human aversion to wasps. Until recently, this worked to the benefit of wasps, but now with modern protective clothing, equipment, insecticides, and other means to attack wasps, the defense is less effective against people. Nevertheless, general human fear and dislike of wasps continue undiminished.

Wasps can pose a minor medical risk to people hypersensitive to their stings. Overall estimates of the incidence of allergic reactions to insect stings range from about 0.5 to 2% of the population, with slightly over half of these being sensitive to wasp stings (the rest are primarily sensitive to honey bee and fire ant stings). Of this wasp-sensitive population of approximately 2 million in the United States, about 20 actually die each year. The remaining 99.999% of the hypersensitive population suffer at most generalized reactions involving the skin or the respiratory or cardiovascular systems. For people who suffer severe allergic reactions, particularly those in which breathing becomes difficult, or fainting or other signs of blood pressure drop occur, preventative approaches in the form of personal epinephrine injectors or immunotherapy are available. For the rest of the populace, wasps present little risk beyond the affront they cause with their stinging.

Water and Ion Balance, Hormonal Control of

 Thomas M. Clark
Indiana University, South Bend

Insects are found in habitats ranging from the driest deserts to aquatic habitats of diverse ionic composition. In many species, the environment changes dramatically during metamorphosis. Their survival depends on the ability to keep their tissues and cells moist, and to regulate the composition of their body fluids. Body fluid composition is challenged whenever exchanges of materials with the environment take place, and such exchanges are unavoidable. Routes of gain include ingestion, osmosis, active uptake, and diffusion. During feeding or drinking, an insect may ingest material that is significantly different in composition from the body fluids. Materials are lost through the excretory system and in the feces, as well as by osmotic, evaporative, or diffusive losses across the body surface. Insects respond to perturbations in body water composition by using a combination of hormonal and autonomous mechanisms to vary the amount and composition of fluid excreted by the excretory system.

STRUCTURE AND FUNCTION OF THE EXCRETORY SYSTEM

The excretory system consists of the Malpighian tubules and the hindgut (Fig. 1). The Malpighian tubules form the primary urine by active secretion of ions into the lumen. Water follows passively
Hormonal Regulation of Malpighian Tubule Transport

Both diuretic and antidiuretic responses of Malpighian tubules to hormones have been reported. Endocrine factors involved in the regulation of Malpighian tubule function include several distinct structurally related groups of peptides, and the biogenic amine serotonin (5-hydroxytryptamine). Diuretic peptides identified to date include corticotropin-releasing factor (CRF)-related peptides, calcitonin-like peptides, kinins, tachykinins, and type \( \beta \_ 2 \) cardioacceleratory peptides (CAP\(_{2\theta} \)). Kinins are small (6- to 15-amino-acid) peptides with a C-terminal amide. Those identified to date have similar C-terminal sequences of Phe-Xxx-Yyy-Trp-Gly-amide, where Xxx can be Asn, Ser, His, Phe, or Tyr and Yyy can be Pro, Ser, or Ala. The kinins have been isolated from several insect species but have not been detected in other animals. A single species may contain several kinins. The CRF-related diuretic peptides range from 30 to 46 amino acids in length and show structural homology to a family of peptides found in vertebrates that includes CRF (hence the name), sauvagine, and urotensin. Available evidence suggests that a single species produces more than one CRF-related diuretic peptide. Serotonin stimulates Malpighian tubule secretion in a number of insect species and is known to hormonally regulate excretory function in the bloodsucking bug Rhodnius prolixus and in larval mosquitoes (Aedes aegypti) (see below).

Short-term hormonal adjustments in Malpighian tubule transport rates in response to immediate challenges may be superimposed upon longer term increases or decreases in basal and maximal transport capacities. These long-term responses may be mediated at least in part by prostaglandins.

Hormonal Regulation of Hindgut Transport

Hormones acting on the hindgut appear to stimulate recovery of fluid and ions from the primary urine, leading to cycling of materials through the excretory system and hemolymph, and clearance of wastes. The majority of our information about regulation of hindgut transport comes from studies on the locust. The locust hindgut consists of two distinct regions, a more anterior ileum and a more posterior rectum. Two peptide factors isolated from the corpus cardiacum are ion transport peptide (ITP), acting on the ileum, and chloride transport stimulating hormone (CSTH), acting on the rectum. The amino acid sequence of these peptides has been determined. Other factors that stimulate water reabsorption by the hindgut include neuroparsins A and B. In addition, a number of factors modulate contractions by the hindgut musculature.

Hormonal Regulation of Midgut Transport

Exchanges of materials between the midgut lumen and the hemolymph have important consequences for hemolymph composition; yet few studies have addressed the role of endocrine regulation of midgut transport in hemolymph homeostasis. In Rhodnius, serotonin stimulates both uptake of fluid across the midgut into the hemolymph and removal of that fluid from the hemolymph by the Malpighian tubules. Evidence suggests that a similar process may occur in larval mosquitoes. Acid/base exchanges between the hemolymph and the midgut lumen of larval Lepidoptera, creating conditions favorable to nutrient digestion and absorption, also appear to be regulated. Hormones inhibit ion transport across the lepidopteran midgut, and serotonin stimulates both acid/base transport and rhythmic muscular contractions of the larval mosquito midgut. Evidence for regulation of more than one midgut transport mechanism by multiple chemical signals suggests that the regulation of midgut

FIGURE 1 The larval mosquito gut and excretory system. The five Malpighian tubules form the primary urine by active secretion of ions, with water following the resulting osmotic gradient. Fluid formed by the Malpighian tubules enters the alimentary canal at the midgut–hindgut junction. This primary urine can be either shunted forward into the midgut and reabsorbed, or passed backward into the hindgut for modification and eventual elimination. Evidence suggests that all three regions, the midgut, Malpighian tubules, and hindgut, contribute to water and ion balance and are under hormonal control. [Modified from Clark, T. M. et al. (1999). The anterior and posterior “stomach” regions of the larval Aedes aegypti midgut: regional specialization of ion transport and stimulation by 5-hydroxytryptamine. J. Exp. Biol. 202, 247–252. With permission of the Company of Biologists Limited.]

by osmosis, drawing with it small hemolymph solutes. This primary urine is then modified as it passes through more proximal regions of the Malpighian tubules and through the hindgut. The Malpighian tubules and the hindgut each frequently consists of several functionally distinct regions and/or distinct cell types, and each region contributes by specific mechanisms to the overall formation and processing of the urine.

Water balance can be adjusted by altering the rate of formation and/or composition of primary urine, and by changing the activity of mechanisms that modify the primary urine. Primary urine secreted by Malpighian tubules can be modified in more proximal regions of the tubules, passed forward into the midgut and reabsorbed, or passed back through the hindgut for final modification prior to elimination. Evidence suggests that Malpighian tubule, midgut, and hindgut transport processes are each regulated by hormones.

REGULATION OF THE EXCRETORY SYSTEM

A number of chemical factors have been isolated that alter fluid and/or ion transport rates of particular regions of the excretory systems of various insect species. The chemical structures of these factors, and their actions at the cellular level, have received considerable attention. In contrast, far fewer studies have attempted to identify their specific roles in the maintenance of hemolymph water and ion balance at the level of the organism. Evidence to date suggests that hormones regulate several related parameters, including hemolymph volume, hemolymph ionic composition, and clearance of metabolic wastes and toxins from the hemolymph. Regulation of water and ion balance in any species involves several different hormonal factors, each acting on only a portion of the excretory system or even on a specific group of cells within an organ. At least some regions appear to be regulated by multiple hormones, with a specific mechanism of action and with combinations of hormones producing responses that are distinct from the actions of the individual hormones acting alone. Adding to the complexity, different concentrations of a single hormone may trigger qualitatively distinct responses in the same organ.
transport may play an important role in hemolymph water and ion homeostasis.

**BIOLOGICAL ROLES OF HORMONAL REGULATION OF EXCRETORY FUNCTION**

**Orthoptera: Grasshoppers**
Locusts ingest considerable volumes of fluid with their food, and produce copious, moist feces when feeding. When deprived of food and water, Malpighian tubules secrete fluid at a low rate, and the feces produced are very dry due to the actions of antidiuretic factors acting on the hindgut. This recovery of ions and water by the hindgut is mediated by a hormone or hormones (ITP and CTSH, mentioned earlier). Upon feeding, a CRF-related diuretic hormone appears in the hemolymph, stimulating fluid secretion by the Malpighian tubules.

**Orthoptera: Crickets**
Cricket Malpighian tubules consist of distinct distal, mid, and proximal regions. These regions may be regulated independently, and secretion rates of a region may be either stimulated or inhibited. Achetakinin (a member of the kinin family of peptides) appears in hemolymph at levels sufficient to stimulate Malpighian tubule secretion in response to starvation, at a time when the insect is conserving water, rather than during feeding or water loading. These data suggest that achetakinin may act to stimulate fluid cycling through the excretory system, leading to clearance of materials from the hemolymph, rather than stimulating diuresis.

**Heteroptera: Rhodnius**
Most of our information concerning regulation of water balance in Heteroptera comes from studies on the bloodsucking bug *Rhodnius*. The physiology of this animal is unusual in that *Rhodnius* seldom feeds, feeds only on blood, and ingests a volume of blood up to 12 times its own body mass when feeding. At this time, serotonin released into the hemolymph causes the cuticle to become more plastic (allowing accommodation of the meal), stimulates anterior midgut fluid and ion absorption, and acts synergistically with a diuretic peptide to cause a 1000-fold increase in Malpighian tubule secretion rates. This leads to rapid removal from the midgut lumen and hemolymph of the fluid and ion load ingested with the meal.

**Diptera: Mosquitoes**
Larval mosquitoes are aquatic, and regulate water, ion, and acid/base status very effectively in a wide range of aquatic habitats. Adults are terrestrial, and adult females of most species consume large volumes of blood in order to obtain protein to support egg production. Larvae and adults thus face very different challenges in water and ion homeostasis. Drinking rates, and hemolymph serotonin levels, of larval *A. aegypti* increase in response to increased ambient salinity. The serotonin stimulates secretion of fluid and ions by the Malpighian tubules, and alters transport rates across the midgut, leading to clearance of ingested material from the hemolymph. Regulation of adult mosquito water and ionic balance is best understood in the context of blood feeding. Females of many species consume blood meals that may triple their body mass within a few minutes, and severely compromise flight. Even while feeding, they begin to eliminate the bulk of the fluid and NaCl ingested with the meal. This response is mediated by mosquito natriuretic peptide, identified as either a CRF-like or a calcitonin-like diuretic peptide. Recent work in the housefly *Musca domestica* has shown that abdominal stretch receptors trigger release of diuretic hormone from the thoracic-abdominal ganglion mass, a response mediated by the brain. This suggests a primary role in volume regulation.

**Lepidoptera: Butterflies and Moths**
Lepidopteran larvae are able to adjust to diets of different water content by regulating the amount of water lost in the feces. This regulation appears to endocrine. Both CRF-related diuretic peptides and kinins stimulate Malpighian tubule secretion *in vitro*, but appear to have very different biological roles. CRF-related diuretic peptide (Mas-DH) has an antidiuretic effect; it stimulates fluid (and presumably ion) recovery from the cryptonephric complex. In contrast, kinins increase the fluid content of the feces. Allatotropins and FLRFamides have been found to inhibit ion transport across the midgut epithelium, but the physiological significance of this response in terms of water and ion balance is not known. Upon emerging from the chrysalis, butterflies discharge a considerable volume of fluid containing metabolic wastes accumulated during the pupal stage. This diuresis is regulated by unidentified hormones.

**Desert Beetles**
Beetles of the family Tenebrionidae are generally very tolerant of dry conditions, to the extent that larvae of at least some species can remove water vapor from unsaturated air across the rectum. Despite this, factors that stimulate Malpighian tubule fluid secretion to high rates have been found in some of the most drought-tolerant species of this family. When injected into the animals, these factors stimulate fluid secretion by Malpighian tubules; but rather than being passed back through the hindgut and eliminated, the secreted fluid is passed forward into the midgut. The water and valuable hemolymph components are recovered, leaving toxins and metabolic wastes in the gut where they can be eliminated. These actions have led to the suggestion that some factors regulating excretory function may be more properly called “clearance hormones” than “diuretic hormones.” In fact, regulation of ionoregulation and clearance of wastes are likely to be more important than diuresis in many insect species due to their high surface area to volume ratios, and the desiccating conditions in which they live.

Wings

Robin J. Wootton
University of Exeter, United Kingdom

Insects are the only invertebrates to have developed the power of flight, and their wings are unique. Unlike those of birds and bats, they are not modified limbs and so have no internal muscles; they consist predominantly of an extracellular material—cuticle. Typical wings nonetheless need to perform—semiautomatically—the complex movements and cyclic changes in attitude and shape associated with flapping flight, and these necessities strongly influence their structural design. The latter shows huge variation within the class Insecta, and this is made greater by the wide range of secondary functions that the wings have evolved to perform, sometimes instead of flight, sometimes in addition to it. While great progress has been made in interpreting wing structures in functional terms, many questions still remain to be answered.

ORIGIN

We have no fossil record of the earliest winged insects nor of the structures from which wings evolved. Majority opinion currently favors their origin from articulated lateral outgrowths—“exites”—of an obsolete basal segment of the legs, long since incorporated in the thoracic wall. Similar, although not homologous, structures are found on the coxae and abdominal segments of some apterygote insects. The articulated gill plates of juvenile Ephemeroptera may actually be wing homologues. Those of some fossil mayfly nymphs indeed resembled tiny wings, although this may simply reflect the fact that both are adapted for accelerating fluid.

The origin of flight is still controversial. Two conflicting theories both have significant support. The first, and more traditional, theory is supported by some experimental evidence and theoretical modeling and proposes that powered flight arose in tree-dwelling insects, through parachuting and gliding stages. These “protopterygotes” would have had winglets, probably movable, on most body segments. Selection would favor enlargement and improvement of winglets close to the center of mass of the body, and reduction and loss of the remainder, together with the evolution of an effective mechanism for flapping and twisting the wings. The second hypothesis suggests that flight arose in semiaquatic insects, initially using their winglets to skim on the surface film of water bodies, as do many modern adult Plecoptera and Ephemeroptera. Selection would favor enlargement and improvement of the thoracic winglets to the point at which they could generate sufficient upward force for the insects to leave the surface and fly.

STRUCTURE

Although some Carboniferous and Permian insects had short, apparently movable winglets on the first thoracic segment, the wings of modern insects are borne on the second and third segments only. They articulate with the back (tergum) and sides (pleura) of the thoracic segments via the axillae: complex, three-dimensional mechanisms of stiff and compliant cuticle through which the muscular forces of the thorax are transmitted to the wings and which control the relative movements of the wings’ basal components. The axillary structures vary greatly in detail, but those of most insects can be referred to a common plan of up to four so-called axillary sclerites and three other sclerotized plates, the humeral and the proximal and distal median plates, linked together by hinges and broader expanses of soft cuticle (Fig. 1). The axillary structures of Ephemeroptera and Odonata, orders that appear primitively incapable of folding their wings back over the abdomen, differ from the typical pattern of wing-folding (neopterous) insects and also from each other. Various attempts have been made to homologize these with the neopterous pattern, which is clearly influenced by the need to fold; but no consensus has been reached.

FIGURE 1 Forewing axilla and wing base of the desert locust, Schistocerca gregaria. 1ax, first axillary sclerite; 2ax, second axillary sclerite; 3ax, third axillary sclerite; dmp, distal median plate; hp, humeral plate; pmp, proximal median plate. (Modified with permission from Wootton, 1979.)
Orthodox wings themselves consist of cuticular membrane supported by, and continuous with, a framework of veins. Both veins and membrane are double structures, formed by juxtaposition of the cuticle of the dorsal and ventral sides as the wing increases in area, thins, and stiffens after the final molt. The veins are typically tubular and contain hemolymph, and major vein branches usually also carry branches of the tracheal system, and some include nerves from wing sensillae. The hemolymph circulates or moves tidally within the veins and serves to maintain the moisture content of the cuticle, which would otherwise become stiff and brittle. Little or no epidermal material appears to remain in the expanded, sclerotized adult wing.

The longitudinal veins run distally from the wing base and many branch as the wing broadens along the span. They are usually to some extent linked by crossveins. Together they form a supporting and conducting framework, which may be structurally very complex (Fig. 2C, 2F, 2I, and 2M) or relatively simple (Fig. 2D, 2E, 2J, 2K, and 2P).

Even the simplest wings are far more complex than conventional illustrations indicate. Most have considerable relief, which adds substantially to their rigidity. The primitive condition may well have been a radially pleated structure, with the longitudinal veins alternatingly occupying the ridges and troughs of the pleats. This is found in many early fossil insects and is still the case in Odonata and Ephemeroptera. Some pleating indeed persists in parts of most insect wings, although it may be absent elsewhere. Many wings show an arched, or cambered, cross section, which again enhances rigidity by bending and introduces other important properties, which will be discussed later.

Further features, often omitted from illustrations, but with great mechanical significance, are lines and bands of flexibility within the wing and the axilla. One can conveniently distinguish between flexion lines, whose primary function is the facilitation and control of wing deformations in flight, and fold lines, whose primary role is in folding the wings to and from the resting position. The distinction is not absolute; there may well be some limited deformation along flexion lines during wing folding and along fold lines in flight. Some other lines of flexible cuticle, for example, in the distal parts of some hymenopteran and dipteran wings, seem to fit neither category and are best interpreted as adaptations to allow the wing tip to crumple reversibly on impact with obstacles. The veins themselves vary considerably in diameter, wall thickness, and shape of their cross section, all factors that strongly influence their local resistance to bending and help determine the pattern of deformation in flight. Figure 3 shows some details of contrasting vein morphology. Many crossveins have a characteristic annulated form (Fig. 3F and 3G), a means of reconciling flexibility with the need to maintain an open section, as in flexible drinking straws and some hoses and flexible pipes. Elsewhere, crossveins can be stout and rigid and can even form high-relief angle brackets, as in the leading edge spar of dragonfly wings (Fig. 3D). Where longitudinal or crossveins are crossed by flexion lines and fold lines, they may be locally interrupted, thinned, or annulated.

The membrane itself can be thickened and sclerotized, either over substantial areas, as in the protective or semiprotective forewings of Coleoptera, Dermaptera, Heteroptera, Orthoptera, and Blattoidea, or in more restricted lines or zones. In the latter case, it may not always be easy to distinguish the result from veins, especially since some true veins are not tubular, but are simply thickened, sclerotized grooves.

The texture of the membrane is also variable. Under the microscope, areas that undergo appreciable stretching in flight may appear crumpled like crêpe paper, as in the hind wing fan of locusts, or as an expanse of hollow papilla, as in those of some Heteroptera. Microtrichia (small unarticulated hairs) are widespread and sometimes very dense, and the wing membrane of many insects, particularly among Holometabola, bears articulated hairs (e.g., Trichoptera) or scales (e.g., Lepidoptera, Psocoptera, mosquitoes). The scales are sometimes extraordinarily complex in structure, providing both insulation and color, including some spectacular physical colors. This complexity is particularly remarkable when one considers that each scale is produced by a single cell.
The veins too may bear scales, hairs, and other ornamentation, including airflow- and vibration-sensitive hairs and sensillae that detect distortions of the cuticle in flight.

In several orders, the fore- and hind (meso- and metathoracic) wings are in physical contact during the wing stroke, the posterior part of the forewing overlying the anterior part of the hind and in many cases physically linked to it by a coupling mechanism. Some mechanisms may in fact provide sensory information about the relative positions of the wings rather than rigid mechanical coupling, but in Hymenoptera the hind wing leading edge bears a row of hooks that firmly clasp a fold of the forewing; in Heteroptera the hind wing edge is held by hairs in a groove in the forewing, and in many Homoptera the wings are held together by interlinking grooves.

**HOMOLOGY AND TERMINOLOGY**

Despite occasional claims to the contrary, there is no good evidence that wings arose more than once within the insects, and it is generally accepted that homologous wing characters should be recognizable throughout the class. In fact this is anything but straightforward. In the course of evolution, some veins have degenerated, or their identities have become obscured by fusion. Vein branches have been gained or lost, or have come to resemble crossoveins. Some mechanisms may in fact provide sensory information about the relative positions of the wings rather than rigid mechanical coupling, but in Hymenoptera the hind wing leading edge bears a row of hooks that firmly clasp a fold of the forewing; in Heteroptera the hind wing edge is held by hairs in a groove in the forewing, and in many Homoptera the wings are held together by interlinking grooves.

**Vein Nomenclature**

Unfortunately, several conflicting systems are in use. Two widely used schemes are illustrated here. Figure 4, adapted from Kukalová-Peck, shows all the longitudinal veins of any trace remains in extinct, as well as living, insects and is an attempt at an overall ground plan for the winged insects. It proposes that veins were initially paired, the anterior member of each pair being convex and situated on a ridge of a pleated wing, and the posterior member being concave and situated in a trough. They are the anterior and posterior precosta, costa, subcosta, radius, media, cubitus, anal, and jugal. This scheme is consistent and logical and is increasingly widely followed. In most modern insects, however, several of the most anterior veins are obscure or absent, and many entomologists tend to ignore these, or indeed to question their existence, and to follow a scheme like that in Fig. 5. The figure shows (Fig. 5A) a diagrammatic wing, (Fig. 5B) the expanded anal fan (vannus) of some hind wings, and (Fig. 5C and 5D) the names in common use for specific regions of the wing. Kukalová-Peck’s precostal veins are omitted, as are her posterior costa and anterior subcosta. The anteriormost veins are hence the convex, unpaired costa and the concave subcosta. Kukalová-Peck’s posterior radius is called by the older name of radial sector. The number of anal veins is regarded as unfixed.
Regions of the Wing

In the wings of a neopterous (wing-folding) insect, distinct areas can be recognized, delimited by flexion lines or fold lines. The main, anterior area, between the leading edge and the claval furrow, is the remigium. In wings without an expanded anal fan, a narrower area between the claval furrow and the jugal fold is the clavus. The remaining, usually small area, which lies posterior to and inboard of the jugal fold, is the jugum. In the hind wings of many forms, the area between the claval furrow and the jugal fold is expanded into a broad anal fan, or vannus, which sometimes, notably in Orthoptera, Phasmida, and Blattodea, has fold lines within it and folds into a pleated fan.

DIVERSITY

The wings of insects are very diverse indeed—far more so than those of birds or bats. They vary in proportions; the relative sizes of fore- and hind wings; relief, texture, and ornamentation; thickness; venational richness; the details of veins, fold lines, and flexion lines; and the extent and manner in which they are coupled in flight. Figure 2 illustrates some of this diversity.

It is widely assumed, although without direct evidence, that fore- and hind wings were originally similar in size and shape. This is true today of zygopterous Odonata (Fig. 2I); of some Neuroptera, Megaloptera (Fig. 2G), Mecoptera (Fig. 2Q), Trichoptera, and primitive Lepidoptera; of Thysanoptera (Fig. 2B); Embioptera, most Isoptera, and a few Plecoptera (Chloroperlidae). In the last two orders at least the condition is clearly secondary. Some Permian fossil Ephemeroptera, Pscoptera, and Hemiptera also had similar fore- and hind wings, as did some members of several extinct orders.

However, some of the earliest insect fossils already show relative enlargement or reduction of one wing pair, and this is true of most insects today. In anisopterous Odonata (Fig. 2F); Orthoptera (Fig. 2C) and winged Phasmida; Blattodea; one family of Isoptera (Mastotermitidae) and Mantodea (Fig. 2M); most Plecoptera, Dermaptera, Trichoptera (Fig. 2A), andColeoptera; and some Hemiptera and male Strepsiptera (Fig. 2P), the hind wing is significantly broader than the forewing and has become the principal lifting surface. In Ephemeroptera, Pscoptera, some Hemiptera (Fig. 2J) and Neuroptera, many Lepidoptera (Fig. 2L, 2O, and 2R), most Hymenoptera (Fig. 2E, 2H, and 2K), and all Diptera (Fig. 2N), the converse is true; the forewings have greater area and usually greater length than the hind wings. In all but the Odonata, which do not fold their wings, it is necessary for the hind wings to fold up along two or more radiating fold lines to lie beneath the forewings at rest. The forewings themselves are often shorter than the hind wings, and in some cases have become thickened, providing some protection for the abdomen and the more fragile hind wings. When moderately thickened, as in many Orthoptera, Blattodea, Mantodea, and some Homoptera, the forewings are often referred to as tegmina (singular tegmen). When thickened to the extent that their flight function is almost lost or wholly so, as in Coleoptera and Dermaptera, they are known as elytra (singular elytron). The typical forewings of Heteroptera, with the basal part thickened but a membranous tip, are known as hemielytra.

Forewings adapted for protection tend to be less effective in flight and are usually accompanied by disproportionately large, elaborately folding hind wings with expanded anal fans or else by total loss of flight capability. Where the forewings are significantly shorter than the hind, for example, in some Orthoptera, winged Phasmida, Dermaptera, and Coleoptera, two different solutions have been adopted to meet the problem of stowing the hind wings at rest. In Orthoptera, for example, Gryllotalpidae, Tridactylidae, and Tettigidae, and in Phasmida, the longitudinally folded hind wings project from beneath the tegmina along the back of the abdomen. In Phasmida and Tridactylidae, the narrow remigium of the hind wing itself is thickened and protects the more delicate fan. However, in Dermaptera and Coleoptera and in several genera of Blattodea, the hind wings fold transversely as well as longitudinally, in a variety of complex and mechanically fascinating ways.

Some reductions and modifications are extreme. Among Ephemeroptera, Caenidae and some Baetidae have lost the hind wings entirely and fly with the forewings alone; the same is true of male Coccidae (Homoptera, Fig. 2D). The hind wings of Diptera are modified as gyroscopic sense organs, the halteres, and the forewings of male Strepsiptera (Fig. 2P) are apparently similarly adapted. The hind wings of nemopticid Neuroptera are elongate plumules or filaments. In the nemopterid species that have been investigated, they do not flap, but are spread out behind the insect, apparently acting as physical stabilizers. Similar long, more or less slender hind wings occur in several families of butterflies and moths, but in some species at least they flap in phase with the forewings, sending ripple-like waves along their “tails.”

The wings of many small moths, flies, beetles, and wasps are fringed with long hairs, which appear to operate aerodynamically as if they were a continuous membrane. This is taken to extremes in the tiny feathery wings of Thysanoptera (Fig. 2B), ptiliids beetles, nymphenyiid Diptera, and nymnariid Hymenoptera, of which most of the lifting surface consists of long hairs, arising from a rodlike rachis. The emarginated wings of orneodid moths (Fig. 2R) consist of a radiating fan of similar feather-like structures, and the pterophorid moths approach this condition, although with fewer plumules.

The forewings of many male Orthoptera in the suborder Ensifera are adapted for sound production and amplification, with distorted venation enclosing large areas of membrane—the “mirrors.” These
regions, and their function, are often retained in species whose wings are otherwise reduced. The forewings of some noctuid moths are also adapted for sound production. Reduccion (brachyptery) and loss (aptery) of both wing pairs have happened in many orders. They are particularly frequent in Orthoptera, Blattodea, and Hemiptera, and sometimes occur polymorphically within a species. The adaptive significance of brachyptery is seldom clear. Short forewings are sometimes retained, apparently as protective structures, as are the elytra of many flightless beetles that lack hind wings.

**FUNCTIONS AND DESIGN**

The primary function of wings is flight. The wings operate as flexible aerofoils, oscillating as first-order levers over a process of the pleuron, which acts as a fulcrum. They need to be rigid enough to resist unwanted deformation under the forces they receive from the air and the inertial forces from the repeated accelerations and decelerations of flapping, but locally flexible enough to allow the cyclic twisting and bending deformations that are necessary to generate the forces to propel the insect and support its weight in air. Because they have no internal muscles, their shape from instant to instant needs to be controlled partly remotely through the axillae, partly automatically by their own structure: the distribution of rigid and flexible elements, of relief, veins, and flexion lines within the wings themselves.

**The Wing Beat**

To interpret these aspects of wing morphology, it is necessary to understand the nature of the wing beat. High-speed still and cine photographs of a wide range of insects show that in the downstroke, the wings are usually relatively straight along their length, with a slightly curved section and a slight nose-down twist along the span. In the upstroke, however, the shape of the wings varies greatly, both between species and according to how the insect is at that moment performing.

In nearly all species, the wings twist backward (supinate) to some extent at the bottom of the downstroke and continue supinated throughout the upstroke, twisting forward (pronating) again at the top. The extent to which they can twist varies greatly. The wings of most Diptera, and of zygopterous Odonata, which have slender bases and operate in individual pairs, are able to twist almost onto their backs. The camber becomes reversed, and they are then capable of generating upward, weight-supporting forces on the upstroke as well as the downstroke. This allows them to fly slowly and to hover. At the other extreme, locusts, and probably most other flying Orthoptera, can twist their wings only slightly and get the necessary stroke asymmetry by limited forewing twisting, but mainly by pulling the hind wings fully forward in the downstroke and partly retracting them for the upstroke. Pulling the hind wing forward extends the fan, and the radiating veins within it become compressed and curved like the spokes of an umbrella, giving the wing a cambered section, which is lost as the wing relaxes into the upstroke. Only the downstroke generates significant weight support, and the insects can fly only forward, at a relatively high speed.

Between these two extremes fall many insects whose wings are capable of varying amounts of torsion and which hence display a range of versatility and maneuverability in flight. Broad wings and fore- and hind wing coupling both tend to limit active twisting, but many wings show a degree of passive, elastic torsion along their span, so that the distal part is significantly supinated for the upstroke and can generate useful lift. In many insects—Plecoptera, sialid Megaloptera, Mecoptera, many Hemiptera and Hymenoptera, some Trichoptera and Lepidoptera—this is enhanced by a degree of ventral bending along a more or less marked transverse flexion line. Where such a flexion line runs obliquely across the wing, ventral bending serves also to twist the distal part of the wing, enhancing upstroke lift generation and increasing flight versatility (Fig. 6).

**The Importance of Wing Camber**

A cambered cross section makes a wing rigid to both bending and torsion, but asymmetrically so. A thin, dorsally convex wing is far more resistant to a bending force applied from below than to one from above, as the latter tends to make the edges buckle outward and flatten the section. Furthermore, if the force is applied behind the axis along which the wing naturally twists, the latter twists far more easily if the force is from above than from below. These effects are exploited by many insects to favor ventral bending and supinatory twisting for the upstroke, whether or not a transverse flexion line is present. There is evidence, moreover, that some insects can actively alter the height of the camber, and hence the wing's rigidity, by longitudinal bending along the median flexion line, and this may prove to be the latter's principal function.

**Automatic Mechanisms**

The mechanisms so far described illustrate that the control of wing shape in flight is to a considerable extent automatic: determined by the local distribution of flexibility and rigidity within the
structure, moderated remotely by the controlling muscles at the wing base. Nowhere is this automation better demonstrated than in the wings of dragonflies (Odonata, suborder Anisoptera).

These agile aerial predators have long complex wings (Fig. 2F), extensively corrugated, with several richly branched longitudinal veins and an abundance of crossveins. The principal support is provided in the basal part of the wing by high-relief, angle-bracket-shaped crossveins (Fig. 3D) into a spar with a V-shaped cross section, rigid to both bending and torsion. About halfway along the wing, the subcosta terminates at the “nodus,” a high-relief structure consisting of a strong transverse strut and a patch of flexible cuticle that interrupts the costa. Beyond the nodus, the costa and the radius form the first branch of the radial sector a more shallow spar with an inverted V-shaped section, supporting the distal part of the wing but compliant to supinatory twisting. The crossveins here, and elsewhere in the wing, are slender, allowing considerable deformation, so that the flapping wing twists forward and backward about its leading edge spar, like the sail of a tacking dinghy. The nodus serves to reinforce the wing and to minimize stress concentrations at the transition point between the two, mechanically very different, sections of the leading edge spar. The extreme twisting, essential to its versatile, high-performance flight, is assisted by an unusually flexible trailing edge; but it is essential that this latter should not be allowed to swing up like a flag to flutter in the airflow, which would be aerodynamically useless and potentially damaging to the wing. This is automatically prevented by two features: a dense, blood-filled space called the pterostigma, near the end of the wing tip, which is believed to act as a regulating counterweight to the swinging wing, and a curious, three-dimensional formation of veins near the wing base—the triangle and the supratriangle—which automatically lever the trailing edge downward in direct response to the aerodynamic forces that the wing generates. This degree of automation in a propulsive appendage is unique in the animal kingdom and has no obvious parallels in technology.

Wing Folding

All modern insects except Odonata and Ephemeroptera have the ability to fold their wings back over the abdomen, an adaptation that increases their ability to move freely over a substrate and to penetrate small spaces. Simple folding back is achieved mainly by muscular rotation of the third axillary sclerite and folding of the wing base along the basal hinge between the sclerite and the side of the thorax and along the jugal fold line. In hind wings with a large vannus (anal fan), there may be many extra fold lines lying parallel to the radiating veins, so that the wing folds like a pleated fan. The hind wings of Dermaptera, Coleoptera, and the cockroach Diploptera, however, fold up transversely as well as longitudinally, in some cases with extraordinary complexity. Because the wings have no internal muscles, folding and unfolding need to be achieved remotely, by mechanisms operated from the wing base and by the action of other body parts, combined with elasticity within the wing. Hydraulic mechanisms have sometimes been postulated, but recent work suggests that these are unnecessary. The unfolding of beetle wings appears to be achieved by active, scissor-like movements of the bases of the main supporting veins, which set in action a cascade of interconnected, simple opening mechanisms similar to those used in pop-up books and three-dimensional greeting cards, assisted in places by elasticity in the cuticle. Refolding the wings involves the reversal of these mechanisms, assisted by movements of the abdomen. Dermaptera, by contrast, use their abdomens to unfold the hind wings by means of a complex array of similar mechanisms, and refolding is largely elastic.

Secondary Functions

Wings have assumed a range of secondary functions. The sound-producing and -amplifying forewings of many Orthoptera, the protective elytra and tegmina of several orders, and the sensory halteres of Diptera and Strepsiptera have already been mentioned. The wings of Odonata and many Lepidoptera assist in thermoregulation. Members of several orders—Orthoptera, Phasmida, Mantodea, Odonata, Diptera, Lepidoptera—use theirs in active signaling: defensive, territorial, and sexual. Wings with warning patterns and colors are found particularly among Coleoptera, Lepidoptera, Orthoptera, and Heteroptera. The use of wings in camouflage is especially widespread in Orthoptera, Mantodea, Heteroptera, and Lepidoptera and may be reflected in their shape as well as color and pattern. Those of leaf mimics may be unusually broad and may bear petiole-like protuberances and emarginations resembling insect damage. It is often hard to determine whether particular wing characters are flight adaptations or have only secondary functions.

MODELS, ANALOGUES, AND APPLICATIONS

Physical, analytical, and numerical models have proved particularly useful in understanding the wings’ unique properties as flexible, smart aerfoils, and the last few years have seen a burst of activity by engineers in investigating and modeling the behavior and aerodynamics of flapping, insect-like aerfoils, and their possible contribution to the development of micro air vehicles: small, semi-autonomous flying robots with a number of potential uses in military and civil contexts.

Unsolved Problems

Many wing characters are still poorly understood. We know far too little about the mechanical properties of the wing materials, and how they vary within wings and between taxa. We are also largely ignorant of the aerodynamic significance of the great variety of wing shapes in, for example, Lepidoptera, and of surface structures like hairs, spines, and scales. While the principles underlying venation pattern and the layout and orientation of flexion lines are broadly clear, the details are often quite obscure. Much work, linking aerodynamics, functional morphology, and structural mechanics, remains to be done.

produced only when an uninfected male mates with an uninfected and uninfected individuals occur together, all possible crosses of embryos when a sperm from an infected male fertilizes the egg of an infected female, whereas all the offspring of uninfected females that have mated with infected males die. This difference in offspring production causes the CI infection to rapidly spread through the population. In the fruit fly *Drosophila simulans*, the infection in California spread at a rate of approximately 100 km per year.

The underlying mechanism of CI is not yet understood, but it is believed that sperm of infected males are somehow modified during spermatogenesis so that only in eggs infected with the same type of *Wolbachia* can this sperm function properly or be “rescued.” This system of modification (mod) of the sperm and rescue (res) in the egg is used to understand the possible CI types. For instance, if in one species two different *Wolbachia* infections exist, this could lead to two-way incompatibility because the modified sperm is not rescued by the eggs infected with the other type of *Wolbachia*. This leads to the death of all the embryos resulting from intertype crosses. Therefore, two infections within one species can cause genetic isolation of the two different subpopulations. This isolation may speed up speciation.

Not only is it possible that different populations within a species are infected with a different *Wolbachia*, but superinfections with several *Wolbachia* types are also common. Individuals infected with two different *Wolbachia* may be incompatible with individuals that are infected with only one of the two types. Sperm from doubly infected males may not be rescued in eggs that are singly infected. In these situations, the double infection should spread through the population, displacing the single infection.

The types of CI *Wolbachia* that have been discussed so far can all be classified as modify plus (mod+) and rescue plus (res+). If we assume that both these functions are energy costly to maintain, one can imagine that once a complete population is infected with the mod+, res+ variant, *Wolbachia* variants that do not modify the sperm any longer (mod-, res+) will spread relative to the modifying form (mod+, res+). Finally, once all of the individuals carry the mod-, res+ variant, the population becomes vulnerable to invasion by mod-, res- variants. Mod-, res- host populations either may lose their infection or can be invaded by new mod+, res+ variants. Examples of mod+, res+; mod-, res-; and mod-, res- variants are all known. Mod+, res- *Wolbachia* do not exist because the males would be incompatible with the females of their own population.

*CI Wolbachia* is thought to be promising in the spread of beneficial traits through a population. The idea is to genetically modify a *Wolbachia* with genes that inhibit the transmission of disease-causing organisms (malaria, dengue fever etc.) through the insects that vector the disease. If this gene were inserted into a CI *Wolbachia*, the CI caused by the *Wolbachia* would lead to the spread of the bacterium through the vector population and all infected insects would be unable to transmit the disease. *Wolbachia* appears to be present in many different parts of the insect body. Consequently, the gene products inhibiting the disease organisms may also be delivered to various insect tissues.

### Wolbachia

**Richard Stouthamer**  
*University of California, Riverside*

In the heyday of light-microscopy studies, intracellular bacteria were discovered in many organisms. In 1924 M. Hertig and S. B. Wollbach observed bacteria in the cells of a mosquito (*Culex pipiens*). Hertig formally described them in 1936 as *Wolbachia pipientis* in honor of his collaborator in earlier work. *Wolbachia* was placed in the Rickettsiales. Its closest relatives are several pathogenetic bacteria (*Cowdria* and *Ehrlichia*) that are transmitted by arthropods to vertebrate hosts. After their discovery, little was reported on these bacteria until Yen and Barr in 1971 discovered that they were involved in causing the death of mosquito eggs when sperm of infected males fertilized the eggs of *Wolbachia*-free females. Since that time the interest in *Wolbachia* has increased rapidly, because *Wolbachia* is very common in arthropods (up to 70% of all insects) and causes a number of unusual manipulations of their host’s reproduction. These manipulations are interesting both from an academic point of view (evolution of sex, speciation, and conflict between different sets of genes within one organism) and from an applied point of view (can these bacteria be used to manipulate their host for our benefit?).

**WOLBACHIA’S HOST MANIPULATIONS**

*Wolbachia* is generally passed on only from an infected female to her offspring; infected males do not pass on their infection to their offspring. This can be understood because insect eggs are large and can harbor bacteria, whereas sperm are small and carry very little cytoplasm in which bacteria can be transported. Such asymmetry in the transmission ability of their host explains many of the effects that *Wolbachia* has.

**Cytoplasmic Incompatibility**

One of the best known and possibly the most common effect of *Wolbachia* is cytoplasmic incompatibility (CI). Several different forms of CI are known. In its simplest form, CI causes the death of embryos when a sperm from an infected male fertilizes the egg of an uninfected female. Consequently, in populations in which infected and uninfected individuals occur together, all possible crosses of infected females result in infected offspring. Uninfected offspring are produced only when an uninfected male mates with an uninfected female, whereas all the offspring of uninfected females that have mated with infected males die. This difference in offspring production causes the CI infection to rapidly spread through the population. In the fruit fly *Drosophila simulans*, the infection in California spread at a rate of approximately 100 km per year.

The underlying mechanism of CI is not yet understood, but it is believed that sperm of infected males are somehow modified during spermatogenesis so that only in eggs infected with the same type of *Wolbachia* can this sperm function properly or be “rescued.” This system of modification (mod) of the sperm and rescue (res) in the egg is used to understand the possible CI types. For instance, if in one species two different *Wolbachia* infections exist, this could lead to two-way incompatibility because the modified sperm is not rescued by the eggs infected with the other type of *Wolbachia*. This leads to the death of all the embryos resulting from intertype crosses. Therefore, two infections within one species can cause genetic isolation of the two different subpopulations. This isolation may speed up speciation.

Not only is it possible that different populations within a species are infected with a different *Wolbachia*, but superinfections with several *Wolbachia* types are also common. Individuals infected with two different *Wolbachia* may be incompatible with individuals that are infected with only one of the two types. Sperm from doubly infected males may not be rescued in eggs that are singly infected. In these situations, the double infection should spread through the population, displacing the single infection.

The types of CI *Wolbachia* that have been discussed so far can all be classified as modify plus (mod+) and rescue plus (res+). If we assume that both these functions are energy costly to maintain, one can imagine that once a complete population is infected with the mod+, res+ variant, *Wolbachia* variants that do not modify the sperm any longer (mod-, res+) will spread relative to the modifying form (mod+, res+). Finally, once all of the individuals carry the mod-, res+ variant, the population becomes vulnerable to invasion by mod-, res- variants. Mod-, res- host populations either may lose their infection or can be invaded by new mod+, res+ variants. Examples of mod+, res+; mod-, res-; and mod-, res- variants are all known. Mod+, res- *Wolbachia* do not exist because the males would be incompatible with the females of their own population.

CI *Wolbachia* is thought to be promising in the spread of beneficial traits through a population. The idea is to genetically modify a *Wolbachia* with genes that inhibit the transmission of disease-causing organisms (malaria, dengue fever etc.) through the insects that vector the disease. If this gene were inserted into a CI *Wolbachia*, the CI caused by the *Wolbachia* would lead to the spread of the bacterium through the vector population and all infected insects would be unable to transmit the disease. *Wolbachia* appears to be present in many different parts of the insect body. Consequently, the gene products inhibiting the disease organisms may also be delivered to various insect tissues.

**Parthenogenesis-Inducing Wolbachia**

*Wolbachia* inducing parthenogenesis in their hosts are known from many wasps and some thrips (Fig. 1). Infected females can produce daughters both from fertilized and from unfertilized eggs. The cytogenetic mechanism through which *Wolbachia* cause unfertilized eggs to grow into females is known for a number of parasitoid wasps. *Wolbachia* exploits the normal sex determination in wasps. In this system, males arise from unfertilized eggs, which contain only one set of chromosomes, whereas females arise from fertilized
eggs, containing two sets of chromosomes. In unfertilized, infected eggs containing only a single set of chromosomes, **Wolbachia** causes a doubling in the number of chromosomes. This is accomplished through a modification of the first mitotic division in the egg, causing the egg to develop into a female.

In most populations in which parthenogenesis-inducing (PI) **Wolbachia** are known, the entire population consists of females. Feeding antibiotics to these females causes them to produce male offspring. In most instances, these males are not able to successfully inseminate the females of their own line. It is assumed that the populations have been parthenogenetic for such a long time that mutations have accumulated in the part of the genome involved with sexual reproduction. An exception to this situation is found in the tiny parasitoid wasps of the genus *Trichogramma* in which, in many populations, both infected and uninfected individuals coexist. In these populations, males that are the offspring of antibiotic-treated mothers can successfully mate with infected females.

**PI Wolbachia** are of interest from the applied point of view as well. Many parasitoid wasps are reared on a large scale in insectaries from which the future eggs of the wasp develop. Photograph by Merijn Salverda.)

**Feminizing Wolbachia**

In many woodlice species (pill bugs: Crustacea, Isopoda), a **Wolbachia** causes infected genetic males to develop into functional females. The feminizing **Wolbachia** accomplishes this through the infection of the male-hormone-producing gland. Without this hormone, genetic males develop into females. The spread of such an infection through a population can result in a severe shortage of males. Because males are needed for reproduction, this has led to counteradaptations by the nuclear genes in such a way that males will be produced even if the individual is infected. The effects of the **Wolbachia** and the counteradaptations against the feminization have led to a dynamic system of sex determination in some species of woodlice.

Feminizing **Wolbachia** have also been discovered in a moth (*Ostrinia scapularis*: Crambidae). Infected individuals grow into females, but how the **Wolbachia** accomplishes this transition is not known.

**Male-Killing Wolbachia**

Many different microorganisms have evolved methods of killing only male offspring of infected mothers. **Wolbachia** have this ability in several lady beetles and butterflies. The advantage of killing male offspring to **Wolbachia** requires that the infected daughters somehow benefit from the death of their brothers. In the case of the lady beetles, this is most easily explained. Ladybird beetles generally lay their eggs in clusters, and the survival of the larvae is greatly enhanced if they find food soon after hatching. If an infected mother has laid a clutch of eggs, the daughters emerge and then consume the eggs containing their dead brothers as their first meal. Because males cannot pass on the **Wolbachia**, the enhanced survival of the infected females benefits the **Wolbachia**. The presence of the male-killing **Wolbachia** can lead to extreme sex ratios in the population, and just like in the case of the feminizing **Wolbachia**, counteradaptations are expected.

Male-killing **Wolbachia** occur with a high frequency in several species of the butterflies of the genus *Acraea* occurring in East Africa. This has led in some populations to extremely female-biased sex ratios and a concurrent change in behavior of the butterflies. Normally, males form leks where females would “choose” the male to mate with, but in these female-biased populations, females form leks where males “choose” their partners. Little is known about the mechanism that allows these **Wolbachia** to kill exclusively infected male eggs.

**Other Phenotypes Induced by Wolbachia**

Several additional effects are known to be caused by **Wolbachia**. In the parasitoid wasp *Axobara tabida*, three different **Wolbachia** are found; two of these can be removed without having much influence on the wasp, and the third one however is necessary for the wasp reproduction. If this strain is absent, the wasps become sterile. A strain of **Wolbachia** named popcorn causes both CI and a reduced life span in infected *Drosophila melanogaster* flies. This popcorn strain divides rapidly in the adult flies and results in the early death of the individuals.

In several cases **Wolbachia** have been found to cause different phenotypes depending on the host in which they are introduced. For instance, a **Wolbachia** causing CI in the moth *Cadra cautella* causes male killing in the moth *Ephestia kuehniella*. Similarly, a **Wolbachia** causing CI in *Drosophila reversion* was introgressed into the closely related species *Drosophila subquinaria*, where it caused male killing in several lines.

**PHYLOGENY OF WOLBACHIA**

The phylogeny of **Wolbachia** has been studied extensively using several **Wolbachia** genes. Initially, the 16S ribosomal DNA sequence was used to derive the relationship between the different **Wolbachia**. From this work, it became clear that within the insect **Wolbachia**, two groups exist, later named A and B, that had diverged from each other approximately 60 mya. Later several other genes were used to get a finer scale picture of the relationship of the different **Wolbachia**.
to each other, and recently, a multi-locus sequence typing (MLST) system has been developed using five different Wolbachia genes to characterize strains. The MLST work has shown that frequent and extensive recombination takes place between different Wolbachia lines. This frequent recombination makes it likely that single gene phylogenies do not correlate with the phenotypes induced by the Wolbachia, unless the gene used for the phylogeny happens to be the one causing the phenotype. In addition, the publication of several Wolbachia genomes has made it clear that several mobile elements and phages are present. Not only do the Wolbachia genomes recombine with each other, but there are now several cases where parts of the Wolbachia genome have become integrated in the chromosomes of their hosts. Little is known if these integrated Wolbachia genomes remain functional or if they become completely silenced.

Yellow Fever

Yellow fever virus is the prototype of the family Flaviviridae, which includes approximately 70 single-stranded RNA viruses, the majority of which are transmitted by mosquitoes or ticks. Yellow fever virus is transmitted principally by insects (mosquitoes), but ticks (Amblyomma variegatum) may play a secondary and minor role in Africa.

DISEASE AND MEDICAL IMPACT

The disease caused by the yellow fever virus is a severe hemorrhagic fever, characterized by high viremia (virus in the blood), hepatic, renal, and myocardial injury, hemorrhage, and case-fatality rates of 20–50%. Today, the disease occurs in tropical Africa and South America. It is estimated that up to 200,000 cases occur annually but far fewer are reported officially. Between 1990 and 1999, 11,297 cases and 2648 deaths were reported; 83% of these cases occurred in Africa. The highest incidence was in Nigeria, where epidemics occurred between 1986 and 1994. Recent epidemics have affected Cameroon (1990), Kenya (1992), Ghana (1993–1994, 1996), Liberia (1995, 1998, 2000), Guinea (2000), Gabon (1994), Senegal (1995, 1996), and Benin (1996). In South America, 1939 cases and 941 deaths were reported between 1990 and 1999, an average of about 200 cases per year. Bolivia and Peru had the highest incidence, reflecting low vaccination coverage. In Brazil, an increase in yellow fever activity occurred over a wide area between 1998 and 2000.

ROLE OF INSECTS IN TRANSMISSION

The enzootic transmission cycle involves tree-hole-breeding mosquitoes such as Aemoglossus janthinomys (South America) and Aedes africanus (Africa), and nonhuman primates. Infection of mosquitoes begins after ingestion of blood containing a threshold concentration of virus (~3.5 log10 ml−1), resulting in infection of the midgut epithelium. The virus is released from the midgut into the hemolymph and spreads to other tissues, notably the reproductive tract and salivary glands. A period of 7–10 days is required between ingestion of virus and virus secretion in saliva (the extrinsic incubation period), after which the female mosquito is capable of transmitting virus to a susceptible host. Vertical transmission of virus occurs from the female mosquito to her progeny and from congenitally infected males to females during copulation. Virus in the egg stage provides a mechanism for virus survival over the dry season when adult mosquito activity and horizontal transmission abate.

In tropical South America, the virus is transmitted by Haemagogus mosquitoes (principally Hg. janthinomys) between monkeys in the rain forest canopy and from monkeys to humans. Transmission peaks during months of high rainfall, humidity, and temperature (January–March), corresponding to the activity of Haemagogus mosquitoes. It is during occupational activities, such as forest clearing, lumbering, and road construction that humans acquire the infection (‘jungle’ yellow fever) from mosquitoes that previously had fed on viremic monkeys; most patients are young adult males. The density of Haemagogus and risk of human exposure are relatively low, and human cases occur in a sporadic fashion. Other mosquitoes involved in jungle yellow fever in South America include Hg. leucocelaenus and Sabethes chloropterus. In the early 1950s an epizootic extended to Central America, where other species were implicated (Hg. lucifer, Hg. equinus, Hg. iridiolor, Hg. mesodentatus). Prior to the 1940s, epidemics of yellow fever due to bites from Ae. aegypti occurred in the Americas. Ae. aegypti breeds in and around houses, principally in artificial containers, and is responsible for direct interhuman transmission of virus (‘urban’ yellow fever). Age and sex distributions are different from jungle yellow fever, because children and females are affected. Most areas of South America had effectively eliminated Ae. aegypti during eradication efforts (1930s–1960s), but the continent was reinvaded in the 1970s, and the vector is now widespread. The first outbreak of urban yellow fever since 1954 occurred in Santa Cruz, Bolivia, during 1997–1998. The wide distribution of Ae. aegypti (including areas juxtaposed to the yellow fever endemic zone) and the rise in air travel have increased the risk of reemergence of urban yellow fever in the Americas.

In Africa, the enzootic cycle involves tree-hole-breeding Aedes mosquitoes, which transmit virus between monkeys, from monkeys to humans, and between humans. In West Africa, cases appear during the middle of the rainy season (August) and peak during the early dry season (October), the period of maximum vector longevity. The principal enzootic vector is Ae. africanus; this species is responsible for transmission between monkeys in the forest zone and in gallery forests. During the rainy season, Ae. africanus and other vector species [Ae. furcifer, Ae. taylori, Ae. luteocephalus, Ae. metallicus, Ae. vittatus, and (in many parts of East Africa) Ae. simpasi] reach high densities in the humid savanna zone (the ‘zone of emergence’ of yellow fever). The prevalence of immunity in the human population accumulates rapidly with age, and children are at highest risk of infection and illness. The domestic vector Ae. aegypti breeds in receptacles widely used by humans for water storage where piped water supplies are unavailable. Where this mosquito is involved in virus transmission, the disease may occur in the dry season in both rural and urban areas. Ae. aegypti has been the principal vector in many recent human epidemics in West Africa. Because the density and biting rates of Ae. aegypti and sylvatic Aedes vectors are high, human infection rates during epidemics may reach 20–30%.

Rainfall and temperature influence vector abundance and transmission rates and the potential for yellow fever epidemics. Prolongation of the rainy season, reflected by vegetational indices in satellite images, predicts a risk of yellow fever epidemics. Increasing temperature shortens the extrinsic incubation period of yellow fever virus in the mosquito, resulting in a significantly increased rate of transmission. Even brief exposure to high temperatures (e.g., in a sunlit forest clearing) can have this effect. Warm temperature also increases biting and reproductive rates of Ae. aegypti.
Ae. aegypti populations differ genetically in vector competence for yellow fever virus. High vector densities may be required for virus transmission by relatively insusceptible populations, such as those occurring in West Africa.

CONTROL STRATEGIES

The principal method for prevention and control is human vaccination. A safe and effective live, attenuated vaccine (yellow fever 17D vaccine) has been in wide use since World War II. The vaccine is incorporated into routine childhood vaccination programs in South America and some parts of Africa. The occurrence of human disease reflects incomplete coverage of the population, because vaccine immunity is probably lifelong after a single dose.

In the Americas, control of Ae. aegypti through larval source reduction was successful in reducing urban yellow fever in the early decades of the 20th century. The increasing size and complexity of urban areas, the proliferation of detritus and objects such as automobile tires that collect rainwater and breed mosquitoes, and increasing costs and competition with other health care priorities have limited the impact of mosquito control efforts. Emergency vector control using space sprays to kill infected female vectors could undoubtedly reduce the impact of mosquito control efforts. Emergency vector control using space sprays to kill infected female vectors could undoubtedly have been evaluated specifically for this purpose. Spraying of large areas of forest and around villages by air- or ground-operated equipment to contain sylvatic yellow fever has been evaluated, with mixed success.

Zoonotic Agents, Arthropod-Borne

Robert S. Lane

University of California, Berkeley

The term zoonosis (plural, zoonoses) is derived from the Greek roots for animal (zoon) and disease (osis) and was coined initially to characterize any infection of lower animals that could be transmitted to humans. The Food and Agriculture Organization and the World Health Organization (FAO/WHO) broadened the definition during the 1950s to include infections that are transmitted in either direction between humans and other vertebrate animals. Thus, zoonoses are those diseases and infections for which the agents are naturally transmitted between vertebrate animals and humans. Zoonoses can be transmitted to humans by direct contact with an infectious vertebrate host or a fomite (i.e., an inanimate object such as an article of clothing that can harbor an agent); by ingestion of contaminated water, food, or other organic matter; by inhalation; or by arthropod vectors. This chapter is devoted exclusively to zoonotic agents that are transmitted from other vertebrates to humans by arthropods. It does not include nonzoonotic disease agents that are transmitted solely from person-to-person by arthropods (e.g., malaria). The terms arthropod vector vs. vector, and arthropod-borne vs. vector-borne, are used interchangeably.

CHARACTERISTICS

Viruses, prions, bacteria (which include the rickettsiae), fungi, protozoa, and helminths can serve as zoonotic agents. Taylor and co-workers reported in 2001 that 868 (61%) of 1415 infectious organisms known to be pathogenic for humans are zoonotic in origin, and that 22% of the zoonotic pathogens can be transmitted by arthropods. An updated literature survey in 2005 similarly identified 1407 human
Zoonotic Agents, Arthropod-Borne

Insects that transmit zoonotic agents belong principally to three orders, namely, the Siphonaptera (fleas), Hemiptera (true bugs), and especially the Diptera (flies). Important families of flies that transmit zoonotic agents are the Culicidae (mosquitoes), Glossinidae (tsetse flies), Psychodidae (phlebotomine sand flies), Ceratopogonidae (biting midges), and Tabanidae (deer flies and horse flies). Other dipteran families, like those comprising the filth flies generally and the house fly in particular (Muscidae), may mechanically contaminate human foodstuffs with bacteria, protozoans, or other agents that can cause gastrointestinal illnesses.

Among the arachnids, ticks overwhelmingly outweigh the mites in importance as vectors of zoonotic agents because of their universal blood-sucking habit. With rare exceptions, all three trophic stages (larva, nymph, adult) of ticks must ingest a blood meal to complete their genetically determined invasiveness (pathogenicity) of the infecting organism, one’s age, and the immune and nutritional status of an exposed individual. Certain of the North American mosquito-borne viral encephalitides may produce more severe disease in disparate age groups. For example, children infected with western equine encephalomyelitis virus (WEEV) experience graver illness than adults, whereas the reverse is true for individuals infected with either St. Louis encephalitis virus (SLEV) or West Nile virus (WNV). Zoonoses may cause comparable harm to humans and other animals, or they may adversely affect one group or the other disproportionately. Thus, some mosquito-borne encephalitic viruses (e.g., eastern equine encephalitis virus [EEEV], Venezuelan equine encephalitis virus, WEEV, WNV) can be highly pathogenic for both humans and horses.

Most arthropod-borne zoonotic infections can be characterized by their focal distribution within particular geographic landscapes. A natural focus, also known as a nidus, is an area where the complex interaction of biotic and abiotic environmental factors ensures the temporal persistence of a zoonotic agent. This concept of the natural nidality of disease, referred to as “landscape epidemiology,” was developed into a doctrine by the Russian scientist E. N. Pavlovsky in 1939. Accordingly, foci exist where macro- and microclimatic, vegetational, and soil conditions support populations of arthropod vectors, vertebrate reservoirs, and the agent.

Foci can be as distinct and limited geographically as the burrow of a small mammal or a tick-infested cottage, or they can be diffuse in which case they encompass much broader territories such as coniferous or mixed hardwood forests. Individual cases or localized outbreaks of relapsing fever in California usually are associated with rodent- and tick-infested cabins at higher elevations in mountainous regions. In such foci, the siphonapteran Borrelia hermsii occasionally is transmitted to sleeping individuals by the bite of the rapid-feeding, nocturnally active, soft-tick vector Ornithodoros hermsi.

In contrast, northern Californian foci of the Lyme disease spirochete B. burgdorferi, although present in several major habitat types, seem to be most intense in certain leaf-litter or fir-needle areas within mixed hardwood forests where infection prevalences in host-seeking Ixodes pacificus nymphs sometimes reach 20–40%. In one such forest, human behaviors involving contact with wood, such as sitting on logs or against tree trunks, were found to elevate the risk of encountering I. pacificus nymphs vs. activities entailing exposure solely to leaf litter. The tiny nymph, which is about the size of a poppy seed (1.0–1.2 mm long), readily attaches to people but often remains undetected while feeding for up to several days. If a B. burgdorferi-infected nymph is not discovered and removed within a day or two of attachment, an individual may develop an erythematous rash of protean shape within 3–32 days. This rash, known as erythema migrans (Fig. 1), is pathognomonic for early-stage Lyme disease and commonly is accompanied by nonspecific, flu-like symptoms.

FIGURE 1 Erythema migrans, the skin lesion that is often present during early-stage Lyme disease. It typically occurs at the site of attachment of an infective tick, but multiple lesions may appear on the bodies of some patients. (Photograph by R. Ritter.)

VECTORS

The phylum Arthropoda contains six classes of varying medical importance but only two of them, the Insecta and Arachnida, are of paramount importance as transmitters of zoonotic agents. Ticks and other mites, solpugids, scorpions, and spiders comprise arachnids of public health interest, but only some ticks and comparatively few mites transmit zoonotic pathogens to humans.

Insects that transmit zoonotic agents belong principally to three orders, namely, the Siphonaptera (fleas), Hemiptera (true bugs), and especially the Diptera (flies). Important families of flies that transmit zoonotic agents are the Culicidae (mosquitoes), Glossinidae (tsetse flies), Psychodidae (phlebotomine sand flies), Ceratopogonidae (biting midges), and Tabanidae (deer flies and horse flies). Other dipteran families, like those comprising the filth flies generally and the house fly in particular (Muscidae), may mechanically contaminate human foodstuffs with bacteria, protozoans, or other agents that can cause gastrointestinal illnesses.

Among the arachnids, ticks overwhelmingly outweigh the mites in importance as vectors of zoonotic agents because of their universal blood-sucking habit. With rare exceptions, all three trophic stages (larva, nymph, adult) of ticks must ingest a blood meal to complete development or to ensure reproductive success. By comparison, most mites are free-living and nonparasitic. In the continental United States, 6 (7%) of the approximately 86 autochthonous tick species are of broad, regional importance because they transmit one or more viruses, bacteria, or protozoan parasites to people with some regularity. Other

pathogens, 816 (58%) of which are zoonotic. Furthermore, two of the three contemporary internationally quarantinable diseases are caused by vector-borne zoonotic agents that are transmitted either by mosquitoes (yellow fever virus) or fleas (plague bacterium). Plague also is transmitted by other routes, but the bacterial agent (Yersinia pestis) is maintained primarily in natural cycles involving rodents and their associated fleas. In the tropics and subtropics, the most important arthropod-borne zoonotic disease agents are transmitted by flies (Diptera) such as mosquitoes, phlebotomine sand flies, and tsetse flies, whereas in temperate regions of the Northern Hemisphere the predominant zoonotic agents are transmitted by ticks.

Humans are “dead-end” hosts for most vector-borne zoonotic agents, that is, secondary cases do not occur following human infection. Notable exceptions are exemplified by yellow fever, plague, and Chagas disease. Humans infected with yellow fever virus can serve as a source of infection for uninfected mosquitoes that feed on them, individuals manifesting primary or secondary pneumonic plague potentially can transmit Y. pestis to other persons by the respiratory route, and people infected with the trypanosome causing Chagas disease can infect triatomine bugs that bite them.

Several factors that affect the ability of zoonotic agents to produce disease in people include the route of transmission (portal of entry), the genetically determined invasiveness (pathogenicity) of the infecting organism, one’s age, and the immune and nutritional status of an exposed individual. Certain of the North American mosquito-borne viral encephalitides may produce more severe disease in disparate age groups. For example, children infected with western equine encephalomyelitis virus (WEEV) experience graver illness than adults, whereas the reverse is true for individuals infected with either St. Louis encephalitis virus (SLEV) or West Nile virus (WNV). Zoonoses may cause comparable harm to humans and other animals, or they may adversely affect one group or the other disproportionately. Thus, some mosquito-borne encephalitic viruses (e.g., eastern equine encephalitis virus [EEEV], Venezuelan equine encephalitis virus, WEEV, WNV) can be highly pathogenic for both humans and horses.

Most arthropod-borne zoonotic infections can be characterized by their focal distribution within particular geographic landscapes. A natural focus, also known as a nidus, is an area where the complex interaction of biotic and abiotic environmental factors ensures the temporal persistence of a zoonotic agent. This concept of the natural nidality of disease, referred to as “landscape epidemiology,” was developed into a doctrine by the Russian scientist E. N. Pavlovsky in 1939. Accordingly, foci exist where macro- and microclimatic, vegetational, and soil conditions support populations of arthropod vectors, vertebrate reservoirs, and the agent.

Foci can be as distinct and limited geographically as the burrow of a small mammal or a tick-infested cottage, or they can be diffuse in which case they encompass much broader territories such as coniferous or mixed hardwood forests. Individual cases or localized outbreaks of relapsing fever in California usually are associated with rodent- and tick-infested cabins at higher elevations in mountainous regions. In such foci, the siphonapteran Borrelia hermsii occasionally is transmitted to sleeping individuals by the bite of the rapid-feeding, nocturnally active, soft-tick vector Ornithodoros hermsi.

In contrast, northern Californian foci of the Lyme disease spirochete B. burgdorferi, although present in several major habitat types, seem to be most intense in certain leaf-litter or fir-needle areas within mixed hardwood forests where infection prevalences in host-seeking Ixodes pacificus nymphs sometimes reach 20–40%. In one such forest, human behaviors involving contact with wood, such as sitting on logs or against tree trunks, were found to elevate the risk of encountering I. pacificus nymphs vs. activities entailing exposure solely to leaf litter. The tiny nymph, which is about the size of a poppy seed (1.0–1.2 mm long), readily attaches to people but often remains undetected while feeding for up to several days. If a B. burgdorferi-infected nymph is not discovered and removed within a day or two of attachment, an individual may develop an erythematous rash of protean shape within 3–32 days. This rash, known as erythema migrans (Fig. 1), is pathognomonic for early-stage Lyme disease and commonly is accompanied by nonspecific, flu-like symptoms.
ticks, like the brown dog tick (*Rhipicephalus sanguineus*), may serve as primary vectors of disease agents in more restricted geographical areas. This tick recently was implicated for the first time as a vector of the agent of Rocky Mountain spotted fever (RMSF) in the United States, but only in eastern Arizona. One commonality shared by many arachnid and insectan vectors is that they feed intermittently upon their hosts and therefore spend more than about 95% of their entire life cycle off the host.

**TRANSMISSION CYCLES**

Arthropod-borne zoonotic agents are maintained in transmission cycles of variable complexity. Nevertheless, four components are evident in all such cycles: the agent itself, one or more efficient arthropod vectors and primary reservoir hosts, and a permissive environment. A reservoir host is a vertebrate that is readily infected with the agent, usually is capable of maintaining the agent within its tissues for an extended period, and can serve as a source of infection for uninfected vectors that feed on it while it is in an infectious state. In reality, arthropods also contribute to the maintenance of zoonotic agents to various degrees; some, like certain hard-tick vectors of spotted-fever group rickettsiae or mosquito vectors of some viruses, may be considered reservoirs as well. That is, they can maintain the agent in their tissues for months or even years, efficiently pass it from one trophic stage to the next (transstadial transmission), and eventually transmit it from one generation to the next via the eggs of infected females (transovarial transmission). In such cases, the reservoir of infection may best be considered polyvalent because both the vertebrate host(s) and the vector(s) help to maintain the cycle of infection.

Arthropods may transmit zoonotic agents from an infected vertebrate to a susceptible one either mechanically or biologically. Of these, biological transmission is much more prevalent than mechanical transmission among most groups of arthropod vectors. Mechanical transmission occurs when an agent adheres externally on the mouthparts, legs, or other bodily regions of a vector and then is transported directly or indirectly to a vertebrate, for example, by means of contaminated foodstuffs or by specific inoculation into the skin or bloodstream by the bite of contaminated mouthparts. In mechanical transmission, the agent does not require the arthropod to complete its life cycle, and the arthropod/agent relationship is accidental in nature.

In biological transmission, the vector plays an indispensable role in the life cycle of the agent. Biological transmission takes three forms: cyclodevelopmental, cyclopropagative, and propagative. In cyclodevelopmental transmission, the agent undergoes cyclical changes within the internal tissues of the vector but does not multiply (e.g., mosquito transmission of the filarial nematode *Wuchereria bancrofti*). In cyclopropagative transmission, the agent undergoes cyclical development and multiplication in the arthropod’s body (e.g., zoonotic babesial piroplasmosis in their tick vectors or nonzoonotic malarial plasmodia in anopheline mosquitoes). In propagative transmission, the agent multiplies, but undergoes no cyclical development, within the vector’s body (e.g., most bacteria and viruses).

Regardless of the specific mode of biological transmission, the vector usually transmits the agent anteriorly via its salivary secretions when ingesting a blood meal from a vertebrate host. In a few instances, zoonotic agents are transmitted posteriorly when infectious feces deposited on the host are rubbed into the bite-wound, scarified skin, or conjunctivae of the eyes (e.g., feces of triatomine bugs infected with *Trypanosoma cruzi*, the causative agent of Chagas disease).

**CLASSIFICATION**

Zoonoses were classified by the FAO/WHO in 1967 according to whether their reservoir hosts are lower animals (arthropozoonoses), humans (zoanthroponoses), or both (amphixenoses), and with regard to the type of life cycle of the infecting organism. The latter classification, which is based upon shared epidemiologic features, is more instructive than one based solely on reservoir hosts. In it, zoonoses have been categorized as direct zoonoses, cyclozoonoses, metazoanoses, or saprozoanoses. However, only two of these categories involve transmission by arthropods. Direct zoonoses are transmitted, in part, from an infected to a susceptible vertebrate host mechanically by a vector, whereas metazoanoses are transmitted biologically by vectors.

**PUBLIC HEALTH IMPORTANCE**

The public health and economic impact of the arthropod-borne zoonoses is immense, particularly in developing countries in tropical or subtropical regions. Losses include morbidity and mortality among humans and domestic livestock and the resultant direct and indirect economic effects to affected individuals and to society at large. For instance, the African trypanosomiases still are among the most devastating diseases afflicting humans and livestock. African sleeping sickness is estimated to have killed over 750,000 people between 1896 and 1906, and one epidemic near Lake Victoria in Uganda claimed about 200,000 lives. Recently, it was estimated that over 25,000 new cases of the disease are contracted annually and that 50 million people in 38 countries of sub-Saharan Africa and an even greater number of livestock are at risk. Besides African trypanosomiases, other zoonotic and nonzoonotic vector-borne diseases such as malaria, dengue, yellow fever, filariasis, leishmaniasis, plague, and louse-borne typhus caused more human morbidity and mortality than all other causes from the 17th to the early 20th centuries, especially in the tropics. Since the 1970s, there has been a resurgence of many of these diseases and the emergence of others (see below), notably tick-borne diseases like Lyme disease, human granulocytic anaplasmosis, human monocytic ehrlichiosis, and human babesiosis in temperate regions of the Northern Hemisphere.

Certain population groups traditionally have been at elevated risk of acquiring vector-borne zoonotic infections. Agricultural and forestry workers, hunters, field naturalists, park rangers, wildlife biologists, woodcutters, and ecotourists represent just a few of the many groups that are vulnerable to such infections. In the northeastern United States, suburbanites may be at considerable risk for contracting Lyme disease in the peridomestic environment because of the presence of host-seeking, spirochete-laden I. *scapularis* ticks on lawns and in adjacent shrubbery or forested areas. Similarly, in the western United States, the risk of human plague increased in peridomestic settings during the late 20th century as human populations encroached into formerly unpopulated foci of *Y. pestis*.

**EMERGING DISEASES**

According to the United States Centers for Disease Control and Prevention (CDC), emerging diseases are those of infectious etiology whose incidence in humans has either increased during the past 20 years or are threatening to increase in the near future. As of 2005, 177 (12.6%) of the 1407 infectious organisms reportedly pathogenic for humans were considered to be emerging. In two published literature surveys (2000, 2005), a higher risk of emergence was found to be associated with zoonotic pathogens (73% or 75% of the emerging pathogens were zoonotic), with certain taxonomic divisions of pathogens...
(viruses and protozoa were overrepresented), and with vector-borne transmission. Although diverse factors have contributed to the emergence or re-emergence of many arthropod-borne diseases during the past 30 years (e.g., agricultural practices, deforestation or reforestation, urbanization), they typically result from environmental changes that produce an increased abundance of arthropod vectors.

In the northeastern United States, human babesiosis and Lyme disease emerged during the 1970s after reforestation and suburbanization combined to increase the abundance of wildlife (e.g., white-footed mice, white-tailed deer) and black-legged ticks (I. scapularis), and consequently the frequency of human-tick contact in the peridomestic environment. WNV “emerged” in New York State in 1999 following its introduction from the Old World. By 2002, it had achieved pandemic proportions as it swept southward and westward across the country; 4136 cases (254 fatalities) were reported that year by 39 states and the District of Columbia. Additionally, RMSF has reemerged as a major vector-borne disease in the United States as the number of reported cases almost quadrupled between 2000 (495 cases) and 2005 (1936 cases). Indeed, among all cases of indigenous vector-borne diseases reported to the CDC in 2005, the number recorded for RMSF was exceeded only by those for Lyme disease (23,305 cases) and West Nile encephalitis/meningitis (3000 cases).

In Europe, the observed pattern of emergence of vector-borne zoonotic infections parallels the current situation in the United States. Fifteen zoonotic and vector-borne agents were identified as emerging public health threats between 2000 and August 2006, and arthropods are involved in the transmission cycles of two-thirds of them.
Zoraptera
Michael S. Engel
University of Kansas

The Zoraptera ("zorapterans," "angel insects," or less appropriately "soil lice") are one of the smallest insect orders with only 35 living species and 10 more known from fossils. Zorapterans are rarely observed; indeed many entomologists have never seen them alive. There is a single family (Zorotypidae) and only two genera, Zorotypus and the fossil genus Xenozorotypus\(^1\) from the middle Cretaceous. Some authors have at times attempted to divide living species of Zorotypus into multiple genera or subgenera, but none have successfully characterized natural (i.e., monophyletic) groups. Owing to the paucity of species and the great morphological homogeneity of the order, the recognition of numerous living genera is unwarranted.

Zorapterans superficially resemble termites (Isoptera) and bark lice (Psocoptera) (Fig. 1A, 1B, and 1D) and they have at times been classified near or within these groups. Individuals are typically less than 4 mm in body length (excluding their antennae) and live in small colonies. The most readily noticeable traits of the order are the expanded hind femora that bear stout spines on their ventral surface (Fig. 1C), the presence of only two tarsomeres (the basal most of which is greatly reduced in size; Fig. 1C), and paddle-shaped wings with reduced venation (Fig. 1C), and paddle-shaped wings with reduced venation (Fig. 1C) that are shed by an ill-defined basal fracture.

**ORIGIN AND EVOLUTION**

Although zorapterans are relatively minute both in size and in species diversity, they have weighed heavily on the minds of evolutionary biologists. The order has been at one time or another classified in a bewildering array of phylogenetic positions, at times being considered relatives of the termites, roaches (Blattaria), mantises (Mantodea), webspinners (Embiidina), or bark lice; sister to Paraneoptera; or even allied to the Holometabola. The most well supported hypothesis is that they are polyneopterans and the living sister to the webspinners, both orders sharing a unique development of the musculature in the hind legs, among several other important traits. The Zoraptera–Embiidina split likely occurred during the middle Mesozoic, perhaps as long ago as the early-middle Jurassic, while the ancestor of both groups diverged from crown-group stoneflies (Plecoptera) perhaps sometime in the Permian or Triassic. The Zoraptera are clearly ancient as evidenced by the presence of extinct species of the living genus Zorotypus in middle Cretaceous amber (e.g., Fig. 1D). These extinct Mesozoic species already show the development of the dual-morphs, with blind–apterous and eyed–winged individuals. Only the extinct genus Xenozorotypus\(^1\) shows a departure in morphology (albeit not nearly as dramatically as the anatomical diversity found in other orders) from all other zorapterans by the primitive retention of additional wing veins and the structure of spines on the hind tibia.

**DISTRIBUTION**

Species principally occur in tropical habitats throughout the world although four species occur north of the Tropic of Cancer (i.e., north of 23.5°N): two in North America and two in Tibet. Similarly, the known fossil zorapterans have all been discovered in ambers that were formed in warm-tropical paleoclimates. The northernmost areas of distribution for Z. hubbardi in North America are likely a result of human activity. Most northerly colonies are formed in sawdust piles (rather than natural logs) where warmth from the decaying material can sustain a colony for a few seasons. Thus, once a pile is no longer suitable, dispersal to new sawdust piles or into natural logs is required or, conversely, those northermost populations repeatedly become extinct and are maintained over the long term by perpetual reintroductions from more southern populations. Once believed to be highly endemic as a result of an inability to disperse, several Zorotypus species are increasingly being recognized over larger geographic ranges (e.g., Z. hubbardi in south-central and southeastern United States), evidence of an ability to disperse to some degree so as to maintain specific integrity.

**GENERAL BIOLOGY**

The biology of zorapterans is poorly documented. Only three species have been studied and only one, Z. hubbardi, generated a sizeable literature. Species are gregarious with colonies consisting of 15–120 individuals in relatively ephemeral, subcortical habitats. Colonies occur in logs (or man-made sawdust piles) but only after wood decay is well progressed. Zorapterans feed principally on fungal hyphae and spores, although they can also be predatory, victimizing nematodes, mites, and other minute arthropods such as springtails.

\(^1\)Extinct group.

**FIGURE 1** (A) Adult female of Zorotypus huxleyi (most legs curled under body), blind–apterous morph. (B) Alate female of Z. goeleti\(^1\) in Miocene amber from the Dominican Republic. (C) Hind leg of Z. huxleyi depicting femoral and tibial spines. (D) Alate of Z. nasutus\(^1\) in Cretaceous amber from Myanmar, with wing veins labeled. [Reproduced, courtesy of the American Museum of Natural History, from Engel and Grimaldi (2002).]
(Collembola). The number of nymphal instars is estimated to be either four or five. Captive individuals live up to 110 days.

Individuals occur in two morphs. Blind, wingless individuals predominate during the general life of a colony, whereas dispersive individuals (with eyes and wings) are generally rare and are produced as resources become depleted and the colony becomes crowded. Winged females are more common than winged males, suggesting that females perhaps mate prior to dispersal. After arriving at a new log, individuals shed their wings and dealated individuals are often found in young colonies. Wide distributions for some species as well as the presence of species endemic to distantly isolated islands such as Christmas Island, Fiji, and Hawaii are evidence for their dispersal abilities.

**BEHAVIOR**

Although Zorotypus species are gregarious and live in small colonies, they evidently do not distinguish between individuals from the same colony and introduced vagrants. Isolated individuals do not survive.

Zorapterans spend much of their time grooming either themselves or other individuals. Grooming may be a way of removing fungal pathogens and this may be important for their colonial lifestyle. Most of the movements in the grooming repertoire are found in other insect orders but some are unique to zorapterans. Most notable are the movements associated with the cleaning of the posterior sterna, the cerci, and the genital–anal area using their mouthparts. This complex action involves the raising of the body on a four-point stance, with both anterior and posterior ends of the body bent downward (perpendicular with the substrate) to meet under the insect and between the middle and the hind legs.

Females mate multiple times (with up to eight mates) and with multiple males (up to three multiple matings). Prior to copulation, zorapteran species have complex courtship behaviors which appear to be species specific. The process is begun by the male who strokes the female with his antennae. If the female reciprocates with similar antennal signals, the male initiates courtship displays during which his head and a portion of his neck are extended. If the female approaches, the male secretes fluids from a cephalic gland, which she ingests while the male and female bend their abdomens toward one another. Copulation is initiated by the linking of the male to the female via a hook located medially on his 10th abdominal tergum (females have a small groove into which the hook is placed on their eighth sternum). Once the hook is coupled with the female, the male inverts himself, assuming an upside-down position and facing away from the female.

**ECONOMIC IMPORTANCE**

Although zorapteran colonies at times can be found in wood or sawdust piles at lumber yards, owing to their relatively minute colony sizes, general scarcity, and apparent minimal ecological impact, it is unlikely that they will ever be considered of any economic importance. If the fragmentary reports of wood ingestion by zorapterans are confirmed as well as studies of their gut fauna (bacteria, protozoa, etc.) undertaken, then the economic role of Zorotypus might be reevaluated.

**Zygentoma**

(Thysanura, Silverfish)

Helmut Sturm

University of Hildesheim, Germany

The Zygentoma (Thysanura sensu stricto) are medium-sized apterygote insects with a body length from 5 to 30 mm. Their body is flattened and the eyes are small or absent. There are no ocelli except for the Lepidothrichidae, which has three ocelli. The flagellate (whiplike) antennae can be short (e.g., in Ateluridae) or much longer than the body (Fig. 1). The mouthparts are ectognathous. The mandibles are dicondylic (have two rotation points) and the maxillary palps have five segments that are of normal length. Nearly all parts of the body and appendices bear bristles of different length and structure. Scales are present on the thoracic segments of Lepismatidae and Ateluridae, but lacking in the three other families.

![FIGURE 1](image-url) Male (above) and female of Thermobia domestica during premating (passing-by behavior), vertical view. In this phase the antennae and the cerci are in contact; body length about 12 mm.
All Zygentoma are able to run quickly, but they cannot jump as do the Archaeognatha. The coxae of all legs are large and flattened. The penis of males is situated on abdominal segment 9; on the hind end, three caudal appendages are present as in the Archaeognatha. Molting continues in adults. Some species of the family Lepismatidae (e.g., Lepisma saccharina, Thermobia domestica, Acrotelsa collaris) prefer to live in human houses.

FOSSIL RECORD, SYSTEMATICS, BIOGEOGRAPHY

The oldest fossils that are clearly Zygentoma were found in Mesozoic layers (Lower Cretaceous) of Brazil. From the Cenozoic on, there are many Zygentoma fossils, and most of them are amber inclusions. Nearly all of them are similar to extant taxa (e.g., Ctenolepisma, Nicoletia, Lepidothrichidae). However, there are representatives of apterygote Hexapoda from the Paleozoic (e.g., Monura and Cercopoda) that cannot be included in extant orders. The Zygentoma comprise 5 families and some 400 species in about 90 genera.

1. **Lepismatidae** This largest family includes the well-known silverfishes, some of which occupy human houses. This family is the richest in genera (more than 21) and species (>200).

2. **Nicoletiidae** Relatively small and slim, and without dark pigment, eyes, and scales, they live in the upper layers of soils within the humus layer or beneath stones. Some species or populations reproduce parthenogenetically. More than 10 genera and more than 30 species are known.

3. **Ateluridae** Small, blind, and of droplike form, apparently all species in this family are commensals with ants or termites. There are more than 10 genera and more than 30 species.

4. **Lepidothrichidae** There are two species: *Lepidothrix pilifera*, which is known from Baltic amber, and the extant *Tricholepidion gertschi*, which occurs in forests of northern California (Fig. 3).

5. **Maindroniidae** There is one genus and three species from the Middle East and Chile; their habitat is somewhat similar to that of the Nicoletiidae.

The Lepismatidae and Nicoletiidae are distributed worldwide. Some Lepismatidae are household pests: *L. saccharina* in northern Europe; *A. collaris* in the tropics; and *T. domestica* in the United States (Figs. 1 and 2). In southern Europe, *L. saccharina* and other lepismatid species also live outside houses. In Africa, Lepismatidae occur in areas with sand dunes. Nicoletiidae are found up to 3000 m elevation in Colombia and enter the northern parts of Europe via transport of potted plants to greenhouses. The distribution of Ateluridae coincides fairly well with that of ants and termites. The distribution of Lepidothrichidae and Maindroniidae appears quite restricted.

Their relatively flat body form enables the Zygentoma to enter small fissures. The Nicoletiidae are especially well adapted to the upper layers of the soil, whereas Lepismatidae generally rest in fissures during the day and are active during the night. If the relative humidity is above 50–60%, Lepismatidae can absorb atmospheric water by means of the anal sac (part of the hindgut).

PHYSIOLOGY AND DEVELOPMENT

As in Archaeognatha and in other orders of apterygote insects, the cuticle of Zygentoma is mainly thin and flexible. The mandibles present an intermediate form between monocondylic and a typical dicondylic structure. The Lepismatidae eat plant material and detritus; *L. saccharina* is able to digest cellulose by the cellulase produced in its midgut.

Development has been studied mainly on Lepismatidae (especially *L. saccharina*, *T. domestica*, and Ctenolepisma spp.). The eggs of *T. domestica* are of oval form with a largest diameter of about 1.2 mm, and are laid underground. At a temperature of 37°C, they need 12–16 days until eclosion. In *L. saccharina*, egg development lasts about 35 days at temperatures near 20°C. The first free-living developmental stage possesses an egg tooth on the front of the head, and the first three stages lack scales. The molting intervals are dependent on age, temperature, loss of scales and/or appendages, species, and even population. At temperatures of about 40°C, *T. domestica* molts in 9- to 11-day intervals. The life span of *L. saccharina* is up to 3 years, whereas that of *Thermobia* is about 2 years.

EVOLUTIONARY ASPECTS

With flattened form, the Zygentoma are adapted to small fissures in soil, detritus, or in houses. The Lepismatidae leave those places...
Zygentoma
during night to find food, favorable conditions (e.g., high relative humidity), and members of the same species for mating. In contrast with the Archaeognatha, their food use is broad. Lepismatidae have been spread widely by humans. For example, of the 13 lepismatid species in the United States, only 3 are believed to be native. In comparison to the Archaeognatha, the Zygentoma show a great adaptability in terms of the different habitats they live in and the astonishing adaptation of the Ateluridae, which live with ants and termites. They possess some morphological structures that correspond to the Pterygota: a special form of mandibles; maxillary palps smaller than thoracic legs; an abdomen with tracheal commissures and connections; and an ovipositor base with well-developed gonangulum. Apparently, however, they are not the ancestors of the Pterygota. Because of the crosswise joining of abdominal terga with correspondent coxites (a unique apomorphy within the Hexapoda), the possession of 11 abdominal segments, styli on abdominal segments, eversible vesicles, three abdominal appendages (filum terminale and two cerci), and the structure of the ovipositor, the Archaeognatha and Zygentoma are obviously linked. However the “jump” from Apterygota to Pterygota probably was from a line separate from the Thysanura.

GLOSSARY

The following glossary defines approximately 800 specialized terms that are found in the articles in the Encyclopedia of Insects. The authors of this encyclopedia have defined these words as they are used in their articles, for the benefit of readers who may not be familiar with the technical vocabulary of insect study. As the name indicates, the glossary is a compendium of the terminology of this particular encyclopedia. It is not a general dictionary and therefore does not include all possible entomological terms that a reader might encounter in other publications.

accessory gland  Any secondary gland of a glandular system.
accessory pulsatile organs (APOs) Very small muscular pumps and veins that direct hemolymph into appendages such as wings and antennae.
acclimation  A process of adjustment to survival at temperatures that are normally lethal.
acetylcholinesterase (AChE) The enzyme responsible for breaking down the neurotransmitter acetylcholine (ACh) at nerve synapses, thereby preventing hyperexcitation of cholinergic pathways in the nervous system. This enzyme is the major target of organophosphate and carbamate insecticides.
acrosome  The anterior portion of the differentiated spermatozoa that assists in the penetration of the egg membrane.
across-fiber pattern code  An often complex code in which each of several cell types sends a message about a single stimulus to higher processing centers. The stimulus may contain one or more than one type of chemical.
aculeate  Any member of a group of families that includes the familiar stinging ants, bees, and social and hunting wasps (e.g., splanids, eumenids, scoliids, pompilid spider wasps). Aculeates are largely characterized by their stinging apparatus, which is derived from the ovipositor of their ancestors but is no longer used for laying eggs.
acylurea  A class of insect growth regulators, including diflubenzuron.
adaptive immunity  A host defense mechanism that is specific for an epitope; it involves B and T cells and exhibits memory.
adaptive radiation  Diversification of species within a lineage associated with ecological change.
adipocytes (trophocytes)  The major cell type of the insect body that accumulates and stores reserve nutrients such as lipids, glycogen, and proteins used primarily during molting, metamorphosis, flight, and oocyte formation. These cells are actively involved in intermediary metabolism and play a crucial role in regulating blood proteins (enzymes), lipids, and carbohydrates. A fundamental function of adult adipocytes is the synthesis and release of vitellogenins (yolk proteins) taken up from the hemolymph by developing oocytes.
adipokinetic hormone (ADK)  A hormone involved in promoting fat metabolism.
aedeagus  The sclerotized terminal portion of the male genital tract that is inserted into the female during insemination.
aerobic  Using molecular oxygen as an electron acceptor; pertains to organisms or metabolic processes.
agent  An organism that can infect a larger organism in which it may cause a specific disease.
alary muscles  Muscles of the dorsal diaphragm that sometimes participate in hemolymph movement in and around the pericardial sinus of the abdomen.
alata  The parthenogenetic winged morph of viviparae, specialized for migration; among dioecious aphids, alatae-terminals emigrants fly from the primary to the secondary host each spring.
alate  1. Winged; having wings. 2. An adult individual with fully developed wings.
allele  Form of a gene. Genes are considered allelic when they occur in the same position on members of a chromosome pair.
allochemical  A nonnutritional chemical produced by one species that affects the growth, health, behavior, or reproduction of another species, e.g., phytochemicals that function in plants as defenses against herbivores or pathogens.
allegory  An antigen that induces an allergic reaction.
allometric growth  A pattern of growth in which a body part grows at a rate different from that of other body parts or the body as a whole. Allometry can be measured within an individual over the course of its development, and also between individuals. Isometry is a special case of allometry in which the relative sizes of two or more structures are constant within or among individuals.
alomone  An allochemical that benefits the producing organism and harms the receiving organism, such as chemicals produced by a stink bug to protect it against natural enemies.
alloparent  An individual that assists the parents in care of the young.
allozyme  A particular variant of an enzyme.
alternative splicing  The ability to create two or more types of proteins from the same (eukaryotic) gene, by selective inclusion or exclusion of exons from mature messenger RNA, whereby regulatory interactions between genes result in great diversity of proteins from the same group of genes and alternative developmental pathways.
altruism  An organism’s behavior that does not directly benefit itself but contributes to the welfare of others within the family group. Associated with kin selection in eusocial insects.
ametabolous  Characterized by no significant metamorphosis. The immature body form does not differ from the adult, except for external genitalia, and the number of stages is variable.
anaerobic Not using molecular oxygen as an electron acceptor; pertains to organisms or metabolic processes.

anaerobic flagellates The heterogeneous assembly of phylogenetically ancient protozoa (archaezoa) that is found exclusively in the hindguts of termites and wood-feeding cockroaches.

anchialine Relating to surface and underground habitats associated with coastal ponds that have only underground connections to the sea.

anemotaxis Directed orientation with respect to wind, usually involving walking or flying in an upwind direction.

anholocyct The asexual reproduction of parthenogenetic viviparous aphids, wherein oviparae, males, eggs, and fundatrices are omitted in a nonrecombinant lifestyle.

anisogamy A condition in which the female sex cells (ova) are larger than the male sex cells (sperm).

Anopheles A genus of mosquitoes (order Diptera, family Culicidae) that contains 422 species, of which 40 frequently may be involved in the transmission of human malaria.

anopheline mosquito A mosquito classified in the family Culicidae, subfamily Anophelinae. The important genus Anopheles is in this subfamily.

anoxic Devoid of molecular oxygen; describes the oxygen status of an environment.

antifeedant A chemical, often toxic, that prevents or reduces feeding.

ant-tending The activity of ants resulting in the consumption of honeydew produced by the tended insects. Also, ant attendance.

aphidophagous Feeding on aphids.

apitherapy Medicinal use of the honey bee or its products.

Apocrita The Hymenoptera with a wasp waist (i.e., the sister group to the Orussidae), which comprises the majority of species in the order.

apoplysia Separation of new and old cuticle caused by release of ecdysteroids at the beginning of each molt.

apomixis Parthenogenesis in which eggs are produced without meiosis.

apomorphous Describing a novel character evolved from a preexisting character.

apomorphy (-ic) A feature of an organism in the derived state, contrasted with an alternative one in the ancestral (primitive) state—a plesiomorphy (-ic). For example, with the character of forewing development, the sclerotized elytron is an apomorphy for Coleoptera, and the alternative, a conventional flying forewing, is a plesiomorphy at this level of comparison.

aposematic signals Conspicuous visual, acoustic, olfactory, or behavioral warnings displayed by an animal to advertise its noxious or dangerous properties. Aposematic colors are contrasting patterns of reds, whites, oranges, yellows, or blacks; sounds are usually generalized hisses or stridulatory squeaks that have low complexity and a wide range of frequency emissions; odors are strongly apparent to most organisms and are distinct from common odors; behaviors are obvious jerks, wing flicks, or accentuated movements.

apostatic selection Evolutionary selection force that confers protective advantage to individuals within a population that have rare color or pattern relative to the others.

aptera The parthenogenetic wingless morph of viviparae, specializing in reproduction.

apterous 1. Wingless; without wings. 2. Describing an individual lacking wings altogether.

aptery A state of winglessness.

apterygote 1. Primitively wingless. 2. Insect orders without wings.

arboreal nest A nest built in a tree or shrub.

archedictyon The primitive original vein network characterizing the wings of many of the most recent insect fossils.

arolium Inflated pad on the tarsus of thrips.

arrenotoky The process of producing males from unfertilized eggs.

arthropod vector An arthropod, such as an insect or tick, that can biologically or mechanically transmit an animal disease agent from one vertebrate to another.

artificial honeydew A sugar-containing solution sprayed onto plants with the aim of attracting natural enemies of homopteran insect pests.

artificial selection Selective breeding under laboratory conditions to change a trait. Such selection may be unidirectional or bidirectional; in bidirectional selection some metric is both increased and decreased by appropriate breeding.

arylphorins Storage proteins, rich in aromatic amino acids, that are synthesized in the fat body, stored in the hemolymph, and utilized for cuticle synthesis in connection with a molt.

attabiote Living above ground.

ATPase An enzyme that cleaves adenosine triphosphate (ATP) and uses the energy derived from this cleavage to drive further chemical reactions. With respect to excretion, ATPase refers to proteins that drive ion transport across cell membranes.

autocidal control The use of insects to control wild-type populations of the same species.

autococious See monoecious.

autogeny The ability to produce eggs without feeding as an adult. Species that can reproduce only in this way have obligate autogeny; species that can produce eggs with or without feeding have facultative autogeny. The opposite condition is called anaautogeny.

automixis Parthenogenesis in which eggs undergo meiosis.

bacillus Bacterium with a rod shape.

balancer chromosome A chromosome with multiple inversions that suppresses recombination.

balooning Aeronautical dispersal by means of air currents acting on straws of silk.

Batesian mimicry A parasitic relationship, named after Henry Walter Bates (1862), in which an undefended (e.g., palatable) species copies the signal of poisonous or otherwise defended species in order to deceive the receiver.

behavioral ecology The study of movements and activities of animals as they relate to interrelations with other organisms and the environment.

behavioral fixity Principle stating that the behavior, ecology, and climatic preferences of fossil organisms will be similar to what is found in their present-day descendants at the generic level; used in reconstructing the behavior and ecological preferences of extinct organisms.

benthic Bottom-living organisms in streams or lakes, including biota that ranges from bacteria to algae to invertebrates to fish.

Bergmann’s rule The principle that individuals within a species should grow larger in size at higher latitudes (and altitudes)
to reduce heat losses by increasing the ratio of surface area to volume.

bioassay (biological assay) The measurement of a biological response (e.g., mortality) to different concentrations of a biologically active compound, using standardized conditions in the laboratory or field.

biodiversity (biological diversity) The variation in all living organisms from gene to ecosystems.

biological amplification The increase in concentration of chemical compounds in higher trophic levels (e.g., predators) of a food web.

biological control The use of living organisms, parasitoids, predators, pathogens, and competitors to suppress pest populations below levels that would occur naturally. Biological control programs are intended to suppress invasive species through importation of specialized natural enemies that have evolved with a pest in its native range.

bioluminescence The production of light by living organisms.

biomonitoring The systematic use of living organisms or their responses to determine the quality of the environment.

biornomics Study of the life history and habits of a species. Often used as a synonym of ecology.

biotype A distinct strain of a species.

bivoltine Describing a life cycle with two generations a year.

blastoderm A one-cell-thick layer of cells surrounding the yolk.

blastomeres The embryonic cells produced during the process of cleavage.

book lungs Respiratory pouches of arachnids, filled with closely packed sheets of tissue to provide maximum surface for aeration.

Brachycera The so-called “short-horned” flies, characterized generally by short, three-segmented antennae, the last segment of which is either stylate or aristate, and by larvae that usually have a reduced head capsule.

brachyptery (-ous) The condition of having shortened wings, whose function in flight is lost.

brood The immature members of a colony collectively, including eggs, nymphs, larvae, and pupae.

brood cell A chamber or pocket built to house one or more immature individuals.

bursa copulatrix An accessory structure in the female reproductive tract of some insects that temporarily accepts the spermaphore or sperm from the male.

Ca\(^{2+}\) signaling Changes in the intracellular calcium (Ca\(^{2+}\)) concentration, through the release of Ca\(^{2+}\) ions from intracellular stores by the opening of ligand-gated ion channels or the entry of Ca\(^{2+}\) ions into the cell through different types of Ca\(^{2+}\)-selective channels located in the plasma membrane, which play a role in the regulation of various cellular processes, including cell metabolism, gene expression, cytoskeletal dynamics, and neurotransmission.

caste Any set of individuals in a colony that are morphologically distinct and/or that perform a specialized task.

cauda A specialized process on the tip of the abdomen; used to flick away honeydew waste.

cavernicole An organism that lives in caves and other cave-like subterranean habitats.

ceca Outpocketings of the midgut epithelium. The cecal cells are often differentiated from the other midgut cells both histologically and functionally.

cecidium plural, cecidia. Technical term for plant gall, an abnormal growth of plant tissue under the influence of a parasitic organism; thousands of insect species induce these growths on a variety of plant species and plant parts.

cecidogenesis The mechanism of instigating physiological changes in host plant tissue to form a gall; this begins with a chemical stimulus passed from insect to plant either at the time of oviposition or as the growing larvae feed upon the plant.

cecidology The study of plant galls and gallmaking.

center of mass The point in a body or system of bodies about which mass is evenly distributed.

center place foraging The process whereby an animal searches for a resource (usually food) starting from a more or less permanent location to which the animal returns after searching is complete.

cephalothorax United head and thorax of Arachnida and Crustacea.

cercus plural, cerci. Simple or segmented appendages of the 11th abdominal segment of insects that usually act as sensory organs; often called “forceps.”

chaetotaxy The arrangement and nomenclature of the setae or bristles on the exoskeleton of an insect.

Chelicerae singular, chelicera. Jaws, each comprising a large basal part and fang.

chemoautotrophic Relating to the ability of an organism to obtain its nourishment through the breakdown of inorganic chemical compounds rather than through photosynthesis.

chemoreceptor Either the chemosensillum (preferably called the “sensillum”) or the receptor protein on the sensory cell membrane.

chemotransduction The process leading from a chemical recognition signal (molecular interaction) to a depolarization of a sensory dendrite. This involves an amplification step that allows a small number of stimulus molecules to yield a large cellular response, thus increasing sensitivity.

chitin A polysaccharide that serves as the major fibrous component in insect cuticle.

chitin synthase A membrane-bound enzyme that polymerizes N-acetyl-d-glucosamine units into a straight-chain amino sugar homopolymer. The protein has a large number of transmembrane segments that may be involved in translocation of the chitin polymer across the cell membrane.

chlorinated hydrocarbons Organic compounds containing chlorine, hydrogen, and occasionally oxygen and sulfur. The first widely used synthetic organic insecticides.
chorion A complex set of eggshell layers produced by follicle cells toward the end of egg maturation.

clad A hypothesized monophyletic group, i.e., a group of related taxa that includes all descendants of a common ancestor.

cladogram A diagrammatic illustration of the branching sequence of purported relationships of organisms, based on distribution of shared derived features (synapomorphies).

clothrin lattice A honeycomblike structure that adheres to the cytoplasmic face of a cellular membrane, where it folds inward and forms a vesicle.

clavus In a neopterous wing without an expanded anal fan, the area between the claval furrow and the jugal fold.

cleptoparasite An insect that feeds on the food resources or uses the nest of another species.

coadapted genetic system The entire set of interacting genetic factors of an organism.

cocoon A part of the nervous system that drives the extracardiac pulsations.

cold hardening An increase in cold tolerance, usually achieved by exposure to a moderately low temperature.

cold hardness The ability to survive subzero temperatures.

colleterial glands In females, accessory glands that secrete fibrous proteins to fasten eggs to a support; in males, accessory genital glands.

colulus A slender or pointed appendage immediately in front of the spinnerets of some spiders; in others it is greatly reduced or seemingly missing; a homologue of anterior median spinnerets or cribellum.

comb A layer of more or less regularly arranged, closely packed brood cells.

commensalism A form of intimate interaction between members of two different species. One partner of a commensal relationship benefits from the association but the other partner neither benefits nor is harmed during the interaction.

community Populations of different species that coexist and interact with each other in a defined area.

competition An interaction between two or more organisms or species that utilize the same resources, in which the presence of one reduces the birthrate or increases the death rate of the other.

competitive exclusion The elimination of one species from an area of habitat due to competitive interaction with another species.

complementary foods Foods that individually are nutritionally unbalanced, but when combined can provide a balanced diet.

complete (holoblastic) cleavage A coordinated series of mitotic divisions wherein the entire volume of the egg cytoplasm is divided into numerous smaller cells that are fully separated from one another and that together comprise a morula.

compound eye A photoreceptive unit functioning through combined action of two or more ommatidia, each consisting of a convex corneal lens, variably shaped crystalline cone, distal pigment-screening cells, composite rhabdom, and retinular cells.

conductor Semimembranous structure in male palp that supports and guides the embolus in insemination.

condyle Any process by means of which an appendage is articulated into a pan or cavity.

convection The bulk movement of a fluid (either gas or liquid) driven by a physical pressure gradient.

copal Semifossilized (subfossil) resin ranging from several years to thousands of years old with a melting point under 150°C, a hardness of 1 to 2 on the Mohs scale, and a surface soluble to organic solvents.

copulation The period or process during which an intramittent organ (almost always of the male) introduces gametes into a reproductive tract of the opposite sex.

cordon sanitaire Literally, sanitary rope; a line of guards stationed to prevent communication with an infected district.

cornicles See siphunculi.

corpora allata singular, corpus allatum. The pair of endocrine glands that make juvenile hormone.

corpora cardiaca singular, corpus cardiacum. A pair of endocrine glands closely associated with the aorta just behind the brain and connected to it by nerves.

coupling A term for processes and structures that convey mechanical events in the environment to the sensitive plasma membrane of a mechanosensory neuron.

courtship Traditionally viewed as communication between the sexes that brings about successful copulation. However, given that communication during copulation may influence fertilization success, courtship can in theory occur anytime during mating.

coxites Flat appendages on the abdominal sterna, often bearing styli and exsertile vesicles.

critical daylength The daylength marking the transition between a daylength that elicits diapause and one that promotes nondiapause development.

critically endangered Synonymous with endangered; a designation used by the International Union for Conservation of Nature and Natural Resources.

critically imperiled Synonymous with endangered; a designation used by the U.S. Natural Heritage Program.

cryoprotectants Low-molecular-weight polyols and sugars that act as classic antifreezes and thus function to depress the insect’s supercooling point.

crypsis Camouflage of color and pattern or of odor such that the individual blends into the background environment and is not readily detected by predators.

cryptobiosis Complete cessation of active life processes that gives hardness to extreme conditions of heat, cold, or drought.

cryptonephric complex A structure in which the distal ends of the Malpighian tubules are closely associated with the rectum, and the structure is enclosed within a perinephric space by a perinephric membrane.

culicine mosquito In general terminology, a mosquito classified in the family Culicidae, subfamily Culicinae. In strict usage, a mosquito classified in the tribe Culicini of the subgenus.

cursorial Adapted for running.

cuticle The outer covering of the insect that serves as its skeleton to which the muscles attach. It is secreted by the epidermis and must be shed periodically to allow for continued growth and for the change of form at metamorphosis.

cyclic AMP A cyclic derivative of adenosine monophosphate that is synthesized from ATP by adenylyl cyclase. An intracellular second messenger involved in the regulation or modulation of ion channels, protein kinase activity, and gene expression.

Cyclorrhapha A subgroup of Brachycera characterized by a flagellum of composite first flagellomere and three aristomeres, papation within the cuticle of the last instar (i.e., puparium), and a life cycle including three instars.

cystoblast Egg precursor cell produced mitotically by division of a germ stem cell into another stem cell and the cystoblast.

cytochrome P450 monoxygenases A ubiquitous group of enzymes involved in the NADPH-mediated oxidation and metabolism of a broad range of endogenous and exogenous substrates.
cytokine  A chemical mediator, secreted by blood cells, that acts at close range on other immunocompetent cells.
cytopathology  Pathology of disease exhibited at the cellular level.
daytime dark fly  A member of the family Lampyridae that is sexually active in the daytime and is without light organs as an adult (e.g., Ellychnia, Pyropyga, and some Lucidota).
dealate  1. Describing individuals that have shed their wings in the form of a reproductively active caste. 2. An adult individual that has shed its wings.
debridement  Removal of dead or contaminated tissue from a wound.
decomposer  An organism that feeds on dead organic material.
dendrite  The part of a chemosensitive cell that bears the receptor proteins. It is in close communication with the environment via pores in the sensillum cuticle.
density  The number of individuals of a species per unit of habitat.
density dependence  The tendency for the birthrates or death rates to change as density of a population increases or decreases.
density independence  Factors operating in population regulation that are not related to population density (e.g., climate).
desmosomes  Special contact zones between the cytoplasmic membranes of epidermal cells.
determinate growth  A pattern of growth in which both growth and molting cease upon reaching the adult stage.
detoxification  The fact or process of reducing or removing toxicity. Once insects have entered the body, they may be metabolically altered by enzymes in insects as well as other organisms. Through this process of detoxification, such alterations generally produce less toxic products called metabolites.
detritus  Organic matter of unidentifiable origin.
detritus feeder  An organism that feeds by eating soil or soil particles, from which nutrients are extracted by its digestive system.
diapause  A programmed state of dormancy or arrest of development mediated by the neuroendocrine system, usually occurring in a species-specific stage of the life cycle. It may be induced obligatorily or facultatively in response to seasonal cues (day length, temperature, food quality, etc.).
dicentric  Having two centromeres.
diffusion  The movement of a molecule from high to low concentration driven by random thermal motion.
diflubenzuron  An acylurea insect growth regulator that disrupts formation of normal cuticle via inhibition of chitin synthase.
digestibility coefficients  Coefficients that measure an organism's food input and waste output and thus allow one to estimate how much food was digested.
digestion  The biochemical process by which food is dissolved and converted into compounds that can be absorbed by the intestinal epithelia.
dioecious  A host-alternating aphid life cycle requiring primary and secondary hosts; synonym: heteroecious.
diploid  Having two complete sets of chromosomes (like a typical adult animal).
disruptive coloration  Patterns of coloration that can blur the outlines of a potential prey's body.
dominance hierarchy  A social order of dominance established among individuals of one sex, usually males, by aggressive or other behavioral displays.
dominant (genetic)  The stronger of a pair of alleles, expressed as fully when in single dose (i.e., heterozygous) as it is when present in double dose (i.e., homozygous). The opposite of recessive.
dorsal diaphragm  A complete or fenestrated membrane separating the dorsal vessel in its pericardial sinus from the alimentary canal in its perivisceral sinus.
dorsal vessel  The principal hemolymph pump in the body, consisting of a heart in the abdomen and an aorta in the thorax and head regions.
dosage compensation  Differential regulation of genes found in different numbers (dosages) within cells of males and females, usually because of heterogametic (XY) sex determination.
ductus seminales  A duct connecting the spermathecal sac with the median oviduct.
Dyar's law  An empirical observation that indicates a geometric progression in head width in successive instars of most holometabolous larvae, as proposed by H. G. Dyar in 1890.
Dzierzon's rule  The original term for haplodiploid sex determination in honey bees, as defined by J. Dzierzon in 1845.
ecolytic  The emergence of an insect from its old cuticle during the final stages of a molt.
ecdysone  In the context of hormonal control of female reproduction, one of a group of hormones called ecdysteroids. Synthesized by the prothoracic gland, it is the precursor to 20-hydroxyecdysone.
ecdysteroids  Steroid-molting hormones of insects that are synthesized in prothoracic glands of larvae and in the reproductive organs of adults.
eclosion  The molting of a new adult insect from the cuticle of its preceding stage.
ecological potential  The ability of a species to adjust to environmental factors.
economic loss  For an agricultural crop, the fraction of the realizable yield that is lost to the combined effect of all pests and the physical forces of the environment.
ecosystem  A community of organisms and their interaction with the physical environment.
ectognathous  Having exerted mouthparts.
ectoparasite  A parasite that lives on the surface or within the skin of its host.
ectophagous hyperparasitoid  Hyperparasitoid having larval offspring that feed externally on the primary parasitoid host.
ectoterm  An organism whose body temperature is strongly influenced by the ambient temperature.
ectothermy  The fact of having a body temperature roughly equal to the ambient temperature.
edaphon  An organism living in soils.
effective (physiological) temperature  Temperature permitting development; the sum of effective temperatures equal to the number of degree days needed for completing a certain developmental period.
elateriform  An insect larva with a cylindrical body shape.
elytra singular, elytron  The anterior leathery or chitinous wings of beetles, serving as coverings to the hind wings, commonly meeting in a straight line down the middle of the dorsum in repose.
embutus  A structure in the male palp containing the terminal part of the ejaculatory duct and its opening; it may be small, long, whip-like, or coiled; sometimes divided into several structures.
embryonic diapause The cessation of development in the embryo stage with metabolism markedly reduced.

encapsulation The response of host blood cells, known as plasmacytocytes, to the presence of a parasitoid egg or larvae, which results in the formation of a multilayered capsule that causes the death of the parasitoid through asphyxiation.

encoding The creation of a train of action potentials from a sensory receptor potential.

endangered Referring to species that face a high risk of extinction in the near future unless action is taken to protect them; a designation used by the U.S. Fish and Wildlife Service and International Union for Conservation of Nature and Natural Resources. (A formal listing as endangered or threatened by the U.S. Fish and Wildlife Service is the only designation that provides legal protection to species that are at risk of extinction.)

endemic Restricted to a certain region or part of a region; describing a species found naturally in one area and nowhere else; such species can be neoeンドemics, frequently formed through adaptive radiation, or paleoendemics, formed through genetic isolation from source populations.

endocuticle The thin (but chemically complex) outermost layer of cuticle. The epicuticle is the first layer to be formed and thereafter delimits the space into which the inner procuticle may be secreted.

endoxyly The fact or condition of living within wood.

endophagous hyperparasitoid A hyperparasitoid having larval offspring that feed internally inside the primary parasitoid micro-wasp host.

endoparasite A parasite that lives within the body of its host.

endophagous hyperparasitoid A hyperparasitoid having larval offspring that feed internally inside the primary parasitoid micro-wasp host.

endoplasmic reticulum A system of cytoplasmic vesicles whose functions include collecting newly synthesized proteins destined for secretion from the cell.

endopterygote A complete metamorphosis with egg, larval, pupal, and adult stages.

endosymbiosis An association of organism in which one organism lives within the other; ants, termites, and other wood-feeding insects contain endosymbiotic bacteria that digest cellulose and make it available as food.

endotaxyli The fact of or condition of living within wood.

epicuticle The thin (but chemically complex) outermost layer of cuticle. The epicuticle is the first layer to be formed and thereafter delimits the space into which the inner procuticle may be secreted.

endorrhaphy The formation of vacuoles that transport fluids and solutes into the cytoplasm of a cell.

endoparasite A parasite that lives within the body of its host.

endophagous hyperparasitoid A hyperparasitoid having larval offspring that feed internally inside the primary parasitoid micro-wasp host.

endoplasmic reticulum A system of cytoplasmic vesicles whose functions include collecting newly synthesized proteins destined for secretion from the cell.

endoxyly The fact or condition of living within wood.

enhancer A DNA sequence that recognizes certain transcription factors to stimulate transcription of nearby genes.

enhancer trapping The identification and cloning of enhancer regions through the nearby insertion of a transposable element containing a reporter gene that becomes regulated by the enhancer.

entomopathogenic Causing disease or death in insects.

entomophobia An unnatural and unreasonable fear of arthropods.

envelope A sheath or carton surrounding the combs of a social wasp nest.

epedaphon An organism living on the soil surface and in leaf litter.

epicuticle The thin (but chemically complex) outermost layer of cuticle. The epicuticle is the first layer to be formed and thereafter delimits the space into which the inner procuticle may be secreted.

epigynum A more or less complicated apparatus for storing spermatocysts, immediately in front of the opening of internal reproductive organs of female spiders.

epitope A site on an antigen that is recognized by an antibody or T-cell receptor.

epizootic Describing an outbreak of disease in an animal population.

epoxide hydrolase An enzyme that inactivates juvenile hormone through hydrolysis of the epoxide substituent.

eracliation The application of phytosanitary measures to eliminate a pest from an area.

eruciform An insect larva having a caterpillar-like shape.

essential amino acids Amino acids that contribute to protein and cannot be synthesized de novo by most animals, usually resulting in a dietary requirement for such amino acids.

etiological agent The causative agent of a disease, such as a pathogen, a chemical, or a genetic mutation.

cuedaphon An organism living wholly within the soil, often well below the surface.

cusocial Fully social; a term applied to some species of insects and other animals that live in groups for at least part of their life cycle. Cusocial insects exhibit cooperative offspring care and an overlap of adult generations in their groups, and some individuals (workers) forgo reproduction to help others reproduce.

cutrophic Describing a pond, lake, or other body of water containing a rich supply of plant nutrients.

exocrine secretion An exudate discharged to the exterior from a specialized or exocrine gland that functions as an interspecific (allomone) or intraspecific agent (pheromone).

exocuticle The rigid and sclerotized (chemically stiffened) outer layer of some procuticles. Because of its chemical cross-linking, the exocuticle cannot be resorbed during the molting cycle, but its stability makes it a good candidate for structural color production.

exopterygote A condition in which wings develop externally and increase in size with each molt.

exoskeleton The external skeletal structure typically composed of chitin and often complexed with protein and strengthened with calcium carbonate.

extracardiac pulsations Minute contractions of the abdominal body wall muscles that cause pressure pulses in the hemolymph, which moves hemolymph around organs and aids in ventilation.

F

facultative diapause A form of diapause that occurs in response to specific environmental cues that have been received.

facultative hyperparasitoid Hyperparasitoid having progeny that can develop as either a primary parasitoid or a secondary parasitoid.

fang A claw-like part of each chelicera, usually with a groove down which venom and digestive juices can flow into prey.

fat body A structure within the cockroach body that contains stored nutrients, uric acid, and endosymbiotic bacteria, each housed in a different cell type.

feeding guild A group of organisms that exploit a resource in a similar manner (e.g., sap-feeding, leaf-chewing, leaf-mining).

filarial nematode Characteristically long, thin, unsegmented roundworms that live everywhere in vertebrates, with the exception of the lumen of the digestive tract.

filter chamber Anastomoses of the foregut and proximal rectum in many (but not all) honeydew-producing insects.
filter feeding  The process of acquiring food by straining small particles from the air or water column.
flagellum  The third (most distal) segment of an insect antenna.
flash pattern  The species-typical unit of light emission of “lightning bug” fireflies that is repeated at somewhat regular time intervals by advertising, mate-seeking males; commonly it is the flash pattern that stimulates the female response flash.
flexion lines  Lines or bands of flexible cuticle within the wing, primarily adapted for deformability in flight.
fluorescence  The process by which a material is able to absorb light of a particular wavelength and re-emit the energy in the form of longer wavelength.
focus (nidus)  A place in the environment where ecological conditions ensure the perpetuation of a zoonotic disease agent for an extended period of time.
fold lines  Lines or bands of flexible cuticle, primarily adapted for folding the wing at rest.
follicle cells  Cells not derived from germ cells that cover oocytes and contribute to their development.
follies  Sperm tubes in the testes in which spermatogenesis occurs.
formulation  The form in which an insecticide is applied; the most common formulations are sprays, dusts, and baits.
fossorial  Of a limb, body part, etc., adapted for digging or burrowing through soil.
founder event speciation  Mode of speciation generally associated with island biotas; a small number of individuals, perhaps even a single fertilized female, colonize and become established on an adjacent island or in a geographically isolated habitat.
fragment island  An island formed as a result of separation from a larger landmass.
frass  Solid excrement from an insect, often containing undigested plant or wood parts.
frequency-dependent selection  Selection that is positively or negatively dependent on the frequency of phenotypes in the population. It is negative when phenotypes that are rare are favored (leading to stabilizing selection and monomorphism) and positive when phenotypes that are rare are disfavored (leading to stabilizing selection and monomorphism).
fumigant  A volatile chemical that acts as a poisonous gas in flight.
functional response  The relationship between the quantity of food available to an organism and the quantity actually eaten.
fundatrix  The parthenogenetic morph that hatches in the spring from the recombinant egg and gives rise to the viviparae; synonym stem mother.

GABA  γ-Aminobutyric acid, a naturally produced inhibitory neurotransmitter that acts on its specific receptor, the GABA receptor, to suppress excitation by opening a chloride channel.
gallmaker  The organism that induces the host plant to form the gall structure, which includes an excess of protein-rich parenchyma upon which the gallmaker can feed.
gametoctyes  Infective haploid blood stage of the malaria parasite acquired by mosquitoes during blood feeding. Sexual union of micro- and macrogametes occurs in the midgut of the definitive mosquito host.
gap genes  Genes expressed in broad domains in the Drosophila embryo; mutations in these genes cause large deletions of the body plan.
gene  The unit of heredity.
gene tagging  The identification and cloning of a gene based on the insertion of a transposable element that inactivates it or alters its expression.
genetic marker  A gene that enables one to detect a transgenic individual. The marker gene is located within the gene vector, usually a transposable element, and its expression indicates that the vector has inserted it into the target DNA.
genetic polymorphism  The occurrence together of two or more discontinuous and heritable forms of a species at such frequencies that the rarest of them may not be maintained merely by recurrent mutation.
genetic sexing  The selective production of one sex over the other as a direct consequence of a genetic difference between them.
genetic transformation  A stable, heritable change in genotype caused by the incorporation of foreign DNA into the genome.
genome  The entire nucleotide sequence of an organism, including the entire set of genes.
genomics  The comparative study of genomes, the entire ensemble of an organism’s genetic material.
genotype  All or part of the genetic composition of an individual or population.
geometagnetic field  A dipolar magnetic field surrounding the earth with poles in the vicinity of the earth’s poles. The field’s lines of force are approximately horizontal in the vicinity of the equator and tilt increasingly upward toward the South Pole and increasingly downward toward the North Pole.
geometagnetic vector  The description of a local geomagnetic field comprising the local total strength of the field, the dip angle (inclination) of its lines of magnetic force relative to the horizontal and the usually small deviation (declination) of these lines of force from true north.
germs anlage  The cluster of cells that forms the embryo proper; the germ anlage represents the ventral surface of the embryo.
germinarium  The distal region of an ovariole, consisting of germ stem cells, young cystoblasts, and precursor to follicle tissue.
germin band  In the blastula, a thickened band of cells that forms the future embryo. The germ band consists of a head, three gnathal, three thoracic, and eight to ten abdominal segments; it has been referred to as the “phylopotypic” stage for insects.
germs cells  Cells that are ancestors of oocytes.
germin-line differentiation  Specification early in the development of testes (spermatogenesis) or ovaries (oogenesis), from a small group of cells in embryos, and subsequent production of mature sperm and eggs.
glowworm  A term historically and currently applied to the north European glowworm firefly, Lampyris noctiluca, but for more than a century used as a general term for worm-like or larviform glowing organisms, including lampyrid and phengodid larvae and larviform females and fungus gnat larvae.
glowworm firefly  A “primitive” member of the family Lampyridae that uses glow signals for sexual communication, typically with glowing females attracting nonluminescent males (e.g., Microphorus, Plecotomus).
gluconeogenesis  A metabolic pathway responsible for the synthesis of glucose from amino acids, lactate, and glycerol.
glutathione S-transferases (GSTs)  Enzymes that catalyze the metabolism of a range of substrates after their conjugation with the endogenous tripeptide glutathione.
glycolysis  The principal metabolic process responsible for oxidation of glucose to pyruvate during cellular respiration.
Gondwanan distribution Having a geographic distribution on more than one of the southern continents that were once united to form Gondwanaland (a supercontinent precursor to current landmasses).

G protein-coupled receptors Integral membrane proteins that constitute a large family of neurotransmitter, hormone, or olfactory receptors. Characterized by seven transmembrane regions. When agonists bind to these receptors, trimeric GTP-binding (G) proteins are activated that then regulate the activity of intracellular secondary effectors, which change intracellular concentrations of second messengers or ion channel activity.

gregarious Liking to be in a crowd. In locusts, this implies that the insects tend to group together spontaneously. Locusts of the gregarious phase tend to be very active and to have conspicuous coloration—black and yellow or black and orange.

gross pathology Pathology of disease exhibited at the level of the whole animal, generally observed externally.

gyne Female reproductives in an insect society.

gynopara The specialized winged vivipara that returns to the primary host in the fall and produces the ovipara.

Glossary

Gonential Referring to the feeding appendages, including the mandible and maxillae.

Golgi bodies Membrane-bound cellular organelles associated with the endoplasmic reticulum; cellular products produced by the endoplasmic reticulum are bound by Golgi bodies possibly for further modification and/or transport.

Gondwanan distribution Having a geographic distribution on more than one of the southern continents that were once united to form Gondwanaland (a supercontinent precursor to current landmasses).

G protein-coupled receptors Integral membrane proteins that constitute a large family of neurotransmitter, hormone, or olfactory receptors. Characterized by seven transmembrane regions. When agonists bind to these receptors, trimeric GTP-binding (G) proteins are activated that then regulate the activity of intracellular secondary effectors, which change intracellular concentrations of second messengers or ion channel activity.

gregarious Liking to be in a crowd. In locusts, this implies that the insects tend to group together spontaneously. Locusts of the gregarious phase tend to be very active and to have conspicuous coloration—black and yellow or black and orange.

gross pathology Pathology of disease exhibited at the level of the whole animal, generally observed externally.

gyne Female reproductives in an insect society.

gynopara The specialized winged vivipara that returns to the primary host in the fall and produces the ovipara.

H

haltére The modified metathoracic wings of the dipteran adult, which are sense organs concerned with the maintenance of stability in flight.

hamulus plural, hamuli Hook-like setae that can allow wings to be temporarily attached.

haplodiploid Describing organisms that have one sex haploid and the other diploid. Haplodiploidy is based upon a sex-determining mechanism by which females develop from fertilized eggs and functional males from unfertilized eggs.

haploid Having one complete set of chromosomes (like a typical egg or sperm cell).

heartbeat reversal During immobile stages or behaviors (e.g., pupal stages), contraction of the dorsal vessel in characteristic peristaltic waves that travel in the anterograde (to the front) or retrograde direction.

heat-shock proteins Stress proteins that are highly expressed in response to heat and other forms of stress and contribute to both high- and low-temperature tolerance.

hematophagous Feeding on vertebrate blood as a food source.

hemidesmosomes Structures that connect the basal cytoplasmic membrane to the basal lamina.

hemiedaphon An organism that completes part of its development in the soil but spends the remainder of its life above ground.

hemimetabolous Describing immature forms that closely resemble the adult form and pass through a fixed number of juvenile instars; the last instar exhibits wing buds and incomplete metamorphosis.

hemocoele The open body cavity of insects and other arthropods through which the hemolymph (blood) circulates.

hemocytes Insect blood cells. The main classes are plasmatocytes, granulocytes, spherule cells, lamellocytes, oenocytes, and crystal cells.

hemoglobin An oxygen-carrying pigment of the blood possessing a high oxygen affinity and occurring in some aquatic insects inhabiting low oxygen environments.

hemolymph The blood of insects that bathes all tissues via an open circulatory system powered by an open tubular heart. It transports all the nutrients and hormones to the cells and removes the cellular wastes.

heterochrony The precocious or delayed appearance of certain features in the ontogenetic development.

heterogeneous See dioecious.

heterogametic sex The sex that carries sex chromosomes of different types and thus produces gametes of two types with respect to the sex chromosome they carry. In humans, males are the heterogametic sex, carrying one X and one Y chromosome.

heterozygote advantage A situation in which the fitness of individuals carrying two different alleles of a particular gene exceeds that of those carrying two alleles of the same type.

hexamerins Abundant proteins in insect plasma, whose main function is storage of amino acids for later use.

Hexapoda A superclass of arthropods containing the Insecta, Collembola, Protura, and Diplura.

higher termites Descriptive term for a family (Termitidae) of Isoptera that lack gut protozoa, instead having bacteria.

histopathology Characteristics of disease observed in specific tissues.

holoblastic cleavage Cleavage in which the entire egg is divided.

holocyclic The seasonally cyclic sexual and asexual reproduction of aphids, in which sexual morphs produce a genetically recombinant overwintering egg.

holometabolous Having complete metamorphosis; having four life stages consisting of egg, larva, pupa, and adult.

homeostasis The maintenance of a steady physiological state by means of self-regulation through feedback.

homeotic genes Genes whose mutations cause transformation of segment identity.

homogametic sex The sex that carries sex chromosomes that are the same. In humans, females are the homogametic sex, carrying two X chromosomes.

homologous Describing or referring to structures or organs derived by evolution from the same ancestral structure.

homology The existence of structures that have a common origin.

homozygote An individual who bears two copies of the same allele at a given locus.

horizon (soil) A layer of soil, roughly parallel to the soil surface, that differs in properties and characteristics from adjacent layers above or below it.

horizontal transmission The transmission of a gene or genetic element from one organism to another by any mechanism other than that normally involved in the inheritance of genetic material by offspring from parents.

host plant The organism upon which a gall grows and from the tissues of which the gall is formed.
humoral immunity Immunity conferred by non-cell-mediated defense mechanisms, with the active molecules being plasma-borne.

humus The relatively stable portion of soil organic matter that remains after the major portions of plant or animal residues have decomposed.

20-hydroxyecdysone The most common biologically active steroid in insects.

hypermetamorphosis Development involving more than one larval stage.

hyperparasitoid A parasitoid that attacks another species that is itself a parasitoid, usually when the latter is feeding with its host. Such species may be detrimental to insect biological control programs.

hypognathous Having mouthparts directed ventrally.

icinculator An agent that facilitates the organization of water molecules into crystals and thus promotes ice formation.

idiobiont A parasitoid whose host is not allowed to develop further after parasitization (e.g., egg parasitoids that complete their entire development within a host egg, larval parasitoids that paralyze their hosts permanently at the time of oviposition).

imaginal discs Clusters of undifferentiated embryonic cells in holometabolous insects that proliferate during larval stages and then differentiate during the pupal stage upon induction by ecdysteroids in the absence of juvenile hormone.

immature Referring to an egg, larval, or pupal stage.

imperiled Synonymous with threatened; a designation used by the U.S. Natural Heritage Program.

indeterminate growth A pattern of growth in which an insect continues to molt after reaching the adult stage.

indirect fertilization The transfer of sperm by means of an externally laid spermatophore.

induced chemical defense Increased production or mobilization of plant allelochemicals in response to some cue (commonly leaf damage) that indicates a high probability of future attack and that is usually absent in unstressed and undamaged plants.

infective juvenile (J3) The third-stage juvenile or filariform larva found within the biting mouthparts of the arthropod intermediate host.

inflammation A localized tissue response to an antigen that is characterized by pain, redness, swelling, and the influx of white blood cells.

injury In this context, the mechanical or physiological effect on a plant of an insect’s feeding, oviposition, excretion, or nesting and sheltering behavior.

innate immunity A nonspecific host defense reaction, such as inflammation, to an infectious agent.

inoculative biological control A form of augmentative biological control in which the goal is to establish reproducibility of natural enemies at the start of the crop.

inquiline A replacement name for permanent parasitism. Inquilines are social parasites that reside entirely within the nest of their host.

insectaries Rearing facilities in which parasitoids and predators are mass-produced, usually for sale as agents for augmentative biological control programs.

insecticide targets Physiologically or biochemically important molecules (such as those comprising ion channels, receptors, enzymes, proteins) and structural molecules (such as chitin) that, when disrupted by insecticide chemicals, cause damage or death to pest insects.

in situ hybridization A technique in which small fragments of DNA are labeled with radioactive or chemiluminescent compounds and used as probes to localize genes or other segments of DNA.

instar The growth stage of an insect between two successive molts.

intake target The optimal nutrient intake over a given period in development that can be represented as a point in multidimensional nutrient space.

integrated Coordinated or harmonious use of multiple approaches to control single or multiple pests.

intensity Intensity of a vibratory signal can be expressed as a displacement (i.e., a vector quantity that specifies the change of position of a body), as velocity (i.e., a vector quantity that specifies rate of change of displacement), or as acceleration (i.e., a vector quantity that specifies rate of change of velocity).

interkernel space An air-filled space between grain kernels.

intermolt A period of feeding and growth; it begins with ecdysis from previous stage and ends with apolysis.

Inter-Tropical Convergence A zone extending across Africa and Arabia along which northerly winds meet (converge) with those blowing from the southwest. Rising air currents along the convergence lead to rain if the converging winds carry moisture, and, if rain occurs at all in the arid regions of North Africa, it is most likely to be along the convergence.

intragenomic conflict A situation in which the action of one gene, by increasing its chances of transmission, is in conflict with the interests of other parts of the genome.

inundative biological control A form of augmentative biological control in which natural enemies are released in large numbers throughout the cropping period, with no expectation that the released biological control agents will establish; pest control is expected from the individuals actually released, not their progeny.

involucrum A sheath of resin and wax surrounding the brood chamber in the nest of most stingless honey bees.

isometric growth A pattern of growth in which a body part grows at the same rate as other body parts or the body as a whole.

ivermectin An oral antiparasitic drug also effective against some ectoparasites.

Johnston’s organ A mechanosensory organ located in the pedicel that responds to changes in antennal position.

jugum The wing area posterior to the jugal fold.

juvenile hormone (JH) One of the two major insect development hormones (the other is ecdysteroid or molting hormone). It is produced by the corpora allata under control of the brain. During larval stages JH maintains larval characters. In the adult it influences egg development and other traits, including migration.

juvenile hormone esterase An enzyme that inactivates juvenile hormone through cleavage of the methyl ester bond, yielding juvenile hormone acid.

kairomone A chemical that is produced by one organism conveying information to another organism of a different species; it is
advantageous to the recipient but detrimental to the producer of the chemical.

karst A landform created by solution of a substrate, usually limestone and other carbonates; characterized by subsurface drainage and fissures, sinkholes, underground streams, and caverns.

key-factor analysis An analytic procedure for identifying the main causes of observed fluctuations in population density.

keystone predator A predator whose activities (or lack of same) determine the species composition of an entire community.

kin selection The principle that reproduction by an individual’s relatives can increase that individual’s genetic representation in future generations, above and beyond its own specific reproductive output. Therefore, adaptations can evolve that favor relatives’ survival and reproduction, as well as personal fitness.

kleptoparasite An individual or species that steals the food resource secured by another. This may be by taking the food away, as with some spider wasps that enter unguarded nest burrows of conspecifics and remove the prey items; another individual has stowed there; or it may involve laying an egg on the food in the nest of another wasp, not necessarily a conspecific, which the kleptoparasite’s larva then consumes.

klinokinesis An undirected change in the turning movements of an organism resulting from the intensity of a stimulus.

koinobiont A lifestyle in which a parasitoid allows its host to continue to feed and/or develop over oviposition, such that its larvae feed on an active host that is killed at a later stage. For example, many endoparasitic larval parasitoids lay their egg into a young host larva (or even egg) but do not complete development until the host has grown, and may be even pupated.

labeled-line code A simple sensory code by which one cell or a single cell type sends a unique message to the higher processing centers.

labellum The apical part of the adult proboscis, comprising the modified labial palpi.

labium The “lower lip” of the insect head.

labrum The “upper lip” of the insect head.

labium The distal median lobe of the insect maxilla.

Lamarckian evolution A theory proposed by Jean Baptiste Lamarck, describing the passing on of an organism’s characteristics to succeeding generations as the result of environmental influence on the organism during its lifetime; a predecessor to the Darwinian theory of evolution.

larviposition The deposition of living larvae that have already hatched inside the female.

latent period The time interval between when a vector acquires a pathogen and when the vector is able to inoculate the pathogen into a susceptible host.

lek behavior A mating system in which assemblages of males defend territories to which females are attracted solely for the purpose of mating.

lerp Sugary and waxy formations made by larval psyllids for their protection.

life cycle The sequence of events in the life of an insect from hatching; immature development up to adult emergence.

life table A summary of the survival rates of individuals in a population to each life stage or age category.

lightning bug flyfirefly A member of the family Lampyridae whose adults use flashes, flickers, or other rapidly controlled bioluminescent emissions for sexual signaling (e.g., Photinus, Photuris).

lignocellulosic diet A diet consisting of wood or other lignified plant materials, whether sound or in different stages of humification.

lineage A clade, or monophyletic group; the group is defined on the basis of definitive derived traits.

lipid A chemically diverse group of molecules that are insoluble in water and other polar solvents.

lipophorin A plasma protein in insect hemolymph that transports lipids between tissues.

locus A site on a chromosome; the term is sometimes also used to refer to the gene itself.

logistic growth Population growth that is influenced by the carrying capacity of the environment.

lower termites A descriptive term for families (Mastotermidae, Kalotermitidae, Termopsidae, Hodotermitidae, Rhinotermitidae, Serritermitidae) of Isoptera that have symbiotic intestinal gut protozoa.

luciferase The generic name given to certain biological catalysts of bioluminescence, which are enzymes that facilitate a light-emitting reaction.

luciferin The generic name given to substrate molecules that are oxidized in many light-emitting reactions.

lumen The open center of a duct.

luminescence The emission of light energy by molecules involving shifting of subatomic particles, contrasting with incandescence.

macroinvertebrate A collective term for aquatic insects and other arthropods without backbones and generally visible to the unaided eye.

macrophyte A large aquatic plant that can occur above, below, or on the water surface.

maggot therapy Therapeutic myiasis; introducing live fly larvae into wounds to treat them.

magnetite A common crystallized ferromagnetic mineral of iron oxide (Fe₃O₄). Submicroscopic particles of magnetite (<100 nm) have been localized in cells of various organisms, from bacteria to pigeons. These particles may implement the sensing of local geomagnetic vectors.

major/minor morphs Forms that result from dimorphism in the size of beetles and the horns and other ornaments on the head and thorax of males.

malaria paroxysm A clinical attack of malaria in a human host; associated with the liberation of parasites from the red blood cells, featuring cold (shivering, lasting <1 h), hot (fever as high as 41°C, 2–6 h), and sweating (fever breaks, temperature drops rapidly to or below normal) stages.

male accessory glands Secretory glands associated with the male reproductive tract that produce seminal fluid and the structural components of the spermatoaphore.

Malpighian tubules Long, narrow outpocketings of the gut; the site of primary urination formation in most insects.

mandibulate Having mandibles adapted for chewing or biting.

mating disruption The application of a formulated pheromone to a crop in order to interfere with mate-finding by a pest insect.

matric potential The application of a formulated pheromone to a crop in order to interfere with mate-finding by a pest insect.

meconium The portion of the total soil water potential due to the attractive forces between water and soil solids.

meconium An accumulation of waste products from the larval stage.
<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>melanin</td>
<td>A black pigment, toxic to parasites and pathogens; formed from the precursors tyrosine and DOPA via the phenoloxidase reaction.</td>
</tr>
<tr>
<td>meristem</td>
<td>Undifferentiated tissue capable of active cell division and differentiation into specialized tissues.</td>
</tr>
<tr>
<td>meroblastic cleavage</td>
<td>Cleavage in which only the nuclear material of the egg is divided.</td>
</tr>
<tr>
<td>metabolic rate</td>
<td>The rate at which an organism converts chemical energy (fuels) into heat. Increased metabolic rate is correlated with greater oxygen consumption and with greater production of carbon dioxide, water, and heat.</td>
</tr>
<tr>
<td>metamere (somite)</td>
<td>A true body segment derived during embryonic development.</td>
</tr>
<tr>
<td>metapopulation</td>
<td>A set of local populations linked together by dispersal.</td>
</tr>
<tr>
<td>microfilaria</td>
<td>The first-stage juvenile in the developmental life history of dog heartworm found in the host’s blood.</td>
</tr>
<tr>
<td>microtubules</td>
<td>Proteinaceous tubular cytoplasmic structures that are part of the cytoskeleton and are involved in force transmission and movements of cell organelles.</td>
</tr>
<tr>
<td>microvilli</td>
<td>Fingerlike projections of cells, bound by the cell membrane and extending outward into extracellular space; usually associated with absorptive or secretory regions to increase the surface area of the cell.</td>
</tr>
<tr>
<td>microwasp</td>
<td>A wasp that is 4–5 mm in length or smaller.</td>
</tr>
<tr>
<td>midgut</td>
<td>A region of the insect gut that lies between the foregut and the hindgut. The midgut is derived from embryonic endoderm. The midgut is the site of food digestion and nutrient absorption in insects.</td>
</tr>
<tr>
<td>mimicry</td>
<td>The close resemblance of insects to different species with the resultant gain of protection by being mistaken for something else that is dangerous, unpalatable, toxic, etc.</td>
</tr>
<tr>
<td>mimicry ring</td>
<td>A group of coexisting species that use the same signal, e.g., a group of unrelated butterflies bearing the same warning coloration. A mimicry ring typically involves one or several models that evolved the signal first and one or several mimics that were later selected to use the same signal as the models.</td>
</tr>
<tr>
<td>mirror</td>
<td>A term for the membranous area whose border is formed by the posterior cubitus vein on the right forewing, serving as a sounding board during stridulation.</td>
</tr>
<tr>
<td>mitochondria</td>
<td>Cellular organelles that, among other functions, produce ATP; the primary energy source for cellular function.</td>
</tr>
<tr>
<td>mode of action</td>
<td>A term for the mechanism by which an insecticide affects an insect.</td>
</tr>
<tr>
<td>mola</td>
<td>Thickened grinding and crushing region at the inner edge of the mandibular base.</td>
</tr>
<tr>
<td>mollicute</td>
<td>A member of a class of bacteria that lacks a cell wall.</td>
</tr>
<tr>
<td>molt</td>
<td>The period during which an insect synthesizes new cuticle and other structures appropriate for the next developmental stage; it begins with ecdysteroid-induced apolysis and ends with ecdysis of old cuticle.</td>
</tr>
<tr>
<td>mononducedylic</td>
<td>Having one condylie (especially on the mandible).</td>
</tr>
<tr>
<td>monoeocious</td>
<td>A nonhost-alternating aphid life cycle that requires a single host; synonym: autoecious.</td>
</tr>
<tr>
<td>monogyne</td>
<td>The presence in the nest of a single functional queen.</td>
</tr>
<tr>
<td>monomorphic/polymorphic</td>
<td>Describing the distribution of body shapes and/or sizes among the members of a social group. If body size variation clusters around a single average value, typically approximating a normal or bell-shaped distribution, and body shapes are isometric, then group members are said to be monomorphic. In polymorphism there are two or more discrete (nonoverlapping) size classes of individuals, or individuals exhibiting differences in body shape.</td>
</tr>
<tr>
<td>monophagous</td>
<td>Specialized to feed and develop on one host plant.</td>
</tr>
<tr>
<td>monophyletic</td>
<td>Referring to a taxonomic group (called a clade) that contains all descendants derived from a single ancestor and recognized by the possession of a shared derived feature(s). For example, the clade Diptera is monophyletic, recognized by shared derived development of the hind wing as a haltere (balancing organ).</td>
</tr>
<tr>
<td>monophyly</td>
<td>The classification or status of being monophyletic (see above).</td>
</tr>
<tr>
<td>morphogenesis</td>
<td>The phase of embryogenesis in which specific tissues, organs, and structures develop.</td>
</tr>
<tr>
<td>Müllerian mimicry</td>
<td>A mutualistic relationship, named after Fritz Müller (1879), in which several prey species, or co-mimics, with anti-predator defenses (e.g., bad taste, toxicity, venom) direct the same signal to the receiver. Despite being mutualistic, Müllerian mimicry is not necessarily coevolutionary and co-mimics do not necessarily benefit equally from the mimicry.</td>
</tr>
<tr>
<td>multivoltine</td>
<td>Describing species that have two or more generations per year. Those that have a single generation per year are called univoltine.</td>
</tr>
<tr>
<td>mutation</td>
<td>Any change in genetic material, though the term usually is used to refer to an error in replication of a nucleotide sequence.</td>
</tr>
<tr>
<td>mutualism</td>
<td>An interspecific relationship in which both partners (symbionts) benefit from the interaction.</td>
</tr>
<tr>
<td>mya</td>
<td>Millions of years ago.</td>
</tr>
<tr>
<td>mycangium</td>
<td>An invagination of the cuticle within which microorganisms are held, facilitating their transfer to uninoculated host substrate.</td>
</tr>
<tr>
<td>mycetocytes</td>
<td>A specialized form of fat body cells harboring symbiotic bacteria that might contribute essential nutrients. Mycetocytes are in proximity to urocytes in the fat body lobe, suggesting a biochemical interaction between the two types of cell.</td>
</tr>
<tr>
<td>mycetophagous</td>
<td>Describing an organism that is fungus feeding.</td>
</tr>
<tr>
<td>myiasis</td>
<td>The invasion of living tissues by fly larvae (maggots).</td>
</tr>
<tr>
<td>myrmeceophiles</td>
<td>Organisms, generally insects other than ants, that live in or around ant nests and that exploit resources from the ants by begging, scavenging, or predation.</td>
</tr>
<tr>
<td>naiad</td>
<td>A term for the larva of the aquatic, hemimetabolous insect orders.</td>
</tr>
<tr>
<td>nasute</td>
<td>A soldier in the family Termitidae that has a well-developed horn-like median projection (nasus) and reduced mandibles. A defensive fluid may be produced and ejected. Soldiers for some species in the family Rhinotermitidae may also produce a defensive fluid from a fontanelle gland on the top of the head, but do not have the horn-like median projection.</td>
</tr>
<tr>
<td>Nematocera</td>
<td>The paraphyletic or grade-level group of so-called “long-horned” flies or “lower Diptera,” characterized generally by long, multisegmented antennae and by larvae with a well-developed, sclerotized head capsule.</td>
</tr>
<tr>
<td>neonates</td>
<td>Newly hatched young</td>
</tr>
<tr>
<td>neopterous</td>
<td>Having a structure that permits folding the wings at rest down to the sides of the body.</td>
</tr>
</tbody>
</table>
Glossary

neosome  An organism altered by neosomy.
neosomule A new external structure resulting from neosomy.
neosomy  The ability to produce new cuticle without molting.
neotenic An individual that retains juvenile morphological features after having reached sexual maturity.
neoteny A condition in which nympha or larval structures are carried over into the adult and the corresponding adult structures are suppressed.
nest  Any modification of the environment by adult insects that provides shelter for the rearing of their offspring.
nestling  A peneblast for a louse egg.
nontarget impact Mortality or injury that may occur to neutral or beneficial species as a consequence of the use of natural enemies in biological control programs or insecticide applications.
nuclear receptors A family of soluble proteins that are mobilized by steroid hormones to coordinate gene expression through direct binding to DNA.
normcritical response An increase in the number of predators or parasitoids in response to an increase in prey density.
nutritional rail A means of representing a food in a nutrient space as a line which moves from the origin into the space.
nymph  The larval stage of hemimetabolous insect orders.

obligate hyperparasitoid A hyperparasitoid that is always a secondary parasitoid; that is, its progeny can develop only on or in a primary parasitoid wasp host.

obligate parasite A parasite that cannot complete development or reproduce without obtaining nourishment from a host animal.

obligatory diapause A form of diapause that is genetically programmed to occur at a specific developmental stage regardless of the environmental conditions that prevail.

osculi plural, oscelli  A simple eye consisting of photosensitive cells and sometimes a single, beadlike lens; multiple ocelli may be present, but their action is not coordinated.

odor-binding protein (OBP) A protein that binds and transports an odor molecule to the receptor protein on the sensory cell dendrite. It is needed to convey the water-insoluble odor molecule across the watery lumen of the sensillum.

oenocytes Special cells associated with epidermis and tracheae. They are involved in synthesis of waxes, such as beeswax and waxes used for waterproofing cuticle and eggshells.

official control A term for the suppression, containment, or eradication of a pest population by a plant protection organization.

oligogyn The presence in a nest of two or more functional queens.

oligophagous Feeding on a few, often related plant taxa, such as different species in one genus or a few genera in one family.

oligosaccharide A molecule composed of 4–20 monosaccharide sugar units.

oligotrophic Describing a pond, lake, or other body of water that is deficient in plant nutrients.

ommatidium plural, ommatidia An individual unit of the compound eye.

oocyte A female gamete or developing egg.
oogenesis The formation and development of the eggs in the female. It includes egg maturation and yolk formation (vitellogenesis).
ootheca A case or other covering of an egg mass that has been laid.

optimal foraging theory A theory that attempts to document the most efficient ways (in terms of evolutionary fitness) for an organism to find food or other resources.

optimal temperature The temperature at which any body performance or activity is most efficient.

orthokinesis An undirected change in speed of movement of an organism resulting from the intensity of a stimulus.

Orthorrhapha A probable paraphyletic subgroup of Brachycera in which the pupae are not enclosed in puparium and in which the sclerotized portions of the larval head capsule are exposed externally.

osmoregulation Control of osmotic pressure or salt and water balance.

osmotic potential The portion of the total soil water potential due to the presence of solutes in soil water.

ostia singular, ostium Valves that can be permanently open or flapped to allow uni- or bidirectional flow of hemolymph into and out of dorsal vessel and accessory pulsatile organs.

ovariole An element of the insect ovary that consists of a tapering tubule in which oocytes are produced.

ovipara The sexual female produced by the viviparae (or gymnoparae) in the fall; oviparae mate with males on the primary host, producing the overwintering genetically recombinant egg.

oviparity Egg laying as the normal means of reproduction.

ovipary Alternate term for oviparity (egg laying).

oviposition The act of laying eggs; the passage of an egg from the median oviduct to outside the insect’s body.

ovispositor The organ by which eggs are deposited.

ovoviviparity The production of well-developed eggs that hatch inside the mother’s body.

ovulation The passage of an egg from the ovariole into the oviduct.

oxic Containing a certain amount of molecular oxygen; describes the oxygen status of an environment.

pair formation The stage before mating during which the sexually receptive male and female are attracted to one another.

pair-rule genes Genes expressed in seven stripes in the Drosophila embryo; mutations in these genes cause deletions in a two-segment periodicity.
Paleoptera  Insect orders that have direct flight muscles and lack the ability to fold their wings over their back while at rest.

paleosymbiosis  Fossil evidence of associations between two different species; this includes paleoinquilinism (two organisms in the same niche but neither benefits nor is harmed by the other), paleocommensalism (one organism benefits, neither is harmed), paleomutualism (both organisms benefit, neither is harmed), and paleoparasitism (one organism benefits by taking nourishment at the expense of the other, which is harmed, often killed).

palp/palpal organs  Variably complex structures found in the terminal part of adult male palp.

pandemic  A disease that affects populations in many countries.

Pangaea  The single continent that existed about 220 mya; about 135 mya, this protocontinent broke up and drifted apart into two pieces, Gondwana to the south and Laurasia to the north.

paracellular permeability  The ability of substances to travel from one side of an epithelium to the other by moving through the spaces between cells.

paracrine  Describing chemical messengers that act on cells in the immediate area without entering the blood.

parameres  Pairs of annulated gonapophyses on abdominal segments VIII and IX or IX.

Paraneoptera  A superordinal group of insects related to the Holometabola and consisting of the orders Hemiptera, Thysanoptera, Psocoptera, and Phthiraptera.

paraphyletic  Referring to a taxonomic group containing a single ancestor and some, but not all, of its descendants.

paraphyly  The status of a group that includes some, but not all, the descendants of a single common ancestor.

parasite  An organism living in a relationship with another organism in which it benefits but the other does not (and typically is harmed).

parasitoid  A specialized form of parasite that develops in or on a host, eventually killing it. Larval parasitoids require one host to complete development. In addition to parasitism, adult female parasitoids can kill hosts through host feeding. Most hosts of parasitoids are other insects, and most parasitoids are in the orders Hymenoptera and Diptera.

paratransgenesis  The process of genetically modifying endosymbionts, which results in the malnutrition and death of the insect that requires them.

parental care  Behavior undertaken by a parent organism that is beneficial to offspring, e.g., in some beetle species the mother remains underground tending the brood mass until development of her offspring is complete.

parental investment  Any behavioral or metabolic investment by a parent that increases the individual offspring's survival at the expense of the parent's ability to benefit other offspring.

parthenogenesis  Reproduction in which eggs develop without fertilization by a male gamete.

pathogen  An organism that causes disease. Viruses, bacteria, microsporidia, and fungi can be pathogens.

pattern formation  The process by which embryonic cells form ordered spatial arrangements of differentiated tissues; during insect embryogenesis, patterning begins with specification of the anterior–posterior and dorsal–ventral axes and ends with the formation of the characteristic structures associated with each segment of the head, thorax, and abdomen.

pattern generation  Control of repeating movements such as walking, wing flapping, swimming, and breathing. The neural circuits that control these behaviors include neurons within the central nervous system that are often influenced by sensory inputs from the periphery.

pedicel  The second segment of an insect antenna.

pedogenesis  Reproduction by an anatomically immature life stage.

pedomorphosis  An evolutionary change in which adults of a later species retain some of the characteristics of juveniles of the ancestral forms.

perimicrovillar membranes  In hemipteran midgut cells, lipid-protein membranes that ensheathe the microvillar membranes like glove fingers and extend toward the luminal compartment; they are apparently involved in amino acid absorption from dilute diets.

peritrophic membrane  A filmlike anatomical structure made of protein and chitin that separates food from midgut cells; it is believed to have evolved from an ancestral nucelus and combines the protection function of this nucelus with several roles in digestion associated with midgut compartmentalization.

permise host  A host insect species in which a parasite or pathogenic organism establishes a successful infection. Species or host strains in which the development of the invader is thwarted by host immunological defenses are nonpermissive.

pest  A general term for any species whose activities interfere in some way with human health, comfort, or profit. In integrated pest management (IPM), a pest can be an insect or other animal, a plant, or a microbial pathogen.

petiole  The slender abdominal segment of Hymenoptera.

phagocyte  A cell that is able to engulf foreign bodies.

phagocytosis  The process of “cell eating,” in which small particles or microorganisms are engulfed by blood cells.

phagostimulant  A chemical that induces and maintains feeding.

phagostimulate  To promote (stimulate) feeding, usually by a nutrient.

pharate  The early period of an instar in which a new cuticle has been formed, and the insect is still enclosed in the cuticle of the former instar.

phenology  The periodicity of life cycle stages in relationship to seasonal occurrences in a given region.

phenotype  The outward appearance of an individual, being determined by its genotype and the influence of the environment on the expression of this genotype.

pheromone  Chemical message released by an individual that induces either a behavioral reaction or a developmental process in other individuals of the same species.

phloem  Active, food-conducting tissue of the inner bark of trees and other woody plants, which with age becomes outer bark. Food is stored in this tissue and is also conducted to the roots for storage.

phosphorylation  Transient, reversible posttranslational modification of proteins in which the terminal phosphate group of ATP is transferred to specific residues of a polypeptide by kinases and often alters the properties of the protein.

photonic crystal  A regular and periodic array that, because of its structure, can impede the propagation (and thus cause the reflection) of some wavelengths of light while allowing the passage of others.

photoperiod  The length of “day,” i.e., photophase, and “night,” i.e., scotophase, usually during a 24-h period.

phreatic  Of or relating to groundwater, specifically the saturated zone below the water table.

phylogenetic  Incorporating the evolutionary history and expressed in ancestor-descendant relationships of a species or taxonomic group.

physiogenesis  A physiological (still unknown) process in the diapause stage that leads to the termination of diapause; sometimes termed diapause development.
phytosanitary regulations  Official rules to prevent introduction and/or spread of pests by regulating the production, movement, or existence of commodities or other articles, or the normal activities of persons.

planidium  The first instar of some hymenopteran parasitoids. Planidial larvae can move about actively because they have hardened integuments and spines.

plasma  The liquid portion of hemolymph, consisting of water and dissolved solutes.

plasmid  An independent, stable, self-replicating piece of DNA in bacterial cells that is not a part of the normal cell genome. Plasmids are commonly used for cloning.

Plasmodium  A genus (order Coccidiida, family Plasmodiidae) that contains 100 species of blood parasites of vertebrates, of which Plasmodium malariae, P. vivax, P. falciparum, and P. ovale cause malaria in humans.

plastron  A structure by which a layer of air is held close to the body and by which gas exchange occurs with surrounding water.

pleisiomorphic  Referring to the ancestral condition of a character state.

pneumonic  Spread from the lungs by coughing and spitting.

poikilothermy  See heterothermy.

polydnavirus  A viruslike entity comprising multiple circular DNA molecules in a protein coat. Polydnaviruses are encoded by the genomes of some parasitic wasps (some ichneumonoids and braconoids), produced in the female reproductive tract, and injected into hosts, where they are expressed and help overcome the host's immune defenses.

polyethism  Caste designation or division of labor in social insects. In caste polyethism, morphological specialization involves different functional castes, whereas age polyethism refers to a change in behavior related to age.

polygenic character (trait)  A trait controlled by the integrated action of multiple independent genes.

polygyny  The presence in a nest of multiple, functional queens.

polymerization  A process by which small molecules (monomers) combine chemically to produce a large network of molecules, or polymers; one of the main processes by which resin becomes amber.

polymorphism  The existence of two or more genotypes for a given trait within a population.

Polyneoptera  A superordinal group of insects consisting of the Plecoptera, Embidina, Zoraptera, Orthoptera, Phasmida, Dermaptera, Gryllloblattodea, Isoptera, Mantodea, and Blattaria.

polyphagous  Feeding on many plant species from a range of families.

polyphenism  The occurrence of alternate phenotypes caused by environmental cues and usually mediated through hormonal signaling. Polyphenisms can occur sequentially as a part of a developmental sequence (larva, pupa, and adult) or alternatively as either seasonal morphs or castes in social insects.

polychelous  Referring to a taxonomic group derived from more than one ancestor and recognized by the possession of one or more features evolved convergently. For example, if the primi-tively wingless silverfish were united with secondarily wingless grasshoppers, beetles, and flies, the resulting group would be polychelous.

polyploid  Having more than two complete sets of chromosomes (e.g., triploid, having three sets; tetraploid, having four sets).

polyploid  Giant chromosomes arising from replication without mitosis, allowing visualization of banding patterns and puffs indicative of transcriptional activity.

population  A particular group of interbreeding individuals more or less separated in time or space from other groups of the same species.

preadaptation  The existence of a preexisting anatomical structure, physiological process, or behavior pattern that makes new forms of evolutionary adaptations more likely.

predator  An organism that attacks and eats another; a true predator is distinct from a parasitoid in that it does not develop on or within the host and usually kills and consumes many prey during its lifetime.

primary host  A term for an aphid's overwintering host, where egg deposition occurs in a dioecious life cycle; usually a deciduous woody angiosperm that was the ancestral host before host alternation was adopted.

primary sex ratio  The sex ratio at fertilization or zygote formation.

proctodeal trophallaxis  The feeding on microbe-rich hindgut fluid solicited from nestmates; found only in termites and wood-feeding cockroaches.

procuticle  The inner layer of cuticle, beneath the epicuticle. In stiffened ( sclerotized) cuticle, it typically consists of exo- and endocuticle, but in flexible cuticle, the exocuticle is not present.

prognathous  Having mouthparts directed anteriorly.

prokaryotes  A collective name for all microorganisms without a true nucleus, comprising the Archaea (formerly Archaeabacteria) and the Bacteria (formerly Eubacteria), which form two phylogenetically independent lineages next to the Eukarya (also, eukaryotes).

prolegs  Unsegmented, false legs, as found in many larval insects.

pronation  A classification of wings; i.e., twisting, anterior margin downward, posterior margin upward.

propagule  The initial group of individuals that found an introduced population.

propolis  Resins collected from plants and used in the nest by honey bees.

prosthecate  Any of a variety of structures—rigid or flexible, simple or complex, lobe-like or setose—arising from the mesal surface of the mandible just distal of the mola.

prothoracic gland  A diffuse endocrine organ in the thoracic area of insects that produces ecdysone, the precursor of 20-hydroxyecdysone.

pseudergate  A caste in some species in the families Termopsidae, Kalotermitidae, and Rhinotermitidae; a nonreproducing and nonsoldier caste that is developmentally very plastic and can do “worker” tasks within colonies.

pseudogamy  A form of sperm-dependent parthenogenesis in which eggs require activation by entry of sperm, but only maternal chromosomes are expressed and passed on.

pseudokarst  A landform mimicking karst in form but created by volcanism or erosion; like karst, drainage is primarily subterranean.

pterogynous  Describing insect orders with wings.

puparium  The sclerotized exuvium of the last instar, within which the pupa ( intermediate developmental stage between larva and adult) is formed.

pyrethroid  An organic synthetic insecticide with a structure based on that of pyrethrum, which is a natural botanical insecticide.
quarantine  A secure importation facility designed to prevent the unintentional release of natural enemy species into new geographic regions after their discovery during foreign exploration.

quarantine pest  A pest of potential economic importance to a given area endangered thereby and not yet present there, or present but not widely distributed and being officially controlled.

quiescence  A forced state of dormancy imposed by an immediate effect of environmental conditions that prevent the normal activity.

resin  A very elastic protein found in insects that is particularly representative of a group of minimally disturbed sites organized by selected physical, chemical, and biological characteristics.

resonance  A condition such that the frequency of an applied force is equal to the natural frequency of a system; the frequency of vibration of a system when the amplitude of vibration is a maximum.

respiration  The collection of metabolic pathways responsible for the oxidation of glucose and fatty acids, with the production of energy involving an electron transport chain.

rhabdome  The rod-like structures that collectively comprise the “retina” of an ommatidium.

RNA interference  The ability of double-stranded RNA to inactivate the expression of the homologous cellular gene.

salivary glands  In mosquitoes and other blood-feeding dipterans, glands located in the thorax of both immature and adult stages. In adult females, the glands are associated with blood feeding. Certain pathogens causing diseases in vertebrates are injected into feeding wounds during blood feeding, thus resulting in a type of transmission known as salivarian.

scape  The first (most proximal) segment of an insect antenna.

scarabaeiform  An insect larva that is grub shaped.

sclerotization  A chemical process in which insect cuticle and other materials are rendered hard, insoluble, dehydrated, and resistant to degradation by the oxidative incorporation of phenolic compounds.

scolopale  A “sense rod,” or minute rod-like structure around the distal end of a sensory neuron.

search imagery  The ability of predators to detect cryptic prey more efficiently by learning to search for potential prey of a specific visual appearance based on color, pattern, size, movement, or location within the environment, often with concurrent emphasis on search in specific habitats and reduction of the search rate.

secondary compound  A toxic or digestibility-reducing compounds synthesized primarily for defense against herbivores. Not involved in the primary metabolic pathways of plants.

secondary host  A term for an aphid’s summer and usually herbaceous host in dioecious life cycles; in secondarily monoeocious aphids it may be the host that remained after the aphid’s ancestors abandoned the primary host.

secondary metabolite  A plant chemical product that is not essential to the basic metabolism of the plant, e.g., phenolic glycosides. Contrast with primary metabolites such as nucleic acids, lipids, proteins, carbohydrates, or ribulose diphosphate. Secondary metabolites may or may not function as allelochemicals.

secondary sex ratio  A change in the sex ratio of a family or population that occurs after fertilization but prior to reproductive maturity of the individuals involved.

secondary sexual traits  Morphological and behavioral differences between the sexes that relate to structures other than the reproductive organs and gametes.

second messenger  An intracellular substance, such as Ca²⁺, cyclic AMP, inositol-1,4,5-trisphosphate, that modifies or modulates cellular responses. Its concentration changes in response to activation of G protein-coupled receptors.

segment polarity genes  Genes expressed in segmental stripes in the Drosophila embryo; mutations in these genes cause deletions and duplications in every segment.

selectivity  The property of given insecticides to selectively affect the target pest species, sparing other organisms collectively called nontarget species.

receptaculum seminis  The spermathecal sac in which sperm are stored.

recessive  Referring to an allele that is not expressed phenotypically when present in a heterozygote, but only when in a homozygote. The opposite of dominant.

rectal pads  Thickened regions of the rectal epithelium in which the cells are specialized for active transport of solutes across the epithelial wall.

reference condition  The environmental condition that is representative of a group of minimally disturbed sites organized by selected physical, chemical, and biological characteristics.

reflex bleeding  The utilization of blood (hemolymph), sometimes fortified with deterrent allomones, as a defensive secretion in adversarial contexts. Reflex bleeders exude hemolymph from weak sutures in the chitin (e.g., at femoral joints). Used by beetles to defend themselves against attack from ants and other predators.

refuge  A location in or near crop fields in which natural enemies are protected from pesticides and provided with resources necessary for their survival and reproduction.

remigium  The area of the wing of a neopterous insect lying anterior to the claval furrow.

reproductive success  An estimate of evolutionary fitness used to measure sexual selection. Measures can include success in obtaining matings with different numbers of the opposite sex as well as fertilization success (by males) when females mate and store sperm from several males.

required nutrients  Nutrients, including essential nutrients, that enhance or optimize growth, development, and/or reproduction.

reservoir  A term for an animal, usually a vertebrate, that is infected with an animal disease agent, can maintain the agent in its tissues for a prolonged period, is fed upon by abnormally by one or more efficient vectors, and is capable of serving as a source of infection for such arthropods. Some vectors that transmit agents transstadially, transovarially, or by both mechanisms also serve as reservoirs.

resin  A water-insoluble exudate emitted from parenchymal cells of various plants, both angiosperms and gymnosperms; it is composed mainly of a mixture of terpenoids, acids, alcohols, and carbohydrates and can be molded by hand.

resin  A water-insoluble exudate emitted from parenchymal cells of various plants, both angiosperms and gymnosperms; it is composed mainly of a mixture of terpenoids, acids, alcohols, and carbohydrates and can be molded by hand.
**Glossary**

**semiochemical** A chemical produced by an organism that has a communication effect on another individual of the same or a different species.

**semivoltine** Describing a life cycle with one generation every 2 years.

**sensillum plural, sensilla.** An organ used for sensing. For olfactory and gustatory (taste) sensilla, cuticular modifications, accessory cells, and sensory cells combine to make a functional sensillum.

**sensitive** Referring to species for which population viability is a concern; a designation used by the U.S. Forest Service.

**sentinel organism** An organism that accumulates pollutants from its surroundings and/or food and is used in tissue analysis to provide an indirect estimate of prevailing environmental concentrations of these substances.

**septicemic** Characterized by the presence and growth of pathogenic infectious agents in the blood.

**serial homology** Similarities between repeated structures in different segments of an organism, caused by shared origin in development.

**sericulture** The industry in which mulberry plants are cultivated and used to raise silkworms, the cocoons of which are used to produce silk.

**serotinous cones** Cones that remain closed and on the tree for one or more years after seed maturation. High temperatures melt the resin that holds the cones closed, causing them to open rapidly.

**sesquiterpenoid** A substituted 15-carbon terpene derived from three isoprene units.

**setae singular, seta.** Slender, rigid, bristle-like hairs extending from the cuticle.

**sex differentiation** The genetic pathway that leads to male or female development, including regulation of somatic sexual differentiation, germ-line differentiation, and (possibly) dosage compensation.

**sex role reversal** A situation that occurs in species in which the sex ratio of individuals available for reproduction is female biased, such that males are the limiting sex. This leads to female competition for males and male choice of females.

**sexual dimorphism** The development of drastically different morphology in the male and female of a species.

**sexually dimorphic** Having morphological differences between males and females of the same species.

**sexual selection** Darwinian selection for traits—including behavioral traits—that promote success in competition for mates or the best mates (operating through discrimination of mates or direct competition). For males—the sex typically subject to the more intense sexual selection—the competition is ultimately for fertilizations.

**signal** Any trait borne by some individual organism, called a sender, and perceived as information by another organism, called a receiver. The receiver usually displays a signal-dependent response (otherwise the signal is meaningless).

**signal system** The program/format of signaling by which males and females identify and reach each other; basic systems are system I, a stationary individual broadcasts a signal, the other sex approaches, and system II, one individual broadcasts a signal, the other responds with a signal, the first approaches the second, which typically remains stationary.

**silk protein** A class of proteins constituting the cocoons produced by the silkworm family (Bombycidae). Silk protein is usually composed of two proteins, fibroin and sericin.

**siphunculi** A pair of specialized pore-bearing structures on the posterior third of the abdomen; involved in production of aphid alarm pheromones; synonym: cornicles.

**sister groups** Species or monophyletic groups that arose from the stem species of a monophyletic group by a singular, identical splitting event. For example, the Lepidoptera and Trichoptera are sister groups; they shared a common ancestor that gave rise to no other lineage.

**social** Living in association and/or cooperation with others of the same species. The term social insect is applied broadly to include presocial and eusocial insect species.

**solitary** In isolation; not grouped. Locusts in the solitary phase do not swarm. The opposite of gregarious.

**solubility** A measure of the amount of a gas that dissolves in a fluid when exposed to a defined pressure of that gas in the air. Carbon dioxide is approximately 1000 times more soluble in water than oxygen.

**somatic cells** A collective term for all cells except gametes.

**somatic sexual differentiation** Specification during development of body parts, including male and female sex organs, and other sex-specific morphological and/or behavioral differences.

**spermatheca** A sperm storage organ in female insects that dispenses sperm as the eggs pass through the oviduct.

**spermatogenesis** The production of spermatozoa from germinal cells.

**spermatophore** An encapsulated package of sperm that is passed during mating and can include proteins that are eaten or absorbed by the female.

**sperm competition** Competition between sperm from two or more males, within a single female, for fertilization of the eggs.

**sperm precedence** The increased likelihood that sperm from a particular mating will be used for fertilizing an egg.

**spinnersets** Finger-like abdominal appendages of spiders containing numerous spigots through which silk is extruded.

**spiracle** An opening in the insect integument that connects the tracheal system to the air.

**sporozoite** Infective stage of the malaria parasite for the human host, inoculated with saliva by Anopheles females during blood feeding.

**stadium** The interval between molts.

**stance** The phase of the leg cycle movement in which the foot, or tarsus, is in contact with the ground, and extension of the leg joints acts on the movement of the body relative to the substrate.

**station-keeping** Activities and movements that keep an animal within its home range or enable it to return to its home range.

**stem mother** See fundatrix.

**stenoxenic phoresy** Relationship restricted to only one host genus or species.

**sterile insect technique** A process in which insects are reared in massive numbers, sterilized, and released to prevent normal mating in target populations.

**steroid** A lipid containing a 17-carbon nucleus of fused rings: three cyclohexane rings and one cyclopentane ring.

**stridulating organ** A file and scraper structure for sound production; may be variously located on chelicerae, palps, legs, abdomen, and carapace.

**stygobite** An aquatic troglobite.

**stylet bundle** A group of stylets (see below) that penetrates the food substrate as a functional unit.

**stylets** Thin, elongated mouthparts of piercing–sucking insects that penetrate into the food substrate.
subimago  The winged, terrestrial instar of Ephemeroptera that molts to the reproducitively mature adult.

subsocial  Describing a social system in which adults protect and/or feed their own offspring for some period of time after birth, although typically the parent leaves or dies before the offspring become adults.

subterranean nest  A nest below the surface of the ground.

tsunami  The ability of an organism to use the sun to maintain a constant direction. This requires a "biological clock" to allow compensation for the passage of the sun across the sky.

supercooled  The absence of freezing at or below the normal freezing point of water.

supercooling point  The subzero temperature at which body fluids freeze, also known as the temperature of crystallization.

supergene  A group of tightly linked genes on a chromosome, functioning as an integrated unit and segregating like a single gene. The genetic subunits usually have a more restricted phenotypic effect than the integrated superfene.

supination  A classification of wings; i.e., twisting, posterior margin downward, anterior margin upward.

swarm founding  The initiation and founding of a colony by a group of workers along with one or more queens.

swing  The phase of the leg movement cycle in which the foot, or tarsus, is raised from the ground and repositioned for the next stance phase.

sylvatic  Living or found in forests or woods.

symbiont  An organism living in intimate association with another dissimilar organism. Symbiotic associations can be mutualistic, neutral, or parasitic.

symbiosis  A condition in which a plant or animal is intimately associated with another organism of a different species; the living together of two taxonomically distinct organisms.

sympatric  Describing two or more species inhabiting the same or overlapping geographic areas.

symplesiomorphy  (ie)  A derived state shared among the members of a monophyletic group, in contrast to a symplesiomorphy, a shared ancestral (plesiomorphic) state from which phylogenetic relationships cannot be inferred.

syncytial cleavage  The condition of all the cleavage nuclei containing a common cytoplasm.

syndrome  In genetics, an association of traits functioning together. To be adaptive and acted upon by natural selection, the traits must be influenced by the same genes (i.e., they must be genetically correlated).

synomone  A chemical signal with a beneficial effect to the sender and to the receiver of the message, as in a floral scent which indicates a nectar source to a pollinator and thereby facilitates pollination.

synovigenic  A form of reproduction in which an adult female continues to produce and to mature eggs throughout adult life.

systematics  The study of the relationships and classifications and naming of sorts of organisms. The terms taxonomy and systematics are often used interchangeably.

taenys ыми  Abbreviation of the developmental cycle, by suppression of one or more instars or their feeding requirements.

tachyogenesis  A derived state shared among the members of a monophyletic group, in contrast to a symplesiomorphy, a shared ancestral (plesiomorphic) state from which phylogenetic relationships cannot be inferred.

taxa singular, taxon.  A collective term for all the taxonomic groups of organisms within a higher taxonomic group (a genus, family, tribe, etc.).

taxonomic  Having to do with the classification and naming of organisms.

taxonomic rank  A classificatory level in the taxonomic hierarchy, e.g., species, genus, family, order. No rank is absolute, and comparisons between ranks of different organisms are inexact or even misleading; despite this, traditional ranks used for insects— notably orders and families— have useful didactic and synoptic value.

taxonomy  The procedure or discipline of classifying organisms.

tegmen plural, tegmina.  A parchmentlike forewing characteris-
tic of the Orthoptera and related orders. The cuticle is somewhat thickened, in association with protection.

temperature threshold  The limiting (minimal or maximal) temperature at which growth and development will occur.

teneral  Describing a condition in which the cuticle is soft and usually pale immediately after molting.

tentorium  A bracing structure inside the head formed by invagi-
nations of cuticle.

testis  The organ in the male that produces sperm.

telytoky  Parthenogenesis in which only females are produced; the production of females from unfertilized eggs.

termoperiod  Daily temperature fluctuations.

thermosensitivity  A decrease in tolerance to high temperature resulting from prior exposure to high temperature.

thermotolerance  An increase in tolerance to high temperature, usually achieved by exposure to a moderately high temperature.

thigmotactic  Contact orientation, as in insects that inhabit crevices or cracks.

threatened  Referring to species that face a high risk of becoming endangered in the near future unless action is taken to protect them; a designation used by the U.S. Fish and Wildlife Service and the International Union for Conservation of Nature and Natural Resources.

tidal flow (of hemolymph)  The reciprocal exchange of oxygen and hemolymph in some adult insects, especially where hemolymph volume is low.

trachea  An air-filled branching tube that transports gases between tissues and the environment, formed by a cylinder of cells (the tracheal epithelium).

tracheal gill  A body appendage with a thin cuticle and containing many trachea, used for gas exchange by many aquatic insects.

tracheal lung  Thin-walled, expanded tracheae, thought to be specialized for oxygen delivery to cells lacking tracheoles such as hematocytes.

tracheole  A small, blind-ended, terminal tube of the tracheal system. Each cell receives oxygen and expels carbon dioxide by means of its own tracheole.

transduction  The conversion of mechanical displacement at a nerve cell membrane into a receptor current that changes the membrane potential.

transformation  A process by which the genetic makeup of an organism is altered by the incorporation of foreign DNA.

transgenic  Describing an organism with foreign genes incorpor-
ated into its genome by recombinant DNA techniques.
transovarial transmission  The transmission of an animal disease agent from an infected female arthropod to its progeny via the egg stage.

transposable elements (TEs)  Mobile segments of DNA that are able to replicate themselves and insert copies into new locations in the genome.

transstadi al transmission  Passage of an animal disease agent from one life stage of an infected arthropod to the next stage during the transstadi al molt, e.g., from an infected larval tick to the nymphal stage.

trichomes  Specialized tufts of hair on some insects that serve to dispense chemical secretions from underlying glands.

tripod gait  A pattern of leg movements used by insects in which the front and rear legs on one side move in conjunction with the middle leg on the opposite side, forming a stable tripod of support. The remaining three legs also form a tripod, and motion occurs when the two sets alternate their motions.

triungulin  The campodeiform first instar of Meloidae, Rhihiphloridae, and Micromalthidae that molts to a less active, feeding second instar. Unlike later instars, triungulins have well-developed legs and move around actively.

troglobit e  A species obligately adapted to live only in subterranean habitats and unable to survive in surface environments.

trogloomorphic  Relating to the suite of morphological, physiological, and behavioral adaptations that are characteristic of troglobites.

troglophile  A species able to live and reproduce in caves but also able to survive in surface habitats.

trogloxene  A species habitually roosting or regularly visiting caves for food or shelter but unable to complete its life cycle underground.

trophallaxis  The exchange by oral transfer of alimentary liquid among members of a colony of social insects. Typically, this liquid serves to feed and unite members of a colony.

trophic cascade  An interaction of trophic levels in a community, such that changes in density of a species at one level have multiple influences on the density of species at other trophic levels.

trophic cells  Specialized cells containing a reserve of fat or other nutritive substance.

trophic egg  An egg, usually degenerate in form and inviable, that is fed to members of the colony.

trophic level  A functional classification of organisms in a community based on what they feed on. The first trophic level consists of primary producers, mostly green plants that obtain energy from the sun. The second trophic level consists of herbivores, organisms that feed on plants. The third trophic level consists of carnivores that feed on the herbivores, and so on.

trypanosome  A type of protozoan that has a leaf-like motile stage.

tubular body  A microtubule-based structure found in the distal sensory dendrites of many mechanoreceptor neurons.

tychoparenthogenesis  The rare or occasional production of eggs that begin developing without having been fertilized.

unprofitability  The character of a prey that gives no net reward to the predator once consumed, leading to learned or evolved avoidance. Examples are toxicity, toughness, difficult handling, and difficult/costly capture.

urocytes  Cells that accumulate uric acid either as a form of nitrogen waste product or as reserves to be used as a nitrogen source by the mycetocytes.

urogomphi  Sclerotized, paired dorsal processes that project from the posterior margin of the ninth larval tergite.

USP  Ultraspiracle, a nuclear receptor that forms a dimer with the ecdysteroid receptor to regulate gene expression.

vannus  The expanded fan-like area of some hind wings, posterior to the claval furrow.

vas deferens  The sperm duct leading away from the testis.

vector  Any agent that transports a microorganism from one host to another.

vectorial capacity  The epidemiological efficiency of Anopheles host species in transmitting malaria parasites, expressed as new infections per infection per day, based on mathematical relationships among the mosquito biological characteristics of daily survival, blood meal host-feeding pattern and frequency, and susceptibility to parasite infection.

veins  The cuticular, usually tubular, rods that support the wing.

venation  The pattern of veins within a wing.

ventral diaphragm  A complete or fenestrated membrane always associated with the ventral nerve cord of insects and defining a perivisceral sinus when present.

vermiform  Describing an insect larva that is worm shaped.

vertical transmission  The transmission of genetic elements from parents to progeny.

vesicle  An extensible organ.

vitelline membrane  The innermost layer of eggshell secreted by the follicle cells; sometimes considered to be the first layer of the chorion.

vitellogenic cycle  A cycle of oocyte development associated with the synthesis of vitellogenin, a protein that contributes most of the protein in yolk. In some insects, such as mosquitoes, vitellogenesis (vitellogenin production) is limited by lack of protein and occurs only following a highly proteinaceous meal, such as blood.

vivipara  The parthenogenetic winged or wingless morphs that bear live young; synonym virginopara.

viviparity  Reproduction by giving birth to live offspring rather than eggs.

voltage-gated sodium channel  A large transmembrane protein that regulates the flow of sodium ions across axonal membranes and mediates the rising phase of action potentials.

vulnerable  Facing a risk of extinction in the medium-term future; a designation used by the International Union for Conservation of Nature and Natural Resources.

V

vannus

W

Wallace’s Line  A term for the junction between the Oriental and the Australian zoogeographical regions at the straits between Bali and Lombok.
wasp waist  The strong constriction between the first and second abdominal segments, present in virtually all members of the Apocrita. The thorax and first abdominal segment in these insects comprise the **mesosoma**, and the rest of the abdomen, the **metasoma**.
wild type  An organism that has no visible mutant phenotype.

**X**
xylem  A plant conductive tissue interior to the cambial layer, composed of several cell types, which transports water from the roots to other sites in the plant and also serves as structural support.
xylophilous  Preferring wood.

**Y**
yolk  An accumulation of protein, lipid, and glycogen particles in the cytoplasm of an egg. The particles are assembled during vitellogenesis and consumed during embryonic development.

**Z**
zoosis plural, zoonoses.  A disease of vertebrates communicable from animal to animal and from animal to human.
zoonotic  Transmitting disease between vertebrate animals and between animals and humans.
