Rotating objects are themselves sources of circulation and concomitant lift production, which is why a tennis ball hit with backspin rises as it moves through the air. The physics of circular balls and flat wings are quite different because the wings have sharp leading and trailing edges, but in both examples the act of rotation serves to create circulation. As an insect’s wing starts to flip over at the end of each stroke, the leading edge vortex grows in size and strength due both to the fact that the angle of attack is larger (which in and of itself increases total circulation) and also because the rotation of the wing abouts its long axis creates additional vorticity. These rotational effects are strongly dependent on the precise timing of wing rotation (the flapping motion of the wing between strokes) relative to stroke reversal (the change in direction from one stroke to the next). For this reason, rotational forces may be particularly important for steering and flight control.

After reversing direction, the wing does not move through undisturbed air, but rather collides with the wake generated during the previous stroke. Because the leading edge vortex moves downward after it is shed, its influence on the flow around the wing is maximal at the start of wing translation but then rapidly diminishes. Nevertheless, the instantaneous air velocity experienced by the wing at the start of each stroke can be substantially greater than that caused by its own flapping speed. Under certain conditions, this increased flow can result in additional force by a mechanism called wake capture. This effect is increased by the fact that many hovering insects generate a U-shaped stroke pattern, such that the wing plunges down at the start of each stroke thereby increasing its interactions with the descending wake. Because a vortex wake represents the energy lost to the fluid by a moving object, wake capture is an aerodynamic mechanism that enables an insect to recover some of the energy otherwise lost to the air. As with rotational forces, wake capture may play a particularly important role in flight control and maneuverability. By changing the timing and speed of wing rotation, insects can manipulate the magnitude and direction of forces during stroke reversal, thereby manipulating force moments around the body’s center of mass.

The wake generated by the wings influences aerodynamic forces in other ways. Vortices shed from the wings drive a column of air downward from the plane of wing motion, which is a change in fluid momentum that is equivalent to the average upward force on the wings. This downwash alters the flow around the wings, but reduces the effective aerodynamic angle of attack and thus attenuates the production of translational forces. In addition, flow interactions may occur among the wings on the same insect. For example, in some insects the close apposition and subsequent rotation of the wings at the beginning of the downstroke, termed the “clap” and “fling,” augment force production at the start of the stroke by enhancing the development of the leading edge vortex. In four-winged insects such as dragonflies, the wake of the forewing can under certain conditions alter the forces created by the hind wing.

Although certain general aerodynamic principles apply to all insects, the precise details of flight aerodynamics vary in concert with the extreme morphological and behavioral diversity found among species. For example, insects that employ a long sweeping stroke and relatively low stroke frequency (such as fruit flies), roughly 80% of the total force generated is explained by the leading edge vortex created during the propeller-like portion of each stroke. Honeybees by contrast, which use a short rapid strokes, rely more extensively on added mass, rotational forces, and wake capture. The force-generating mechanisms described earlier, as well as additional mechanisms yet to be discovered, are best viewed as a palette from which the flight behavior of any given species is constructed. The long-term goal for the study of insect flight aerodynamics is not only to uncover the mechanism by which any particular species stays in the air but also to show how it manipulates various mechanisms to maneuver and accomplish the aerial behaviors that are necessary for its survival and reproduction. Recent work in elucidating specific aerodynamic mechanisms must be viewed as only a starting point toward a more comprehensive understanding of flight mechanics and behavior.

**NEURAL CONTROL**

**Sensory Systems**

The extreme morphological adaptations associated with flight behavior in insects are paralleled by equally impressive specializations within the nervous system. Perhaps most extreme among these alterations relative to the basic neural organization of wingless insects is the hypertrophy of the compound eyes and associated visual ganglia. Large eyes capable of rapid response and broad adaptation to ambient light level are the characteristics of diurnal insects such as butterflies, dragonflies, bees, wasps, and true flies. The visual system provides essential sensory feedback for flight control in most diurnal species and is used for a variety of tasks, including velocity and altitude control, obstacle avoidance, landing responses, target recognition, and spatial memory. Features of the anatomy and physiology of the visual system of individual species correlate well with flight behavior and habitat. The elevated translational and rotational speeds characteristic of flight, particularly compared with those of walking and running, place a premium on rapid response time of the visual system. The enhanced visual processing speeds of insects are exemplified by the flicker fusion rate of house flies, which at roughly 300 Hz is the highest found among all animals.

In addition to the eyes, several other sensory modalities on the head provide critical feedback during flight. Although incapable of extracting detailed spatial information, output from the three ocelli helps to stabilize pitch and roll. Because the associated neural computations are relatively simple, the ocellar system can detect and process changes in body orientation more rapidly than can the visual system. Hair cells on the head and mechanoreceptors at the base of the antennae are capable of measuring the magnitude and direction of airflow during flight. In conjunction with visual measurements of ground speed, the input from these wind-sensitive cells is crucial for calculating ambient wind direction, an important capability for flying upwind or tracking odor sources, which are detected in part by chemosensory sensilla on the antennae.

Although sensory structures on the head provide relatively slow tonic cues used for modulating wing motion or body posture over many wingbeats, sensory input from mechanosensory cells on the thorax provides fast phasic input that can alter wing movements on a cycle-by-cycle basis. These mechanosensory structures include the tegula, an organ below the wing that is stimulated during the downstroke, and stretch receptors embedded in the wing hinge that fire during the upstroke. Wing veins contain arrays of tiny campaniform sensilla that encode deformations of the wing surface throughout the
stroke. In flies, these arrays are greatly elaborated at the base of tiny drumstick-shaped hind wings called halteres, which function as equilibrium organs. Associated sensory fields detect the Coriolis forces that deflect the beating haltere when the animal’s body rotates during flight. Remarkably, a similar specialization is found among strepsipterans, but in these insects it is the forewing that has been transformed into an equilibrium organ, whereas the hind wings retain the aerodynamic function. Although the precise role of the thoracic mechanosensory organs varies from species to species, their general function is to tune the output of interneurons and motor neurons that pattern the activity of the flight muscles. The phasic, phase-locked nature of this feedback is impertinent because the mechanical properties of steering muscles are extremely sensitive to the precise time at which they are activated within the wingbeat cycle.

**Muscles**

As with sensory systems, motor systems of insects exhibit many specializations related to flight behavior. Unlike the wings of birds, bats, and pterosaurs, insect wings contain no intrinsic muscles. The wing is attached to the thorax by a complicated hinge structure that amplifies the tiny strains of the flight musculature into the large sweeping motions of the wing. The hinge is composed of a connected set of hard selerotized elements (the wing sclerites or pteralia) embedded within a matrix of more compliant cuticle. Flight muscles may be segregated into two morphological groups according to how they transmit force to the wing. Direct flight muscles insert upon apodemes connected directly to the wing sclerites. In contrast, indirect flight muscles insert within the thorax some distance from the base of the wing. Odonates are distinct in possessing only direct flight muscles, whereas most insects possess some combination of direct and indirect muscles. In many of the most species-rich orders, including the Coleoptera, Hymenoptera, and Diptera, direct and indirect muscles differ physiologically and serve distinct functions (Fig. 2).

Large indirect “power” muscles provide the mechanical energy to drive the gross up-and-down motion of the wings, whereas a set of small direct “steering” muscles controls the fine changes in wing kinematics during flight. Each contraction in a steering muscle is activated one for one, by action potentials in presynaptic motor neurons, but contractions in the power muscles are asynchronous with motor input. By a molecular mechanism not yet fully understood, rapid stretch activates the crossbridges in asynchronous muscles, causing them to shorten after a brief delay. The low-frequency drive of motor neurons is sufficient to elevate calcium concentration within the sarcoplasm of asynchronous muscle to a level that maintains crossbridges in a stretch-activated state. During flight, contractions within sets of antagonist downstroke and upstroke muscles provide the requisite mechanical stretch to activate each other. Stretch activation frees muscles from the requirement of an extensive sarcomplasmatic reticulum (SR), which is necessary in synchronous muscle for the release and subsequent uptake of calcium during twitches.

Asynchronous muscles are capable of generating elevated levels of mechanical power because their internal volume is filled almost exclusively with contractile fibrils and mitochondria. The advantage of stretch activation is especially strong at high frequencies for which typical twitch muscles would require an enormous surface area of SR, severely compromising their ability to generate power. Thus, asynchronous fliers can attain much higher wingbeat frequencies, and thus smaller body size, than can insects using synchronous flight muscles. The mechanical efficiency of asynchronous muscles should also be high because the normal costs associated with cyclic release and uptake of calcium through the SR are not incurred. Because their contraction is only partially controlled by the nervous system, indirect asynchronous muscles are ill-suited to mediating rapid changes in wing motion. The nervous system exerts its control of flight behavior primarily through the action of the direct synchronous steering muscles.

**Pattern-Generating Circuits**

The motor neurons that innervate insect flight muscles are driven by complex rhythm-generating circuits within the nervous system. Seminal studies by Don Wilson on locust flight led to the discovery of central pattern generators (CPGs), circuits consisting of interneurons and motor neurons capable of generating rhythmic patterns in

---

**FIGURE 2** In insects using an asynchronous flight motor, the wing muscles are segregated into two anatomically, physiologically, and functionally distinct groups. (A) The large indirect power muscles, which fill the thorax, are arranged in two antagonistic groups. (B) A cross section through the thorax (as indicated by line in A) showing the action of the power muscles. The laterally placed dorsoventral muscles drive the upstroke, whereas the more medial dorso-longitudinal muscles drive the downstroke. The contraction of each muscle set stretches the antagonist group thereby activating the next phase of oscillation. The motion of the thorax is indicated by black arrows, motion of wings is shown by gray arrows. (C) The arrangement of direct steering muscles. (D) Illustration of how activity of a steering muscle changes wing motion (enlargement of rectangular region in C); as muscle becomes active (dark gray), wing trajectory changes.
the complete absence of phasic sensory feedback. Cells within CPGs excite and inhibit the motor neurons of upstroke and downstroke muscles so that they fire antiphasically during the stroke cycle. Even stretch-activated muscles are driven by CPGs, although the firing rate is roughly 10 times lower than wingbeat frequency. Although there is no doubt that insect nervous systems contain CPGs, research pioneered by Kier Pearson and colleagues has demonstrated that sensory feedback from thoracic mechanosensory structures plays an essential role in patterning motor output during flight. For example, electrical stimulation of wing stretch receptor cells can reset the timing of the flight rhythm in locusts—thus fulfilling a strict criterion that is used to test whether a neuron is a member of a CPG. The circuitry underlying flight behavior is best described as a distributed pattern-generating network, consisting of both central and peripheral neurons.

ENERGETICS

Fuel and Oxygen Delivery

Metabolic rates during flight exceed resting values by a factor of 50-200, and the thoracic muscles of flying insects exhibit the highest mass-specific rates of oxygen consumption known for any locomotor muscle. Mitochondrial densities within flight muscle fibers are correspondingly high, ranging in some insects to values as high as 45% of the total muscle volume. Energy during flight is derived almost entirely from the oxidation of chemical fuels; anaerobic pathways are absent from flight muscles. Metabolic fuels diffuse from the hemolymph surrounding muscle fibers to the point of oxidation within mitochondria, whereas bulk movement of hemolymph within the body cavity transports fuels from the abdominal fat body to the thoracic musculature. The type and composition of the fuel used in flight (i.e., lipids, carbohydrates, or amino acids) vary with phylogenetic association and may even change with time during a single flight duration in some species. Oxygen influx and carbon dioxide eflux during flight occur primarily via diffusion within tracheal pathways, but may be augmented by convective motion. For example, contraction of flight muscles and the associated deformations of the thorax can compress and expand internal air sacs and even first- and second-order tracheal branches. Although most higher order branches within the tracheal network are unlikely to experience convective pumping, muscular contraction may augment diffusion by deforming tracheoles that invaginate muscle fibers.

One important issue relating to flight energetics concerns the limits of insect body size. In dragonflies, studies of tracheal geometry suggest an upper limit to thoracic radius of about 0.5 cm if diffusion alone supplies oxygen during flight. The thoraces of many extant insects are well above this limit, however, and the relative contribution of convection to oxygen supply has yet to be determined for any insect. The existence of some flight-related constraint on maximum body size is supported by the observation that many large insects (e.g., the giant stick insects of Southeast Asia) are secondarily flightless. In a modern species of dragonfly, flight metabolic rates vary in direct proportion to ambient oxygen concentration, a result that is consistent with diffusion-limited oxygen transport. The existence of widespread gigantism in late Paleozoic insects (and among other arthropods) during periods of elevated atmospheric oxygen concentration provides further evidence for diffusive limits to flight metabolism, and thus body size, of flying insects.

Energy Requirements for Flight

Although selection has presumably acted to minimize mechanical power expenditure, most of the energy consumed during flight is lost as heat in the flight musculature. Estimates for the mechanical efficiency of insect flight muscle range from only 4% to 30%, depending on taxon and assumptions as to the amount of elastic energy storage within the thorax. Thus, a comparatively small fraction of the fuel an insect consumes is available as mechanical power to drive the wings. This mechanical energy must support three requirements: parasite, inertial, and aerodynamic power. Inertial power is the power required to accelerate the wings back and forth during the stroke. Unless inertial power is substantially greater than aerodynamic power, even moderate elastic storage within the thorax renders inertial costs small. Parasite power is the work required to overcome the drag on the animal's body as it moves through the air. Thus, parasite power is negligible at low advance ratios but increases with the cube of flight speed. The aerodynamic power is the rate of the work the wings perform on the air, which may be further subdivided into induced power, the cost of generating lift, and profile power, the cost of overcoming drag on the wings. Because the lift-to-drag ratio for most wing kinematic patterns capable of generating sufficient lift is quite low, profile power requirements may substantially exceed the induced power, especially in smaller insects. Also, recent measurements of drag on dynamically scaled model insect wings indicate that values of profile power may be two to three times higher than previously thought. Underestimates of aerodynamic power resulting from unrealistically low values for wing drag may explain the low estimates of mechanical efficiency for asynchronous flight muscle.

The variation in power requirements with forward airspeed is of ecological and evolutionary interest because of its implications for optimal foraging and dispersal strategies. Both direct measurements and aerodynamic modeling of bumblebees in forward flight suggest that mechanical power requirements are approximately constant over an airspeed range of 0-4.5 m s⁻¹. In contrast, calculations for various lepidopteran and odonatan species show substantial increases in mechanical power expenditure, with forward airspeed due to the rise in parasite power. In situations in which parasite power is large relative to aerodynamic power, the choice of airspeed during flight has significant energetic implications. One study with dragonflies suggests, in fact, that maximum flight speeds are determined predominantly by the dramatic increase in body drag and associated power requirements at extreme airspeeds.

Temperature Effects

As with many features of flight muscle physiology, power production is strongly temperature dependent, an effect that has several implications for overall flight performance. Measurements on isolated muscles show that mechanical power output typically increases with temperature and is maximal near muscle temperatures characteristic of the free-flying insect. However, the temperature dependence of power output differs greatly among taxa, and although some insects can instantly take off from the surface of glaciers, others must warm their thoraces to 40 °C before their muscle generates sufficient power to sustain flight. In insects for which the flight muscles require elevated temperatures to attain adequate performance, the heat generated during flight that results from low muscle contractile efficiency is available as a source with which to regulate thoracic temperature. In small insects, most metabolic heat generated during flight is lost via convective cooling, and body temperature is close if not equal to ambient air temperature. In larger insects, however, metabolic heat gain is high relative to convective loss and body temperatures are correspondingly elevated. Many large insects regulate internal heat distribution via control of hemolymph circulation between the thorax and the abdomen, using the latter to radiate excess heat. The dramatic amounts of heat produced by muscular contraction are illustrated by the capacity of bumblebees and of some moths to maintain thoracic temperatures exceeding 30 °C when ambient air temperature
is only 2–3°C. Evolution of such thermoregulatory capacity in many insects is consistent with strong historical selection on muscle performance to meet the exacting energetic demands of flight. Further evidence supporting the link between thermoregulation and flight is the phenomenon known as preflight warm-up. In larger insect taxa, pronounced contraction of the thoracic muscles and low-amplitude wing vibrations precede flight. These actions elevate thoracic temperature to values at which the muscles yield sufficient mechanical power for takeoff. Ontogenetic variation in the temperature dependence of muscle power output can also be substantial. In some dragonyflies, for example, thermal sensitivity of force production by flight muscle is correlated with changes in the expression of myosin isoforms through development. This finding suggests that physiological features of flight performance are matched to particular environmental conditions and selective demands.

**ECOLOGY AND DIVERSITY**

**Wing Arrangement**

The origin of wings was followed by an explosive diversification of insect orders. Many Carboniferous insects possessed wings of approximately equivalent size, shape, and aerodynamic function that were probably limited to low-amplitude flapping. Equivalently sized fore- and hind wings persist to this day in at least seven orders. However, major differences in the sizes of meso- and metathoracic wings are evident in both contemporary fauna and fossils from the Paleozoic. With the exception of the Coleoptera and Strepsiptera, enlarged hind wings are for the most part confined to extant exopterygote orders. Many endopterygote orders (Hymenoptera, Lepidoptera, Diptera), by contrast, reduce the aerodynamic role of the hind wings. In many insects in which the hind wings provide aerodynamic force, the forewings have been modified for supplemental function. Far from isolated events, the evolutionary transformation of the forewing into either a tegmen or an elytron has occurred at least three times at the ordinal level. Elytra of the Coleoptera have much reduced aerodynamic roles relative to the hind wings and provide for greater mechanical resistance to crushing in conjunction with increased sclerotization of the body as a whole. A similar functional role may be hypothesized for tegminized forewings (e.g., Blattodea and Orthoptera) and for the hemelytra of Hemiptera. Insect wings may also serve a variety of behavioral functions unrelated to flight, including sound production and visual communication. None of these functions are mutually exclusive, although the role of aerodynamic force production remains paramount for at least one wing pair.

**Flightlessness**

With the behavioral and ecological advantages of flight notwithstanding, flightlessness has evolved independently many times in insects. Approximately 5% of the extant insect fauna may be classified as flightless, if all forms of variable wing expression and of reduced flight musculature are included. One common feature of the otherwise diverse manifestations of flightlessness is a reduced need for locomotor mobility. Selection for maintaining flight may be weak if this capability is not required for dispersal, reproductive behavior, or predator avoidance. Even in flying species, the costly development of wings and associated musculature may not occur under all ecological conditions.

**Flight Diversity and Body Size**

Changes in body size represent major trends in the evolution of winged insects. Although direct paleontological evidence is not available, body lengths of the first flying insects were probably in the range of 2–4 cm. Substantial increases in body length appear to have occurred by the mid-Carboniferous, and gigantism relative to today’s forms was typical of many late Paleozoic insects as well as of other arthropods. The most parsimonious explanation for Paleozoic gigantism is a contemporaneous increase in atmospheric oxygen concentrations, possibly to values as high as 35% relative to today’s 21%. Such high oxygen concentrations, together with higher diffusion constants due to an increase in total atmospheric pressure, would have relaxed diffusional constraints on flight metabolism and thus would have permitted the evolution of giant flying forms. Increased atmospheric density would also have yielded increased augmented lift production during flight, both effects possibly being advantageous during the initial periods of wing evolution. Furthermore, geophysical evidence suggests a decline in atmospheric oxygen concentration through the mid- to end-Permian. As would be consistent with asphyxiation on a geological time scale, all giant terrestrial arthropod taxa of the late Paleozoic went extinct by the end of the era.

In sharp contrast to the late Paleozoic giants, the contemporary insect fauna is characterized by a diversity of miniaturized forms. For example, mean adult beetle body length lies between 4 and 5 mm. Much of the wealth of dipteran and hymenopteran diversity is similarly associated with small body sizes, particularly among the parasitoid and hyperparasitoid taxa. Wingbeat frequencies vary inversely proportional to body size, and today’s small insects typically fly with wingbeat frequencies in excess of 100 Hz, rates achievable only with the use of asynchronous muscle. Thus, the acquisition of asynchronous flight muscle has played a major role in morphological diversification among different insect orders. Asynchronous flight muscle is phylogenetically derived relative to synchronous precursors and has evolved repeatedly among pterygote lineages (Fig. 3). Because flight at small body sizes

![FIGURE 3 Phylogenetic distribution of asynchronous flight muscle](image-url)
mandates elevated wingbeat frequencies, this repeated evolutionary acquisition of asynchronous muscle may have facilitated taxonomic radiations of small insects. For example, systematic comparison of sister insect lineages that differ in muscle type statistically demonstrates a decrease in mean body size and an increase in species number if asynchronous flight muscle is present. Three-quarters of all described insect species and three of the four largest orders (i.e., Coleoptera, Diptera, and Hymenoptera) are characterized by asynchronous muscle. Because higher wingbeat frequencies yield increased aerodynamic force, asynchronous muscle may also permit a reduced wing area relative to body mass. This effect may help to explain how one wing pair in many insect groups evolved nonaerodynamic roles.

**Flight Behavior and Ecology**

Flight plays a central role in the life history patterns of most pterygote insects. A partial list of important insect behaviors mediated by flight includes pollination, phytophagy, hematophagy, escape from predators, mate acquisition, and migration. Forces of both natural and sexual selection have demanded ever-increasing flight performance from insects throughout evolutionary time, whereas different selective agents are often mutually reinforcing. For example, intra- and intersexual selection often acts synergistically on maneuverability, as does escape from predation attempts by bats, birds, and other insects.

Coevolutionary defensive responses among insects, including increased maneuverability and erratic flight styles, parallel the diverse radiations of insectivorous vertebrates worldwide. The morphological and behavioral mimicry among certain chemically defended insects provides wonderful testimony to the strength of such natural selection.

Another major coevolutionary theme in the terrestrial biosphere concerns relationships between flying insects and plants. Phytophagy and pollination by insects are particularly influenced by three-dimensional aerial mobility, the capacity for which dramatically increases access to nutritional resources and suitable oviposition sites. The antiquity of such interactions is well demonstrated by fossil evidence for feeding on plants in the Upper Carboniferous, whereas high rates of herbivory imposed by insects characterize most present-day floras. The evolutionary presence of flying insects has similarly influenced the reproductive biology of many plants. Contemporary angiosperms are pollinated primarily by a broad diversity of insect taxa, most of which are miniaturized forms that can hover at flowers either before or during pollination. Small body size facilitates both incidental and intentional dispersal by wind, and as a consequence tiny insects can act as long-distance pollen vectors.

Continuous aerial entrainment by winds interacts with the large individual numbers of insects worldwide to result in a transient but substantial population of insects moving at heights up to 10 km from the earth’s surface. Remarkably, insects from continental fumans have been captured in the mid-Pacific far from any land mass or island. The ability to decouple the flight trajectory from ambient winds depends on the relative magnitude of insect airspeeds, which rarely exceed typical wind speeds. Thus, directed movement is likely only a few meters from the ground or within canopies of vegetation. Dispersal, on the other hand, is readily attained simply by flying upward into moving air masses. Even migratory flights of larger, more powerful insects (such as locusts and butterflies) are influenced by the directionality of prevailing winds.

**Folk Beliefs and Superstitions**

James N. Hogue
California State University, Northridge

An integral part of any society’s cultural heritage is the collection of stories and traditions passed from generation to generation through the ages. Folklore serves to define a people’s identity by mirroring its beliefs, concerns, and fantasies. The passing on of traditional tales thus creates a lasting, tangible bond between the living and their ancestors and provides meaning to a people’s existence in the present.

As with other aspects of human culture, the characters, lessons, and motivation of human folklore are greatly influenced by a people’s surroundings. It is therefore not surprising that ubiquitous insects are common elements in the variety of traditional stories told...
by people from both past and present societies. Among the variety of loosely categorized stories, traditions, and beliefs typically passed orally through time in human societies are folk tales and superstitious beliefs. Although such a medium for passing on information often results in inconsistent transmission across time, it provides an avenue for the creative embellishment of stories that reflects the ideals of the teller and the contemporary state of the particular culture. Other aspects of a people’s culture passed on in this way, such as religion or mythology, can be thought of as fundamentally different and thus treated separately.

**FOLKLORE AND MYTHOLOGY**

Although one certainly grades into the other and it is impossible to generalize across every situation, there are some marked differences between folk tales and stories classified as mythology. Myths are typically more infused with expressions of the unconscious and have more symbolic or religious significance than folk tales. Entire societies are grounded in myths, not folklore. Myths also accompany rituals and ceremonies much more so than folk tales. For example, myths are a common medium for reenactments of the past, such as the creation of the world or other significant events in a culture’s history. This is true sometimes for stories treated as folklore, but they are much less engrained with ritual or any extended meaning much beyond the particular focus of the tale. In general, folk tales tend to be more for entertainment, whereas myths tend to be more for spiritual instruction.

Folk tales and superstitions serve a variety of purposes, some of which reveal possible reasons for their origin. Some beliefs and tales deal with societal problems and incompatibilities between culture and nature. Some are used as vehicles for wish fulfillment or as a means to speculate on explanations for phenomena observed in nature. They also may serve as mere tales for the enjoyment and entertainment of both the teller and the listener. Other tales serve to instill moral lessons or provide instructions for living one’s life in a particular way. Such tales, because they are inherently interesting and entertaining, are particularly suited to providing historical or moral instruction to young minds that might otherwise be unresponsive to such teachings.

**TALES THAT EXPLAIN OBSERVED PHENOMENA**

Many folk tales dealing with insects are based on fanciful explanations of natural phenomena. The ancient tale of the bugonia apparently originated from such confusion. Bugonia comes from a Greek word that means ox progeny, and is based on the notion that a swarm of honey bees could be spontaneously generated from the rotting carcass of an ox (Fig. 1). This was not merely a description of something perceived to occur in nature, but was a means whereby people could generate many new individuals of these beneficial insects. For this to be successful, precise instructions had to be followed regarding the proper methods and timing of the slaughter and preparation of the ox carcass. This European tale is also found in Chinese and Japanese folklore, and similar beliefs existed for the generation of other bee-like insects from the carcasses of other animals, namely wasps from horses and hornets from mules.

The bugonia tale originated in ancient Egypt, in a place and time at which the ox and the bee were revered as gods. A Biblical reference to this phenomenon (Joshua 14:8) attests to the antiquity of this belief. This tale of ancient times persisted well into the 1600s, when more careful observations of insect biology led to other explanations. In 1883, the eminent dipterist C. R. Osten Sacken proposed an explanation for the origin of the bugonia story that led to it being discredited. The supposed bees and wasps occurring in the carcasses of dead animals were in fact the drone fly, Eristalis tenax (Syrphidae). This fly, a Batesian mimic of honey bees, breeds in putrefying organic matter and could easily be mistaken for a bee by the untrained eye.

The presence of particular forest clearings in western Amazonia is ascribed to the activities of forest gnomes known as chulla chaqui. These mischievous creatures live near the clearings and eat the fruits of the only shrub that grows in such places, Durio a spp. (Rubiaceae). Like many other figures in zoological folklore, these gnomes can take on the appearance of other forest creatures. They take particular delight in transforming into a brilliant blue morpho butterfly, whereby they attract the attention of human visitors and lure them into the forest, only to disappear and leave the disoriented humans lost. In reality, these clearings are formed and maintained by ants that live in a symbiotic relationship with Durio a. The ants clear potential competitor seedlings from areas around their myrmecophytic host plants in exchange for a place to live. This folk explanation is similar to that for small clearings in temperate forests or fields that serve as places where woodland fairies commonly gather. Fairies, those furtive, entomologically inspired imaginary beings of diminutive human form that typically bear insect-like wings (Fig. 2), are common figures in European folklore. In fields, the clearings known as fairy rings, supposedly caused by dancing fairies, are in reality caused by underground fungi that make their appearance in the form of an ever-expanding ring of mushrooms that encircles a bare patch among the surrounding vegetation.

Another example of transformation surrounds the explanation for the name of a famous insect used by people as an object of adornment. In Mexico, the jewel-adorned ironclad beetles that serve as
living brooches are known as *Ma’Kech* after a legend about a Mayan Prince of Yucatan who is said to have escaped his lover’s guards by transforming, with the help of the Moon Goddess, into this beetle. His lover was so impressed by his resolve that she uttered “*Ma’Kech.*” This phrase not only means “you are a man” but also means “does not eat,” and refers to this insect’s and the Prince’s ability to go without food for long periods of time.

The phenomenon of crypsis (imitating the background in form, color, pattern, or behavior by an organism to avoid detection) is explained by some indigenous peoples using yet another example of transformation. It is said that leaves can transform into insects such as katydids and mantids. This is a reasonable explanation given the striking leaf-like appearance of these insects. The transformation of plants into insects was also implicated by some early European naturalists in their explanation of the issuance of insects from galls, nuts, and fruit. This fanciful theory supposed that the various insects brought forth from these sources were generated by the “vegetative and sensitive soul” of the plant. The origin of another organism associated with insects is similarly explained. The elongate fruiting bodies of certain fungi (*Cordyceps* spp.) that commonly attack insects in the American tropics are thought to be the first stage in the development of particular jungle vines that are used for binding poles.

Explanations for insect behavior often take the form of folk tales. Several stories and rhymes tell the tale of the origin of the katydid’s song. These short tales typically center on a girl or young woman named Katy who is accused of committing some bad deed such as deceiving or killing another person. The shameful act is immortalized by the singing insects in the trees that continue to debate whether “Katy did” or “Katy didn’t.” Some insects spend the greater part of their lives boring through and feeding upon living or dead wood. According to a story from the Tahltan of British Columbia, these insects were tricked into searching for their food in this manner by another insect. Long ago a beetle larva and a mosquito lived together. Every day, the larva watched his friend the mosquito come home engorged with blood. Upon being asked by the beetle larva where he was able to regularly find food, the mosquito, not wanting to give up his secret, replied that he sucked his meal out of trees. The next day the larva began boring into wood looking for food, an activity that continues to this day.

In addition to biological phenomena, stories about the origins or some geophysical entities similarly incorporate insects. The origin of fire has been attributed to the actions of fireflies that were responsible for starting the mythological first campfire. According to the Yagua Indians of the upper Amazon, the origin of the river is a result of the misguided actions of insects. Before the existence of the river, the water used by people came from the “tree of water” that, when cut, would release some of this precious liquid. In an effort to liberate more water, wood-boring insects were deceptively used by some children in a plan that damaged the tree such that it released all its waters at once. This resulted in the formation in the mighty Amazon River.

**BENEFICIARY TALES AND ENTOMOPHOBIC LEGENDS**

Another force behind some folklore is a means of obtaining some diffuse or ancillary benefit for the originator or propagator of the tale. The tale of the Machaca among some inhabitants of Amazonia is a good example. The purportedly deadly consequences of the bite from the Machaca, which in actuality is the harmless but menacing looking fulgorid *Fulgora laternaria,* can be thwarted by having sexual relations within 24 h. These insects instill fear and should be avoided, but should the unfortunate happen, a cure is available. Such “sex antidotes” are fairly widespread among folk cures. The potential benefits to those disseminating such tales are obvious.

Other superstitious beliefs benefit particular insects by protecting them from undue harm from people. The Cornish believed that fairies were the souls of ancient heathen people that were too good for Hell but too bad for Heaven. These beings had gradually shrunk from their natural size to that of ants. It was therefore unlucky to kill ants. Similar tales of bad luck when people willingly or inadvertently step on or otherwise harm particular insects are found throughout the world. This is particularly true for insects perceived as beautiful or beneficial to human endeavors such as butterflies and ladybird beetles.

Some insect folklore stems from a general dislike of insects by people and serves to pass this feeling on to others and propagate fright and ill will toward insects. In some stories, insects may be stigmatized with imagined, dangerous qualities. This is most common for insects that have a frightening appearance and gives reason for them to be despised and avoided. Dragonflies and damselflies, for example, are the bearers of nearly 100 English folk names related to their appearance or supposed behaviors. One of their names is “the devil’s darning needle,” referring to their ability to sew closed the mouth, nostrils, and eyelids.
of someone unfortunate enough to be the focus of their displeasure. Other examples focus on fanciful abilities of certain pestiferous species to invade nearly any aspect of human life. One fictitious tale describes the plight of an unlucky woman who kept her hair pinned up for such a long time that it became infested with cockroaches.

A little known legend surrounds the comings and goings of body lice, _Pediculus humanus humanus_, an ectoparasite long associated with humans. There was a belief during the 16th century that during trans-Atlantic voyages, lice on the heads and bodies of mariners would miraculously disappear from the westward traveler at a line of longitude roughly 100 leagues west of the Azores. Furthermore, these parasites would return to the eastbound sailors at the same meridian. The basis of this sailor’s tale is unclear, but it may be loosely related to the effects that the increase in ambient temperature and the associated shedding of clothing had on the number of observed lice as ships approached more tropical climates.

**INSECTS AS OMENS AND SOOTHSAVERS**

Insects that are most commonly featured in human folklore are those that most closely associate with humans or impact human affairs. It is not surprising then that insects such as cockroaches, mosquitoes, and bees are some of the most common subjects in stories and superstitions in which an insect’s presence or activity is related to significant events in people’s lives.

Because humans have practiced honey hunting and beekeeping for thousands of years, it is not surprising that there is much folklore surrounding these activities. The discovery and collection of honey is reason for merriment and joy in many hunter–gatherer societies and much significance has been attributed to the presence of bees and their role as makers of honey. The activities of foraging honey bees are used to predict the weather. When bees forage far from the hive, good weather is expected, but when they forage nearby, poor weather is sure to come. In ancient Rome, swarms of bees foretold impending misfortune. The significance of the timing of bee swarms is exemplified by the following rhyme:

_A swarm of bees in May, is worth a load of hay._

_A swarm of bees in June, is worth a silver spoon._

_A swarm of bees in July, is not worth a fly._

This saying is relevant to the beekeeper whose summer swarms of bees heading off into the distance mean lost assets.

In addition to bees, the presence and behavior of other insects are used to predict the weather. The most widely known insect-mediated weather forecaster is the larva of some tiger moths (Arctiidae), known as woollybear caterpillars. These caterpillars, in particular those of the banded woollybear, _Pyrrharctia isabella_, are thickly covered with erect black hairs and have a band of reddish brown hairs encircling the middle of their body. The width of the central band supposedly predicts the weather conditions of the coming winter. Narrow bands indicate a long, cold winter, whereas wide bands indicate a short, relatively warm winter. Other insects associated with weather forecasts are butterflies, flies, wasps, and ants. The Zuni of the American Southwest say to expect rain when the white butterfly flies from the southwest. American folklore tells us that when the gnats swarm, rain and warmer weather are believed to be coming, and when hornets build nests near the ground a harsh winter is expected. Rain is expected when ants withdraw into their nests or if someone steps on an ant. The European stag beetle, _Lucanus cervus_, is supposed to be able to attract thunderbolts. This association is perhaps explained because these beetles were commonly found in old oak trees that were often struck by lightning.

Because of this belief, these beetles were sacred to Thor, the Germanic god of thunder.

The association of particular insects with common events in distant parts of the world sometimes depends on the characteristics of a particular taxon. Praying mantids are considered pious prophets or soothsayers in various parts of the world. There is also a considerable body of folklore associated with ladybird beetles. Named after the Virgin Mary (Our Lady), these beetles are widely equated with good luck and are often associated with the ability to portend happy events. These beetles are reputed to have been sacred to Freyja, the ancient Norse goddess of love. To harm one of these insects would certainly bring bad luck. That the most common European species of ladybird has seven spots is the basis for one explanation why this beetle is venerated in this part of the world. The number 7 has long been considered a mystical, powerful, and “perfect” number. In southeastern France, a young girl can predict the year when she will marry by placing a ladybird beetle on her finger and counting the years aloud until the beetle flies away. In other instances, an insect’s significance depends on characteristics or behaviors shared between quite different taxa.

In general, the insects found in the folklore of a particular place are drawn from the local fauna. Consequently, significant events common to people worldwide are associated with different species of insect. In British folklore, the presence of deathwatch beetles (Anobiidae) is correlated with the demise of someone in the household. These beetles that live in wood, such as that framing an old English house, send telegraphic messages to each other by tapping their heads on the tunnel walls. This tapping sound is audible to people when all else is quiet, such as in a silent room during a bedside deathwatch. In parts of the Neotropics, the activities of termites fulfill this role as a harbinger of death in a similar manner. Other insects associated with impending death include the appearance of lice in one’s dreams, cockroaches flying in one’s room, and the sighting of a death’s head hawk moth (Acherontia atropos). The scales on the dorsum of the thorax of this moth form the readily recognizable image of a whitish human skull against a dark background. The association of this moth with death in the minds of humans was inevitable.

Often the appearance of a given insect conveys a different meaning in different places or at different times. For example, in some parts of the world, a cricket in the house means good luck, but in other places the presence of this insect means ill fortune. According to one superstition in Brazil, careless contact with fireflies can cause blindness, but in the hands of a curandeiro (folk healer or medicine man), fireflies can be used to cure blindness.

**INSTRUCTIONAL TALES**

In addition to being entertaining, some folk tales serve as a useful means of instruction. Many tales are told to convey a moral message or pass on useful information in an interesting, amusing, and hence more easily remembered format. An example is that of Aesop’s fable of the ant and the grasshopper. While the ant concerned himself all summer with gathering provisions for the upcoming winter, the grasshopper spent his time in leisure and song. The grasshopper even derided the ant for spending so much of his time at work instead of play. When winter came, the grasshopper was not prepared and suffered the consequences of his folly. The ant, on the other hand, lived comfortably through the winter on the stores he gathered all summer. The activities of these insects in this story are used to show the importance of preparation for future times of necessity. In addition to ants, the behavior of other social insects such as termites, honey bees, and wasps is commonly used to exemplify the benefits of cooperation, diligence, and hard work.
FOLK MEDICINE

Folk remedies for the treatment of the innumerable ailments that befall humans and their animals are found worldwide. Although less important than herbal remedies, insects play a role in the folklore of healing and drug use. One of the most well-known insect-derived folk medicines is cantharadin. This powerful vesicant is derived from dried blister beetles, particularly Lattea vesicatoria. Although cantharadin can be extremely toxic to humans, as recently as the early 1900s, cantharadin was used to treat a variety of ailments such as asthma, epilepsy, warts, sterility, and bedwetting. In Europe, where the drug as well as the beetle is known as “Spanish fly,” powdered cantharadin was taken orally for its purported qualities as an aphrodisiac. Cossinus, a close friend of the Roman Emperor Nero, reportedly died when an Egyptian doctor gave him “cantharis” to drink for treatment of a skin disease.

Many other insects and insect-derived products have been, and sometimes continue to be, used to improve health and treat disease. One product of insects that is widely used today in the context of what might be called folk medicine is bee pollen. The consumption of bee pollen is said to improve general health and increase stamina. Tonics and teas derived from nearly every insect order, from bedbugs to beetles and cicadas, have found their way into the human apothecary. In China, exuviae left behind by newly emerged adult cicadas are used to prepare a tonic to treat eye disease and ailments of the lungs and liver and to soothe crying children. Another particularly interesting use of insect-derived pharmaceuticals in China has recently received much publicity. A tonic made from the fruiting body of the entomophagous fungus Cordyceps sinensis is considered a general-health and stress-relieving tonic. The fungus is collected in the wild from the dead caterpillar hosts of heptialid moths. In addition to the variety of ailments purportedly treated with this tonic, caterpillar fungus is also used to improve stamina and endurance. The tremendous performances of Chinese female distance runners in the early 1990s were attributed in part to the use of this caterpillar fungus tonic as part of their training regimen.

Although generally based on some empirical observation some time in the distant past, the validity of insect-based folk medicines should not be assumed, even on the grounds of widespread and long-term use. This is particularly true of aphrodisiacs. The symbolic, religious, and ceremonial associations common to the historical use of many drugs tend to obscure evidence on actual potency. On the other hand, the medicinal use of insects in folk remedies should not be dismissed outright as untrue. Each insect species possesses a unique biochemistry that has the potential to perform any number of medicinal tasks. Some insect-based folk remedies, such as the use of bee venom to treat arthritis and rheumatism, may eventually find a place in modern medicine or may at least serve as the basis for the derivation of modern treatments.

In addition to folk remedies that use insects to cure ailments, another body of insect folklore deals with ways to rid ourselves of pestiferous insects. Pliny the Elder wrote that one sure way to rid one’s fields of pests, particularly plagues of cantharid beetles, is to have a menstruating woman walk through the field. This treatment was said to cause the “caterpillars, worms, beetles, and other vermin to fall to the ground.” One widespread remedy for an infestation of cockroaches is to seal a few roaches and three coins in an envelope and leave it outside. Whoever picks up the envelope would not only be a little richer, but would also be the new owner of your roaches. A simpler remedy was to slip some roaches to some unsuspecting acquaintance to take home with them with the assurance that your roaches would soon follow. Problem ants can be dealt with in much the same way. By rolling several of the bothersome ants in a leaf and leaving it at a neighbor’s house, you could be sure that the ants in your house would soon depart to take up residence with the neighbor. Similarly, some folklore deals with how other animals rid themselves of pestiferous insects. Scottish foxes infested with fleas were said to hold a lock of wool in their mouth and then slowly submerge themselves in water until only the nose and the wool were above water. In trying to escape the water, the fleas end up on the fox’s nose and the wool. To finish the job, the fox puts its nose under water and releases the wool along with its passengers of fleas.

CONCLUSION

The acculturation of indigenous peoples worldwide, the disconnection of people from the natural world, and the spread of scientifically based knowledge facilitated by modern means of communication all work in concert to diminish the generation and proliferation of folklore in modern societies. With the ongoing loss of folk traditions in the modern world, so goes the place of insects in traditional folk beliefs and superstitions. Some continue to live on in various forms among contemporary societies, especially among indigenous peoples in places where the impact of the modern world has yet to take hold. The tidbits of factual observations and the incorrect information that came from antiquity through folklore formed the basis on which the first truly scientific naturalists started their work in the 16th century and led to modern scientific investigation. What was once a way of dealing with problems of unknown nature in our world is now being supplanted by stories of mere curiosity, which although largely untrue, provide interesting insight into the origin and development of human societies, cultures, and religions and are aesthetically pleasing to study.

Food, Insects as

Gene R. DeFoliart
University of Wisconsin, Madison

Insects in certain taxonomic groups have played an important role in the history of human nutrition. Although their use as food has long been taboo in almost all Western cultures, their traditional use in tropical and subtropical countries continues to be widespread.
and to provide significant benefits—nutritional, economic, and ecological—especially for rural communities. The potential benefits of continued or wider use are obvious enough that there seems to be a lessening of the negative attitude in the West.

The type of metamorphosis undergone by an edible species determines which life stage(s) is likely to be consumed. In insect orders with simple or incomplete metamorphosis (i.e., the Hemimetabola), the life stages usually eaten are the nymphs and/or adults. These orders include the Orthoptera (grasshoppers, locusts, katydids, crickets), Isoptera (termites), Heteroptera (true bugs), and Homoptera ( cicadas). Legs, wings, head, and any other hard parts are usually removed before cooking. Orders having complex or complete metamorphosis (i.e., the Hemimetabola) include the Lepidoptera (moths, butterflies), Coleoptera (beetles, weevils), and Hymenoptera (bees, ants, wasps). The life stage usually eaten is the larva, but sometimes it is the pupa or, rarely, the adult.

The insects used as food are, for the most part, clean-living in their choice of food and habitat. Most feed on leaves or other parts of plants. Some of the coleopterous and lepidopterous larvae are wood borers in either dead or living trees and bushes; some, such as cicada nymphs, feed on plant roots. Some hemipterans and coleopterans are aquatic, and some of these and other edible insects are predaceous. Some hymenopterans such as wasps provision their nests with insect prey upon which the young feed. Some edible species have other aesthetic qualities. Some African termites are architects, erecting earthen cathedral-like termitaria that may rise to heights of 3 or 4 m or more. Cicadas and crickets are songsters.

To collect wild insects for use as food, one should be knowledgeable about which local species are edible, particularly in Western cultures in which insects are not among traditional foods that are widely recognized. Some insects secrete toxins or sequester toxic chemicals from food plants or serve as a source of insectant, ingestant, contactant, or inhalant allergens. Bright colors, especially red, or showy behavior such as slow, deliberate flight may suggest that an insect contains toxins, or is unpalatable, and should be avoided.

There are many environmental and ecological ramifications relevant to the use of insects as food. Because of the large number of insect species and the consequently wide variety of plants used as hosts, in general, insects are potentially capable of converting a much wider range of vegetation and waste substances into animal biomass than are the animals currently considered acceptable as food by Western cultures. Many plants that either are not used efficiently or are not used at all in food production serve as hosts for edible insects. In Mexico, it has been suggested that some plants that are widespread and characteristic of arid regions, but of limited food value, such as mesquite, madrono, and some cacti, could be used for cultivation of their associated insects, the weevil Metamasius spinolae and the larva of the skipper butterfly, Aegiale hesperiars. The protein and fat content of these insects is many times higher than that of their plant hosts. In general, insects also are higher in their food conversion efficiency than are other food animals when both are fed diets of high quality (see the house cricket, Acheta domesticus).

**ORTHOPTERA (GRASSHOPPERS, LOCUSTS, KATYDIDS, CRICKETS)**

**Family Acrididae (Shorthorned Grasshoppers)**

Grasshoppers and locusts are included among the foods of almost every culture having any history of using insects as food. In southern Africa, before there were crops to protect, the arrival of a locust swarm, some of which were dense enough to block out the sun, was hailed with rejoicing as a time of harvest. Villagers collected them in the evenings after the swarms had alighted and were benumbed by the cool of the night. The locusts were roasted or boiled or, when plentiful, dried and crushed in mortars to make a much appreciated flour. Sometimes the flour or porridge was mixed with honey to make a sort of cake. Early reports noted that indigenous populations with access either to these vast locust swarms or to winged termites soon grew “visibly fatter and in better condition than before.” Grasshoppers were also an important food of Indian tribes in western North America. Various methods of harvest were used, but, most frequently, the grasshoppers were encircled by a number of people and driven into a pit previously dug or onto a bed of coals. Thus, slightly roasted, they could either be eaten or dried and kept for winter food.

In more modern times, within the past 20 years, grasshopper harvest has at one time or another replaced insecticide spraying in parts of Mexico, Thailand, and the Philippines. Sphenarium is the grasshopper genus of greatest commercial food importance in Mexico. The rice grasshopper, Oxya velox, was formerly widely eaten in Japan and Korea. Following reduced use of pesticides on rice in both countries, it is again increasing in numbers. Known as inago in Japan, it is now found in supermarkets as a luxury item; known as metdugi in Korea, it is considered a health food.

**Family Gryllidae (Crickets)**

Several species of crickets are important as food. In Southeast Asia, Brachytrupes portentosus lives in tunnels that are about 30 cm deep, usually one cricket per hole, and comes out only at night. They feed on young plants and are an agricultural pest. They are collected by digging, by filling the holes with water, or as they fly around lights at night. After the wings are removed they are eviscerated, then fried, grilled, or put into curry as a substitute for meat. They are sold by villagers in the markets. In the market at Chiang Mai in Thailand, the shopkeeper takes the crickets live from a plastic bag and puts them longitudinally from head to abdomen on a bamboo stick, three or four crickets per stick. They are then fried in oil in front of shoppers.

Another species of Brachytrupes, the sand cricket (B. membranaceus), occurs widely in eastern Africa. Like its cousin in Asia, its presence is indicated by a small heap of soil pushed out from its burrow. It is usually collected by the women and children, and as many as 100 can be collected in a day. It has been said of the sand cricket, “When well prepared it is considered a delicacy, for it turns an ordinary meal into a dinner.” In Zimbabwe and likely elsewhere, B. membranaceus is one of the species that has increased in numbers in recent years because it is particularly suited to the new kinds of agroecosystems. It is now a significant pest in sand-soil fields, and it is sold in urban markets.

The cricket most readily available to Western insect gourmets is the cosmopolitan house cricket, A. domesticus (Fig. 1), which is widely reared commercially as food for pets and other small animals. Studies in the United States led to estimates that this cricket, when kept at temperatures of 30°C or higher and fed diets equal in quality to those used in bringing conventional livestock to market condition, shows a food conversion efficiency about twice as high as those of broiler chicks and pigs, four times higher than sheep, and nearly six times higher than steers when losses caused by dressing percentage and carcass trim are taken into account. In addition, female crickets have much higher fecundity than beef animals; each cricket lays 1200–1500 eggs over a period of 3–4 weeks. In beef production, by contrast, four
animals exist in the breeding herd for each market animal produced, thus giving crickets a true food conversion efficiency close to 20 times better than that of beef.

**ISOPTERA (TERMITES)**

Termites are a highly regarded food throughout sub-Saharan Africa. They are eaten raw, fried, or roasted and are found widely in village markets. The fungus-growing termites of the genus *Macrotermes* (family Termitidae) are most widely used as food.

The large winged adults (sexual forms) are collected as they emerge from the nests on their mating flights at the beginning of the rainy season. They are strongly attracted to light and this behavior is utilized in harvesting them. The high termitaria of some species of *Macrotermes* are a spectacular feature of the African landscape; they are even considered private property in some areas. In southern Congo (Kinshaza), the termitaria average three to five per hectare and may cover 4.3–7.8% of the miombo woodland. The flora of the mounds is characteristic and quite different from that of the surrounding *miombo*, thus increasing habitat diversity. This diversity is in danger of being lost, however, because in suburban regions and towns, the characteristic flora and fauna are being destroyed and the mounds converted to other uses.

Winged termites are a rich source of fat; analysis of *M. subhyalinus* in Angola yielded an energy value of 613 kcal/100 g and *M. falceiger* in Zimbabwe a value of 761 kcal/100 g on an ash-free basis. Protein and fat content of the latter were shown to be 41.8% and 44.3%, respectively, on a dry weight basis. In addition to the winged adults, soldier termites are also eaten.

The high regard in which winged termites are held in Zambia has been documented by Silow in 1983 and appears typical for other countries in Africa: “The Mbanda, Nikangala, Lucazi, Luvala, Colwe, and Yauma generally agree that the meat of *Macrotermes* ssp. [winged sexuals] is better than meat of animals, birds, [or] fish. Perhaps one or another of the edible caterpillars is comparable with them, but most of my informants are of the opinion that [Macrotermes] or honey is the best existing food.” Silow notes that there are a few people who simply do not like termites and that some missionaries have condemned termite eating as a heathen custom. But he further states that Bemba, Namwanga, Nyanja, and Nsenga whom he has met unanimously declare that *Macrotermes* winged adults “are more delicious than anything else, or at least among the most delicious dishes.”

**HETEROPTERA (TRUE BUGS)**

**Family Belostomatidae (Giant Water Bugs)**

A giant water bug, *Lethocerus indicus*, is widely eaten in Southeast Asia and is especially popular in Thailand, where it is known as *nu-lang-da-na*. The bugs are 5–8 cm in length and fierce predators on frogs, large insects, and small fish. They are caught using nets or at lights, to which they are attracted. There are many methods of preparation, including roasting, frying, steaming, and grilling. After cooking they may be pounded and used for flavoring sauces and curries. The males secrete a fragrant liquid from two abdominal glands and are made into a much-prized sauce to accompany meat and fish. In the markets, males sell for three or four times the price for females. Artificial fish bug flavoring is now produced, but people still prefer to eat the real bugs.

Imported bugs (known as *mangda*) from Thailand and extracts of the bug (known as *mangdana essence*) can be found in Southeast Asian food shops in California. They are popular with Thai and Laotian customers who use them to make a bug paste called *nam prik mangda* prepared by mashing a whole bug with salt, sugar, garlic, shallots, fish sauce, lime juice, and hot Thai capsicum peppers. The *nam prik mangda* is commonly used as a vegetable dip and as a topping for cooked rice. The extracts known as mangdana essence can be used as a substitute for a whole bug in the preparation of *nam prik mangda*, but they are considered inferior in taste to that prepared from a whole bug.

**Families Corixidae (Water Boatmen) and Notonectidae (Backswimmers)**

The famous Mexican “caviar,” also known as *ahuahutle*, is composed of the eggs of several species in these families. These insects formerly bred in tremendous numbers in the alkaline lakes of central Mexico and were the basis of aquatic farming for centuries. Lake water pollution has now reduced their numbers. The eggs are harvested by what amounts to setting oviposition trap lines. Bundles of shore grass are tied together and weighted with a stone and then distributed by canoe. They are left in place for about 3 weeks during which the adult bugs swim up and lay their eggs on the submerged grass. The bundles are then collected, brought to shore, and dried in the sun. When dry, they are shaken and the eggs fall off. The “caviar” is a true delicacy that appears on the menus of the finest restaurants in Mexico.

**HOMOPTERA (CICADAS AND OTHERS)**

When there is an emergence of one of the species of periodical cicadas (family Cicadidae), many Americans, for whatever reasons, seem to regard them as legitimate fun food. During a recent (1990) emergence in Chicago and northern Illinois, for example, the Chicago Sun-Times carried several articles, the second of which began: “Millions of tasty, entrees-if-you-dare will be available for the gathering during the next month in northern Illinois, and some Chicagans will want to know how cicada fanciers prepare them.” Several recipes were provided. Articles described cicada biology and how to prevent damage caused by egg laying on very young plants and urged Chicagans to forego the use of insecticidal sprays. There were many radio reports, a cicada hotline, and even *Time* magazine published a recipe.

There are six species of periodical cicadas (Magicicada) in North America, three with a 13-year cycle and three with a 17-year cycle. The nymph remains in the soil, feeding on the roots of various plants until ready for the final molt. It then digs itself out of the ground, climbs the nearest tree or shrub, and attaches itself firmly. The adult lives for a month or longer. The so-called dog-day cicadas, such as

**FIGURE 1** Mass-reared edible house crickets, *A. domestica*. 
those of the genus *Tibicen*, have shorter life cycles, but even they require at least 4 years. Cicadas are eaten in many countries, but probably most widely in the countries of southeastern Asia.

**LEPIDOPTERA (BUTTERFLIES, MOTHS)**

Lepidopterans reach their maximum food importance in Africa where, in many countries, more than 20 species are consumed. In the southern part of Congo (Kinshasa), for example, caterpillars of at least 35 species are consumed.

**Family Saturniidae (Giant Silkworms)**

In 1980, Malaise and Parent analyzed 23 species (17 of which were Saturniidae) eaten by humans, using samples that were prepared in a manner identical to that preceding their culinary preparation and then dehydrated. Crude protein content averaged 63.5%, kcal per 100 g dry weight averaged 457, and most species proved to be an excellent source of iron, 100 g averaging (in 21 species analyzed for iron) 33.5% of the daily requirement. In Angola, the saturniid caterpillar *Usta terpsichore* was found to be a rich source of zinc, iron, thiamine, and riboflavin.

Probably the best known of the edible caterpillars is *Goninbrasia belina*, the so-called mopanie worm, which is widely eaten in southern Africa. The South African Bureau of Standards has estimated annual sales of mopanie through agricultural cooperative markets at about 40,000 bags, each containing 40 kg of traditionally prepared, dried caterpillars. This total represents only those entering reported channels of commerce and does not include those privately collected and consumed or sold. The caterpillars, up to 10 cm in length, grip the host plant tightly and cannot be shaken off; they must be picked by hand. A good picker in an average infestation can collect 18 kg per hour. In areas where they are abundant and bulk-dried, they are first eviscerated and then roasted for 15 min before being spread out to dry. About 2 days are required for the product to become dry enough for storage.

The mopanie caterpillar is an important food item and is actively traded not only in South Africa but also in Botswana and Zimbabwe and is exported by the ton to Zambia. From extensive studies in South Africa, Dreyer and Wehmeier concluded in 1982 that “the consumption of mopanie caterpillars can to a substantial degree supplement the predominantly cereal diet with many of the protective nutrients.” The amino acid composition of the dried caterpillars is relatively complete, with high proportions of lysine and tryptophan (which are limiting in maize protein) and of methionine (limiting in legume seed proteins). There is increasing concern in South Africa where protection of caterpillars as a food resource enhances biodiversity.

**Family Bombycidae (Silkworm Moths)**

A by-product of the silk industry, pupae of *Bombyx mori* remain after the silk is reeled from the cocoons. These pupae are widely sold, often canned, in markets in Eastern Asia. In China, the pupae, along with waste materials from the reeling factories and from the silkworm rearing, are also used as fish food in pond-fish culture. Canned pupae are exported, especially from Korea, and can be found in Asian food shops in the United States.

**Family Cossidae (Carpenterworms, Leopard Moths)**

Many insects were important foods for the Aborigines of Australia and among the most prized were the *witchety* or *witiwiti* grubs, several species of root-boring cossid larvae belonging to the genus *Xyleutes*. Tindale conducted in 1953 the definitive study on these insects and stated, “Aborigines with access to *witiwiti* grubs usually are healthy and properly nourished. …Women and children spend much time digging for them and a healthy baby seems often to have one dangling from its mouth in much the same way that one of our children would be satisfied with a baby comforter.” Over a period of several months spent observing nomadic Pitjandjaras in the Mann and Musgrave Ranges, it was noted that part of nearly every day’s diet consisted of these larvae. Tindale states elsewhere that the taste of *witchety* grub, “when lightly cooked in hot ashes, would delight a gourmet.”

Recently in Australia there has been an explosion of interest in native, or “bush tucker,” foods, including *witchety* grubs and other insects such as *hardt* grubs (*Cerambycidae*) and honey ants. Bush food is increasingly found in restaurants frequented by tourists, and book stores are well stocked with books on bush tucker. *Witchety* grubs are on the menu of the posh restaurant Rountrees on Sydney’s North Shore; the chef says of them, “They have a nice, nutty flavor when roasted.”

**Family Megathymidae (Giant Skippers)**

The larva of the giant skipper butterfly, *Aegiale hesperiaria*, known as *gusano blanco de maguey*, or the white agave or maguey worm, is in demand by people of all social classes in Mexico. Whereas campesinos with access to maguey plants can collect their own larvae to eat or to sell, restaurants in the larger towns and cities charge as much as U.S. $25 per plate. The *gusanos* are served fried or roasted in butter, chili, or garlic sauce. They are also exported as gourmet food. Two other edible insects are associated with the maguey. The pink worm of the maguey, *Xyleutes redtenbachi* (family *Cossidae*), also called the red agave worm or *gusano rojo de maguey*, is the larva used in bottles of tequila. They are sold in the markets and are also used to season sauces or they may be roasted or fried with salt and eaten in tacos. Along the maguey’s roots are often colonies of ants, which serve as a source of the prized *escamoles*, or so-called ant eggs, which actually are ant pupae.

**Family Pyralidae (Wax Moths, Grass Moths)**

Taylor and Carter wrote in 1976 as follows: “Larvae of the greater wax moth (*Galleria mellonella*) are tasty and, fortunately, easily reared, hardy and odorless. If only they were commercially available, we would probably have centered most of our recipes around them. They are our favorite insect. They are thin-skinned, tender, and succulent.
They would appear to lend themselves to commercial exploitation as snack items.” The authors note that the larvae, when dropped into hot vegetable oil, immediately swell, elongate and burst, looking then not like an insect, but like popcorn, and having the flavor of potato chips, corn puffs, or the like. These larvae, known as wax moths, are now available from various dealers in North America.

**COLEOPTERA (BEETLES, WEEVILS)**

**Family Curculionidae (Snout Beetles, Weevils)**

The larvae of palm weevils, several species of *Rhynchophorus*, also called palm worms, are widely eaten and greatly esteemed. A modern cookbook on Cameroon cuisine includes a recipe describing “coconut larvae” as “a favorite dish offered only to good friends.” The major species are *Rhynchophorus palmarum* in the Western Hemisphere, *R. phoenicis* in Africa, and *R. ferrugineus* and *R. bilineatus* in southeastern Asia, Indonesia, and the western Pacific. All of these species have long been semicultivated or “farmed” by indigenous peoples and are excellent examples of how harvests of edible insects from natural populations can be increased by intentional creation of additional breeding sites. Cultivation consists basically of cutting down palms and leaving the logs in the forest with the expectation that larvae will be ready to harvest from the decaying pith 1–3 months later. The flavor of the sago grub (*R. ferrugineus papuanus*) in Papua New Guinea has been described as “tender and sweet with a slightly nutty flavor.” The insect not only sells regularly in local food markets and is bought by foreigners as well as Papua New Guineans, it also is the focus of annual “grub festivals.”

Palm weevils are also destructive pests of palms and, in the Western Hemisphere, are vectors of the nematode *Bursaphelenchus cocophilus*, the causal agent of red-ring disease. Although insecticides have been used in attempts to control the weevils, emphasis is on cultural methods. With the palm worms considered such a delicacy, it has been suggested it might be possible to combine increased production with more efficient recycling of dead and diseased palms and as part of reduced-pesticide integrated pest management (IPM) programs and disease control on coconut and other palms.

**Family Scarabaeidae (June Beetles, Dung Beetles, Rhinoceros Beetles)**

Of the several edible groups within this family, the most interesting is probably the subfamily Dynastinae or giant rhinoceros beetles, particularly the genus *Oryctes*. Three species, including two that breed mainly in dead standing palms, are eaten in Africa, whereas *Oryctes rhinoceros* is a major pest of palm in Asia and the western Pacific. Main hosts of the adult beetles are coconut, oil, and date palms, whereas the larvae live in a variety of dead but not yet decomposed plant material, including dead standing coconut palms, stumps and logs on the ground, and other types of decaying wood, as well as compost, dung heaps, rotting straw, rotting coconut husks, coffee and cacao pulp waste, refuse from sugar cane factories, rice mills, and sawmills, and other wastes from agricultural processing. Control of rhinoceros beetles is based on sanitation and cultural practices similar to those recommended for *Rhynchophorus* weevils, suggesting that *Oryctes* might also be incorporated into palm IPM programs, recycling an endless variety of tropical wastes into animal protein and fat.

**Family Cerambycidae (Longhorned Beetles)**

In this family, it is the larvae, primarily, that are used as food. They are wood borers in both living and dead trees and in logs and stumps. They have long life cycles, a year or more, so would not be good candidates for mass-rearing under controlled conditions. A major genus, with edible species, is *Bacotera* in Asia.

**Family Tenebrionidae (Darkling Beetles)**

Tenebroides have a bad reputation as pests of meal, flour, and other stored and packaged cereal foods, but, despite this, the yellow mealworm, *Tenebrio molitor*, has been reared by zoos, aquaria, and commercial dealers as food for birds, fish, and a variety of small animals since at least the 18th century. Their easy availability makes them one of the insects most commonly recommended for inclusion in recipes in the West. There is a problem of quinone contamination in some tenebroid-infested food products, but this appears to be much less a problem in *T. molitor* than in species of the genus *Tribolium*.

**HYMENOPTERA (ANTS, BEES, WASPS)**

**Family Apidae (Honey Bees)**

Honey is prized by many indigenous cultures, and bee pupae/mature larvae, sometimes called “grubs” or “brood,” are often as highly prized as the honey. In southeast Asia, three species of wild bees, *Apis dorsata*, *A. florea*, and *A. indica*, are important sources of honey, wax, and brood. *A. dorsata* is the largest species and its nests, in the higher branches of large trees, may be up to 2 m in diameter. Its honey is also the most expensive, but honey from *A. florea* is most commonly found in the markets. People often eat the grubs uncooked, but they are also fried or put into soup. In Latin America, the grubs of *A. mellifera* and of species in several genera of stingless bees (subfamily Meliponinae) are used as food, and some of the bees, in Brazil and Mexico, for example, are semi-domesticated. Bees, including stingless species, are also important in Africa. In some places, such as the Congo (Kinshasa), honey and brood are still harvested by cutting down the tree although the practice has been much criticized. Apiculture in the United States is based on the introduced honey bee, *A. mellifera*, and it has been suggested that, because of its good public image, this species might be a valuable tool in helping to reshape attitudes toward insects as food in the United States.

**Family Formicidae (Ants)**

Many kinds of ants serve as food in different parts of the world and they are generally considered delicacies. In Colombia, for example, toasted leafcutter ants (genus *Atta*) are said to constitute the highest attainment of Colombian cookery. A campesino, by collecting and selling *Atta* ants, can earn during the 3-month season the equivalent of a year’s wages for the average rural worker. The genus is restricted to the Western Hemisphere. Only the alates are eaten, the large females being especially prized. They are collected as they swarm from the nest by the thousands on their mating flights during the early part of the rainy season. Two species, *A. cephalotes* and *A. sexdens*, are the most widely consumed, being relished across northern South America, with the former extending up into Mexico.

Fungus gardens grown on chewed leaf fragments are tended in the underground chambers of the large nests of the leafcutter ants. The fungus converts cellulose into carbohydrates that can be metabolized by the ants, thus allowing them to tap the virtually inexhaustible supply of cellulose in their forest environment. Forest trees are able to survive the grazing pressure of the ants, but the ants are serious pests of many cultivated trees and other crops when nests are located at the edges of forests adjacent to cultivated areas.

**Forensic Entomology**

M. Lee Goff

Chaminade University of Honolulu

In its broadest sense, forensic entomology includes any situation in which insects or their actions become evidence within the legal system. Medico-legal entomology involves insects as evidence in a criminal case, most frequently homicide, and this is the area that has been most closely associated with the term “forensic entomology” by the general public and, in fact, most entomologists. The use of insects and other arthropods as evidence in criminal investigations dates from 12th century China. Other records appear sporadically in both the forensic and the entomological literature from various parts of the world until a resurgence of interest in the field in the mid-1980s. Prior to this period, the primary application of entomological evidence was to determine the postmortem interval of decomposed bodies. Although this remains the primary application of forensic entomology in criminal investigations, it is now recognized that insects and other arthropods can provide insights into movement of a corpse following death, assessment of wounds (ante-mortem vs. postmortem), characteristics of a crime scene, and abuse and neglect of children and the elderly, as well as serving as alternate specimens for toxicological analyses and sources of human DNA.

**INSECTS AS INDICATORS OF THE POSTMORTEM INTERVAL**

Decomposing remains provide a temporary microhabitat offering a progressively changing food source to a variety of organisms, ranging from bacteria and fungi to vertebrate scavengers. The arthropods constitute a major element of this fauna, with the insects as the predominant taxa in terrestrial environments worldwide, in terms of both numbers of individuals and species diversity. In North Carolina, for example, 522 species in three phyla were recovered from decomposing pig carcasses, and of these, 84% were insects. In the Hawaiian Islands, 133 different kinds of arthropods were collected from pig and cat carcasses and of these, 83% were insects. There have been numerous decomposition studies conducted worldwide using different animal models, ranging from lizards and toads to elephants. There has been considerable variation in the numbers of different taxa recovered. These differences may be related to both geographic variation and differences in the animal models used.

**RELATIONSHIPS OF INSECTS TO THE REMAINS**

The use of insects to estimate the postmortem interval requires an understanding of the insect’s life cycle, the relationship of the insect to the remains, and the relationship of the remains to the habitat in which they are discovered. Insects pass through a number of distinct stages during their life cycle. Using a blow fly in the family Calliphoridae as an example, the female fly arrives at the body and deposits eggs in body openings associated with the head, anus, and genitals, or in wounds. After hatching, larvae or maggots feed on the decomposing tissues. There are three larval stages, with a molt in between each stage. Once the maggot is fully developed, it ceases to feed and moves away from the remains before pupariation. The puparium is an inactive stage during which the larval tissues are reorganized to produce the adult fly.

Escamoles are eaten by all social classes in Mexico and the ants have been described as the most enjoyable and expensive edible insect in the markets. Although called “ant eggs,” escamoles are mainly mature larvae/pupae of two species of the genus *Lio me totopus*, *L. apicalatum* and *L. occidentale var. lug t ussum*. Digging out the underground nest where the escamoles are found is very labor intensive. After harvest of ants from the nest (two or three times per year between February and June), the nest is covered with nopal, dried grass, and fresh weeds to maintain an environment suitable for survival and regrowth of the colony. People who collect escamoles, known as escamaderos, sometimes make more money during the harvest season than other rural people make during the entire year. The *Lio me totopus* ant is considered such a special treat in Mexico that it is the subject of songs, dances, and festivities.

Honey ants are a source of sweet treats in Mexico (species of *Myrmecocystus*) and Australia (several species in the genera *Camponotus* and *Melophor h*). Specialized worker ants, called repletes, store the honey in the abdomen, which may become the size of a small marble. They are eaten by grasping the head of the ant and sucking the honey from the abdomen. In Australia, *Camponot us in flatus* develops the largest repletes and they are considered a great luxury by the indigenous population. The repletes are found in galleries in the underground nests, where they are immobile and must be fed by the workers. Some aborigines expend much time and effort digging for the repletes but they only partially dig up the nests so as not to destroy the colonies and thus to preserve this valuable resource.
The insects encountered on a corpse in any given habitat consist of species unique to that particular habitat and those having a wider distribution. The unique components may be restricted to a particular geographic area or a particular habitat type within a given geographic area. Those taxa having wider distributions are frequently encountered in several different habitat types and are typically highly mobile species. Many of those taxa closely tied to carrion show this wider pattern of distribution. In estimating the postmortem interval, taxa from both components may, under given circumstances, provide essential information on the history of the corpse.

Of those insects having a direct relationship to the corpse, there are four basic relationships.

**Necrophagous Species**

Taxa feeding on the corpse comprise this group, including many of the Diptera [Calliphoridae (blow flies) and Sarcophagidae (flesh flies)] and Coleoptera (Silphidae and Dermestidae). These species may be the most significant taxa for use in postmortem interval estimates during the earlier stages of decomposition, defined here as days 1–14.

**Parasites and Predators of Necrophagous Species**

This is the second most significant group of carrion-frequenting taxa and includes Coleoptera (Silphidae, Staphylinidae, and Histeridae), Diptera (Calliphoridae and Stratiomyidae), and hymenopteran parasitoids of larvae and puparia of Diptera. In some instances, dipteran larvae that are necrophages during the early portions of their development turn into predators.

**Omnivorous Species**

Ants, wasps, and some beetles, which feed on both the corpse and associated arthropods, comprise this group. Large populations of these may severely retard the rate of carcass removal by depleting populations of necrophagous species.

**Adventive Species**

This category includes taxa that use the corpse as an extension of their own natural habitat, as in the case of the Collembola, spiders, and centipedes. Acar in the families Acaridae, Lardoglyphidae, and Winterschmidtiidae that feed on molds and fungi growing on the corpse may be included in this category. Of less certain association are the various Gamasida and Actinedida, including the Macrochelidae, Parasitidae, Parholaspidae, Cheyletidae, and Raphignathidae, that feed on other acarine groups and nematodes.

**DECOMPOSITION**

Although there have been many decomposition studies conducted in different parts of the world and under different environmental conditions, most studies have been conducted in temperate areas and fewer in tropical and subtropical habitats. Common to the majority of these studies has been an attempt to divide the decompositional process into a series of discrete stages. Decomposition is a continuous process and so discrete combinations of physical parameters and arthropod assemblages do not occur. There is a value to these stages, however, in providing reference points when faced with the problem of explaining the events associated with decomposition to a jury.

Regardless of locality, there are common patterns. The faunas involved tend to be regional, except for some widely distributed species of Diptera and Coleoptera, but the families involved are relatively stable. The division of decomposition into five stages can be applied to most studies.

**Fresh Stage**

This stage begins at the moment of death and ends when bloating is first evident. The first insects to arrive at the corpse are flies in the families Calliphoridae and Sarcophagidae. Adult females investigate the corpse, frequently feed, and then, depending on the species of fly, deposit either eggs or larvae around the natural body openings associated with the head (eyes, nose, mouth, and ears) and anogenital regions. Wounds are secondary sites of attraction to tropical species but also may be of major significance in temperate environs.

**Bloated Stage**

Putrefaction, the principal component of decomposition, begins. Gases produced by the metabolic activities of anaerobic bacteria first cause a slight inflation of the abdomen and, later, the corpse appears balloon-like and fully inflated. Internal temperatures rise during this stage as the result of bacterial decay and metabolic activities of feeding dipteran larvae. Calliphoridae are strongly attracted to the corpse during this stage. As the corpse inflates, fluids are forced from natural body openings and seep into the soil. These fluids combined with the by-products (ammonia, etc.) produced by the metabolic activities of the dipteran larvae cause the soil beneath the corpse to become alkaline and the normal soil fauna departs.

**Decay Stage**

This is the only stage in the decomposition process which has a distinct starting point. The decay stage begins when the skin is broken, allowing gases to escape and the corpse to deflate. Dipteran larvae form large feeding masses and are the predominant taxa present (Fig. 1A). Although some predatory forms, such as beetles, wasps, and ants, are present during the bloated stage, both necrophagous and predatory taxa are observed in large numbers during the later portions of the decay stage. By the end of this stage, most Calliphoridae and Sarcophagidae have completed their development and departed the corpse for pupariation (Fig. 1B). Dipteran larvae will have removed most of the soft tissue from the corpse by the end of the decay stage.

**Postdecay Stage**

As the remains are reduced to skin, cartilage, and bone, Diptera cease to be predominant. In xerophytic and mesophytic habitats, various Coleoptera predominate throughout this stage, and the diversity of these taxa increases. Associated with this increase is an increase in the numbers of parasites and predators of beetles. In wet habitats (swamps, rain forests, etc.), however, other taxa, primarily Diptera, and their predator/parasite complexes predominate.

**Skeletal Stage**

This stage is reached when only bones and hair remain. No obvious carrion-frequenting taxa generally are present and there is a gradual return of the normal soil fauna to the area under the corpse. An examination of the soil during the early portions of this stage will reveal various acarine groups that may be of use in estimating the postmortem interval. There is no definitive end to this stage and changes in the soil fauna may be detectable months or even years following the death.
BIOLOGY OF DIPTERA

One of the major problems facing forensic entomologists is the accurate identification of the larvae collected from the remains. Too frequently, the entomologist must work with dead specimens collected by crime scene investigators and submitted in marginal states of preservation. Even when the local faunas are well known, identification of these specimens is difficult, especially for early instars. Work by Erzinclioglu in England and Liu and Greenberg in the United States has provided identification keys to larvae of forensically important taxa. Excellent keys for adults of the blow flies and flesh flies have recently been published by Whitworth. Given the wide distributions of many of the sarcosaprophagous taxa, these keys have a wider application than suggested by their regional titles.

Seasonal variation in the populations of Calliphoridae has been documented in North America and Europe. There are also seasonal patterns in Calliphoridae. In northern Mississippi, for example, Phaenicia caeruleiviridis was the first species to arrive during spring, while Cymomyopsis cadaverina was the first species to arrive during the fall and winter months.

Considerable emphasis has been placed on how temperature influences the duration of the various stadia for different species of flies. Accumulated degree hours (ADH) or accumulated degree days (ADD) can be used to estimate the postmortem interval. Ambient temperature data from weather stations in the vicinity of the corpses are used as an indicator of the temperatures at which larvae developed. These temperatures, however, may not reflect the temperatures at which the larvae actually develop. Based on a Hawaiian study, internal temperatures associated with the maggot masses can be as much as 22°C above ambient. Similar observations have been made for human corpses in the former Soviet Union.

In instances of heavy maggot infestations, it is obvious that there is little, if any, direct relationship between ambient air temperature and the temperatures at which the maggots are developing. Although heat generated by maggot masses influences the rate of larval development, this heat generation may not occur immediately, but requires a period of several days to develop. Such a delay may be because of a lack of an organized maggot mass during the early instars. For corpses found during cool weather when colonizing fly populations are low, ADH or ADD calculations generally are more accurate than in higher temperatures with high fly populations. In addition to the rate of development, temperatures may also serve to limit the species that can use the corpse for development. Only some species of Calliphoridae can tolerate high temperatures inside a maggot mass during development. Thus, maggot-generated heat can influence the rate of maggot development, the nature of the corpse arthropod community, the character of the subcorpse community, and the validity of ADH or ADD calculation-based postmortem interval estimates.

FACTORS DELAYING INVASION OF THE CORPSE

The initial invasion of the corpse by insects and other arthropods starts the clock that is ultimately interpreted to give the estimate of the time since death. The basic assumption underlying this is that the invasion occurs soon after death. In decomposition studies, fly activity begins as soon as 10 min after death, but there are factors that may delay this invasion. Invasion can be delayed by wrapping of the corpse or submersion in water. Adverse climatic factors such as cloud cover, temperature, and rainfall may inhibit adult fly activity. Darkness has long been believed to inhibit calliphorid activity, but nocturnal oviposition has been observed in Calliphoridae commonly associated with decomposing human remains in North America and Hawaii. In these instances, temperatures during oviposition were above 20°C. Although nocturnal activity and oviposition may be expected for some species in tropical habitats, it appears to be the exception rather than the rule in temperate regions. Clearly, care must be taken in forensic interpretations dealing with nocturnal activity of Calliphoridae.

APPLICATIONS TO DEATH INVESTIGATIONS

In the preceding sections, the biological basis for using insects as evidence in estimating postmortem interval (time since death), patterns of decomposition, and several of the problems have been presented. An understanding of insect biology and ecology is necessary as a template for determining postmortem interval, but it does not always provide an accurate estimate. In processing insect data, a forensic entomologist must bear in mind that an estimate based on insect activity only determines the period of insect activity. This time frame may not correspond to the entire period of time since death. Each case is unique and must be analyzed on its own merits with careful attention to all data available.

As noted earlier during discussions of decomposition, there is great geographic and seasonal variation in insect populations associated with a corpse. Even in areas where the species populations are similar, there may be seasonal changes in developmental patterns which may complicate the analyses.

In addition to gathering and processing of entomological data, it is necessary to develop protocols for cooperation between the forensic...
entomologist and various law enforcement agencies, medical examiners, coroners, and the courts. As these individuals better understand the functioning of the forensic entomologist, the end results of the investigations will improve.

COLLECTION PROTOCOLS

Several workers have independently formulated their own protocols for collecting and processing entomological evidence. Among those published, Lord and Burger provide the best general procedures.

ESTIMATION OF THE POSTMORTEM INTERVAL

In the actual process of estimating the postmortem interval from entomological data, each case will be unique. Regardless, the process tends to follow the same general sequence of events:

1. The stage or physical state of decomposition based on physical parameters for the corpse should be determined, and any indications of disturbance or dismemberment of the corpse that may have occurred following death are noted. If the community collected under the corpse does not conform to the observed stage during later analysis, the possibility of movement of the corpse following death must be considered.
2. Specimens collected from the corpse and crime scene must be identified as completely as possible. Immature stages must frequently be reared to the adult stage for final species-level identifications. Representative specimens of immatures (species and stages) must be preserved properly to provide a record of what was present on the corpse at the time of examination.
3. For outdoor scenes, appropriate climatic data (temperatures, rainfall, cloud cover, etc.) from weather stations and on-scene observations must be obtained. Aspects of the scene that may serve to influence the effects of these climatic factors on arthropod invasion of the corpse should be considered (cover by vegetation, shading by trees, slope of the ground, burial of the corpse). For indoor scenes, the temperatures (automatic heating, thermostat settings, air conditioner) possible for the time period in question should be noted; positioning of the corpse relative to windows and doors may be significant in terms of both heat and solar radiation.
4. From the autopsy report or one’s own observations, the sites of infestations by arthropods should be noted.
5. The postmortem interval is estimated. In the earlier stages of decomposition, this estimate may be based on the developmental cycles of dipteran larvae. In simplest form, the time required to reach the mature stage of development of the earliest arriving species on the corpse under prevailing conditions would correspond to the minimum postmortem interval. Further consideration must be given to factors that could delay the onset of insect activity (climatic factors, wrapping of the corpse, seasonal variation). When these factors are considered, the final postmortem interval estimate may be greater than the estimated faunal ages. During this comparison, both presence and absence of taxa and developmental stage must be considered. For this reason, it is essential that collections from the corpse and the surrounding area be as complete as possible. In general, the parameters for the postmortem interval estimate will become wider as the time since death increases. During the earlier stages of decomposition, the estimate may be expressed conveniently in terms of hours, whereas later it may be in days, months, or even seasons of the year.

MOVEMENT OF THE BODY FOLLOWING DEATH

Although insects and other arthropods are among the most widely distributed organisms on earth, they are often quite specific in their distributions. As noted earlier, the fauna of the decomposing corpse is composed of species having a wide distribution and species specific to the particular area in which the body is discovered. Presence of species not typically associated with the habitat in which the body is discovered is an indication that the victim died in one location and the body was exposed to insect activity for a period of time. Following this, the body was transported to another location where a second colonization by insects took place.

ASSESSMENT OF TRAUMA

The initial sites of fly egg-laying activity on a decomposing body will normally be the natural body openings associated with the head, anus, and genitals. For many species, the presence of blood associated with wounds is also attractive and egg-laying occurs at those sites. A wound that occurs prior to death (antemortem), while the heart is still beating, produces blood, which is attractive to the flies. If the wound occurs following death (postmortem), similar quantities of blood are not associated with the wound and it will be less attractive to flies for oviposition. If a body is encountered during the earlier stages of decomposition with significant infestations of maggots in areas other than the natural body openings, the possibility of antemortem wounds must be considered. In like manner, if there are wounds present on the body, but infestations are primarily restricted to the natural body openings, these wounds may well be postmortem artifacts.

ABUSE AND NEGLECT

Although most of the applications of entomological evidence involve the dead, in some instances entomological evidence may involve living victims. In these instances, the maggots are encountered feeding on live tissues. This is a condition known as myiasis and is an obligate condition in the life cycles of many flies, primarily in the families Calliphoridae and Sarcophagidae. In other species of flies, myiasis may be a facultative situation. Stages of development recovered from wounds or sores on children, the elderly, or those otherwise unable to care for themselves can be used to document the period of abuse or neglect.

An additional potential problem is in situations in which myiasis occurs prior to death. If the sites of infestations are not noted, the period of development of the maggots on the living individual may be added to the postmortem development, thus increasing the estimated time since death. Any departure from the normal pattern of arthropod invasion of a corpse should be a cause for care in interpretation of entomological evidence.

ENTOMOTOXICOLOGY

Over the past two decades, drug-related deaths have increased in the United States and other countries. In many instances, these deaths are not immediately reported and the remains may be undiscovered for several days. Because of decompositional processes, estimations of the time of death or postmortem interval are based on analyses of insects and other arthropods infesting the remains. The data most frequently employed are those associated with insect development rates and successional patterns. Recently, the accuracy of these estimations has been questioned in deaths involving narcotic intoxication. relatively
Detection of Drugs and Toxins

It is not unusual for remains to be discovered in a highly decomposed or skeletal stage, when there is insufficient tissue for toxicological analyses. There frequently are, however, arthropods or their cast larval or puparial skins still associated with the remains. Various toxic and controlled substances can be detected by analyses of these arthropods and their residues. Generally, arthropod materials have been homogenized and then processed in the same manner as other tissues or fluids of toxicological interest. Analytic procedures include radioimmunoassay, gas chromatography, thin layer chromatography, and high-performance liquid chromatography–mass spectrometry.

Effects of Drugs on Development of Insects

Although many of the studies mentioned documented the potential for use of maggots or puparia as alternate specimens for toxicological analyses, few were concerned with the potential effects of these drugs on the development of the insects ingesting them. In providing an estimate of the postmortem interval, particularly within the first 2–4 weeks of decomposition, it has been assumed that the insects will develop at predictable rates for given environmental conditions. That this might not always be true was established by studies on the effects of cocaine on development of the sarcophagid _Boettcherisca peregrina_. In this example, maggots were reared on tissues from rabbits that had received known dosages of cocaine, corresponding to 0.5, 1.0, and 2.0 times the median lethal dosage by weight. Two patterns of development were noted. Control and sublethal-dosage colonies developed at approximately the same rate, as indicated by total body length. In contrast, the colonies fed on tissues from the lethal and twice-lethal dosages developed more rapidly. This difference continued until maximum size was attained and the postfeeding portion of the third instar was reached. Due to the increased rate of development during the feeding stages, pupariation occurred first in the lethal and twice-lethal colonies, but the actual duration of the puparial period was the same for all colonies and there were no detectable differences in puparial mortality.

The potential significance of these alterations in the rates of larval and puparial development is illustrated in trying to establish the postmortem interval of a Caucasian woman, approximately 20 years of age, discovered in a pine woods area northeast of Spokane, Washington. The body was in the early bloated stage of decomposition and had extensive populations of maggots on the face and upper torso. Maggots were submitted to the entomologist after being refrigerated for 5 days and reared to the adult stage. Two species were identified from the adults: _C. cadaverina_ and _Phaenicia sericata_. Typically, _P. sericata_ oviposits within 24h following death, whereas _C. cadaverina_ oviposits 1–2 days following death. Three size classes of maggots were present on the corpse. The first consisted of maggots measuring 6–9 mm in length that were consistent of a period of development of approximately 7 days. The second consisted of smaller maggots, consistent with continued oviposition by adult flies. The third consisted of a single maggot measuring 17.7 mm in length and indicative of a developmental period, under prevailing conditions at the scene, of approximately 3 weeks. Given the other data associated with the case, this period did not seem possible. The possibility that this maggot had migrated from another nearby source was eliminated, as no carrion could be located nearby and the probability of only a single maggot migrating was low. The alternate explanation was that the maggot’s growth rate had been accelerated in some manner. It was learned that the victim had a history of cocaine abuse and that she had snorted cocaine shortly before her death. This maggot had most probably developed in a particular pocket in the nasal region containing a significant amount of cocaine.

**Sources of Human DNA**

Recent advances in technology have provided means to identify individual hosts from analyses of hematophagous arthropod blood meals. Using polymerase chain reaction and amplified fragment length polymorphism DNA characterization procedures, two human DNA genetic markers, D1S80 and HUMT01, have been typed from human DNA material derived from excreta from the human crab louse, _Pthirus pubis_, fed on human volunteers. Although these results are preliminary, they demonstrate the potential for this technology to provide individual characterizations for cases of rape or homicide in which hematophagous arthropods are encountered by investigators at the scene. More recently, human mitochondrial DNA (mtDNA) has been isolated, amplified, and sequenced from crab lice fed on human volunteers. This study demonstrates the potential for mtDNA analyses to characterize individual hosts even from desiccated and frozen arthropod blood meals, and it is yet another example of the stability of mtDNA.

**Conclusions**

Applications of entomological evidence have increased significantly since the 1980s. Although the major application is estimation of the postmortem interval, entomological evidence also can be applied to toxicology, DNA analyses, and aspects of crime scene assessment. Although there have been many advances, there is still a need for much basic research. Questions remain with regard to the life cycles of many of the necrophagous arthropods, particularly Coleoptera. One problem in application of entomological evidence is the diversity of the insect fauna which changes from one geographic area to the next. Databases are still needed for many parts of the world where the sarcosaprophagous fauna is poorly known. Even in areas relatively well investigated, there may be significant microgeographic variation in the insect fauna. Additional investigations are needed in the areas of toxicological analyses and applications of DNA technology. A current underlying problem is the relative lack of trained forensic entomologists. Most individuals now working in the field are employed in academic institutions where only a small part of their research effort is assigned to forensic concerns.

Forest Habitats

David L. Wood
University of California, Berkeley

Andrew J. Storer
Michigan Technological University, Houghton

Forest habitats may be broadly defined as those in which trees are a significant component. Forest habitats may be natural or manmade, managed or unmanaged, comprised of native species or species transplanted from other geographic regions. All orders of insects can be found in these habitats and thus all feeding habits such as saprophagous, phytophagous, entomophagous, and parasitic species are represented. Forest habitats may include associated lakes, streams, and meadows. In this article, we give greatest emphasis to those orders of insects that feed on trees and the predators and parasitoids that consume these phytophagous species. Insects found primarily in soils, lakes, and streams; those that feed on other vegetation found in forests; and those that parasitize other animals are considered elsewhere in this encyclopedia.

THE DIVERSITY OF FOREST HABITATS

Forest habitat diversity is a reflection of geographic location of the forest, as well as the influences of humans on the forest. Natural forests vary in complexity based on species composition resulting from a combination of environmental factors. Perhaps the most useful classification system for natural forests is that developed by the Food and Agriculture Organization of the United Nations in the 1970s. This system divides the natural forests of the world into five broad categories as follows:

1. The cool coniferous forests are a circumpolar belt of boreal forests across northern latitudes. They occur between tundra to the north and temperate mixed forests to the south. Conifers are the dominant species in these forests, with a few species of broadleaf trees.

2. The temperate mixed forests are found south of the cool coniferous forests and also are found in parts of the Southern Hemisphere. Pines and deciduous and evergreen broadleaf trees tend to dominate these forests.

3. Tropical moist evergreen forests are rainforests characterized by high annual precipitation (>2000 mm) evenly distributed during the year. Amazonia, western equatorial Africa, and the Indo-Malayan region are the three main regions for this forest type.

4. Tropical moist deciduous forests are found in tropical regions with 1000–2000 mm annual rainfall and a dry season for 1 or more months. These forests include monsoon forests in Asia where a dry period of 2–6 months is followed by heavy rains.

5. Dry forests are found in both temperate and tropical zones where annual precipitation is less than 1000 mm and are low and simply structured wooded areas.

These forest types may be further subdivided according to dominant species types and climatic differences among other factors. Additional forest types can also be recognized, including those heavily influenced by humans, such as urban forests and plantations. The influence of humans as a result of population growth has resulted in depletion of the area covered by natural forests in both developed and developing countries.

Forest habitats exhibit extraordinary diversity. Within them are complex assemblages of species, and myriad interactions occur among these species. In California, over 5000 species of insects inhabit oak forests alone. The species of host plants naturally influence the species of phytophagous insects present in a forest. Through their activities, humans have the potential to alter the distribution and density of insects, trees, or both. Examples of when this occurs include forest management in natural forests, plantation forests involving native or exotic tree species and introduction of exotic insect species, as well as changes resulting from a warming global climate.

Forest management in natural forests may involve fire suppression that may favor insects that can exploit shade-tolerant tree species. For example, the fir engraver, Scolytus ventralis, has increased in density in mixed conifer forests of the Sierra Nevada in California because fire suppression has led to a dense understory of white fir. Abies concolor. Regeneration of shade-intolerant pines is suppressed and this in turn leads to an overly dense forest dominated by white fir. Periodic logging or thinning may result in a build up of insect populations in cut material or associated waste. For example, neglect of forest hygiene following thinning operations in European pine forests may result in an increase in populations of the European pine shoot beetle, Tomicus piniperda, which subsequently may damage the shoots of standing trees during its adult feeding stage. Clearcutting and replanting or natural regeneration of forests favors insects that feed in young trees. For example, the pine weevil, Hylobius abietis, is perhaps the most significant forest insect pest in Europe. Adults feed on the bark at the base of conifer seedlings, resulting in seedling mortality. In many locations, any efforts to establish a plantation or naturally regenerated forest must have a management protocol to reduce the impact of this weevil.
In human-made forests, the species composition may be very simple, as in monocultures, or more complex, depending on the management goals of the plantation. Age and size classes of trees are frequently very limited. These plantations may comprise native or exotic tree species and may be on previously forested land or on previously unforested land. Perhaps the simplest forest habitat is a plantation monoculture of even-aged trees (such as in Monterey pine, *Pinus radiata*, plantations in New Zealand or loblolly pine, *P. taeda*, plantations in areas of the southeastern United States). This habitat is nevertheless very diverse as a result of the array of different ecological niches present on the dominant tree species. Usually, plantation monocultures involve areas of forest that are even-aged and that therefore encounter pressure from phytophagous insects that are adapted to, or more pestiferous during, certain stages of forest growth.

Plantation forestry may involve tree species that are not native to the location where a forest is planted. Any insects that occur in these forests, but which were not present prior to the existence of that forest, are therefore introduced. Often these insect populations are not under natural regulatory pressures that limit their numbers. The eastern five-spined ips, *Ips grandicollis*, generally infests stressed or diseased trees in its native habitat in the southeastern United States and is generally not considered a primary agent of tree mortality. Its introduction into Australia in the mid-20th century has resulted in significant tree mortality in pines that have been transplanted to Australia from North America and Europe. As spruce forests have been planted in areas of Europe, using spruce as an exotic species, the European spruce beetle, *Dendroctonus micans*, moved westward from Eurasia during the 20th century. Damage caused by this bark beetle has been most severe at the edge of its expanding range before natural enemies spread or are introduced into the areas now exploited by *D. micans*. In the creation of new forest habitats, the interactions among the species in the forest are unpredictable, because an essentially novel habitat has been created.

Two emerging factors that are altering interactions among insects and forests are the increased movement of exotic insect species into novel geographic areas, and the changes that are becoming evident as a result of global climate change. Exotic species have the potential to alter the species composition of forests. For example, Hemlock woolly adelgid, *Adelges tsugae*, threatens to eliminate hemlocks from forests. For example, woolly adelgid, *Adelges tsugae*, threatens to eliminate hemlocks from forests. For example, woolly adelgid, *Adelges tsugae*, threatens to eliminate hemlocks from forests. For example, woolly adelgid, *Adelges tsugae*, threatens to eliminate hemlocks from forests.

Figure 2: Mountain pine beetle, *Dendroctonus ponderosae* (Coleoptera: Scolytidae), killed lodgepole pine, *Pinus contorta* var. *latifolia*, in 2005 near Prince George, British Columbia, Canada. (Photograph by Andrew J. Storer)

caused mortality of pines, especially lodgepole pine, over millions of hectares (Fig. 2). Previous outbreaks had apparently never moved this far north, perhaps due to limitations on the insect posed by cold winter temperatures. As the global climate continues to warm, we can expect to see additional effects on insect populations and their interactions with forested areas.

**DIVERSITY OF INSECTS IN FORESTS**

Approximately half of the insect orders are directly or indirectly associated with trees. As with humans, insects use trees for food, shelter, support, and travel. Among all plants, trees present the most diverse habitats for insects to occupy. Insects feed on all parts of the tree, that is, vegetative structures such as leaves, stems, and roots and reproductive structures such as flowers, fruits, and seeds. Some insects are specialized to feed on phloem and/or xylem tissues, dead sapwood, and heartwood. Insects that feed on these structures and tissues vary in size from 1–2 mm (scale insects) to 6 cm (longhorned...
beetles). Life cycles (from egg to adult) can be completed in a few days or weeks (aphids) or be prolonged for 50 years (metallic wood borers).

Although all orders of insects are found in forest habitats, only a small number feed on the trees or are the predators or parasites of these taxa. Species from the following orders are generally referred to as “forest insects”: Hemiptera, Isoptera, Orthoptera, and Thysanoptera (in the Exopterygota, which undergo incomplete metamorphosis) and Coleoptera, Diptera, Hymenoptera, Lepidoptera, and Raphidioptera (in the Endopterygota, which undergo complete metamorphosis).

Habitat diversity is greatly favored by the large size of trees, in both mass and height. Thus, both the abiotic and the biotic environment can vary considerably from the roots to the upper canopy. For example, a bark beetle, *Hylastes nigrinus*, spends its life cycle feeding beneath the bark on the roots of Douglas-fir, *Pseudotsuga menziesii*, growing in California, whereas a cone midge, *Contarinia oregonensis*, feeds in a gall in the seed coat within a cone. Old-growth Douglas-firs with a height over 100 m and a diameter of 3 m are not uncommon. Over 240 insect species from the above-mentioned orders are listed as feeding on Douglas-firs. However, only a few of these would be found at the same time on a large, living tree. Similar diversity of insects feeding on trees can be found in broadleaved deciduous forests and broadleaved evergreen forests. Deciduous oaks in England are fed upon by over 250 insect species, and some evergreen oaks in coastal California provide food for about 300 insect species.

This complexity is magnified further when the guilds of insects in the canopy are considered. The phytophagous insects are represented by chewing, mining, gall-making, and sap-sucking species. Chewing insects are found in the Coleoptera, Lepidoptera, Hymenoptera, and Orthoptera; mining species in the Hymenoptera, Lepidoptera, and Diptera; gall-making species in the Diptera and Hymenoptera; and sap-sucking species in the Hemiptera (Homoptera and Heteroptera) and Thysanoptera. Predators are found in the Coleoptera, Diptera, Hymenoptera, and Raphidioptera and parasites in the Diptera and Hymenoptera. Insects that feed on epiphytes such as lichens, algae, and mosses are found in the Psocoptera (bark lice), Collembola (springtails), Dermaptera (earwigs), and Plecoptera (stoneflies). Mosquitoes (Diptera) breed in water contained in tree holes, which are decayed cavities in the wood.

Many detritivores are found in the canopy as well as on other parts of the tree. They feed on many food sources such as protozoa, bacteria, fungi, nematodes, and small particles of plant and animal tissues. These species are found, for example, in the Psocoptera, Collembola, and Blattodea.

Finally, many insects that do not feed on the trunk or foliage use them for a resting or hiding place, mating, pupation and/or hibernation, or estivation. These temporary residents have been classified as “tourists.” Many of these insects feed on the surrounding vegetation. Their predators and parasitoids would be included as tourists also. For example, ants and spiders, which are very important predators of tree-inhabiting insects, use tree trunks as roadways from the forest floor to the canopy in search of prey. Another example, a sawfly, *Strongylogaster distans*, that feeds on bracken fern in the Sierra Nevada of California, pupates in the bark crevices of nearby ponderosa pines.

**ROLE OF INSECTS IN FOREST SUCCESSION**

Although trees can live for thousands of years (e.g., giant sequoia, *Sequoiadendron gigantea*), natural forests are dynamic plant communities that can change very slowly over thousands of years or very quickly over a few days to a few years. Fires, volcanic eruptions, strong winds, floods, and snow and ice often have dramatic effects on forest succession. Insects can also have this effect during outbreaks (referred to as epidemics or gradations). For example, bark beetles, together with their associated blue-stain fungi, are known to kill millions of trees over thousands of hectares. Lodgepole pine forests of western North America may change from old-growth (ca. 90 years), even-aged, predominantly lodgepole pine forest to a younger forest of lodgepole pine if a fire occurs subsequent to a mountain pine beetle infestation. Lodgepole pine cones often remain closed for many years and thus can store a large seed crop on the tree. Following a fire, which opens the cones, an almost pure forest of lodgepole pine is established over very large areas. Thus, the stage is set for another mountain pine beetle outbreak in 80–100 years.

Insects affect the growth rate and mortality of trees by feeding on various parts of the tree. Thus they affect the life cycle of trees by influencing the size of the seed bank, the amount of recruitment, the growth of individuals in height and volume, and the reproduction and dispersal of the tree species. Insects consume seeds within fruiting structures or on the ground, thus reducing the size of the seed bank. They consume young seedlings, thus decreasing the recruitment of new trees into the population. They kill tips and shoots, suck plant fluids from the phloem and xylem, and consume the foliage, thus reducing the photosynthetic capacity of the tree and, as a result, reduce the growth of individuals. Insects also kill trees by reducing their growth rate so they cannot compete with other individuals of the same or different species for light, space, water, and nutrients. Trees are killed quickly, often in a few weeks, following severe defoliation by moths or sawflies and by bark beetles that introduce pathogenic fungi into the phloem and xylem. Direct and indirect interactions occur between insect species and between insects and forest pathogens. Root disease pathogens may indirectly affect bark beetle populations by weakening trees and thus predisposing them to attack by bark beetles. Direct interactions with pathogens may occur when, for example, insects transmit the pathogen, as with the pitch canker pathogen, *Fusarium circinatum*, in California and the Dutch elm disease pathogen, *Ophiostoma novo-ulmi*, in Europe and North America. All of these effects occur through interactions with other biotic and abiotic agents as part of the complex forest cycle that involves gaps, building, and mature and degenerate phases. Insects therefore impact forest succession by influencing the forest cycle. The changes in these parameters affect the distribution and abundance of trees at a given moment in time and can be projected into the future using mathematical modeling techniques.

The examples drawn upon in this article emphasize those insect taxa that affect the survival of trees and in turn influence successional patterns of forests. This treatment thus includes phytophagous species and their natural enemies. Some authors refer to this interaction between insects and plants as a predaceous or parasitic relationship. The predator kills the host but the parasite does not kill the host directly. Insects may also form commensalistic and mutualistic associations with trees. In a commensalistic interaction, the tree is not affected, for example, when it is used as a resting place, whereas the tree benefits in a mutualistic interaction, such as with a pollinator. Our objective then is to emphasize the negative interactions between insects and their host trees, in which only the insect benefits and the tree is debilitated or killed. The tree does, however, benefit in the long term at the population level, where succession allows nutrient turnover and reproduction allows adaptation of the tree species to environmental changes.
FEEDING GROUPS

Insects can be assigned to feeding groups based on the part of the tree they attack and the method of feeding they use. In forest habitats, these feeding groups are as follows:

A. Insects that feed on cones and seeds
B. Insects that feed on shoots and tips
C. Insects that feed on foliage
D. Insects that feed on the trunk and large branches
E. Insects that feed on roots

In the following discussion, species have been selected from each feeding group to demonstrate the great diversity of insect adaptations to their tree hosts. An example is given from each of the major orders of insects associated with each feeding group. The examples are taken mostly from the Old (Palearctic) and New (Nearctic) World faunas that have received the greatest scientific attention to date. We select examples based on insect orders, knowledge base, and a diversity of biological attributes, all within each feeding group. This approach should give the greatest insights into the mechanisms of insect interactions with their host trees. Thus, the reciprocal responses of the host and the insect are considered at the level of the individual tree and how this affects forest successional patterns.

Insects That Feed on Cones and Seeds

Important species of cone and seed insects are found in the Coleoptera, Diptera, Hemiptera, Hymenoptera, and Lepidoptera. They damage the reproductive structures of trees, resulting in reduced seed production. These insects may feed on the seed itself or on structures associated with the seed. The number of insects feeding in conifer cones is very large when the small size of the feeding substrate is considered. For example, in western Europe, cone- and seed-feeding insects number some 59 species from 30 genera, 13 families, and 4 orders.

CONOPHOTHORUS SP. (CONE BEETLES); COLEOPTERA: SCOLYTIDAE (BARK AND AMBROSIA BEETLES) Species in this genus colonize only pine species in North America. Thus, many species were described based on their host associations as separation based on morphology is often difficult. Recent studies of pheromone components and DNA are helping to establish the status of these sibling (closely related and difficult to distinguish) species.

Except for the time spent between emergence from the brood cone and colonization of a new cone, the entire life cycle is spent within the cone. A single female tunnels into a new cone in the spring through the cone scales near the supporting stem (as in the “hard” pines, e.g., ponderosa pine) or into the supporting stem of “soft pines” (e.g., eastern white pine, Pinus strobus). She excavates a gallery along the cone axis and deposits eggs in the gallery wall. The gallery is packed with frass, which is composed of uneaten fragments of cone tissues and excrement. The male mates with the female inside the cone prior to gallery elongation. One female can infest more than one cone. In general, infested cones from the soft pines fall prematurely from the tree, while infested hard pine cones remain attached to the branch until they drop in the fall. Beetle attacks cause the death of the cone before or after the cone reaches full size. New brood adults can overwinter in the cone or emerge and mine twigs on living trees (C. ponderosa) or mine first-year cones (C. radiatae) and spend the winter as nonreproducing adults.

Other insect species enter the galleries of the cone beetle. The dry twig and cone beetle, Ernobius punctulatus (Anobiidae), feeds in the drying cone tissues that follow cone beetle feeding activity. A parasitic wasp (Bethylidae: Cephalonomia sp.) enters the cone beetle tunnel to lay eggs. The wasp larvae then feed on the cone beetle larvae.

CONTARINA OREGONENSIS (DOUGLAS-FIR CONE MIDGE); DIPTERA: CECIDOMYIIDAE (GALL MIDGE) This midge infests cones of Douglas-fir in California, Oregon, Washington, and British Columbia. Eggs are laid in young female cones as they open for pollination in the spring. Larval feeding tunnels stimulate gall formation on the seed coat, which destroys the seed. Several galls may form on the seed coat. In the fall, the mature larvae leave the cone and fall into the litter beneath the tree where they spend the winter. There is one generation each year; however, some individuals remain in a resting stage in the litter for more than 1 year. Arrested development, termed diapause, is common in insects that infest cones and seeds. This mechanism permits the insects to survive through periods when few cones are produced. Many other species of insects can inhabit these cones with this midge, including moths, beetles, and wasps.

MEGASTIGMUS SPERMATROPHUS (DOUGLAS-FIR SEED CHALCID); HYMENOPTERA: TORYMIDAE (TORYMIDS) Most species in this family are parasites of gall-forming insects, which are usually other wasps or flies. However, in the Douglas-fir seed chalcid, the female inserts her long ovipositor through the cone scales and into the seed where she deposits an egg. The larva develops entirely within the seed coat. The seed coat continues to develop normally. In the spring of the following year, the adult cuts a round hole in the mature seed coat and emerges to begin a new generation. Adult emergence may be delayed 2–3 years. Cones are harvested in the fall to extract seed for future plantings. Infested seeds cannot be distinguished from uninfested seeds by external appearance. This species has been introduced into Europe and has become a serious pest in plantations of Douglas-fir. Parasites reared from infested cones in western North America have been introduced into France to help reduce populations of this seed chalcid. M. speculatris was also introduced from North America and now infests cones of Siberian fir, Abies sibirica and Nordmanns fir, A. nordmanniana in Europe.

LEPTOGLOSSUS OCCIDENTALIS (WESTERN CONIFER SEED BUG); HETEROPTERA: COREIDAE (COREID BUGS) This insect is named the “leaf-footed bug” because the tibiae of the hind legs are broad and flat while the tibiae of the first two pairs of legs are tubular in shape. This insect feeds on the seed of many conifer species, including Douglas-fir, incense cedar, Libocedrus decurrens, and ponderosa pine. This bug sucks plant juices, which results in damage to the seed. The eggs are barrel-shaped and are deposited in rows on the needles. The adults overwinter in protected areas including inside buildings. The broad host range of this species favors survival during years with low cone production in one or more host species.

CYDIA STROBILELLA (SPRUCE SEED MOTH); LEPIDOPTERA: TORRICIDAE (TORTRIX MOTHS) The female spruce seed moth oviposits between the cone scales of spruce flowers. After hatching, the larvae feed on the central stalk of the cone before moving to the developing seeds. Each larva consumes several seeds to complete its development. Fourth instars return to the cone stalk to overwinter and may remain in extended diapause for two or more winters. Higher than average summer temperatures result in extensive cone production in the following year and also stimulate the larvae of spruce seed moth to break diapause. However, even in good years, not all larvae within a cone break diapause. In some European seed orchards, over 50% of cones may be damaged by this species.
Insects That Feed on Shoots and Tips

Insects feeding in or on shoots and tips are found in the orders Coleoptera, Diptera, Hemiptera, and Lepidoptera. These insects may feed externally or internally on these structures. In addition, they may induce the tree to produce a gall as a result of their feeding activities. This gall may have nutritional as well as protective benefits to the insect. Some insects that feed externally gain protection by, for example, producing a spittle mass, as in spittlebugs, or wax, as in woolly aphids. Feeding may be on foliage in addition to the shoot and/or tip.

**TOMICUS PINIPERDA (PINE SHOOT BEETLE); COLEOPTERA: SCOLYTIDAE (BARK AND AMBROSIA BEETLES)** In spring, adults of the pine shoot beetle emerge from overwintering sites in the “duff,” the needle and bark litter on the ground. They also overwinter in short galleries below the litter layer. They attack trees weakened by root disease (e.g., annosum root disease caused by *Heterobasidion annosum*) and broken and cut trees, but are also capable of killing apparently healthy trees. There can be two or more early emergence periods that result in “sister” broods. This bark beetle infests several pine species, but Scots pine, *Pinus sylvestris*, is its principal host in Europe. The female excavates an egg gallery in the phloem, which is parallel with the grain of the wood. The male mates with the female in the egg gallery. She cuts niches in the gallery wall and deposits one egg in each niche. Larvae then tunnel laterally from the egg gallery. The larval gallery gradually becomes wider as the larvae develop. Pupation occurs in the early summer and emergence occurs in midsummer. These adults fly to living trees and tunnel into the axils of young shoots, which causes the shoots to die and break off. The feeding that occurs in the shoots is necessary for maturation of the gonads. The beetles emerge from the dying shoots and attack host material as described earlier. This habit has been termed “maturity feeding.” Death of the terminal shoot causes flattened canopies. The pine shoot beetle was discovered in Ohio in 1992 and has since spread to adjoining states and Ontario, Canada. It infests eastern white pine and Scots pine Christmas tree plantations.

**CECIDOMYIA PININOPSIS (GOUTY PITCH MIDGE); DIPTERA: CECIDOMYIIDA (GALL MIDGE)** The gouty pitch midge feeds on a large number of pine species in North America. Only the hard pines are infested. It is usually found feeding on young, open-grown pines in both natural stands and plantations. Damaged shoots are first observed in early summer, when new shoots droop and turn yellow and then red. Repeated infestations in northern California slow tree growth and eventually kill the tree. Heaviest infestations occur on ponderosa pines exhibiting sticky twigs while lightest infestations occur on dry, powdery stems, suggesting that some genotypes are resistant to the feeding-induced damage caused by this midge. The bright red larvae overwinter in small resinous pits beneath the bark. In spring, larvae migrate to the needles where they pupate. There is one generation per year. Dead shoots resemble frost-damaged tips.

**ADELGES COOLEYI (COOLEY SPRUCE GALL ADELGID); HOMOPTERA: ADELGIDAE (ADELGIDS)** The Cooley spruce gall adelgid is distributed from coast to coast in North America where it infests many species of spruce, including Sitka, *Picea sitchensis*, Engelmann, *P. engelmannii*, white, *P. glauca*, blue, *P. pungens*, and Brewer, *P. brevifolia*. In the west, Douglas-fir is the alternate host. It was introduced into Europe along with Douglas-fir. In Great Britain, it is named the Douglas-fir woolly aphid. Infestations are also found on Sitka spruce, which has also been introduced into Europe as a plantation species. This aphid has a complex life cycle. When both hosts are present, there can be six life stages in addition to eggs and crawlers. The life cycle, which includes all life stages, is completed in 2 years. Immature females overwinter under bark scales near the tips of spruce twigs. In the spring, they develop into mature females, termed stem-mothers. They each lay up to several hundred eggs under a white cottony, waxy mass. The newly hatched nymphs feed at the base of needles. Light green to purple elongate galls are formed that enclose the nymphs. A chamber at the base of the needle may contain 3–30 wingless adelgids, which are covered with a white wax. A few winged adelgids may also be produced. The galls vary between 12 and 75 mm in length. After the nymphs leave the gall, it turns brown and hardens, often remaining on the tree for many years. Infestations kill branch tips, which stunts and deforms the trees. Nymphs transform to adults on needles and fly to Douglas-fir and lay eggs on newly developing needles, shoots, and cones. Infested needles are twisted and chlorotic and can drop from trees in large numbers. No galls are formed on Douglas-fir. Winged adults produced on this host fly back to spruce to oviposit. Where each host occurs independent of the other, continuous generations are produced on one host. In areas of western North America where spruce is rare or absent, two partheno-gentic generations are produced on the needles of Douglas-fir in one season. No galls are produced on spruce where Douglas-fir is absent.

**RHYACIONIA BUOLIANA (EUROPEAN PINE SHOOT MOTH); LEPIDOPTERA: OLETHREUTIDAE (OLETHREUTID MOTHS)** This moth occurs throughout Europe where it feeds on almost all pine species. It was first discovered in America in New York State in 1914 and later was found in British Columbia, Washington, and Oregon. It has not spread into other Western North American states. This moth is a serious pest of pine plantations in Europe and North and South America. Recently, it has spread rapidly throughout the extensive Monterey pine plantations in Chile. Lodgepole pines planted in France are often heavily damaged, as are red pine, *Pinus resinosa*, plantations in the states and provinces that border the Great Lakes in North America. In summer, the female lays yellowish, disk-shaped eggs in rows on needles as well as under and on bud scales and on small twigs. The larvae hatch from the eggs and feed on the needles where they are attached to the twig. The larvae then spin a silken web between the needle sheath and the twig. The web is usually coated with resin. The larvae tunnel into the bud, which produces a resinous crust. These larvae overwinter under this crust or within the bud. In the spring, they mine another bud and then feed on the base of needles. They pupate within mined shoots, but the pupal skin protrudes from the shoot so that adult emergence is not impeded by the shoot or resin. The mined shoots are killed and buds formed later produce new shoots that grow around the dead shoot. Repeated infestations produce a bush-shaped tree. A crock is formed on the main stem when the terminal bud is killed.

Insects That Feed on Foliage

The foliage is the predominant photosynthetic part of the plant. Loss of foliage results in loss of photosynthetic area with resulting reduction in the production of carbohydrate. Defoliation may be tolerated in some species of trees, but less so in others. Successive cycles of defoliation, however, are rarely tolerated and often result in tree death, usually in association with other insect groups. Insects that feed on the foliage of trees are predominantly found in the orders Coleoptera, Diptera, Hemiptera, Lepidoptera, and Orthoptera. Most of these feed externally on the foliage, though some mine into the foliage for part or all of their feeding stage. Various larvae in the Coleoptera, Diptera, and Lepidoptera mine the leaves of broadleafed...
plants, including trees. This activity protects the insect from desiccation and from predators. Many Hymenoptera induce galls to form on leaves as a result of oviposition into the leaf. These galls can take on many shapes and all protect the developing larva from desiccation and predation. Additional protection from abiotic and biotic effects may be provided by webbing to hold needles together, leaf rolling, or producing a silken nest in which insects congregate for protection from predators, as in the case of tent caterpillars.

**PYRRHALTA LUTEOLA (ELM LEAF BEETLE); COLEOPTERA: CHRYSOMELIDAE (LEAF BEETLES)** The elm leaf beetle is a native European chrysomelid beetle. It infests all species of elm. This beetle often causes severe growth loss, which weakens trees and, in turn, makes them susceptible to invasion by bark beetles and the Dutch elm disease fungus, which they carry into the tree.

The elm leaf beetle overwinters as an adult in sheltered, dry habitats, such as inside houses and barns and under loose bark on trees. They can become a nuisance in fall and spring as they enter and leave hibernation sites inside residences. They can be active in houses during the winter. Adults emerge from overwintering quarters and fly to elms at the time leaves are beginning to emerge from buds in spring. They lay eggs (up to 800 per female) in groups or irregular rows, along the major leaf veins on the underside of leaves and on nearby twigs. Larvae emerge from eggs in late spring and feed on the underside of leaves, causing skeletonization, where small veins are visible between the major lateral veins that emanate from the midrib. The later instars consume some of the area between these lateral veins. The leaves soon become desiccated and brown. At high densities, the entire tree turns brown and appears to be dead. However, in late summer some trees refoliate with smaller leaves. Repeated infestations can kill trees. Two or more generations are produced each season. This insect was introduced into the United States in the late 1890s and has since spread to the west coast. It feeds on all species of elm; however, American elm, *Ulmus americana*, and the introduced Siberian, *U. pumila*, and European elms are severely damaged by this beetle. Introduction of parasites into the United States has met with mixed control results.

**ELATOBium ABiETINum (GREEN SPRUCE APHID); HOMOPTERA: APHIDIDAE (APHIDS)** The green spruce aphid feeds on native and introduced spruce species in Europe and frequently occurs in forest nurseries. Introduced North American species such as *Sitka* spruce are most susceptible, whereas most European species, with the notable exception of Norway spruce, *Picea abies*, are less suitable as hosts. In parts of Europe, a sexual as well as an asexual stage is found, and overwintering occurs as eggs. Elsewhere, such as in Great Britain, the sexual stage is absent, and parthenogenetically reproducing females remain on the needles during the winter. In North America, where this aphid is presumed to be an introduction, only the parthenogenetic form is known. Most feeding occurs when amino acid levels in the leaves are high in the winter and early spring. In late spring/early summer, longer day length coincides with a drop in amino acid levels, and winged individuals (*alatae*) are produced, which disperse to new hosts. Most outbreaks coincide with mild winters. The nymphs and adults feed on the lower side of older leaves where they use piercing mouthparts to access the phloem sap. They may completely defoliate trees and attack current-year needles later in the year.

**PRISTOPHORA ERICHSONI (LARCH SAWFLY); HYMENOPTERA: TENTHREDINIDAE (SAWFLIES)** The larch sawfly is a native European species. It was first recorded in North America in 1880, in Alberta, Canada, in 1930, in Oregon in 1964, and in Alaska in 1965. Some strains are now believed to be native to North America. The prepupal stage overwinters in a cocoon in the ground or dust under defoliated trees. Adults emerge in spring and as late as late summer depending on location. They lay eggs in rows under the bark of newly elongating shoots. This oviposition behavior causes the shoots to droop. The common name of this family is derived from the saw-like ovipositor that females use to cut slits into the bark where they lay eggs. This species reproduces parthenogenetically. Larvae emerge from eggs and feed on the needle margins and then move to the older needle clusters. They feed gregariously and eat most of the needles on one shoot before moving to another. Between summer and fall, mature larvae drop to the ground and spin a paper-like cocoon in the forest litter. Here, they enter a diapause where they spend the winter. However, some individuals overwinter 2 or 3 years.

Successive defoliation results in tree mortality, especially of eastern, *Larix laricina*, and western larch, *L. occidentalis*, in North America, and European larch *L. decidua*. It has been most destructive in the states around the Great Lakes. Where black spruce, *Picea mariana*, and eastern larch co-occur, black spruce is favored in succession because the larch sawfly kills both larch seedlings and mature trees. In the Alps, when aphid densities are high, larch sawfly densities are low, due in part to predation by ants that are tending aphids seeking their honeydew. Biological control efforts in the western United States have been successful in lowering the overall average densities of the larch sawfly. This program is considered one of the most successful biological control programs aimed at a widely distributed forest insect. During studies of the parasitoids of this sawfly, encysted larvae were discovered in certain populations. A cellular layer surrounding the larva is produced by the hemolymph (phagocytosis), a rare phenomenon in insects.

**LYMANTRIA DISPAR (GYPSY MOTH); LEPIDOPTERA: LYMANTRIIDAE (TUSSOCK MOTHS)** The gypsy moth is an important defoliator of hardwood trees in Europe and North America. It was introduced into Massachusetts in 1869. Since then it has slowly spread southward to North Carolina and westward into Wisconsin. Small populations have been eradicated repeatedly in California, Oregon, Washington, and British Columbia. In North America, massive defoliation has occurred over thousands of hectares. This species feeds on over 50 tree species, including mostly hardwoods, such as apple, beech, basswood (*Tilia americana*), elm, hornbeam, oak, poplar, and willow. During outbreaks, larch and pine are consumed. In southern Europe and northern Africa, outbreaks occur at irregular intervals. In North America, considerable resources are directed toward control and slowing the spread to uninfested areas. The Asian form of this species has been found in the western United States and Canada, but apparently has not become established.

In spring, larvae emerge from overwintering egg masses, at about the time oak leaves emerge from buds. The young caterpillars move to the tops of trees where they feed on the bases of young leaves or they chew small holes in the leaf surface. They also drop from trees on silken threads and are windblown. Older larvae feed mostly on the leaf margins. The larger veins and midribs of leaves are usually not consumed. At high densities (tens of thousands per hectare), the larvae literally “eat themselves out of house and home.” They move to new areas in search of food or pupate, often giving rise to small adults. The larvae are very colorful, exhibiting six longitudinal rows of tubercles. On the thorax and first two abdominal segments, the tubercles are blue and on the rest of the abdomen they are red. Larvae crawl down the tree and aggregate in sheltered places. At night they crawl
up the tree to feed. In June, larvae pupate on many substrates, including rocks, limbs and trunks of trees, picnic tables, automobiles, and forest debris. In North America, females are flightless, and after emergence from the pupa they crawl a short distance and emit a sex pheromone that attracts male moths. After mating, the females lay eggs in a mass and cover them with larval hairs from their abdomen. These egg masses may be transported on vehicles or on lawn furniture and rocks that are moved inside vehicles. This means of dispersal gave rise to the common name, "gypsy" moth. The eggs overwinter in a diapause state. The Asian gypsy moth is of major concern because the females are excellent fliers. It has frequently been intercepted on the west coast of the United States, and flying females enhance the dispersal of this species if it becomes established. Many natural enemies of this moth, including parasitoids, predators, and protozoa, have been collected in Europe and introduced in North America. These biological control studies are among the earliest attempts to use indigenous natural enemies to lower densities of an introduced pest.

**DIAPHEROMERA FEMORATA (WALKINGSTICK); PHASMATODEA: HETERONEMIDAE (WALKINGSTICKS)**

Walkingsticks are very unusual insects because, as their name signifies, they are long, slender, and oval and thus resemble a stick or defoliated branch. Most species are wingless. Their body color varies from gray to green to brown to red, which is similar to the leaves and branches on which they are feeding. Through this camouflage they may escape predation from birds. In late summer and fall, they deposit their hard, seed-like eggs directly on the ground or by dropping them from trees where they are feeding. At high population levels, the large number of eggs falling on the forest floor literally sounds like rain. Most young hatch during the following spring throughout the southern United States, whereas in the northern portion of its range, the young hatch in the second spring. Occasionally, severe outbreaks occur in the northern United States that last several years, causing extensive tree mortality. Two defoliations can occur during the same season. They feed on a variety of hardwood species, including cherry, basswood, birch, aspen, elm, hickory, oak, locusts, and dogwood.

**Insects That Feed on the Trunk and Large Branches**

Insects that feed on the trunk and larger branches of trees are found in the Coleoptera, Hemiptera, Hymenoptera, Isoptera, and Lepidoptera. Insects that tunnel into the trunk and large branches of trees may exploit two resources: they may derive most of their nutrition from the xylem, or they may tunnel into the wood and derive their nutrition from the xylem. Insects that do not tunnel into the host, such as scale insects, are sucking insects and use nutrients in the xylem or phloem depending on the species. Many insects that infest the wood of trees, such as termites, serve as primary decomposers of the woody material.

**DENDROCTONUS PONDEROSAE (MOUNTAIN PINE BEETLE); COLEOPTERA: SCOLYTIDAE (BARK AND AMBROSIA BEETLES)**

The mountain pine beetle is one of the most important forest insects in North America. It is widely distributed in many pine species throughout western North America, from southeastern Alaska to northern Baja California, and eastward through the Yukon territory in Canada and the Rocky Mountains of both the United States and Canada to the Black Hills of South Dakota. The eight-toothed spruce bark beetle, *Ips typographus*, shows a similarly wide distribution in Europe and Asia, but it has a more limited host range than *D. ponderosae*. During outbreaks, this bark beetle kills millions of trees over large areas. It infests some of the most widely distributed and important timber-producing species, including ponderosa pine, western white pine, *P. monticola*, and sugar pine. Extensive mortality of ponderosa pine at the turn of the 19th century in the Black Hills of South Dakota attracted public attention that led to the establishment of the Federal Forest Insect Research Program in the United States. The effects of mountain pine beetle are greatest in climax lodgepole pine forests where lodgepole pine is self-perpetuating or in even-aged stands where shade-tolerant species are not abundant enough to replace lodgepole pine. These even-aged forests are usually created by a stand-replacement fire. Mountain pine beetle infestations kill the largest trees and leave behind small-diameter, low-vigor, and mistletoe-infested trees. Young seedlings that have survived in the understory because of their shade tolerance are then released. New seedlings appear in new openings where trees have died. The resultant forest following mountain pine beetle outbreaks is uneven aged and multistoried.

The life histories of tree-killing *Dendroctonus* (meaning "tree killers") species are generally similar. The female emerges from overwintering sites beneath the bark of trees killed in the previous year. She penetrates the outer bark and begins feeding in the phloem. She releases a pheromone component, *trans*-verbenol, and a host monoterpenic hydrocarbon, myrcene (in lodgepole pine) or α-pinene (in western white pine). The male joins the female gallery and releases *exo*-brevicomin, another pheromone component. This mixture of compounds is highly attractive to other mountain pine beetles and a massive aggregation of beetles occurs on the tree. The attracted beetles introduce a pathogenic bluestain fungus, *Ophiostoma clavigerum*, which, together with tunneling females, causes the death of the tree. The growth of this bluestain fungus in the sapwood interrupts water conduction (a vascular wilt) to the crown. As the tree begins to die, females excavate egg galleries that are positioned vertically in the trunk, 30–90 cm in length. The egg gallery etches the sapwood superficially and may be quite sinuous, as with the western pine beetle, *D. brevicomis*. Eggs are laid in niches cut in the phloem on both sides of the gallery. Larvae hatch from the eggs and they excavate lateral galleries that increase in size as the larvae grow. A pupal cell is excavated at the end of the gallery, and the larvae transform to pupae and then to adults in these cells. Both larvae and adults are known to overwinter. Generally there is one generation per year depending on the latitude and altitude one generation may take 2 years to complete or there may be as many as two generations and a partial third in 1 year.

**CRYPTOCOCCUS FAGISUGA (BEECH SCALE); HEMIPTERA: ERIOCOCCIDAE (ERIOCOCCIDS)**

The beech scale is a native European species that was introduced into Halifax, Nova Scotia, about 1890. Since then it has slowly spread eastward to Toronto, Ontario, and Ohio and south to West Virginia and western Virginia. Infestations are found in North Carolina, Tennessee, and Michigan. The beech scale in combination with the fungus *Nectria coccinea var. faginata* causes beech bark disease, which has killed a large number of native and ornamental beeches in Europe and the northeastern United States. European beech, *Fagus sylvatica*, and American beech, *F. grandifolia*, are severely impacted by this scale and its associated fungus, and it also infests other native as well as ornamental beeches from the Orient and Europe.

In late spring and early summer, pale-yellow females deposit up to 50 yellow-colored eggs in groups of 5–8 that are coated with a white-colored wax-like substance. Only wingless females are known for this species. The newly hatched nymphs or “crawlers” search out a location on the bark to settle and insert their tubular mouthparts. During this crawler stage they can be dispersed by wind, often over
SIREX NOCTILIO (STEELEY-BLUE WOOD WASP); HYMENOPTERA: SIRICIDAE (HORNTAILS/WOOD WASPS)

*S. noctilio* is indigenous to Europe where it infests pines weakened by fire, insects, and diseases. In its native habitat, it seldom causes tree mortality. However, this species was introduced into New Zealand in the late 19th century, where it became a serious agent of mortality in planted forests of Monterey pine. It has since been introduced into Monterey pine plantations in Australia and South Africa, and has been found infesting red pine and scotch pine in New York State and Ontario, Canada. The host and geographic range of this insect in North America will increase in the coming years. Females have a long ovipositor that extends straight back from the anus and is often mistaken for a stinger. The female drills a hole about 12 mm deep through the bark and into the sapwood. As many as four side holes are drilled from the primary entrance hole. One hole is filled with mucus from the female’s accessory glands, as well as spores of the symbiotic fungus, *Amylostereum areolatum*, that reside in a specialized gland (mycangium) at the base of the ovipositor. Eggs are deposited in the other side tunnels. Adults tend to aggregate on weakened trees for oviposition. The mucus secretion has toxic properties that cause interruption of water conduction in the sapwood (i.e., a vascular wilt). Needles are subsequently killed and they fall from the tree. Young larvae feed on the fungus growing in the egg chamber. Older larvae tunnel deeply into the sapwood and their finely divided frass (mostly woodchips) is tightly packed into their galleries. They pupate near the surface and excavate a round hole in the bark through which they emerge.

A major biological control program for *S. noctilio* was undertaken and many species of hymenopteran parasitoids were collected from Europe and North America and introduced into New Zealand and Australia. Two species of nematodes, *Deladenus siricidicola* and *D. wilsoni*, were introduced into Australasia where they have caused a significant reduction in tree mortality. These nematodes infect the reproductive system and prevent ovarian development.

Horntails occur in both hardwood and softwood species and they are found in forests throughout the Northern Hemisphere (Fig. 3). The life cycle can be completed in 1 year, but in some cases development is delayed for several years.

RETICLUSERME FLAVIPES (EASTERN SUBTERRANEAN TERMITE); ISOPTERA: RHINOTERMITIDAE

Subterranean termites are social insects that live in colonies in the soil. They feed on a variety of cellulosic materials as their principal energy source. Termites and fungi are the most important organisms that can digest plant cell walls and thus reduce cellulose from a complex polysaccharide to simple sugars. Symbiotic fungi and protozoa live in the hindguts of termites and possess the enzymes needed to digest cellulose. Thus termites play an important role in recycling nutrients in a forest. Subterranean termites coexist in soils with many other microorganisms, especially fungi. Some of these fungi have been shown to produce chemicals that are the same as the trail-following pheromones produced by the termites, as well as chemicals that act as feeding stimulants and deterrents to termites.

The eastern subterranean termite is distributed throughout the eastern and mid-western part of the United States where it feeds on most species of wood found in forested habitats. Related species of subterranean termites are found in western North America and in Europe and Asia. Subterranean termite colonies contain seven castes: larvae or immatures, workers, soldiers, nymphs, winged (alate) primary reproductives, wingless (dealate) primary reproductives, and supplementary reproductives. Workers feed all the castes. Supplementary reproductives can occur in colonies with primary reproductives. They take over the oviposition role if the primary “queen” reproductive dies. Soldiers have large hardened (sclerotized) heads and mandibles, which they use to defend the colony from invaders, especially ants.

With the onset of warm rains in spring or fall (western United States), large numbers of winged females and males (termed swarmers) emerge from earthen tubes extending out of the ground or from the surface of logs, stumps, and wooden structures. These adults are weak fliers and soon drop to the ground where they lose their wings. Copulating adults paired end-to-end can be seen running about. The mated female seeks a damp piece of wood and excavates a chamber where she lays her first eggs. The young hatch into a worker caste and when large enough, they begin foraging for food to feed the queen and other castes as they are produced.

Subterranean termites are a critical component of forest habitats because of their important role in recycling wood. However, they are also the most destructive pests of human habitations made from wood. They construct earthen tubes from the ground into wooden structures and thus can consume wood in dry habitats long distances from the colony in the ground. They often escape notice because they travel in hollowed-out timbers and in tubes constructed in wall cavities. Their galleries parallel the grain of the timbers and are excavated first in the early wood (springwood) and later in the late wood (summerwood). This damage to structures can be extensive before it is discovered. A large pest control industry has developed to protect wooden structures from termites and other wood-destroying insects and fungi.

SYNANTHEDON SEQUOIAE (SEQUOIA PITCH MOTH); LEPIDOPTERA: SESIIDAE (CLEAWING MOTHS) The sequoia pitch moth is attracted to the resin that flows from wounded

---

pine trees. Larvae hatch from eggs deposited individually on the bark of limbs and the trunk and tunnel into the phloem–cambial layer beneath the outer bark. As they feed on the phloem, they excavate a chamber that fills with resin and frass. This material is deposited on the outer bark surface over the chamber and forms a white resinous mass that is interspersed with reddish brown fecal material. As this resin mass ages, the surface turns reddish brown. Resin streaming is occasionally observed from these masses. Larvae pupate beneath the resinous mass, but with the pupal integument extending through the mass. This enables the moth to emerge from the mass without contacting the resin. These resinous masses often exhibit two or three pupal cases, indicating that these areas are often recolonized by later generations of this species. Oviposition occurs in summer. The life cycle is completed in 1 or 2 years.

Infestations of this species rarely cause tree mortality directly. However, heavy infestations may result in attraction of tree-killing bark beetles. This moth infests many native species of pines as well as European species such as Scots pine, Austrian pine, Pinus nigra, maritime pine, P. pinaster, and Italian stone pine, P. pinea. Pines growing in urban environments can be heavily infested around wounds caused by pruning and by vehicles. The sequoia pitch moth is distributed throughout western North America, including California, Oregon, Washington, Idaho, Montana, and British Columbia. Coast redwood, Sequoia sempervirens, is not a known host for this moth. Similar pitch masses are occasionally observed from these masses. Larvae pupate beneath the resin. These resinous masses often exhibit two or three pupal cases, indicating that these areas are often recolonized by later generations of this species. Oviposition occurs in summer. The life cycle is completed in 1 or 2 years.

In populations of native and introduced forest insects, especially defoliators, it has been possible to identify viruses that are specific to their host insect. Rearing and release of these viruses offer promise for pest control in some situations, especially for defoliating Lepidoptera and Hymenoptera. The nuclear polyhedrosis virus (NPV) of the European pine sawfly, Neodiprion sertifer, has been applied to thousands of hectares of forests in Europe over the past 35 years. An NPV that infects gypsy moth has also been used in efforts to slow the spread of this species in North America. The accidental introduction of an NPV in the 1930s, along with a parasite of the European spruce sawfly, Diprion hercyniae, into eastern Canada has reduced this species to very low densities.

Biological control has achieved considerable success in managing forest insect populations. It is especially useful when addressing problems caused by introduced insects. For example, as the European spruce beetle spread westward across Europe during the 20th century ahead of the natural spread of its natural enemies, mass releases of the predatory beetle, Rhizophagus grandis, had some success in limiting the impact of this species in many European countries. Similarly, in urban forests where many tree species are introduced, management of exotic pests is often achieved by introduction of predatory or parasitic insects. In California, eucalyptus is widely planted in urban landscapes, and in the latter part of the 20th century, many new pests were introduced. Prompt identification and monitoring of pest populations coupled with introduction of appropriate biological control agents have successfully reduced the adverse impacts of many of these introduced insects, especially the eucalyptus longhorned beetle, Phoracantha semiplunctata.

Much scientific research has focused on the pheromone systems of forest insects, especially defoliators and bark beetles. Pheromones have been incorporated into management plans aimed at reducing the impacts of the target pest species. For example, mountain pine beetle pheromones are used to bait living lodgepole pines that are to be logged following infestation. This treatment attracts beetles into plots that will be harvested, and the beetles are removed with the logs. The treatment is aimed at reducing mortality in the unharvested areas. It prevents trees from dying at more scattered locations in these unharvested areas where most trees would not be harvested because of cost and accessibility. Other techniques for reducing the impacts of target pest species can be achieved in a number of ways. Pheromones can be used to monitor insect populations as a guide for when to apply pesticides or embark on an alternative management strategy. They are also used to detect invasive pest species in new areas. Throughout the western states of North America, pheromone traps are placed to detect gypsy moth so that early detection can be met with rapid response eradication programs. Similar use of pheromone traps and traps baited with other behaviorally active compounds occur at ports to detect the arrival of exotic organisms.

Attempts have been made to use pheromones to mass trap insects and thereby reduce their density to nonpestiferous levels. Because insect populations naturally decline at some point following an outbreak due to a range of factors, it is often difficult to determine whether such mass trapping efforts were in part responsible for a return of the insect population to endemic levels. In Scandinavia, mass trapping of the eight-toothed spruce bark beetle occurred during 1979 and 1980, and billions of insects were caught. The subsequent drop in population size of this insect may have been in part a result of this intensive mass trapping effort. Mass trapping may be useful locally where a small-scale disturbance may have resulted in elevated activity of a particular insect. This situation may occur when management activities have produced a large amount of host material such as occurs following tree harvesting. Pheromone traps may be deployed in this situation to reduce populations. Trap logs that have become infested with bark beetles are removed from the forest in an attempt to lower population levels. Pheromones may be used to bait the logs or trees to enhance the effectiveness of this technique.

Pheromones have also been used in larger doses to confuse or disrupt their natural function. Male moths following pheromone plumes to locate females for mating are not able to find the female if there is a large concentration of the pheromone present, such that the plume is effectively hidden. Western pine shoot borer, Eucosma sonomata, pheromone release of 10–20 μg ha⁻¹ has been shown to reduce damage by over 65% in ponderosa pine plantations in the western United States.

Many forest management practices are available for use to reduce the impacts of insect populations. Removal of susceptible trees, thinning of the stand to increase tree vigor, prescribed burning to eliminate susceptible host material, and enhancement of natural enemy populations are all tools available for the management of forest insect populations. The thinning of lodgepole pine stands reduces tree mortality from mountain pine beetle. Prescribed fire following harvesting operations in ponderosa pine forests reduces populations of the California five-spined Ips, Ips paracoccus, that breeds in logging debris. This practice lowers the probability of these populations emerging and killing living trees in the area.

**THE FUTURE**

Insects perform essential roles in forests as part of these complex ecosystems. However, when transplanted from one forest habitat to another, or when the natural forest habitat is disturbed, their role in the ecology of the forest may change. Increased global transport of forest products undoubtedly will result in introductions of both pestiferous and potentially pestiferous insects into different parts of the world. Ongoing efforts to reduce this occurrence are essential if we are to maintain forest habitats that meet environmental and economic goals. Furthermore, research that addresses environmentally sound methods for the integrated management of forest pests is essential if humans are to minimize their indirect impacts on forest habitats resulting from the introduction of new insect species. Some insect outbreaks are important natural processes in forests, whereas others are the product of human activities. Recognizing the causes of outbreaks, detecting signs of imminent outbreaks, and having appropriate management options available help to ensure the viability of forest habitats and the environmental and economic benefits they provide.

**Further Reading**

Insects are the most evolutionarily successful group of organisms in the 4-billion-year history of life on earth, with perhaps 5 million species alive today and untold millions of extinct species. Although fossils of insects are not as abundant as has been found for some other types of organisms, the insect fossil record extends back for 400 million years, making them among the oldest terrestrial animals known, and the fossils contribute unique insight into the evolutionary history of insects. Particularly significant periods in the evolution of insects are the Paleozoic, Triassic, and Cretaceous. Key features that gave rise to their spectacular success, notably flight and complete metamorphosis, originated at least 300 and 250 million years ago (mya), respectively.

FOSSILS

Fossils are generally, but not necessarily, extinct species whose remains have been preserved for thousands to millions of years. The remains are most commonly mineralized replacements of original tissues (Figs. 1 and 2); in rare situations, portions of the original organism are preserved (Figs. 2B–2E and 5D–5F). Remains of apparently existing (or extant) species that are thousands to several million years old are sometimes called subfossils. Earth’s fossils are dominated by organisms from marine continental shelves, where deep sediments efficiently preserved durable calcified parts such as shells and skeletons. Terrestrial life is less well known in the fossil record and largely is preserved as bones, leaves, and pollen in freshwater sediments. Well-preserved insects, by comparison, are rare; their occurrence depends on conditions under which the sediments were fine grained, anoxic (i.e., lacking oxygen), and deposited rapidly but without significant disturbance. Even amber is usually deposited in lacustrine or swampy sediments; it would otherwise completely decompose from oxidation and other processes. Insects preserved in such sediments were aquatic or semi-aquatic and died in situ (autochthonous), or their bodies were transported via winds or water from surrounding habitats (allochthonous).

SIGNIFICANCE OF FOSSILS

There are at least five reasons why fossils are uniquely significant for understanding the evolutionary history of organisms:

1. Fossils provide the only direct record of extinct lineages, such as giant dragonfly-like forms from the Carboniferous and Permian (e.g., †Meganeuridae) (in this article, † signifies an extinct group).

2. Fossils reveal patterns and timing of extinctions and radiations. The mass extinction at the end of the Permian, for example, was the most cataclysmic event in the history of life and may have caused the extirpation of †Paleodictyoptera (known almost exclusively from the Carboniferous and Permian). The extinctions at the Cretaceous/Tertiary boundary that extinguished the remaining dinosaurs, ammonites, and other groups, appear to have had little impact on families of insects. Although insects have been affected by some mass extinction events, major lineages of insects appear particularly resistant to extinction.

3. Fossils provide the only direct information on the ages of lineages. Because there is never assurance that a fossil is the earliest, original occurrence of a taxon, the age of the earliest fossil is the minimum age of a taxon. This information, in conjunction with

FIGURE 1 Various kinds of fossil insects, modes of fossilization, and degree of preservation. Different scales. (A–C) Iron hydroxide concretion of a heteropteran in Cretaceous limestone from Brazil, showing preservation of thoracic muscles [B, light micrograph; C, scanning electron micrograph (SEM)]. (D) Silvery carbon film of a belostomatid on fine-grained, Triassic shale (Virginia). (E) Nymph of †Herdina (in this article, † signifies an extinct group) in ironstone concretion from the Carboniferous of Mazon Creek, Illinois. (F) Trichopteran case of sand pebbles in volcanic shale from Florissant, Colorado (Late Eocene/Early Oligocene). (G) Part of the head of tabanid fly from Florissant, showing the eye facets. (H) Portion of the wing of †Typus (“Protodonata”), from the Permian of Elmo, Kansas, with the wing fluting preserved.
the phylogenetic positions of all fossils in a group, can be used to estimate actual ages and significant gaps in the fossil record. Such information is further useful for calibrating and then estimating rates of change, such as rates of genetic change among living species and dates of divergence.

4. Fossils may assist in reconstructing the phylogeny of a group. While fossils are widely acknowledged to possess combinations of characters unique from those of living species, their significance in reconstructing phylogenetic relationships is controversial. Nonetheless, fossils also provide the only direct evidence for the evolutionary sequence of character change. For example, in the fossil record of the Blattaria (cockroaches and their primitive roach-like relatives), tegminous forewings and a large, discoid pronotum appear well before the loss of an external ovipositor—a sequence not revealed by the study of living species alone.

5. Fossils can provide evidence that a taxon is old enough for its distribution to have been affected, for example, by Cretaceous continental drift. Indeed, many families of insects extend to the Cretaceous or even earlier, whereas some large groups are apparently too young to have been affected by continental drift, such as the ditrysian Lepidoptera and the schizophoran Diptera. Often, too, a fossil is found outside the present-day range of its group, indicating formerly widespread distribution. A famous example is the occurrence of Glossinidae (tsetse flies) in the Cenozoic of North America and Europe.

**SUMMARY OF THE INSECT FOSSIL RECORD**

Figure 3 summarizes the chronology, approximate diversity, and possible relationships of major groups of living and extinct insects.

**Paleozoic (570–245 Mya)**

The earliest remains of terrestrial animals are arthropods from the Silurian, including primitive scorpions, millipedes, and †Trigonotarbidida
FIGURE 3 Living and extinct orders of insects, their possible relationships, and chronology. Width of lineages is a rough approximation of diversity. Some groups with a meager or nonexistent fossil record (i.e., Phthiraptera, related to Pscoptera) are not included.
THE DEVONIAN (408–362 MYA) The Devonian was a period when the continents were largely inundated and joined into the large supercontinent Pangaea. Lycopsods, lycopsids, and horsetails (Equisitoidea) were common terrestrial plants; primitive groups of fishes radiated, and amphibians first appeared. The earliest record of hexapods is from the Rhynie chert of Scotland, ca. 400 mya, and is the collembolan Rhyniella praecursor (Fig. 4A), although a pair of mandibles in this chert is suggestive of dicondylic insect mandibles. The Rhynie chert also contains mites, trigonotarbids, and a primitive spider.

Approximately 10 million years younger is an undescribed archaeognathan (= Microcoryphia) from the Gaspé Peninsula in eastern Canada. Apterygotes, each with a single, long caudal filament (“Monura” = Archaeognatha), occur in the Carboniferous and Devonian (Fig. 4B). Unidentified insect remains from 378 mya are known from Gilboa, New York, along with centipedes (Chilopoda) (Fig. 2A), true spiders (Araneae), and body segments of extinct, primitive arachnids. Two major hypotheses on the origins of the hexapods (including insects) are that they are most closely related to either the myriapods (centipedes and/or millipedes) (all comprising the Tracheata, or Atelocerata) or the Crustacea. Crustacea may actually have the oldest fossil record of all animals (formerly held by the trilobites) because some Precambrian fossils have recently been reinterpreted as crustaceans. If hexapods are closely related to crustaceans, it is most likely to be a group within Crustacea, and the earliest evidence of this stem group will probably be found in the Silurian.

THE CARBONIFEROUS (362–290 MYA) The Carboniferous period is famous for the wet, warm climates and extensive swamps of mosses, ferns, seed ferns, horsetails, and calamites. Remains of insects are scattered throughout Carboniferous coal deposits (particularly blattarian wings); two particularly important deposits are Mazon Creek, Illinois, and Commeny, France. The earliest pterygotes appear in the Carboniferous, including the Blattaria, †Caloneurodea, primitive stem-group ephemeropteroids (Fig. 4F), Orthoptora, †Paleodiptyopteroidea (Figs. 4C and 4D), †Protodonata” (Fig. 4E), and †Protorthoptera”; the latter two are paraphyletic assemblages of primitive pterygotes.

Hypotheses on the evolution of insect wings include their use originally as gills or gill covers, or for mating displays, but early outgrowths of the insect pleuron most plausibly served in gliding. Feeding damage on plants is also recorded first in the Carboniferous, in the form of punctures and deep holes probably made by the long, beaked mouthparts of paleodiptyopteroid insects. Thus, insects have been evolving in close association with plants for at least 350 million years, which is longer than any other group of terrestrial animals. Arborescent plants appear in the Upper Devonian, and as Carboniferous insects increasingly dwelled in them to feed, gliding probably became so adaptive for escape and dispersal that flapping wings and powered flight evolved rather suddenly.

Putative Holometabola are recorded from the Carboniferous. One is a larva from Mazon Creek, Srokalarva berthei, many features of which are inconsistent with extant holometabolan larvae, including segmented abdominal legs, ocelli, and possible compound eyes. Legs and body segments of Srokalarva are undifferentiated, as in myriapods. Some tree fern galls (ca. 300 mya) are attributed to the Holometabola on the basis of size of frass pellets in the galls. Some Paleozoic arthropods were considerably larger than living relatives, and Carboniferous gall-making mites are also known, and so it is possible that large mites caused these ancient galls. The earliest definitive Holometabola occur in the Permian.

Blattaria (Blattoptera) This group consists of the Dictyoptera (mantises, termites, and ovipositorless roaches) plus the Paleozoic and Mesozoic “roachoids” that possessed an ovipositor. Very early, Carboniferous blattarians possessed a large, discoid pronotum and coriaceous forewings with a distinctive CuP vein. From the Carboniferous to the Cretaceous, there was a gradual diminishment in the length of the ovipositor. The first true, ovipositorless roaches as well as probable oothecae appeared in the Triassic. Thus, the common view that modern roaches are exceptionally ancient is inaccurate.

†Caloneurodea and †Miomoptera Both orders are known only from the Upper Carboniferous to Permian and, with Orthoptera and Blattaria, were among the earliest known Neoptera. These insects had homonomous wings with small anal lobes. In Caloneurodea,
the wings had many crossveins that formed numerous square cells. Wing structure and unsegmented cerci (the latter known from only few genera) suggest relationships with the orthopteroids. The wings of Miomoptera were shorter and broader and had very reduced venation. A close relationship of Miomoptera is plausibly with the Psocoptera, but probably with the Hemiptera. With a wing length of 3–5 mm, these are the smallest Paleozoic pterygotes known.

Orthoptera This is an ancient Recent order extending from the Carboniferous, from which time even the distinctive synapomorphy (advanced defining feature) of saltatorial hind legs is preserved (†Oedischidae). By the Triassic, stridulatory organs on wings evolved, and some extant families had first appeared (Haglidae, Gryllidae). †Elencaidae and related families (Permian to Cretaceous) are distinctive for the reduced forewing venation with numerous parallel M and Cu veins; they were probably the most diverse and abundant Orthoptera in the Late Paleozoic and Early Mesozoic. Many extant families do not appear until the Cretaceous (e.g., Eumastacidae, Gryllotalpidae, Tridactylidae, Tetrigidae) or even the Cenozoic (Acrididae, Tettigoniidae, Gryllacrididae).

†Paleodictyopteroidea This group includes the orders †Diaphanopterodea, †Megascoptera, and †Paleodictyoptera, which had very long cerci, an ovipositor, and wings with little or no anal lobe (all primitive features). It is the only definitively monophyletic group from the Paleozoic, defined by a long, rigid beak with five stylets, as well as (primitively) a well-developed pair of possible maxillary palps. Nymphs were terrestrial, with large, free wing pads bearing rudimentary venation (Fig. 4D) and mouthparts similar to those of the adults. The group is among the most primitive pterygotes, and their distinctive paraprosternal lobes (often with a rudimentary venation) probably are part of the ground plan of pterygote insects. The Paleodictyoptera are probably paraplethycetic with respect to the other two orders, because they possess complete wing venation with an archedictyon. Diaphanopterodea folded wings over the abdomen at rest, an ability convergent with Neoptera. Megascoptera had substantially reduced venation, often with a graded series of crossveins (Fig. 4C). Some had striking color patterns on the wings (e.g., Spliapteridae), and some were impressively large (e.g., Homoptera, approximately 40-cm wing span).

†Protodonta This group is a paraphyletic assemblage of primitive pterygotes similar to true Odonata but lacking the derived features of modern, true Odonata, such as the nodus, pterostigma, and arculus. Some (i.e., Permian Meganeuridae) were the largest insects ever, with a 70-cm wing span (Fig. 4E). They existed from the Upper Carboniferous to the Permian and were clearly the dominant aerial predators for some 100 million years until flying reptiles appeared in the Triassic. Fossils with the venation of true Odonata did not appear until the Triassic.

†Protorthoptera (≡ †Paraleptoptera) (Fig. 4G) This is another paraphyletic assemblage of primitive pterygotes, with affinities not necessarily suggested by their name. Some refer to this group as the Gryllloblattida (sensu lato), but there are no derived features that indicate a relationship of these extinct insects with this relict, extant order. Some had forewings that were coriaceous (i.e., sclerotized and leathery), but usually with an archedictyon. Unlike Orthoptera, most did not have hind wings with expanded anal lobes, and none are known to have folded their forewings roof-like over the abdomen (instead, folded flat and over each other), none had saltatorial hind legs nor a tarsomere number reduced to 3. Some had raptorial forelegs; †Geraridae had large pronotal spines.

PERMIAN (290–245 MYA) The Permian was a relatively short but very important period, when extensive mountain ranges were formed, such as the Appalachians; this caused the interior climates of continents to become cooler and drier. Extensive glaciation of the Southern Hemisphere also occurred. Voltzioidae and glossopterid plants radiated. Insect orders from the Carboniferous extended into the Permian, and many even extensively diversified. Numerous new orders appeared in the Permian: the †Protelytroptera (Fig. 4J) and primitive relatives of the Plecoptera ("Paraleptoptera") (Fig. 4H), Psocoptera (Fig. 4I), Mecoptera (Fig. 4K), Raphidioptera (Fig. 4L), Neuroptera, and Coleoptera (Fig. 4M), the last four orders being the earliest definitive records of the Holometabola. The most significant and diverse Permian insect deposit is from Elmo, Kansas (ca. 260 mya); others are from New South Wales, Australia (ca. 240 mya) and central Eurasia (ca. 250 mya).

The Permian is biologically most notable for the mass extinction that marks the brief interval between the end of this period and the beginning of the Mesozoic. It is estimated that as much as 95% of all Permian life forms became extinct by the Early Triassic, although this is based largely on the marine fossil record. It is difficult to estimate the impact of the Permo-Triassic extinction on insects because many of the Paleozoic orders are paraphyletic, and it is likely that particular lineages within each survived into the Mesozoic (Fig. 3). One definitive monophyletic group, the Paleodietyopteroidea, may have become extinct at the end of the Permian, but a possible survivor of this group (†Thuringoptera) occurred in the Triassic. Otherwise, major groups of insects show few effects of the most cataclysmic extinction known.

Hemiptera The earliest Permian records are the auchenorrhynchan-like wings of †Dunstaniidae, †Palaenoptiniidae, and †Prosobolidae, which also extend into the Mesozoic. True auchenorrhynchans from the Triassic are Cercopoidea, Cicadoidae, Cercidellidae, Cixiidae, and Membracoidea. The earliest Sternorrhyncha are †Archescytiniidae, †Pincemberiidae, †Boreoscytidae, and †Protopsyliidae (all from the Permian into the Mesozoic). The first diverse records of true aphids and coccoids occur in Cretaceous amber; psyllids are older. Heteroptera are slightly younger than homopterans. Presumed Permian heteropterans are †Actinoscytina (†Progonocimidae) and †Paraknightia (†Paraknightiidae). Veneration of the former is barely different from Auchenorrhyncha; the latter had expanded paraproctal lobes, a large ovipositor, and forewings with unusual venation (perhaps an aberrant roach). The earliest true Heteroptera are various predatory aquatic bugs (Nepomorpha) from the Triassic of Virginia (Fig. 1D). By the Jurassic, phytophagous pentatomorphs and cimicomorphs appeared, and modern families were widespread in the Cretaceous.

Neuroptera This group includes the orders Raphidioptera and Neuroptera. Systematic position of the one Permian family of putative raphidiopteran (†Isjanoraphidiidae) (Fig. 4L) has been considered doubtful, although it had a long ovipositor distinctive to this order and a series of short costal crossveins (distinctive to Neuroptera); the wing venation, however, is quite primitive. Jurassic and Cretaceous raphidiopterans were diverse, belonging to the †Alloraphidiidae, †Baissopteridae, and †Mesoraphidiidae. Raphidioptera is relict today, with three genera in two families having a disjunct distribution in the Northern Hemisphere. The only Southern Hemisphere raphidiopterans are from the Lower Cretaceous of Brazil, indicating that the group was formerly more widespread.

Definitive Neuroptera also appear in the Permian (†Archeosmyliidae, †Palaenomerobidae, †Permithonidae, and †Stalioididae). Triassic diversity is very poorly known (e.g., Psychopsidae), and by the
Jurassic there appeared forms that are primitive relatives or members of the Chrysopidae, Coniopterygidae, Nymphidae, Osmylidae, and Polystoechotidae. An impressive Mesozoic family was the Kalligrammatidae, with broad, patterned wings and a long, rigid proboscis. In the Cretaceous are the earliest records of the Ascalaphidae, Berothidae, Mantispidae, and Pyrrhocoridae. Berothidae were particularly abundant and diverse in Cretaceous ambers. An unusual, dip- terous mantispid (†Mantispidiptera) is known in Cretaceous amber New Jersey.

Coleoptera The earliest Permian forms (i.e., †Tsekardocoleidae) had long, pointed, coriaceous forewings with definitive venation and arrays of small cells and pits (Fig. 4M). Beetles similar to modern cupedooids were diverse in the Upper Permian and the Mesozoic. Cupedoidea today are a small, relict group. Fossil forms were probably all wood borers as larvae and adults, like modern relatives. By the Jurassic, the Triassic, Adephaga appeared (Carabidae, Trachypachidae) as ably all wood borers as larvae and adults, like modern relatives. By Cupedoidea today are a small, relict group. Fossil forms were probably all wood borers as larvae and adults, like modern relatives. By the Jurassic, the Triassic, Adephaga appeared (Carabidae, Trachypachidae) as did some basal Polyphaga (definitive Staphylinidae). By the Jurassic, the first Hydradephaga (†Coptoclavidae, Dytiscidae, Gyrinidae) appeared, as well as other living families (Elateridae, Hydrophilidae, Silphidae). The earliest records of many living families are from the Cretaceous and the Lower Tertiary (especially Baltic amber). Interpretation of compression fossil beetles is greatly compromised by the lack of wing venation characters and restriction to the use of simple features such as elytral structure.

Plecoptera Permian †Palaeperlidae, †Perlopseidae, Eustheniidae, and Taeniopygidae had venation consistent with this order. Several extant families are recorded from the Jurassic and Cretaceous. †Lemmatophoridae and †Liomopteridae (Figs. 4G and 4H) had expanded parapronotal lobes (sometimes with distinctive venation like the wings) and have been placed in "Protorthoptera." These families are probably related to the Plecoptera because they had nymphs with abdominal tracheal gills and so were probably aquatic.

†Proteolytroptera Found only in the Permian, this group is characterized by narrow, elytrous/prinose forewings and with hind wings with an expansive anal lobe and radiating venation (the latter one reason they have been allied with Dermaptera) (Fig. 4J). The forewings of some species have very few veins; others have intricate reticulation. The †Umenocoleidae from the Cretaceous, formerly placed in this order, are actually blattarians.

Psocoptera The earliest putative members of this order are the Permian †Psociidae, but these have cerci and five tarsomerens (vs. lack of cerci and generally three tarsomerens in living species) (Fig. 4I). †Psociidae do possess the areola postica (short, terminal branch of vein CuA), although this feature also occurs in the Zoraptera and Embioptera. Psocoptera are poorly known in the Triassic, but are diverse and abundant in Cretaceous ambers, which include many living families (e.g., Prionogloriidae, Lepidopsocidae). †Lophioneroidea (Permian–Cretaceous) have traditionally been placed in this order, but the reduced wing venation (especially in Permian †Zoropsocus) and (where preserved) the narrowed, projected mouthparts indicate relationship to the thrips (Thysanoptera). †Lophioneroidea lack extensive vein reduction, the marginal fringe, and the flagellum and tarsal structure distinctive to true thrips.

Mesozoic (245–65 Mya)

The Mesozoic was an era when terrestrial ecosystems became modern, with the rise of cycads and ginkgos and the diversification of conifers in the Triassic and Jurassic. In the Lower Cretaceous, there occurred what was probably the most profound evolutionary event: the explosive radiation of the angiosperms.

**TRIASSIC (245–208 MYA)** This was a period when arid and semi-arid savannas developed and when the first mammals, dinosaurs, and pterosaurs also appeared. Most deposits with insects are from the Upper Triassic (especially Carnian, ca. 230 m.ya), including South Africa; Virginia; Queensland, Australia; Tadjikistan; and France. The first evidence of a diverse freshwater insect fauna appears during the Triassic, as did the oldest living families: Cercopidae, Cicadellidae, Cixiidae, and Membracidae (Auchenorrhyncha); Belostomatidae (Fig. 1D); Nancoridae (Heteroptera); Carabidae; Staphylinidae; Trachypachidae (Coleoptera); Anisopodidae, Chironomidae, and Tipulidae s.l. (Diptera); and Xyelidae (Hymenoptera). The first true Odonata, Heteroptera, Thysanoptera (Fig. 5A), Diptera, and Hymenoptera appeared during this time. The Triassic Hymenoptera

Representative Mesozoic (A–F) and Cenozoic (G, H) insects (not to the same scale). (A) Primitive, oldest known thysanopteran (Triassic, Virginia). (B) †Protorhynphiidae (Diptera) (Jurassic, Kazakhstan). (C) Sphecidae (Cretaceous, Brazil). (D) Oldest known zorapteran (Cretaceous amber, Burma). (E and F) Oldest definitive ants [Formicidae; Sphecomyrma (E), Kyromyrma (F)] (Cretaceous amber, New Jersey). (G) Large, extinct tsetse fly (Diptera; Glossinidae) (Upper Eocene/Late Oligocene, Colorado). (H) Spoon-winged lacewing (Neuroptera: Nemopteridae) (Colorado).
have been exceptionally important in the study of smaller insects, nor have deposits from the Early Cretaceous of Lebanon, which are dominated by Rhagionidae. Other deposits, such as from Koonwarra, Victoria, Australia; Orapa, Botswana; Ceará, Brazil; Purbeck, Dorset, and Weald, England; Baissa, Russia; and Llérida, Spain, have revealed the earliest bee (Apoidea), ants (Formicidae) (Figs. 5E and 5F), Zoraptera (Fig. 5D), and Stepsipteran, as well as the oldest definitive Embioptera and Lepidoptera and many families of insects. All Cretaceous Lepidoptera belong to phylogenetically basal families. Cretaceous amber has also revealed a great diversity of primitive parasitoid Hymenoptera, sternorrhynchan hemipterans (especially Coccoidea), and euphidiid flies. Cyclorrhaphan Diptera were rare and primitive in the Cretaceous.

Many of the oldest records of blood-sucking insects are from the Cretaceous: Ceratopogonidae, Culicidae, phlebotomine Psychodidae, Tabanidae, and a possible stem group to the Siphonaptera (†Bethylonymidae). Diptera in the Jurassic were diverse nematocerans. †Bethylonymidae. Diptera in the Jurassic were diverse nematocerans. (i.e., Fig. 5B), and the oldest definitive brachycerans evolved, dominated by Rhagionidae. Cretaceous continental drift fragmented Gondwanaland and Laurasia into the continents seen today. One result was fragmentary regions of the southernmost regions of Africa, South America, Australia, and New Zealand (the “Austral Region”). This region harbors many primitive, relict insect groups.

Conifers were still diverse in the Cretaceous, which produced virtually all of the amber found during the Cretaceous. The oldest amber with insect inclusions is from the Lower Cretaceous of Lebanon, Japan, and England. Highly fossiliferous, somewhat younger amber deposits occur in northern Burma, western Canada, New Jersey, northern Spain, and the Taimyr Peninsula in northern Siberia. These have been exceptionally important in the study of smaller insects, having revealed the earliest bee (Apoidea), ants (Formicidae) (Figs. 5E and 5F), Zoraptera (Fig. 5D), and Stepsipteran, as well as the oldest definitive Embioptera and Lepidoptera and many families of insects. All Cretaceous Lepidoptera belong to phylogenetically basal families. Cretaceous amber has also revealed a great diversity of primitive parasitoid Hymenoptera, sternorrhynchan hemipterans (especially Coccoidea), and euphidiid flies. Cyclorrhaphan Diptera were rare and primitive in the Cretaceous.

**CRETACEOUS (145–65 MYA)** In many respects, the insect fauna of the earlier part of the Cretaceous has more similarity to the Jurassic than to the later part of the Cretaceous. No doubt this is the result of the radiations of angiosperms 120–100 mya. Today, insects pollinate some 85% of the angiosperms, and so pollinating Cretaceous insects must have helped spawn the diversification of angiosperms; also, the diversification of phytophagous insects (and probably their parasitoids) was promoted by angiosperms. Radiations of some very speciose insect groups began during the Cretaceous, including the Scarabaeoidea, Cerambycidae, Chrysomelidae, and Curculionoidea (Coleoptera) and the Lepidoptera (the largest lineage of phytophagous organisms). The Yixian Formation of China (Lower Cretaceous, ca. 130 mya) has yielded important vertebrate fossils, as well as early angiosperms and nemestrinid flies with long proboscides; these are the earliest records of specialized insect pollination. Early sphoeroid wasps (Fig. 5C), empidoid and other flies, and some beetles were probably very important, generalized pollinators of early angiosperms. Other important Cretaceous deposits are from Koonwarra, Victoria, Australia; Orapa, Botswana; Ceará, Brazil; Purbeck, Dorset, and Weald, England; Baissa, Russia; and Llérida, Spain. Isoptera appeared first in the Cretaceous, represented entirely by the primitive families Hodotermitidae, Termopsidae, Mastotermidae, and Kalotermitidae. True, eusocial termites and ants existed for at least 50 million years before they became abundant in the Cenozoic. Eusocial wasps and bees did not first appear until the Upper Cretaceous.

Cretaceous continental drift fragmented Gondwanaland and Laurasia into the continents seen today. One result was fragmentation of ancestral ranges, the areas most famous for this being disjunct temperate regions of the southernmost regions of Africa, South America, Australia, and New Zealand (the “Austral Region”). This region harbors many primitive, relict insect groups.

Conifers were still diverse in the Cretaceous, which produced virtually all of the amber found during the Cretaceous. The oldest amber with insect inclusions is from the Lower Cretaceous of Lebanon, Japan, and England. Highly fossiliferous, somewhat younger amber deposits occur in northern Burma, western Canada, New Jersey, northern Spain, and the Taimyr Peninsula in northern Siberia. These have been exceptionally important in the study of smaller insects, having revealed the earliest bee (Apoidea), ants (Formicidae) (Figs. 5E and 5F), Zoraptera (Fig. 5D), and Stepsipteran, as well as the oldest definitive Embioptera and Lepidoptera and many families of insects. All Cretaceous Lepidoptera belong to phylogenetically basal families. Cretaceous amber has also revealed a great diversity of primitive parasitoid Hymenoptera, sternorrhynchan hemipterans (especially Coccoidea), and euphidiid flies. Cyclorrhaphan Diptera were rare and primitive in the Cretaceous.

**JURASSIC (208–145 MYA)** One of the more significant events during this period was the origin of birds in the Upper Jurassic. Birds and (much later) bats are the only other skilled fliers and are perhaps the most important predators of modern insects. Numerous Jurassic deposits of insects occur in Europe and Asia: Grimmense and Solnhofen, Germany (the latter famous for the earliest birds, Archaeopteryx); Dorset, England; Issy-Kul, Kirghizstan; and, the most diverse and productive site of all, Karatau, Kazakhstan. Jurassic deposits of insects are barely known in North America and in the Southern Hemisphere. The earliest aculeate (stinging!) Hymenoptera appeared in the Upper Jurassic and were of the family †Bethylonymidae. Diptera in the Jurassic were diverse nematocerans (i.e., Fig. 5B), and the oldest definitive brachycerans evolved, dominated by Rhagionidae.

The sudden radiation of orders of modern mammals occurred in the Paleocene (65–56 mya). This period is very poorly known from the insect fossil record, the most diverse deposit being the fur formation from Denmark, which preserved giant ants, noctuid moths, and others. The first butterflies (Papilionoidea) are known from the Upper Paleocene.

The Eocene (56–35 mya) is far better known for insects, with extensive compression deposits from British Columbia, Canada (Horsely, Merritt, Princeton); Green River, Wyoming; Gurnet Bay and Bembridge Marls, Isle of Wight, England; and Florissant, Colorado. Florissant (e.g., Figs. 5G and 5H) was an ancient lake inundated with volcanic ash and is probably the most diverse compression fossil insect deposit from the Cenozoic. The greatest diversity of fossil insects is preserved in Baltic amber, huge deposits of which occur throughout northern Europe (from Eocene to Oligocene). The Baltic amber has preserved the first diverse faunas of schizophoran Diptera, ditrysian Lepidoptera, advanced termites, bees, and ants, all of which are relatively young, very speciose groups whose greatest radiations occurred in the Cenozoic. At least 30 species of bees have been found in Baltic amber; paradoxically, the great majority of them are corbiculate bees belonging to extinct genera. The diversity of advanced eusocial bees was much greater than today. The oldest definitive muscoid flies and fleas occur in Baltic amber. Other important Eocene amber deposits are from Fushun, China, and Arkansas.

Deposits from the Oligocene (35–23 mya) and the Miocene (23–5 mya) indicate that the insect fauna was essentially modern, with virtually all species (distinct) belonging to modern genera. Particularly rich Oligocene deposits are from the Ruby River Basin of Montana (compression) and Chiapas, Mexico (amber). Rich Miocene deposits occur in Oeningen, Switzerland (compression), and the Dominican Republic (amber). The age of the Dominican amber has been cited as Eocene but is definitely Miocene. The Dominican amber forest was very similar to contemporary neotropical forests, but there were some groups now extinct from the Caribbean (meliponine and englossine bees, certain genera of ants, and others) or even from the Western Hemisphere (Mastotermes termites and some genera of ants, acrocerid and phorid flies, and others). Dramatic extirpation of ranges has also been found in other Cenozoic deposits, such as tsetse
(now entirely African) (Fig. 5G) and nemopterid lacewings (Fig. 5H, now Southern Hemisphere) from Florissant and many currently austral taxa preserved in Baltic and Cretaceous ambers of the Northern Hemisphere. Although some specimens of insects preserved in Cenozoic ambers are very similar to modern species, it is unclear (especially genetically) if these are conspecific. The average duration of insect species is difficult to estimate, but the upper limit probably extends to 10 mya.

Study of Pliocene (5–1.5 mya), Pleistocene (1.5–0.01 mya), and Holocene (10,000 years ago–Recent) deposits has been extremely useful along with that of fossil pollen in reconstructing paleoclimates and ecological succession. These remains are preserved in existing or ancient lakebeds, bogs, and tarps. Paleoclimatic use of these remains depends on the availability of indicator taxa or readily identified extant species whose distributions are well documented. Particularly persistent and abundant in lakebeds, and therefore commonly used, are fragments of beetles (Fig. 2G) and the larval head capsules of chironomid midges.

Fruit Fly

see Drosophila melanogaster
Plant galls, which are abnormal growths of plant tissue that often resemble plant organs, can be induced by a wide variety of different insect species. The gallmaking insect stimulates the host plant through a complex chemical interaction so that the resulting gall is much more than a simple response to wounding or feeding damage. The precise gall form and position of the gall on the host plant is consistent and characteristic for each species of gallmaking insect.

Although cecidology, the formal study of plant galls, was initiated in 1679 with Malpighi's study of gallmaking insects, humans have admired and utilized galls for thousands of years. For example, gallic acid (3,4,5-trihydroxybenzoic acid) was first derived from an oak gall induced by the cynipid wasp Andricus gallaetinctoriae. These galls have been commercially traded from source trees in the Middle East and the gallic acid derived from them has been used historically as a dye as well as an antiseptic astringent skin medication. Derivatives and the gallic acid derived from them has been used historically as a dye as well as an antiseptic astringent skin medication. Derivatives of these galls have been used as photographic developers and the ink base made from them has been used to make permanent inks for purposes such as printing the U.S. dollar bill.

In 16th century England, the cynipid gall, Biorhiza pallida, was used for personal ornamentation. On May 29, the English parliament's official “Oak Apple Day,” sprigs of oak leaves and gilded galls were worn to commemorate restoration of the English monarchy.

**CECIDIA: PLANT GALLS**

Cecidia, or plant galls, are abnormal growths of plant tissue under the influence of a parasitic organism. Within the growing cecidium, plant cells proliferate (hyperplasy) and enlarge (hypertrophy) into a characteristic structure specific to that particular gallmaking organism. The organism inducing cecidogenesis (gall formation) receives nourishment and shelter while the host plant seldom benefits. Plant galls are induced by a variety of organisms including bacteria, fungi, nematodes, and arthropods.

Insect gallmakers span six orders (see Table 1) within which two entire insect families (Cecidomyiidae: the gall midges, and Cynipidae: the gall wasps) are found only within cecidia. While individual insect species make a characteristic gall on only one part of a single plant species, the thousands of gallmaking insects induce cecidia on nearly all plant parts of a wide variety of plant species worldwide.

**CECIDOGENESIS: MECHANISMS OF GALL INDUCTION**

The process of cecidogenesis (gall induction) involves increased levels of plant growth regulators (auxins, cytokinins, gibberellins, abscisic acid, etc.), the stimuli for which differ among taxa of gallmaking insect. For example, galls induced by tenthredinid sawflies (Hymenoptera) form in response to chemicals produced in the female accessory gland and placed on the plant at the time of oviposition. However, the chemical stimulus for galls induced by cynipid gall wasps (Hymenoptera) is released with larval feeding, and gall formation ceases if the larva dies. The exact mechanism by which insects induce gall structures characteristic to that insect species and markedly different from those of other gallmaking insects is still poorly understood.

The plant tissue stimulated to form a gall is always unspecialized parenchyma. As these plant cells undergo hyperplasy and hypertrophy, some cells may specialize to form the characteristic structures associated with that gall. However, some of the gall cells always remain unspecialized. These parenchyma cells sequester macronutrients (such as amino acids) and micronutrient minerals (such as calcium, iron, and magnesium) so that the galls act as physiological sinks in the host plant.

† Deceased September 3, 2003.
ECOLOGY OF GALLMAKING

Biology of Gallmakers

Formation of the gall has an adaptive advantage to the gallmaking insect, for nutritive gall tissues feed the growing larva and the gall structure hides it from natural enemies. These insect benefits of gallmaking are produced at the cost of photosynthate and energy to the host plant. The majority of insect gallmakers are plant parasites with a notable exception: fig wasps in the family Agaonidae (Hymenoptera) form mutualistic associations with their host plant (in the genus *Ficus*) as pollinators. Agaonid wasps from male flowers are introduced into fig orchards in the ancient agricultural process of caprification to allow pollination of the female flowers necessary to produce the fruit.

A number of gallmaking insect species exhibit heterogeny, alternating generations that include both sexes with generations including only females. Alternate generations frequently make very different galls on different parts of a plant, as does the homopteran grape phylloxera, *Daktulosphaira vitifoliae*, of which one generation induces galls on the leaves and stems while another generation induces galls on the roots of grapes (Fig. 1). Some alternating generations of gallmaking insects form galls on different host plants, as is found in the cynipid gall wasp, *Andricus quercuscalicis*, with the unisexual generation forming galls on acorns of *Quercus robur* (English oak) and the bisexual generation forming galls on staminate flowers of *Quercus cerris* (Turkey oak).

Other Insects in the Gall Community

Although a plant gall would appear to offer a place for an insect to escape predators and parasites, it is also a sedentary structure where natural enemies can predictably locate insect larvae. Predators of hidden insect larvae, such as woodpeckers, regularly prey upon galls. Many parasitoids, insects which receive their nutrients from a single host insect, eventually killing the host, have adapted to the predictability of plant galls.

In addition to gallmakers and parasitoids, the gall community also contains inquilines, which are insects that live in the gall and consume the plant gall tissue. Some inquilines deliberately kill the gallmaker, probably to prevent lignification of the gall tissues. However, many galls have both gallmaker and inquiline emerging as adults unless one or both have succumbed to parasitoids. The presence of inquilines, and the chemical stimulants they secrete, can sometimes alter the shape of the final gall, especially among cynipid gall wasps.

ECONOMIC IMPACT OF GALLS

The majority of plant galls harm the host plant only by diverting plant resources and thus have little economic impact. The economic impacts of gallmaking insects include the benefits of fig pollination as well as some negative economic effects in the form of crop losses.

Three examples of gallmaking insects with negative economic impacts are the Hessian fly (Diptera: Cecidomyiidae), the grape

![FIGURE 1](image-url) Heterogeny in grape phylloxera. In October, males and females of the bisexual generation emerge, mate, and lay eggs on leaves. Their offspring form blister galls on grape leaves. In April, the all-female leaf gallers lay eggs on leaves or drop to roots to lay eggs. In June, all-female root gallers lay eggs on roots. Their offspring form nodular galls on grape roots. In late August, a winged generation of females crawls out of the soil to lay their eggs (of the bisexual generation) under bark.
Phytophthora (Oomycota: Phytophthorales), and the oriental chestnut gall wasp (Hymenoptera: Cynipidae). The Hessian fly, Mayetiola destructor, is well known for the damage it causes to wheat crops. This fly does not cause galls on wheat, but rather exhibits a kind of facultative cecidogenesis by inducing galls only when the eggs are laid on barley, where the galls are much more damaging to the host plant than the necroses it forms on wheat. Grape phytophthora, D. citri foliae, nearly destroyed the wine industries of Europe in the late 19th century. Although the leaves of European vines are resistant and are not infested with the leaf- and stem-galling forms, genera-

Genetically Modified Plants

David A. Andow

*University of Minnesota, St. Paul*

Although there is no one absolute definition of a genetically modified (GM) plant, to some it is any plant that has had its genes deliberately altered by humans, by whatever means. This definition includes all plants produced by conventional plant breeding. Even though specific genes cannot be altered deliberately using conventional plant breeding, these conventional processes modify many genes simultaneously in statistically predictable ways. Hence, conventionally produced plants can be considered GM plants, broadly speaking.

To most others, a GM plant is more narrowly defined as a plant that has been produced using transgenic methods. These plants are also called transgenic or genetically engineered plants. Transgenic methods are molecular methods that enable the transfer of a gene or potentially a group of genes from an individual of one species to an individual or individuals of a different species. Currently, there are two common methods by which purified genes are introduced into plant cells: one uses the Ti plasmid of *Agrobacterium tumefaciens* to transfer the gene as a part of the plasmid; the other uses a metal particle or fiber or an electric pulse to pierce the cell wall and carry the gene into the nucleus (also called gene gun or electroporation). Transgenic methods enable humans to alter specific genes deliberately. The term transgenic is sometimes restricted only to genetic transfers across the species boundary, but usually includes molecular gene transfers within species as well.

The European Union (EU) uses GM plants in the narrow sense in discussing the regulation of biotechnology. Within the Cartagena Protocol on Biosafety under the Convention on Biodiversity, the term living modified organism is defined as a GM plant (narrow sense) that is intended to be grown, which excludes grain shipments and most other trade from consideration. The U.S. Office of Science and Technology Policy, which authorized the Coordinated Framework for the regulation of biotechnology in the United States, uses GM plants in the narrow sense, except that it is broadened slightly to include a couple of methods that would normally be considered conventional methods. All of these organizations have chosen a definition of GM plants to exclude conventional plant breeding, in part because they do not want to regulate conventional plant breeding.

Although it has become less common, several others have used GM plants (broad sense) to blur the distinction between transgenic plants and conventionally produced plants. Because commercialized conventionally produced plants and their food products have generally been assumed to be safe for the environment and human consumption, blurring the distinction has often been a device to suggest that there are few legitimate concerns about transgenic plants. More recently, this argument has been reversed. Some conventionally produced plants are in fact potentially harmful to the environment or human health, and it may become useful to evaluate the potential dangers associated with some of these plants.

**Genetically Modified Plants**

David A. Andow

*University of Minnesota, St. Paul*

The first commercial transgenic crops were planted in China during the early 1990s. These were primarily virus-resistant tobacco and tomato. In the United States, the first commercialized crop was Calgene’s FLVR SAVR tomato in 1994. This product was not a commercial success in part because it did not pack well for shipping. Initially, a variety of transgenic crops were planted (Table Ia); by 1999, however, four crops dominated: soybean, corn, cotton, and canola. The primary traits of these GM plants are herbicide tolerance and insect resistance (Table Ib). In 1999, herbicide-tolerant soybeans, Bt (B. thuringiensis) corn, herbicide-tolerant corn, Bt cotton, herbicide-tolerant cotton, and herbicide-tolerant canola accounted for over 99% of the commercial transgenic crops grown worldwide. All of the insecticidal-transgenic crops currently available are based on *cry* toxin genes from *B. thuringiensis*, and a few now under development are based on other toxin-coding genes from *B. thuringiensis*. The *cry* genes code for crystalline proteins that are toxic to some insects.

Bt genes have been incorporated into broccoli, cabbage, canola, cotton, corn, eggplant, poplar, potato, soybean, tobacco, and tomato, and the commercially available crops during 2001 in the United States are Bt corn and Bt cotton. Since their introduction during 1995, the cropping area of all of these transgenic crops has grown substantially (Table II). By 1999, Bt corn was grown on 9.6 million ha.
Bt cotton lagged behind substantially in total area because about five times more corn than cotton is grown in the United States. Clearly, Bt corn in the United States is one of the dominant transgenic crops in the world today. Interestingly, Bt corn area has decreased during 2000, probably in response to market uncertainty. In contrast, Bt cotton area increased, perhaps tied to increased demand for herbicide-tolerant cotton.

Several factors probably account for the predominance of Bt genes in transgenic crops. First and foremost, transgenic technology is relatively new, and consequently the products are those that are technically feasible, are readily accomplished, and have a clear path to commercialization. The cry genes present in Bt have been technically easier to use than genes from plant or animal sources. The cry gene structure is simple, and Cry toxins require no post-transcriptional or post-translational processing to be functional. Initially, cry genes did not express very well in plants, in part because bacterial DNA is A–T rich, whereas plant DNA is G–C rich. By directed mutagenesis, the “wobble” codon and other triplet redundancies were converted from A or T to G or C, and the resulting cry genes were expressed more consistently in plants. The commercialization path for Bt crops was believed to be relatively clear. Several Cry toxins have been used in commercial formulations of insecticides and these have been considered much safer for the environment and much less toxic to humans than nearly all other synthetic chemical insecticides. More recently, however, the differences between the Cry toxins in the insecticides and the Cry toxins in the transgenic plants have received increasing scientific and regulatory attention. Another reason for the predominance of cry genes is that as each particular Bt crop variety was approved for commercial use by U.S. regulatory agencies, the regulatory requirements became increasingly clear, making it increasingly easy to prepare for regulatory evaluation. Thus, the transformation technology, the regulatory environment, and the toxicological and insecticidal characteristics of Cry toxins have contributed to the present abundance of Bt crops.

### THE POTENTIAL OF THIS TECHNOLOGY

There are many different kinds of transgenic crops under development, including some that are expected to be commercialized in the next few years, others that may reach commercial status on a midterm horizon sometime during the next decade, and finally others that are mere ideas that require significant research breakthroughs before they can be realized. Most of these aim to address one of four broad needs: improved agricultural characteristics, improved post-harvest processing, improved food quality and other novel products for human use, and improved mitigation of environmental pollution.
Among the transgenic traits near to commercial release are new Bt genes that provide protection against additional types of insect pests. One of these traits is a gene that protects corn against rootworm damage. Some traits are based on Cry toxins, but others are based on novel Bt toxins (a binary toxin requiring two components that are toxic to insects). Other agriculturally useful traits include tolerance to abiotic stresses, such as drought, salt, and cold. These traits, however, probably require significant research breakthroughs before they can become realities.

Transgenic technology is also being applied to several commercially important tree species, including poplar, eucalyptus, aspen, sweet gum, white spruce, walnut, and apple. The first traits being genetically engineered into trees are herbicide tolerance and insect resistance, which may be useful for establishing and maintaining young trees and protecting valuable fruits. Several traits are under development to better adapt trees to postharvest processing. For example, the lignin content of certain tree species is being engineered to improve pulping, the process by which wood fibers are separated to make paper. Reduced lignin may improve the efficiency of paper production and reduce pollution from the paper-production process.

Transgenic technologies are being applied to alter macronutrients, starch, protein, oil, and micronutrients in several food crops, such as maize and soybean. For example, soy protein is deficient in the essential amino acids that contain sulfur. Increased production of these essential amino acids has been approached through genetic engineering by altering the activity of the enzymes that synthesize them, by overproducing a protein that contains them, or by blocking production of major proteins that lack them, which thereby increases the percentage of these amino acids in the remaining proteins. There are 17 minerals and 13 vitamins required at minimum levels to prevent nutritional disorders, and all of these have attracted biotechnology research. For example, increased levels of tocopherol, the lipid-soluble antioxidant vitamin E, has been engineered in the model plant Arabidopsis thaliana by overexpressing the gene responsible for the last step in vitamin E synthesis. Using a similar approach, current efforts are creating transgenic soybean and canola plants with enhanced levels of vitamin E.

In the future, transgenic plants may be grown to mitigate pollution. For example, it has been proposed that transgenic plants could contribute to removing or detoxifying heavy metal pollutants in contaminated soils ("phytoremediation"). A particular problem in some locations is mercury. Plants have already been created that can accumulate mercury, and genetic engineering may be able to enhance this ability so that growing such plants could become a potential solution for cleaning up mercury pollution at despoiled sites.

Few of these future potential applications are directly related to insects or insect control. However, each of them is likely to create significant needs for entomological investigations. Traits such as abiotic stress tolerance, altered lignin content, altered macronutrient or micronutrient content, and metal accumulation are all likely to have profound effects on plant physiology and growth. Because insect herbivores and their natural enemies are very sensitive to changes in plant physiology, growth rates, and morphological structure, these new transgenic crops are likely to create new kinds of pest control problems that will require entomological solutions. Indeed, it may become necessary to devise variety-specific pest-management systems for some of these novel plants.

THE LIMITS OF THIS TECHNOLOGY

The rate at which new transgenic traits can be expected to appear in the near future depends largely on the number of genes encoding them. Traits controlled by single genes, or traits that can be altered or eliminated by the loss of expression through silencing of a single gene or group of related genes, have been the first developed and commercialized. Genetically complex traits probably will require additional years of research to understand them, let alone to express and regulate them in a genetically engineered crop species. Nevertheless, many complex traits, including those controlling adaptation to abiotic stresses such as drought and salinity, flowering and reproduction, and hybrid vigor, are being investigated, and it is possible that some of these traits could appear in transgenic crop plants during the next decade.

The social acceptability of products from transgenic plants has affected and may continue to affect their adoption. Social acceptability has many components, including environmental and human health risks, food choices, the ownership of agricultural inputs and production process, the future structure of agriculture, and so on. This issue is extremely complex and volatile, and it may take several more years before it has stabilized sufficiently so that it will be possible to anticipate how various societies around the world might accept or reject transgenic plants.

Although these and other factors are involved currently in limiting the application of transgenic plants, the central trade-off that may limit it ultimately may involve a classic gene–environment trade-off in crop production. A broadly adapted trait may not be able to be used optimally without a corresponding management system. For example, the short-statured rice varieties of the Green Revolution required an intensive management system oriented around high fertilizer and pesticide use to attain their high yields across vast areas of Asia. These varieties, whether transgenic or conventional, are limited by the applicability of the attendant management system, which creates the environment in which they can flourish. Conversely, a plant with a trait adapted to specific environments associated with a single field or valley would not be broadly applicable to vast growing regions because the environment would not be equally suitable throughout.

The scale of use of such locally adapted varieties depends on a system of seed production and distribution that reliably delivers the appropriate seed at the proper time. The system of self-propagated land races admirably meets these needs, but it remains to be seen whether a commercial seed distribution system is able to deliver varieties that are so locally adapted. Finally, as noted above, transgenic plant varieties are being developed for extremely specialized uses on areas of only hundreds of hectares. The scale of use of these specialty varieties will probably depend on how many different such uses are commercially successful as well as the intensity of management needed to produce them. In conclusion, if technical factors and social acceptance do not limit the adoption of transgenic crops, the costliness of management associated with the specialty transgenic crops, the applicability of management of the broadly adapted transgenic crops, and the delivery of seed of locally adapted transgenic crops likely will limit their applicability, much like conventional varieties are limited today.

POTENTIAL ADVERSE EFFECTS

The risks associated with transgenic plants stem from, but are not directly caused by, the nature of the transformation process. First, transgenic methods enable traits to be expressed that have never before been expressed in a plant. This widened range of traits creates potential risks that should be evaluated. Second, the present transgenic methods cannot incorporate foreign DNA into precise locations in the plant genome. Because expression of genes can depend on where the gene occurs in the genome, and because the incorporation
Genetically Modified Plants

409

can be complex, the expression of the transgene cannot be predicted completely. The scope of potential traits and the uncertainty associated with trait expression create the circumstances requiring the evaluation of risks to human health or the environment.

Because transgenes code for proteins, human health risks associated with these proteins and products produced by these proteins are possible. These potential risks include creation of novel toxicants, possible shifts in the nutritional content of food, and the possible creation of novel allergens. Most of the scientific attention has focused on allergens, because they are difficult to assess and there has been an increase in the incidence of food allergies. Novel proteins and their products can be altered after synthesis by alterations in amino acid sequence and by reactions with other chemicals, such as glycosylation. Assessing each of these possibilities will be challenging.

Environmental risks stem from several types of potential effects: (1) effects associated with the movement of the transgene itself and its subsequent expression in a different organism or species, (2) effects associated directly or indirectly with the transgenic plant as a whole, (3) nontarget effects associated with the transgene product outside of the plant, (4) resistance evolution in the targeted pest populations, and (5) indirect effects on human health that are mediated by the environment. The EU recognizes affects on genetic diversity as a separate category of environmental effect in the modified 90/220 directive. The United States government has not recognized this as an environmental effect because it believes that it is the effects of altered genetic diversity, such as increased extinction rate, a compromised genetic resource, inbreeding depression, or increased vulnerability to environmental stresses, that are the actual environmental hazards. The EU recognizes this category as a precautionary measure, because the effects of movement of the transgenes are uncertain and are at present incompletely characterized. By recognizing the more easily measured, intermediate effects on genetic diversity as a potential effect, the EU risk analysis will address all of the effects caused by movement of transgenes without having to assess them specifically.

Hazards Associated with Movement of the Genes

Horizontal transfer is the nonsexual transfer of genetic material from one organism into the genome of another. Although there are no cases of transgenes moving horizontally from plants to any other organism at rates higher than normal, new discoveries could change the assessment and significance of this risk. Pollen dispersal provides an opportunity for the sexual transfer of transgenes to relatives of the crop, including other varieties of that crop, related crops, and wild relatives. Potential effects include the evolution of increased weedingness (i.e., more vigorous agricultural weeds, more invasive plants) or increased risk of extinction of native species by hybridization.

Hazards Associated with the Whole Plant

The transgenic plant itself may become an environmental hazard if the traits it receives improve its fitness and ecological performance. Although many crop plants may pose little hazard, insofar as they are unable to survive without human assistance, most crops have weedy and/or wild populations in some part of their global distribution. In these areas, transgenes that improve fitness could increase weedingness of the crop. In addition, because transformation includes forage grasses, poplars, alfalfa, sunflowers, wild rice, and many horticultural species, the risk of invasiveness may increase.

Nontarget Hazards

Nontarget organisms are any species that are not the direct target of the transgenic crop, and consequently, the list of potential nontarget species is very long. These organisms can be grouped conveniently into five categories: (1) beneficial species, including natural enemies of pests (lacewings, ladybird beetles, parasitic wasps, and microbial parasites), and pollinators (bees, flies, beetles, butterflies and moths, birds, and bats); (2) nontarget pests; (3) soil organisms, which usually are difficult to study and identify to species; (4) species of conservation concern, including endangered species and popular, charismatic species (monarch butterfly); and (5) biodiversity, which is the entire group of species in an area.

Hazards of Resistance Evolution

Resistance evolution can occur in pests that are targeted for control by or associated with the transgenic crop. If the pest becomes resistant, then alternative, more environmentally damaging controls may be used. Insects, weeds, and microbial pathogens all have the potential to overcome most control tactics used against them. Insect resistance to Bt crops is considered inevitable, and efforts are being made to manage resistance evolution to these transgenic crops.

Indirect Hazards

Transgenic crops can have indirect environmental impacts, especially when scaled up for commercial production. Many of these effects are associated with changes in production practices or cropping systems. For example, transgenic maize resistant to corn rootworms may lead to an expansion of continuous corn (corn planted after corn) and its attendant environmental risks, such as soil erosion. In addition, it is possible that crops transformed to produce pharmaceutical or other industrial compounds might mate with plants grown for human consumption with the unanticipated result of novel chemicals in the human food supply.

Further Reading

Tremendous progress has been made in the development of genetic engineering technologies in insects. This article emphasizes studies with the vinegar fly, *Drosophila melanogaster*, because, as a result of its successful use as a genetic model for eukaryotic genetic systems, developments in genetic engineering with this species establish a benchmark for what can, or could, be done in other insect species. The article also discusses the more recent use of transposable-element-based genetic transformation procedures in nondrosophilid insects and concludes that many of the tools required for genetic manipulations of nondrosophilid insects are now available.

The term “genetic engineering” is typically taken to refer to the direct manipulation of genes. It has become synonymous with a more general term, “DNA technology,” which has come to encompass all contemporary molecular-based techniques. However, many insect geneticists were using “DNA technology” before the development of recombinant DNA technology in the 1970s and 1980s. Genetic control approaches applied to such insect pests as the Mediterranean fruit fly (*Ceratitis capitata*) (medfly), the mosquito (*Culex tarsalis*), and the Australian sheep blowfly (*Lucilia cuprina*) used genetics to develop new strains that could be used in insect control and/or eradication programs. The tools of these pioneers were not DNA modification and restriction enzymes, thermocyclers, or DNA sequencers, but rather radiation sources, microscopes, and the knowledge that mutations and chromosomal rearrangements could be created and selected for. These tools have now been surpassed, but one aim remains the same: the generation and application of new genetic strains of insects that can be used to control pest insect species. The development of sophisticated genetic tools, in conjunction with the rapid progress being made in genomics, will provide insect scientists with the ability to characterize and manipulate, in hitherto unimaginable ways, insect genes.

**GENETIC ENGINEERING IN DROSOPHILA MELANOGASTER**

**Genetic Technologies are More Advanced in *Drosophila* than in Other Insect Species**

One cannot discuss the genetic manipulation of insects without describing the molecular genetic tools that are available in *D. melanogaster*. Traditionally, a gulf has existed between entomologists who view the harmless vinegar fly as being distant to the problems of insect control and *Drosophila* geneticists who utilize the many biological attributes of *Drosophila* to understand the basis of gene action. This gulf will close as comparative genomics reveals similarities and differences in the conservation of many genes and molecular pathways between *Drosophila* and other insect species. The power of this comparative approach to modern biology will offer insect scientists and traditional entomologists exciting opportunities to bring the power of genetics and molecular biology to the control of insects. The development and application of these tools is what insect scientists seek to achieve in pestiferous and beneficial insects.

Genetic engineering in *D. melanogaster* is an extremely mature technology. It is founded on several independent phenomena:

1. The presence of a transposable element, called the *P* element, which is an efficient genetic transformation vector. This vector has been available and exploited since the early 1980s.
2. The ability to create and maintain genetic mutants by traditional techniques such as chemical- or radiation-induced mutagenesis or by transposon insertion mutagenesis, and the construction and availability of balancer chromosomes to maintain many of these mutants.
3. The presence of strains that lack the *P* element, thus providing recipient strains suitable for *P* element transformation.
4. The completion of the *Drosophila* genome project and the public availability of the data generated.

These planks of achievement are a consequence of the intense and sustained research that has been invested into *Drosophila* over the course of the last 90 years. The picture in all other insect species is, by comparison, sparse. For example, transposable elements capable of transforming nondrosophilid species have been available only since 1996. Also, traditional mutagenesis approaches have been used to generate mutations in a handful of insect species. Many of these have been lost because of problems arising from the rearing of these species (it should be noted that what attracted T. H. Morgan to *Drosophila* was the ease with which it could be reared and mated in the laboratory) and, often, because it had been necessary to depend on a handful of dedicated workers to maintain these strains. (In *Drosophila*, by contrast, there are central repositories for strain maintenance as well as hundreds, if not thousands, of researchers who maintain even the most problematic genetic stocks.) Except for medfly, balancer chromosomes have not been constructed in nondrosophilid insects.

Two other factors are important. The interactions, if any, of the transposable elements so far known to transform nondrosophilids with components of the insect genome remain unknown, as do the molecular mechanisms by which these elements move both within and between insect genomes. Second, to date, no insect species other than *Drosophila* has had its entire genome sequenced. Some mosquito genomes are the target for current and future genomic projects.

**Transformation Technologies in *D. melanogaster***

**P ELEMENT TRANSFORMATION** Population geneticists in the 1970s had observed that when males from certain strains of flies recently established from wild populations were mated to females from long-established laboratory populations, a number of abnormal traits were observed in the progeny. These traits included high rates of mutation, sterility, and recombination in males, traits that are not usually seen in this species. Collectively, the traits that arose only when specific hybrid insects were created were thought to be manifestations of a single syndrome that became known as “hybrid dysgenesis.” Because the factors responsible for this syndrome were
transmitted by males, they were referred to as paternal or "P" factors. Those working on P-factor-mediated hybrid dysgenesis quickly realized that there were multiple factors that mapped to many different locations within the genome. Some of the mutations that were induced during hybrid dysgenesis were very unstable and were themselves capable of mutating further to result in more extreme phenotypes or to revert to wild type. This instability as well as other genetic observations suggested that the P factors were mobile genetic elements or transposons. As long ago as 1989, Engels gave a comprehensive description of the P element, P factors, and their use in genetic transformation.

Concurrent with the efforts of population geneticists to understand the phenomenon of hybrid dysgenesis were efforts of molecular geneticists to clone genes from D. melanogaster. The eye color gene known as white was one of the first genes to be cloned from this species, largely owing to the great amount of genetic analysis that had been done on this locus. Having the white gene cloned, provided a unique opportunity to isolate P factors. Because P factors were responsible for causing mutations, a genetic screen was performed to seek mutations induced by hybrid dysgenesis of the white gene. The reasoning behind this experiment was that once a P-factor-induced mutation of the white gene was obtained, it should, in theory, be readily cloned by conventional genomic DNA library screening using the wild-type allele of the white gene as a probe. By comparing the mutant allele with the wild-type allele, the nature of the P factor might be deduced. As expected, mutations of the white gene induced by hybrid dysgenesis contained insertions, and the insertion sequences had all the characteristics of a transposable element. In fact, P factors were transposable elements and became known as P elements. Complete P elements were about 31 kb in length and contained four open reading frames encoding for a protein essential for P element movement. The terminal sequences of P elements consisted of inverted repeat sequences of 31 bp. In structure, the P elements generally resembled other transposable elements that had been isolated from bacteria and were referred to as short, inverted repeat-type transposable elements.

The physical isolation of an active transposable element from D. melanogaster provided researchers with a unique opportunity to integrate foreign DNA into the chromosomes of this species. Efforts to integrate exogenous DNA into the chromosomes of insects can be traced back to the late 1960s. While there was an interest in genetically transforming insects and a few reports of minor successes, there was no reliable method for creating transgenic D. melanogaster. The P element solved that problem. It was reasoned that if the terminal, noncoding sequences of the element, which serve as signal sequences directing the cutting and pasting of the element, were attached to any piece of DNA, that piece of DNA would acquire the mobility properties of a P element. Furthermore, if this altered transposable element could be introduced into a cell that was going to form gametes and the element jumped (i.e., transposed) onto one of the chromosomes of this cell, then the gametes arising from this cell would be transgenic and would give rise to transgenic progeny. This reasoning proved to be precisely correct. Under the appropriate conditions, genes to which the terminal noncoding sequences of a P element have been attached can readily integrate into the chromosomes of presumptive germ cells and lead to the efficient creation of transgenic insects (Fig. 1).

This relatively simple technology helped fuel a revolution in the study of this model organism. Today, this transposable element forms the basis for a suite of technologies that allow researchers to identify and analyze genes in a variety of ways. The P element gene transformation system has also served as a paradigm for the development of similar technologies applicable to other species of insects.

**GENE TAGGING WITH TRANPOSABLE ELEMENTS**

The key to the identification and isolation of P elements was the availability of the cloned white gene. The white locus was used as a trap; once the P element had been identified and cloned, it could be used as a way of identifying and isolating genes. As already discussed, one of the prominent features of P element movement (as revealed by the phenomenon of hybrid dysgenesis) was the creation of mutations. These mutations are caused by the insertion of the P element into an essential region of a gene, thereby altering its level or pattern of expression.

Mutations and their associated phenotypes define genetic loci. The existence of a mutant insect with an altered eye color defines a locus that plays some role in eye pigmentation. Although the existence of a mutant reveals the presence of a gene and its location, it does not provide researchers with a means of readily isolating the DNA containing the gene. If, however, the mutation is caused by the insertion of a sequence, such as a P element, and we know the sequence of the insertion sequence, we can use this information to isolate the DNA of the gene that was mutated. By making a genomic DNA library from the mutant insect, one can use conventional DNA hybridization techniques to identify sequences in the library that contain the P element. Because the mutation was caused by the

---

**FIGURE 1** P element transformation of D. melanogaster. Two plasmids, one containing a P element into which has been cloned a genetic marker (green) and a helper plasmid containing the P element transposase (white) placed under the control of an inducible promoter (blue) are coinjected into embryos. The P element inverted terminal repeats are shown as black arrowheads. G0 adults arising from injected embryos are not transgenic but some will contain a percentage of gametes containing the P transposable element. These adults are outcrossed and G1 progeny are examined for the presence of transgenic individuals (green fly).
The significant difference between this method of gene identification and of the reporter gene. By identifying enhancers with particular moving the transposon around the genome and looking for expres- ase binding site but no associated enhancers. Consequently, this a minimal basal promoter, meaning that it contains an RNA polymer- ize to contain a gene whose expression is readily detected. A transposon tagging system that ensures unambiguous gene identification are an active transposon that has little integration site specificity and insect strains that contain few or only one transposon-tagging transposable element. Roberts has described the use of the P element for gene tagging and enhancer trapping.

**ENHANCER TRAPPING** Transposable element-based muta- genesis or transposon tagging is a powerful technology with one limitation: it can identify only genes that have a recognizable mutant phenotype following element integration. Many of the genes that one mutates either do not result in a visible phenotype or cause the death of the organism. Such genes will never be recovered from a screen based on transposon tagging.

A complementary methodology that does not rely on mutagenesis for gene identification is called enhancer trapping. Enhancers are gene expression regulatory elements, and they function to fine-tune the control of gene expression, temporally and spatially. They are quite distinct from gene promoters in that enhancers are not sites of RNA polymerase binding but are instead sites for protein binding that influence when and how often RNA polymerase will associ- ate with a promoter. A remarkable and useful feature of enhancers is their ability to act over long distances by mechanisms that are not entirely clear. That is, an enhancer may be located hundreds or even thousands of bases away from its target promoter. If a new pro- moter is inserted near the enhancer, it too will become regulated by that enhancer. This phenomenon provides a clever, nonmutagenic method for gene identification based on patterns of gene expression called enhancer trapping.

Like transposon tagging, enhancer trapping relies on the move- ment of a transposable element. The element in this case has been engineered to contain a gene whose expression is readily detected. Today the green fluorescent protein (GFP) from the jellyfish is a common choice. The reporter gene has been engineered to contain a minimal basal promoter, meaning that it contains an RNA polymerase binding site but no associated enhancers. Consequently, this enhancerless gene construct does not result in reporter gene expres- sion unless the transposon in which it is contained integrates near an active enhancer. The presence of enhancers can be detected by moving the transposon around the genome and looking for expres- sion of the reporter gene. By identifying enhancers with particular properties, one then has indirectly identified the genes controlled by these enhancers. Often, the genes regulated by enhancers identified by using this method are located in the proximity of the enhancer. The significant difference between this method of gene identification and transposon tagging is that enhancer detection does not require mutating the enhancer or its associated gene. Consequently, genes that may not have been detected by a transposon-tagging screen might be detected using an enhancer trap (Fig. 2).

Transposon tagging and enhancer trapping are rather intense genetic methods for gene identification. Such methods require the ability to efficiently perform genetic crosses, to recognize mutants or desirable reporter gene expression patterns, and then to main- tain large numbers of distinct genetic lines of insects. Although *Drosophila* is readily amenable to such manipulations, other insects may be less so. Nevertheless, these methods will be of great value to those entomologists working on a variety of insect species.

**HOMOLOGOUS RECOMBINATION** Transposon tagging and enhancer trapping are methods of identifying genes based on patterns of expression or analysis of the protein gene product. Today, however, it is possible for researchers who know the DNA sequence of a specific gene to create *D. melanogaster* with mutations in that gene. This method of targeted mutagenesis relies on the process of homolo- gous recombination.

Homologous recombination, the process of gene exchange that typically occurs during meiosis, depends on the association of DNA sequences that are identical or nearly identical. Breaks in one of the strands of a DNA duplex can result in this strand becoming associated with its homolog on another chromosome, leading to gene exchange. It is now possible to exchange a gene located on a chromo- some of a fly with a nearly identical gene created in the laboratory. This somewhat involved process relies on the use of a site-specific recombinase and a site-specific endonuclease, but it is potentially a method that will be generally applicable to any insect. Rong and Golic have described this technology in *D. melanogaster*.

The strategy behind using homologous recombination takes advantage of the high recombinogenicity of linear molecules of DNA. Such molecules will preferentially recombine with sequences homologous to the sequence at the end of the linear molecule. Gene targeting by homologous recombination in *D. melanogaster* is based on a clever method for generating the highly recombinogenic target- ing molecule *in vivo*. The process begins by creating a transgenic insect using, for example, a P element gene vector that contains the targeting sequences flanked by site-specific recombination sites such as the FRT sites of the FLP recombinase system. When FLP recom- binase is expressed (from a previously integrated transgene) in the

---

**FIGURE 2** Example of enhancer trapping in insects: three pairs of chromosome with their centromeres (purple). One strain contains a MOS element into which the Hermes transposase has been cloned (orange). The MOS inverted terminal repeats are shown as pink arrowheads. A second strain contains a Hermes element containing a genetic marker (blue) placed under the control of a weak promoter. The two strains are crossed, whereupon the Hermes transposase causes the Hermes elements to move to new regions of the insect genome. Should a Hermes element insert near an enhancer element (black box), the genetic marker in the Hermes element would show the same tissue- and stage-specific expression of the gene controlled by the enhancer. The gene and the enhancer can then be cloned by standard gene tagging techniques.
insect, the FRT sites will recombine causing the targeting gene to be excised from the integrated gene vector. This recombination event results in the creation of extrachromosomal circular molecules in the nuclei of the insect. These extrachromosomal circles are then linearized by expressing a site-specific endonuclease (from a previously integrated transgene) that recognizes a DNA sequence that has been placed in the targeting gene in such a way that digestion results in the target gene sequences being located at the ends of the linearized circle. This highly recombinogenic molecule will then recombine with the chromosomal homolog, resulting in gene disruption.

Homologous gene replacement has been achieved for two Drosophila genes, the yellow gene and the pugilist gene, and most likely will be applicable to a large number of D. melanogaster genes. In particular it should enable gene function to be assigned to the thousands of new genes identified in the Drosophila genome project through replacing the wild-type forms with nonfunctional mutations that have been created in vitro.

A prerequisite for targeted gene replacement is a set of transgenic insects that can express the appropriate restriction enzyme and the FLP recombinase. This is readily achieved in D. melanogaster and now can also be accomplished, in principle, in other insect species because transposable elements exist that can be used to genetically transform them. The FLP recombinase system has been shown to function correctly in the yellow fever mosquito, Aedes aegypti, and most likely will function in all insects into which it is placed. Similarly, the ability of a yeast restriction enzyme to function in Drosophila suggests that it should also function correctly in a range of insect species into which it is placed.

**GENETIC ENGINEERING IN NONDROSOPHILID INSECTS**

**Genetic Transformation of Nondrosophilid Insects**

The P element paradigm is successful in nondrosophilid insects. Despite many attempts, the P element was found to be unusable as a gene vector in nondrosophilid insect species. The reason for the narrow host range of P is unknown; however, it has been proposed that P is dependent for its mobility, in part, on the presence of host-encoded factors. These are thought to be absent, or at least sufficiently diverged, to prevent the mobility of P in these species. The P element is, however, not required for insect transformation because of the discovery and performance of four transposable elements, each from a separate family of transposable elements. Each of these is endowed with a broad host range, and each can transform D. melanogaster as well as a number of nondrosophilid species. They are briefly described below.

What is conserved between drosophilid and nondrosophilid transformation has been described as the P element paradigm. This refers to the mode of transformation. The P element and the four elements described shortly are class II transposable elements. They all transpose by a “DNA-only” type of mechanism—no production of an RNA intermediate is needed. These elements have an overall structure that is shared between them. They are short (<4 kb), have inverted terminal repeated sequences, and encode a transposase enzyme that catalyzes the movement of the transposable element from one genomic location to the next. The same methodology is used to introduce these transposable elements regardless of species. Typically, two plasmids are co-injected into preblastoderm embryos. One plasmid contains the transposable element, into which has been placed a genetic marker and an effector gene—a gene meant to alter the phenotype of the insect in a desired way. The placement of the marker gene and the effector gene interrupts and inactivates the transposase gene within the element, necessitating the use of a second plasmid containing the corresponding transposase, which is typically placed under the control of an inducible promoter such as the hsp70 promoter of D. melanogaster. This transposase mediates the transposition of the transposable element from the donor plasmid to the genome of the developing germline cells. As for D. melanogaster transformation, the individual arising from the injected embryo is not transformed; rather, it contains genetically transformed gametes. Individuals are mated, and transgenic insects are screened for in the next generation.

**TRANSPOSABLE ELEMENTS USED FOR NONDROSOPHILID INSECT TRANSFORMATION**

Four transposable elements can be used to genetically transform nondrosophilid insects: piggyBac, Hermes, Mariner, and Minos.

**PiggyBac**

The 2.5-kb piggyBac element has 13-bp inverted terminal repeats and 4-bp direct repeats located proximally to these. It contains a 2.1-kb open reading frame that encodes a transposase enzyme. piggyBac was discovered through its ability to transpose from the chromosomes of the Cabbage looper Trichoplusia ni into the genome of a baculovirus that had infected this TN368 cell line. Transposition of piggyBac into the baculovirus genome led to a mutation that resulted in few polyhedra being generated, in turn causing a clear change in cell morphology. piggyBac inserts only at TTAA sites and generates duplications of this sequence at the target site. Excision of piggyBac is precise—unlike other class II insect transposable elements, no deletions or additions of DNA remain at the empty excision site. piggyBac has found wide use as a gene vector in insects and has been used to genetically transform the flies C. capitata, Bactrocera dorsalis, Anastrepha suspensa, Musca domestica, L. cuprina, and D. melanogaster; the mosquitoes Anopheles albinanus, Anopheles stephensi, Anopheles gambiae, and Anopheles aegypti; the moths Bombyx mori and Pectinophora gossypiella; and the beetle Tribolium castaneum. Little is known about the distribution of piggyBac throughout insects, although highly similar elements have recently been found in three strains of B. dorsalis. Over the 1.5 kb of nucleic acid sequence examined, these B. dorsalis elements are 95–98% identical to the element originally isolated from T. ni cells. Two of these B. dorsalis piggyBac-like sequences contain small deletions that interrupt the open reading frame, whereas the third has an intact open reading frame over the region examined. Conceptual translation of this region yields a sequence identity of 92% compared with the corresponding region of the T. ni piggyBac transposase. The basis of the distribution of piggyBac-like elements combined with the possible effect that incumbent piggyBac-like sequences may have on introduced elements in transgenic lines is a fertile field for investigation.

**Hermes**

Hermes elements are members of the hAT family of transposable elements that are widely dispersed in animals and plants. Some members of this family, such as the Ac element of maize and the Tam3 element of snappingdragon, have a broad host range, and this attribute is shared with the Hermes element. Hermes was isolated from the house fly, M. domestica, and was first recognized by its ability to cross-mobilize the related hobo element when this was introduced into house fly embryos by microinjection. The 2.7-kb Hermes elements contain 17-bp inverted terminal repeats and a 1.8-kb open reading frame that encodes a transposase of 70 kDa. Hermes elements exhibit a preference for inserting at 5'-GTnmmAC 3' sites and create 8-bp duplications of these sites upon insertion. They have
been used to genetically transform *D. melanogaster*, *C. capitata*, *Stomoxys calcitrans*, *A. aegypti*, *Culex quinquefasciatus*, and *T. castaneum*. Plasmid-based transposition assays have shown that *Hermes* can transposase in several other insect species as well. *Hermes* transposes by a cut-and-paste mode of transposition in higher Diptera but seems to integrate by another, transposase-dependent mode in mosquito germlines. The molecular basis of this remains unknown. *Hermes* elements can interact with the related *hobo* element (and vice versa) when both are present in the genome of *D. melanogaster.*

**Mariner** *Mariner* elements are widespread among arthropods. They are approximately 1.3 kb with inverted terminal repeats typically around 30bp long. *Mariner* elements can be present in an extremely high copy number in some species; however, it seems likely that only a handful (if any) of these may contain a single open reading frame that encodes an active transposase of approximately 33kDa. Based on DNA sequence comparisons, five different superfamilies of *Mariner* elements exist in arthropods. The distribution of members of these superfamilies is inconsistent with the established evolutionary histories of their host species and it is now accepted that *Mariner* elements have been horizontally transferred throughout evolutionary time. At present only one naturally occurring, active *Mariner* element has been discovered. This is the MOS element from *Drosophila mauritiana* and has been used to genetically transform *D. melanogaster*, *A. aegypti*, and *M. domestica*. Indeed MOS displays a broad host range and has been used to genetically transform *Leishmania*, chickens, and zebrafish. The mobility characteristics of MOS are preserved in these species; it transposes by a cut-and-paste mechanism and inserts at, and duplicates, TA nucleotides. A second active element, *Himar*, was constructed based on a consensus of *Mariner* sequences obtained from the horn fly, *Haematobia irritans*. *Himar* is active in *Escherichia coli* but so far is inactive in insects.

**Minos** The *Minos* element is a member of the *Te1* family of transposable elements. The *Te1* family of elements is related in sequence and mobility properties to the *Mariner* family of elements, and both are grouped into a single superfamily of elements. *Minos* elements are approximately 1.8 kb and possess long, 254-bp inverted terminal repeats. *Minos* contains two long open reading frames that are interrupted by an intron. Conceptual translation of the *Minos* transposase gene reveals a greater than 40% identity with the *Te1* transposase of *Caenorhabditis elegans*. *Minos* has been used to genetically transform *C. capitata*, *D. melanogaster*, and *A. stephani*.

**Transposable Elements in New Hosts**

These four transposable elements just discussed provide the means by which genes can be introduced into pest insect species. Although these elements represent four different transposable element families, the transformation frequencies achieved, with some exceptions, are in the range of 1–10%. It seems likely that all will enjoy use as gene vectors in a range of insect species, and all may well be subject to interactions with endogenous transposable elements or other host factors present in these species. This is an important point that is not encountered by geneticists working on *Drosophila*. The recipient strains used for *P* element transformation are devoid of *P* elements (and any other related elements) and are deliberately chosen for this reason. This is not possible in other insect species in which the composition of the target genome with respect to transposable elements is unknown.

Whether interactions with endogenous transposable elements and/or host factors occur at levels that detrimentally affect transgenic stability is an issue that must be addressed. Central to this is development of a complete understanding of how these transposable elements are regulated both in their original host species and in species into which they have been introduced.

**Genetic Markers**

The development of universal genetic marker genes, together with the identification of promoters to drive their expression in heterologous species, has played a major role in the extension of genetic engineering into nondrosophilid insects. Natural and modified forms of the GFP gene of the jellyfish, *Aequorea victoria*, have enabled transgenic insects in several species to be easily identified from non-transgenic siblings at most stages of development. These include *D. melanogaster*, *C. capitata*, *B. dorsalis*, *A. aegypti*, *A. stephani*, *C. quinquefasciatus*, *P. gossypiella*, *T. castaneum*, and *S. calcitrans*. In these species, the GFP gene has been placed under the control of a promoter that enables either organelle-specific or tissue-specific expression of the marker gene to occur. Examples of the former are the actin5C and polyubiquitin promoters of *D. melanogaster*. Examples of the latter are the Pax6 and actin58 promoters. The actin58 promoter is from *D. melanogaster* and is specifically expressed in the indirect flight muscles of the pharate adult and adults. Pax6 is a member of the Pax family of transcription factors and is specifically involved in the development of the eye and central nervous system.

The enhanced GFP (eGFP), cyan fluorescent protein (CFP), yellow fluorescent protein (YFP), and Ds Red forms of the fluorescent protein genes can also function as genetic markers in insects.

**OTHER APPROACHES TO GENETIC ENGINEERING IN INSECTS**

**FLP/FRT Recombinase in Nondrosophilid Insects**

The FLP/FRT recombinase system of the yeast *Saccharomyces cerevisiae* can also function correctly in at least one nondrosophilid species. Plasmid-based excision and integration assays showed that the FLP recombinase enzymes could recognize and recombine FRT sites in the soma of developing *A. aegypti* embryos. Excision at the FRT sites was high—60% of plasmids examined had undergone an excision event mediated by FLP recombinase. Integration, as measured by the formation of heterodimeric plasmids arising from the recombination between two plasmids each containing an FRT site, occurred at a low, but statistically significant, frequency. The ability of the FLP/FRT recombinase system to function correctly in *Drosophila* and *Aedes* suggests that it should function across a range of insect species. It cannot, however, be used to directly genetically transform an insect species because to achieve this, FRT sites must first be introduced into the target genome by some other means, such as transposable elements. When combined with transposable element technology, this yeast recombination system should allow investigators to undertake precise manipulations of both introduced and host DNA. This ability will be of particular importance if DNA sequences necessary for the movement of transposable elements need to be inactivated (e.g., for regulatory reasons) following initial integration of the element into the target genome.

**RNA-Mediated Interference (RNAi) in Insects**

RNA-mediated interference (RNAi) refers to the targeted disruption of gene expression arising from the introduction of double-stranded RNA (dsRNA) into the cell. This disruption is targeted only to RNA molecules homologous to the invading dsRNA. It was
initially characterized in plants and in the nematode C. elegans but is now thought to be a general phenomenon of eukaryotic cells that enables them to overcome invasions of RNA viruses. The mechanism by which RNAi works is unknown. It does not work through a simple titration of nascent or messenger RNA as would occur for an antisense RNA-based mechanism because the RNAi response can be elicited by far fewer dsRNA molecules per cell than, target RNA molecules. A catalytic mechanism in which the presence of dsRNA induces the destruction of homologous cellular RNAs has been recently proposed. RNAi technology has been harnessed to allow the targeted inactivation of specific genes and will prove to be a valuable component of genomics projects in those species in which nucleic acids can be introduced into cells. In its original experimental design, the effects of RNAi were not inherited. RNAi technology has recently been combined with P transposable element technology in D. melanogaster to produce heritable RNAi-mediated gene inactivation. Thus it is possible to examine the functions of expressed in later stages of development of this insect and also the generation of genetically stable mutant lines in which the production of the dsRNA can be induced or terminated based on the promoter used to drive expression of the extended hairpin loop RNA. RNAi technology should be extendible into other insect species in which transformation systems exist, and its exploitation in insects such as mosquitos will enable the effects of the selective inactivation of specific genes to be quickly determined. This will represent a significant advance over traditional methods of creating and isolating mutants in these insect species that have not traditionally been amenable to genetic analyses.

EXAMPLES OF INSECT GENETIC ENGINEERING FOR INSECT POPULATION CONTROL

Transgenic technology in nondrosophilid insects has already been applied to examine promoter function and gene expression in transgenic lines of A. aegypti and C. capitata. In addition, recent work performed in D. melanogaster illustrates how transgenic approaches may be applied to pest insect control in the foreseeable future. This approach involves using transgenic technology to develop new genetic sexing strains. Although these experiments have been performed in D. melanogaster, the concepts are applicable to any insect species in which transgenic technology has been developed, and the ability to generate and test novel genetic strains in pest insect species should result from such additional experiments.

Both systems were centered on exploiting the tetracycline-controlled transactivator (rTA) gene, which is inactivated in the presence of tetracycline. As a dietary component, tetracycline can readily be administered to Drosophila larvae in measured doses. Both systems consist of two components, which are combined in a single strain when transgenic lines containing each component are crossed. The rTA gene was placed under the control of the enhancer from the yolk protein 1 (yp1) gene of D. melanogaster. This enhancer results in fat-body- and female-specific expression of the yp1 gene. The second component of their system was a proapoptosis gene (head involution defective—hid), the expression of which leads to apoptosis and the death of the organism. The hid gene was placed under the control of the tetracycline operator (tetO), which contains the binding site for the rTA protein. Thus, in females the yp1-rTA gene is induced and, in the absence of tetracycline in the diet, the rTA protein binds to the tetO sequence and so induces the expression of the hid gene. All transgenic females that were raised in the absence of tetracycline and possessed both components of this lethal genetic system died. When tetracycline was added to the diet, the rTA protein was inactivated, and there was no female lethality. Males containing both components were unaffected on either diet.

These experiments clearly demonstrate that transgenic technology can be used to construct efficient genetic sexing strains in at least one species of insect—D. melanogaster. The genes, promoters, and enhancers chosen to do so are predicted to be of generic use in insects. The tetracycline-controlled transactivator system is from bacteria and, given that it functions correctly in Drosophila, will most likely be applicable to all insects in which tetracycline, or its analogs, can be delivered in measured doses. Female-specific enhancers would be expected to exist in nondrosophilids, should the D. melanogaster enhancers not function correctly in these species. Similarly, should conditional lethal alleles of Drosophila genes not function in other species, it should be possible to generate analogous mutants either by established procedures or by employing an RNAi-based approach. The extension of these strategies into nondrosophilid insects requires, in the end, genetic transformation procedures and, as already discussed, several of these now exist for nondrosophilid insect species.

CONCLUDING REMARKS

For many years, the absence of genetic transformation techniques for nondrosophilid insect species was seen as a bottleneck for the full extension into these important pest species of strategies based on molecular genetics. The development of successful transposable-element-based transformation technologies enables the potential of these strategies to be tested at last. Insect geneticists have at their disposal gene vectors, universal genetic markers, promoters that can be utilized in heterologous insect species, and many target genes to test and manipulate. In addition, as outlined here, there is reason to be confident that generic techniques such as gene tagging, enhancer trapping, homologous recombination, FRT/FLP recombination, and RNAi-based gene silencing can now also be applied to insects other than D. melanogaster. Reports of sex-specific lethal genetic systems working in Drosophila have been published, and there is every expectation that similar systems will soon be established and tested in pest insects. All these technologies are precise—targeting only the genes that investigators seek to change—and the effects on a laboratory population can be predicted and are unambiguous. How successfully these technologies can be extended into pest insects, both in the laboratory and in the field, will be a matter of some interest in the years ahead.

GENETIC VARIABILITY: TYPES AND ORIGINS

How much genetic variation exists in natural populations? Before easy access to DNA sequences themselves, genotypic variants or polymorphisms were examined at the level of chromosome banding, particularly in the salivary glands of Drosophila, and through genetically based variation in enzymes as revealed through allozyme electrophoresis. In the mid-1960s, studies of enzyme variation of Drosophila pseudoobscura by Levontin and Hubby showed that an unexpectedly high number of loci were polymorphic (two or more alleles were found in 30% of all loci examined) and that over all loci nearly every individual was genetically unique. This work prompted the question of what was responsible for all this genetic variation, and in particular, did natural selection maintain this polymorphism or was the variation selectively neutral, being influenced only by processes of random genetic drift? That many loci are in fact polymorphic has been confirmed with information directly from DNA sequences of both protein-coding and noncoding regions of DNA.

How is the genetic variation then expressed in the observable phenotype? The link between the genotype and the phenotype is sometimes straightforward. Some phenotypic traits are determined by only one or a few genetic loci. However, other traits are influenced not by one or two loci, but by many loci, each with a relatively small effect; here, the link between genotype and phenotype is described by quantitative genetics. Usually such traits have measurable genetic and environmental components and frequently an interaction between the two. For such traits, the amount of variation that is “genetic” is described as the heritability, usually denoted h2, which can be estimated through breeding studies or by examining relatives of known genetic relatedness. Crosses of inbred lines that differ in traits of interest can be used to determine the inheritance, approximate number, and relative importance, of loci responsible for variation in those traits. In such analyses, loci responsible for variation in quantitative traits are termed quantitative trait loci, or QTLs.

The origins of genetic variability rest in the processes of mutation, which are typically classified by the type of change caused by the mutational event. Mutations can arise through substitution (one nucleotide is replaced by another), recombination (crossing over and gene conversion), deletion (one or more nucleotides are removed), insertion (one or more nucleotides are added), or inversion (180° rotation of a double-stranded DNA segment). In protein-coding regions, some nucleotide substitutions do not change the amino acid for which they code—such substitutions are termed synonymous or silent. Substitutions that change the amino acid are termed nonsynonymous—these substitutions are less common because they modify the gene’s product, and thus are less likely to go undetected by selection. Rates of mutation vary widely and can be influenced by the internal genetic environment as well as by the external environment. Aspects of the genetic environment that have been shown to affect rates of mutation include the functional role of the region (whether coding or not) and, for a given base, its position within a gene (e.g., stems or loops of ribosomal DNA) or within a codon (e.g., third positions change much more frequently than first or second positions due to redundancy in the genetic code). Rates of mutation are also affected by genome size and type, i.e., whether organellar or nuclear. For example, in insects, rates of mutation for protein-coding regions are typically higher for haploid mitochondrial DNA than for diploid nuclear DNA, a fact usually attributed to a lack of an efficient mechanism for DNA repair in insect mitochondrial DNA. Recent findings have shown that parts of the genome of organisms may originate from other biological sources. For example, recent research on Orthoptera and Diptera has revealed nuclear DNA inserts of what were previously mitochondrial genes, and transposable elements—highly mobile pieces of DNA—are widespread in insect nuclear genomes. Of course, rates of mutation are also affected by external environmental variables, such as temperature and radiation.

Recent advances both in DNA sequencing technology and bioinformatics have made possible the complete DNA sequencing and annotation of genomes of over 100 eukaryote organisms, including numerous insect species. These projects use an approach termed “shot-gun sequencing” in which the DNA for an organism is broken
up into random fragments, each of which is then sequenced and reassembled using computer programs that match overlapping ends of the sequences. For insects and terrestrial arthropods at least 20 sequencing projects have reached the assembly stage, including black-legged tick *Ixodes scapularis*, human body louse *Pediculus humanus corporis*, pea aphid, *Acyrthosiphon pisum*, a parasitic wasp *Nasonia vitripennis*, honeybee *Apis mellifera*, red flour beetle *Tribolium castaneum*, silk moth *Bombyx mori*, three species of mosquitoes—*Anopheles gambiae*, *Aedes aegypti*, and *Culex quinquefasciatus*—and 11 species of *Drosophila*. In addition, whole genome sequencing projects are in progress for approximately 30 more insect species, as well as other arthropods and arthropod relatives.

The boom in DNA sequencing is quickly revolutionizing all fields of biology. Comparative studies of insect genomes, which are much more diverse than comparable vertebrate lineages, are revealing much about the evolutionary mechanisms and origins of animal genotypes. In insects, as for other animals, protein identities are typically very conserved (in the insects, ranging from 53 to 95%, depending on evolutionary distance between taxa), whereas the amount of shuffling of genes along chromosomes varies widely. Whole genome sequencing has also greatly accelerated gene discovery and associated functional analysis. For example, in comparison to the fruit fly and mosquito genomes, the honeybee genome has more genes for odorant receptors and newly discovered genes for nectar and pollen utilization, but fewer genes for detoxification enzymes and gustatory receptors. The honeybee genome also revealed novel microRNAs thought to be important in social organization. In evolutionary biology and ecology, genome sequencing provides an untapped wealth of loci. For example, at the level of insect orders, multiple single-copy orthologous genes have been used to support the hypothesis that Hymenoptera branched early from a group containing Coleoptera and Lepidoptera + Diptera. At the population level, genome-derived single-nucleotide polymorphisms (SNPs) are becoming the marker of choice because of their abundance and distribution throughout the genome. For the honeybee, *A. mellifera*, SNPs show that the species originated in Africa, not western Asia, and migrated at least twice into Eurasia. SNPs also confirm that New World “European” honeybee populations stemmed from an admixture of several subspecies and illustrate the current extent of introgression between an introduced African subspecies of “killer-bees” and pre-existing populations. At present, many of these advances are limited to species for which whole genome sequences are available, or taxa closely related to these species. However, sequencing technology continues to improve rapidly and in the very near future high-throughput, parallel sequencing based on nanotechnology should make genomic approaches feasible for many more studies and taxa.

**MAINTENANCE OF GENETIC VARIABILITY**

At equilibrium, the gene frequencies in a population will not change from one generation to the next. This important concept has been formalized in the Hardy–Weinberg Principle (H-W), which forms the foundation for the general understanding of population genetics of sexually reproducing organisms and, by extension, the understanding of the genetic theory of evolution. H-W is best thought of as a population genetic “null” model. The basic idea is that a single generation of random mating results in genotype frequencies that are directly predictable by the frequency of alleles in the population, no matter what history gave rise to the current mixture. This concept results in the familiar equation for a system of two alleles at one locus, where $p$ and $q$ are the frequencies of the two alleles in the population and $p^2$, $q^2$, and $2pq$ are the frequencies of the three possible genotypes (two homozygotes and heterozygote, respectively). A number of assumptions are explicit in H-W including random mating, infinite population size (i.e., no random genetic drift), no gene flow or migration, no mutation, and individuals all having equal probabilities of survival and reproduction (i.e., no natural selection). It is the study of deviations from these assumptions that makes the principle so useful, particularly for examination of nonrandom mating, genetic drift (chance events), gene flow and migration, and selection.

**ADAPTATION**

Genetic variation is fundamental to Darwin's theory of evolution through natural selection, although when the idea was initially developed the mechanisms of inheritance were not yet known. Selection acts to favor some phenotypes over others, resulting in differences in relative fitness. The extent to which these phenotypes have a genetic basis determines whether those phenotypes that survive will pass on their attributes to their offspring. This process of genetic change through natural selection is termed adaptation. It can most readily be studied in recognizably polymorphic species, i.e., those in which genetic variability can be monitored over space and time. Accordingly, perhaps the best-known study of natural selection in the wild is that of industrial melanism in the peppered moth, *Biston betularia*, in Britain. The typical form (*typica*) of this moth is light colored with black, pepper-like spots and is well camouflaged on lichen-covered birch trees. Following industrialization of certain areas of England, a darker form (*carbonaria*) started to appear in great abundance. This prompted the question, were the typical forms more subject to bird predation where the lichen on trees was socket covered and darker, leaving the darker forms in greater numbers? In the 1950s, Kettlewell addressed this issue by manipulating the relative frequency of morphs and monitoring their subsequent success. His findings were consistent with the hypothesis of predation—*typica* were eaten from dark backgrounds much more often than from light backgrounds, and vice versa for *carbonaria*. Further, a more recent reanalysis has demonstrated that, associated with the postindustrial reduction in pollution, there has been a shift to a lower frequency of the darker *carbonaria* forms. Still, a number of issues remain unresolved, demonstrating the difficulty involved in studying such systems in nature. For example, the *carbonaria* form was found to persist even in areas relatively unaffected by pollution and two melanic forms have been shown to exist in nature.

Adaptation has been studied in nature using a number of other genetically determined polymorphisms as indicators of variability. These traits include not only the now familiar color polymorphisms, such as are found in butterfly wing patterns, ladybird beetles, walking sticks, and happy face spiders, but also behavioral polymorphisms such as caste structure in social insects, and polymorphisms of economic importance including insecticide resistance. Because of the relative ease by which polymorphisms can be measured phenotypically, and the often relatively simple genetic basis that underlies the variation, studies of polymorphisms have contributed much to the general understanding of natural selection in the field, particularly in demonstrating that selection can be a very powerful force and that balancing selection for a diversity of phenotypes can maintain genetic variability.

**SPECIATION**

How much genetic divergence is necessary for two populations to maintain themselves as separate species? In part, the answer to this
question depends upon how the species themselves were formed. In a study of allozyme polymorphism in allopatric populations (those found in different localities) within the *Drosophila willistoni* group in Venezuela, Ayala and colleagues showed that isolated populations of the same species were very similar genetically, with a mean genetic identity (the proportion of loci identical in two samples) of $I = 0.970$. However, the genetic identity was lower in populations that were practically reproductively isolated (termed "semispecies"; $I \approx 0.8$) and even lower in well recognized, reproductively isolated sibling species ($I = 0.517$) and closely related, but nonsibling species ($I = 0.352$). Species formed in sympathy (i.e., in the same locality) might potentially be more similar genetically than those formed in allopatry, particularly if only a small number of loci are important for initial divergence. Sympatric speciation is most commonly associated with true fruit flies (Tephritidae) in the genus *Rhagoletis*. Bush in the 1960s suggested that speciation in these flies may have occurred following shifts in host use within the same habitat. He offered as an example of the process the host shift of the apple maggot, *Rhagoletis pomonella*, from its native hawthorn host to introduced apples in New York State in the 1860s. There was considerable resistance initially to the concept of a nonallopatric mode of speciation. However, more recent work by Bush and colleagues has provided a convincing case for sympatric speciation in *Rhagoletis*, with differences between species being maintained through genetic control of emergence times on the different hosts. There also exists at least partial prenaturing reproductive isolation associated with host-plant fidelity. Berlocher in 1976 measured the mean genetic identity between *R. pomonella* and two other species of *Rhagoletis* that were likely formed in sympatry through host shifts and found the species to be nearly identical genetically ($I = 0.980$ and $I = 0.989$) and significantly more similar than were *Rhagoletis* species formed in allopatry and the *Drosophila* species noted above. Recent work suggests that the genetic variation contributing to the host shifts for *R. pomonella* originated in geographically separate populations—Mexico and North America—with subsequent episodes of gene flow between them. The conclusion from these studies is that the average genetic divergence itself is not critical for speciation, nor for the maintenance of reproductively isolated species, but rather that the effects of a small set of nonrandom loci may be important in species formation. Recent advances by Feder, facilitated through better understanding of the *Rhagoletis* genome, and by others studying *Heliconius* butterflies and pea aphids suggest that changes in only relatively few functional loci can lead to rapid speciation.

### THE IMPORTANCE OF GENETIC VARIABILITY

How important is genetic diversity itself to the persistence of insect populations? This question is difficult to answer. Clearly, the presence of resistant alleles in pest populations has led to the development of resistance to numerous insecticides or to the development of virulence on resistant plant varieties. For example, it is not uncommon to find alleles for resistance in mass screening that takes place through field applications of insecticides or in the field use of transgenic plants expressing insecticidal proteins. By contrast, it is far more difficult to detect such alleles in laboratory studies in which only a relatively small handful of individuals are sampled. Yet, for many species, genetic diversity seems to matter little. Many parasites, for example, are notoriously lacking in genetic polymorphisms, perhaps as a result of years of brother–sister mating. Invasive species such as the Mediterranean fruit fly, *Ceratitis capitata*, have reduced genetic variability, likely as a result of successive population bottlenecks, yet survive well while expanding their range. Indeed, the lack of variability may explain the success of some invasive species. Invasive populations of the Argentine ant, *Linepithema humile*, for example, have lost the genetic ability to distinguish one colony from another, and are thus hypothesized to escape from population control imposed by intercolony conflict. Another example of success with reduced genetic variability is seen in the parasitic *Varroa* mite, which jumped to feed on the European honeybee *A. mellifera* from the eastern honeybee *Apis cerana*, when the former was introduced into Asia. The parasite has spread worldwide in 30 years. Surprisingly, only 2 of 18 original Asian haplotypes switched to *A. mellifera*, and only one of these two has been successful in colonizing new geographical regions.

In these examples, high levels of genetic variability do not seem to be necessary for survival. However, it should be noted that the pests and invasive species that are the largest economic problems are only a very small sample of the diversity of insect species and that these insects have experienced selection over many generations to be successful as pests or invasives. During this period, such insects may have overcome potential genetic obstacles associated with low levels of genetic variability. Further, those individuals that did not make it in the past because of low genetic variability would have left no ancestors and would not be around today to be sampled. Natural populations of insects the importance of genetic diversity still remains poorly understood.

### APPLICATIONS

Knowledge of genetic variability and processes that underlie its origins and maintenance is central to many research questions in insect biology. For example, the genetic variability held within individuals and populations can provide critical insights into the structure and dynamics of populations that would otherwise be difficult or impossible to study by tracking individual insects. Variation in allele frequencies among populations can be used to assess the genetic structure of populations summarized by $F_{ST}$ (calculated as the variance in allele frequencies standardized by the mean) or related measures. From these measures, with appropriate assumptions, it is often possible to infer additional information on the biological dynamics in those populations, including attributes such as effective population size ($N_e$), degree of inbreeding, and rates of gene flow or migration ($N_m$). Genetic variability also provides the opportunity for tracing the history of populations, species, and their ancestors through methods that recognize the genealogical nature of genetic material. A second application of genetic variation is in insect pest management. For example, an understanding of the genetic basis of resistance to chemical insecticides (whether administered externally or through genetic modification of plants) has been important in the development of strategies to delay the evolution of resistance in herbivorous insects. A third example is classical biological control, in which genetic variability is one factor that determines the ability of imported insects to establish themselves, as well as in their potential to attack nontarget hosts; similar factors may be relevant for invasive species. Finally, genetic variation figures prominently in conservation biology, such as in efforts to determine which insect species or populations are most worthy of protection. Specific applications include genetic estimation of population sizes and assessment of genetic or phylogenetic uniqueness for assignment of conservation priorities. Each of these areas of research is moving rapidly, and each will no doubt benefit in the very near future from new insights provided by genomic information.

PUBLISHED INSECT GENOMES

To date, 25 insect genomes have been published or are currently in advanced stages of being sequenced (Table I). The first published insect genome, that of *D. melanogaster* in the year 2000, was an obvious choice as it was (and remains) the most-prominent model organism in molecular biology with the most-studied eukaryotic genome to date. Following *D. melanogaster*, the choice of insect species selected for whole-genome sequencing was driven largely by species of particular interest as vectors of human disease pathogens (mosquitoes, body louse, blood-sucking bug, and tsetse fly) and species of economic importance (honeybee, silk moth, flour beetle, parasitic wasp, and aphid). Additionally, the genomes of 11 additional species in the *Drosophila* genus were made available in 2007.

The results of these genome-sequencing efforts are publicly available on various online databases (Table I). Even insect genomes that have not been formally published are typically available for public download. The reasons for making these data so quickly and easily available are several. First, all insect genome-sequencing projects have been, in part or wholly, funded with public money obligating the researchers to make the data widely available. Second, it is recognized that publication of such data is of interest to a large number of researchers. Third, publication of a genome does not end with reporting the nucleotide sequences, but also includes “annotations” that indicate where on the nucleotide sequence genes begin and end, where gene regulatory sequence are located, where transposable elements may be found, and many other features. By making this information available early in the genome-sequencing process, individual researchers not directly involved with the project can help improve the annotation either by correcting previous annotations or submitting their own. Each genome-sequencing project has its own process for such submissions which is typically detailed on the relevant online database.

OBTAINING THE NUCLEOTIDE SEQUENCE OF A GENOME

Any study of an insect’s genome fundamentally requires that the sequence of nucleotide bases that make up the chromosomes and mitochondria be determined. It should be noted that genome-sequencing projects typically concentrate on the euchromatic portion of the genome which contains most of the genes and ignore the highly repetitive heterochromatic portions (concentrated in the centromeric and telomeric regions of chromosomes). A notable exception is *D. melanogaster* where an effort to sequence all the heterochromatic regions has been underway since 2002. Although the technology used to obtain the nucleotide sequence of specific areas of the genome has been available since the early 1970s it was the advent of whole-genome-sequencing technology in the 1990s that made it possible to determine the millions of base pair sequences that make up a typical insect genome (Table I). The modern technique of whole-genome sequencing was developed by The Institute for Genomic Research (renamed in 2007 as the J. Craig Venter Institute, JCVI). This technique relies on fragmenting the genome into small random sections, 300–1000 nucleotide long, obtaining the sequence of these sections, and finally assembling these sections into larger fragments (Fig. 1).
The two main advantages of this method over previous techniques are speed and relatively low cost compared to earlier methods that concentrated on sequencing specific regions on the chromosome. However, the biggest weakness of the method is the assembly of the small random sections into larger fragments (section F in Fig. 1). This assembly relies on matching nucleotide sequences with overlapping ends to each other to form larger fragments. However, when two fragments have the same end sequences (which occurs often when a fragment comes from a region of the genome where the same nucleotide sequence is repeated multiple times) it becomes difficult to determine which two fragments should be joined. This problem can be overcome to some extent by increasing the number of random fragments sequenced. Typically, enough fragments are sequenced from an insect genome so that any one nucleotide position should be present on average on at least four or five DNA fragments (referred as 4X or 5X coverage). A second method to try to overcome the assembly problems is to sequence large sections of the genome (thousands of nucleotide long) into “Bacterial Artificial Chromosomes” (BAC clones), that are engineered so that DNA sequence inserted into them can easily be sequenced. The resulting long sequences can then be used to guide the assembly of smaller fragments. Unfortunately,
even with both the high numbers of random fragments and BAC clones, assembly problems remain significant for insect genomes beyond *Drosophila* and *Anopheles gambiae* due to the large amounts of repeated sequences and, in many cases, large overall genome sizes. The result is that although some insect genomes have been assembled to the level of chromosomes (*D. melanogaster* and *A. gambiae*), most other insect genomes are still too fragmented to be put together into large contiguous pieces. For example, the yellow fever mosquito *Aedes aegypti*, which is riddled with high numbers of repeated fragments, is (as of this writing) still a collection 1257 fragments (called scaffolds) that have yet to all be placed on the three chromosomes of this important vector species.

It is evident from the sheer number of fragments to be matched that the work of genome assembly is only possible with the aid of specialized computer software. Assembly software such as ARACHNE is publicly available, but the memory and processing time required to assemble an entire insect genome is beyond the capability of today’s typical desktop computers. Instead, assembly of whole genomes is typically left to institutions with the computing capacity to process large amounts of data quickly. Often, the sequencing and genome assembly will be performed in the same facility, such as JCVI or the Broad Institute. However, smaller subsections of a genome may be assembled by individual researchers. This can be an important check for the individual researcher to check that the section of the genome he or she is concerned with was correctly assembled. Both genome assembly and sequencing technology are rapidly changing fields. The genome-sequencing outline we have provided here is applicable to all the currently sequenced genomes, but advances such as the rapid genome-sequencing technique developed by the 454 Life Sciences company will undoubtedly make its way into the next generation of insect genome-sequencing projects.

**Obtaining Additional Genome Data Sets as a Part of a Genome Project**

In addition to the nucleotide sequence other data sets are often also collected subsequent to ordering the whole-genome sequencing. One of the most commonly collected data sets are expressed sequence tags (ESTs), that are used to inform which parts of the genome may be involved in coding for genes. ESTs are short nucleotide sequence fragments (500–800 nucleotides long) derived from cloned messenger RNAs (mRNAs). Because they are derived from mRNAs, EST sequences represent portions of the genome that are transcribed by RNA polymerase and thus could potentially be translated into a protein product. Only a small percentage of the transcriptome (the collection of all mRNA sequences from a genome) is translated into protein. Nevertheless, EST data sets are essential to accurately map the location of genes on the genomes (detailed below). EST data sets are relatively inexpensive to generate and are typically available for each insect genome either on the online database web site, or on the larger EST database maintained by the National Center for Biotechnology Information (NCBI) (http://www.ncbi.nlm.nih.gov/dbEST/). Because not all genomes are expressed continuously during development or under the same environmental conditions, mRNAs are typically collected from insects at various life stages (e.g., larva, pupae, and adult), from different environmental conditions (e.g., mosquitoes before and after a blood meal), and even from individual tissues (e.g., midgut tissue from the silk worm moth or mosquitoes). Because of their low cost, small EST data sets are often available for an insect before the genomic sequence, but larger and more representative data sets are collected in conjunction with a whole genome-sequencing effort.

In addition to ESTs, insect mitochondrial genomes are often usually assembled as well, since they can easily be determined from the whole-genome-sequencing output. Sometimes additional sequences are also collected which are specific to an organism. For example, the strain of *A. gambiae* chosen for whole-genome sequencing was found to be a mixture of two molecular forms of this species. Additional sequencing of the two forms (called the M and S form) is currently underway to tease these sequences apart.

**MAPPING THE LOCATION OF GENETIC FEATURES ON AN INSECT GENOME**

Having only the nucleotide sequence of an insect’s genome is of very limited value to most researchers. What is required is a “map” of important features of a genome such as the location of genes, controlling elements, transposable elements, etc. Details of how all these features are mapped are beyond the scope of this article, but we provide a rough outline here. There are typically two phases to generating such maps, first computer algorithms are used to identify genome features (this phase is sometimes called a “gene build”), second the results of the computer search are reviewed (typically by researchers with expertise in a particular set of genes or genome features) and refined.

A number of computer algorithms have been developed for the first mapping phase (the “gene build”). These are incorporated into programs such as RECON, REPEATSCOUT, and others which try to assemble into a single processing queue the knowledge of previously determined gene sequences, gene models, transposable element sequences, information from EST data sets, and other kinds of data. Taking all this into account, these programs try to make informed predictions about the location on the genome nucleotide sequence of all the mapable features. The variety of different algorithms available for this task stems from the fact that no one algorithm is best suited for predicting the location of the wide variety of genomic features. For example, the output of one program may be conservative and accurately predict the location of some genes, but at the expense of completely missing others, while another program may be too liberal, finding the missing genes but also reporting false positives (i.e., mistakenly identifying a gene in a location where there is none). Because of this, it has become common practice to use several algorithms for the same task and then to merge the results into a single set of features (termed a “gene merge”); this is the method that was used for all three mosquito genomes. The generation of “gene builds” is very computer intensive and not within the scope of individual researchers. Instead, these are often conducted by specialized teams at genome-sequencing centers or by other specialized groups (such as the European Bioinformatics Institute).

After the initial mapping by computer algorithms, the second mapping phase begins. In this phase, researchers with expertise in a particular gene family or in features such as transposable elements will review the computer-generated results and improve upon them. For some genomes (such as *Drosophila*, and the mosquito genomes) “community representatives” are assigned to review any suggested modifications of a genome annotation and to ensure that the proposed changes become publicly available after they have been approved. While this system ensures that anyone can contribute to the annotation of a genome, the vast majority of genes in a typical insect genome will not be reviewed by experts. A notable exception is the genome of *D. melanogaster* where a comprehensive effort has been undertaken to manually review each gene, with a similar effort currently underway for the three mosquito genomes as well.
The results of the computer-generated and human-curated annotations are displayed in one of two basic formats, and are publicly available over the internet. At the NCBI website, a separate record for each gene (or any other genome feature) is generated providing all the available information in text form, in the equivalent of an electronic card catalog. Other sites, such as ENSEMBL (http://www.ensembl.org), can display the information on a graphical interface, showing the location of individual features on the genome as well as nearby features. Often more than one feature will be mapped to the same physical location on the genome. This may come about for several reasons. First, it may represent alternate splicing of the same gene. Second, if a change has been done to a feature, the old version will typically not be removed. Third, some features do overlap in nature, such as a transposable element sitting inside a gene intron. The resulting array of annotations often yields a genome map that may be confusing at first glance, but that reflects some of the real complexity of an insect genome.

**Drosophila Genomics**

*D. melanogaster* is by far the most studied and best understood of all available insect genomes. Even though this insect has been at the forefront of genetic research since the days of Thomas Hunt Morgan at the start of the last century, less than 20% of its genes had been identified prior to the publication of its genome in the year 2000. Many specialized databases exist to assemble genomic data derived from *Drosophila*. The two most-important ones are FlyBase (http://flybase.bio.indiana.edu/) and the Berkeley Drosophila Genome Project (http://www.fruitfly.org/). These data repositories attempt to assemble, in one place, all of the most-important fruit fly genomics related information. The accumulation of such vast amounts of data has made possible the development of several new fields of research. We outline two of them here. Neither of these fields is exclusive to insect genomics, but both fields have seen major recent developments using the fruit fly genome.

**FUNCTIONAL GENOMICS**

The aim of functional genomics is to describe and understand the pattern of gene expression. It has long been established that gene expression is typically influenced by the expression of not one, but many, genes. Before the entire set of *Drosophila* genes became known, study of gene expression relied heavily on the generation of fruit fly mutants for specific genes and on deducting the function of these genes based on observation of physical or behavioral differences compared to wild-type flies. While generating mutant *Drosophila* flies is far easier than for any other insect (mainly because the methods have been so thoroughly developed for the flies) it remains a time consuming and labor intensive task. Furthermore, some mutations may not be possible to observe as they may not yield any observable change or the changes may be lethal, killing the fly before the mutation can be observed. The sequencing of the *Drosophila* genome revolutionized the study of insect gene expression by making microarray assays possible for the entire set of *Drosophila* genes.

First developed in the late 1980s but significantly improved in the 1990s, the purpose of DNA microarray technology is to examine whether a particular gene region is transcribed under specific environmental conditions, and if it is, how high or low the level of transcription is. Whether a genetic region is transcribed or not (as well as the level of transcription) is taken as an indication that the gene may be translated into a protein product (it is important to remember that only a fraction of all the mRNAs are eventually translated).

The technology behind DNA microarrays is similar to that of standard nucleic acid hybridizations, but can be accomplished on a much bigger scale with the introduction of “gene chips.” Gene chips are solid surfaces, onto which a series of nucleotide sequences have been bonded. The physical location and nature of each bonded nucleotide sequence (a bonded nucleotide sequences is called a “probe”) is recorded. Probes are typically arranged in a grid pattern. There is no constraint on the type of nucleotide sequence that can make a probe, but some of the most-used gene chips are those where each probe contains the entire sequence (or at least a substantial portion) of a single gene. In this way, thousands of different gene sequences can be placed on one or more gene chips, making it possible to have all the known *Drosophila* genes (over 13,500 genes) available in a single assay. Such genome-wide gene chips are commercially available not only for *Drosophila* but for the malaria mosquito (*A. gambiae*), and there are plans to make a similar chip available for the yellow fever mosquito (*A. aegypti*) and the southern house mosquito (*Culex pipiens quinquefasciatus*).

To detect expression using a gene chip, a solution of cDNA (DNA sequence reverse transcribed from mRNA) is preferred for this assay because it is much far stable than RNA which can degrade rapidly) labeled with a fluorescent dye is washed over the probes. Both the cDNA and probes are denatured (i.e., the two DNA strands of the double helix are separated from one another) during the assay. The assay is conducted under such conditions that if the cDNA and probes have complementary sequences they will become attached to one another reforming the double helix, a process referred to in this context as hybridization. After hybridization, any unattached cDNA is washed away. The chip is then illuminated with ultraviolet light, which will cause the dye attached to the hybridized cDNAs to fluoresce, and become visible. Under the right assay conditions, not only the presence but the amount of hybridized DNA can be measured. The end result is a grid with probes that are either dark (no hybridization, so these genes did not have matching cDNAs in the assay) or illuminated probes with various levels of intensity proportional to the amount of matching cDNA in the assay. Different colored dyes enable genes that are up- or down-regulated to be identified.

An example of how this type of assay has significantly improved our understanding of gene function can be found in the recent studies of the *Drosophila* circadian rhythms. Ueda and colleagues reared flies under different intensity light conditions and collected sample flies at specific time intervals. From each time, 100 fly heads were collected and total RNA was extracted. After creating cDNAs based on these RNA extractions, the cDNA extracts were washed over a gene chip containing the entire set of *Drosophila* genes. By analyzing which genes were transcribed in different samples, 712 genes were found to have fluctuating mRNA levels under varying light conditions, leading these researchers to significantly expand the number of genes known to be involved in *Drosophila* circadian rhythms. To further elucidate which of these candidate genes were most directly involved in regulating circadian rhythm, this same group subsequently applied a second technique, RNA interference (RNAi). RNAi is a laboratory technique developed to reduce the expression of targeted genes through the generation of double-stranded RNAs. By modifying standard RNAi techniques they were able to significantly reduce the expression of 133 genes in a tissue-specific manner. Based on these results, Matsumoto *et al.* were able to identify five new genes directly involved in *Drosophila* circadian rhythm regulation. As this example demonstrates, advances in existing fields of research can occur rapidly with the introduction of genomic techniques.
COMPARATIVE GENOMICS

Although studies of the *Drosophila* genome on its own have yielded significant contributions to our understanding of this model organism, it is the comparison of one genome to another that may hold the greatest promise for significant advances in the years to come. Comparative genomics is the study of relationships between genomes, be they different species or strains of the same species. Prior to whole-genome sequencing, this field was severely limited both by the types of data available for comparison and by the low number of completed genome projects. While the number of insect genomes with published whole genome sequences is still infinitesimally small in comparison to the number of described insect species, the amount of information available for comparison between these genomes is now sufficient to enable meaningful comparisons across species to be made at the genomic level. Furthermore, comparative genomics is not limited to studies within insects, but can be very productively applied to comparisons of distantly-related organisms. For example, it has become clear that a great number of genes shared by fruit flies and humans are not only homologous (i.e. derived from the same ancestral gene) but perform similar functions in both organisms. Studies have found that a number of human genetic disease loci have homologs in *Drosophila* showing similar patterns of expression. This observation has made possible the use of *Drosophila* as model organism for the study of certain human diseases. We will not go any further into the advances made by fruit fly to human comparisons but this example serves to demonstrate the great potential of comparative genomics.

One of the most exciting developments in comparative genomics is the recent publication of 12 entire *Drosophila* genomes. For researchers interested in the mechanisms of evolution in animals this provides a unique opportunity to observe which genes (or genome regions in general) have evolved between species and which have remained unchanged. For example, these 12 genomes show a remarkable amount of variation in the both the types and amount of transposable elements (small sections of DNA sequences that can catalyze their own movement to different locations the genome) between species. This observation lends some support to the hypothesis that transposable elements may have a role to play in insect speciation mechanisms. Comparison of these genomes also shows that much *Drosophila* speciation is associated with chromosomal inversions (i.e., rearrangement of chromosomal segments). What makes this data set such a powerful tool for the study of evolutionary mechanisms is that the ancestral relationship between these *Drosophila* species (the phylogeny) is well established, allowing researchers not only to observe what change has occurred between species, but in what sequence (i.e., what the ancestral and derived states are), and even to be able to put time boundaries on when some changes occurred, allowing for an estimate of the absolute time it took to undergo this change. This is a level of detail previously reserved for bacterial and yeast genomes. The success of this approach has lead to calls for the expansion of it to other insects with published genomes, such as mosquitoes.

MOSQUITO GENOMICS

As vectors of some of the deadliest human diseases mosquitoes are the second-most-studied insects using genomic tools after fruit flies. One of the challenges of mosquito genomes is their large genome size compared to *Drosophila*. For example, the *A. aegypti* genome is more than ten times the size of *D. melanogaster* (Table I). This increase in size is not correlated with a similar increase in gene number, but appears to be mainly due to an increase in the number of repeat elements in the mosquito genome. The reason why so many more repeated elements accumulate in mosquito genomes is a question of active research. Although fruit flies are of little economic importance and are studied mainly as “model” insects, much of the focus of mosquito genome research is centered on finding ways to prevent human disease transmission. Because of this, functional genomic studies of mosquitoes have tended to focus on gene families that could be targets for vector control strategies, such as immunity genes, or genes involved in host-seeking behavior (e.g. genes involved in olfaction).

*A. gambiae* the main vector of malaria in sub-Saharan Africa was the first mosquito to have its entire genome sequenced. An immediate benefit of the genome sequence was the dramatic increase in potential microsatellite markers. Microsatellites are used by population geneticists to study gene flow between field mosquito populations to understand patterns of malaria transmission in the field. A number of potential vector control genes have been identified, including 79 odorant receptor genes, and 76 gustatory receptors genes. Comparative genomic studies demonstrated that the majority of immunity genes are similar in function between *Drosophila* and *A. gambiae*. The combination of such studies with RNAi techniques (discussed above) has been very fruitful in elucidating the pathways by which these immunity genes function in this mosquito. Another area of exciting research in mosquito genomics, was the sequencing of *Plasmodium falciparum* the unicellular protist that can lead to the development of human malaria when it is transmitted through a mosquito host. Much of the research involving the *Plasmodium* and *Anopheles* genomes has centered on trying to identify which genes are involved in trying to suppress *Plasmodium* infection by the mosquito, and how *Plasmodium* is able to evade the mosquito immune response. While the other two mosquito genomes, *A. aegypti* (the primary vector of dengue and yellow fever) and *C. pipiens* (a vector of the West Nile virus) have not yet been examined in as much detail as *A. gambiae*, the opportunity to compare genetic difference and similarities on a genome scale between the three mosquito species promises to be very fruitful in the search to understanding vector transmission by mosquitoes.

CONCLUSIONS

The field of insect genomics has revolutionized many existing areas of insect molecular biology and genetics. The ability to identify many candidate genes for a specific function by analysis of an insect’s genome has significantly increased the speed with which genes have been linked to specific functions. The ability to compare multiple genes across multiple genomes has, and will continue to, yield insights into the way genes and genomes evolve. The development of microarrays has led to the elucidation of gene function at much higher rates than previously possible. These are advances that would have taken many additional years of research using conventional genetic techniques. In this article, we have covered only DNA sequences but proteomics (the large-scale study of protein structures and function) have also seen advances using insect models. However, this wealth of information also comes at a price. So much data have been generated that it has become increasingly difficult to appropriately analyze it. The difficulty is not the availability of the data as most of the databases are open to all researchers and even to nonacademics. Instead, the problem is to find which of the myriad databases contains the required information, and once found, being able to retrieve it. Several publicly accessible databases attempt
to centralize genomic data, the best known and largest of which is Genbank. However, retrieving large amounts of genomic data can be a time-consuming effort, particularly if the data is spread across multiple databases. In an effort to standardize the retrieval of genomic data, many databases have adopted the Generic Model Organism Database (GMOD) model, a standard for classification of almost any biological information. Databases that have adopted this model benefit from a large collection of open source software that can be used to retrieve stored data. Until the advent of whole-genome sequencing, molecular biology and computer science rarely overlapped. Looking into the future, it appears likely that the next generation of molecular biology researchers will have to be as comfortable manipulating database queries as they are at using micropipetters at the laboratory bench.

**Grassland Habitats**

Teja Tscharntke, Ingolf Steffan-Dewenter, Andreas Kruess, Carsten Thies

*University of Göttingen*

Grasslands are plant communities that are based on grasses and herbs, and in which shrubs are rare and trees are absent. Perennial grasses represent the dominant species of grasslands, and make up the largest portion of their biomass, but not necessarily of their species richness. Grasses are often followed by legumes in abundance and herbs from many other plant families. Grassland is the natural vegetation in areas of low or strongly seasonal rainfall (250–1000 mm), but naturally occurring mammalian herbivory (e.g., by elephants) may also effectively suppress establishment of trees. Grasslands naturally encompass a wide range of habitat and vegetation types and span a large latitudinal gradient, from tropical grassland (savannas) to temperate grassland (the prairie in North America and the steppe in Eurasia) to the arctic tundra, totaling about 25% of the earth's land surface. Herbivory in temperate grasslands is often dominated by insects, whereas large ungulate herbivores dominate in tropical grasslands. The temperate meadows and pastures are seminatural grasslands growing in essentially deforested areas with a forest climate, and their succession to forests is inhibited by mowing, burning, and human-controlled grazing.

**INSECT COMMUNITIES ON GRASSLANDS**

Grasslands are habitats for many insects and may harbor an extraordinarily species-rich community. One temperate old-field grassland may be the habitat for more than 1500 insect species, whereas cereal fields, which are monocultures of annual grasses, may contain 900 species. Compared to forests, the structural complexity of the grassland vegetation is obviously simpler, so that the insect diversity is reduced. Similarly, the litter layer of forests is larger and more heterogeneous, with a correspondingly richer decomposer community. Further features of grassland-specific insect communities include the dominance of species adapted to feed on grasses.

Plant and insect communities of grasslands greatly differ depending on climate, soil type, and management practices. Some marked differences are apparent between the plant–insect communities of temperate and tropical habitats. Plant species richness, which determines much of the insect diversity, may be only 10–15 species in intensively managed and highly fertilized grasslands, but 50–70 in extensively managed and low-input temperate grasslands. In contrast, tropical grasslands may contain over 200 plant species. Chalk-rich temperate grasslands with abundant earthworm populations tend to support the highest faunal biomass (often >100 g fresh mass per square meter), whereas arid and semi-arid steppe and desert soils, dominated by microfauna such as protozoans and nematodes, may have a biomass of only 1 g m⁻². Tropical grasslands and tundra tend to be somewhere in-between. Termites and ants are dominant groups in tropical and subtropical grasslands, some surface-dwelling predatory arachnids such as scorpions and solifugids are restricted to warm, arid soils, while cold tolerance limits the range of many species in arctic and antarctic conditions. The ways in which insect communities of grasslands are influenced will be the subject of the remainder of this article.

Which insect species attack grasses, and what are the typical plants of grasslands? Ectophages, which feed externally on leaf tissue by chewing, scraping, or sucking, are distinct from endophytic feeders, which include leafminers, galls, and borers. Grass foliage-chewing insects belong primarily to the Orthoptera, Lepidoptera, Coleoptera (mainly Chrysomelidae and Curculionidae), Hymenoptera (Tenthredinidae), and Phasmiida. Of the specialized grass chewers in Great Britain <2% are Coleoptera, 6% Lepidoptera, 6% Hymenoptera, and 41% Orthoptera (the grasshoppers). Specialization on grasses appears to be particularly important in grasshoppers, and their abundance in grasslands is high. Sap-feeders on grasses are Homoptera (Auchenorrhyncha, Sternorrhyncha, Pseudococcidae), Heteroptera (mainly Miridae), and Thysanoptera. The endophagous, mostly stem-boring herbivores belong primarily to the Diptera (mainly Cecidomyiidae, Chloropidae, Agromyzidae), Hymenoptera (Cephidae, Eurytomidae), Lepidoptera (mainly Pyralidae, Noctuidae), Coleoptera (mainly Cerambycidae, Mordellidae, Chrysomelidae), and mites (Acari). The number of endophagous insect species associated with grass species can be predicted by (1) the annual–perennial dichotomy
Grassland Habitats

(annuals, in contrast to perennials, support almost no endophagous insects); (2) the mean shoot length; and (3) the abundance of the host plant. Annuals have impoverished communities and both shoot length and abundance are positively correlated with insect diversity. Plant height is usually a surrogate for the complexity of the plant architecture and, generally, a well-known predictor of plant–insect ratios. Furthermore, the more widely distributed and abundant a plant is, the more insects it should encounter in its evolutionary history. Annuals, which typically dominate in early-successional habitats, are characterized by a faster relative growth rate than perennials and, therefore, a short exposure time, so that they are a spatiotemporally unpredictable resource for insects.

Grasses (which are monocots) are hosts of many specialized endophagous insects and a multitude of ectophagous insects, a pattern that shows no principal difference from that of dicots. Host-plant preferences of oligophagous grass feeders often differ between grass species. Even more, variability among the many commercially available strains of the perennial ryegrass Lolium perenne to frit fly (the stem-boring chloropid fly Oscinella frit) attack is greater than the variability between many pasture species. Attack of many species, such as frit fly, are negatively correlated with silica content, which presumably influences the females’ choice of oviposition site and larval performance. Further, wild biotypes are often better resources than grasses grown from commercially available seeds and support richer insect communities, which may be of importance for sowings with a nature-conservation background.

GRASSES AS FOOD RESOURCE

Grasses make up the largest portion of the grassland biomass; consequently, the insect communities of grasslands are determined more by the monocotyledonous Poaceae than by the dicotyledonous herb families. Grasses differ from the Dicotyledonia in that their architecture is simple, and the intercalary meristems, which substitute for growth from terminal buds, are protected by hard leaf sheaths. Most grasses lack the variety of secondary compounds that deter herbivory in most dicotyledons. For example, cyanogens and toxic terpenoids are rare, and alkaloids are present in <0.2% of grass species but in 20% of all vascular plants. Grass-feeding insects such as the oligophagous grasshoppers select their pooid-grass host plants in that they simply reject plant tissues enriched with secondary compounds (deterrents), while no phagostimulants characterizing grasses as a group have been found. Grasses are not toxic, but this does not mean that they are little protected from herbivory; just the contrary is true (see below).

Endophytic fungi have been considered to have acquired chemical defenses in grasses, and the main mechanism is the production of mycotoxins, notably alkaloids. The presence of these seed-borne Neotyphodium endophyte fungi may cause dramatic toxicosis to grazing livestock, best known from L. perenne and Festuca arundinacea. In addition to deterring vertebrate herbivory, these endophytes are also well known for increasing resistance to insect pests, microorganisms, and drought. Endophytes may also alter attack of natural enemies in that they enhance larval development time of the herbivore (the slow growth–high mortality hypothesis) or directly affect immature enemies, for example, parasitoids feeding on the toxic tissues of their hosts.

Within and among grass species, a considerable chemical and morphological variability may be found. Nutrient availability of grass shoots is greatly determined by the shoots’ age. Fresh internodes have high concentrations of the major nutrients (water, protein, minerals) and reduced concentrations of plant-resistance factors (raw fiber, siliocate). High levels of plant nitrogen are generally associated with a high assimilation efficiency and density of phytophagous insects.

HERBIVORE–PLANT INTERACTIONS

Long-term experiments with chemical control to eliminate insect herbivores indicated an average annual yield loss of 15%, and nematode control increased biomass by 12–28%. The biomass losses appeared to be mainly the result of frit fly and other stem-boring Diptera, which kill the central grass shoots, root-feeding wireworms (Agriotes spp., Elateridae), root-feeding scarabeid grubs, the range caterpillar Hemileuca oliviae, armyworms (Spodoptera spp.), grass worms (Crambus spp.), the Mormon cricketer (Aubrus simplex), and leather-jackets (Tipula spp., in wetter soils). Planthoppers (Auchenorrhyncha), grass bugs (genera Labops, Irbisia, Leptopterus), and grasshoppers (Acrididae), and plant-feeding nematodes may also be important pests. In Sweden, the grass-feeding antler moth Cerapteryx graminis may reach densities of 100–1500 individuals per square meter; their corresponding effects on grass biomass consequently enhance herb populations. In the years following C. graminis outbreaks, shifts from herb dominance to renewed grass dominance show effects of competitive release and the return to competitive exclusion.

In temperate grasslands, the belowground standing crop of insects is 2–10 times greater than the aboveground insect mass, although the effects of belowground insects remain largely unseen, unless scarab beetles larvae or nematodes cause heavy decreases in shoot growth or even kill grass over large areas. In a latitudinal gradient across North American grasslands, root-to-shoot ratios vary from 2:1 to 13:1, with high values in cooler climates; tropical grasslands have even lower ratios (0.2:1–2.6:1). As can be expected from these data, the soil fauna is less abundant in tropical savannas and forests compared to temperate ecosystems. Earthworms usually dominate the soil biomass, but in the tropics, termites and ants are particularly important. These belowground species can be a key in nutrient dynamics determining plant growth and aboveground plant–insect interactions.

Grasses are well adapted to herbivory and, in general, tolerate grazing better than herb species; therefore enhanced grazing pressure increases the fraction of grasses in pastures. The high resistance, tolerance, and compensatory ability of grasses are the result of (1) the generally high silicate content, lignification of vascular bundles, and additional sclerenchyma in mature leaves that make foliage hard to chew and digest; (2) the rapid induction of dormant buds that develop into lateral shoots following defoliation or destruction of apical meristems, which is based on the belowground nutrient reserves; (3) the location of meristematic zones that are in many instances near the ground and not at the top of the plant, where they would be better accessible to grazers; and (4) the compensatory photosynthesis and growth stimulation by bovine saliva, which may also play a role. The concept of a herbivore-optimization curve is based on findings that the conversion of tall canopies into shorter and denser grazing lawns reduces shading and the deposition of feces and urine enhances mineralization, both contributing to increased plant productivity. Grazing causes much sprouting from dormant buds and heavily grazed pooid populations are smaller and have higher silicate concentrations, exhibiting ecotypic variation as a result of different grazing histories. The mitigation of predation by the highly silicified grasses is presumably not confined to mammals, because the mandibles of many grass-chewing insects are adapted to biting and grinding and are analogous to the teeth of grazing mammals. Although the evolution of siliceous grass leaves appears to be
driven by many stress factors (including drought and fungal attack), both mammal and insect herbivory may have been important factors.

**CONSERVATION OF SPECIES-RICH GRASSLANDS**

Insect diversity in grassland ecosystems can be best predicted by floral diversity or related characteristics of vegetation structure, especially biomass and structural heterogeneity of the plant community. Species richness of butterflies, wild bees, phytophagous beetles, true bugs, etc., was found to be positively related to the species richness of plants. However, age of the habitat as well as fragment size is known to disproportionately enhance the number of species in higher trophic levels. The fraction of specialized predators and parasitoids increases greatly with area and age of grasslands, although the plant species richness may respond little.

Intermediate levels of vegetation disturbance, caused by ants, rodents, foxes, rabbits, sheep, and other mammals, significantly increase species richness of vegetation with consequent effects on the insect community. For example, gaps reduce the likelihood of competitive exclusion in a plant community when space is monopolized by a few dominant species. The openings are rapidly exploited by seedlings. Rotational management also may enhance grassland heterogeneity, creating a mosaic of old and young, tall and short, early- and late-successional patches.

Grasslands established by sowing are colonized in the beginning by relatively few insects. As these grasslands age, communities become more species rich in both plants and insects, and the biotic interactions, such as between predators and their prey or parasitoids and their hosts, increase. Ants and subterranean insects are absent on newly created fields because establishment of nests and populations needs time, and their highest densities occur in mature grasslands. Percentage of macropygy (i.e., those with full wings) in dimorphic insects such as grass-feeding planthoppers is high in early-successional habitats, whereas brachyptery (short-winged) species dominate in persistent habitats.

The destruction and fragmentation of habitats has become one of the major threats to biodiversity. Not all insect species are equally affected by habitat fragmentation: species of higher trophic levels, rare species, species with specific habitat requirements, species with greatly fluctuating populations, and species with poor dispersal abilities are expected to be more prone to extinction. For example, butterfly communities on calcareous grasslands show positive species-area relationships, and the most specialized and endangered butterflies profit most from large grassland fragments. For a few butterflies, morphological characters associated with flight ability have been shown to change with isolation of limestone habitat fragments. This indicates that habitat fragmentation in simple, human-dominated landscapes may also have evolutionary consequences for the life-history traits within populations. As a result of changes in community structure, interspecific interactions such as plant-pollinator interactions may be disrupted. Grasses are wind-pollinated, but most herbs, such as the many legume species that typically play a major role in nutrient-poor or extensively managed grasslands, depend on insect pollination. Populations of pollinating bees need nectar and pollen resources as well as suitable nesting sites. Both may be limiting in small grassland fragments, and so very small plant patches usually receive fewer pollinator visits. Plant ecologists have found clear evidence that pollination efficiency, gene flow by pollen dispersal, and seed set are reduced in small calcareous grasslands. Habitat fragmentation is known to also affect specialized populations of higher trophic levels, for example, in a plant-herbivore-parasitoid food chain. Communities of monophagous, but not polyphagous butterflies show a steeper increase with the area of grasslands than communities of plants. Theoretical models and empirical evidence show that specialized parasitoids (and predators) suffer even more, so that food chain length tends to be shortened and herbivores tend to become released from possible control of their natural enemies. In addition, grasslands experience higher immigration and lower extinction rates when the surrounding landscape is complex, providing a diversity of resources.

Habitat quality of species-rich grasslands such as the calcareous grasslands mainly depends on the opposing forces of management (see below) and succession. Speed of succession may be related to fragment size because late-successional shrubs and trees often invade from the edge. Abandoned grasslands will often increase in species richness of both plants and insects, but they will certainly decrease on late-successional grasslands (e.g., after 10–20 years of abandonment), when shrubs and trees become dominant. Many specialized butterflies mainly occur on regularly mown or grazed calcareous grasslands as they appear to rely on warm microclimates and host plants associated with only sparse vegetation (Fig. 1). The rare British butterfly *Hesperia comma* prefers small plants of the grass *Festuca ovina* surrounded by sunny bare ground and nectar resources as oviposition sites. Death of rabbits from the myxomatosis virus appeared to enhance population declines of this butterfly, because the reduced rabbit populations caused less grazing. Ground-nesting species such as solitary bees are also more abundant on regularly mown or grazed grasslands, because the sparse vegetation and open soil provide nesting sites and thereby greatly enhance populations. In contrast, aboveground-nesting solitary bees are enhanced by dense, high, and woody vegetation that offers the necessary plant material for nest construction. Altogether, species will profit from early-, mid-, or late-successional stages depending on their life-history traits, and highest overall diversity should be conserved with a mosaic of different successional stages.

**FIGURE 1** Calcareous grasslands belong to the most species-rich habitat types in Central Europe and depend on annual cutting or grazing (near Göttingen, Germany, photograph by Jochen Krauss).

**MANAGEMENT OF GRASSLAND**

Cutting, grazing, and burning are typical methods of grassland management. As management alters plant growth and vegetation
In general, vegetation height and, therefore, the structural complexity of grasses decrease with intensity of grazing or mowing, and the complexity of plant architecture is a good predictor of insect species richness. The positive correlation between aboveground plant biomass and insect species richness is well established, whereas root feeders and other soil invertebrates are often more abundant at intermediate levels of grazing or mowing (of temperate grassland) than on unaffected patches. When a grassland has been left unmanaged for a few years, the hemipterous and coleopterous fauna quickly recovers. With increasing number of mowings per year, which may be best observed in the sometimes extremely often mown urban turf-grass areas, species richness of both plants and insects (e.g., planthoppers and true bugs) becomes extremely poor. Moderate cutting or grazing may promote grasshopper populations, possibly through tillering rejuvenation or through changes in the proportions of nutritious grasses. Because the quality of grass shoots as a food resource declines with age, the induction of tillers and side shoots by cutting make nutritious food available later in the season (e.g., for the populations of many grasshoppers and enhanced infestations of stem-boring Diptera). In conclusion, the effects of cutting or grazing on insect communities can be divided into short-term effects (simplification of plant architecture, regrowth of young and nutrient-rich plants) and long-term effects caused by changes in the structure of plant communities.

Grazing adds to the effects of cutting in that grazers feed selectively on the more-palatable plants, compress or loosen the ground by trampling, and fertilize grassland patches by urination and the deposition of dung. Accordingly, the changes in the plant community following grazing affect insect community structure in a complex way and make the habitat more heterogeneous than a homogeneous cutting regime. Further, grazing is a gradual form of vegetation removal, except at high stocking densities, and thereby differs from the large-scale disturbance of cutting (or burning). Cattle feed on taller vegetation than sheep and may open up tall vegetation. The cattle’s trampling effects are usually high compared to those of sheep and enhance vegetation heterogeneity with disturbed and bare areas that improve habitat quality of many invertebrates. High cattle densities, however, lead to short and uniform swards and create problems due to vegetation damage, especially on wetter soils and on slopes. Most of the nutrients removed by grazing are returned through the deposition of dung. Cow dung harbors a unique and specialized insect community. The breakdown of unlagulate dung in temperate environments is enhanced by fly maggots, such as Scatophaga sp. and dung-burying beetles such as the scarabeid Geotrupes sp. Deposition of bovine dung poses no problems where bovines have an evolutionarily associated fauna that exploits the fecal resources. However, in Australia, native detritivores could not process cow dung because cows were brought over by the first English colonists only at the end of the 18th century. The loss of pasture under dung has imposed a huge economic problem to agriculture in Australia, and only the decision in 1963 to establish African dung beetles there led to a solution.

Burning grassland is less common in Europe than in America or Australia, where burning is a widespread natural phenomenon. Burning, like cutting and grazing, tends to produce a greater floristic uniformity, and it is considered to be very detrimental to grassland invertebrates. Controlled burning has been suggested as an alternative to chemical or biological control of pest arthropods. Direct effects are diverse, depend on the intensity of the burn, and include the escape of many flying insects as well as few changes in many soil insects. Indirect effects are the xeric conditions after burning and the mineral-rich regrowth after burning, which for many animals is a superior resource quality.
Greenhouse gases, the gases involved in determining the Earth’s average temperature and climate, are accumulating at a rapid rate within the atmosphere. Such gases include carbon dioxide, methane, nitrous oxide, ozone, and chlorofluorocarbons. By far the most important of these is carbon dioxide, CO₂, whose contribution to the total greenhouse gas warming effect is at least 73%. For this reason, most research pertaining to insects and greenhouse gases has focused on the response of insects to elevated levels of CO₂. Global atmospheric carbon dioxide levels are increasing at an astonishing rate, mainly because of the burning of fossil fuels. The atmospheric concentration of CO₂ has increased from a preindustrial level of about 270 ppm to a current level of about 381 ppm, an increase of over 100 ppm or 41%. According to some reports, the atmospheric concentration of CO₂ will likely stabilize at four times the preindustrial levels. Most studies indicate that CO₂ levels will at least double from preindustrial levels over the next five to ten decades. This increase represents one of the most large-scale and wide-reaching perturbations to the environment.

Many of the changes in insect populations likely to result from elevated CO₂ will be brought about by changes in plant chemistry. The chemical changes in plants result from increases in plant carbon, decreases in nitrogen, and increases in levels of defensive compounds such as phenolics. In addition, global warming, which will result from elevated levels of greenhouse gases, may increase the reproductive capabilities of some insects and change their distributional ranges. This could change the abundance of some pest species and disease vectors. Some of the myriad effects of elevated CO₂ on insects are summarized in Fig. 1.

**STUDYING THE EFFECTS OF GREENHOUSE GASES ON INSECTS**

Most published studies on the effect of CO₂ on insects tell of experiments in which plants and insects are confined to CO₂ levels of 700–710 ppm, or about double the 2000 level. Such experiments are typically conducted in the laboratory, where well-watered potted plants are grown in nutrient-rich soil and maintained under elevated CO₂ for several months. Insects are introduced onto these...
experimental plants, and their feeding rates and performance are measured.

Studying the effects of elevated CO₂ on altered temperature and rainfall patterns, and the effects on insects of these modifications of the environment is much more problematic. It is not easy to warm whole communities in the field, except through the use of greenhouses—which tend to change many other features such as precipitation patterns. Thus, the effect of temperature is often studied on laboratory populations. In addition, mathematical models are used to determine the likely range alterations of plants and insects in the face of increased global temperatures and changes in precipitation patterns.

### CHANGES IN PLANT CHEMISTRY

Plants commonly respond to elevated CO₂ by increasing their rates of photosynthesis. Higher rates of photosynthesis usually result in higher accumulations of carbon-rich carbohydrates. Furthermore, the increased atmospheric CO₂ levels mean that stomatal conductance is reduced because plants can get sufficient atmospheric CO₂ into their leaves even when their stomates are closed more often. A reduction in stomatal conductance results in greater efficiency of water use by plants, because less water is lost through transpiration. Both these factors have important effects on plant chemistry.

First, increased carbon uptake by plants results in higher plant growth rates, with leaf area index, woody biomass, and below-ground biomass sometimes increased by as much as 25–50%. Despite the increase in plant growth, there is usually no increase in the availability of soil nutrients, particularly nitrogen, and these nutrients must be spread further among the available plant biomass. The usual result is a decrease in total plant nitrogen because nitrogen is diluted over the entire plant. Herbivore growth is most often limited by nitrogen rather than by carbon, so that plants grown in atmospheres of elevated CO₂ become poorer quality forage. Plant water content usually affects digestibility, so that the poorer quality diet is partly offset by an increased ease of digestion.

The second major change in plants grown under conditions of elevated CO₂, namely, is a change in the ratio of carbon to nitrogen (C:N), as described in the preceding section. This has major implications for the concentration of defensive compounds in the leaves, the so-called secondary chemicals. Carbon-based secondary chemicals often increase and deter insect feeding. The overall effect of increased CO₂ on insect herbivores is to decrease plant palatability because of decreases in nitrogen levels and increases in secondary chemicals.

For secondary chemicals, the increases seem to be greatest for soluble phenolic compounds, especially condensed tannins, which are found in a variety of trees, especially oaks. These compounds are known to negatively affect many herbivorous insect species. Yet for other defensive compounds, such as linear furanocoumarins, found in celery, and monoterpenes and sesquiterpenes, found in peppermint, a slight decrease has been noted.

### CHANGES TO INSECT HERBIVORE FEEDING

There have been over 75 studies of the performance of insect herbivores of various types under conditions of elevated CO₂. The majority of these have been conducted with leaf-chewing insects, especially lepidopteran caterpillars. A commonly reported change is that food consumption increases, between 10 and 20% as the insects struggle to obtain sufficient nitrogen in their diet. The efficiency of food conversion to insect biomass (conversion efficiency) decreases, probably because of the increased concentration of secondary chemicals, such as tannins, which bind digestive enzymes and render them less effective. Thus, it takes insects much longer to develop, and their final weight is often reduced. Early instars seem to be more susceptible than late instars. Of course such changes in diet could, in theory, be partly offset by the increase in digestibility due to the increased water content. However, at least in the studies done so far, the net outcome of elevated CO₂ on herbivorous insect digestibility has been negative.

The responses just outlined may vary somewhat according to the feeding guild of insects involved. Thus, chewing insects, which often digest the whole leaf and encounter both reduced nitrogen levels and increased defensive compounds, are particularly susceptible to changes in nitrogen and phenolics. Insects that feed in a different way may be less susceptible. Phloem and xylem feeders in particular may be less affected by increased CO₂ because these plants try to maintain high levels of nitrogen in their reproductive parts. In cotton, for example, the C:N ratio of cotton balls is unaffected by elevated CO₂ and lepidopterans feeding there are unaffected. The concern is that pest insects could be stimulated to feed on these reproductive parts when the quality of the remainder of the plant decreases, which in turn would increase the pest status of some insects.

Of course CO₂ has also the direct effect of increasing temperature via the greenhouse effect, which may stimulate feeding activity because of increased metabolic rate in higher temperatures. Over a 20 year period, from 1985 to 2005, the peak date of caterpillar biomass in mixed oak woodland in Holland advanced by 15 days. Studies on the green peach aphid, *Myzus persicae*, a pest of many crops, suggest that elevated temperature increases aphid population growth rate and thus the likelihood that aphids will become more important pests in the future. In this case, both elevated CO₂ and elevated temperature increased aphid densities in experiments. Since, however, very few experiments have examined both CO₂ concentration and temperature in factorial experiments, the generality of the aphid results is unknown. It is also possible that the effects of elevated CO₂ and elevated temperature could cancel each other out for other insect species, especially leaf chewers.

### EFFECTS OF CHANGED PLANT CHEMISTRY ON INSECT DENSITIES AND MORTALITIES

There has been relatively little research into how CO₂-mediated changes in plant chemistry affect insect densities and mortalities. This is because most plant–insect work has been done in laboratory conditions, where insects are fed foliage grown in elevated or ambient CO₂ and insect weight gains, losses, and digestibility coefficients are measured. To predict the effects of elevated CO₂ on insect densities, a population must be established on CO₂-treated foliage. However, in the few cases where insects have been reared from first instars through to pupae and adults, a significant decrease has commonly been found in resultant population sizes. This is usually because nutritionally inadequate foliage kills the immature insects. In some species (e.g., leafminers), we can get a good estimate of host-plant-induced mortality. Here, larvae that die from nutritional inadequacy are entombed with the leaf and can be counted, permitting an accurate assessment of deaths induced by the host plant.
Mining insects are a valuable study organism with which to examine the effects of elevated CO₂ on natural enemies. Experiments like this are very costly to do because of the huge quantities of CO₂ needed to arrive at a large enough increase in CO₂ under field conditions. However, it is widely thought that the net result of increased plant consumption and slower growth by herbivorous insects in elevated CO₂ is likely to result in increased exposure to natural enemies. For example, consumption of additional foliage increases the probability of ingestion of viruses or pathogenic bacteria, such as Bacillus thuringiensis, which can cause death. Once again, leafmining insects are a valuable study organism with which to examine the effects of elevated CO₂ on attack rate by natural enemies. This is because the leafmines themselves leave a permanent record of the fate of the insect inside. Parasite larvae can often be found within a mine, or the emerging adult parasitoids leave characteristic small shotgunlike holes in the upper mine surface. A recent study by the author, at Kennedy Space Center, was able to examine attack rates of leafminers by parasitic Hymenoptera in field chambers under conditions of ambient and elevated CO₂. The open-top chambers contained the full complement of herbivores and their natural enemies on naturally occurring oak vegetation (Fig. 2). Leafminer density was reduced inside the chambers, and leaf nitrogen content was reduced. The leafminers died more frequently inside the mines in elevated CO₂ and the mine area was bigger, indicating that larval leafminers had to eat more. Attack rate by natural enemies, particularly parasitoids, was significantly increased inside the chambers in which CO₂ was elevated. Perhaps the leafminers had created bigger, more obvious mines. Alternatively, their developmental time might have been slower in elevated CO₂, exposing them to natural enemies for a longer time, or they might have been physiologically less well able to resist attack.

![FIGURE 2] Open-topped chamber at Kennedy Space Center, Florida used to elevate atmosphere CO₂.

In other systems, aphids known to produce alarm pheromones show a reduced capacity to do so under elevated CO₂. Once again, the result is an increased susceptibility to natural enemy attack. Finally, increased global temperatures are also likely to increase parasite and predator abundance as a result of increased population growth rates. This in turn could also lead to higher insect herbivore mortalities.

**EFFECTS OF TEMPERATURE CHANGES ON INSECT DISTRIBUTION PATTERNS**

Greenhouse gases are likely to change insect distribution patterns both directly, via increases in temperature and rainfall, and indirectly, via changes in the distribution of host plants. Research on a sample of 35 nonmigratory European butterflies showed that 63% had ranges that shifted to the north by 35–240 km during the 20th century, while only 3% shifted to the south. Thus for many insects, global warming has already changed range boundaries. The data appear to be robust because for most of these species, northward shifts have been shown in more than one country. Furthermore, the data appear to be robust across families, with many members of the Lycaenidae, Nymphalidae, Satyrinae, and Hesperiidae showing such range shifts.

Changes in rainfall, likely to have at least as big an impact as rising temperatures, have not been much studied. Global rainfall patterns clearly will change as a result of changes in global temperature, with many coastal areas becoming wetter and many interior continental areas becoming drier. This set of changes will affect the distribution of host plants and the insects that live on them. In addition, rainfall changes can directly affect the hatching of immatures from eggs laid in the soil, including eggs of many species of locust. Increased soil moisture increases the likelihood of locust outbreaks because it increases hatching and stimulates growth of host plants on which the locusts feed. The threat of locust plagues in new areas of the globe is therefore very real.

Margaret Davis, a paleobotanist from the University of Minnesota, showed that in the event of a CO₂ doubling, beech trees, presently distributed throughout the eastern United States and southeastern Canada, would die back in all areas except northern Maine, northern New Brunswick, and southern Quebec. Of course favorable new locations would develop in central Quebec, but the trees would take a long time to colonize such areas. Presumably the animals that feed on beech trees, including insect herbivores, would suffer a severe range contraction too, though this has not yet been studied.

**EFFECT OF GREENHOUSE GASES ON SOIL INSECTS**

It is doubtful that soil-inhabiting insects will respond directly to increased levels of CO₂ because of existing high concentrations in the soil. However, there are many likely indirect effects of CO₂ on soil insects. Light interception by a larger canopy may lower soil temperature and moisture. The most important change, though, is likely to be increased litterfall. Soil organic matter is likely to accumulate, rendering grasslands and forests net sinks of carbon under conditions of elevated CO₂. However, before senescence, most leaf nitrogen is reabsorbed by the plant, so that whereas living leaves in elevated CO₂ generally have a lower nitrogen content than leaves in ambient
CO₂ conditions, litter quality remains unchanged. However, the increased volume of litter is likely to increase the number of litter-decomposing insects there.

In addition, increased root production may benefit root-feeding insects. Total numbers of Collembola per kilogram of soil have been shown to be significantly higher in experimental laboratory-based mesocosms where CO₂ levels were 60% above ambient. Species composition of Collembola also changed. Part of these increases in Collembola may be due to changes in abundance of mycorrhizal and nematode-fungi on which they feed.

**AQUATIC COMMUNITIES**

Aquatic insect communities are unlikely to be directly influenced by increased CO₂ as much as terrestrial systems are. However, the increased litterfall associated with forest productivity is likely to increase allochthonous (i.e., leaf fall from riparian zones) litter input into forest streams and lakes. Such increased litter input is likely to increase stream insect populations. Litter quality itself, because it does not generally differ between ambient and elevated CO₂ treatments, is unlikely to affect aquatic decomposer communities. This has been verified by adding litter from ambient and elevated CO₂ to laboratory microcosms (simulated treeholes) and examining effects on eastern treehole mosquitoes, *Aedes triseriatus*. No differences in mosquito development time or survival were found. However, the elevated water temperatures and precipitation may increase the abundance of disease vectors such as mosquitoes. On the other hand, some cold water species may be reduced in abundance.

**ELEVATED CO₂ AND DISEASE VECTORS**

One of the main concerns voiced about global warming is that the delicate balance between diseases, their vectors, and humans might be upset as tropical climates that are so hospitable to spawning and spreading diseases move poleward. The spread of infectious diseases is controlled by the range of their vectors—mosquitoes and other insects. Increases in temperatures mean increases in the activity and ranges of these vectors.

Data on recent trends support this observation. An increase of 1°C in the average temperature in Rwanda in 1987 was accompanied by a 337% rise in the incidence of malaria that year as mosquitoes moved into mountainous areas they had not previously inhabited. Also, *Aedes aegypti*, a mosquito that carries dengue and yellow fever, has extended its range high into the mountainous areas of such diverse areas as Colombia, India, and Kenya. Although global warming is expected to deliver its most deadly punch in the tropical areas of the world, where over 500-million people are affected (and 2.7 million die), the United States is not immune. A computer model by a Dutch public health team proposed that an average global temperature increase of 3°C in the next century could result in 50–80 million new cases of malaria each year. In the United States, public health facilities are likely to keep new incidences of disease in humans to a minimum, because of vaccinations. But disease outbreak in wildlife, which is not vaccinated, could be more severe.

**Growth, Individual**

**Martin B. Berg**  
Loyola University Chicago, Chicago, IL

**Richard W. Merritt**  
Michigan State University, East Lansing, MI

The growth of individual insects proceeds in a progressive manner throughout the immature period of development, although the rate of growth can vary depending on a variety of factors such as molting frequency, temperature, and nutrition. Growth can be measured as an increase in biomass or body size, although biomass can be more variable than body size owing to differences in food and water intake. Growth usually is distinguished from development in that the latter refers to the various morphological and physiological changes that occur throughout the life span of an insect as it progresses toward maturation.

**HOW INSECTS GROW**

The limited ability of the rigid exoskeleton of insects to expand imposes a considerable constraint on individual growth resulting in the necessity to shed (i.e., to molt) the old exoskeleton, a process
termed ecdysis, for growth to continue. Some insects (e.g., collembo-
lans, diplurans, and thysanurans) exhibit indeterminate growth and
continue to molt even after reaching the adult stage, although little
if any increase in biomass occurs. In contrast, the majority of insects
exhibit determinate growth in which both growth and molting cease
upon reaching the reproductively mature last instar (i.e., the adult).

The pattern of individual growth differs depending on whether
growth is measured as an increase in biomass or as an increase in
body size. When measured as an increase in biomass, individual
growth occurs between molts and is more or less continuous in most
insects, although decreases in biomass often occur at the time of
molting. When measured as an increase in body size, however, indi-
vidual growth is largely dependent on the amount of sclerotization
of the insect or of a particular body part. Membranous body parts,
and those insects that are not highly sclerotized, can continuously
increase in size between molts as folds in the cuticle expand, whereas
insects or body parts that are more highly sclerotized increase in size
immediately following each molt and exhibit a more discontinuous
pattern.

Different body parts of insects may exhibit either isometric or
allometric growth compared with the body as a whole. Isometric
growth occurs when body parts grow at the same rate as the body as
a whole, i.e., body length. Allometric growth occurs when body parts
grow at rates different from that of the body and can be expressed
as a power function of the form \( x = ky^a \), where \( x \) is the dimension
of the whole, \( y \) the dimension of the part, \( a \) the growth coefficient, and
\( k \) a constant. Thus, a straight line results from a log–log plot of body
part size versus body length (Fig. 1).

![Figure 1](image)

**Figure 1** Allometric relationships between body part length and
body length for *P. albimanus* (Diptera: Chironomidae) (Data from
Ward and Cummins, 1978.)

**INCREASES IN BIOMASS**

Biomass increase of insects during development can be appreci-
able, with immature final instars weighing as much as 1000 or even
10,000 times greater than first instars. Changes in biomass can be
expressed as either an absolute (weight/time) or a relative (weight/
weight/time) increase in biomass. Absolute growth usually is greatest
in later instars and for the tobacco hornworm, *Manduca sexta*, larval
weight increases as much as 90% (10-fold) in the final two instars.
Similarly, 90% of the growth of larval *Paratendipes albimanus*
(Diptera: Chironomidae) occurs in the final 10% of the life cycle. In
contrast, relative growth rates normally decrease in later stages of
development as the insect increases in size.

**INCREASES IN BODY SIZE AND DYAR’S LAW**

In 1890, H. G. Dyar noted that the head capsule widths of lep-
dopteran larvae followed a geometric progression in growth. During
development of an immature insect, increases in body size occur
in discrete steps, with highly sclerotized body parts exhibiting pre-
dictable and regular increases by a relatively constant factor, subse-
sequently known as Dyar’s Law (or Rule). Although initially based on
observations of lepidopteran larvae, Dyar’s Law has been applied to
immature insects in general and refers to the geometric progression
in the size of sclerotized structures that is constant throughout devel-
opment. Dyar’s Law has been widely used in entomological studies
to discern instars of immature insects and also has been used to pre-
dict the size of instars missing from samples. The ability to distin-
guish instars is crucial to accurately describe insect life histories and
growth patterns and is widely used in secondary production studies.

Because membranous portions of the less-sclerotized cuticle (e.g.,
interssegmental membranes of the abdomen) allow the body to grow
more or less continuously, overall body size is not considered a good
indicator of instar. In addition, the increase in body size at each molt
varies with different species and the growth of various body parts of
many insects may differ from the growth rate of the body as a whole
(i.e., allometric growth). In contrast, the rigid exoskeleton of imma-
ture insects prevents expansion and results in discontinuous growth
of highly sclerotized cuticular parts (e.g., head capsule, legs). Thus,
theses structures increase in size incrementally in a stepwise manner
following a molt. It is these distinct increases in the size of sclero-
tized structures that allows for the distinguishing of different instars
with little overlap occurring between size classes.

The publication of Dyar’s observations was in response to two
previous papers that presented contradictory data concerning the
number of molts in other species. Dyar studied the number of molts
in 39 individuals of 28 species of caterpillars and chose the head
capsule as the structure to measure for ease of measurement and
because it was not subjected to growth during each stadium as was
body length. The taxa chosen by Dyar ranged from 4 to 10 instars.
Dyar calculated head-width ratios of successive instars and found
that the progression was often nearly constant for a given species
(mean = 1.5; range 1.3–1.7), what one would expect from a geomet-
ic progression. Dyar then calculated expected head capsule widths
of each instar by multiplying the width of the final instar by this
ratio and then back-calculating to the first instar. To test the appli-
cability of the ratio, Dyar compared calculated head widths to those
observed from reared specimens. Using this approach, it was possi-
ble to detect whether some instars had been missed or mismeasured.
The most common method for detecting these problems is to plot the
logarithm of the head capsule width measurement (or a measure-
ment of another highly sclerotized structure) against the appro-
priate instar (Fig. 2). Conformity to Dyar’s Law results in a straight
line the slope of which is constant for a given species. According to
Dyar’s Law, deviations from a straight line indicate potentially missed
instars or errors in measurement.

Although Dyar’s Law has been widely used in entomological
studies, the progression in the size of sclerotized body parts is not
always constant and can be influenced by abiotic and biotic factors such as temperature and food. In addition, apparent contradictions to Dyar’s Law occur when two requisite conditions are not met: (1) the number of instars is constant and (2) head capsule growth occurs only at ecdysis. Despite these constraints, approximately 80% of the entomological studies published from 1980 to 2007 that have examined the validity of Dyar’s observations provided support for his law. There has been some disagreement as to whether Dyar should be credited with the findings of geometric progression in growth. In a paper published 4 years prior to Dyar’s article, Brooks reported that the total larval length of a species of crustacean stomatopod (Stomatopoda: Squillidae) sequentially increased in size by a factor of 1.25 at each molt. Brooks also noted, as did Dyar, that this relationship could be used to determine whether larval stages were missing from the series. Thus, Dyar’s Law may occasionally also be referred to as Brooks’ Law (or Rule) in the literature. It is likely that entomologists were unaware of Brooks’ observations because they were documented in a specialized publication on stomatopods.

**EFFECTS OF TEMPERATURE ON INDIVIDUAL GROWTH**

Because insects are ectotherms, temperature can have a profound impact on individual growth. In general, insect growth is correlated with environmental temperature; however, the strength of this relationship may be species- and habitat-specific. For example, many terrestrial insects exhibit little to no growth at low temperatures (0–4°C) because of either reduced feeding rates or overall low metabolic activity. Aquatic insects, in contrast, particularly those whose evolutionary ancestral habitat was in cold streams or lakes, can exhibit high growth rates during winter, assuming the presence of an adequate food supply. Although feeding rates of these insects may be low at reduced temperatures, basal metabolic needs also are low and result in the ability of the insect to direct more of the energy derived from ingestion to growth. The interactions between food quantity and quality and temperature are complex. In some streams, water temperature can influence the growth of microbial populations attached to detrital particles that are ingested by filter-feeding aquatic insects, and in turn, this can enhance their growth rate. This type of indirect control on aquatic insect growth and survivorship is difficult to separate from the direct effects of temperature on insect metabolism.

Elevated environmental temperatures also can result in either high or low larval growth rates because of the influence of temperature on larval ingestion, digestion, and development time. In general, larval ingestion and digestion are positively correlated with temperature and should result in increased growth rates at higher temperatures. The effect of temperature on growth rate, however, is confounded by an inverse relationship between ingestion rates and assimilation rates. In contrast, high temperatures can accelerate developmental time, resulting in the inability of larvae to maximize absolute growth rates.

**EFFECTS OF NUTRITION ON INDIVIDUAL GROWTH**

Individual growth of immature insects is strongly influenced by food availability, feeding selectivity, and food quality. Insect growth is often directly related to food availability, in that larval growth rates are highest in the presence of an abundant food supply. Because availability of food resources can vary temporally, growth responses also can be expected to vary throughout the year. For example, several species of stream chironomids (Diptera: Chironomidae) that feed primarily, but not exclusively, on attached algae, exhibit periods of maximal larval growth that coincide with times of the year when instream algal production is highest.

Feeding selectivity and food quality, however, also influence the relationship between growth and food availability. Even in the presence of an apparently abundant food supply, larval growth rates may be reduced if that food resource is not preferred or if it is of low quality or lacking essential nutrients. For example, the leaf-shredding crane fly, *Tipula abdominalis*, shows a strong preference for hickory, maple, and American chestnut leaves and a low preference for American beech, white oak, and red oak leaves. Larval growth rates are highest on the more-preferred leaf types and lowest on the less-preferred leaves. The higher growth rates on more-preferred leaves are not due to higher food conversion efficiencies, but rather result from increased consumption rates due to a more palatable food source.

Although food availability may not be a limiting factor for growth in some insects, food quality may impose a substantial constraint to larval growth. Differences in food quality also can affect larval growth rates and the ability to complete development and reproduce. Absolute and relative growth rates of the caddisfly *Clistoronia magnifica* (Trichoptera: Limnephilidae) reared on diets differing in quality were significantly higher on a diet rich in triglycerides (conditioned alder leaves plus whole wheat grains) compared with diets of conditioned alder leaves, conditioned alder leaves with a fatty acid mixture, conditioned alder leaves plus hyphomycete fungi, or hyphomycete fungi alone. In addition, only larvae fed the high-triglyceride diet successfully completed development and reproduced. Some insects, however, even in the absence of higher quality food, can maintain a relatively uniform growth rate throughout development by increasing ingestion rates of lower quality food.
Grylloblattodea

(Rock Crawlers, Ice Crawlers)

D.C.F. Rentz
California Academy of Sciences

Sigfrid Ingrisch
Museum Koenig, Bonn

The Grylloblattodea, or ice crawlers, are a small group of soft-bodied, apterous, terrestrial, and termite-like insects confined to the Northern Hemisphere. They occur under rocks in forest leaf litter or above the treeline in the high mountains. In parts of the United States, Canada, and China they are found under rocks in the soil at or below freezing temperature. In Japan and Korea, they are active in midsummer in the deep leaf litter of mixed conifer and deciduous forests, where daily ambient temperatures approach 30°C. In Japan and Korea, some have been found in caves; in the western United States, they are known from subterranean lava tubes. Grylloblattids are slender, depressed insects covered with fine hairs and having reduced eyes. Adults range from 2 to 3.5 cm in length. Ice crawlers appear to be primarily nocturnal. They are considered to be some of the most primitive of orthopteroid insects and have been thought to be related to cockroaches (Blattodea) and stick insects (Phasmida). However, recent molecular phylogenetic and morphological studies of the attachment structures in insects support a sister group relationship with the Mantophasmatodea. Some authors even place both groups as superfamilies in a single order, the Grylloblattodea (or Neoptera).

CLASSIFICATION AND FEATURES OF THE ORDER

The Grylloblattodea (Grylloblattida of some authors) comprise a single extant family, Grylloblattidae, which includes only five genera. Grylloblatta occurs in western North America and Canada, where at least 11 species are known. Grylloblattina is known from one species from Russian Far East. Grylloblattella has two known species from Siberia. Galloisiana contains at least 12 species from Japan and eastern continental Asia. Nambungia has two known species, including the largest-known grylloblattid. The group, however, is undoubtedly larger, since new species are discovered every few years. Kim and Lee (2007) provided an excellent review of the group and its 27 known species in their revision of Galloisiana Gurney. The Tree of Life web project has provided a phylogeny of the known living genera following the molecular analysis of Jarvis and Whiting (2006). There is considerable interest and controversy in the fossil species of the group because these insects contain the sister groups of the modern Plecoptera (see Béthoux et al., 2005). Other work using molecular analysis by Terry and Whiting (2005) has shown that the Grylloblattodea is a sister group of the recently discovered order Mantophasmatodea.

Grylloblattids are cryptic, ground-dwelling insects that prefer wet habitats and cool temperatures. They shun light and occur under stones or in dense leaf litter. Species of Grylloblatta that live under rocks under or near snowbanks emerge after dark and feed as scavengers or predators on dead or dying insects that have been blown onto the snow from lower elevations. During winter, the species probably occupy the airspace between the ground and overlying snowpack, where they remain active at temperatures of 0°C. Massive fat bodies build up prior to winter; during winter, the insects may feed on decaying plant material. Korean species live under debris on the floor of caves at only 200 m altitude and apparently never venture forth from their cave habitat. The most-widespread species in Japan, Galloisiana nipponensis, is found at elevations ranging from 300 to 3000 m, where the insects live under stones and in the leaf litter of thick, mixed coniferous and hardwood forests. These species consume both insects and plant material day and night.

The resemblance of grylloblattids to Dermoptera has been shown to be superficial and is limited to the fact that both have a projecting head. The head, however, is typical of orthopteroid insects. The antennae are elongated and thin. The mouthparts are structured like those of a predator. Ocelli are absent, and the eye comprises fewer ommatidia in young instars than in adults. The legs are simple, slender, and not suited for jumping. The abdomen has 11 segments, with long and flexible cerci and asymmetrical male genitalia. The ovipositor has three pairs of slender, tapering, partly free valves.

Although grylloblattids are normally considered to be cold-adapted insects, they cannot withstand temperatures much below 0°C. At −5.5 to 8.0°C, they become stressed. Contrary to the popular belief that they can withstand very low temperatures, they can be killed by ice formation within the body as a result of their low levels of glycerol, sorbitol, or erythrol.

Copulation has been observed in a few species. In G. nipponensis (Fig. 1), the female is chased and seized by the male. The resulting...
copulation can last from 30 min to 4 h. Males always assume a position on the right side of the female as a response to the male’s asymmetrical genitalia. Oviposition occurs 10–50 days after copulation. Females lay eggs with the elongate ovipositor in wood or under stones and decaying plant material. No eggs have been found in moss. Oviposition for each egg takes about 3 min, and females lay five or six eggs per day to a total of about 30 eggs. A captive female can lay 145 eggs in her lifetime. The large, black eggs, develop over periods ranging from 5 months to 3 years.

**Gypsy Moth**

**Joseph S. Elkinton**

*University of Massachusetts, MA*

The gypsy moth, *Lymantria dispar*, is one of the world’s most damaging defoliators of hardwood forest trees. It is native to Europe and Asia. It was introduced from Europe to North America near Boston, MA in 1868 and has been spreading slowly south and west ever since. A large body of research has focused on the biology, management, and population dynamics of this species.

**GEOGRAPHIC RANGE AND SPREAD**

Gypsy moth occurs throughout much of the northern hemisphere. Its native range stretches from Japan, China, and Siberia across Russia to Western Europe and as far south as the Atlas Mountains of North Africa. In North America, gypsy moth has spread over much of the eastern United States and Canada. Currently, the leading edge of the infestation stretches from North Carolina to Minnesota and adjacent regions of Ontario (Fig. 1). Because female gypsy moths from Europe have wings but do not fly, the rate of spread of this insect has been extremely slow. The spread occurs when newly hatched larvae spin down on silken threads and are blown in the wind. Most of this dispersal is less than 50 m, although some larvae are carried by wind currents for greater distances. Natural spread has been augmented by inadvertent human transport of egg masses laid on vehicles or other backyard objects, often to locations well outside the region infested by gypsy moth in the northeastern United States (Fig. 1). Such new infestations have been eradicated at many sites throughout North America. The spread along the front is monitored with an extensive array of survey traps baited with the gypsy moth sex pheromone. A. M. Liebhold and colleagues have used these data to develop sophisticated models of the rate of spread and understand the various factors that affect it. Chief among these, are factors called Allee effects that limit the rate of spread and cause many incipient populations ahead of the front to go extinct without human intervention, mainly because densities are too sparse for gypsy moth females to find mates. This phenomenon has made eradication possible in many locations (Fig. 1). These studies have made important contribution to the general theory of invasion biology.

**LIFE HISTORY AND HOST TREES**

The gypsy moth female lays a single egg mass (Fig. 2), usually on the stems of trees, and she covers the eggs with her body hairs. The egg mass typically contains from 100 to 600 eggs. The eggs are laid in midsummer, but overwinter in this stage. Larvae developing within the egg enter diapause and hatch the following spring at the time of host-tree budbreak. Emerging larvae climb to the tops of trees, where many of them spin down on silken threads and are borne away by the wind. If larvae land on an acceptable host tree, they begin feeding. They develop through five larval instars for males or frequently six for females throughout May and June. Beginning in the fourth instar, larvae seek resting locations during daylight hours, either in the forest litter at the base of trees or under bark flaps on tree stems. They usually pupate in these same locations. The adults emerge after about 12 days in the pupal stage. Soon after eclosion, the female releases a

**FIGURE 1** Copulating pair of grylloblattids, *G. nipponensis*: the female is the lower individual (note ovipositor); the male has the eversible sac of the left phallicore exposed. [From Nagashima et al. *In Ando, H. (ed.)* (1982). “Biology of the Notoptera,” p. 48, Kashiyo-Insatsu, Nagano, Japan.]
sex pheromone from a gland on the tip of her abdomen. Males locate females by flying upwind when they detect the pheromone. After mating, the female lays her egg mass, often just a few cm from where she eclosed, and dies soon thereafter. There is one generation per year.

Gypsy moth larvae feed on a wide range of tree species. Favored tree species include oaks (Quercus spp.), aspen (Populus spp.), and in Japan, Japanese larch, Larix leptolepis. Gypsy moth outbreaks occur in forests that are dominated by these species. Gypsy moth will feed on many other tree species, such as maple (Acer spp.) and many conifers, but significant damage to these trees usually occurs only in gypsy moth outbreaks, when more favored hosts have already been defoliated. If defoliation is complete, most deciduous hardwood trees will put out a new set of leaves. Most trees will survive one defoliation, but if outbreaks persist for several years in a row a significant proportion of the trees may die. Trees that survive defoliation suffer growth loss in subsequent years.

**DISEASES OF GYPSY MOTH**

As with most insects, gypsy moths are host to a suite of natural enemies and these play a pivotal role in the dynamics of the gypsy moth populations. There are two major diseases: a nuclear polyhedrosis virus and a fungal pathogen. The virus, LdMNPV, causes epizootics that are largely responsible for the collapse of gypsy moth outbreaks. Similar viruses terminate the outbreaks of many defoliating Lepidoptera. High mortality from these viral diseases only occurs in dense populations, because transmission of the virus takes place when larvae feed on leaves contaminated by cadavers of larvae that have previously died from the disease. Encounters with cadavers are only likely in dense populations. Transmission of LdMNPV from one generation of gypsy moths to the next occurs primarily by way of external contamination of the egg mass; larvae become infected as they emerge from the mass in the spring. It is not entirely clear how the virus persists at low density, but it does survive in the forest litter for several decades.

The fungal pathogen, Entomophaga maimaiga was, until recently, known only from the Far East, especially Japan. In 1989, a dramatic epizootic of E. maimaiga occurred throughout the northeastern United States from Pennsylvania to Maine. In subsequent years, the fungus spread across the mid-Atlantic States and was introduced intentionally by researchers to Virginia and Michigan. It is now established throughout the region infested by gypsy moth in North America. E. maimaiga produces two kinds of spores: conidia and resting spores. The conidia are released from cadavers and are carried by wind currents to uninfected larvae, which they infect by penetrating the cuticle; these conidia are responsible for the rapid spread of E. maimaiga in North America. Late-instar gypsy moths produce resting spores that overwinter in the forest litter, where they persist for up to 10 years before...
Gypsy Moth

germinating to infect new gypsy moths. A. Hajek and colleagues analyzed the DNA of *E. maimaiga* and showed that the pathogen in North America is identical to *E. maimaiga* in Japan. How *E. maimaiga* was introduced to North America is unknown. Since 1989, it has continued to cause high levels of mortality in gypsy moth populations, particularly in years with high rainfall in May and June. A key difference from *LdMNPV* is that *E. maimaiga* causes substantial mortality in low-density as well as high-density populations of gypsy moth. This means that *E. maimaiga* can prevent outbreaks from occurring, whereas *LdMNPV* can only cause the collapse of outbreak populations.

PARASITOIDS

As with most insects, various parasitoid species attack the different life stages of gypsy moth. In North America, efforts to introduce parasitoids of gypsy moth from Europe and Asia began around 1905, and ten species have been established. The egg parasitoid *Ooencyrtus kusaeae* (Encyrtidae) from Japan is frequently observed on gypsy moth egg masses in late summer and may cause as much as 30% mortality. Larval parasitoids include *Cotesia melanoscela* (Braconidae) and the tachinids *Blepharipa pratensis*, *Compsilura concinnata*, and *Parasetigena silicots*. The most common pupal parasitoid is *Brachypemria intermedia* (Chalcididae). The impact of these parasitoids on gypsy moth populations remains equivocal. Total mortality caused by parasitoids in North America is typically below 50% and is not consistently density dependent, so that their ability to regulate gypsy moth populations is in doubt. In Europe, on the other hand, parasitism of gypsy moth is often much higher than that observed in North America. European gypsy moths are attacked by several parasitoid species that were never established successfully in North America. It seems likely that parasitoids are responsible for preventing gypsy moth outbreaks, which are rare in Western Europe, but more common in central and southern Europe.

PREDATORS

Compared with parasitoids, an even larger community of vertebrate and invertebrate predators feed on gypsy moth. Very little is known about the impact of most predators, because predation is extremely difficult to measure. Many bird species worldwide feed on gypsy moth, but it is generally believed that most birds dislike the hairy cuticle of gypsy moths and avoid them.

Research groups led by H. Bess in the 1940s and R. Campbell in the 1970s, concluded that predation by small mammals, particularly the white-footed mouse, *Peromyscus leucopus*, has a major impact on low-density gypsy moth populations. The mice feed on late-instar larvae and pupae, particularly on the forest floor. Both research groups demonstrated an increase in gypsy moth survival in forest plots from which small mammals had been removed or excluded. More recently, J. Elkinton and colleagues showed that predation on gypsy moth pupae was strongly correlated to density of mice, and that gypsy moth densities increased when mouse densities declined. The density of mice, in turn, was correlated to the abundance of acorns, which in oak-dominated forests are their principal overwintering food. Indeed, there are many studies that link forest-dwelling mice to abundance of acorns crops. Poor acorn crops, which occur on a regional scale and are caused by a variety of weather events, could thus be the ultimate trigger of gypsy moth outbreaks. C. Jones and colleagues provided further experimental proof of these ideas. They removed mice from experimental plots and observed an increase in gypsy moth and they augmented food in other plots and observed an increase in mice.

There are a number of invertebrate predators of gypsy moth. One of these is the introduced ground beetle, *Calosoma sychophanta* (Carabidae). R. Weseloh has shown that this insect becomes quite abundant in outbreak populations of gypsy moth and may cause substantial mortality. Several researchers have documented predation by ants as a significant source of mortality in low-density populations, but it is usually much less than predation by mice.

POPULATION DYNAMICS

In the 1970s, R. Campbell developed the first comprehensive theory of gypsy moth dynamics, wherein populations alternate between low-density and high-density phases, each maintained by different factors and sources of mortality. At low density, predators,
particularly mice, maintain gypsy moth populations indefinitely at a low-density equilibrium. The concept of an equilibrium implies that predation is density dependent, which means that it increases as gypsy moth density increases until total mortality balances fecundity of gypsy moth and the population density stops growing. The equilibrium is an unstable one, however, because the density-dependent response of most natural enemies is constrained by a variety of factors. For example, most predators or parasitoids have their own natural enemies. These constraints produce a threshold density above which gypsy moth population growth outpaces the mortality caused by natural enemies, and as a result densities of gypsy moth increase rapidly into an outbreak phase. At the much higher outbreak densities, a different set of natural enemies become predominant. These natural enemies, coupled with competition of gypsy moth for available foliage, limit further increases in gypsy moth density. The outbreak population either persists for several generations at high-density, or collapses back to the low-density phase. The model is particularly appropriate when the principal mortality factors maintaining the low-density equilibrium are generalist predators, such as mice. Unlike specialist natural enemies, whose densities often track those of their hosts, the densities of mice are not determined by gypsy moths. Instead their densities are determined by their overwintering food supply, mainly acorns. Whether this conceptual model is an accurate description of the gypsy moth system remains to be demonstrated.

Adding to the complexity of gypsy moth dynamics in North America is the recent appearance of the fungal pathogen _E. maimaiga_. In the northeastern United States, epizootics of this fungus have occurred nearly every year since 1989, except in years that were extremely dry. We still have much to learn about this agent, but it causes substantial mortality in both low- and high-density populations and appears to have prevented several incipient outbreaks. It appears that incidence of _E. maimaiga_, which is largely determined by rainfall in May and June, is now a prime determinant of whether outbreaks occur.

Gypsy moth outbreaks are spatially synchronized (Fig. 3). Outbreaks tend to occur simultaneously over a large region. A cause of this pattern may be acorns crops, which are heavy or meager over a region in response to regional weather patterns. However, as indicated by P. Moran, populations of many species are synchronized by a variety of weather-related influences. Weather may synchronize

---

**FIGURE 3** Historical record of area defoliated by gypsy moth in each of five states in northeastern United States from 1924 to 1996. [Reproduced from Liebhold et al. (2000), with permission.]
gypsy moth populations by exerting a common influence across populations on many of the factors that affect gypsy moth growth and survival. Recent analyses by Johnson et al. indicate that there is a 10-year cycle of abundance of gypsy moth embedded in the erratic temporal pattern evident in Fig. 2. If these cycles exist, the factors that cause them remain poorly understood. However, a mathematical model of the gypsy moth system developed by Dwyer et al. that incorporates predation by mice and mortality caused by NPV exhibited periodic behavior that mimicked the behavior of real gypsy moth populations.

Management of Gypsy Moth

Management of gypsy moth in North America and elsewhere has evolved over time as different tools became available and as public attitudes toward pest control have changed. In the 1960s, large areas were sprayed by air with DDT. In the late 1960s, DDT was banned and was supplanted by other chemical pesticides, such as Carbaryl. In the late 1980s, Bacillus thuringiensis (Bt), a bacterial pesticide, became a viable alternative to chemical pesticides and became the material of choice in many regions. The advantage of Bt is that it is more selective than most chemical pesticides; it only affects larval Lepidoptera that feed on Bt-contaminated foliage. Bt is one of several biopesticides that have entered the market in recent years. Government agencies in the generally infested region in northeastern United States have abandoned large-scale application of pesticides against gypsy moth because it was neither ecologically acceptable nor worth the considerable cost. Most forests trees survive gypsy moth outbreaks and the outbreak populations soon collapse on their own. Control activities in these regions generally aim at foliage protection on high-value trees, rather than suppression of gypsy moth populations. Management of gypsy moth by state and federal governments in recent years has focused on the slowing of the spread of gypsy moth along the invasion front that currently extends from Wisconsin to North Carolina (Fig. 1). Spread is monitored with pheromone-baited traps and new infestations that are detected at the leading edge of the advancing front are eradicated using a variety of tools that include pesticides and application of gypsy moth pheromone to disrupt mating. Eradication has been achieved many times because once infestations fall below a threshold density they will decline to extinction due to failure of females to find mates. Other successful eradication efforts have focused on various ports where there have been occasional new introductions of gypsy moth from Asia, particularly the Russian Far East. Adult female gypsy moths from these regions are able to fly. Consequently, the rate of spread would be much faster, if they became established.

Further Reading

Among all terrestrial animals, only vertebrates and insects are richly endowed with a sense of hearing. By “hearing,” we usually mean the ability to detect minute, time-varying changes in air pressure that we familiarly experience as “sound.” Under this restricted definition, we can say that audition has evolved in at least seven orders of insects, including all of the major orders except the Hymenoptera (wasps, ants, bees). However, if we were to include under “hearing” the ability to detect sound waves in water and solids, or the displacement of molecules in a sound’s near field, then the number of “auditive” insects would expand enormously to include not only the Hymenoptera but even small orders such as Plecoptera (stone flies) and Isoptera (termites). Initially, we focus on the form and function of tympanal ears, which are organs that are sensitive to sound signals that are propagated through the air or water as fluctuations in pressure and which come to mind when we (humans) use the term “hearing with ears.” Following this, we provide some examples of nontympanal hearing organs.

Using sound, vertebrates and insects are often capable of sensing, identifying, and locating their predators, prey, conspecific rivals, and mates by hearing their intentional or unintentional acoustic signals. As might be expected, natural selection has shaped the form and function of hearing organs (ears) in insects over evolutionary time. In this respect, the ears of insects show much greater diversity than those of vertebrates, for reasons that will be apparent in our discussion. However, it must be emphasized that despite the scope of morphological diversity among insect ears, there is a morphological “bauplan” (structural design) that underlies their great range in behavioral and physiological function.

**MORPHOLOGICAL REQUIREMENTS**

There is tremendous morphological diversity of insect ears (Fig. 1). The multitude of different ear designs and locations reflects the unique physical and behavioral challenges faced by each insect. Yet despite their many differences, most ears follow a similar morphological plan. Each typically consists of three identifiable substructures: a tympanal membrane, a tracheal air chamber, and a chordotonal sensory organ.

**Tympanal Membrane**

The tympanal membrane (eardrum) is a thinned region of exoskeleton, typically supported by a chitinous ring and stretched across an enlarged air-filled cavity. Sound impinges upon the membrane, setting it and its associated nerve cells into motion. The thickness of the membrane can vary from 1 to over 100 μm. The ultra-sound-sensitive...
ears of many nocturnal Lepidoptera (butterflies and moths), for example, are so thin that they are transparent. Such fragile membranes are typically protected within body cavities or by external flaps of cuticle. In contrast, the thicker, opaque tympanal membranes of some diurnal butterflies or grasshoppers are conspicuously positioned on the outer surface of the body.

**Tracheal Air Chamber**

The internal face of the eardrum backs onto an enlarged air-filled chamber, which forms part of the tracheal respiratory system. In some ears, the air chambers are connected directly to other sound input sources (spiracles or contralateral ears) or resonating chambers via the tracheal system. In a few rare cases [e.g., green lacewings (Chrysopidae) and some water bugs (Corixidae)] the tympanic chambers are largely fluid filled.

**Chordotonal Organ**

Associated with the inner surface of the tympanal membrane is one to several chordotonal organs. Chordotonal organs are specialized mechanoreceptors unique to insects and crustaceans, but not unique to ears. Each chordotonal organ comprises one or more individual sensory units called scolopidia, and each scolopodium consists of three cells arranged in a linear array: a sensory cell, a scolopale cell, and an attachment cell (Fig. 2A). The total number of scolopidia in an ear ranges from one in some moths (Notodontidae) to almost 2000 in the bladder grasshopper (*Bulacris membracioides*). A chordotonal organ may attach directly to the inner surface of the tympanic membrane (e.g., Fig. 4E) or to tracheal air sacs indirectly associated with the tympanum. The axons of the sensory neurons collectively make up the auditory nerve that forms the neural link between the mechanosensory stimulation of the eardrum and its “perception” by the central nervous system. Vibrations of the eardrum and/or air chamber cause bioelectric currents to flow in the sensory cell, initiating action potentials in the auditory nerves and signaling neurons in the auditory pathways of the nervous system.

**MECHANISMS**

Sound waves are fluctuations in pressure traveling through a medium away from a source of mechanical disturbance. Tympanic ears are designed to detect these minute pressure changes traveling through air or water. Depending on the structural design of the ears, they may convey information about the location, frequency, and intensity of an acoustic stimulus.

There are two distinct types of insect tympanal ears: pressure receivers and pressure difference receivers (or pressure gradient receiver). In a pressure receiver, the tympanal membrane forms one side of an otherwise enclosed air chamber. The membrane vibrates in response to sound waves arriving only to the external surface of the tympanal membrane. In insects whose ears are sensitive to high-frequency sounds (like many bat-detecting moth ears), the sound shadow of the body is sufficient to cause a difference in sound amplitudes arriving to each ear, which provides useful directional cues to the animal. Many insects using lower frequency sounds are faced with the difficulty of being able to localize sounds that arrive almost simultaneously to both ears. They overcome this problem using pressure-difference receivers in which the sound impinges on both the outer and the inner surfaces of the membrane, and the membrane vibrates in response to the difference in pressure between the two sides (e.g., Fig. 3).

**FIGURE 2** Insect tympanal sensory receptors. (A) A typical tympanal scolopidial organ, consisting of three cell types. The dendrite of a bipolar sensory neuron projects into a fluid-filled space (lumen) formed by the walls of an enveloping scolopale cell. The distal tip of the dendrite inserts into the scolopale cap, an extracellular secretion of the scolopale cell. The attachment cell connects the sensory neuron and scolopale cell to the tympanal membrane, either directly or indirectly via a tracheal air sac. A chordotonal organ may have from one to several thousand scolopidia. (B) A schematic diagram depicting the hypothetical transition from a wing-hinge proprioceptive chordotonal organ to a tympanal hearing chordotonal organ. The top two images show a chordotonal organ functioning as a proprioceptor monitoring wing movements. At the bottom, the chordotonal organ has been mechanically isolated within a rigid tympanal cavity and attaches to a thinned region of cuticle (the tympanic membrane) that detects sounds. (A was modified, with permission, from Gray, E. G. (1960). The fine structure of the insect ear, *Philos. Trans. R. Soc. B* **243**, 75–94. Illustrations by M. Nelson.)

A third and very unusual way to localize sounds has been “invented” by certain parasitic tachinid and sarcophagid flies. These flies localize their hosts (field crickets, katydids, and cicadas) by hearing and then honing in on the mating calls. The ears possessed by these flies are conventional chordotonal organs, containing 70 or more scolopidia. However, the *fly’s* ear drums are mechanically connected, which conveys an acute sense of directionality such that they can detect and localize their calling hosts/prey from a distance of tens of meters, even from high in the air. Such ears appear to be unique to these parasitoid flies.

The frequencies detectable by insect tympanal ears range from a few kilohertz (e.g., the water boatman *Corixa*) to over 100kHz (e.g., some tetrigoniid species). This broad bandwidth of frequency sensitivity is used by some insects for mate calling and in others it enables them to detect their predators (e.g., echolocating bats). Some insects have the ability to discriminate between different sound frequencies, which may be achieved at the level of the tympanal membrane or the chordotonal organ. To date, most insect ears studied appear to be tone deaf (i.e., different tones are indistinguishable).

**LOCATION**

Ears can be located just about anywhere on insects (Fig. 1). There is one striking difference between insect ears and vertebrate
ears: those of the latter, because of developmental constraints, are always on opposite sides of the head and always on the head, whereas insect ears have been found on virtually every part of the body. Of course, in any given species of insect, ears are always found on the same part of the body, but from group to group, ears may be found on the head, legs, wings, thorax, or abdomen.

Although the ears of most insects are clearly recognized by the presence of a conspicuous tympanal membrane either on the body's external surface or within an ear cavity, the ears of other insects are morphologically cryptic. For example, some hawk moths (superfamily Sphingoidea) possess hearing organs in their mouthparts, and by inflating their palps while they are feeding on flowers at dusk, they create functional ears that alert them to the echolocation calls of bats. The “cyclopean” ear of the praying mantis is located within a deep groove between the hind legs, and the tympanal membranes are not morphologically distinct from surrounding body parts, even to the trained eye. Even more cryptic are the ears of the Madagascar hissing cockroach, Gromphadorhina portentosa, in which there is no obvious eardrum or tympanal membrane overlying the internal chordotonal organs contained within the tibiae of its forelegs.

Although most insects possess a single pair of hearing organs, there are at least two reports of insects with multiple ears. One lineage of praying mantids has two sets of ears: one located between the mesothoracic legs and tuned to ultrasonic frequencies (25–40 kHz) and another between the metathoracic legs and tuned to lower frequencies (2–4 kHz). The multieared bladder grasshopper (B. membracioides) of South Africa has six pairs of serially repeated abdominal ears that function in detecting mating calls at distances of ~2 km.

**DEVELOPMENTAL ORIGINS**

In vertebrates, ears are always located on the head, behind the eyes, and above the jaw, but in insects they are virtually anywhere on the body. Why are they not confined to one place like those of vertebrates? Evolutionary and developmental origins of the vertebrate ear, drawing from embryological anlagen (organs or structures in their earliest state) such as the gill arches, neural crest, and the otic capsule, have constrained the ears to their canonical position in the head. Insect ears require two structural modifications, cuticular and spiracular, combined with innervation by a chordotonal organ. In the insect body, chordotonal organs do not function only as hearing organs, but are actually widely distributed throughout the body, where they act as detectors of self-induced body movements ( proprioceptors) or substrate vibrations. Insect bodies are made up of a series of hard cuticular plates joined by flexible membranes, and chordotonal organs are frequently suspended between moving joints. We now know through developmental studies and comparative anatomy that it is not so difficult to “construct” an ear by making a few peripheral modifications to an existing proprioceptor and its surrounding cuticular and tracheal structures. By simply thinning the cuticle, enlarging the surrounding tracheal air sacs to allow membrane vibration, and mechanically isolating the sensory organ from body movements, a proprioceptor can be converted into a sound-pressure receiver (Fig. 2B). For example, the bat-detecting ears on the thorax of noctuoid moths are thought to have evolved from proprioceptors monitoring wing movements. Given the jointed, segmental body plan of any insect, the ubiquitous branching of the respiratory tracheae lining the inner face of the cuticle, and the widespread occurrence of chordotonal organs that span different segments in the body and appendages, the precursors of an insect ear can be found virtually at every joint in the body and appendages. There seem to be few developmental constraints in positioning an ear, should an adaptive need arise.

Given so many possibilities for developing an ear, how does it come about that a particular insect possesses an ear in one place, say its forelegs, and another species in another, say its abdomen? One can imagine a host of anatomical, biophysical, ecological, and evolutionary constraints and advantages that might play important roles in the selection process. Such factors as the distances between the ears, the degree of protection offered by surrounding structures, the availability of tracheal air sacs, or the preexisting connections to the central nervous system may all be important. For example, if the function of hearing in a flying nocturnal insect like a moth is to detect and avoid echolocating bats, then a proprioceptor with preestablished neural connections to wing flight musculature would be a better ear candidate than, say, a leg proprioceptor. Or, possibly, the reason the thorax and abdomen are so “busy” with ears (Fig. 1) could be because these locations offer maximum interaural distance and a high degree of protection.
EVOLUTION

Tympanal ears have evolved independently at least 20 times within the class Insecta, and this number surely underestimates the number of ears that do exist. Still, hearing appears to be the exception, not the rule, for insects, with only 7 of the 25 recognized extant neopteran orders having tympanate species. The Orthoptera (crickets, grasshoppers, and katydids) and the Lepidoptera (moths and butterflies) boast the largest number of eared species. In two of the most species orders, the Diptera (flies and mosquitoes) and the Coleoptera (beetles), tympanal ears are rare, and surprisingly, the Hymenoptera (wasps, ants, and bees) are completely atympanate as far as we know. Following is a brief introduction to the major taxonomic groups for which tympanal ears have been identified to date.

Orthoptera

Orthopteran ears come in two different forms and are divided nicely by the taxonomy of the order. The Acridoidea (locusts, grasshoppers) have ears on either side of the first abdominal segment. The tympanal membranes are nearly circular, opaque, and clearly visible upon inspection with the naked eye. Tracheal sacs connect both ears, allowing the locust to determine the direction of a sound source. The acridid ear is one of the few insect ears known to have the capability of pitch discrimination. About 60–80 scolopidia form four separate groups that attach to different regions of the eardrum, which, in turn, resonate to different sound frequencies. The ears of extant acridids function primarily in conspecific communication, but comparative evidence suggests that the primitive function was for predator detection.

In the suborder Ensifera (crickets (Gryllidae), katydids (Tettigoniidae)) the ears occur just below the “knee” region, on the tibia of the forelegs. Each leg has two eardrums—one on each side of the leg (Fig. 3). The tympanal membranes are connected to other sound input sources (the spiracles, contralateral ear) via a system of tracheal tubes and air chambers, which play important roles in directional hearing. The ensiferan auditory chondotonal organ (crista acoustica) has typically between 60 and 80 sense cells arranged in a linear array down the leg, connecting indirectly to the tympanal membrane by tracheal air sacs. Like the acridid ear, the ensiferan ear is capable of pitch discrimination. Presumably, the function of hearing in primitive Ensifera was conspecific communication, which remains the primary function in extant species. Some species are sensitive to ultrasound and use their ears to detect bats in addition to communicating with conspecifics. Fossil records demonstrate that the ancestors of modern Ensifera, which predate the appearance of bats by at least 100 million years, had ears on their legs and therefore, ultrasonic hearing for defense against bats seems to have evolved secondarily.

Lepidoptera

Tympanal ears have evolved more times within the Lepidoptera than any other insect order. To date, at least seven ears of independent origins have been described. Ears are located in the mouthparts (Sphingidae), at the base of the forewings (butterflies: Hedyloidea, Nymphalidae), in the thorax (Noctuoidea), or on anterior abdominal segments (Tineoidea, Pyraloidea, Drepanoidea, Geometroidea, Uranidae). Moth ears are among the simplest of all insect ears in that they have very few auditory sensory cells (one, two, or four). K. D. Roeder first demonstrated that the primary function of hearing in moths is to detect the ultrasonic echolocation cries of insectivorous bats. Despite their simplicity, moth ears are capable of determining the distance and direction of an approaching bat. Flying moths evade bats by either turning away from a distant bat or engaging in evasive and erratic flight maneuvers to avoid a sudden and unexpected attack. W. E. Conner has shown that some species, including many day-flying tiger moths (Arctiidae), use their hearing in social interactions. In most Arctiidae, ultrasound production functions to either jam a bat’s echolocation calls or warn the bat of a distasteful meal (aposmatic display), but in those species that use sounds for social interactions, both hearing and sound production have secondarily taken on different roles.

Hearing in butterflies has only begun to be explored. The hedylid butterflies of the neotropics, unusual because of their nocturnal habits, have ultra-sound-sensitive ears on their wings that function as bat detectors (Fig. 4). Some diurnal butterflies of the family Nymphalidae possess earlike structures on their wings, and there is evidence that the “cracker” butterfly (Hanadrys hermonia) uses its ears for conspecific communication. No doubt there will be further examples of butterfly hearing in the near future, since tympanal-like structures have been described anatomically in many species.

FIGURE 4 Nocturnal butterflies of the superfamily Hedyloidea possess ultra-sound-sensitive ears on their wings that mediate evasive flight maneuvers to avoid bats. The hind wing and a dense fringe of scales have been removed to reveal the tympanic cavity. Ca, canal; Cj, conjunctiva. Scale bar, 110 μm. (D) Consecutive video images (30 frames/s) of a free-flying M. hellionaria responding to a short (~250 ms), high-frequency (25 kHz), high-intensity (>100 dB) sound. The direction of flight is marked with an arrow and the stimulus onset with an arrowhead. (E) Scanning electron micrograph of the two most proximal chondotonal organs (arrows), viewed from inside the tympanic chamber. The largest organ attaches to the proximal border of the tympanal frame (black arrow). TM, tympanic membrane. Scale bar, 50 μm. (A and E courtesy of J. Yack. B–D were modified, with permission, from Yack, J. E., and Fullard, J. H. (2000). Ultrasonic hearing in nocturnal butterflies. Nature 403, 265–266.)
**Homoptera and Heteroptera**

Most people are familiar with the loud “buzzing” sounds of cicadas (Cicadidae) during hot weather; these are typically males calling to females. Cicada ears are located within cavities on the ventral side of the second abdominal segment. They are among the largest of all insect ears, with over 1000 scolopidia in each ear. It has been suggested that the large number of sense cells enhances the ear’s sensitivity for long distance communication, but cicadas do not appear to have more sensitive hearing organs than other insects with far fewer scolopidia.

Water bugs (suborder Hydrocorisae) are reported to have ears on various body parts, including the mesothorax, metathorax, or first abdominal segment. The best known is the ear of the water boatman, *Corixa* (Corixidae), which occurs on the lateral mesothorax between the wing and the leg. The ears, like those of moths, are simple, with only two auditory cells, both tuned to low-frequency sounds (1–2 kHz), within the range of conspecific calls. The insect carries a bubble of water with it to allow the membrane to vibrate under water. Unlike most other insect ears, the tympanal membrane is backed by fluid, not air. Hearing in corixids appears to function primarily for mate attraction.

**Diptera**

Although it had been well documented that certain parasitic flies were attracted to the songs of crickets, katydids, and cicadas, until recently, it was not known how these flies were eavesdropping on their hosts. Two families of parasitoid flies (Sarcophagidae and Tachinidae) have independently evolved a pair of peculiar ears on their prothorax, just below the head, in the “neck” region (Fig. 5). The gravid females use their ears to locate singing insect hosts upon which to lay their predaceous larvae. The ears of the two parasitoid groups are described earlier in this article. The design features of these dipteran ears show remarkable convergence in anatomy and function, despite the fact that tachinids and sarcophagids are only distantly related. This suggests that evolutionary and developmental constraints are at work here in ways that we do not yet understand.

**Mantodea**

Until recently, praying mantids were thought to be deaf; now we know that 65% of all mantid species can hear. The ears occur in the most bizarre location: the two tympanal membranes face one another inside a narrow groove between the metathoracic legs. The mantid ear is functionally an “auditory cyclops” because the close proximity of the eardrums (less than 150 μm) provides no directional information to the animal. The ears function as bat detectors and are most sensitive between 25 and 50 kHz.

**Coleoptera**

Tympanal ears have been described in two beetle families to date. Several species of the genus *Cicindela* (Cicindelidae) have ears on the dorsal surface of the first abdominal segment, beneath the wings. Some scarabs (two tribes in the subfamily Dynastinae) have ears located just beneath the neck membranes (pronotal shield). The ears of both families are tuned to ultrasonic frequencies, and there is strong evidence that they function as bat detectors. It is a little bit surprising that there are not much examples of hearing in beetles. Given the large number of species, the wide diversity of niches worldwide, and numerous reports of sound production, we expect that more examples will be uncovered.

**Neuroptera**

Green lacewings (Chrysopidae) have an ear near the base of each forewing in a location similar to that of the ears of some butterflies. The ear consists of a swelling of the radial vein, with a region of very thin cuticle on the ventral side that functions as a tympanal membrane. Like the corixid ear, the tympanal chamber is predominantly fluid filled. The ears respond to sounds between 40 and 60 kHz and are sufficiently sensitive to detect echolocating bats at close distances.

**NONTYMPANAL HEARING ORGANS**

Until now we have focused on tympanal ears, which are sensitive to traveling waves of changing pressure in air and water, known as the acoustic far field. In the broadest sense of the word, however, hearing encompasses the detection of near-field sounds, as well as vibrations traveling through solid substrates. By and large, the near field can be thought of as a short distance, a few body lengths, from the sound source. Substrate vibrational signals have also been described as “seismic communication.” In this larger sense, then, we could argue that most insects can hear. We highlight a few recent developments in the study of these alternative, but no doubt widespread, forms of hearing.

**Detecting Near-Field Sounds**

When a sound is produced, air particles are being pushed back and forth near the source of disturbance. These particle movements, or near-field sounds, are generally of low frequency (typically below

![FIGURE 5](image-url) The prothoracic tympanal ear of a parasitoid tachinid fly, *Ornoria ochracea* (Tachinidae). (A) A female fly resting on its host (*Gryllus integer*); (B) a light micrograph of the pronotal ear in a female. The outline of the tympanal membrane is indicated with arrows. (Photograph courtesy of D. Robert, R. Hoy, and G. Haldimann.)
Avoidance and possibly for close-range conspecific communication. Setae on the cerci of crickets and cockroaches function in predator avoidance and possibly for close-range conspecific communication.

Some caterpillars can detect the near-field sounds produced by the beating wings of a flying wasp up to distances of 70 cm. Specialized hair on the dorsal thorax of the caterpillar are displaced in the sound's near field, eliciting an evasive response, such as freezing or dropping from a leaf. Similar particle-displacement-sensitive setae on the cerci of crickets and cockroaches function in predator avoidance and possibly for close-range conspecific communication.

The antennae of many insects also function as near-field sound detectors. In many Diptera (mosquitoes, chironomids, and fruit flies), for example, the males are attracted to the near-field “buzzing sounds” of females (Fig. 6). The long flagella of the antennae in male mosquitoes resonate to the tune of flying females, and these antennal movements in turn stimulate many thousands of scolopidia in the Johnston’s organ, a chordotonal organ located at the base of the antennae. The Johnston’s organ may also be involved in the detection of near-field sounds produced by honey bee waggle dances. It is also the sensory organ by which the well-known *Drosophila melanogaster* detects the patterned wingbeats that make up the mating songs of these species.

**FIGURE 6** The near-field sound hearing organs of a mosquito. (A) Micrograph of the head of a male *Toxorhynchites brevipalpis*, showing the plumous flagella of the antennae (blue arrows), which resonate in response to the near-field sounds of flying females. (B) A cross section through the antennal base, showing the location of the Johnston’s organ (green arrows), where the auditory scolopidia are located. (Part A is courtesy of D. Huber. Part B was adapted, with permission, from Göpfert, M. C., and Robert, D. (2001). Active auditory mechanisms in mosquitoes, *Proc. R. Soc. London B** 268, 333–339.)

**Detecting Substrate-Borne Vibrations**

The detection of vibrations traveling through solid substrates may be one of the most ubiquitous but least appreciated forms of acoustic communication in insects. With recent technological advances in the detection of substrate-borne signals (e.g., laser vibrometry and piezoelectric sensors), we are learning that a large number of insects can detect vibrations produced by both intentional and unintentional senders. In fact, most insect orders probably include species capable of detecting vibrations. At present, however, there are few complete studies on this subject. We provide two recent examples out of many possibilities.

Membracid treehoppers (Homoptera; Membracidae) transmit alarm calls through tree stems to communicate with conspeicies. Nymphs living in colonies of up to 100 individuals on the stem of a host plant produce coordinated waves of vibrations when threatened by a predator. The mother treehopper detects these alarm calls and rushes to defend her offspring, by kicking her hind legs and fanning her wings at the intruder (Fig. 7A). For many species of caterpillars that live in social or crowded conditions, vibrational signaling may be the principal means of communication. The common North American masked birch caterpillar (*Drepana arcuata*) engages in acoustic “battles” with invading conspeicies. The nest owner drums and scrapes its mandibles and scrapes modified “oars” against the leaf in ritualized acoustic displays. Acoustic “duels” between residents and intruders can last from a few minutes to a few hours (Fig. 7B). At present, we know little about how insects detect substrate vibrations. The subgenual organ (a chordotonal just “below the knee” in many insects) functions as a vibration receptor in some groups (like some crickets and termites), but for most insects, the receptor organs are yet to be identified. Clearly further research is required before we gain a full appreciation of this important form of communication in insects.

**FUNCTION**

Because of their physical properties, acoustic signals are highly adaptive for certain kinds of behavioral interactions: sound waves can travel at any time of the day or night, through thick vegetation or muddy...
Hemolymph

Michael R. Kanost
Kansas State University

Hemolymph is the circulating fluid or “blood” of insects. It moves through the open circulatory system, directly bathing the organs and tissues. Insect hemolymph differs substantially from vertebrate blood, with the absence of erythrocytes and a high concentration of free amino acids being two of the common distinguishing features. The main component of hemolymph is water, which functions as a solvent for a variety of molecules. Water in hemolymph makes up to 20–50% of the total water in insect bodies, with larval stages generally having a larger relative hemolymph volume than adults. Hemolymph serves as a water storage pool for use by tissues during desiccation and as a storage depot for other types of chemicals. It also contains circulating cells called hemocytes. Hemolymph can function as a hydraulic fluid, for example, in the expansion of a newly molted butterfly’s wings. Hemolymph serves important roles in the immune system and in transport of hormones, nutrients, and metabolites.

INORGANIC COMPONENTS

The composition of inorganic ions in hemolymph varies widely among different insect groups. The pH of the hemolymph of most insects is in the range of 6.4–6.8. Apterygotes contain high levels of sodium and chloride, similar to mammalian blood. In hemolymph of exopterygotes, sodium and chloride are also high but magnesium makes

CONCLUSION

Since antiquity we have known that many insects produce sounds, but only during the past 150 years have scientists realized that some insects can hear. Detailed descriptions of ear anatomy, and the behaviors associated with hearing, began in the early 1800s, providing the basis for current developments in the field of insect bioacoustics. Over the past 40 years there have been significant advances in the field: many new ears have been discovered, and previous claims to tympanal hearing (based on morphological studies) have been validated. With the development of new instruments for detecting acoustic signals outside the realm of human perception (e.g., ultrasound, solid-substrate-borne vibrations), and for recording neurophysiological responses to sound, we are now beginning to better appreciate the immense diversity of insect sound receptor organs.

There is still much to learn about insect hearing. We know little, for example, about the chain of physical and bioelectrical events leading to sound reception at the level of the auditory cells or how acoustic sensory responses are integrated at the level of the central nervous system to promote adaptive behaviors. New tympanal ears will no doubt turn up in the years ahead, but perhaps most significantly, future explorations into substrate-vibrational and near-field sound communication are sure to yield exciting insights into how insects communicate acoustically.

Further Reading

up a large portion of the total inorganic cations. In endopterygotes, particularly Lepidoptera, Coleoptera, and Hymenoptera, concentrations of sodium and chloride tend to be much lower and are replaced with high levels of potassium, magnesium, and organic anions. This difference has been attributed to the coevolution of these insect groups with flowering plants and the consequent dietary importance of leaves (which contain high concentrations of magnesium and potassium). However, the concentration of inorganic ions is not a function of only the diet, because insects are able to regulate the ion composition of hemolymph to some degree.

LOW-MOLECULAR-WEIGHT ORGANIC COMPONENTS

Citric acid and other organic acids and organic phosphates (such as glycerol 1-phosphate and sorbitol 6-phosphate) account for much of the anion content in hemolymph from many insect species. The most abundant carbohydrate in hemolymph of most insects is the disaccharide trehalose. Transport of trehalose as an energy source for tissues is an important function of the hemolymph. Trehalose levels are hormonally regulated and can be increased through synthesis from glucose phosphate derived from glycogen stored in the fat body. Glucose may also be present in hemolymph, although generally at a lower concentration than trehalose. In some insects, diapause or exposure to low temperatures can stimulate synthesis of glycerol and sorbitol (from glycogen stored in fat body). The resulting high concentration of these compounds in hemolymph depresses the freezing point and protects the insects from damage that would occur if ice crystals were to form in hemolymph.

Hydrophobic lipoidal compounds present in hemolymph are carried by specific transport proteins. Diacylglycerol is the major transported form of lipid in most insects, but triacylglycerol, fatty acids, phospholipids, and cholesterol are also present. Pigments such as β-carotene, riboflavin, and biliverdin, which give hemolymph of many insects a characteristic yellow or green color, are also carried by specific proteins.

Free amino acids are present at high concentration (up to 200 mM) in hemolymph and make a major contribution to hemolymph osmolality. All 20 of the amino acids found in proteins exist as free amino acids in hemolymph. Although the relative concentrations of the amino acids vary in different species, glutamine and proline are typically abundant. Proline is known to serve as an energy source for flight muscles in some species. Hemolymph may also contain ammonia from the diet, because insects are able to regulate the ion composition of hemolymph to some degree.

PLASMA PROTEINS

Proteins are a major component of the hemolymph plasma. Typical protein concentrations in plasma range from 10 to 100 mg ml⁻¹. In most species, the concentration of proteins in plasma increases during each instar and decreases at each molt. The fat body is responsible for the synthesis of the majority of plasma proteins, but there is also a contribution of some specific proteins from epidermis and hemocytes. Plasma from each species contains a few very abundant proteins and more than a hundred other proteins at much lower concentrations. Although the identities and functions of the major proteins are understood, many of the minor hemolymph proteins have not yet been thoroughly investigated.

Storage Proteins

The most abundant proteins in larval hemolymph belong to a class known as storage proteins or hexamerins (because they are assembled from six ∼80 kDa polypeptide subunits). The storage proteins are synthesized by the fat body and reach extremely high concentrations in the last instar. At the end of this stage, most of the storage proteins are taken back into the fat body, through interaction with specific receptors, and stored in protein granules. During metamorphosis the storage proteins are broken down into free amino acids, which are used for synthesis of other proteins required in the adult stage. In some exopterygotes, hexamerins are again synthesized by the adult, although their function at this developmental stage is unclear. The hexamerins can be classified according to their amino acid compositions. Those rich in the aromatic amino acids (phenylalanine, tyrosine, and tryptophan) are called arylphorins, whereas another group of hexamerins are known as methionine-rich storage proteins. In addition, some other proteins that function as storage proteins but are not similar in sequence to the hexamerins have been identified in lepidopterans.

Transport Proteins

Several hemolymph proteins function to transport small molecules that have low solubility in water. Insect plasma contains two proteins that specifically bind iron; ferritin appears to sequester dietary iron, whereas transferrin acts as a shuttle to transport iron between tissues. The most abundant transport protein in hemolymph is lipophorin, which transports lipids between tissues. Like lipoproteins in mammalian plasma, lipophorin is composed of proteins that complex with lipids in such a way that the lipids are protected from contact with the surrounding water. Lipophorin docks with specific receptors on the surface of tissues to either accept or unload diacylglycerol. Lipophorin contains two polypeptide subunits, apolipophorin-I and apolipophorin-II, which are produced by proteolytic cleavage of a larger protein precursor. In insects that use lipids as a fuel for flight muscles, diacylglycerol is released from the fat body into the hemolymph under control of a peptide hormone known as adipokinetic hormone. As lipophorin accepts large amounts of diacylglycerol, its volume increases and its density decreases as it is converted from high-density lipophorin to low-density lipophorin. Low-density lipophorin contains a third type of protein subunit, apolipophorin-III, which binds to the surface to stabilize the expanding lipid-water interface.

Juvenile hormone (JH), a sesquiterpenoid lipid, has low solubility in water and is transported through hemolymph bound to a specific carrier protein. JH binding proteins of ∼30 kDa have been well characterized from plasma of lepidopterans, whereas in other insect orders lipophorin or a specific hexamerin takes on the role of JH transport. In addition to keeping JH in solution, these proteins also protect the hormone from degradative enzymes that help to regulate JH concentration in plasma. JH binding proteins may also aid in delivery of the hormone to target tissues.

Egg Yolk Proteins

In adult female insects, certain proteins synthesized by the fat body and secreted into the hemolymph are delivered to the ovary, where they are taken up by developing oocytes. The most abundant of these is called vitelligenin. Once vitellogenin becomes a part of the egg yolk, it is called vitellin. Vitellogenins are typically large,
phosphorylated lipoglycoproteins that are expressed specifically in adult females. Lipophorin is also taken up from hemolymph into eggs and provides additional lipids for use by the developing embryo. Vitellogenin and lipophorin are related in their amino acid sequences, indicating that they have a common ancestral gene. Vitellogenin, lipophorin, and a few other plasma proteins are taken up into oocytes by receptor-mediated endocytosis.

Proteins and Peptides Involved in Immune Responses

A group of plasma proteins functions in defense against microbial infection. Hemolymph of many insects contains lysozyme, an enzyme that degrades bacterial cell walls. In addition, low-molecular-weight antimicrobial peptides are synthesized in response to bacterial or fungal infection. Many of these peptides act by disrupting the integrity of bacterial cell membranes. Phenoloxidase, an enzyme present in plasma of some species and stored in hemocytes of others, is synthesized as an inactive precursor, prophenoloxidase. In response to infection or injury, prophenoloxidase is activated and catalyzes the production of quinones that polymerize to form the pigment melanin, which helps to trap and kill invading organisms. The tendency of hemolymph to darken has been known for more than 100 years, but this melanization has only recently become understood at a molecular level. Plasma contains proteins that bind to carbohydrates on the surface of microorganisms. This causes activation of a cascade of proteases that results in the proteolytic activation of prophenoloxidase. To regulate this immune response, plasma contains several types of proteins that function as protease inhibitors.

HEMOCYTES

The circulating cells in hemolymph are called hemocytes. Insects lack erythrocytes, and hemocytes cannot be directly equated with vertebrate leukocytes. Some fraction of hemocytes remains sessile and attached to the surfaces of tissues, and in some species (e.g., mosquitoes) such cells may account for a majority of the hemocytes. Several different morphological types of hemocytes can be identified in each insect species. Some commonly observed hemocyte types are illustrated in Fig. 1. Prohemocytes are small, round cells that may be precursors from which some other cell types develop. Granular hemocytes contain conspicuous cytoplasmic granules that can be discharged as part of a defensive response to invading parasites. Plasmatocytes usually contain few granules and are characterized by their ability to change from round or spindle-shaped cells in suspension to extensively flattened, amoeboid cells after attaching to a substrate. Spherulocytes contain very large cytoplasmic granules, which may contain mucopolysaccharides. Oenocytoids are large cells that synthesize phenoloxidase.

Plasmatocytes and granular hemocytes are usually the two most abundant hemocyte types, although their proportions can vary between species and within a species at different developmental stages. These two hemocyte types participate in immune responses, including (1) phagocytosis of small organisms such as bacteria; (2) nodule formation, in which multiple hemocytes aggregate to trap microorganisms; and (3) encapsulation, in which hemocytes attach to the surface of a larger parasite and form a multilayered hemocyte capsule, in which the parasite is killed. Nodules and capsules often become melanized as an inactive precursor, prophenoloxidase. Hemocytoids, especially plasmatocytes, also aggregate in a type of coagulation response, sealing wounds to prevent hemolymph loss. Another function of hemocytes is in synthesis of the extracellular matrix that covers tissues exposed to the hemolymph. Granular hemocytes appear to be the primary cell type involved in this aspect of hemocyte function.

Hibernation refers to the state in which animals pass the winter. In discussion of insects overwintering is often used as a synonym for hibernation; usually hibernation is associated with entry into a dormant state. Estivation is a term used for animals that become dormant in the summer. Some insects enter an extended period of dormancy, referred to as estivation, which begins in summer and continues through the winter. This term also is used commonly in connection with those mammals that lower their body temperature slightly (e.g., carnivorean lethargy in bears and skunks) or extensively (e.g., hibernation sensu stricto in ground squirrels) during the winter.

It is critical for insects to synchronize their periods of feeding, growth, and reproductive activities with those times of the year when food is available and environmental conditions are suitable. Hibernation generally includes entry into diapause, a dormant state that promotes survival by depressing metabolism and energy utilization when host plants and other food sources are unavailable. Typically, this also includes reduced morphogenesis in immature stages; hibernating adults typically hibernate before reproducing.

Specific behavioral changes are often associated with movement to overwintering sites, termed hibernacula. One of the most extreme examples is the monarch butterfly (Danaus plexippus), which may migrate more than 5000 km from southern Canada and New England to mountain sites in central Mexico. Other insects migrate locally as they move to hibernacula within the soil where they may burrow to avoid exposure to winter cold. Still others seek sites beneath rocks, logs, bark, and leaf litter.

In temperate regions, insects typically hibernate in a specific life stage. The egg, larva, and pupa are more common stages for overwintering than is the adult. However, alpine and polar insects or others living in extreme environments, in which growing seasons are short or unpredictable, and having life cycles that may be extended over several years may hibernate multiple times in one or more life stages.

In temperate regions, most hibernating insects enhance their resistance to environmental extremes, particularly cold and desiccation. During autumn, many species markedly enhance their tolerance to low temperature, termed cold-hardening. Most insects are freezing intolerant and are unable to survive freezing within their body fluids. These species typically enhance their capacity to supercool (i.e., remain unfrozen at temperatures below the melting point of their hemolymph) by synthesizing glycerol, sorbitol, trehalose, or other cryoprotective compounds, often at high concentrations of 1 M or more. Production of antifreeze proteins, avoidance of inoculative freezing by external ice, and ridding the body of ice nucleators that may catalyze ice formation are other mechanisms used to avoid lethal freezing.

In contrast, a few insects are freeze tolerant and can survive the freezing of 70% or more of their body water. Cryoprotectants are also commonly synthesized by freeze-tolerant species, as are ice-nucleating proteins that induce ice formation at high subzero temperatures. Overwintering insects also may acquire exceptionally high levels of desiccation resistance, comparable to those of desert species.

Behavioral and physiological changes associated with hibernation, diapause, and cold-hardening are commonly triggered by environmental cues, including photoperiod, temperature, moisture conditions, and changes in host plant quality. These cues ensure that adaptive responses occur before severe winter conditions arrive.

History of Entomology

Edward H. Smith
Cornell University (Emeritus), Ashville, NC

George G. Kennedy
North Carolina State University, Raleigh, NC

This brief history traces the interactions of humans and insects dating from the adoption of agriculture some 10,000 years ago and its inherent ecological disruptions. Humankind’s early preoccupation with survival focused on insects as relentless pests, competitors for food and fiber, threats to health and comfort. The high hopes following World War II for relief from the bondage of insects through the use of chemical insecticides such as DDT proved unrealistic. The reassessment that followed led to a concept, based on ecological principles, that is referred to as integrated pest management (IPM). In this system, multiple control technologies are used, with the additive effect being to hold insect injury at acceptable levels, while avoiding excessive environmental insult. The age-old struggle continues; entomologists are now armed with the lessons of the past and aided by advances in insecticidal chemistry, biological and cultural control, and visionary new technologies based on genetic modification of plants and animals. Entomologists are also facing new challenges from invasive species brought on by the increased international movement of people and goods in the global economy.
and by global warming, which threatens to dramatically alter the geographic ranges of plant and animal species, including agricultural crops and their pests, as well as vectors of human and animal pathogens. Simultaneously, the rise of the environmental movement and ecological awareness has placed insects in a new context, highlighting their essential role in biodiversity on which the viability of the earth depends. The vision for the 21st century calls for compatibility between insect control and conservation; both are prerequisites to human well-being. Stewardship of the earth is the greatest challenge ahead and one that places awesome responsibility on the shoulders of entomologists.

IN THE BEGINNING

The history of life on earth reaches back some 4 billion years. From this beginning, the long evolutionary trail unwound. Along the way, 99% of the forms that appeared met with extinction. The great exterminations that have occurred since the appearance of insects in the Devonian period, 400 mya, have revealed insects' remarkable survival qualities. Insects witnessed the last of the trilobites that preceded them by 175 million years. By the time dinosaurs appeared in the Triassic period, 210 mya, the major orders of insects existing today were well established. Dinosaurs became extinct 66 mya, leaving a niche occupied in time by mammals. The mammals, in turn, provided a niche for insects, offering furry cover and warm meals. The disappearance of the dinosaurs coincided with a great radiation of insects based on insects' symbiosis with flowering plants. For the past 150 million years, the flowering plants and insects have honed their intricate coevolution, which accounts for their immense biodiversity on which human habitability of the earth depends.

Insects have withstood trial by ice and fire, meteorite strikes, volcanic eruptions, global dust veils, acid rain, and continental upheavals. This evolutionary experience is encoded in their DNA and attests to the advantage of their small size, external skeleton, flight, metamorphosis, and specialized systems of reproduction. These are significant credentials in insects' rivalry with Homo sapiens, a species that draws on an evolutionary history of a scant 7 million years.

COEXISTENCE, HUMANS AND INSECTS

The class Insecta has plagued and fascinated humans for all of their history. The most striking features of the Insecta are diversity and numerical superiority. Of the 5–30 million species estimated to compose the global flora and fauna, approximately 1.7 million have been named, and more than half are insects. It is estimated that insects make up 75% of the known animal kingdom.

Because insects occupy almost every conceivable terrestrial niche, they interact with humans in countless ways that accord them status as "pests." This same diversity bestows on insects essential roles in the functioning of the biosphere as a sustainable biological system. Considering the countless interactions between humans and insects, it is not surprising that insects have become fixed in the fabric of human culture. They have become important components of our art, language, literature, music, philosophy, and religion. In addition, insects are remarkable sources of knowledge, ideal models for the study of biological processes, including genetics, physiology, and molecular biology.

Professional entomologists find challenge in our universities, where they engage in teaching, in research to advance knowledge, and in extension, applying knowledge to the solution of applied entomological problems. In addition to professional entomologists, amateur naturalists are drawn to the study of insects because of their form, color, and behavior. As the expanding human population continues its modification of the natural habitat, the interface between humans and insects will become more problematic.

ENTOMOLOGICAL ROOTS

A mere 10,000 years ago, primitive hunter-gatherers made a great leap forward; they entered into partnership with plants, and thus agriculture was born. Thereafter, humans would seek to alter ecosystems to their advantage. They would intervene to favor some plants and animals over others, thereby altering the evolutionary process that had shaped the biological world for the preceding 4 billion years.

Insects in their coevolution with plants and animals had been a powerful force in shaping the biosphere. They posed a primary threat to humans' alteration of ecosystems to provide food, fiber, shelter, and comfort for themselves and their domestic animals. The struggle that followed moved through stages of ignorance, myth, religion, and then enlightenment through science and technology.

Our brief historical sweep will jump the seemingly long sleep of ancient civilizations and go to the Greek civilization in the time of Aristotle (384–322 B.C.). The orderly study of biology began with his speculations. He relied on his own observations, defined the field, posed questions, and accumulated evidence to answer them. Aristotle's vision of rationality lay dormant for centuries until the Renaissance. In the meantime, Judaism and Christianity imposed a new concept, one focused on God and creation as depicted in the book of Genesis. Accordingly, God created the world, directing man to "be fruitful and multiply..." and "with domination over every living thing that moves upon the earth" (Genesis 1:28). Man was not part of nature. Nature was subservient to man.

The scientific revolution of the 16th and 17th centuries marked the beginning of modern science and included mathematics, mechanics, and astronomy but had little impact on biology. While the revolution rejected superstition, magic, and the dogma of medieval theologians, it did not reject the ideological bias of the Judeo-Christian religion. The hand of God was still directing the course of the natural world.

Not until the 17th and 18th centuries was entomology advanced as a field of study within zoology. Anton van Leeuwenhoek (1632–1723) used the microscope to extend the power of the human eye. He was obsessed with the study of detail, including the morphology and specialized organs of insects. His revelations established insects as proper subjects for scientific study. Francesco Redi (1626–1697) demonstrated in 1668 that insects arose not from spontaneous generation but from eggs laid by fertilized females. Jan Swammerdam (1637–1680) did superb anatomical work on insects, including the honey bee.

The excitement of these discoveries was further enhanced by the flow of exotic plants and animals brought back from voyages on other continents. Charles Darwin's voyage of HMS Beagle in 1831–1836 followed this tradition. The wealth of material acquired made students aware of the need to classify the organisms collected and to assemble specimens in orderly collections. Other investigators focused on the activity of insects in the field and their role as pollinators and as agricultural pests.

A prerequisite to advancing the study of insects was the development of a classification system that would bring order out of chaos. The Swedish naturalist Carl Linnaeus (1707–1778) met this need. Although trained in medicine, he studied botany extensively and turned to the classification of plants, animals, and minerals. His Systema Naturae (10th Ed., 1758) is the foundation stone of zoological nomenclature.
He greatly simplified insect classification by using insect wings (hence the suffix -ptera, meaning wing, for most order names) as the basis for classification. The other great feature of his system was the designation of genus and species each by a single word, thus providing a binomial system to replace the unwieldy descriptive names employed earlier. Linnaeus’s “artificial” system of insect systematics based only on wings was in time modified by adding other characters to construct a “natural” system.

Another great naturalist, René Antoine Ferchault de Réaumur (1683–1757), infused a new perspective into the emerging study of insects. He deplored the confusion that existed regarding metamorphosis, distribution, and “industries” of insects. He championed the study of insects out of sheer curiosity, claiming that useful discoveries would be made in the process. His six volumes of *Mémoires pour Servir a l'Histoire des Insectes* (1734–1742) with their exacting attention to morphology and function, complete with accurate drawings, established a new standard of excellence.

The work of Linnaeus and Réaumur provided the templates for orderly classification and elucidation of fundamental and applied aspects of entomology. Their works were extended and refined by French naturalists Pierre André Latreille (1762–1833), Georges Cuvier (1769–1832), and Jean Lamarck (1744–1829). By the 19th century, entomology was firmly established in European zoological science. The taxonomic treaties established in this process were to provide guides for the classification of American insects. These sources were augmented by two sources in Great Britain, Gilbert White’s (1720–1793) *The Natural History and Antiquities of Selborne* (1789) and William Kirby (1759–1850) and William Spence’s (1783–1860) *Introduction to Entomology* (1816–1826). The writings of these field naturalists on the biological characteristics of insects made insects, at one point, the most popular components of natural history in Victorian England. In addition, they contributed to the development of the concept of the biological species. This concept, essential to the understanding of biological communities, recognizes a species as a reproductively (genetically) isolated group of interbreeding populations.

The next step in the unfolding of the biological sciences was a great one: the publication in 1859 of Charles Darwin’s (1809–1882) theory, *On the Origin of Species*. This event placed conceptual biology in a new light. In a single stroke, Darwin’s work challenged the natural theology that had dominated biological thought for three centuries. Natural theology had been elaborated in John Ray’s (1627–1705) *The Wisdom of God Manifested in the Works of the Creation*, published in 1691. The concept provided a truce between science and religion. It contended that God created the world and the evidence of His omnipotence was to be found in the study of His creatures.

There was no middle ground between Darwin and Ray. Darwin provided a new way of viewing biology. The living world had evolved; it could be explained on the basis of descent with change. It was noteworthy to entomologists that much of Darwin’s supporting evidence was derived from his study of insects dating from his days at Cambridge University (1828), where he was an avid insect collector.

Intense debate followed the publication of Darwin’s theory. Nowhere was the debate more intense than at Harvard University, where Asa Gray (1810–1888), a botanist and staunch Darwinian, challenged Louis Agassiz (1807–1875), the foremost naturalist of the world and unrelenting defender of the creationist view.

An unlikely pair of outspoken individuals led the pro-Darwinian entomologists of North America. Benjamin D. Walsh (1801–1869), who had collected beetles with Darwin at Cambridge University, emerged from obscurity on the Illinois frontier to assert his long-dormant entomological interest and declare his support for Darwinism. He was joined by the youthful Charles V. Riley (1843–1895), a fellow Englishman and self-taught entomologist who was then writing on entomology for the *Prairie Farmer*, the leading farm journal of the Midwest (Fig. 1). Their early collaboration on the issue of Darwinism bode well for the future. In time, evolution was accepted by biologists as a fundamental basis of the discipline, although segments of the public still oppose it as a challenge to the Creation story as reported in the Old Testament book of Genesis. The distinguished geneticist Theodosius Dobzhansky (1900–1975) summarized his views on the major fields of biology in his essay entitled “Nothing in Biology Makes Sense Except in the Light of Evolution” (1973).

**FIGURE 1** Charles V. Riley’s nine annual reports as the state entomologist of Missouri (1868–1876) figured prominently in the knowledge base on which the philosophy of insect control in North America was based.

**ENTOMOLOGY IN THE NEW WORLD**

**Nurturing Environment and Supporting Institutions**

**EMPIRE AND INSECTS**

Early entomological developments in the United States occurred in the climate of Thomas Jefferson’s America. Jefferson took office as the nation’s third president in March 1801 and proceeded to sell his vision to his countrymen, then numbering just over 5 million. The United States had only recently gained its independence from England. Louisiana, stretching from the Mississippi to the Pacific Ocean, although claimed by Spain, was available and being considered by Russia, France, and England. Of these three, France, energized by Napoleon, was feared the most. Despite the tenuousness of the situation, Jefferson clung to his
vision of this vast landmass, stretching from sea to sea, being united under a stable government of the United States. Napoleon’s agreement to sell Louisiana came as a surprise; its purchase, although not applauded by some leading politicians, was a masterful stroke. It doubled the landmass of the United States and resolved the feud over the control of the Mississippi River. But what had been purchased? To answer that question, Jefferson dispatched an expedition led by Captain Meriwether Lewis and Lieutenant William Clark (1804–1805) to explore the new acquisition. Their report, on their return, removed some of the mystique of the Pacific Northwest but provided only tantalizing glimpses of the area’s natural history. Unfortunately, the expedition included no trained naturalists.

The follow-up to Lewis and Clark’s report came in 1819–1820. Major Stephen H. Long, under authorization of President Monroe, led an expedition of “Gentlemen of Science” to study this vast unexplored territory, its natural history, and the American Indians of the Rocky Mountain region. Entomology was well represented by Thomas Say, whose affiliation with the Academy of Natural Sciences of Philadelphia had won him the reputation as “perhaps the most brilliant zoologist in the country.” Say epitomized the confidence and vision of the young nation’s leaders in natural history.

Although Say’s primary interest was insects, he covered the entire field of botany and zoology and conducted studies on the American Indians. His entomological studies provided the foundation for his American Entomology, published in three volumes (1824, 1825, and 1828). These were the first books on North American insects. They were beautifully illustrated by the artistic talents of his wife Lucy and Titian Peale of the distinguished family of Philadelphia artists. They provided a stimulus for American entomologists and signaled their emancipation from the European centers to which the study of American insects had previously been consigned, named by Europeans, and retained in their collections. With the spirit of the revolution still vibrant, consigning American insects to European collections offended national pride.

The Long Expedition imparted an American quality to the study of the nation’s natural history. The gentlemen of science who manned the expedition were trained in the nation’s centers of learning. They were not closet naturalists; they were adventurers. Their spirit was described by Say himself: “If our utmost exertions can perform only a part of a projected task, they may, at the same time, claim the praise due to the adventurous pioneer for removing the difficulties in favor of our successors” (American Entomology).

THE CULTURAL CENTERS Natural history found strong support in the cultural centers of Philadelphia, Boston, and New York. Philadelphia led the way, with the American Philosophical Society and the influence of the distinguished Benjamin Franklin (1706–1790). The Academy of Natural Sciences, founded in 1812, nurtured the founding of the Entomological Society of Philadelphia in 1859, which in turn launched the Practical Entomologist in 1865.

Boston looked to Harvard College and the Massachusetts Society for Promoting Agriculture. William D. Peck (1763–1822) was appointed professor of natural history at Harvard in 1805 and offered the first lectures in entomology in North America. Thaddeus William Harris (1795–1853), a physician turned Harvard librarian, found time to become entomological author, teacher, collector, and correspondent. His report on A Treatise on Some of the Insects Injurious to Vegetation (1841) summarized the knowledge of insect control in Europe and North America, earning him the title “Father of Economic Entomology.”

New York asserted its interest by appointing Amos Eaton and John E. LeConte to the Lyceum of Natural History of New York. Other distinguished leaders included John Abbot (1751–1840), Thomas Say (1787–1834), and Frederick V. Melsheimer (1749–1814). A striking feature of these men and their institutions was their support for both classical and applied entomology. The individuals were well trained by the standards of the day, often completing training in medicine or theology, because there was no specific training in entomology.

Systematics was the primary entomology interest, followed by aid to agriculture, which was beset with countless insect pests. These leaders experienced the frustration of gaining access to the European literature, founding periodicals for the publications of their own findings, and establishing reference collections.

In the 1840s, American entomologists turned to the task of establishing institutions that would sever their European dependence. The institutional framework took shape rapidly, led by the American Association for the Advancement of Science (AAAS), founded in 1847. It marked a transition from amateur to professional status, provided a national scientific forum, and nurtured the founding of professional societies. Within approximately 2 decades, 1859–1881, five additional societies were established in North America: the Entomological Society of Philadelphia (1859), The Entomological Society of Canada (1862), and the Entomological Club of the AAAS (1872). The institutional framework was now in place to expand the scientific and technical dimensions of entomology.

STATE AND FEDERAL ACTION IN THE UNITED STATES Agriculture held the key to moving the nation from an agrarian to an industrial society. The farmer was viewed as the noblest and most independent man in society. Unlike in Europe, the availability of fertile soil was seemingly unlimited. While great physical obstacles lay in the path of progress, limits of the human intellect posed the greatest obstacle. With these elements in the national outlook, it followed that state and federal action would augment the private efforts in support of agriculture and entomology. In 1854, two landmark appointments were made: Townsend Glover was appointed to the Federal Patent Office for work in the newly established Bureau of Entomology, and New York State, responding to pressure from the New York State Agricultural Society, appointed Asa Fitch as its first state entomologist. Illinois and Missouri followed suit in 1868 with the appointments of Benjamin D. Walsh and Charles V. Riley.

These appointments represented historic landmarks, because state and federal funds were appropriated in support of agriculture with entomology in the vanguard. These men were able individuals whose evangelical zeal and sound professional grounding were attuned to national goals. Their publications, with Charles V. Riley’s nine Missouri reports forming the core, laid the foundation for applied entomology in North America.

National goals for agriculture led to enabling federal legislation in three steps. The Morrill Land-Grant Act of 1862 provided grants to each state, the proceeds from which funded a college, “to teach such branches of learning as are related to agriculture and the mechanical arts...” In 1887 the Hatch Act added a research dimension by establishing in each college state experiment stations coordinated by a central office in the Department of Agriculture in Washington, DC. The foregoing events, occurring within approximately 3 decades, provided an impetus for applied entomology that was unprecedented in the world. Cooperative Extension, the outreach arm of the Land-Grant University, which had been active from the start, was formally recognized and funded by the Smith-Lever Act of 1914. This institutional framework with its catalytic feedback from teaching, research, and extension has been recognized as one of the greatest educational innovations of all time.
With economic entomology rapidly expanding under the stimulus of experiment stations, Charles V. Riley, then chief of the Bureau of Entomology, perceived the need for a national organization to advance the goals of economic entomology. His organizational abilities and partnership with his Canadian counterpart, James Fletcher, led to the establishment of the American Association of Economic Entomologists in 1889. At Riley’s insistence, the association focused on economic entomology, leaving unmet the needs of the broader dimensions of biology, taxonomy, morphology, and fanciful studies of insects. In 1906, the Entomological Society of America was organized to meet those needs, with John Henry Comstock of Cornell University serving as president. With the various forces that shaped these professional and governmental institutions in mind, we can examine how the institutions responded to the challenge posed by insect pests.

Insect Pests

That the world is not awash in insects, despite their remarkable potential for reproduction, attests to the “balance of nature.” But nature’s balance, while avoiding extremes, does not preclude insect activity that is annoying to humans. Insects that take human’s crops or blood, and invade their dwellings, are termed “pests.” The term has no biological significance; it only expresses a human perception.

Let us examine a few insect outbreaks that occurred in agricultural, medical, and veterinary entomology in the late 1800s. They were to test the mettle of the institutions crafted to address such problems. They taught us much about insects, ourselves, and our vast landmass with its unique biomes and punctuated with its geographical features: the Rockies in the west, the Appalachian range in the east, the Great Plains, the Great Lakes, and the Mississippi. It was this abundance of land that appealed to the early settlers from land-poor Europe. It was from the vastness of the land with its rich flora and fauna, coupled with the democratic spirit of its people, that the American dream was fashioned. However, the dream’s social fabric was not matched by its concept of stewardship of the land. New England’s forest primeval had to be breached to make way for agriculture. Conquering nature was viewed as a prelude to progress, and the American Indians and the bison fared poorly under this credo.

AGRICULTURAL ENTOMOLOGY

The Colorado potato beetle, *Leptinotarsa decemlineata*, existed in the foothills of the Rockies on the buffalo bur, *Solanum rostratum*. As pioneer settlers pushed westward with their crops, the beetle colonized the cultivated potato, *Solanum tuberosum*, and began its eastern migration along the “potato trail.” It was observed as a potato pest in Nebraska in 1859, reached the Atlantic coast by 1874, and traveled thence to Europe in 1876, where it remains an important pest.

The early search for control measures established the arsenal Paris green, an industrial pigment, as an effective poison. It soon became the standard treatment and was the first widely used poison to kill by ingestion.

The early marketing of insecticides invited fraud through adulteration and false claims. It was not until 1910 that a federal legislation was passed, requiring labeling to reveal the efficacy of and the ingredients in the two most widely used insecticides, Paris green and lead arsenate.

The boll weevil, *Anthonomus grandis*, crossed the Rio Grande to Texas in 1894 and began its eastward trek, occupying the entire 1,500,000 km² cotton belt by 1925. Efforts to impede its progress by establishing no-cotton barriers failed for lack of community compliance. Countless control measures were tried, but insecticides eventually won as the first line of defense. Calcium arsenate was adopted for control in about 1920, and its use soon reached 20,000 tons per year. This marked a new scale of area-wide pesticide treatment with its attendant environmental and human safety problems.

The social and economic impact of the weevil was incalculable. The prosperity of the South evolved around a single crop, cotton. With its loss, the economic infrastructure collapsed, and panic ensued. Black laborers left, mortgages were foreclosed, and banks failed. The potential for economic disaster in the wake of insect outbreak was seared in the memory of the people of the cotton-producing states. Only the Civil War had greater impact on the economic and social life of the southern states than did the boll weevil.

The Rocky Mountain grasshopper, *Melanoplus spartus*, appeared in an epidemic eastward migration, borne on wind currents from the foothills of the Rockies to the Mississippi valley in 1874–1876. Presumably, this migration was in response to the agricultural disruption of the ecosystem that had been dominated by the American bison. The ravages of these hordes of airborne insects created a crisis for the affected states, whose governors appealed to Washington, DC, for federal intervention. In response, the U.S. Entomological Commission was created with the colorful Charles V. Riley as its chairman. This was not a staid Washington bureaucracy; it was a mobile force that reached out to the crisis whenever it arose. Riley scoffed at Sundays devoted to prayer for divine intervention to restrain the pest. Rather, he urged the people to adopt control measures based on intricate knowledge of the life history of the pest. His insights led to bold predictions of the pest’s demise from natural causes. With some sound observations and a modicum of luck, his predictions held. The commission, despite its denials, was credited with solving the problem, bringing new credibility to entomologists and federal aid to the states.

The gypsy moth, *Lymnaecia dispar*, was introduced from France, not by accident but by design, by Leopold Trouvelot (1827–1895), a Harvard astronomer and amateur entomologist who was interested in silk-producing moths. Larvae emerging from egg masses he had imported escaped from his Medford, Massachusetts, residence in 1869. After a period of 20 years, the moth reappeared in an epidemic outbreak, after having been mistakenly overlooked as a native species. This head start, the scorched earth practice of cutting and burning infested trees, augmented by arsenical sprays, failed. The effort did stimulate advances in the technology of spray machines. Today this introduced pest has spread westward and southward, occupying a swath from the Great Lakes to the Carolinas.

Biological control was enthusiastically touted, following the spectacular success achieved by Charles V. Riley’s innovative introduction of the vedalia beetle, *Rodolia cardinalis* (Coleoptera), into California to destroy the cottony cushion scale, *Icerya purchasi*. The pest had been introduced from Australia about 1868 and soon threatened destruction of the state’s citrus industry. Two years after the introduction of the predator, the pest was miraculously under control.

The whole array of control measures, cultural, mechanical, chemical, plant resistance, and biological, was employed, seeking to cope with these problems. The entomologists were influenced by expectations and perspectives of their farmer clientele. The farmer’s time frame was established based on the harvest date and sale of the crop; the farmer’s risk tolerance was low. Insecticides provided immediate and predictable results and became the backbone of control programs.

Meanwhile, several factors intensified the pressure for insect control, including monoculture, susceptible crops, exacting market standards, and introduced pests; all required greater interventions and modification of the agroecosystem.
MEDICAL AND VETERINARY ENTOMOLOGY  The foundation for modern medical and veterinary entomology was laid by Louis Pasteur, a French microbiologist who formulated the theory of microscopic causation of disease, based on his work with the silkworm, Bombyx mori, in 1857. Without benefit of the germ theory, Josiah Nott, a Mobile, Alabama, physician, proposed (1848) that the causative agents of malaria and yellow fever were transmitted by mosquitoes. In 1881, Carlos Finlay, a Cuban physician, postulated that mosquitoes transmitted the yellow fever agent, setting the stage for Major Walter Reed and associates to verify his claim. In 1897, Ronald Ross demonstrated the occurrence of the malaria parasite in mosquitoes that fed on a human patient whose blood contained the parasite, thus leading to the elucidation of the epidemiology of malaria.

In 1889, Theobold Smith discovered the causative agent of Texas cattle fever and, working with F. I. Kilbourne, showed in 1893 that the cattle tick, Boophilus annulatus, was the vector. Their work paved the way for tick prevention and development of the cattle industry in the southern United States.

These experiences in control of insects of agricultural, medical, and veterinary importance were unprecedented in the American experience and left no region untouched. They revealed the social, political, biological, economic, and environmental dimensions of insect problems. A nation leaning so heavily on agriculture was sensitive to the impact of these problems on its well-being.

The fundamental principles gleaned from these experiences were to shape the philosophy of insect control for the future. They included the following: (1) Taxonomic knowledge of the vast insect fauna is a prerequisite for detection and development of control programs; (2) advances in international commerce breach the ancient oceanic barriers to the dispersal of insects and increase the likelihood of introducing exotic species; (3) introduced species, uninhibited by their natural controls, often become major pests in their new habitat; (4) the economic well-being of vast regions of the nation is vulnerable to insect attack; (5) intervention at the federal level is required for insect problems beyond the scope of individual states; (6) alterations of ecosystems trigger changes in patterns of insect behavior; (7) the use of insecticides requires federal regulations to protect the user, the public, and the environment; and (8) an informed public will underwrite sound programs of insect control.

PARTNERSHIP IN PEST CONTROL, 1880 TO WORLD WAR I

The institutional framework for colleges of agriculture was well established by 1880. The first department of entomology was founded at Cornell University in 1874 under the leadership of John Henry Comstock; others followed shortly. The primary objective of the department was to train students who wished to become farmers, to identify and classify the insect fauna, to study life cycles, to devise control measures, and to train farmers in their use.

As insecticides became a more important component of production technology, an alliance of increasing importance developed among the agricultural constituency, the agricultural colleges, and the chemical industry. As this partnership developed, agribusiness expanded to provide the goods and services required for agricultural production and became even more mechanized, technical, and capital intensive. The three partners shared a common objective, pooling their resources to increase the efficiency of agricultural production that accrued ultimately to the benefit of the consumer.

The arrangement involved the agricultural constituency, lending political support to the agricultural colleges, in return, for their services. The colleges then aided the chemical industry by testing their products and giving their approval, which enhanced their marketability. A grateful chemical industry provided grants to the entomology departments, which were always short of operational funds. The deans at the agricultural colleges had the difficult task of being a broker between the college faculty leaning toward basic research and the farm constituency seeking low-risk pest control programs. The arrangement was an American innovation that seemed to please everyone. Furthermore, the chemical industry was greatly stimulated by the economic and political activities of World War I. Food and fiber production was given high priority, and new discoveries advanced the pesticide industry.

The period from 1880 to 1940 witnessed the maturing of the Agricultural Experiment Stations as a national, highly coordinated network. The extension entomologists became the connecting link between the agricultural college and the agricultural producer. Because insecticides had become the first line of defense, the growing chemical industry added strength to this already-solid partnership with the colleges and farmers in the aftermath of World War II. Furthermore, this was the threshold of an era of discovery of new molecules that would affect biological processes of plants and animals.

Along the way, some ominous straws in the wind signaled trouble ahead. In 1913, the San Jose scale, Quadraspidiotus perniciosus, developed resistance to lime sulfur, but the phenomenon was not recognized as an expression of Darwinian selection. In 1929, the codling moth, Cydia pomonella, was shown to be resistant to lead arsenate. The apple industry was dealt a severe blow in the mid-1930s when British markets rejected fruit from the United States because of high arsenical residues. Simultaneously, fruit trees were showing loss of vigor because of insecticidal toxicity to foliage and accumulation of residues in the soil.

Although these disquieting revelations were not widely publicized, they were of concern to entomologists, as they and the pesticide industry were marshaled to meet the greater demands for food and fiber required for World War II. Even then, the sustainability of insecticidal control was clearly in doubt.

ENTOMOLOGY, POST-WORLD WAR II

Technology’s Triumph

The explosion of the atom bomb over Nagasaki in 1945 brought a dramatic end to World War II and, in so doing, highlighted the role of science and technology in the victory. Following this, the age-old ritual of “beating swords into plowshares” turned scientific and technical advances to peaceful ends. No field emerged with more exciting prospects than did the field of entomology. DDT, with its wartime secrecy removed, was hailed as the answer to insect control. Its use in arresting an epidemic of typhus in Naples in 1943–1944 dramatically neutralized the lethal companion of armed conflict, vector-borne disease.

Overnight, the entomological community documented DDTs remarkable effectiveness in controlling insect pests of agricultural, medical, and veterinary importance. The race was on, and an old alliance assumed new vigor. The Land Grant Universities joined with industry and agriculture to exploit the new possibilities of chemical pest control.

Although industrial grants to the Agricultural Experiment Stations to fund trials of mutual interest dated from the early 1930s, they assumed a greater role in experiment station research as the partnership geared up for a new era in the synthesis of pesticides. The chlorinated hydrocarbons, with DDT as their prototype, yielded
related compounds, followed by the development of organophosphates, methyl carbamates, and pyrethroids—all neuroactive compounds. By the 1950s, post-World War II insecticides had become the mainstay of insect control, with the prewar calls for biological and cultural controls in eclipse.

Enter Rachel Carson

Early warnings of the danger of insecticide mania were sounded within the entomological community, but these warnings were largely ignored. It was the publication by Rachel Carson (Fig. 2) of *Silent Spring* in 1962 that triggered the avalanche of public concern. She lamented that “so primitive a science has armed itself with the most modern and terrible weapons” and that “in turning them against the insect, it has turned them against the earth.”

FIGURE 2  Rachel Carson’s *Silent Spring* (1962) focused public attention on the pesticide issue. Her crusade catalyzed the environmental movement. (Harbrace photograph.)

Overnight, her exhortation changed the public’s perception of entomologists. Their traditional obscurity was swept away. They were in the public eye, viewed as allies with the corporate giants, poisoners of robins and the earth, all under the pious veil of aiding the consumer by adding the farmer.

Response to Rachel Carson’s charges came largely from industry, whose strategy was to discount the witness. This proved ineffective as accumulating evidence reinforced her concerns. Practices that endangered birds, especially the national symbol, the American eagle, were certain to stir emotions.

Carson’s *Silent Spring* became a cornerstone of the environmental movement. Her thesis focused on the “web of life,” which placed humanity’s relationship to all forms of life in an ecological context. Concern for the environment and the natural world triggered by *Silent Spring* melded with other concerns for humans—women’s rights, the war in Vietnam, and Native American rights—to give rise to the broadly based environmental movement embracing the rights of humans and nature, animate and inanimate. This great philosophical debate extending over the past 4 decades proceeded without the active involvement of the entomological community.

One of the immediate effects of *Silent Spring* was to make pesticide policy a matter of public debate. While focusing on DDT, the issue became broader and embraced the central tenet of the environmental movement that human intervention had become the dominant environmental influence on the planet. The fact that DDT residues could be found in Antarctica incorporated entomologists in the global insult.

In 1967, a group of concerned individuals formed the Environmental Defense Fund to use litigation in defense of citizens’ rights to a clean environment. In protracted public hearings, entomologists were called to testify that their practices were not infringing on citizens’ rights to a clean environment. It was an uncomfortable defensive position in which these dedicated “defenders of agriculture” were placed.

In 1972, a decade after *Silent Spring*, the Environmental Protection Agency banned DDT. Its meteoric rise and fall, from discovery to banning, had spanned only 3 decades.

Economic entomologists in general viewed *Silent Spring* as an attack on their professional competence and integrity. Since the late 19th century, they had cultivated a self-image as dedicated public servants, bringing science “to the distressed husbandman” whose labors were closely aligned with the national interest. This explains in part their emotional response and the sense of hurt that has lingered among entomologists of the DDT era.

Ecology’s Promise

Economic entomologists of the 1960s faced two daunting challenges: the loss of public confidence in the aftermath of *Silent Spring* and the failure of their programs of insect control. These were powerful incentives for reassessment.

In the early 1950s, well before *Silent Spring*, the concerns regarding the insecticidal treadmill led a group of entomologists at the University of California at Berkeley and at Riverside to reassess control practices. Drawing on the biological control heritage pioneered by Harry Scott Smith (1883–1957), they sought to “integrate” features of biological control and chemical control. This concept, with further refinement, led to the adoption of IPM by the late 1960s. In practice, IPM seeks to integrate multiple control measures into a cohesive package, the additive impact of which would hold pests within acceptable levels while taking into account economic, environmental, and social costs and benefits. The abbreviation “IPM” was soon adopted worldwide to identify a holistic approach to pest control. Its enthusiastic reception reflected that optimism accorded a new paradigm, one that placed pest control on an ecological foundation.

The most impressive feature of the movement has been its evolving nature. The underlying theory and the fundamental question that has plagued population ecologists—What factors determine the number and distribution of animals?—remain under debate. Views of the role of pesticides in IPM are likewise evolving. Progress has been made in tailoring pest-specific insecticides with reduced environmental disruption. Although impressive reductions in overall pesticide use have been made in specific programs and levels of insecticide use have declined overall, the IPM era has not resulted in
major declines in the total quantities of pesticides used. The euphoria induced by the IPM concept has run its course, and its promise after 3 decades is a subject of lively debate. One of the problems affecting acceptance and support of IPM is the difficulty of assessing its effectiveness. It is a complex system with many obstacles and a restricted database for evaluating a variety of constraints: technical, financial, educational, organizational, and social. Whatever the outcome is, there is no turning back. The human intellect has been unable to construct a more promising strategy for keeping humans’ age-old competitors in check. For millions of people threatened with disease and hunger, IPM constitutes their safety net for tomorrow.

In seeking to understand the strategy employed by applied entomologists, it is helpful to note the historical perspective. Applied entomologists were late to embrace ecology, despite the entreaties of the distinguished president of the Entomological Society of America in 1912, Stephen A. Forbes. He insisted that “the economic entomologist is an ecologist pure and simple whether he considers himself so or not.” In retrospect, it appears that entomologists opted for the certainty of insecticides favored by their farmer clientele over the uncertain promise of ecology. Their adherence to the conventional wisdom of insecticidal control in the DDT era tarnished their image as environmentalists.

In medical and veterinary entomology, the post-World War II experience with the miracle insecticides paralleled the experience with agricultural pests. First, there was euphoria following the miraculous effectiveness of the insecticides. So promising were the prospects that in 1955 the World Health Organization (WHO) proposed global eradication of malaria. However, the development of resistant strains of vectors and parasites as well as economic and political factors doomed the eradication program. In 1976, the WHO abandoned eradication in favor of more modest programs of control. Research languished under the demoralizing effect of this decision. With antimalarial drugs and insecticides losing their effectiveness, the battle against malaria was being lost. Alarmed at these developments, the WHO, in 1993, called for a renewed global effort. The initially slow response has gained support, with unprecedented funding available during the initial decade of the 21st century.

An ambitious objective is the development of a vaccine against malaria. Although the scientific obstacles are enormous, significant progress is being made. The most ambitious and futuristic of all approaches to combating malaria is creating a strain of *Anopheles gambiae* mosquito unable to transmit the parasite. To displace the native vectors involves three steps: find genes that interrupt the parasite’s life cycle, develop techniques to transfer those genes into the mosquito, and finally, develop ways of replacing existing mosquito populations with the genetically engineered model. One additional hurdle remains. With such a mosquito in hand, there may be strong resistance to releasing such transgenic forms into nature. In the meantime, the disease continues to cast its shadow over the malaria-endemic areas of the world, which are home to 40% of the world’s population.

**Advancing the Science**

The past 5 decades have witnessed remarkable advances in both applied and basic entomology. The collapse of chemical control of insects forced reassessment, which gave rise to IPM. While the pesticide issue dominated public interest, basic science was forging ahead.

A primary stimulus was the discovery in 1953 that DNA encodes genetic information that provides the blueprint for synthesis and cellular differentiation; this discovery elucidated the great mystery of life, the cells’ ability to self-replicate. Many aspects of biology were catalyzed by the discovery. It dramatically reaffirmed Darwin’s hypothesis of common descent and revealed evolutionary pathways. Studies of molecular systematics that followed have resulted in accumulation of DNA sequence data that complement and enhance the morphological and ecological data of classical systematics, thereby making substantial contributions to evolutionary biology.

The DNA breakthrough also paved the way for biotechnology, the introduction of genes from various species into plant and animal species. This technology places the cornucopia of biodiversity in the service of agriculture and medicine. But it comes with complex ethical and scientific issues in environmental stewardship and human health. Both scientists and the general public have been aggressive in identifying and have been actively debating the ecological ramifications of introducing genetically modified organisms (GMOs) into the environment.

With biotechnology, plants can be genetically engineered to produce their own pesticides. In 1995, corn and cotton genetically engineered express genes from the bacterium *Bacillus thuringiensis* (Bt) coding for a protein toxic to several important caterpillar pests were approved for sale in the United States. In 2006, Bt-corn and Bt-cotton were grown commercially on a total of 32 million hectares in 19 countries. Drawing on lessons learned during the insecticide era, entomologists have been aggressively studying the potential environmental and human health risks and benefits relating to the release of GMO crops. They have been proactive in developing deployment strategies for Bt-crops that minimize selection on pest populations to become resistant to the Bt-toxins. Entomologists have also been active participants in the development of the science-based regulatory framework used by the U.S. Environmental Protection Agency and comparable agencies in many other countries to regulate the commercialization and use of Bt-crops.

The benefits of Bt-crops to farmers have been dramatic. In countries where Bt-cotton has been adopted, insecticide use in Bt-cotton has averaged 33–77% less and the effective yield of cotton fiber has increased by average 10–34%, with the greatest gains occurring in developing countries. Industry has been quick to recognize biotechnology’s commercial potential, and substantial segments of the seed market have been given over to GMOs. As the technology has advanced, it has become possible to stack multiple genes conferring an array of different traits in the same crop varieties. GMO corn and cotton varieties are now available. They express multiple Bt-toxins, each effective against different pest species, as well as genes that make the crop tolerant to broad-spectrum herbicides, which can now be used to control weeds after the crop has emerged. Where only stacked-gene varieties are available, farmers requiring only one of the pest management traits have to plant varieties expressing all traits. Questions of a scientific nature are joined by social and economic questions. For instance, should corporate interest determine and control the genetic profile of the three crops—corn, rice, and wheat—that provide sustenance for most of the peoples of the world?

The economic issues surrounding GMOs seem to overshadow the more basic issues they pose. For instance, the biodiversity program seeks to conserve natural forms, whereas biotechnology seeks to replace natural forms with modified ones exempted from evolutionary testing. Over time, how will this practice affect the gene pool and the timeless and priceless biological resource? Will the economic benefits of GMO crops lead to such widespread adoption that they displace the traditional crop varieties and land races that are an important source of genetic diversity used in crop improvement?

Although elucidation of the structure and function of DNA is clearly the most important discovery of the 20th century, other discoveries have greatly advanced our understanding of insects. This progress
is largely due to advances in fields such as insect olfaction, acoustics, flight, and communication (e.g., by pheromones). Technological advances have altered the way scientists communicate in person and in professional literature. They became more informed and democratic. The excitement was often centered in youth, in graduate students, with women strongly represented.

The excitement of discovery and exuberant professional exchange produced masses of data, leading to new specialized journals. The worldwide computer network has catalyzed the processing and exchange of data among colleagues on a global scale. The predominant use of English in scientific journals has reduced language barriers. Thus, in both applied and basic entomology, the latter half of the 20th century has represented a new order, new methodologies, new discoveries, and new organizational arrangements. The paths of progress in multifaceted phases of entomology are well documented in the Annual Review of Entomology, published since 1956.

**HISTORICAL PERSPECTIVE**

The preceding two centuries of entomological enterprise in North America have been directed primarily to two activities: (1) protecting human's food, fiber, and health and (2) basic research to advance knowledge of insects. These were and continue to be appropriate objectives in the national interest. In the past half-century, the environmental movement and the emerging science of ecology have highlighted two salient points: (1) Insects play a vital role in the sustainability of the global biosphere, and (2) the biodiversity essential to sustainability is threatened by human intervention. The factors of habitat destruction, pollution, and introduction of exotic species are believed to account for extinction rates much higher than before the coming of humans. In addition, the ecological impact of global warming looms on the horizon. The movement to preserve biodiversity has been led by Edward O. Wilson (Fig. 3), following publication of his *The Diversity of Life* (1992). The concept has been generally accepted and is now part of the American culture. The extinction dilemma poses new challenges to the field of entomology and calls for modification of the image entomologists hold of themselves and of the institutions established to deal with entomological matters.

Since the mid-20th century, urbanization of the human population on a global scale has increased at an ever-accelerating rate. By mid-2008, over 50% of the world population will be living in cities. In the United States, as in other developed countries, the shift has been extreme, and the population has been largely separated from its agrarian heritage. This same period saw dramatic advances in physics, chemistry, and the basic biological sciences that have resulted in medical and technological breakthroughs that have spawned unprecedented economic growth. With these advances has come widespread recognition that universities, the centers of basic research, are powerful engines driving growth in the post-agrarian economy, just as they were in the agrarian economy. This recognition has resulted in a shift in funding and infrastructure support to more fundamental and transitional research focused on the economic, environmental, technological, and social priorities of a largely urban populace. The forces of population growth and urbanization are imposing new demands on agriculture to satisfy the global demand for food and fiber. This new order calls for entomological statesmanship that looks beyond entomology's traditional agricultural constituency to embrace global, environmental, and biomedical issues. The age-old challenge of insect control is being joined by compelling new challenges that entomology must embrace if it is to remain vibrant.

**FIGURE 3** Edward O. Wilson's prolific writings advanced the science of entomology, established the field of sociobiology, and led the 21st century movement to preserve biodiversity.

Homeostasis, Behavioral

P. Kirk Visscher
University of California, Riverside

Behavioral homeostasis refers to mechanisms of behavior that allow an insect or group of insects to maintain conditions within a certain range of values. These conditions may be the temperature of the body or the environment, internal water balance or environmental humidity, nutritional state or food stores, the balance between different activities of the individual or of the group, or the number and composition of individuals in a group. Behavioral mechanisms of homeostasis are important to individual insects, whether solitary individuals or part of a group, and include such nearly universal behaviors as feeding and drinking, as well as behavior concerned with thermoregulation and habitat choice. This article, though, is mostly concerned with homeostasis in groups of insects, such as the colonies of bees, wasps, ants, and termites. Individual behavioral homeostasis in physiological regulation, thermoregulation, and habitat choice are covered elsewhere in this encyclopedia.

ENVIRONMENTAL REGULATION

BY GROUPS OF INSECTS

Insects are relatively small animals, with high surface-to-volume ratios. Because of this, they readily lose body heat or water to the environment (or gain heat if the ambient temperature is high). However, a few species of insects form large groups that are able to exert some control over these processes. The most striking examples of this come from the social insects (the wasps, ants, bees, and termites), but some other insects also form groups that enhance homeostasis (Fig. 1).

The control of groups of insects over heat exchange may take two forms. First, they may form a cluster that effectively makes them more similar collectively to larger organisms. If the surface-to-volume ratio is of a cluster of insects rather than an individual, it has a smaller value, and heat exchange is slower. Second, most social insects construct nests, and the architecture of these nests can result in the interior environment being substantially different from the ambient environment outside the nest.

Honey Bees

Honey bees exhibit both of the above strategies. Honey bees (Apis mellifera) arose in the tropics, but A. mellifera and A. cerana have colonized much of the temperate zone as well. These honey bees are unique among temperate insects in maintaining a high temperature in their nests throughout the winter, even when environmental temperatures are dramatically lower. For example, an A. mellifera colony can maintain a temperature in the center of its winter cluster inside the nest of 35°C, even when the temperature outside the nest is ~40°C. The bees accomplish this by clustering together tightly so that the bees themselves, as well as the nest structure (often a hollow tree or wooden beehive) serve as insulation. The bees consume honey as metabolic fuel and contract their large flight muscles to create heat. Bees on the outside do get chilled, but they trade places with bees in the warm interior from time to time. Even when a bee colony is not in a nest, as when they are moving as a swarm to a new homesite, they maintain warm temperatures inside the cluster of thousands of bees.

The environment is not always cold, so temperature homeostasis for a bee colony sometimes involves cooling the nest. Honey bees fan their wings to move outside air through a colony to remove excess metabolic heat (and carbon dioxide). When this does not cool the colony enough, the bees begin to collect water and evaporate it within the nest to provide cooling. Also, when the nest becomes too warm, many bees leave the cavity and cluster outside the nest, reducing the heat input from their metabolism.

Termites

Many species of termites, like honey bees, live in large groups. Indeed, the largest colonies of social insects occur among the termites, some species of which may have several million individuals in a nest. Unlike honey bees, termite workers do not have wings, and so they cannot move air by fanning. Instead, some species of termites rely on the structure of the nest to regulate temperature and humidity. Macrotermes subhyalinus colonies, for example, construct tall "chimneys" on their nests. These chimneys are thought to increase airflow in two ways. As the metabolic heat of the termite colony (and the fungus gardens that they cultivate in the nest) warms the air in...
the chimneys, it rises and is replaced by cooler air from passages near the ground. Also, when wind blows across the open tops of the chimneys, the Bernoulli effect causes lower air pressure at the chimney top and draws air upward.

Other species of *Macrotermes* build nests with a closed-circuit air circulation system. In these nests gas exchange takes place by diffusion through the relatively thin walls of air channels in ribs on the outer edges of the nest. As air moves through the channels by convection of warm air, carbon dioxide diffuses out, and oxygen diffuses inward in, while limiting loss of moisture. The refreshed air is pulled back to the central nest to replace the air drawn off by convection. In the nest, respiration of termites themselves and the fungus they cultivate uses oxygen and produces carbon dioxide. The cycle repeats over and over, insuring oxygenated air with less loss of water than would occur with an open-circuit system.

In Australia, *Amietermes meridionalis* nests are constructed as flat towers, always oriented with their long axis north and south. The result is that they are warmed by sun as it rises in the east early in the morning and strikes their broad side, but they receive relatively little sunshine at midday when the sun is in the north and strikes the nest edge on. These termites are known to sense the earth’s magnetic field and use it to coordinate the nest-building activity of the colony’s many workers to achieve this striking geographic orientation of the nest.

**Tent caterpillars**

Although less organized in their social behavior than most social insects, tent caterpillars use some of the same thermal strategies to get a jump on the warm season. The larvae of tent caterpillars cluster together and form tents from silk that they produce. A group of caterpillars clusters together inside the tent during the night, where both the tent and the presence of many clustered insects reduce heat losses. The higher temperatures that the caterpillars experience allow them to develop more quickly than they would if they were isolated and exposed to the low temperatures that are common, especially at night, in their environment. Tent caterpillar behavior is adapted to keeping with the group. They find their way back to the tent by trails of odors and silk that are laid down as the caterpillars move from the tent to the foliage on which they feed during the day.

**COMMUNICATION AND GROUP ACTIVITIES**

An individual organism must allocate its time and resources between food collection, reproduction, habitat selection, and other activities. In the social insects, one sees similar behavioral adaptations. There is added complexity, though, because in social insects they occur at both the level of the individual and the level of the group. Group-level adaptations include the regulation of numbers of individuals in the colony, the allocation of reproduction between workers and sexual forms, the division of labor among individuals (e.g., caste), and the social organization of food collection (e.g., recruitment). All of these homeostatic activities by colonies of insects require mechanisms of communication to coordinate the activities of multiple individuals. It is for this reason that the social insects provide so many examples of communication among insects, because in nonsocial insects, communication is largely restricted to behavior associated with mating or defense. As in other insect groups, much of the communication in social insects is carried on chemically, by means of pheromones.

Homeostasis is fundamental to the survival of organisms, because the processes of life occur in a well-regulated manner only within a certain range of conditions. The same could be said about the processes conferring advantages of group living on those insects that live in groups. If a colony is too large, or fails to coordinate its activities in foraging, reproduction, or defense, it may perish. It is the function of behavioral mechanisms of homeostasis to regulate both the group environment and the properties of the group itself in a manner that preserves its efficient functioning.

Honey

Eva Crane†

International Bee Research Association

P. Kirk Visscher

University of California, Riverside

Honey is a sweet substance produced by social bees and some other social insects. They collect nectar or honeydew from living plants and transform it into honey, which they store as a nonperishable food for use in dearth periods. Its sweetness, flavor, and nonperishability have made it attractive to humans, who have harvested honey from several of these species since prehistory.

**THE ORIGIN OF HONEY**

Honey is produced and stored by some social insects. They are principally those with a perennial life cycle that provide a significant source of honey to humans, including all honey bees (*Apis* spp.) and stingless bees (*Melipona* and *Trigona* spp.) as well as *Nectarina* wasps in South America and several species of honey ants, especially *Melophorus inflatus* in Australia. Many other social wasps and bumblebees (*Bombus* spp.) with annual life cycles produce honey, but only very little.

†Deceased September 6, 2007.
Honey is mostly derived from nectar produced in flowers, but some plants (including cotton, *Gossypium* spp., and rubber, *Hevea brasiliensis*) also provide nectar in extrafloral nectaries. Some honey is also made from honeydew, which is excreted by certain sap-feeding insects in the order Hemiptera as they feed. The honey produced by the honey bee, *A. mellifera*, has been most studied, and accounts for nearly all honey in human commerce. The rest of this article principally concerns *A. mellifera* honey.

**WHY HONEY KEEPS**

Foraging workers collect nectar, and carry it back to their colony in their foregut, or crop. In the colony it is transferred to other “house bees” who process it and store it in the wax combs. Several changes made in this process result in a product that resists microbial degradation, in spite of being a rich energy source. These are diagrammed in Fig. 1. The most important factor is removal of most of the water in the nectar. Bees evaporate water from nectar by manipulations that increase its surface area, while other bees fan to maintain a current of warm air through the hive. Honey is a supersaturated solution of sugars, and this high sugar concentration (low water content) gives it a very high osmotic potential. Bacteria and yeast cells in honey are dehydrated by osmosis, and thus cannot grow. Products of reactions catalyzed by enzymes the bees add to honey also contribute. The first of these enzymes, from the hypopharyngeal gland of the bees, is invertase, which cleaves the disaccharide sucrose into the two simpler sugars glucose (=dextrose) and fructose. This doubling of the number of molecules contributes to the osmotic potential. It also makes the honey taste sweeter to humans, because we perceive fructose as sweeter than sucrose. The relative amounts of the two sugars depend on the nectar sources, and on the preferential absorption of glucose by the foraging bee. Fructose is more soluble in water than glucose, and high-fructose honeys (e.g., from acacia, *Robinia pseudacacia*) rarely if ever granulate (crystallize), whereas high-glucose honeys (e.g., from dandelion, *Taraxacum officinale*, or alfalfa, *Medicago sativa*) do so very quickly.

Although concentrated honey defies microbial attack, the honey is not so concentrated during the evaporation process, which may take several days, when it is rediluted with water for feeding larval bees, or when sugars crystallize out of solution. At this time the honey gains protection from another mechanism, the glucose oxidase system. Glucose oxidase, produced and added by the bees, is active in dilute honey solutions, and converts some of the glucose into gluconic acid and hydrogen peroxide. Hydrogen peroxide is a potent antimicrobial, but also quite volatile, and most of it is evaporated out of the honey as it is concentrated, although it may be produced again when the honey is rediluted. Gluconic acid gives the honey a low pH, or acidity, that further helps discourage bacterial growth, as well as contributing to the flavor of honey.

**COMPOSITION AND PROPERTIES OF HONEY**

The composition of honey varies according to its plant origin and the weather conditions when the honey was produced. An analysis of 490 U.S. honey samples gave an average of 69.5% fructose + glucose, 8.8% other sugars, 17.2% water, and small amounts of free acids, lactones, ash, and nitrogen. Honey is hygroscopic, and may absorb water if exposed to air with a relative humidity above 60%.

The color of fresh honey varies with plant source, and honeys become darker during storage, especially at high temperatures. The color of liquid honey is important in marketing, and a number of countries have established systems for color grading.

Crystallization of honey (often referred to as granulation) consists of the spontaneous crystallization of glucose monohydrate from a supersaturated solution. Transparent, runny honey becomes an opaque, semisolid slurry of glucose crystals in a mostly fructose solution. In Europe and the United States most honey is sold in liquid form, but in Canada, Australia, and New Zealand granulated honey is the norm. Granulated honey can be reliqified by gentle warming.

The aroma and flavor of a sample of honey depend on its plant source, and beekeepers learn to recognize the plant origins of the honeys their bees produce. Honey processed for sale on the mass market is often blended to maintain a constant product. Honeydew honey, which contains certain sugars not present in floral honey, lacks any floral fragrance. It is much favored in some regions where it is produced—such as the Black Forest in Germany—but elsewhere the more delicate flavor of honey from nectar is preferred.

**HONEY PROCESSING**

In a beekeeper’s hives the bees store honey in the combs of an upper honey box that is removed when it is full. Bees may be cleared from combs in the honey box by various methods: brushing and shaking bees off combs, using a bee-escape board through which bees can leave the honey box but not return, using a bee repellent, or blowing the bees out of the boxes with a stream of air.

Honey can be sold in the beeswax combs in which is produced. However, the wax is energetically expensive for the bees to produce, so honey yields are greater when the honey is removed and the combs returned to the bees. Honey sold in the comb, though, has the least-altered flavor, and is obviously not adulterated. These considerations maintain a market for comb honey. Comb honey may be produced in “sections” in which the bees are provided with small wooden or plastic frames fitted with a thin wax comb foundation on which they build and fill cells, or it may be cut from larger combs. Sometimes comb and extracted honey are combined in a jar, as “chunk honey.”

Most honey is separated from the wax comb and processed for sale in containers, without any comb or wax. Processing the honey

---

**FIGURE 1** Honey is produced from nectar by removing most of the water, converting sucrose to fructose and glucose, and other enzymatic changes. These contribute to make honey keep.
consists of the following stages: (1) clearing bees from the combs to be harvested, and taking them to the honey house; (2) warming the combs to 32–35°C; (3) removing the wax cappings that the bees use to seal finished honey into the comb; (4) extracting the honey from the combs in a centrifuge; (5) clarifying the honey either by settling or filtration by passing it through a strainer and/or baffle tank. Beyond this, the honey may be heated to dissolve any crystals, to increase liquid shelf life and clarity; and may be pressure filtered. If a uniform granulated honey is desired, seed crystals may be added.

HONEY AS A PRODUCT

Present World Production and Consumption

According to figures available, 1.1 million tons of honey was produced in 1999. Honey yields per hive are usually highest in countries with an extensive belt between latitudes 23 and 30° (N or S), including China, Argentina, Mexico, and Australia.

Honey as Food

Honey from bees’ nests was probably eaten by some mammals, including bears, before humans did so, and chimpanzees have been observed using tools to get access to honey in bees’ nests in a tree. In Africa, India, and Spain, rock art from Mesolithic times and later shows human honey hunters harvesting honey from nests in trees or rocks. Historically the use of honey is recorded from around 3000 B.C. onward. In India it was used by the famous surgeon Susruta around 1400 B.C. and much prized in the Vedas, sacred Hindi books collected together about 1500 B.C. In Rome, Columella judged honeys by their plant source, that from thyme being the best. Honey from a few plants, including Rhododendron, is toxic; in 399 B.C. when Xenophon’s army retreated from Persia across Pontus in Asia Minor, the soldiers ate honey near the Black Sea coast that probably came from R. ponticum. It made them very ill, but they recovered by the third day. Records of baking with honey survive from 1200 B.C. onward in ancient Egypt.

Honey in Medicine

Honey has been regarded as a health-giving substance since ancient times, Pythagoras (ca. 530 B.C.) was said to have attributed his long life due to his constant use of honey. Honey is a common ingredient of cough mixtures and lozenges and is often recommended as a symptomatic treatment for dyspepsia and peptic ulcers; the organism Helicobacter pylori, which is a common cause of peptic ulceration, is inhibited by honey. Some sufferers from hay fever may be helped by eating honey that contains pollen.

A beneficial effect on wound healing has been known since early times. In the 1960s, hydrogen peroxide from glucose oxidase was shown to contribute to this, as well as the hygroscopic properties of honey. For these reasons, honey is currently used in a number of hospitals, especially on wounds that are difficult to dress.

Honey in Alcoholic Drinks

From ancient times onward, drinks have been made by fermenting fruit to make wine, or cereals to make ale or beer. In many regions where bees were kept in hives, an important use of honey was its fermentation to produce an alcoholic drink, often referred to as mead. Where vines were grown, wine had a higher social status than honey-based drinks and tended to displace them, but honey-based drinks remained important north of the warmer vine-growing areas. In tropical Africa “honey beer” was made by fermenting honey for a short period.

Honeydew

Angela E. Douglas
Cornell University, USA

Honeydew is a sugar-rich liquid released from the anus of some phloem sap-feeding insects of the hemipteran suborders Sternorrhyncha and Auchenorrhyncha. It consists principally of the residue of ingested phloem sap after digestion and assimilation in the insect gut, but it also contains waste products of insect metabolism eliminated via the gut. Honeydew deposited onto plant or other surfaces is an important source of energy-rich food for other animals, including some flies, parasitoids, ants, and microorganisms, and is used as a foraging cue by predators and parasitoids of these insects. Ants also collect the honeydew directly as it is being released from the producing insect, a behavior known as ant attendance.

THE NATURE OF HONEYDEW

Honeydew has historically been a source of wonderment. For example, the honeydew produced by the coccid Trabutina manniipara on tamarisk trees may have been the “manna from heaven” on which the Israelites fed during their escape from Egypt; honeydew has also been described as “the milk of Paradise” by Samuel Taylor Coleridge. However, the biological nature of honeydew is more mundane. The phloem sap of plants contains very high concentrations of sugars, usually the disaccharide sucrose or oligosaccharides of the raffinose family. Phloem-feeding insects ingest very large amounts of sugars relative to other essential nutrients, and up to 90% of the ingested sugar may be egested via the anus, and this sugar-rich material is honeydew. Honeydew is produced by phloem-feeding insects, not by xylem feeders, primarily by members of the hemipteran suborders Sternorrhyncha (including aphids, whiteflies, mealybugs, and psyllids) and Auchenorrhyncha (including planthoppers and leafhoppers).
**PRODUCTION**

The amount of honeydew produced by insects can be substantial. For example, first instars of the willow aphid *Tuberolachnus salignus* release more honeydew than their own body weight on an hourly basis. However, the rate of honeydew production by other hemipterans, including other aphids, is generally considerably lower.

The fluid that comprises honeydew accumulates in the rectum and is then ejected as a single droplet via the anus at fairly regular intervals, usually once every 15–40 min. Both the volume of each droplet and the frequency of production are influenced by many factors, including aphid age, size, species, and host plant.

Honeydew can be hazardous for the insect producing it because droplets may smother the insect and promote microbial growth on or near the insect. Various mechanisms reduce these risks in insects both on exposed plant surfaces and in confined spaces, including galls. On exposed surfaces, aphids generally project the honeydew droplet from the anus to a distance of up to several centimeters by either a kicking action of one of the hind legs or by using the cauda (a small appendage dorsal to the anus) to catapult the droplet ventrally. The legs and cauda bear hydrophobic cuticular hairs that prevent the sticky honeydew from adhering to the insect surface. Honeydew production by some species has been reported to be interrupted in windy conditions, presumably to avoid being smothered by the honeydew.

Insects in galls or other confined spaces (e.g., subterranean forms) are not wetted by their honeydew because they are coated with hydrophobic wax secreted from cuticular glands. In addition, each honeydew droplet produced by these insects tends not to be projected away from the insect body but remains poised at the anus until it is coated by wax. In some insects, notably certain nymphal psyllids, the honeydew and waxes coalesce to form a gelatinous or crystalline substance (called lerp), which acts as a solid protective covering for the growing insects.

Honeydew production may serve purposes additional to the elimination of waste compounds, with implications for the pattern of honeydew production. This is illustrated by two phenomena: “honeydew-panting” and ant-tending.

Honeydew-panting is displayed by certain aphids, notably *T. salignus*, at elevated temperatures. The aphids raise their abdomens almost at right angles to the plant surface with their mid- and hind legs extended, and small honeydew droplets are alternately protruded and retracted from the anus. This behavior may cool the insect as a result of evaporational water loss from the droplets.

The ejection of honeydew from some insects is modified by the attendance of ants or other insects. When solicited by an ant, the insect releases the honeydew droplet slowly and holds it at the anus while the ant imbibles, and, if the droplet is not removed by an ant, the insect may repeatedly extrude and retract the droplet, as if advertising the availability of honeydew. However, certain obligately ant-tended species apparently excrete honeydew droplets only in response to solicitations by their attending ants. The cauda and rectal musculature of some ant-tended aphids is much reduced, presumably reflecting their dependence on ants to remove their honeydew.

**COMPOSITION**

From a physiological perspective, honeydew is dominated by sugars. In the best-studied group, the aphids, the principal sugars in honeydew are typically different from the sugar ingested by the insect and usually of higher molecular weight. This reflects the vital osmoregulatory function of the gut in phloem-feeding insects. The osmotic pressure of phloem sap is generally considerably higher than the osmotic pressure of the insect body fluids, creating a tendency for the insect to lose tissue water to the gut.

Amino acids are the principal nitrogenous compound in phloem sap. Not all of the ingested amino acids are absorbed across the insect gut and assimilated (estimates of assimilation efficiency vary from 60 to 99%), and amino acids are routinely recovered from insect honeydew. Honeydew also contains nitrogenous excretory compounds, either uric acid or ammonia, but generally at very low concentrations.

Honeydew may contain microorganisms and viruses derived either from the ingested phloem sap (and passed directly through the gut) or from the resident insect microbiota. For example, aphids feeding on plants infected with the luteovirus barley yellow dwarf virus will ingest viral particles from the phloem sap; those particles that are not transported into the insect hemocoel are expelled in the aphid honeydew. Plant viruses multiplying in the insects may also pass into the gut and occur in honeydew.

**HONEYDEW AS FOOD**

Honeydew production can be substantial, in tree canopies amounting to 30–70 carbon m−2 in a season. Many insects in several orders, including Diptera, Hymenoptera, Lepidoptera, Coleoptera, and Neuroptera, feed on honeydew that has fallen onto plant or other surfaces. Among these insects are herbivores (e.g., tephritid flies, butterflies, and moths) and many entomophagous taxa, such as chrysopids, coccinellids, syrphids, tachinid flies, and hymenopteran parasitoids. A number of nectarivorous birds in Mexico and Australia forage on honeydew and lerp; lerp is also consumed by flying foxes in Australia. Other small mammals and reptiles feed on honeydew, and some dipteran vectors of human diseases (e.g., mosquitoes and phlebotomine sand flies) may rely on honeydew for an energy source. The honeydew is also a potentially important source of accessible carbon for microorganisms on plant surfaces.

Because it is usually freely accessible on leaf surfaces, it can readily be imbied by insects that lack the specialized mouthparts needed to exploit floral nectar. However, several features of honeydew reduce its availability and suitability as food. First, there is the tendency of honeydew sugars to crystallize. Second, the performance of various predators and parasitoids is generally lower on honeydew than on nectar. Third, plant-derived secondary compounds in certain honeydews are toxic to other insects. It has been suggested that insects have selection pressure to produce honeydew of little nutritional value; hence, potential competitors and natural enemies may be one factor shaping honeydew composition.

When animals consume honeydew as it is voided they are described as “tending.” By far the most widespread group of tenders are the ants, including most species of the subfamilies Myrmicinae, Dolichoderinae, and Formicinae. Other insects reported to tend hemipterans include polybiine wasps (e.g., *Brachygastra* and *Parachartergus* spp. associated with membracid and planthoppers, respectively) and silvanid beetles (e.g., *Coccidotrophus* spp. with the mealybug *Pseudococcus brescii*). It is believed widely that only insects tend honeydew-producing hemipterans, but several Madagascan gekkoes have been reported to stimulate planthoppers of the family Flatidae to release honeydew droplets on which they feed.
In the interactions involving ants, both the ants and their tended hemipterans generally benefit from the association, which is therefore described as mutualistic. Access to honeydew has been shown to enhance the rate of increase of ant colonies, but the magnitude of the nutritional benefit varies widely with ant species and environmental circumstance. Predominantly predaceous species feed on honeydew only very occasionally; some ants switch between tending and preying on hemipterans, depending on the nutritional quality of the honeydew (as shaped by plant physiology) and the nutritional needs of the ant colony, and honeydew accounts for more than half of the diet of many temperate wood ants of the genus Formica and is the dominant, even sole, food of certain subterranean ants, such as Acropyga spp., and of Solenopsis (fire ants). In some interactions, the hemipteran is stimulated by ant attendance to produce elevated amounts of honeydew of high nitrogen content, and also to display reduced dispersal behavior. This response is correlated with a reduction in the performance of the hemipteran, suggesting that it is costly.

An indication that honeydew is an important food source for many tending ants is that the ants protect the tended hemipterans from predators such as lacewings, syrphids, and coccinellids. In addition, certain ant species enhance their supply and quality of honeydew by transporting their tended hemipterans to suitable parts of the host plant where the phloem nitrogen content is high and concentration of toxic plant chemicals is low (e.g., Lasius and aphids of genus Stomaphis), and some members of the genus Acropyga that tend coccids bear live coccids in their mandibles during the nuptial flight. The hemipteran partner benefits from the protection from natural enemies and ant-mediated removal of honeydew, as frequently indicated by elevated rates of population increase in field conditions. Many ant species tending hemipterans also consume other plant-associated arthropods including taxa which cause more damage to the plant than the hemipterans. As a consequence, the hemipteran–ant association often increases plant growth and reproduction in natural conditions.

Honeydew has been used as a source of food by people. Encrustations of honeydew produced by scale insects have been eaten since biblical times in the Middle East. Certain groups of Australian Aborigines and American Indians also used lerp from psyllids and honeydew from scale insects as a source of sugar. In Central Europe, large amounts of honeydew are consumed indirectly, because the honeydew of aphids on conifers is the principal, and sometimes sole, source of food for some honey bees. The honey produced from this source, often referred to as Wald Honig (forest honey), is considered of inferior in quality to floral honey but is, nevertheless, consumed extensively.

In agricultural contexts, the growth of molds on deposited honeydew can depress plant photosynthesis and crop yield and contaminate fruits, vegetables, and flowers, making them unmarketable. For example, sooty molds arising from untreated infestations of greenhouse whitely can halve the yield of glasshouse tomato crops, and cotton growers in the United States have suffered financially as a result of the “gray cotton” caused by sooty mold growing on cotton lint contaminated with whitely and aphid honeydew. Other detrimental effects of honeydew are sticky sidewalks, glazed windshields, and gummed up harvesting machines.

**HONEYDEW AS A KAIROMONE**

The smell or taste of honeydew on the plant surface is used as cues by various predators and parasitoids of hemipterans to locate their hemipteran prey or, for reproductive females, as a stimulus for oviposition. This has led to the use of “artificial honeydew” sugar sprays onto crops to increase the numbers and effectiveness of natural enemies.

**Host Seeking, by Parasitoids**

J. Daniel Hare

*University of California, Riverside*

Ronald M. Weseloh

*The Connecticut Agricultural Experiment Station*

Parasitoids are holometabolous insects that are free living as adults; their larvae are parasites within the bodies of other insects, which they invariably kill as they develop. Most parasitoids are small-to-large wasplike insects in the hymenopteran superfamilies...
FUNCTIONAL TERMINOLOGY FOR BEHAVIORAL CHEMICALS

A terminology has been developed for chemicals that function as signals between organisms, paralleling the activity of the chemical cues involved in host-seeking behavior of parasitoids. All chemical attractants, arrestants, and so on that are important as modifiers of behavior between different organisms are grouped under the general term “semiochemicals.” Pheromones are semiochemicals that serve to communicate between organisms of the same species; sex pheromones are an obvious example. Allelochemicals have effects between species and are further divided into those depending on whether the producing or receiving organism is helped or hurt by the cue. If the species producing the material is helped and the receiving one is harmed, the chemical is called a kairomone. Examples of allomones include repellents that a stinkbug may produce to ward off predators such as ants or birds. A substance that seemingly harms the producing species but helps the receiving one is called a kairomone. The chemicals produced by insect hosts that serve as cues to parasitoids are kairomones because the parasitoid exploits them to the host’s detriment. Usage and context are important here. A sex pheromone may be beneficial in the context of reproduction to attract a male moth to a female, but if a parasitoid cues on this chemical, the substance also functions in the context of interactions between hosts and parasitoids as a kairomone. Unless compounds acting as kairomones are beneficial in some other ecological context, then kairomones should be eliminated through natural selection. There are some materials that may benefit both sender and receiver species. These are called symonomes, and the plant volatiles mentioned below that attract parasitoids to host plants may be symonomes because they make it easier for the parasitoid to find herbivores damaging the plant.

HOST HABITAT FINDING

A female parasitoid may find herself far from potential hosts. This could occur if the host stage she emerges from is different from the one attacked. Also, many parasitoid females have a preoviposition period before eggs are ready to be laid. During this interval of a few days to several weeks, the parasitoid may leave the vicinity of the host to mate and obtain nourishment. For example, the ichneumonid wasp, *Pimpla ruficollis*, is a parasitoid of the European pine shoot moth, *Rhagonycha luteolana*. Yet for the first few weeks of her adult life, she is repelled by the odor of pine, and thus avoids the forest where the host is located. As a consequence, the initial stage in host seeking in many parasitoids is to search for locations where the host is likely to occur. Parasitoids often respond to general stimuli such as light, humidity, or vegetation form, leading them to meadows, forests, swamps, ponds, soil, or different vegetation strata. These behaviors considerably narrow the areas that must be actually searched for hosts.

Insect behavior is sometimes perceived as a rigid, instinctive, inherited phenomenon not subject to change. However, there is ample evidence that many insects vary their behavior depending on circumstances, and that often learning is involved. This is also true for parasitoids. Many female parasitoids respond to host stimuli more strongly after they have parasitized a host. The heightened response, which may take the form of faster host finding and/or more intensive searching, may be considered to be a form of reward conditioning in that the female responds more avidly to host stimuli once she has been “rewarded” by being able to oviposit. Indeed, the response to host stimuli may wane if the parasitoid is prevented from oviposition. This occurs in the ichneumonid *Campoplexis sonorensis* if it is not allowed to oviposit after contacting host frass or damaged plant material. Also, when the eucalid parasitoid *Leptopilina heterotoma* is not able to oviposit, it becomes unresponsive to host cues (*Drosophila larvae*), but it searches more avidly if placed in a novel environment.

Another ability that some parasitoids demonstrate is associative learning. In this type of learning, the parasitoid becomes able to associate a nonhost stimulus with the presence of hosts. For example, the ichneumonid parasitoid *Itoplectis conquistator* can learn to distinguish between different shapes, sizes, and colors of artificial tubes holding host lepidopterous pupae, depending on which ones it has been allowed in which to oviposit. The advantage of such flexibility is probably greatest for parasitoids that are not strictly host specific. Suitably malleable behavior would help these parasitoids take advantage of changes in host and habitat composition.

Some parasitoids are drawn from a distance to chemicals produced by plants in response to damage caused by host herbivores. For example, the braconid larval parasitoid, *Cotesia marginiventris*, can learn to respond to volatile terpenoids released from corn seedlings as a result of feeding damage caused by host *Spodoptera* caterpillars. These chemicals may be components of the induced resistance that plants have developed against pathogens, herbivores, and other stresses. Even leaves not directly damaged by a herbivore may produce such volatile compounds.

Wind tunnel experiments have shown that when such a parasitoid perceives a plant volatile, she reacts by walking or flying upward (aememotaxis), thus often leading to the plants where her preferred host feeds. In fact, in some cases the plant attraction is so important that the parasitoid host range encompasses the often diverse herbivores that feed on that plant rather than hosts that are taxonomically closely related. Plants are not the only habitat characteristics that can produce such attractive volatiles. Parasitoids of carrion-feeding flies are attracted to fresh or decaying meat, and parasitoids of *Drosophila* fruit flies respond to odors from yeast in decaying fruits where their hosts are likely to be present.

The range of odors and other chemical cues that can be learned by insect parasitoids is so broad that it would only be possible to list here a small fraction of the compounds that can be learned.
Learning abilities are so well developed in insect parasitoids that they can even learn to associate the presence of hosts with the odors that are entirely unrelated to their hosts or host plants. For example, the ichneumonid, Venturia canescens, which attacks lepidopterous larvae in cereals, can learn to associate the presence of hosts with the odor of a nonhost chemical such as geraniol. Also, the braconid, Bracon mellitor, learned to associate with its host an antibiotic incorporated into the artificial diet of that host, the boll weevil. Because parasitoids can learn to associate hosts with nonhost chemicals, some investigators think that we may utilize trained parasitoids to identify the particular odors of explosives and illegal drugs much like we utilize trained dogs today.

HOST FINDING

Unless random search is important, parasitoids usually find their hosts as a result of cues derived directly or indirectly from the host itself, often after they have entered the host habitat. Often host cues are perceived at close range. For example, the braconid Cardiochiles nigriceps, increases its searching when it contacts secretions produced by the mandibular glands of its host, Heliothis spp. caterpillars, as the latter feed on plants. The braconid Microplitis croceipes searches areas contaminated by chemicals contained in the feces of Heliothis caterpillars, whereas the braconid Cotesia melanoscia intensely searches leaf areas where host gypsy moth (Lymantria dispar) caterpillars have deposited silk strands. Once these materials have been perceived, stereotyped searching behaviors occur that typically consist of intense examination of the area with the antennae or tarsi. Parasitoids often also decrease their walking speed (orthokinesis) and/or increase turning rates (klinokinesis). These behaviors, which serve to keep the parasitoid in the area having the host products, often lead to host discovery.

Other parasitoids are attracted from longer distances directly to hosts. Some parasitoid females respond to pheromones produced by their host. Parasitoids of the European elm bark beetle, Scolytus spp. caterpillars, are attracted to “multilure,” the aggregation pheromone of the beetles as well as to the aggregation pheromone produced by herbivores, to attract parasitoids. For example, parasitoids of bark beetles are attracted to a combination of plant chemicals produced by trees as a reaction to the mass attack of the beetles as well as to the aggregation pheromone produced by these beetles. Simultaneous responses of parasitoids to long-range host and plant cues illustrate that the division between the categories of habitat and host finding is often arbitrary.

HOST ACCEPTANCE

Although perhaps not technically part of host-seeking behavior, whether a host can be recognized as such after it has been contacted by a parasitoid is very important for the parasitoid. If a female cannot recognize a host as suitable for her progeny, habitat and host-finding activities would be wasted. Parasitoids have evolved behaviors that enable them to accurately choose suitable hosts. Many detect chemicals in the host cuticle or egg chorion that enable them to differentiate one potential host from another. These chemicals are usually detected by their antennae (Hymenoptera) or front tarsi (tachinid flies). The aphidial parasitoid, Aphytis melinus, begins investigating its host, the California red scale, Aonidiella aurantii, after perceiving a particular chemical that is incorporated into the scale’s nonliving cover as though the wasp were “measuring” the host scale insect. Some parasitoids are also able to distinguish between hosts after insertion of the ovipositor by use of sensory organs on the egg-laying organ itself. Acceptance of hosts via other sensory modalities, such as touch, sound, or sight, have also been documented. For instance, a Trichogramma wasp female examines a host egg with her antennae to determine its size. The ichneumonid parasitoid Campsotetra sonorensis is influenced by host caterpillar shape. A cylindrical shape that approximated the shape of the Heliothis virescens host was more effective in stimulating oviposition than round or flat shapes. The egg-larval parasitoid, Cheilonis texanus, accepts host lepidopteran eggs that have a rough or sculptured surface rather than a smooth one. Hairs from the body of gypsy moth larva are enough to cause examination behavior in the parasitoid C. melanoscia. Movements perceived by sight or through vibrations of the substrate are important cues for a number of different parasitoids.

HOST DISCRIMINATION

A behavior related to host seeking involves the discrimination between hosts that have already been parasitized and those that have not. Some parasitoid females, after they have successfully parasitized a host, deposit a chemical marker on the surface that serves to tell other parasitoids of the same or other species that the host is already parasitized. Such marking pheromones have most often been found in parasitoids that attack sedentary hosts, such as eggs or pupae. Often the oldest parasitoid in a host is the one that survives; consequently, host marking saves other parasitoids from wasting time and eggs on a host in which their offspring are likely to perish. Also parasitoids whose ovipositor has been inserted into a host are often able to distinguish parasitized from unparasitized hosts. Whether the cues perceived are the result of marking materials specifically injected by the first parasitoid or of chemical changes in the host resulting from parasitoid development is generally not known.

VARIATIONS IN HOST-SEEKING BEHAVIOR

Although the host-seeking process in parasitoids may be very efficient, such that eggs are deposited only in host species suitable for their development, other strategies are used. Some parasitoids lay eggs in an area likely to be inhabited by their host. The larvae hatching from these eggs then must find their own way to the host. Members of the hymenopteran family Eucharitidae are parasitic on ant larvae. Adult females lay eggs on or in plants. Each hatching larva is a planidium and so is free living and waits until it can attach to a passing adult ant, whereby it is taken into the nest and transfers to ant larvae. Many immature blister beetles (family Meloidae) are also parasitoids. Adult females lay eggs in the soil or sometimes on plants, and the emerging larvae are called tritugnilus. These active larvae find their own way to the eggs of locusts or nests of solitary bees, where they devour the eggs and/or provisions of the hosts. (Strictly speaking, meloids should probably be called “egg predators”, but their impact is much like that of true parasitoids.) Some tachinid flies lay large numbers of very small eggs on foliage that potential hosts may eat. In some cases, the females are attracted to damaged leaves, and this increases the chances of success for their larvae, but suitable hosts may never ingest many eggs. Nevertheless, these parasitoids may be as host specific as those that actively search for hosts.

TRITROPHIC INTERACTIONS

The involvement of plant volatile chemicals in the host-seeking behavior of parasitoids has an ecological and an evolutionary aspect.
By facilitating the parasitization of herbivores feeding on a plant, these synomones would seem to aid both the plant and the parasitoid. Plant and parasitoid then might be expected to coevolve such that natural enemies might impose natural selection on plants for plant traits that enhance the success of natural enemies. A possible example of a coevolved tritrophic interaction may be when a parasitoid is attracted to volatile chemicals produced by a plant only when that plant has been damaged by herbivores. This may make the cue more meaningful to the parasitoid than a cue produced by all plants at all times. The plant also presumably benefits by not wasting resources to produce a cue that is not needed. However, one of many possible alternative explanations is that substances produced by plants as a result of injury are part of a direct induced resistance response of the plant to herbivory; thus the primary purpose of the material would be to decrease foliage palatability or otherwise directly harm the herbivore. A parasitoid then might evolve to use these materials as cues, but the parasitoid would have little or no impact on the evolution of the plant responses. Although intriguing, coevolution has been difficult to demonstrate in any system and should not be assumed in the host-seeking behavior of parasitoids without clear proof.

**IMPLICATIONS FOR BIOLOGICAL CONTROL**

In biological control, high searching capacity is considered to be a very desirable trait of natural enemies. Host-seeking behavior influences searching capacity greatly. The more readily a parasitoid can find a host, the better it will realize its full reproductive potential. Also, for a parasitoid to control a host at low densities, it is necessary to find that host under conditions of scarcity. By using specific cues, especially volatile chemicals produced directly or indirectly by hosts, many parasitoids are able to find these hosts very well. Research on host-seeking behavior has progressed far enough to permit the development of some general concepts that should aid biological control workers as they evaluate the effectiveness of parasitoids. Chemicals involved in host habitat finding are usually perceived from relatively long distances, and they orient parasitoids to travel upwind. Chemicals involved in host finding may be perceived from long distances, but often these are plant materials induced by feeding damage by herbivore hosts. Other chemical cues emanating directly from the host are short range or can be perceived only upon contact. Thus, plants strongly influence initial stages of the host-seeking process. There has been much concern about whether exotic natural enemies imported for biological control can have the detrimental effect of attacking nonpest species, especially endangered species. Because host-seeking behavior effectively determines the host ranges of many parasitoids, the general concepts developed from studies of host-seeking behavior should aid in efforts to delineate host ranges of parasitoids. For example, candidate parasitoids are now often screened for their ability to attack nontarget hosts. These screening tests usually occur in a laboratory, often using insect hosts that are removed from their usual plant hosts. Thus, only host-seeking behaviors associated with cues directly derived from hosts are assessed. This ignores the often strong winnowing effect that attractions to plants exert on potential host ranges, and the laboratory-derived host range may be substantially wider than the natural range. Also important is learning, because the degree of flexibility in host seeking could quantify the likelihood of host switching in parasitoids.

The above-mentioned considerations illustrate the most important implications that host-seeking behavior in parasitoids has on practical biological control, but there is another dimension. *Trichogramma* egg parasitoids intensively search areas in which scales from female moth hosts have been deposited. The main attractive material in these scales is tricosane. When tricosane is artificially deposited on foliage containing eggs of the host moth, the resulting parasitism by *Trichogramma* is higher than in areas not having tricosane. Thus, the direct use of such kairomones could improve pest control by manipulating the behavior of natural enemies. Although such schemes have so far not been economically viable, similar manipulations may prove to be workable in situations not yet tested. Continued research may well lead to some useful control methods.

**Host Seeking, for Plants**

Elizabeth A. Bernays  
*University of Arizona*

Plant-feeding insects may find their hosts by seeking appropriate habitats, by increases in activity that maximize the chances of encountering a plant, by completely random activity in combination with strong arrestant properties of the host, or by attraction to a plant from a distance by smell or vision or both. Often generalized plant odors are attractive, but commonly host-specific odors can be distinguished by specialist insects, and recently it has become known that most such insects are highly sensitive to one or a few host odors that are particularly attractive. Host color and shape can be important in plants with characteristic visual features and in insects that are day flying, although visually mediated responses are usually relatively unspecific.

**FINDING HOSTS INDIRECTLY**

Habitat location appears to be the first step for a number of species, although it is difficult to prove in practice. For example, grass-feeding grasshoppers are attracted to open habitats where grasses are generally abundant, but there are likely to be other reasons for this behavior. The pierid butterfly *Euchloe belemia*, however, is attracted to patches of thorn plants where, typically, its small host plants grow most densely.

Some small insects that find their hosts within fairly short distances may simply rely on increases in activity and turning behavior...
when they detect the appropriate odor, so that they are more likely to encounter their hosts. Among chrysomelid beetles, some engage in random movements that show little change with level of host odor; crucifer flea beetles in the genus *Phylloscota*, for example, move randomly within and between host patches. It has been shown mathematically that random activity is important in overall efficiency of search strategies because, under many circumstances and especially when host signals are weak and plant suitability variable, exploratory search enhances the likelihood that an individual will contact the better plants.

**USING ODORS TO FIND HOSTS**

There are many examples of insects being attracted to the odors of their host plants, both by flying and by walking or crawling. Generalists such as the moths *Trichopisasia ni* and *Heliothis cirescens* and the desert locust *Schistocerca gregaria* fly or walk upwind in wind tunnels toward general green plant odors, and there are examples among all orders of specialist herbivores being attracted to chemicals arising specifically from their host plants (Table I).

</table>

Because of air turbulence, concentration gradients that an insect might follow do not generally exist, except within centimeters of the plant. Instead, there are pockets of odor-carrying air that are carried downwind in a rough plume, and an insect encounters and perceives an irregular series of these pockets. An insect usually responds in two stages. First, there is “arousal,” preparing the insect to respond to some further stimulus. Then orientation occurs, either on the substrate or in the air. Usually the orientation response is a response to the wind, with the insect turning upwind, and this is termed an odor-induced upwind (positive) anemotaxis. Among flying moths, this has been demonstrated clearly in wind tunnels, and the same kind of response may be seen when moths fly upwind toward the source of female pheromone.

Once airborne, the insect needs to monitor its ground speed, so that it can increase its airspeed if the wind is strong. To do this it uses visual information (i.e., image movement across the eyes from front to back). If the wind is too strong and the insect is unable to keep the images flowing, it turns and flies downwind or lands. The use of visual images by a flying or swimming insect to maintain orientation to a current flow is called an optomotor reaction. It enables the insect to maintain an orientation at any angle to the wind, not just directly up- or downwind. If the insect is unable to see the pattern of objects on the ground, it cannot orient. As well as generally flying upwind in response to a particular odor, many moths and beetles follow zig-zag flight paths. This behavior, which evidently is programmed in the insect central nervous system, has the possible function of increasing the chances of encountering a pocket of odor.

Walking insects also show odor-induced anemotaxis. This has been demonstrated in locust nymphs, certain beetles, and aphids, for example, where individuals walk upwind in response to host odors.

In a number of smaller insects such as phytophagous flies, the odor-induced anemotaxis is slightly different; this is well studied are the onion maggot, *Delia antiqua*, and the cabbage maggot, *D. radicum*. In these species, after perception of the host odor, an individual fly turns into the wind and makes short flights. After landing, and again detecting the odor, it reorients into the wind and takes off. This tactic is particularly effective for host finding in vegetation, where the path to the food plant may be rather devious and the odor plume very broken.

A different response to host odor after the initial arousal is to move toward or land on a relevant visual target. This odor-induced visual orientation is believed to occur for, for example, in the cabbage seed weevil, which uses odor-conditioned anemotaxis from a distance and then odor-conditioned landing responses on yellow targets close to the source. A number of insect species may be readily trapped by means of a yellow water trap combined with a host odor source, and it is probably generally true that landing responses induced by the host odor are responsible.

Insects living in soil use odors alone to find hosts. Since, the air moves little in soil, steep gradients of volatile chemicals can be achieved and maintained. Carbon dioxide is commonly used by such larvae, but for specialists, host-specific compounds are also used. Root-feeding larvae, such as that of the carrot fly, *Psila rosae*, and the corn rootworm, respond by moving directly up a concentration gradient. Larvae of the carrot fly respond to a mixture of five compounds found in carrot odor.

For insects that fly or walk, the distances from which olfactory cues elicit responses vary from less than a meter as in the Colorado potato beetle, *Leptinotarsa decemlineata*, to about 30 m in some bark beetles and 100 m in some flies such as the onion maggot. Those that crawl in soil respond from just a few centimeters.

**USING VISION TO FIND HOSTS**

Visual attraction can result from responding to the color or form of the host plant. Because these vary so greatly within a species, and because there is relatively little specificity of shape among plant species, visual responses often occur only in the presence of an appropriate olfactory signal.

In a few examples, visual responses to host features have been demonstrated without the presence of odors. Walking insects of several species are attracted to narrow vertical targets in a plain arena, but the precise significance of this attraction is unknown. Perhaps it is a response to potential vegetation or shelter. Several species of
butterflies, however, have been shown to land preferentially on leaves of particular shapes, with further discrimination occurring only after landing. Shape may interact with color as in the apple maggot, *Rhagoletis pomonella*. Host odors play a role here, but when colored rectangles are offered, the only color to attract flies is yellow, perhaps representing vegetation. If colored spheres are presented, the red and black shapes attract flies, perhaps representing the host fruit.

With respect to color, both wavelength and intensity are important. *D. radicum* lands preferentially on leaves with a leaf reflectance pattern characteristic of its host, whereas the western flower thrips, *Frankliniella occidentalis*, land most on yellows and whites, and more at highest intensities of reflected light. Patterns can also matter. For example, females of *Heliconius* butterflies lay their eggs on *Passiflora* leaves but tend not to oviposit on leaves that already have eggs on them. This is known to be a visual response to the yellow eggs, because if the eggs are painted green to match the leaf, butterflies do not discriminate against them.

A response to color is often coupled with a chemical cue. *Pieris rapae* require the presence of glucosinolates to oviposit but still respond to these chemicals only if they are on blue, yellow, green, or white substrates. Females reject red or black substrates.

Visual cues are usually important only at close range, though occasionally they attract specific herbivores from 10 m or so. This is true for the apple maggot, which has a very clear signal in the bright red fruits of its host substrate.

### LEARNING IN HOST SEEKING

Although the studies are few, it is clear that many insects take advantage of experience in their foraging activities and thus improve efficiency of host finding. For example, butterflies learn to land on leaf shapes that resemble their hosts’ leaf shapes, making many fewer mistakes with experience, and they learn many visual cues, especially color, when these are coupled with nectar rewards. Grasshoppers have been shown to learn that certain colored backgrounds are associated with the presence of high-quality food, and the time taken to find the food inside colored boxes in laboratory training experiments with *Melanoplus sanguinipes* was reduced from about 40 min for naive individuals to less than 10 min after a single experience.

Less is known about olfactory learning, but the work so far suggests that it may be more important than visual learning. Grasshoppers in experiments have been trained with different food odors associated with high-protein, low-carbohydrate diets and low-protein, high-carbohydrate diets. They were then fed untreated diets of one or the other type of imbalance until they were relatively deprived of one or the other major nutrient. Then, given a choice, grasshoppers tended to select against the odor that had originally been paired with the unbalanced food. Thus, if they were overfed protein and underfed carbohydrate, they were more likely to avoid the odor that had originally been paired with high-protein food and instead be attracted to the odor that had originally been paired with high-carbohydrate food.

Food aversion learning has been demonstrated in grasshoppers and caterpillars, whereby individuals having a deleterious postigestive experience after eating a certain food thereafter reject it or eat little of it. However, the role of odor and the importance of the associated cues in behaviors prior to contact have not yet been investigated.

### ECOLOGICAL INTERACTIONS

The abiotic environment and the presence of other organisms influence host-seeking behavior in nature. Among abiotic factors, temperature constraints and needs are probably the most important. For example, thermoregulating grasshoppers choose sites off the ground for cooling, and warm sunny substrates for basking. This can dictate the plants that are immediately available for feeding upon, so selection of thermoregulatory sites influences food selection. For example, the black lubber grasshopper, *Taenioptera equestris*, is highly polyphagous; when temperatures become very high in its desert environment in the middle of the day, it roosts as high off the ground as possible on mesquite or acacia bushes, and thus, any feeding is on these plants. During the cooler mornings and evenings it feeds only on plants at ground level. Many temperate butterflies seek out sunny or warm patches, and thus plants in those patches. For example, the meadow brown butterfly, *Pararge aegeria*, oviposits on various grasses but the actual choice depends on the temperature of the leaves, which in turn is influenced by whether the leaves are in sun or shade.

Wind is important for most insects. Wind speed and constancy influence odor plumes used by orienting insects. The wind speed also limits flight, with larger, stronger flying species remaining airborne at higher speeds. Very small insects are often carried by wind, and depending on the terrain, are deposited preferentially in certain places, such as the lee side of trees and hedges.

The presence of certain nonhost plants and the relative abundance or clumping of the host plant can alter the detailed behaviors involved in host seeking. For example, butterflies ovipositing in a habitat where two or more host plant species occur commonly tend to choose the species they laid eggs on previously, so that they land more often on the common host. In other insects, the host being selected for oviposition is dependent on factors such as the need for additional resources. In one example, the celery fly, *Phyllophaga heraclei*, requires trees near to the celery host because this is where mating occurs and the adult food of aphid honeydew is available.

Insects that show odor-induced anemotaxis to their host plants presented alone in a wind tunnel in the laboratory do not always show the same behavior in field situations. For example, the Colorado potato beetle is attracted, at least from short distances, to its preferred host, potato. However, if nonhosts are also present, the response may be reduced or absent, and the host odor is said to be masked. Such interactions reduce the distance over which some host odors can be detected by phytophagous insects, and the phenomenon may be one of the mechanisms involved in reduction of pest numbers in certain crop mixtures.

In addition, some insects are influenced by olfactory or visual evidence of prior occupation of a plant, competitors of the same or different species, and of the presence of natural enemies.

### PHYSIOLOGY OF THE HERBIVORE

Host-seeking behavior is restricted to times when the ovipositing or feeding insect is in a suitable physiological state. For example, insects about to molt do not feed and are generally not responsive to host odors; in adult females, a load of eggs ready for laying alters motivation so that searching for a host takes priority over other behaviors. Similarly, an insect that has been deprived of food seeks hosts more readily than one that is replete. In nymphs of the desert locust, for example, positive anemotactic responses to the odor of grass in a wind tunnel were not seen in well-fed individuals but were dramatic in nymphs that had been deprived of food for 4 h.

In the bean aphid, *Aphis fabae*, winged individuals that fly distances from one host to another are attracted, when they take off, to the short wavelengths of the blue sky. After flying certain distances, they are preferentially attracted to the longer wavelengths of yellow,
so that they then tend to land on plants in the vicinity. A number of aphid species bias their landings toward the yellower greens that often are associated with plants in an appropriate physiological state rather than toward plants of a particular species.

**LIFE CYCLE AND BEHAVIOR**

**Mating Behavior**

Courtship and copulatory behaviors are the most important and the most complex behaviors exhibited by the house fly. Visual, chemical, tactile, and auditory cues are all used, to various degrees, in courtship and copulation. The elimination of a male’s production of, or a female’s reception of, any one stimulus may not greatly affect mating success. However, if combinations of stimuli are simultaneously eliminated, mating can be significantly affected. In general, males mate as often as they can, whereas females mate just once.

The courtship behaviors of *M. domestica*, and many other calyptrate Diptera, are initiated when the male first sights a prospective female-like object. Males are not very discriminatory in their initial choice of partners and strike other males, other species of flies, and small inanimate objects moving through their visual field.

The discovery of cuticular hydrocarbons that serve as sex pheromones in the house fly triggered a burst of investigations into the role of such pheromones in the mating behavior of the calyptrate Diptera. No evidence has been found that these pheromones are olfactory stimulants; rather, they appear exclusively to be contact excitants. In house flies, chemosensilla involved with contact chemoreception (or “taste”) are located on both the mouthparts and the tarsi. Thus, house flies can “taste” with their feet. When a male touches a female with his tarsi, as he grasps her upon initial contact, he can use the female-produced sex pheromone to determine whether a potential mate is of the correct species, sex, and even mating status. This pheromone is a very important stimulus for the male, and a male repeatedly attempts to copulate with an object that is of appropriate size and “tastes right.”

Behaviors that involve the touching or bodily movement of males and females beginning after the initial contact may be elicited by tactile cues. Tactile cues may be given by either sex during courtship, but it appears that the male’s role is much more complex than that of the female. High-speed photography has shown that the house fly’s courtship is extremely brief and complex. The highly ritualized

**House Fly**

(Musca domestica)

Gregory A. Dahlem

Northern Kentucky University

The house fly, *Musca domestica* (Fig. 1), is one of the best known and most widely distributed insects known to humans. It is a classic example of a synanthropic animal, one that lives in association with humans and their domesticated animals. House flies occur and thrive wherever humans are found but are very rare in natural or wild areas throughout the world. “Insects will survive long after humans disappear” is a common expression, but it is not true of the common house fly. House flies would likely not be able to survive in the absence of humans because their relationship is so closely linked.
sequence of movements that the male performs immediately after contact with the female seems to be very important to the female in her choice of potential mating partners. Males often strike females in mid-flight and perform the courtship ritual during their plunge to the ground. If the courtship is performed to the female’s satisfaction, she allows the male to mate with her. If not, she can dislodge the male and stop mating from occurring by performing one of several different rejection maneuvers.

Mating pairs of *M. domestica* are normally quiescent during copulation. However, if the pair is disturbed, they move, and the female flies short distances carrying the male on her back.

### Development

The number of eggs that mature in a fly’s ovaries at one time is about 120. The female requires both sugar and protein meals for egg production. After copulation, egg laying takes place in 4–8 days. The female requires nearly a day to deposit the eggs, which may be deposited in a single mass or distributed in a number of locations. Each female is capable of developing several batches of eggs during her lifetime. Animal manure is the preferred ovipositional substrate, although a variety of decaying organic material can be used if fecal material is not available. Egg-associated bacterial symbionts appear to serve as resource-partitioning cues in the ovipositional behavior of gravid females.

The developmental time is highly temperature dependent. Hatching usually takes place within 1 day after oviposition. Larval development occurs rapidly, with the larva (maggot) normally passing through all three instars in 5–9 days. After full larval development, the third instar turns into a dark, cylindrical puparium, which is composed of the scerotized skin of the last (third) larval stage. The process of pupation normally lasts about 5 days.

Most adults live for 2–3 weeks at normal summertime temperatures in the temperate regions. Adult flies in the laboratory show longest life spans when fed a diet of sucrose alone, with a mean life span of 34 days. During the summer in temperate regions of the world, the entire life cycle (from egg to egg-laying adult) can be accomplished in 10 days to 2 weeks.

### Flight and Dispersal

House flies are comparatively slow fliers, with a normal flight speed of about 2 m s⁻¹ (or 7.2 km h⁻¹). They have an innate tendency to disperse from their rearing site, even when conditions are favorable. Capture-release studies with marked house flies indicate that 85–95% of the flies stay within a 3 km radius of their release point after 4 days, although a few individuals may travel over as much as 20 km.

House flies are one of very few species of flies that purposefully enter human structures, such as houses and barns. This propensity for entering dark openings has implications on the dispersal of this species, because house flies readily enter cargo or passenger areas of trucks, trains, ships, and airplanes. By this means, gene flow between geographically distant populations is easily, although accidentally, promoted.

### Ability to Land and Walk on Ceilings and Vertical Surfaces

A common question about house flies is, “How do the flies land on ceilings, and how do they walk up smooth vertical surfaces, such as glass windows?” In landing on ceilings, a house fly normally performs a “half-roll” and reaches its legs out to the ceiling. Contact of the tarsi with the ceiling inhibits flight and the fly comes to rest, generally facing the direction that it was flying. A close look at the structures found on the tips of the tarsi help to explain the fly’s ability to cling and walk on ceilings or smooth glass windows. The apical tarsal segment bears a pair of curved claws that are used to cling to rough surfaces. At the base of each claw is a padlike structure, called the pulvillus, which bears a large number of glandular setae. These setae are coated with secretions that make them sticky, allowing the fly to walk on vertical, or even inverted, smooth surfaces.

### THE HOUSE FLY AS A VECTOR OF HUMAN AND ANIMAL DISEASE

House flies, particularly in large numbers, are a nuisance to humans when they enter houses, land and feed on human food, and spot windows with their feces. Of greater importance to humans, however, is their ability to spread human and veterinary disease agents. House flies have been associated with over 100 pathogens that can cause disease in humans and animals. Unlike the pathogens responsible for many other insect-borne diseases, the pathogens spread by the house fly do not usually multiply within the fly, nor do they require association with the fly for part of their life cycle. Instead, the usual association between house flies and pathogenic organisms is one of physical transmission of pathogens the flies pick up on their bodies at one feeding site (e.g., a garbage can or manure pile) and transfer to human and/or animal food on which they land and feed. House flies have been associated with the transfer of a variety of viral and bacterial diseases, such as typhoid fever, cholera, dysentery, and infantile diarrhea, as well as a variety of parasitic worms.

Human History, Insects Effect on

James N. Hogue
California State University, Northridge

Insects have influenced the course of human history by impacting events that shape history, such as wars, or by changing the way societies or important individuals can or cannot accomplish critical activities. This essay will focus on examples of how human interaction with insects has had a profound or noteworthy effect on the course of important events over the past few thousand years. This is not to ignore the impacts of insects on our species earlier than this period. Insects have interacted with our mammalian and hominid ancestors throughout the course of evolutionary history, and their presence undoubtedly influenced many aspects of our evolution. Indeed, insects played a role in the radiation in a lineage of mammals that gave rise to the arboreal, manually dexterous, relatively intelligent primates with binocular vision from which we evolved. Our predecessors evolved in the three-dimensional world of large, angiospermous trees that owe many of their characteristics to coevolutionary relationships with insects. Likely, Homo sapiens would never have existed in the absence of insects.

EVENTS AND GEOGRAPHY

Some insect-influenced historical events resulted from singular interactions between humans and insects, whereas others involved more prolonged association. Among the former are serendipitous instances of inspiration by example that led to important technological advances. Ever since the “invention” of paper was first proclaimed to the Chinese emperor Ho Ti in 105 A.D. by Ts’ai Lun, a variety of plant fibers were used in the production of paper. As writing flourished, supplies of raw materials for making paper became in short supply. Such was the situation in 18th century Europe, where paper was made primarily from cotton and linen. It was here that observations of paper wasps inspired the French naturalist and physicist Rene Antoine Ferchault de Réaumer to suggest the use of wood as a papermaking fiber in 1719. These wasps, which chew wood and mix the fibers with saliva to make their nests, served as the inspiration for the use of the plentiful fiber on which modern papermaking is based. This encounter helped to revolutionize the production of one product that has greatly shaped the whole of human civilization over the past 2000 years.

An insect also played a central role in one of the independent discoveries of the process of animation. Segundo de Chomón, Spanish pioneer filmmaker, developed the technique of stop-motion animation in film in 1902 after observing the results accidentally produced by a fly slowly walking across pieces of paper. The different positions of the fly during a series of frames produced by slow and irregular exposures of a still object (title cards for a silent film), resulted in the appearance of a fly jumping about the screen. A single encounter with a mosquito may have even been the downfall of Alexander the Great in Babylon in 323 B.C. Had these encounters never taken place, the path of history leading to the present would have been different.

Insects have also served as important determinants in the fates of human societies and economies throughout human history, sometimes through exploitation of resources provided by the insects themselves. The survival of the Israelites during their extended journey through the Sinai Desert was apparently made possible by insects. The manna that they gathered, ate, and survived upon was most likely the excreta of scale insects. Likewise, if not for the arrival and help of “divinely inspired” seagulls, a plague of Mormon crickets in 1848 may have ruined the crops and doomed the Mormons soon after their arrival in their new home in Utah. In direct economic terms, insect products such as cochineal and silk were central to the economies of the Aztec and Chinese empires respectively. Furthermore, the silk trade helped establish cultural and economic relationships between China and the rest of the world.

Other influences of insects on the geographical history of mankind were mediated by negative impacts of insects on humans. At least 3 of the 10 plagues of Egypt that are described in the Bible and in the Ipuwer papyrus of ancient Egypt directly involved insects. These plagues and the resultant exodus of the Jews from Egyptian bondage are important elements of the cultural history of these people. More recently, the Panama Canal was built and ultimately controlled by the United States in part because the earlier effort by France was thwarted by mosquito-borne yellow fever.

The role of insects affecting societies is clearly seen in Africa, where the human species originated. For example, as vectors of African sleeping sickness, Glossina spp. (Diptera) have made huge pieces of land in Africa uninhabitable by humans. Other parts of Africa were “protected” from European colonization by Anopheles mosquitoes that transmit malaria. Indeed entire cities changed place because of insects.

Other parts of the world clearly show human influences as well. According to ancient writings, the inhabitants of the city of the Miatines were driven out by fleas as were the people of Myas, a major city of Ionia (now part of Turkey), that was abandoned because of these insects. Contenebra, an ancient city near the Volscian Lake (now part of Italy), was overthrown by ants. The people of the Isle of Crete were displaced by bees, whereupon these insects used their homes to build their hives. The American explorers Lewis and Clark tell of the native inhabitants of the upper Missouri River that would relocate their settlements on account of torment from fleas. According to Thomas Moufet’s “Theater of Insects” of 1658, persecution by hordes of mosquitoes similarly depopulated cities in ancient Greece and many nearby regions around the Mediterranean Sea in ancient times. On a larger scale, the downfall of the Roman Empire was apparently hastened by mosquito-borne disease such as malaria. As a result of deforestation and subsequent siltation of waterways, vast swampy areas around Rome developed into a breeding ground for mosquitoes.

WARFARE

The activities of insects, primarily by transmitting disease to troops in battle, can have profound effects on warfare between humans. In many military campaigns, the number of casualties attributed to insects has exceeded that caused by actual fighting. This is even true in recent conflicts, such as the American–Vietnam War. In cases where such losses of men and resources are one-sided, the actions of insects have determined the outcome of entire wars and thus have altered the course of history.

History records the deliberate use of insects as agents of war and conquest. According to the Old Testament (Deuteronomy 7:20, Joshua 24:12), hornets were the agents of providence used to drive out the unworthy inhabitants of Canaan and allow them to
be overthrown by the Israelites. During an invasion of the Roman city of Nisibis by the Persian king Sapor in 360 a.d., Bishop James ascended a tower, prayed for deliverance, and was answered when swarms of gnats descended against the invaders and drove them out. More than one instance of besieged inhabitants fending off intruders with bees, either by driving the bees toward the enemy with fire or bombarding the attackers with hives, is recorded in ancient writings. Instances and accusations of entomological warfare span the course of written history and include the introduction of agricultural pests by the north onto southern crops during the American Civil War, dispersal of plague infested fleas into China by Japan during World War II, and the introduction of many species of bacteria-laden insects into Korea by the United States during the Korean War.

Although human-manipulated insects have played a minor role in military actions, natural encounters with insects have played the most important role in shaping the outcomes of military campaigns and thus the direction of history. By their persistent torment or role in transmitting disease, insects often mediate the greatest pain and suffering experienced on the battlefield and it was typical that more loss of life was attributed to insect-borne disease than to bullets or bombs. A prominent example of this comes from the American Civil War (1861–1865).

Although the effect of insects on the outcome of the war is unknown, the constant presence of filth flies, mosquitoes, lice, and fleas among both Union and Confederate troops was the greatest cause of misery among the soldiers. Hordes of filth flies generated by the bodies of dead combatants, cattle, horses, mules, and the associated waste from the vast numbers of living men and animals helped spread cholera, typhoid, diarrheaa, and dysentery. Such diseases killed tens of thousands of troops on both sides of the battle lines. Lice and fleas brought general torment on a daily basis, especially in prison camps. Voracious mosquitoes (gallinippers) were a tremendous nuisance and malaria was common on both sides. The effects of this disease among Union troops debilitated so many soldiers that at least one campaign, the first attempt to capture Vicksburg, Mississippi, in 1862, was unsuccessful.

The effect of insects on the outcome of other military campaigns is more definite when the negative impacts are more one-sided. For example, the army of Julian the Apostate, Roman emperor (~361–363 a.d.) Flavius Claudius Julianus, was so fiercely attacked by biting flies (likely mosquitoes) in one campaign that they were driven to retreat. Flea-borne plague is attributed with decimating the Assyrian army of King Sennacherib, causing them to turn back and abort their assault of Jerusalem in 701 B.C. Other examples include ravaged European Crusaders throughout the Middle East (bubonic plague—fleas), failed campaigns of Germany against Hungary (typhus—lice) in 1566, and the Austrian defeat by the French (typhus—lice) in 1741. The most exemplary and well-researched instances of insect-mediated effects on the outcomes of military operations and the resulting consequences are those involving tremendous losses of personnel and unsuccessful campaigns of the French under General Napoleon Bonaparte.

Three military campaigns of the French under Napoleon Bonaparte, the invasion of Egypt and Syria (1798–1799), the establishment of a stronghold in the Caribbean on Saint Dominique (Hispaniola) (1801–1803), and the invasion of Russia (1812–1813), all proved unsuccessful, largely because of obstacles and losses resulting from insect-borne diseases. With the goal of checking the power of England in the east, Napoleon and 13,000 troops invaded Syria from Egypt. Within months, bubonic plague, transmitted by fleas, killed an estimated 2000 troops and demoralized and frightened thousands more. The mission was abandoned and France’s army retreated to Egypt.

Napoleon’s dream of establishing a New World empire was linked to French control of Haiti. From here it was a short distance to the real goal of controlling the vast lands of the Mississippi Valley in North America. These French holdings had tremendous potential and were a major threat to British interests in the region. By 1798, France controlled the island after the British withdrew, primarily because of mosquito-vectored yellow fever. French troops sent to secure the island in January of 1802 were soon experiencing this disease, with devastating consequences. By April, one-third of the troops had succumbed to yellow fever and by late in the year only a few thousand of the nearly 50,000 French military and support personnel survived to return to France. The failure to control the island, largely because of staggering losses from yellow fever, led Napoleon to abandon hopes of an empire in North America and France sold its holdings ($28,000 square miles) to the young United States in 1803 for a mere $15 million. As a consequence, the United States remained neutral in France’s war with England. The following year, Haiti declared independence, the first country in Latin America to do so.

The most dramatic and well-documented French military catastrophe that was mediated by insects involved the destruction of Napoleon’s Grand Armée, in large part from louse-borne typhus. In June 1812, 500,000 French and allied troops set out to invade Russia in an effort to gain control of lands in central Asia whereby Napoleon could invade and ultimately control British-ruled India from the north. By the time they invaded Moscow in September, Napoleon’s army was reduced to 100,000 men, to a significant extent because of typhus that was nearly 100% fatal under the prevailing conditions. The troops were undernourished and in poor health from living in filthy conditions, and they were battling increasingly harsh weather as well as opposing forces as they moved through and encountered the louse-ridden peasants of Poland and eastern Russia. With nothing to support them in Moscow, nearly destroyed by the Russians as they burned and left the city to the French, Napoleon’s forces began their retreat during the cold Russian winter. The suffering on the way back was worse. By the end of the year, fewer than 40,000 remained to cross the western border of Poland. The Grand Armée was decimated and General Bonaparte lost his reputation of invincibility. Within a few years he would suffer his last defeat at Waterloo, see his end as Emperor of France, and die in British-enforced exile on the south Atlantic island of Saint Helena.

Dreams of toppling English supremacy in the world and plans for a French empire were never realized. Although many factors influenced the ultimate outcome of the military campaigns that sought to impose French rule on geographically strategic lands, the role of insects, in this case as vectors of disease, was significant. History would have taken a different, albeit unknown, course in this case and world geography would be different if not for the ever present companions of the battlefield—fleas, mosquitoes, and lice.

### Plague and Society

Perhaps the greatest and most lasting effect of insects on the course of history was the result of sweeping economic, religious, and social reform because of the deadly bubonic plague of Medieval Europe that was spread by fleas. This disease, particularly the huge epidemic known as the Black Death (1346–1353) that ravaged Europe, Asia Minor, the Middle East, and northern Africa, resulted in drastic and significant changes in the social and economic
structure in Europe during the 14th and 15th centuries, changes that influence the nature of human society to this day.

Economic trends during the Late Medieval Period such as the rising cost of food, falling incomes, increasing population pressures on natural resources, and general increase in cost of living were reversed in the time following the significant drop in the size of the population, particularly among the working people. Modern analysis of demographic data describes a 50–60% reduction in the size of the population in Europe during the Black Death, a staggering loss of some 50 million people. The impacts of demand and consumption changed, the large landowners lost their labor force, and the peasantry achieved newfound bargaining power. This time became the golden era of the working class and poor country folk that survived the plague.

Increased purchasing power of the lower classes changed consumption patterns of resources and goods. The collapse of feudalism allowed the rise of a capitalist market economy and a more organized workforce, particularly in western Europe. The greatly increased cost of labor resulting from the reduced workforce provided a stimulus for technological innovation that could permit more efficient production. This in turn led to better, more productive machinery and mass production of cheap goods, particularly by the Dutch and English, whereby the economic and financial center of Europe shifted from Italy to England and the “Low Countries” of northwestern Europe; eventually setting the stage for the Industrial Revolution and ultimately the age of technology in which we live today.

Consequent struggles over power at this time resulted in a series of wars in Europe, including Spanish victories over the Muslims in the Iberian Peninsula in the late 1400s. The resultant reconquest and unification of Spain under Ferdinand and Isabella gave Spain the opportunity, while other powers were busy (England engaged in civil war, War of the Roses) or unwilling, to conquer faraway lands. Thus the exploration that led to the definitive discovery and conquest of the New World.

Another aspect of this tragedy was that the Black Death was interpreted by many as punishment by God, partly for their own lack of piety and perhaps for allowing non-Christian peoples (i.e., the Jews), to live among them. These socially and economically convenient scapegoats were subsequently driven away or killed. Many Jewish people thus fled from western to eastern Europe where they, to live among them. These socially and economically convenient scapegoats were subsequently driven away or killed. Many Jewish people thus fled from western to eastern Europe where they would experience near annihilation six centuries later. Furthermore, dealing with the religious conclusions of this interpretation, and the general experience of individuals coming to grips with such tremendous loss of life in this and subsequent plague events, was influential in the religious transformation of Europe that culminated in the Protestant Reformation of the early 16th century. This time also saw a shift from purely religious education to more secular educational ideals that were based on classical ideas. This in turn opened the mind to the scientific exploration of reality.

Lastly, the organized process of combating the plague spawned the notion that governments had responsibilities toward maintaining the welfare of the people they governed. What is important is that the structure of society did not go back to pre-plague conditions, but was drastically altered in a new and lasting way that is still felt today. These profound economic, demographic, and political changes were ultimately spawned by human interactions with fleas.

CONCLUSION

The focus of history is usually on the impacts of human choices and action. Few historians discuss the implications of environmental conditions and events on important events shaping the course of human history. For example the effects of insects and the diseases transmitted by them on events such as military campaigns are typically underappreciated. The fact that epidemics have profoundly influenced human culture and history has received more attention.

In light of the ubiquity of insects, their prominent role in the function of terrestrial ecosystems, and their myriad interactions with human beings, it is not surprising that insects have been involved in nearly every aspect of human history. Insects were there when we started on the path to domesticating a set of plants and animals and entered into the age of agriculture, technology, and civilization; insects were there for some of science’s biggest triumphs such as the development of the microbial theory of disease and the role of genetics in organic evolution; and will likely be there when the last of our kind passes from the earth.

Hymenoptera

(Ants, Bees, Wasps)

Donald L.J. Quicke

Imperial College, University of London

The Hymenoptera are a major order of holometabolous insects. That is, they undergo complete metamorphosis with distinct egg, larval, pupal, and adult stages. They are one of the five megadiverse insect orders along with Coleoptera, Diptera, Lepidoptera, and Heteroptera, and perhaps even the most species rich of any insect order—certainly this is true at temperate latitudes. They are generally cosmopolitan and, except for some specialized groups, they are most speciose in the tropics.

Although after working with Hymenoptera for a while it becomes easy to recognize members of this order, there are almost no conspicuous defining characters, because the majority of hymenopteran
attributes are plesiomorphic; that is, they are shared with the common ancestors of various other orders. It is not surprising therefore that although almost everyone on earth, save perhaps those living at extreme northern latitudes, is familiar with ants, bees, and social wasps and has vernacular names for these particular taxa, there is not a single vernacular name in any language that refers to them in toto. Hymenoptera are also diverse in terms of their life histories: they include phytophagous, parasitoid, and predatory taxa, both solitary and highly social species, and they range in size from the rather large and intimidating spider-hunting pompilid wasps that can reach 12 cm wingspan down to the tiniest parasitic wasps that are approximately 0.1 mm in length (males of the wingless mymarid chalcidoid, Dicopomorpha echmepterygis). It is hard to overstate their ecological importance because they are collectively involved in so many types of interaction, and it is likely that many are effectively “keystone” species in their own habitats.

The Hymenoptera get their name from the Greek words humen and pteron, meaning membrane and wing, respectively, and this gives the first clue to identifying them. Excluding the numerous exceptions of apterous and brachypterous species that are widely distributed through the order, hymenopterans possess two pairs of membranous wings that are devoid of scales. The forewings are larger than the hind wings, and the two are interlocked during flight by a row of special hooks called hamules (or hamuli) that are on the anterior margin of the hind wing; these hamuli engage (or interlock) with a fold on the posterior edge of the forewings. This system makes the Hymenoptera functionally dipterous (two-winged) during flight, since the wing surfaces on either side of the body acts as a single aerofoil. Hamules are unique to this order of insects.

**GENERAL BIOLOGY**

Since Hymenoptera is a very large order, it is not surprising that a considerable number of biologies and life history strategies are exhibited by its various taxa. Broadly speaking, the basal lineages are phytophagous as larvae, feeding both ecto- and endophytically on a large range of herbs, shrubs, and trees; a few tropical pergid sawflies even feed on slime molds! The great majority of the remaining species are either parasitoids of other insects or predators of insects (e.g., the yellowjackets or social wasps, which are members of the Vespidae) or spiders. However, among the higher taxa, there have also been several reversals to phytophagy, especially through the formation of galls on plants (cecidogenesis). The bees (Apidae) and one other, small tropical group, the Masarinae within the Vespidae, have evolved to make use of pollen and nectar as a larval food source.

**Development**

Like other holometabolous groups, hymenopterans primitively pass through generally five instars, though the number of instars is typically smaller in endoparasitic taxa, and in one such genus there seems to be just a single instar. The final instars of hymenopterans are rather morphologically conservative, with most sawflies having rather caterpillar-like larvae with well-developed true legs and variously developed prolegs on several of the abdominal segments. Adoption of an endophytic way of life by cephoid sawflies and wood wasps was accompanied by a reduction in the prolegs and more generally by reduction of sensory structures. Final instar apercritan wasp larvae are all quite similar and are termed hymenopteriform. They are superficially rather maggotlike in that they lack legs and other processes and often have a rather reduced head. However, many endoparasitoids have highly bizarre, first instars characteristic of their particular families, and for which a variety of specific terms have been coined.

The pupal stage of hymenopterans is exarate; that is, the antennae, legs, and wings are free from the body (in contrast to the Lepidoptera, e.g., in which these components are fused with the body). The pupae tend to be rather delicate and are easily damaged. All sawflies and most members of the Ichneumonoidea + Aculeata clade produce a silken cocoon to protect the pupa. Most of the other parasitic taxa do not, however, probably because they pupate within the host remains or, if they pupate externally, they do so in a location where the pupa is likely to be protected by the surroundings, such as within a leaf mine, gall, or wood boring.

**Key Features in Hymenoptera Evolution**

Given the huge size of the order, it is interesting to consider what features have enabled hymenopterans to be so successful in terms of both individuals and total number of species. Most attention has focused on a small number of features such as selection of oviposition site, modification of that site, the use of venoms, and the evolution of the thin wasp waist, all of which are discussed in this article. In addition, the unusual form of sex determination mechanism, haplodiploidy, may have been particularly important in the evolution of sociality. It is likely, however, that few of these traits have operated in isolation, and it is the interactions of these and other factors that have been important. Thus, for example, evolution of sociality may have been facilitated by the sex determination mechanism but also requires the abilities to remember where the nest is, to recognize nestmates, and to be able to defend the nest.

Several studies have emphasized that the success of the Hymenoptera has probably been a consequence of the general tendency of these insects to provide their offspring with particularly nutritious food sources, and when necessary (and that has been often) to modify poorer foods to better ones. Although this may be most familiar in terms of the provisioning of larvae in the nests by the social wasps and bees, such behaviors and physiological adaptations are to be seen all through the order and are manifested in many different ways.

First, there is egg placement and the larval food resource. The morphology of the ovipositor has been crucial in this respect. The hymenopteran ovipositor is used not only for laying eggs, it is also used to pass venom and/or other secretions to the place of oviposition. In the parasitoid taxa, these venoms either cause paralysis of the host or are important in overcoming the host’s immune response against the parasitoid. The ovipositor is typically well supplied with sensilla, and the insects receive and interpret the resulting sensory information and use it in deciding whether they have located a site or host suitable for egg laying. This organ has been especially well studied in parasitoid taxa, and such observations have been used to test many evolutionary concepts.

In the majority of the aculeates (stinging wasps, bees, and ants) the egg-laying role has been lost, but the same structures are still present and are used for envenomation of prey or enemies. The venoms of most of these act on the nervous systems or nerve–muscle junctions of their prey insects, permanently paralyzing them. In this sense, the venoms are rendering their larval food sources manipulable and safe by preventing the prey insect from wriggling or moving to damage the wasp’s developing young.

“Venoms” were important even before the evolution of parasitoidism. For example, at least some and possibly most wood wasps inject chemicals into their host trees along with their eggs and symbiotic fungi fragments, and these toxins probably either kill the living
Evolution of the thin wasp waist, which defines a large group of families called the Apocrita, was another absolute key feature in that it greatly increased the mobility of the posterior abdomen relative to the thorax. This in turn allowed greater control of the ovipositor and greater variety in its use; later, it allowed the sting, which is in fact just a derived ovipositor, to be much more effective as a weapon of defense and offense. It is interesting that vertebrates can learn that a bee or wasp can deliver a sting and that part of the recognition of this ability involves the very conspicuous abdominal movements of the insect as it probes for a vulnerable spot with its sting. Because male Hymenoptera never possess stings (because the males do not have an ovipositor-derived apparatus!), they are harmless in this respect. Often, however, males very effectively mimic female wasp stinging movements such that people, and probably many experienced predators, do not take the risk and quickly release them—this behavior has been termed aide-mémoire mimicry.

The wasp waist, contrary to many people’s initial expectations, is actually not located between the thorax and abdomen, but is a constriction between the first and second abdominal segments (Fig. 1). In the ants, posterior abdominal mobility is increased even more by second and sometimes third constrictions between the second and third, and third and fourth, abdominal segments, which give rise to the distinct node or nodes between the middle and posteromost body regions. There is a very good reason for the wasp waist to be positioned after the first abdominal segment. Higher hymenopterans are typically strong fliers, and their longitudinal flight muscles are consequently large. Because these muscles are attached internally on the anterior of thorax (actually the mesonotum) and posteriorly on a large internalized chitinous phragma that slants posteriorly, if there were a constriction immediately behind the last (third) thoracic segment, the size of the flight muscles would be greatly restricted. By having the first abdominal segment fused to the thorax, larger flight muscles can be accommodated. Thus, the middle body part of an apocritan hymenopteran is comprised of the pro-, meso-, and metathorax, plus the first abdominal segment, the latter being termed the propodeum. Of course, this nomenclature has often led to confusion among those who lack detailed familiarity with wasp physiology. Nowadays, to avoid ambiguity, it is becoming increasingly common to refer to the middle body region as the mesosoma and the part behind it as the metasoma. Further nomenclatural confusion can arise when, as in the ants and some parasitic wasps, the first metasomal segment (i.e., the second abdominal segment) is greatly reduced. The most conspicuous part of the metasoma is then referred to as the gaster.

Venoms

Most if not all Hymenoptera, even the sawflies (which are phytophagous), have a “venom” gland associated with the ovipositor or sting. In fact, most have at least two distinct glands, the venom gland proper, also referred to as the acid gland on account of its typical histological staining properties, and a second gland, referred to as the alkaline gland of Dufour’s gland in the Aculeata (see later). Details of the function of the secretions of these glands are known for only a few species; for the sawflies, such knowledge is almost completely lacking. It may reasonably be assumed that the initial function was production of lubricants that assisted passage of the egg down the ovipositor; but natural selection would have acted quickly to favor organisms that showed an ability to benefit from modification of the substrate.

In the parasitic wasps, the venom gland products are thought to be primarily associated with two roles: to help overcome the host’s immune defense against the parasitoid’s egg or larva, and sometimes, especially among the ectoparasitic idiobionts, to paralyze the host. In some taxa, perhaps in many, there may also be secretory products from parts of the female reproductive tract itself, and these may play important roles in overcoming host immunity. Of great interest among these are the “polydnavirus soups” produced by the calyx gland in a few groups of Ichneumonoidea; this gland is a modified part of the lateral oviduct.

The venom glands in the aculeate wasps are the source of the well known, pain-inducing toxins that many social and some solitary Hymenoptera use to such good effect in self-defense. One solitary aculeate, a mutillid wasp (or velvet ant), is commonly called the camel-killer because its venom is reputedly strong enough to have that effect, and there are anecdotal reports of soldiers who have been incapacitated by the pain caused by encounters with this substance. Typically, however, the venoms are rather less fearsome. These pain-causing venoms are very specialized and contain a variety of neurotoxins, including, in some taxa, small ringlike peptides that insert themselves in cell membranes and cause depolarization of nerve cells, and consequently pain. It is easy to envisage how these peptides could have evolved from toxins that were originally selected to cause paralysis of the arthropod prey of their ancestors, although probably most are so highly modified that any initial similarity has been lost. A few of the larger parasitic wasps have also developed pain-causing venoms for defense, but their stings are quite mild and the effects short-lived compared with those of many aculeates.

The main function of Dufour’s gland seems to be the production of substances that are involved in intraspecific communication. In the parasitic wasps, the gland probably serves primarily as a source of marking pheromones that indicate where an egg has been laid, likely
to minimize self- and intraspecific superparasitism. Among the social aculeates, the functions of this gland have been greatly elaborated, and it is the source of many other pheromones that are involved in colony organization.

The Ovipositor: A Key Organ

Since Hymenoptera in general are known to take great care in the placement of their eggs, it is not surprising that the ovipositor is an important organ, and one that has shown many specializations for particular modes of life.

The hymenopteran ovipositor is derived from abdominal appendages and comprises three independently movable parts, called valves, that together form the egg canal. The dorsal valve is a fused structure, but the ventral ones are separate. There is no intrinsic ovipositor musculature; rather, the movements of the valves depend on muscles within the abdomen that pull on the internal apodemes of the three valves. Nevertheless, several parasitic taxa have evolved mechanisms that enable them to steer their ovipositors and thus increase their chances of successfully attacking a mobile host that might otherwise be able to wriggle away from its attacker. Although the penetration of the substrate by wasp ovipositors is usually referred to as “drilling,” it is important to realize that there is no circular motion; penetration is achieved by the to-and-fro motion of the three valves relative to one another. In the simplest mode of operation, one valve has a projection or nodus that interlocks with the substrate, and this acts as a support for the others to be pushed forward.

The sawflies get their name from the laterally compressed, strongly serrated, ovipositors with which they insert their eggs under plant cuticle. These ovipositors are unsuited, however, for penetration of wood, and the wood wasps’ ovipositors are longer and rounder in cross section, with serrations used for rasping wood fibers, located just at the tip (see Fig. 2). Most of the parasitic Hymenoptera have a similar ovipositor except that in many of those with exposed hosts it is much shorter and has reduced serrations because there is no substitute to “drill” through. Some ovipositors are very long (up to 12 times longer than the wasp’s body), and various mechanisms and behaviors have evolved to enable the wasp to manipulate them.

The Road to Parasitoidism

The evolution of parasitoidism has long been of interest, and several possible scenarios have been discussed at various times. As our understanding of the phylogenetic relationships of the basal parasitic wasps has firmed up over recent years, it now seems most probable that the transition to a parasitoid way of life occurred first among some ancestral wood wasp, because the closest extant sister group of the parasitic Hymenoptera is almost certainly the Orussidae; which collectively are derived from wood wasp ancestors. The most widely discussed and generally accepted proposal for the evolution of parasitoidism in the Hymenoptera envisages an ancestral wood wasp gaining an advantage by producing a larva that could encounter, kill, and eat another wood-boring insect—possibly the larva of another wood wasp or of a beetle—because such a food item would have a greater nutritional value than the plant diet. An advantage therefore would have been gained if the female ancestral parasitoid were to seek out oviposition sites branches where such food bonuses occurred. This could occur only if the prey item, such as a batch of eggs or perhaps a minimally mobile prepupa or pupa, did not pose a danger to the ancestral parasitoid. The next step would be from a facultative utilization of vulnerable prey insects to supplement a plant-based diet with an obligate one, eventually eliminating the need to consume plant material. So by evolution of the wood wasps, prey species become hosts. At first, as in extant orussids (see later) the larva might have done the final prey location, but the pretoparasitoid in this scenario always evolves to use its ovipositor to injure or kill the prey, perhaps by stabbing. Subsequently, venoms evolved greater sophistication until they were able to induce permanent host paralysis, and even to help keep the host fresher for longer by preventing it from becoming infected with fungi and bacteria.

Gall Formers

As with several other insect orders, some groups of Hymenoptera have evolved ways of making plants produce especially safe and nutritious places (i.e., plant galls) in which to shelter their young. Because hymenopterans produce venoms that contain a wide range of pharmacologically active compounds that affect host insect physiology, it is not very surprising that some of these might affect plants—and the typical plant response to damage is cell proliferation, forming a callus. Thus, venom usage may have preadapted parasitic wasps for the evolution of gall forming (cecidogenesis). We cannot know whether this has always been true, and at least in the extant Cynipidae, the gall wasp family, the phytotoxins that stimulate gall production are produced by the wasp’s larva and are not components of the female venom. Gall-forming sawflies, however, do seem to have undergone this preadaptation. True gall wasps (cynipids) have colonized and diversified upon only a few plant groups, notably Rosaceae and Fagaceae, although the other gall-forming Hymenoptera collectively attack a huge range of plants.

One family of chalcidoid wasps, which are also gall formers in a sense, are of particular interest. These are the pollinating fig wasps belonging to the Agaonidae. These insects develop within the ovaries.

FIGURE 2 A large ichneumonid wasp, Megarhyssa sp., using its ovipositor to “drill” through a tree trunk to reach its host, a siricid wood wasp larva. The ovipositor is very thin and pointing between the fore legs; the large black structures are the protective ovipositor sheaths. (Photograph by Nathan Schiff.)
of fig flowers, consuming as larvae the galled tissue. Many people eat figs, but few know that originally at least, the cultivated fig and all its relatives in the genus *Ficus* (Moraceae), relied absolutely on the pollinating activities of these specialized agaonid wasps. Figs are actually not fruit in the strict sense but are syconia—that is, a hollow flasklike structure containing many flowers. The female fig wasps collect pollen from the flowers within the fig in which they have developed, and upon entering another developing fig, actively pollinate the flowers. Figs and their pollinator wasps have evolved in a tight association, and each of the 400 or so species of fig (all members of the genus *Ficus*) has one or, rarely, a couple of pollinating wasp species associated with it that pollinate no other fig species. In these wasps, the males are especially highly modified and do not leave the interior of the fig as adults. Instead they compete with one another for mates and frequently kill competitors with their large mandibles. Males are also responsible for chopping an exit hole through the wall of the fig that enables the female pollinator fig wasps to escape and go in search of new figs.

**The Road to Sociality**

Perhaps the greatest claim to fame of Hymenoptera is that the order includes several highly social groups of insects, various bees, yellowjacket (vespid) wasps, and ants. The only other insect order with such a large number of highly social species is the termites (Isoptera). Within the Hymenoptera, sociality has evolved on quite a few separate occasions, and much consideration has been given to the reasons for this circumstance. Probably a variety of factors have contributed.

Provision of a good food source for the larvae first involved selection of a suitable host plant species, but with the evolution of parasitoidism, the degree of selectivity increased. Further selectivity is apparent with the very narrow host ranges of many of the parasitic taxa and, also, their ability to assess the suitability of individual hosts of the right species. This may be viewed as a progression in the degree of individual attention provided to each individual offspring. In several lineages, all in the Aculeata, additional behaviors have evolved to make hosts, in a sense, more suitable—at first these changes consisted of moving a host to a slightly preferable location before oviposition. This is seen in several members of the Bethylidae. Some bethylids also show a degree of parental care in that the female remains with her single brood through their development to guard them against predators and to guard the host against other parasitoids including conspecific females. In the bethylid wasps the degree of parental care is limited to the brood care, but in a number of groups, notably among the pompilids and sphecids, the female wasp prepares a hideaway in which to cache the insect or spider that will provide her offspring with food. Probably at first, once a host had been identified, the female would locate, dig, or modify a burrow; a further evolutionary step was likely the postponement of burrow construction until the search for a host had begun. This stage required the behavioral sophistication of being able to remember the location of the burrow and to relocate it once a prey had been found. This step was crucial for the evolution of sociality because nest members must be able to locate their nests after foraging expeditions. Another major development allowed by this evolutionary advance was the use of hosts, now usually called prey, that are smaller than what would be necessary for the development of the wasp, because it was now possible to bring back multiple individual hosts for each of the wasp’s larvae. This is the stage exhibited by many sphecid wasps.

In these, the paralyzed prey are first accumulated until there are sufficient, then an egg is deposited on the cache, and this set is sealed into a cell, after which the female starts collecting more prey for her next egg. Bees and vespid wasps have independently dispensed with sealing their larvae in individual closed cells with all the food that they need; instead, they provide food continuously upon demand—prepared food, that is, rather than whole prey individuals.

**Reproduction and Sex Determination**

As far as is known, all hymenopterans have a haplodiploid sex determination system, which means that haploid individuals (having only one set of chromosomes and resulting from unfertilized eggs) are males, whereas diploid individuals (having two copies of each chromosome and resulting from fertilized eggs) are females. This sex determination system is found in a few other groups of organisms, notably in thrips and some rotifers. Development of unfertilized eggs into males is a form of parthenogenesis and is termed arrhenotoky.

There is certainly more than one sex determination mechanism even within this haplodiploid system, and this has important consequences in matters such as biological control. The best understood (or surmised) mechanism, called complementary sex determination (CSD), is characterized by the occasional occurrence of diploid (but infertile) males and by the tendency of the proportion of these to increase with inbreeding. Culturing species with this sex determination mechanism is difficult because small population sizes result in the gradual loss of sex alleles and so an increase in frequency of diploid males and loss of colony vigor. In the rearing of insects for biological control programs, the appearance of an abnormally high number of diploid males can be a very serious setback, because when colonies become inbred, they go extinct.

**COMPLEMENTARY SEX DETERMINATION (CSD)**

Although the exact molecular details are unresolved, there is a reasonable hypothesis that CSD may involve polymeric proteins, the most simple of which are dimers. A heterodimer (i.e., an association of two different protein chains) has a different shape from a homodimer (two identical protein chains), and this shape difference determines the sex of the offspring. Because haploid individuals can make only one form of the protein (they only have one gene locus), they must make the homodimeric form, and this means that they will develop as males. It seems that in natural populations there are typically quite a few sex alleles (roughly between 6 and 50), with the result that the proportion of fertilized eggs that contain two copies of the same allele is rather small. Thus the proportion of eggs that either fail to develop or produce infertile diploid males would be expected to be small, as well.

**NONCOMPLEMENTARY SEX DETERMINATION**

Not all Hymenoptera can possess CSD, as is evidenced by the routine inbreeding that occurs, for example, in some parasitic wasps. In these species, a female lays on or in a single host an often large brood of eggs consisting mostly of daughters (from fertilized eggs) and a single haploid male (or at least a very low number of sons), which fertilizes all his sisters when they emerge. This goes on for many generations and undoubtedly must lead to increased homozygosity, but these wasps show no progressive change in sex ratio or fecundity as CSD would necessarily cause. However, what sex determination system is involved in these insects is not known, and while a gene dosage mechanism is widely postulated and seems highly likely, it is not proven.
RELATEDNESS AND MATING  A particular consequence of haplodiploidy that has been invoked as a major reason for the multiple independent evolutions of sociality within the Hymenoptera is that it leads to a change in the normal degrees of relatedness between a mother and her sons and daughters and between siblings, and this difference is most pronounced if the female has mated only once. The reasons are as follows. A male offspring gets all his genes from his mother (because he is haploid and so has no male parent), but he gets only half of the mother’s chromosomes; in the Hymenoptera, therefore, a son is 50% related to the mother just as in mammals. However, if the female has mated only once, her daughters, which come from fertilized eggs, contain half her set of chromosomes plus 100% of those from the male parent (because he is haploid and all his sperm are identical). Overall, therefore, each daughter is 75% related to each other daughter, whereas daughters are related to their mother only 50%. The argument regarding sociality is that because sisters in Hymenoptera are more closely related to each other than they are to any potential offspring they could have, their fitness will be better enhanced by helping their mother to produce more sisters than by reproducing themselves.

The vast majority of species of social ants, bees, and wasps only mate once. Thus, the foregoing arguments may generally hold. However, there are exceptions, and honey bee queens typically mate about a dozen times. Thus, for these insects the disparity in relatedness between offspring and sisters is much closer to the 50:50 ratio of normal diploid taxa.

PHYLOGENY, CLASSIFICATION, AND WHAT PARTICULAR GROUPS DO

The Hymenoptera are member of the monophyletic group of insects known familiarly as the Holometabola, and it is among these therefore that their relationships must be sought. The search for such relationships, however, has thus far proved to be rather difficult, and despite a growing body of molecular data, a consensus about the exact relationships of the order has yet to emerge. Weak evidence has been put forward to suggest a relationship with the Mecoptera, but the characters involved are liable to homoplasy. One possibility is that the Hymenoptera form a sister group to the whole of the rest of the Holometabola (or at least, of the extant holometabolan orders).

Classification

For a long time the Hymenoptera have been broadly divided into three groups: the sawflies or “Symphyta,” the aculeates; or stinging and social wasps, bees, and ants and their close allies; and the remainder, which are typically referred to as the parasitic wasps or “Parasitica,” even though many of them are not parasitic at all. It has long been realized that this is an unnatural arrangement, and slowly an attitude more consistent with our understanding of hymenopteran phylogeny has been filtering into the literature. Thus, although it is still useful to be able to refer to sawflies as a group, the use of a formal classificatory term for them to the exclusion of all other Hymenoptera (i.e., Symphyta) is rather unsatisfactory. This is because it has long been known that the “Symphyta” are a basal grade that leads to the wasp-waisted Hymenoptera; “Symphyta” are therefore not a monophyletic group (i.e., all the descendants of its single basal species are not included); rather, they are a paraphyletic one, and so from a cladistic standpoint, should be recognized as such. The situation, though, is complicated because most languages, lack a vernacular term for all the sawflies exclusive of the wasp-waisted taxa. Thus, use of informal terms, typically indicated as such by the use of quotation marks, is seen more and more. Terms like “Symphyta” indicate that the name is being used as a handle of convenience and should not be taken as a reference to a monophyletic group.

The wasp-waisted Hymenoptera have also been traditionally classified into two groups, the “Aculeata” and the “Parasitica,” the former group being largely (though not entirely) distinguished from the latter by the loss of use of the ovipositor for egg laying, being used instead for stinging prey and/or potential enemies. As with the “Symphyta,” the “Parasitica” are no longer recognized as a formal group because there is a reasonable consensus that the aculeates are derived from within them, so rendering them paraphyletic. The Aculeata are strongly supported as monophyletic, at least on morphological grounds.

Sawflies and Wood Wasps

The basal representatives of the order from within which the parasitic and social families of wasps have evolved are the sawflies and wood wasps. There is little doubt that the most ancient extant family of the Hymenoptera is the Xyelidae, represented today by two subfamilies, one whose larvae feed on gymnosperms (either pollen of male cones or on buds or young shoots), and the other having rather caterpillar-like larvae that feed exposed on the leaves of elms and walnut species. Xyelid sawflies possess distinctive antennae (Fig. 3) with the first section of the flagellum very enlarged (possibly as a result of the fusion of multiple segments). Fossil xyelids date from the middle or late Triassic, some 200 mya, and are the earliest known fossil Hymenoptera (Tables I and II).

Three other superfamilies of typical sawflies are recognized: the Pamphiloidea, which are relatively uncommon (though they include

*The Chrysidoidea, Vespidea, and Apoidea comprise the aculeate Hymenoptera. The true number of species in the Ceraphronoidea, Platygastroidea, Diapriidae, Chalcidoidea, and Ichneumonoidea, in particular, are likely to greatly exceed the figures given here.*

*The Chrysidoidea, Vespidea, and Apoidea comprise the aculeate Hymenoptera. The true number of species in the Ceraphronoidea, Platygastroidea, Diapriidae, Chalcidoidea, and Ichneumonoidea, in particular, are likely to greatly exceed the figures given here.*
a few pest species), the Cephoidea or stem sawflies, which are rather slender and feed endophytically in grasses and a few woody plant stems, and the very large and speciose Tenthredinoidea. All these are predominantly Holarctic in distribution, although it is likely that at least the tenthredinoids have moderate species diversity in the tropics, even though they are typically quite uncommon there. Some tenthredinoids form galls (e.g., the genera *Euura* and *Pontania*), and it appears that secretions from the female sawfly contain the cecidogenic compounds. A few are interesting because they show a degree of parental care (Fig. 4), and in some Australian pergids, the caterpillar-like larvae form resting aggregations during the day but disperse over the food plant at night to feed on the leaves, apparently communicating by means of vibrations.

The wood wasps were recognized as a group of three superfamilies, the Siricoidea, Xiphydroidea, and Anaxyeloidea (by Vilhelmsen in 2001), although the greater part of the literature on wasps refers to them simply as Siricoidea. This division is intended to reflect better the phylogeny of the group (Fig. 5), which forms a grade rather than a monophyletic group. Their endoxylous larvae are typically associated with fungus-infected wood, and the adults are responsible for transporting these fungi to their host trees in a special mycangial pouch that is associated with the reproductive system and lies near the base of the ovipositor. In addition to these fungi, at least in some siricid species, components of the secretions injected into the tree at the time of oviposition are actually phytotoxic and may be important in helping their fungi overcome the tree’s defenses. Some siricids are important pests of conifer plantations.

There is a very large body of evidence that the Orussidae form the sister group of all the wasp-waisted or apocritan Hymenoptera and, therefore, its biology is of such interest that the family warrants some separate discussion, small though it is. There have been few detailed biological studies on the group, but it is clear that some, probably all, are parasitic on wood-boring insect larvae, although in at least one species the final instar continues to feed on and in its host when it is fairly well decayed. The orussids cannot be considered to represent the ancestral condition of the parasitic wasps as a whole because they show many very derived features not found in any other Hymenoptera. It is tempting, however, to consider at least that their biology is closely similar to and perhaps not modified much from the earliest parasitic wasps. Recent studies have shown that they use vibrational sounding (i.e., echolocation through a solid substrate) to detect their host boring. The females’ antennal apices are massive and solid and are used to tap the substrate, and their foretibiae contain massive subgenual organs that are used to detect the vibrations that are transmitted through the wood. This form of host location has evolved on several independent occasions within the order, but the Orussidae are particularly interesting because the egg may be laid into a boring some distance from the host (in the studied species a beetle pupa), and it is the first instar orussid that seeks out the host.

**Apocrita or Wasp-Waisted Hymenoptera**

In terms of numbers of species, the Apocrita is dominated by parasitoids, but the very great biological developments leading to the evolution of sociality in bees, yellowjacket wasps, and ants has had the effect of polarizing study and discussion, and, in the past, also classification. It has long been appreciated that the aculeate Hymenoptera, which include the social taxa, have evolved from within the Apocrita (in fact, they seem to be most closely related to one particular superfamily, the Ichneumonoidea).

**THE “PARASITICA”** The “Parasitica” is a paraphyletic group (with respect to the aculeates) that comprises some 11 or 12 superfamilies, the exact number being a little unstable because rapid advances in phylogenetic studies are tending to suggest that some previously recognized taxa are paraphyletic or polyphyletic. Consequently, the number is likely to increase by a few when new evidence leads to robust and better resolved phylogenetic trees. A rather conservative phylogenetic hypothesis is shown in Fig. 5, but even this is problematic. Areas of particular uncertainty are the monophyly of the Proctotrupoidea (even after the Platygastridea, once included therein, have been removed to a separate group), and of the evaniomorph superfamilies
parasitoids of other insects. The term “parasitoid” is used almost universally nowadays to distinguish the interactions of these insects from those of parasites, although purely for reasons of euphony, we still often refer to them as parasitic wasps rather than parasitoid wasps. Whereas true parasites live off the living bodies of their hosts, they seldom kill them; indeed, it would usually be maladaptive for them to do so because the longer the host lives, generally the greater will be the reproductive opportunity of the parasite. Parasitoids, however, always kill their host and treat it as a single meal that will provide all the food necessary for their own development. Once the parasitoid wasp has eaten all of the host that it needs, the host is no longer of use, and so there is no need to leave it to recover. In this respect, parasitoids are rather akin to predators but, unlike predators, they require only a single host (i.e., prey) individual to provide all their needs. (Predators, on the other hand, eat multiple, often very many, prey during their life span.) Even so, a few groups of “parasitic” wasps actually behave more like predators. These include species that attack egg masses of, for example, spiders, and species whose larvae will eat not one egg but many or all in the spider’s batch.

IDIOBIONTS AND KOINOBIONTS Almost all parasitoids can be classified into one of two classes defined by whether their hosts continue developing after parasitization (the koinobiont strategy) or whether further host development is curtailed at that time (the idiobiont strategy). These strategies explain many other aspects of the wasp’s biology, such as longevity, egg development, egg size, and fecundity, and host range, as discussed in greater detail elsewhere in this volume and in works by Godfray and Quicke. There has been general agreement that the first parasitic wasps were probably idiobionts. However, it is far from proven that this means that within any given parasitic wasp family or superfamily, the idiobiont taxa are necessarily ancestral. Indeed, the most parsimonious explanation for the distribution of parasitoid life history strategies on several of the most widely cited phylogenies suggests that endoparasitoids have evolved into ectoparasitoids on many occasions within the Chalcidoidea, though probably not within the Ichneumonoidea.

Hymenoptera

Aculeate Hymenoptera

The very familiar, often social, ants (Formicidae), bees (Apidae or Apini depending on classification system), and yellowjacket wasps (Vespidae) have rather dominated the traditional classifications of Hymenoptera. These taxa are united with a number of other, rather less familiar ones to form a monophyletic group called the Aculeata. Most members of this clade have derived biologies, though some families are still functionally parasitoids. In these, however, the ovipositor proper is not used for reaching hosts, and only in a few (possibly derived) cases is it actually used for passing the egg. Even among the essentially parasitic species there is a strong tendency toward physically manipulating hosts. Many spider wasps (Pompilidae), for example, drag paralyzed hosts to a hiding place before ovipositing on them, sometimes biting off the spiders’ legs to facilitate handling and carrying. The least-derived biology is to use a preexisting cavity as a hiding place, and subsequent evolution has led to many levels of modification or de novo nest construction.

SOCIAL KLEPTOPARASITES AND SLAVE MAKING The great resources afforded by social insect nests have attracted the evolution of numerous thieves, some of which are other hymenopterans, often closely related to the species being robbed. The most interesting of these interactions are exhibited by social kleptoparasites when a female of a nonsocial species replaces the queen of a social one and makes use of the workers in the host colony to rear her own brood, rather than relying on more of their own siblings. This ability obviously depends on sophisticated mimicry, not just visual, but more particularly chemical and tactile, or otherwise the usurped workers would detect the intruder. Social kleptoparasitic taxa have evolved independently on numerous occasions and are known among bees (Apidae), vespid wasps, and ants. “Slave making,” another form of social parasitism, is known only among the ants, but within this family it has been evolved by several different lineages. The workers of one species are abducted by the slave-making species and forced to forage for the latter.

RELATIONSHIPS TO MAN

Beneficial Species

The number of beneficial hymenopterans greatly outweighs the number of harmful ones, though some taxa fall into both categories depending on circumstance. Even the vespid wasps (yellowjackets), which are well-known misfits at picnics and barbecues, and occasionally have serious medical consequences, are responsible for eating a very large number of other insects (their larvae are fed almost entirely on chewed-up insect muscle), and in agricultural settings undoubtedly devour many pest insects. Humans have made use of the voracious insect-eating capacities of some ants for many years. For example, Chinese citrus growers have traditionally transferred tree ants, Oecophylla spp., into their orange groves to consume potential pests, and central European foresters have had considerable success in controlling pest outbreaks by transporting into forests the nests of wood ants, Formica rufa.

Biological control programs have made a great deal of use of parasitic Hymenoptera to control host pest populations, sometimes with spectacular results, and when such controls work, the cost–benefit ratio is very favorable. It is becoming increasingly possible to use commercially produced parasitic wasps to control pests in private gardens and greenhouses as well as on large commercial enterprises, and this has obvious desirable features such as reducing the need to apply pesticides.

Bees and Honey

Probably best known of the beneficial affects of Hymenoptera is the production of honey, which people have valued as a sweetener since prehistory. Originally various honey-producing wild bee nests would have been harvested, and indeed are still harvested by indigenous peoples on several continents. However, one species, the European hive bee or honey bee, Apis mellifera, was found to be both productive and manageable, and it was effectively domesticated by getting it to nest in artificial hives several thousand years ago. The first records of beekeeping come from ancient Egyptian wall paintings, some 2500 years B.C. Bees also produce wax from which their larval cells are formed, and this is also widely used for a variety of purposes, from candles to cosmetics and from pharmaceuticals to polishes.

Although most people think of A. mellifera when they talk of bees, there are in fact more than 25,000 bee species in the world, the majority of which are solitary rather than social. Collectively, bees are of
immense economic importance because of their major role in plant pollination, which includes the pollination of a large number of crop species, and this service is far more valuable than the production of honey and beeswax. In addition to the economic importance of bees, most ecosystems rely on them for pollination, largely because bees have evolved, diversified, and specialized together with the angiosperm plants they pollinate, and it cannot be doubted that loss of many bee species would have a long-term dramatic impact on the floral composition of many habitats. Interest has been increasing of late in non-"Apis" bees because of the realization that they may be excellent pollinators of many crops, sometimes better than honey bees, and that changes in habitat use have led to a decline in many of these useful species. Additionally, Varroa, a parasitic mite that has spread from its natural eastern honey bee host, A. cerana, onto the common honey bee, has resulted in serious losses of the latter and thus in pollination rates.

All bees feed their larvae on pollen that is harvested and processed by the adult females (worker bees among the highly eusocial taxa). Typically the pollen is mixed with nectar, although plant oils are sometimes used. The honey made, for example, by Apis is not a food for the bee larvae at all, but rather a high-energy food source that is produced and stored by the social bees for times when their normal source of energy food, nectar, is in short supply or simply unavailable—as in temperate winters.

### Pests and Medical Importance

Considering the great abundance and species diversity of the Hymenoptera, it could easily be argued that the order includes very few pests. There is general awareness that many bees and most social wasps are capable of delivering a quite painful sting, but for most people these stings are relatively minor, if unpleasant, quickly forgotten occurrences. In the United States approximately 50 people die each year as a result of hymenopteran stings. To put this statistic into perspective, about 25 people are killed each year by lightning in the United States.

The major cause of death from hymenopteran sting is respiratory block, sometimes as a result of a sting in the inside the throat as a consequence of inhaling a wasp or bee, but also often because of more systemic reactions. Approximately 2% of the population is hypersensitive to hymenopteran stings, but although such sensitization puts the victims at a greater risk, only about one death per year in the United States is attributable to a hyperallergenic response.

Some sawflies and gall wasps are economically important pests of crop and ornamental plants, but many of these have potential roles in the biological control of weeds as well. Notable pest sawflies include both external foliage feeders such as the pine sawflies (Diprionidae), which can be major defoliators of coniferous forests, and concealed feeders such as the wheat stem sawfly, Cephus cinctus (Cephidae) and the siricid wood wasp, Sirex noctilio, with the latter having caused considerable harm to pine (Pinus radiata) plantations in Australia and New Zealand.

Probably the largest number of pest taxa is to be found among the ants. There are a number of introduced taxa in many parts of the world that cause considerable damage to crops, are harmful to livestock, and have nuisance value to humans. Three of many possible examples will serve to illustrate the range of harmful interactions that can occur.

The tiny pharaoh ant, Monomorium pharaonis, a tropical species widely introduced into buildings in the Northern Hemisphere, often gets into hospitals, where it is a potential vector of bacteria—it has the habit of getting into almost anything in its foraging, including under bandages. The Argentine ant, Linepithema humile, is a highly invasive species that fights and outcompetes other ants in introduced regions, and its huge colonies cause damage in agricultural situations because they protect aphids and other honeydew-forming pest insects. Third, the red imported fire ant, Solenopsis invicta, which has spread alarmingly in the southern United States in recent years, is very aggressive, especially when its mounds are disturbed. Fire ants will sting people, pets, and livestock many times, with resulting pain, blisters, and even systemic reactions, and small pets are sometimes killed by them. Interestingly, many of these pests are far less harmful in their native regions.

### IDENTIFICATION

As might be expected with such a large insect order, identification of hymenopteran species, but also genera and even families, is not without its difficulties. Even in parts of the world where the insect fauna is quite well known, such as Europe and North America, there will be many groups for which there are no satisfactory identification keys. In less well-known parts of the world, almost any reasonably sized sample will contain numerous undescribed species and within some families even genera. The presence of so many unclassified hymenopterans reflects a combination of innate taxonomic difficulties such as the insects’ small size, the large number of similar species, and often a great deal of superficial convergence. In addition, because the order, with few exceptions, has not attracted a great deal of amateur attention, relatively little work has been done on it. Recent years have, however, seen vast improvements to the situation. Several well-illustrated keys to all families have been published, as well as several major works on the more popular aculeates. Particularly useful works are by Gauld and Bolton, and Goulet and Huber.

Hypermetamorphosis

John D. Pinto
University of California, Riverside

Hypermetamorphosis is a form of complete insect metamorphosis or holometaboly in which at least one of the instars in the life cycle differs considerably from the others. The term heteromorphosis, preferred by some entomologists, carries a degree of ambiguity in that it also refers to the relatively minor differences characterizing consecutive instars in virtually all insects, as well as to the phenomenon of organ replacement following mutilation. Hypermetamorphosis is most common in parasitoids, where it usually is the first instar that deviates structurally and behaviorally from the others. In some groups one or more of the subsequent instars also are distinctive. In the same way that holometabolous development allows a division of function between the larva and adult insect, hypermetamorphosis can be viewed as an exaggerated form of holometaboly characterized by additional division of function within the larval stage.

GENERAL CHARACTERISTICS AND TERMINOLOGY

Two broad categories of hypermetamorphosis can be recognized in insects. In the most widespread form, there is a decoupling of oviposition site and the larval food; in the other, the oviposition and larval feeding sites are identical. For convenience, these can be referred to as type I and type II hypermetamorphosis, respectively.

Type I adult females do not oviposit directly at the larval feeding site; instead, the first instars must find the food source. Such larvae are active, slender, and well-sclerotized (Fig. 1A); they are further characterized by their ability to exist for a considerable time without nourishment and without becoming desiccated. Depending on the group, the first instar may attain the feeding site by direct searching, or indirectly by phoresy, in which it is carried to its food usually by the host itself. Once on the larval food, the first instar begins feeding, and subsequently molts into a grublike and less mobile larva (Fig. 1B). Phoretic larvae are commonly equipped with elongate caudal cerci and a terminal suction process (or pygopod), which allows them to stand erect, thus facilitating contact with passing hosts. Although comparative studies are few, hypermetamorphic taxa seem to be more fecund than nonhypermetamorphic relatives. This apparent difference is attributed to the reduced likelihood of larvae finding suitable hosts. Two general characteristics of adult females with this form of development are the absence of a well-developed ovipositor and the laying of eggs in masses rather than one at a time.

Type I hypermetamorphosis is found in the Strepsiptera (all groups), Neuroptera (Mantispidae), Coleoptera (several families), Diptera (Nemestrinidae, Aceroceridae, most Bombyliidae, some Tachinidae), Hymenoptera (Perilampidae, Eucharitidae, some Ichneumonidae), and Lepidoptera (Epipyropidae).

Although there is some inconsistency in usage, the active first instar in type I hypermetamorphic taxa has generally been referred to as a *triumgulin* or triumgulinid if it has legs (Neuroptera, Coleoptera, Strepsiptera, Lepidoptera; Fig. 1A), or as a *planidium* if it is legless (Diptera, Hymenoptera; Fig. 2A). However, triumgulin is an inappropriate term for most of the groups it is applied to. Usage stems from the fact that the first instar of *Meloe* (Coleoptera: Meloidae), the first hypermetamorphic group studied, has trident-shaped claws. Such claw structure does not occur in other hypermetamorphic families and is uncommon in the Meloidae itself. Thus, planidium, signifying “little wanderer,” although usually restricted to the larvae of Hymenoptera and Diptera, is perhaps more appropriately applied to all type I first instars. This usage is followed here and was adopted by R. E. Snodgrass in his 1954 review of insect metamorphosis.
In type II hypermetamorphosis the oviposition and larval feeding sites do not differ. In these insects the first instar (sometimes the second as well) has a distinctive morphology (Fig. 2B–2E) compared with the relatively simple and often amorphous subsequent instars (Fig. 2F), but these modifications are associated with functions other than host finding. The adaptive significance attributed to the often bizarre larvae of type II hypermetamorphic groups includes locomotion, protection and combat, ingestion, and respiration. This type of development occurs in several families of parasitic Hymenoptera and in the dipteran family Cryptochetidae (Cryptochetum). Correlated with the greater possibilities of larval function, the morphology of type II first instars is considerably more variable than that found in type I taxa.

Reviews by Clausen and Hagen identified 12 structural forms of first instars in the parasitic Hymenoptera with type II hypermetamorphosis. The generalized type in nonhypermetamorphic species (and in hypermetamorphic species as well after the first instar) is referred to as hymenopteriform. It is ovoid or fusiform and relatively featureless (Fig. 2F). Examples of deviations in hypermetabolic groups include the following. The caudate type has a tail-like prolongation of the terminal segment and is found in many Ichneumonoidea and Chalcidoidea (Fig. 2C). It is believed to be an adaptation for locomotion within the host and/or food absorption. The mandibulate and cyclopiform types have enlarged falcate mandibles and are found in several groups (e.g., Ichneumonoidea, Diapriidae, Platygasteridae) (Fig. 2B and 2C). They are associated with feeding as well as combat in cases of multiple or superparasitism. The vesiculate larva (several Ichneumonoidea) is similar to the hymenopteriform type, except its hindgut is evaginated to form an external vesicle to aid in respiration within the host (Fig. 2D). Several of these larval types are characteristic of taxonomic groups. For example, the cyclopiform larva (Fig. 2B) characterizes the Platygasteridae, and the teleaform larva (Fig. 2E) is typical of Scelionidae.

Hypermetamorphic development not falling into types I or II occurs in the Hydroptilidae in the order Trichoptera (caddisflies), a group with aquatic larvae. There are modifications in shape, setation, sclerotization, and leg development in the fifth instar not found in the four preceding instars. The first four instars of hydroptilids are free living, whereas the fifth lives within a case constructed of varying materials.

The term hypermetamorphosis generally is applied only to the Holometabola. However, the validity of the practice of excluding hemimetabolous groups belonging to the Sternorrhyncha (Homoptera), namely the Aleyrodidae (whiteflies) and Coccoidea (scale insects), is questionable. Although these groups are phytophagous they also have instars with considerable differences in structure and function. The first instar, or crawler, is responsible for locating the feeding site and for dispersal. The following instars are sessile and modified for a sedentary existence.

Type I hypermetamorphosis with its planidium larva is widespread in insects and is an excellent example of convergence in evolution. It is convenient to summarize the occurrence of this form of development by surveying the groups where it is known to occur.

**SURVEY OF INSECT TAXA DISPLAYING TYPE I HYPERMETAMORPHOSIS**

**Neuroptera**

Only the Mantispidae have true hypermetamorphosis. Most of the species feed on spider eggs associated with a single egg sac. The first instar either enters a previously constructed egg sac or attaches onto a female spider and enters the sac as she constructs it. Other species feed on the larval of various aculeate Hymenoptera. Several of these are phoretic and reach the food source by attaching to the adult bee or wasp.

**Lepidoptera**

The only lepidopteran family with hypermetamorphosis is the Epipyropidae. This group is parasitic on various Homoptera, a unique association for the generally phytophagous Lepidoptera. The active first instar seeks out a host and the grub-like instars that follow occur on the body of a single homopteran.

**Coleoptera**

Hypermetamorphosis occurs in several families of beetles. Most are parasitoids of other insects. The larvae of Bothrideridae, and a few Carabidae and Staphylinidae, attack the larvae or pupae of other coleopterans or diptera. The genus Sambus (Rhipiceridae) feeds on cicada nymphs. All are hypermetamorphic to some degree, with active and relatively long-legged planidia followed by short-legged, grub-like feeding instars.

Hypermetamorphosis perhaps is best known in the Meloidae and Rhipiphoridae. Most meloids parasitize grasshopper eggs or, more
Hyperparasitism

Daniel J. Sullivan
Fordham University

Hyperparasitism is a highly evolved behavior in the Hymenoptera and in a few species of Diptera and Coleoptera, in which an adult hyperparasitoid (or secondary parasitoid) oviposits on or in a primary parasitoid host that has attacked another (usually herbivorous) insect species. The larval offspring of the hyperparasitoid cause the death of the primary parasitoid. Ecologists emphasize this interaction as a food-web “community.” This article focuses on the hymenopteran microwasps in which hyperparasitism occurs.

There are a variety of behaviors of hyperparasitoids depending on the species of secondary and primary microwasp parasitoids, which in turn are influenced by the species of phytophagous host, often an insect pest. In addition, there is an economic interest in hyperparasitism because if primary parasitoids are considered to be beneficial insects when used in biological control programs, it would seem that hyperparasitoids that attack primary parasitoids would be detrimental. However, hyperparasitoids may play a positive role by preventing extreme oscillations of the primary parasitoids that might reduce the numbers of the phytophagous host enough to cause the local elimination of both the insect pest and the beneficial primary parasitoid.

Hyperparasitism has evolved in only three insect orders: in Hymenoptera (in 17 families) and in a few species of Diptera and Coleoptera. Its evolution was preceded by that of primary parasitism that evolved in the Hymenoptera during the Jurassic period, about
Hyperparasitism

135 mya. In the primary parasitoids, ectophagous feeding probably evolved before endophagous, with the parasitoid egg deposited near or on the host rather than in it. Hence, ectophagous parasitoids usually attacked concealed hosts, often within galleries in wood or plant galls. The use of venom by primary parasitoids apparently developed very early and produced physiological changes in the host. Although the venom of the more ancestral ectophagous parasitoids resulted in idiobiosis (permanent paralysis or death), the venom of the specialized endophagous species tended toward koinobiosis (temporary or nonlethal paralysis).

Facultative hyperparasitism probably evolved from primary ectophagous parasitoids because few special adaptations are needed to oviposit and feed externally on a primary parasitoid as well as on the primary parasitoid’s phytophagous host. Obligate hyperparasitism has a wider taxonomic distribution and may have evolved via facultative hyperparasitism as an opportunistic behavior to specialize only in attacking readily available primary parasitoid hosts—especially if they share similar physiological and/or ecological attributes. Hence, it is not surprising that hyperparasitoid species can be either ecto- or endophagous, whereas some are idiobionts and others are koinobionts.

The host spectrum of hyperparasitoids is broader at the species level than that of primary parasitoids, but hyperparasitism is usually restricted to immature stages of hymenopteran hosts (larvae and/or pupae) that are natural enemies mainly of phytophagous insects in the Hemiptera (mainly suborder Sternorrhyncha), Lepidoptera, and the hymenopteran suborder Symphyta. Hyperparasitoids rarely attack the egg and adult stages of primary parasitoids. Also interesting is that some families of Hymenoptera that are well known for their species of primary parasitoids (Braconidae, Trichogrammatidae, Aphidiidae, Mymaridae, and almost the entire superfamilies: Chalcidoidea (Pteromalidae: Asaphes; Encyrtidae: Syrphophagoidae; Eulophidae: Tetrastichus), Cynipoidea (Alloxystidae: Alloxysta, and Ceraphronoidea (Megasypilidae: Dendrocerus)).

Aphid hyperparasitoids can be divided into two categories based on adult ovipositional and larval feeding behaviors:

1. The female wasp of endophagous species such as Alloxysta (Charipus) cinctrix (Fig. 1A) deposits her egg inside the primary parasitoid larva while it is still feeding on and developing inside the live aphid, but before the aphid has become mummified (a mummy is the hardened exoskeleton of the dead aphid that remains attached to the leaf). Being a koinobiont hyperparasitoid, the larva usually does not hatch until after the mummy has been formed by the primary parasitoid larva. Then the hyperparasitic larva feeds internally on the primary parasitoid larval host.

2. The female wasp of ectophagous species such as Asaphes lucens (Fig. 1B) and Dendrocerus (Lagocerus) carpenteri (Fig. 1C) deposits her egg on the surface of the primary parasitoid larva while the aphid has been killed and mummified. To do this, the female must first drill a hole in the mummy in which to deposit her egg. Then the hyperparasitic larva feeds externally on the primary parasitoid larva while both are still inside the mummy. The venom of species varies such that Asaphes is an idiobiont, whereas Dendrocerus is a koinobiont. An unusual species is Syrphophagus (Aphididencyrtus) aphidivorus, whose females display a “dual ovipositional” behavior by attacking primary parasitoid larvae both within living aphids (Fig. 1D) and inside dead aphid mummies (Fig. 1E). Either way, S. aphidivorus develops as an endophagous koinobiont hyperparasitoid.

However, in all species of aphid hyperparasitoids, further development is similar to that of primary parasitoids, such that puptation is also inside the dead aphid mummy. Then the single adult hyperparasitoid emerges by cutting a hole in the dorsum of the mummy. After pulling itself out, the new adult male or female is ready for mating. From the time of the female’s attack on the primary parasitoid larva/pupa, the period of hyperparasitoid development from egg deposition to adult emergence varies with different hyperparasitoid species from as short as 16 days to 25 days or more.

NONAPHID COMPLEX

Hyperparasitism exists not only with aphids but also with almost all insect taxa. There is a complex of primary and secondary parasitoids associated with other members of the subborder Sternorrhyncha (scale insects, whiteflies, mealybugs, psyllids), as well as with various orders such as the Lepidoptera (gypsy moth, leafminers, budworms, stem borers), Diptera (gall makers, leafminers), Hymenoptera ( cynipid gall makers, leafcutter bees, sawflies), and Coleoptera (lady beetles, weevils).
Hyperparasitism

Hyperparasitism intrigues entomologists because of its multi-disciplinary relationship to evolution, ecology, behavior, biological control, taxonomy, and mathematical models. More field studies are needed to determine whether hyperparasitoids are always detrimental to biological control programs. Perhaps, instead, they could have a beneficial influence by regulating the extreme/detrimental population oscillations of the beneficial primary parasitoids.

CONCLUSIONS

Hyperparasitism intrigues entomologists because of its multi-disciplinary relationship to evolution, ecology, behavior, biological control, taxonomy, and mathematical models. More field studies are needed to determine whether hyperparasitoids are always detrimental to biological control programs. Perhaps, instead, they could have a beneficial influence by regulating the extreme/detrimental population oscillations of the beneficial primary parasitoids.

Imaginal Discs

Seth S. Blair
University of Wisconsin

The term imaginal disc is used to describe structures found in the larvae of the Holometabola. Holometabolous insects can be defined as those in which the final larval instar metamorphoses into a radically different adult during a quiescent pupal stage; they are thought to be a monophyletic group, distinct from the Hemimetabola. During the metamorphosis of Holometabola, the epidermis must form novel structures that were lacking in the larva, and in some cases, replace larval tissues that were lost. The cells that give rise to the new epidermal tissues of the adult imago are often referred to as histoblasts. When histoblasts are organized into morphologically distinct clusters, these structures are commonly referred to as imaginal discs or imaginal buds. This article discusses this definition, and briefly reviews some of the experimental studies examining the biology and, especially, the development of imaginal discs.

WHAT IS AN IMAGINAL DISC?

Usage of the terms imaginal disc and histoblast varies from author to author. This is because the number, arrangement, and development of the cells that give rise to adult structures during metamorphosis vary considerably between taxa, and even between different regions in a single larva. For instance, a few authors only use the terms imaginal disc and histoblast cell for those taxa where imaginal discs are formed in the embryo, several molts before metamorphosis. These early-developing discs may in some cases secrete a thin cuticle-like substance but they do not contribute appreciably to larval life, and thus can be considered as specialized, relatively undifferentiated structures set aside during embryogenesis for adult development. However, most authors have also used the terms for cells and structures that cannot be detected until the final larval instar and that are apparently derived from cuticle-secreting, differentiated larval cells. It is likely that late-developing imaginal discs are the more ancestral condition and that early-developing discs are the more derived condition within the Holometabola.

There is also variation in the development of different appendages. Because larvae do not have external wings, these must be formed during metamorphosis; the wing precursors usually appear prior to this and are often organized into disc-like structures in the larva or embryo. However, many holometabolous taxa have larval legs and antennae that were formed at embryonic stages. This likely represents the more ancestral state, as it resembles the non-metamorphic growth of appendages in hemimetabolous insects; legless larvae evolved several times in different homometabolous taxa. There is a great deal of variation in how larval appendages grow and change during metamorphosis to form the larger, more complex appendages of the adult. At one extreme, as in some Coleoptera, most or all of the cells of the larval leg divide to give rise to the adult leg. At the other extreme, as in some Lepidopteran antennae, the dividing cells are organized into an invaginated imaginal disc. Between these extremes are cases, as in some Lepidopteran legs, in which each adult appendage is derived from several zones of dividing cells. As these zones are not disc-like in structure, more neutral terms like “adult primordia” are often used. The remaining non-dividing cells of the larval appendage can either die or persist to give rise to small regions of the adult appendage.

FIGURE 1 Eversion of D. melanogaster leg disc, shown in cross section. After Blair (1999).
Thus, the organization of the cells fated to form adult structures into a morphologically identifiable imaginal disc is simply one of several ways these cells can be arranged. And although the term imaginal disc is used only for holometabolous insects, it is only the invaginated morphology of most discs that distinguishes them from structures like the external wing pads of hemimetabolous insects, which also are morphologically distinct and form adult wings during the final molt. Thus, the evolution of invaginated wing imaginal discs from the evaginated wing pad may have required only a morphological change, rather than the evolution of a radically different cell type or organ. In fact, a similar change has apparently evolved in some Hemimetabola, such as thrips, which have invaginated wing precursors instead of external wing pads.

**EXPERIMENTAL STUDIES ON IMAGINAL DISCS**

The biology of imaginal discs has been described in a number of species, but has only been experimentally analyzed in a few. As with other metamorphosing organs, there have been studies on the endocrine control of imaginal disc eversion, differentiation and cuticle secretion. Other types of experiments, such as ablation or transplantation of portions of imaginal discs, have been used to study aspects of developmental patterning, such as the development of pigmentation patterns in the wings of butterflies and moths. And in a sense, all studies of the evolution of adult Holometabola reflect on the histoblast cells and discs from which portions of those adults are formed.

However, far and away the most extensively studied imaginal discs are those of the fruit fly, *Drosophila melanogaster*. This species has been the subject of intense genetic studies for the last century, and has become a model for the study of a variety of biological problems. Gaining an understanding of the imaginal discs in this species has been particularly critical because the entire adult epidermis is derived from imaginal discs or disc-like structures. Thus, any mutation that alters the external form of the adult *D. melanogaster* does so by altering the development of these imaginal structures. This has led to a large literature on the genetics, development, and cell biology of these structures and, via comparisons with other Drosophilids and Diptera, to a number of evolutionary studies.

It should be noted that the imaginal discs of *D. melanogaster* are at one extreme in the spectrum of imaginal tissues, and it is not clear to what extent the mechanisms underlying this apparently derived state are shared by other Holometabola. As in other Cyclorrhaphan Diptera, the metamorphosis of *D. melanogaster* is unusual in several respects. First, the cuticle of last larval instar is not shed during the formation of the pupa (pupariation), as it is in most Holometabola. Rather, the larval cuticle is retained and converted into an outer covering, the pupal case. Second, in *D. melanogaster* the non-disc cells of the larval epidermis are polyploid (containing more than the diploid number of chromosomes), and these die during the early stages of metamorphosis. In many other Holometabola, large portions of the larval epidermis and appendages are retained in the adult. Finally, in *D. melanogaster*, the imaginal disc primordia are formed during embryonic development, rather than during the last larval instar as they are in some other Holometabola.

In *D. melanogaster* embryos, each imaginal disc primordium contains 10–40 cells, which divide during the three larval instars to form, by pupation, as many as 50,000 cells by late third instar. The arrangement of imaginal discs in the late third instar larva is shown in Fig. 2. The adult head is derived from a pair of fused eye–antennal discs, as well as pairs of proboscis (labial) and labral (cibarial or clypeo-labra) discs. The adult thorax is derived from the three pairs of ventral leg discs and, dorsally, pairs of prothoracic (humeral), wing, and haltere discs. Each of these makes portions of the body wall as well as the appendages for which they are named. Each segment of the adult abdomen is formed from four pairs of small “histoblast nests” and the genitils from the genital disc.

At the late third instar, each imaginal disc consists of a simple epithelial sack invaginated from the larval epithelium (Fig. 1). One surface of each sack forms the thickened and folded disc epithelium from which most of the adult structures are derived. The other surface of the sack is the thinner peripodial membrane, and each disc remains connected to the larval epithelium by a long, narrow stalk. During the first few hours of pupariation, each disc everts through the stalk, expands, and eventually sutures together with adjacent discs. The peripodial membrane is lost during this process, and the polyploid cells of the larval epidermis are histolyzed and replaced. The portions of each disc epithelium that are fated to form the appendages unfold and lengthen: the prospective legs and antennae form long tubes, whereas the prospective dorsal and ventral surfaces of the wing lengthen and flatten together. The disc cells then secrete the pupal cuticle, which is separated from the epithelial surface shortly thereafter. After a delay during which further morphogenesis and differentiation occurs, the adult cuticle is secreted.

Many aspects of the biology of imaginal discs of *D. melanogaster* have been examined over the years, and continue to be the subjects of intense research. These include the hormonal control of disc development and cuticle secretion, the molecular genetics of cell division and tissue growth, and various problems in cell biology. Perhaps the most striking advances, however, have been made in the field of developmental patterning, examining for the most part the large wing, leg, and eye–antennal discs. Space constraints prevent the discussion of many fascinating and important research areas, such as the role of the eye–antennal imaginal disc in the development of the compound eye's optic lobes; and the use of imaginal discs to study the development of the nervous system, secretory differentiation and metamorphosis.
as the patterning of the compound eye, the formation of sensory organs, and the planar polarity of the disc epithelium. Instead, the following discussion briefly reviews some early developmental events that help establish the identities and axes of the discs.

**PATTERNING IMAGINAL DISCS IN D. MELANOGASTER**

The identity of each disc primordium is specified during embryonic development. This specification relies on the disc-specific expression of a small number of genes, encoding largely transcription factors or their co-factors, and by stimulatory and inhibitory signals from neighboring cells. The localized expression of these genes and signals is inherited from earlier stages during which the embryo was subdivided into anterior–posterior and dorsal–ventral domains. The loss or mis-expression of these genes and signals can block or enlarge disc development, and in some cases cause dramatic "homeotic" transformations of disc identities.

**FIGURE 3** Signaling and anterior boundary cells in wing disc of *D. melanogaster*.

How are different tissues formed within each disc? Even at late third instar most imaginal disc cells appear morphologically similar, as only a few (mostly sensory) elements have begun to differentiate terminally. However, the premetamorphic imaginal disc is in no sense a tabula rasa, as it has already been subdivided into a number of regions. In fact, most disc primordia are subdivided into anterior and posterior lineage "compartments" from the earliest stages of their development. This subdivision is controlled by the posterior-specific expression of the *engrailed* and *invected* transcription factors in each disc, which acts as a binary switch, controlling the choice between posterior and anterior identities and preventing cells from crossing between compartments. The wing and haltere discs are further subdivided into prospective dorsal and ventral lineage compartments, in this case by the dorsal-specific expression of the *apterous* transcription factor.

Why have lineage compartments? Cells in different lineage compartments have different signaling capabilities, and this has important developmental consequences. Posterior cells secrete the signaling molecule Hedgehog, but only anterior cells are capable of responding to that signal (Fig. 3). Because Hedgehog diffuses only a short distance into the anterior compartment it induces the formation of a specialized group of cells just anterior to the compartment boundary. The formation of this group of boundary cells is critical for appendage development, because boundary cells in turn secrete several important signals (Fig. 3), including Decapentaplegic (a member of the Bone Morphogenetic Protein family of morphogens generated in the wing, dorsal leg and dorsal antenna) and Wingless (a member of the Wnt family of morphogens generated in ventral leg and ventral antenna). Cells outside the boundary region judge their approximate position in the disc by the levels of boundary signal they detect. Thus, these boundaries define important axes used to pattern the entire disc.

The subdivision of the wing into dorsal and ventral compartments by the dorsal expression of *apterous* plays a very similar role. This establishes reciprocal signaling between dorsal and ventral cells, this time via the Notch signaling pathway, that results in the specification of cells on either side of the dorsal–ventral boundary (Fig. 4). These cells secrete Wingless, which helps pattern the wing blade along the proximo-distal axis.

*D. melanogaster* imaginal discs are also specified along the proximo-distal axes by characteristic zones of gene expression. While these zones are not compartmental (the gene expression patterns shift during development and do not define cell lineage domains), these zones are nonetheless crucial for the subdivision of the discs into prospective proximal, intermediate, and distal regions.

Do the other Holometabola share these axis-defining patterning mechanisms? Many of the basic axis-defining genes are conserved in other insects, and the expression patterns of these genes in the few wing imaginal discs that have been examined are largely similar to *D. melanogaster*, even in taxa as distantly related as lepidopterans and winged ants. Most of the work on non-wing appendages in the Holometabola has been limited to the larval legs and antenna, rather than histoblast and adult tissues. While expression patterns of the proximo-distal patterning genes are largely conserved; there are some curious differences in the expression of compartmental signals in larval legs. While Engrailed is expressed in the posterior and Wingless just anterior to the compartment boundary, the boundary-specific expression of the signal Decapentaplegic observed in *D. melanogaster* is not conserved in other Holometabola. Therefore, compartmental BMP signaling, which plays a crucial role in patterning the highly derived imaginal discs of *D. melanogaster*, may not represent the ancestral state. With the advent of new methods for altering gene expression in taxa not amenable to standard genetic techniques, a growing number of laboratories are experimentally testing the roles played by these patterning genes in a variety of taxa.

Immunology

Nancy E. Beckage

University of California, Riverside

Insect immunity is a rapidly maturing discipline, with exciting prospects for novel applications in control of vector-borne diseases and agricultural pests, biotechnology, and medicine. The outcome of the interactions between a parasite or pathogen and its host is determined by a combination of the susceptible vs. refractory status of the host and the virulent/avirulant characteristics of the infecting agent. Such a “pathogen offense/host defense” interface is a coevolutionary “arms race,” the outcome of which determines whether the invader is successful or whether robust immunocompetence of the host thwarts the infection. By manipulation with biotechnology, insect immune responses to parasitoids, pathogens, or symbionts, the vectors of plant and animal diseases can be disarmed, thereby curtailing disease transmission. Similarly, the economic impact of agricultural pests can be reduced by enhancing pest susceptibility to pathogenic bacteria, viruses, and fungi, as well as development of biotechnological approaches to manipulating the host range of beneficial parasitoids.

In insects, both cellular and humoral immune responses figure prominently in host defense pathways, with many parasitic and pathogenic infections resulting in the deployment of both cellular and humoral defenses, which act synergistically. Insect hemocytes participate in phagocytosis, nodulation, and encapsulation processes. Humoral defenses include production of antibacterial, antifungal, and antiviral molecules, the melanizing enzyme phenoloxidase and its toxic reactive precursors, agglutinins, serpins, immunolectins, and many more humoral mediators of immune defense.

Although much recent progress has been made in deciphering cellular and humoral responses and their regulation by signaling pathways, considerably less is known about the recognition mechanisms responsible for the initial discrimination of “nonself” material that sets the stage for a defense response. The biology of insect pattern recognition processes and proteins is garnering increasing attention from immunologists. This is especially true for the recognition of multicellular parasites including parasitoids, which exploit a combination of active and passive strategies to avoid being detected as foreign.

CELLULAR IMMUNE RESPONSES

Insect Hemocytes

Initially, hemocytes were classified on the basis of morphological criteria alone, resulting in the publication of numerous conflicting classification schemes, even for the same species. The different hemocyte types display marked inter- and even intraspecies variability in appearance and behavior, further complicating classification. Additionally, hemocytes that are examined before they have attached to a substrate are difficult to identify in the unspread state, in contrast to spread cells such as plasmacytocytes which are readily recognized by their filamentous processes (Fig. 1). Today, tools such as monoclonal antibodies, which bind cell-type-specific epitopes, are used in combination with other biochemical markers to facilitate identification of the different hemocyte classes. Techniques such as fluorescence-activated cell sorting using antibodies or density gradient centrifugation have been employed to purify homogeneous populations of the individual hemocyte morphotypes, facilitating in vitro studies of their biochemistry and behavior.

In the Lepidoptera, the two most abundant hemocyte classes are plasmacytocytes and granulocytes, which are the primary phagocytic and encapsulative cells. In the higher Diptera including Drosophila melanogaster, the multifunctional lamellocytes play these roles, and crystal cells carry the melanizing enzyme phenoloxidase. Taxonomic variations are seen in the total hemocyte count, with the Lepidoptera having abundant hemocytes in contrast to dipterans (e.g., mosquitoes), which have many fewer cells per microliter of hemolymph.

The fat body is also an immunoresponsive organ and synthesizes many antimicrobial peptides (defensins, attacins, and others), enzymes including lysozyme, eicosanoids, and other immune mediators. Indeed, the fat body represents the primary source of...
hemolymph-borne macromolecules and is the most metabolically active tissue in the insect. The gut, which is constantly assaulted with both pathogenic and nonpathogenic microbes ingested by the insect, also produces a battery of antimicrobial molecules to prevent the insect from succumbing to active infection. During molting, when the newly synthesized cuticle is most fragile and the cuticular linings of the fore- and hindguts are shed, enhanced production of antimicrobial peptides occur when the animal is most vulnerable to infection.

**Hemocyte-Mediated Immune Responses**

Phagocytosis is the process by which pathogens such as bacteria and small particles (\(<1\mu\text{m}\) in diameter) are engulfed by host hemocytes, culminating in death of the invader. The membrane of the cell invaginates, and the pathogen is engulfed in a membrane-bound vesicle into which lytic enzymes are released causing the pathogen’s demise. This process appears to be mediated by prostaglandins (eicosanoids) produced by the hemocytes. The phagocytic cells include plasmatocytes and granulocytes, although other cell types may also participate in this response to a lesser degree. Large numbers of bacteria-laden hemocytes may clump together to form nodules, which attach to the host’s internal tissues and are removed from circulation. Frequently these nodules are melanized and deposited on lobes of fat body, the Malpighian tubules, or gut tissues.

To counter eukaryotic invaders that are too large to be phagocytosed by a single cell, several classes of hemocytes cooperate in the mobilization of the multiphasic encapsulation reaction. Usually the capsule is formed from several hundred to several thousand cells that form tight layers enclosing the parasite. In the initial phases of encapsulation of parasitoid eggs or larvae, or encapsulation of abiotic implants such as Sephadex or latex beads, granulocytes are the first cells to make contact with the target. They attach to the target surface and release their contents in a degranulation reaction, forming a sticky matrix on the surface of the target which induces deposition of multiple layers of plasmatocytes that comprise the bulk of the capsule. The encapsulation reaction is terminated by the adherence of additional granular cells to form a thin envelope around the capsule. Mature capsules frequently undergo melanization; they may adhere to the host’s internal tissues including lobes of fat body, Malpighian tubules, salivary glands, or the gut and are thereby removed from circulation. In rare instances, the encapsulated parasite may actually be extruded from the hemocoel and pass through the epidermis, to be shed with the host’s exuvial cuticle during ecdysis in a molt. This phenomenon is termed “cuticular encystment,” and this process sometimes occurs when a parasitoid develops in a nonpermissive host.

In some insects with encapsulated parasitoids, usually in cases in which the host species or strain is completely refractory to that parasitoid, the host can undergo successful metamorphosis and survive to the adult stage. In other host–parasitoid combinations, the host dies prematurely following encapsulation of parasitoid eggs or larvae, frequently showing symptoms of developmental disruption due to endocrine imbalance. When the host dies prematurely, the parasitoid also fails to survive and the reproductive fitness of both partners is zero.

Endoparasitoids belonging to the hymenopteran families Braconidae and Ichneumonidae inject symbiotic viruses termed polydnaviruses (poly-disperse DNA viruses or PDVs) that subsequently play a critical role in suppressing the host immune response so that successful development of the parasitoid can proceed. These viruses, which are integrated in the genomic DNA of the wasp and undergo replication only in the female’s ovary, rapidly enter host hemocytes, fat body, and nervous system following parasitization, and viral genes are expressed. Depending on the host–parasitoid combination, the host’s hemocytes either alter their behavior and fail to spread (thereby inhibiting the encapsulation response) or, alternatively, undergo programmed cell death and apoptosis. In *Manduca sexta* larvae parasitized by *Cotesia congregata*, massive numbers of dead and dying hemocytes undergo clumping and then are removed from circulation soon after parasitization, resulting in a dramatic drop in the host’s total hemocyte count. The final biochemical events that culminate in death of the parasite remain unclear for the most part. Although melanin and its precursors are toxic, much recent evidence points to the pivotal role of other toxic molecules such as reactive intermediates of nitrogen (nitric oxide) or oxygen (superoxide), released by cells localized in the innermost layers of the capsule, in causing lethality. Although it was formerly presumed that death of the parasite/parasitoid was induced by asphyxiation inside the capsule, biochemically mediated parasite-killing strategies are now recognized as causing the ultimate death of the invader. Phagocytosis is followed by the generation of these cytotoxic intermediates in the phagolysosome, indicating that this pathway is also important to the function of phagocytic cells.

**HUMORAL IMMUNE RESPONSES**

In addition to hemocyte-mediated immune reactions, insects possess a variety of potent plasma-borne defense molecules that are toxic to parasites and pathogens. Usually these are synthesized by the fat body or the hemocytes and secreted into the plasma, where they act either on the invader directly or via the hemocytes in altering their behavior to enhance the immune response. A battery of antibacterial proteins are produced by many insects, including defensins, drosocin, cecropins, attacins, and diptericins, depending on the species, and, in addition, the ubiquitous lysozyme family of antibacterial proteins. These proteins differ in their specificity for gram-positive vs. gram-negative bacteria, with some acting on both types of bacteria with varying degrees of potency. Often the proteins disrupt the bacterial cell membrane function by inducing pore formation, causing lysis of the cell. Antifungal molecules are also produced by insects, providing a first line of defense against fungal invaders that often infect the insect via penetration of the cuticle. Antiviral responses are emerging as a new subdiscipline in insect immunity (see below).

Many antimicrobial peptides also exhibit effective antiparasite activity against *Plasmodium*, filarial nematodes, and other harmful eukaryotic species. Microarray analyses have also confirmed that up-regulation of the same or slightly different suites of AMPs by pathogen vs. parasitic organisms provides a window of opportunity to develop strategies to stop transmission of both classes of infectious agents by enhancing AMP production in transgenic mosquitoes by activating the signaling pathways which induce their synthesis.

Dramatic recent progress has been made in deciphering the biochemically complex phenoloxidase pathway leading to melanization of nodules and capsules. The pathway begins when tyrosine is converted to DOPA via the action of the monophenoloxidase enzyme (also called tyrosinase). DOPA is then converted to DOPA quinone by diphenoloxidase and thence to melanin via a series of toxic intermediates. Phenoloxidase precursors (prepro- and pro-phenoloxidase) may be associated with hemocytes, but these enzymes can also circulate freely in plasma before they are activated by serine proteases and peptide fragments are removed from the precursor molecules.

In many host–parasitoid systems, including *M. sexta* larvae parasitized by *C. congregata*, levels of hemolymph phenoloxidase activity have
been found to be suppressed, which benefits the parasitoid by inhibiting melanization of the egg and/or larva. Expression of polydnavirus gene products that inhibit translation of phenoloxidase mRNA, thereby suppressing levels of this enzyme in the blood, occurs in several species.

In refractory strains of mosquitoes, melanization of the malaria oocyst occurs in the midgut wall to form Ross’s black spores in the midgut epithelium, which were recognized early on by Ronald Ross before the entire life cycle of the malaria parasite was known. Disease transmission stops because the melanized arasites die trapped in the gut wall, short-circuiting their entry into the hemocoel and subsequent movement to the lumen of the salivary gland. With the advent of improvements in mosquito transformation technology, medical entomologists sought to use phenoloxidase genes to bioengineer refractory transgenic mosquitoes using transposable elements to halt malaria transmission by the insect vector. One approach has been to link this gene to highly active promoters, particularly those which are activated when the mosquito takes a blood meal in preparation for production of eggs including the vitellogenin promoter. New strategies and constructs may eventually fulfill the promise offered by biotechnological approaches for control of major scourges like malaria, yellow fever, and dengue. However, there will be a need to overcome regulatory hurdles and public attitudes toward biotechnology in challenging environments such as Africa comprised of many countries with different cultures.

**IMMUNITY MODELS**

Insects exhibit both innate and inducible immunity to parasites and pathogens. Several insects such as the fruitfly *D. melanogaster*, the tobacco hornworm, *M. sexta*, and mosquitoes including the malaria vector *Anopheles gambiae*, have served as exemplary model systems in insect immunology. The *Drosophila* beetle is also gaining ground as a model system for immunological research. The wealth of genomic and genetic information available for *Drosophila* has rapidly accelerated progress in the areas of immune recognition, antimicrobial mechanisms and molecules, and signaling pathways. Many parallels between *Drosophila* immune mechanisms and mammalian immune pathways link these distantly related phyla and provide strong arguments to support the use of *Drosophila* as a mammalian immunological model. The concept that some genes and their protein products play dual roles in immunity and development was first discovered by immunologists studying the fruitfly. Conversely, studies of mammalian immune specificity and memory have generated novel insights into how insect immune systems function despite the lack of production of antibodies targeted to specific epitopes. Our extensive knowledge of the physiological factors regulating immune pathways in *M. sexta*, *Bombyx mori*, and other lepidopterans, together with the relative ease of isolation and sequencing of immune peptides, enzymes, and other biochemical modulators from hemolymph and tissues of large species, complements the enormous genomic and proteomic databank now available for many species.

**TECHNOLOGIES FOR MANIPULATING IMMUNITY**

Major recent advances in mosquito genomics, transformation, and immunity are facilitating development of new application technologies to achieve enhancement of insect immunity to vector-borne parasites and pathogens with the goal of reducing rates of human disease transmission. Both transgenic and new genetic approaches to manipulation of insect immunity offer tremendous potential advantages as well as challenges in disease vector management. Controlling insect pests via genetic manipulation of symbiotic partners including bacteria also offers exciting prospects for the future.

Recent dramatic advances in the fields of bioinformatics, microarray analysis, and proteomics are facilitating rapid breakthroughs in both basic insect science and its applications to health and agriculture. New gene silencing strategies that shut down production of immune-related gene products such as RNA interference (RNAi) are now being applied across many insect taxa, yielding fruitful insights into the roles of homologous gene products in diverse phyla.

**NEW VISTAS IN IMMUNOLOGY**

**EVOLUTIONARY IMMUNOLOGY** Evolutionary immunology and the interface between immunity and ecology is a rapidly expanding subdiscipline, posing intriguing questions regarding the physiological “costs” of immunity. The extent to which enhanced levels of immunocompetence are offset by negative impacts on longevity, mating success, reproductive output, and fitness clearly must be considered in developing new technologies to manipulate refractoriness to animal or plant pathogens. Indeed, some recent studies show that there are indeed “metabolic fitness impacts” of launching an immune response on longevity and reproduction. Holistic approaches to analysis of how immunological constraints influence ecological inter- and intraspecies interactions are yielding insights into how physiological “tradeoffs” impact the links between immunity, behavior, and fitness. Framing immunity in an evolutionary context is a concept that has evolved during the past 5 years and is fostering collaborations among physiologists, biochemists, molecular biologists, ethologists, ecologists, and evolutionary biologists who pose questions about the metabolic price of immunity and its impacts on insect life history. Given that enhancing effects of nutrient deprivation and starvation on insect susceptibility to disease has been long recognized, it is not surprising to find that resistance requires metabolic resources that would normally fuel other physiological processes including reproduction.

**ANTIVIRAL IMMUNITY** In contrast to the huge databank of information available about antibacterial peptide chemistry and regulation, the mechanisms of insect immunity to viruses have only just begun to be explored. Baculoviruses, many of which attack agriculturally important pest species, must be ingested by the insect and then cross the gut wall to enter the hemocoel and initiate successful infection in target tissues, replicate, and complete their life cycle in the host. As seen in Fig. 2, species-specific genetic factors regulate temporal patterns of virus (i.e., *Baculiplusia on* multiple nucleopolyhedroviruses) entry into target tissues including the tracheolar epithelium, hemocytes, fat body, and gut. Genetic factors also influence rates of virus propagation in different hosts. Latent infections can occur with viruses that initially remain cryptic but ultimately erupt to epizootic levels when the
host is physiologically stressed. Disruption of “successful” interactions between arboviruses and vector species is clearly promising and likely to be a highly effective strategy to curb disease transmission.

DEVELOPMENTAL AND HORMONAL REGULATION OF IMMUNITY Isolated reports of hormonal influences on insect immunity have peppered the insect literature for decades, and strong experimental support linking hormones to immune regulatory pathways has now materialized. Endocrine impacts on immunity are well established in the vertebrate realm, with long-standing appreciation of the roles of testosterone, corticosteroids, and other hormones on mammalian immunity. The observation that in many larval-stage insects immunity to parasitoids and pathogens is significantly enhanced in late larval development when the animal approaches pupation has been experimentally documented to be due to the decreasing levels of juvenile hormone (JH) associated with the last instar. The concept that juvenile hormone and 20-hydroxyecdysone (20E) could have antagonistic effects on the induction of antimicrobial peptide gene expression was recently experimentally tested in Drosophila using both in vivo microarray experiments and in vitro approaches with cell cultures maintained under different hormone regimens. JH was shown to be a potent hormonal immuno-suppressor, whereas 20E functions as an immune potentiator, at least with respect to antinicrobial peptide synthesis. More research to investigate roles of hormones in modulating insect immunity is obviously needed, as findings may have impacts on potential usages of hormonally-based insect growth regulators to render pests more susceptible to pathogens, or conversely, more refractory to parasites (e.g., Plasmodium).

Surprisingly, even embryonic-stage hosts can mount effective encapsulation responses against parasitoids, indicating that hemocytes are differentiated by hemopoietic tissues very early during development and are fully functional even prior to eclosion of the first instar larva. The encapsulation response seen in egg-stage eucalyptus borers against eggs of an encyrtid wasp parasitoid is illustrated in Fig. 3. Production of antibacterial proteins by insect embryos and extraembryonic tissues has also been documented. These findings document the ability of insect embryos previously thought to be incapable of mobilizing immune responses to be immunocompetent even while the egg is protected by

FIGURE 2 Patterns of virion distribution in host tissues following baculovirus (Rachiplusia ou multiple nucleopolyhedrovirus) infection of semi-permissive and permissive lepidopteran host species. Larvae of the European corn borer Ostrinia nubilalis, a semi-permissive host (upper panel), and Heliothis virescens, a permissive host (lower panel) dissected 72 hours after infection with Rachiplusia ou multiple nucleopolyhedrovirus expressing β-galactosidase under the control of the hsp70 promoter. Infection of H. virescens is significantly more advanced with extensive lacZ blue staining indicative of infection in the tracheoles (T), fat body (FB, arrow), and gut epithelium (G) in permissive H. virescens larva (lower panel). Virus distribution in semi-permissive O. nubilalis is restricted to foci of infection in these tissues (upper panel). The Malpighian tubules (M) are also shown. [Reprinted from Sparks et al. (2008) with permission from Academic Press/Elsevier.]

FIGURE 3 Appearance of encapsulated parasitoid egg in non-permissive embryonic stage host eucalyptus longborer Phoracantha recurva egg. Fluorescence micrographs showing encapsulation response mounted by eucalyptus longborer P. recurva host egg against the egg of the encyrtid parasitoid Avetianella longoi (A) vs. appearance of an nonencapsulated parasitoid egg in the permissive host P. semipunctata (B). Arrows indicate areas of host hemocyte attachment in (A). Eggs were stained with the vital dyes ethidium bromide and acridine orange. Note that living cells fluoresced green but changed color (yellow to orange/red) as layers of cells were deposited. The innermost cells of the capsule flattened and released components of the phenoloxidase cascade, melanized and died. The hemocyte-free surface of the parasitoid egg in the permissive host P. semipunctata is seen in (B). HC = host egg chorion, M = melanization, P = parasitoid egg pedicel, and PE = parasitoid egg. [Reprinted from Reed et al. (2007) with permission of Academic Press/Elsevier. Scale bars = 50 μ.]
its chorion. Whether hormonal factors can modulate immune responses in developing insect embryos or regulate differentiating pathways during hematopoiesis has yet to be addressed.

**IMPACTS ON AGRICULTURE, AND HUMAN AND ANIMAL HEALTH** Another novel area with potential for economically important impacts is the exploitation of the immune-disrupting genes evolved by many insect-specific microbes as well as the parasitoid-associated symbiotic Polydhnaviruses to develop hybrid biopesticides, with enhanced virulence to more effectively kill insect pests that are particular scourges in agriculture, forestry, and human and plant disease transmission. Polydhnavirus genes, including several ichnos- and bracovirus genes, are also being exploited in the medical realm as valuable technological tools that enhance levels of expression of baculovirus-promoter-driven pharmaceutical agents, as well as in transgenic plants to suppress insect feeding activity and development. Insect antifungal defensins also offer therapeutic potential for use in treatment of human pathogens. Paratransgenic technology in which genetically modified insect symbionts are induced to express potent antiparasite or antipathogen compounds are being implemented in control of human/animal disease vectors to block disease transmission as well as in economically important agricultural pests and plants.

**Industrial Melanism**

Michael E.N. Majerus†

University of Cambridge

Industrial melanism may be defined as a proportional increase of dark, or melanin, pigments in individuals of a population, caused by changes in the environment resulting from industrial pollution. Both increases in the frequencies of distinct melanic forms and the general darkening of some or all forms within a population may be involved.

The increase in dark forms of some species of moth in industrial regions of Western Europe, and latterly elsewhere, has provided some of the best known, most easily understood, and most often quoted examples of evolution in action. Increases in pollution following the industrial revolution led to changes in the environment. In particular, sulfur dioxide denuded trees and other substrates of lichens, while particulate air pollution blackened the resulting surfaces. In response to these changes, the color patterns of many species of moth and some other invertebrates that rely on camouflage for defense against some predators have changed, becoming darker, in line with the darkening of the substrates that they rest upon by day. These changes have occurred largely in the past 150 years and are cited as examples that illustrate the central mechanism of Charles Darwin’s theory of evolution: natural selection.

**TYPES OF INDUSTRIAL MELANISM**

Three categories of industrial melanism have been recognized:

A. Full industrial melanistic polymorphism involves distinct melanic forms that have arisen since the industrial revolution and have increased as a consequence of the effects of industrialization on the environment.

B. Partial industrial melanistic polymorphism involves polymorphic species that had distinct melanic forms prior to the industrial revolution.

†Deceased January 27, 2009.
These forms have increased in frequency following and as a consequence of the effects of industrialization.

C. Polygenic industrial melanism involves species in which the average ground color of some or all members of a population has darkened gradually as a consequence of the effects of industrialization.

It should be noted that melanism is a common phenomenon throughout the animal kingdom, with many factors unrelated to industrialization or pollution influencing the success of melanic forms in some species, including humans.

FULL INDUSTRIAL MELANIC POLYMORPHISM

The Peppered Moth

The peppered moth, Biston betularia, has dominated the literature on industrial melanism. In Britain, the ancestral form of this species (form typica) is white, liberally speckled with dark brown or black scales (Fig. 1). In 1848, a predominantly black form of B. betularia, form carbonaria (Fig. 2), was recorded in Manchester, England. Within 50 years, 98% of Mancunian peppered moths were black. From this original location, carbonaria spread to many other parts of Britain. In 1896, the renowned Victorian lepidopterist J. W. Tutt suggested that camouflage and bird predation could be involved in the spread of carbonaria. Arguing that the typical form was camouflaged well on surfaces covered by lichens, he noted that many natural surfaces had changed as a consequence of pollutants resulting from heavy industry. In particular, the combined effects of sulfur dioxide, which killed foliose lichens, and soot fallout, which blackened the denuded surfaces, had led to darker and more uniform substrates. He stated that on these surfaces carbonaria would be better camouflaged than typica and so gain protection from bird predation. Natural selection, through the medium of differential bird predation, augmented by "hereditary tendency," had led to an increase in the frequency of the black form.

Tutt's hypothesis was largely rejected for over 50 years because most entomologists and ornithologists concurred in the view that birds are not major predators of cryptic, day-resting moths. A variety of other explanations for the increase in melanic forms of some moths were thus put forward during this period (pollutants acting as mutagenic agents, Lamarckian evolution, and heterozygote advantage).

One important advance during this period was the calculation by Haldane in 1924 that carbonaria would have to have been 1.5 times as fit as typica to account for the rapidity of the rise in carbonaria frequency in Manchester. This fitness difference was much higher than most evolutionary biologists of the time thought feasible.

In the 1950s, Tutt's bird predation explanation of industrial melanism was tested by scientific experimentation. Dr. Bernard Kettlewell, using direct observation of the predation of live moths released onto tree trunks, and mark–release–recapture techniques, in two populations, one in a polluted and the other in a nonpolluted oak woodland, obtained strong evidence to support Tutt's differential predation hypothesis. Both experiments showed that the typica form of the moth had lower fitness than carbonaria in the polluted woodland but a higher fitness in the nonpolluted wood. It was the fact that Kettlewell obtained reciprocal results in the two environments that made his conclusions convincing. Kettlewell also mapped the frequency of carbonaria against sulfur dioxide and soot fallout, finding a significant correlation between the frequency of carbonaria and both pollutants, that with sulfur dioxide being strongest.

Kettlewell's work made the case of industrial melanism in the peppered moth the most cited example of evolution in action through an identified agent of natural selection: differential bird predation. As Professor Sewall Wright wrote in 1978, industrial melanism in the peppered moth provided "the clearest case in which a conspicuous evolutionary process has actually been witnessed." Here was Darwin's missing evidence.

Since the 1960s, many other studies have been carried out on the peppered moth. Some have focused on the fine details of the case, including the intermediate form insularia (Fig. 3). Others have considered how the peppered moth has been affected by antipollution legislation, while still others have addressed criticisms of some of Kettlewell's experimental protocols.

The main elements of the peppered moth case as they are now known are:

1. The melanic, carbonaria form of the peppered moth was first recorded in 1848.
2. This carbonaria form is controlled by a mutant allele of a single gene, which is genetically dominant to the allele controlling the pale typica form.
3. The carbonaria form spread and increased rapidly in industrial regions of Britain but not in rural regions.
4. Peppered moths rest by day on the bark of trees.
5. Birds find peppered moths on tree bark and eat them.
6. The likelihood of a moth being found by a bird depends on its degree of camouflage.
7. Nonmelanic peppered moths are better camouflaged than melanics on lichen-covered tree bark. Melanic peppered moths are better camouflaged than nonmelanics in areas where tree bark has been denuded of lichens and blackened by soot fallout.
8. The frequencies of melanic and nonmelanic moths in a particular area depend on the level of bird predation of each form and the rate of migration of moths into the area from adjacent districts in which the form frequencies are different.
9. Following the Clean Air Acts and other antipollution legislation of the 1950s and subsequently, levels of pollution in Britain have declined, bark is no longer heavily soot covered, and lichens have regrown to a significant extent. Since the mid-1960s, the frequencies of carbonaria have declined substantially in Britain.
10. Rates of decline are broadly in line with theoretical predictions from computer simulations. If the decline in carbonaria continues at its present rate, this form will be reduced in Britain to the status of a rare mutation by 2020.
11. Similar declines in melanistic frequencies correlated to declines in pollution levels have been observed in Holland and in the United States.

Data on the declines of the melanic forms of the peppered moth in Britain, continental Europe, and America are important for three reasons. First, they show that evolution is not a one-way process. Evolutionary changes can be reversed if the selective factors that lead to them are reversed. Second, the data sets from different populations in Europe and America, in effect, replicate natural experiments. The consistency in the patterns of increase and decrease in the frequencies of melanic forms correlated to pollution levels adds weight to the selective explanation of the evolutionary changes observed. Third, the accord between predicted decreases in melanistic frequencies and the observed frequencies currently being recorded argues that the factors incorporated into the models are broadly correct.

Since 1998, the case of the peppered moth has been attacked by antievolution lobbyists, who have emphasized both weaknesses in Kettlewell's experimental procedures and differences in opinions between scientists who have worked on or commented on the case. The case has thus been at the center of the evolution vs. creation debate, with calls being made, particularly in the United States, for it to be removed from biology textbooks. It is notable that the focus of these criticisms is almost invariably the well-known experiments of Kettlewell, whereas later independent experiments in which improved protocols have been used, and which have led to the same basic deductions as Kettlewell's work, are not cited. The controversy took another turn in 2002, when a journalist, Judith Hooper, published a book in which she makes thinly veiled accusations of data fudging and scientific fraud aimed at Kettlewell, and a conspiracy of silence aimed at the scientists who have conducted the experimental work on the peppered moth.

The controversy over the peppered moth case has engendered new interest in the case, with scientific historians examining the accusations of fraud aimed at Kettlewell. The conclusion of these examinations is that there is not one shred of evidence to support Hooper's accusations. In addition, a new series of experiments have been undertaken to address the flaws in Kettlewell's experiments and address other issues raised by the antievolution lobby. In brief, these have shown that (1) the peppered moths do rest by day on the bark of deciduous trees, most commonly on the underside of lateral branches (Fig. 4) but also sometimes on the trunks; (2) that bats feeding on peppered moths at night do not differentiate between the forms of the peppered moth, refuting the suggestion that they, rather than birds, could be the agent of selection; (3) that greater levels of bird predation of carbonaria, compared with typica, in a 6-year period from 2002 to 2007, is entirely sufficient to explain the observed decline in carbonaria frequency in Cambridge, England, over this period. This work fully supports Tutt's differential bird predation hypothesis.

**FIGURE 3** The peppered moth has a third intermediate form, *insularia*.

**FIGURE 4** A peppered moth in its most common resting position, on a lateral tree branch.
its arrival, f. fusca spread to many industrial parts of Britain and increased in frequency rapidly, although its frequency is now declining again in response to reductions in pollution.

The current declines in melanism seen in the peppered moth, the figure of eighty, and several other species, following antipollution legislation, suggest that future studies of industrial melanism may have to shift to countries in which industrialization is still increasing and antipollution measures are as yet limited.

**PARTIAL INDUSTRIAL MELANIC POLYMORPHISM**

Melanic forms of many species of moth are independent of industrialization. The factors that can favor melanism are numerous and varied. These have been discussed in detail by Kettlewell and Majerus. Their relevance to industrial melanism is that in some moths, the presence of melanic forms prior to, and independent of, industrialization provided a repository of melanic variants that were favored as pollution levels increased.

Indeed, it is likely that the majority of moths that exhibit melanism in species, with melanin frequency correlated to pollution levels, had melanic forms occurring at relatively low equilibrium frequencies prior to the industrial revolution. Changes in the environment resulting from increased pollution favored these dark forms and their frequencies increased. The willow beauty, Peribatodes rhomboidaria, well illustrates this idea. In Britain, this species has long had a non-industrial melanic form, perfumaria. The perfumaria form greatly increased in frequency in industrial regions in the late 19th century.

In the 20th century, perfumaria, which still occurs at low frequency in some rural areas, particularly in Scotland, was replaced in industrial areas, but not elsewhere, by an even darker form, f. rebeli. Here then, f. perfumaria should be regarded as a partial industrial melanic, while f. rebeli is a full industrial melanic.

Many probable instances of partial industrial melanic polymorphism could be cited, but rather few of the species that fall into this class of melanism have been investigated in detail. Exceptions are the pale brindled beauty, Phigalia pilosaria (Fig. 6A and 6B); the mottled beauty, Alcis repandata; and the green brindled crescent, Allophyes oxyacanthae. All are bark-resters, the increase in melanic frequencies in industrial regions being attributed to increased crypsis.

Some of these species show morph-specific habitat preferences. Morph-specific habitat preferences in Lepidoptera showing melanism polymorphism were first suggested to explain abrupt differences in melanin frequencies of the mottled beauty and the tawny-barred angle, Semiothisa liturata, either side of sharp habitat boundaries. Such differences have subsequently been recorded in 14 species, in all cases melanics having higher frequencies in woodland with dense canopies than in adjacent more open habitats.

Many species that now have industrial melanic forms first evolved melanism in specific ecological circumstances prior to industrialization. It is known, for example, that a number of species now show melanism polymorphism in unpolluted ancient coniferous forests, such as Rannoch Black Wood in Scotland. Similar habitats were more widespread in the past and are likely to have supported melanic forms. These melanic forms would have been at a selective disadvantage if they moved from areas with the specific ecological circumstances to which they were adapted. Consequently, the melanics evolved behaviors that restricted them to such habitats. Recent changes in forestry and land usage and increases in pollution have provided new habitats (e.g., conifer plantations and polluted woodlands) with ecological conditions that favor melanics. The melanics have consequently spread

**Other Examples of Full Industrial Melanic Polymorphism**

The vast majority of research and comment on industrial melanism has been focused on the peppered moth. However, the case of the peppered moth is not unique. A small number of other examples of full industrial melanism are known. The melanic forms in most of these cases are controlled by dominant alleles of single genes. An exception is that of the brindled beauty, Lycia hirtaria, in which the melanic form nigra (Fig. 5) is controlled by a recessive allele. That most recent melanic forms are genetically dominant is not surprising because a dominant mutation will be fully expressed as soon as it arises and will quickly be favored by selection if advantageous. Recessive mutations would not be exposed to selection until they occurred in homozygotes in which their effects would be expressed phenotypically.

In some species showing full industrial melanism, such as in the lobster moth, Staurropus fagi, melanism has developed at roughly the same time as in the peppered moth. In others, industrial melanism has developed much more recently, as in the cases of the sprawler, Brachionycha splinit, and the early grey, Xylocampa areola, in which industrial melanism developed only in the second half of the 20th century. The reason that industrial melanism did not evolve earlier in these species is probably serendipitous: a melanic mutation simply did not occur previously in an appropriate population.

The different timings of the initial occurrence of industrial melanic forms of different species help emphasize that natural selection cannot cause change unless phenotypic variation exists. This is manifest in the oak beauty moth, Biston strataria, the closest British relative of Biston nigra, which is a common industrial melanin in Holland, but has never been recorded, except as a rare mutation, in Britain. In terms of its Ecology, behavior, and distribution, the oak beauty is similar to the peppered moth. However, the melanaria mutation seems never to have arisen in Britain in favorable circumstances nor has this form reached Britain from continental Europe as a migrant. Melanism in the oak beauty in Europe can be contrasted with that of another moth, the figure of eighty, Tethea ocularis. The melanic form, fusca, of this species was known in Belgium and Holland in the early part of the 20th century but was absent from Britain. This form arrived in southern England, by migration, in the mid-1940s. Following

**FIGURE 5** Nonmelanic and melanic forms of the brindled beauty, L. hirtaria.
and risen in frequency, producing examples of partial industrial melanic polymorphism in which morph-specific habitat preferences are retained to some extent.

**POLYGENIC INDUSTRIAL MELANISM**

Of all categories of melanism, polygenic industrial melanism has been the least considered and is the most difficult to address. Examination of specimens collected over the past century and a half suggests that many species have experienced a gradual darkening of the colors and loss of patterning in industrial regions, irrespective of morph. Although some of this change may be attributed to the gradual fading that occurs in museum specimens with time, it is difficult to ascribe all of the differences to this phenomenon. Comparison of series of specimens of six species, from rural and industrial regions, collected between 1880 and 1914 with those collected between 1992 and 1996 showed that the ground color had darkened more in industrial regions than in the rural areas.

This gradual darkening is probably the result of selection acting on polygenic variation. Small variations in the color patterns of many species are known to be controlled by many genes, each having a small effect. The selective predation of lighter and thus less cryptic forms in regions affected by particulate air pollution will result in those alleles which produce darker morphs increasing in frequency. It is difficult to see how this hypothesis can be tested. However, if it is correct, the recent decrease in pollution should lead to a reversal of this trend, with ground colors lightening and patterns becoming more clearly defined again. Novel, digital methods of measuring the spectral reflectance of surfaces and storing data should allow measurement without reliance on museum specimens or photographs, both of which may fade with time.

**MELANISM AND THE STUDY OF EVOLUTION**

The significance of industrial melanism in the Lepidoptera to evolutionary biology has been considerable. It has provided one of the best observed examples of evolutionary change caused by natural selection and has shown that Darwinian selection can be a strong force. In the peppered moth, differential bird predation, together with migration, has been primarily responsible for the rise and fall of the melanic form *carbonaria*.

Although the story of the peppered moth is undoubtedly more complex than usually related, data accumulated over the past 50 years have done nothing to undermine Tutt’s initial hypothesis of the role of differential bird predation or Kettlewell’s experimental demonstrations of this role.

Within the Lepidoptera, the factors responsible for melanism and the forms of melanism that result are very variable. Because a great variety of factors may promote melanism, it may be misleading to extrapolate from one population to another, let alone from one species to another. Even within one class of melanism, the relative influence of different aspects of a species’ biology will vary between species. Each species that has evolved melanic forms will have done so in the presence of a variety of different intrinsic and extrinsic circumstances. The differences in the factors affecting melanism in even the few well-studied cases suggest that there is still enormous scope for original research into this phenomenon. However, as the frequencies of dark forms of full industrial melanics decline in North America and Europe with reductions in pollution, the focus of such work may have to shift to the developing industrial nations of Asia and South America.

Insecta, Overview

Vincent H. Resh  
University of California, Berkeley

Ring T. Cardé  
University of California, Riverside

The species-rich superclass Hexapoda includes all insects and their near relatives that share the characteristic arrangement of having, as adults, three major body regions and six legs. The number of described insect species has increased greatly from the time of the early catalogers of life. Those 18th-century pioneers in biodiversity, such as Carl Linné, would not have conceived that there would be over one million species described by the 21st century. Most estimates today suggest that this number represents only 10–30% of the actual number of insect species thought to exist. The richness of living things is essentially the result of insect richness; animal biodiversity is therefore, in reality, mainly insect biodiversity.

Within the class Insecta, major forms of insects are grouped in orders. Ordinal-level groups represent divergent lineages that are nearly always recognizable by a set of distinctive characteristics. Almost always, an adult insect can be readily determined to order at a glance. The number of recognized orders has fluctuated slightly as entomologists’ understanding of the included taxa and methods for classifying have developed. Classification schemes are both organizational systems and true scientific hypotheses. In this way they are dynamic, changing as new information becomes available. There are several important ways in which a classification may evolve. One is the subjective change in taxonomic rank. For example, in the 1950s, all Ephemeroptera (the order containing mayflies) in North America were assigned to three families, and today they are in 40! Mostly, this is the result of raising subfamilies to family status.

If substantial evidence is found that a group previously recognized as an order is paraphyletic (i.e., does not contain all descendants of that group), then new monophyletic arrangements will be proposed. A good example is the order Hemiptera. The taxa included in the order now were traditionally divided into two groups (often given ordinal status): Heteroptera (true bugs) and Homoptera. Recent analyses suggest a more complicated pattern of relationships. Three groups within the order Hemiptera are treated separately as suborders in this encyclopedia: Auchenorrhyncha (cicadas, spittlebugs, leafhoppers, and treehoppers); Prosternalyncha (Heteroptera and Coleorrhyncha); and Sternorrhyncha (aphids, psyllids, scale insects, and whiteflies).

Perhaps the most exciting way that classifications may change is by the discovery of something genuinely novel. However, in insects, finding a truly new order (i.e., a group of taxa that have a combination of characteristics unique at that level) is an astounding event. A new order (Mantophasmatodea) was recently discovered in southern Africa. It is the first order of living insects to be described in almost 90 years! This discovery reinforces the point that there is much left to learn about our earth’s biodiversity.

In many classification systems, orders are grouped into superorders but what comprises a superorder is far from fixed. For example, zorapterans are viewed as being in the superorder Orthopteroidea by some and in the superorder Hemipteroidea by others. Although a close link between Trichoptera (caddisflies) and Lepidoptera (moths and butterflies) is supported by a wealth of concordant evidence and consequently is undisputed, relationships among many endopterygote (e.g., Coleoptera and Hymenoptera) orders are unclear because different data sets present conflicting evidence. Some orders (e.g., Collembola (springtails) and Protura) are considered to be noninsects (placed in the class Parainsecta), but evidence clearly places them in the superclass Hexapoda with insects.

The classification presented here is a snapshot of the current hypotheses of insect relationships. Because the field of systematics that underlies this classification scheme is ever evolving, future arrangements will undoubtedly shift. The extant (or existing) orders of insects, their common names, and estimates of their worldwide species and family richness are listed in Table I.

Insecticides

Fumio Matsumura

University of California, Davis

Insecticides

as oil film on the surface of water for mosquito larval control), are considered to be insecticides.

BRIEF HISTORY

Insecticides used prior to the 1940s were mostly inorganic compounds such as arsenicals. After World War II, DDT and other chlorinated pesticides came on the market. There is no question about the spectacular insect-controlling effects achieved on many crops, and populations of some pests that affect both public and veterinary health were greatly diminished. The shortcomings of these compounds, particularly their lack of selectivity and harmful environmental effects, were eventually realized, however, leading to the termination of their use by the late 1970s. Meanwhile, organophosphorus and carbamate insecticides gained in popularity and have established themselves as two of the major classes of insecticides. Many of them offer at least some degree of selectivity (malathion is particularly outstanding in this regard) and are less persistent in the environment. In more recent years, functional synthetic analogues of naturally occurring toxic chemicals were developed. Pyrethroids, for example, are essentially synthetic mimics of naturally occurring pyrethrins found in the flowers of species of chrysanthemum. The synthetic neonicotinoids mimic naturally occurring nicotine from tobacco plants. Useful microbial products were also developed in the 1980s and 1990s; examples are Bacillus thuringiensis (Bt) toxins, avermectins, and spinosyns. Modern insecticides used today are generally very selective, mostly affecting only the targeted pest insect. They are potent, requiring only small quantities to achieve their effects, and they are much less persistent in the environment.

CLASSIFICATION OF INSECTICIDES

Synthetic organic insecticides may be divided into several major classes: (1) chlorinated hydrocarbons, (2) organophosphorus compounds (often referred to as organophosphates), (3) carbamates, (4) pyrethroids, (5) nicotinoids, (6) fumigants, (7) γ-aminobutyric acid (GABA) receptor antagonists, (8) chitin synthesis inhibitors (benzoylureas), (9) mitochondrial poisons, and (10) insect hormone mimics. These classifications are based on either group-specific chemical characteristics (classes 1–6) or their action mechanisms (classes 7–10).

Other insecticides belonging to minor classes (i.e., fewer compounds per class or less frequent use) are: (11) botanically derived naturally occurring insecticides (other than pyrethroids and nicotinoids), (12) microbially produced insecticides, (13) synergists, (14) semiochemicals such as attractants, including pheromones, (15) insect repellents or feeding deterrents, and (16) behavior-modifying agents for use on insects.

USE PATTERNS

Insecticides as a class of pesticides constitute about one-quarter of total pesticides (approximately a billion pounds per year) used in the United States. By far the largest volume of pesticides used is herbicides (620 million pounds), followed by insecticides (247 million pounds) and fungicides (131 million pounds) (all 1993). Approximately 75% of all pesticides used in 1993 were for the control of agricultural pests. Other uses are for pests found in the home (including gardens), industry, commerce, and public and veterinary health. The top 17 insecticides used in 1993 were: (1) chlorpyrifos, (2) terbufos, (3) methyl parathion, (4) carbofuran, (5) carbaryl, (6) phorate, (7) cryolite, (8) aldicarb, (9) propargite, (10) acephate, (11)
Insecticides

malathion, (12) fenofos, (13) methomyl, (14) dimethoate, (15) azinphos-methyl, (16) ethyl parathion, and (17) profenfos. Most of these are organophosphates (1–3, 6, 10–12, and 14–17) or carbamates (4, 5, 8, and 13), but propargite is a sulfite ascaricide and cryolite (sodium fluorosilicate, Na$_3$AlF$_6$) is a naturally occurring inorganic fluoride compound. Of these, the use of methyl parathion (3) and ethyl parathion (16) has been phased out. Among organochlorine insecticides, most of which have been eliminated, the only ones remaining are endosulfan (19th) and dicofol (22nd). The most popular pyrethroid is permethrin (25th, approximately 1,000,000 pounds) followed by cypermethrin (225,000 pounds) and fenvalerate (66,000 pounds). Pyrethroids are used in much lower quantities than organophosphates and carbamates mainly because the former compounds are much more powerful than the latter, and therefore only small amounts of pyrethroids per hectare are needed to control insect pests.

MECHANISMS OF ACTION OF INSECTICIDES

The great majority of insecticides used today are nerve poisons. This is because insects have highly developed nervous systems, and furthermore, many of their sensory receptors are exposed to the atmosphere outside the insect body. The insect nervous system relies on several key functions that have been exploited as the targets of insecticides: the sodium channel, acetylcholinesterase, the GABA receptor, and the acetylcholine receptor.

The sodium channel, which is the insecticidal target of DDT, pyrethroids, pyrethrins, and other minor classes of insecticides, lines the outer surface of the neurons and functions as the voltage-dependent sodium ion pore (i.e., the pore opens or closes depending on the change in voltage). Upon the arrival of stimuli, this pore allows the selective entry of sodium ions into the neuron for a brief moment and then abruptly shuts down the flow (this phenomenon is called “inactivation”). Thereafter, the sodium channel goes through an internal rearrangement to recover its original state. Such an action causes a brief local equalization of sodium ions between the outside and the inside of the neuron (depolarization), and this change is sensed as a local signal for excitation by the affected neuron. These insecticides delay the shutdown process and furthermore delay the recovery process, resulting in a prolongation of the period of excitation. Insects thus affected continue in a state of hyperexcitation, leading to exhaustion and, at high doses of the insecticide, death.

The next important insecticidal target is acetylcholinesterase, which is attacked by organophosphorus and carbamate insecticides. This enzyme, by inducing hydrolysis, inactivates the interneuron nerve transmitter acetylcholine. This excitatory transmitter is released upon the arrival of a signal from the distal end of one neuron, travels across the intercellular gap, arrives at the frontal end of the second neuron, and reacts with its specific acetylcholine receptor on the surface that sends the signal of excitation to the second neuron. It is important to stress here that such a successful signal transmission must be followed with an abrupt termination of the action of the transmitter; this allows for the second neuron to recover quickly enough and thereby stay ready for the next message, maintaining the normal function of the message-transmitting neuron. This termination action is mainly carried out by acetylcholinesterase, which eliminates acetylcholine from the vicinity of the acetylcholine receptor of the second neuron. All organophosphorus and carbamate insecticides, or their active metabolites, show potent inhibitory actions on acetylcholinesterase of insects as well as other animals. The insects affected by these chemicals show overt signs of excitation, exhaustion and, at sufficient doses, death.

The acetylcholine receptor also can be deactivated to cause the same type of hyperexcitation. Indeed, nicotinoids (which include naturally occurring nicotine analogues and their modern derivatives, sometimes called “neonicotinoids”), such as imidacloprid, are known to directly activate the acetylcholine receptor just like acetylcholine.

Nicotine’s excitatory action is well known. Neonicotinoid derivatives readily penetrate the insect’s body and nerve sheath, arriving at critical sites of neurons, and persisting there long enough to exert a powerful excitant effect.

The GABA receptor, in contrast, acts as the receiver for the inhibitory transmitter, GABA. That is, unlike acetylcholine, it is not an excitatory transmitter. The signal generated by this GABA–GABA receptor interaction is converted to the opening of chloride channels, which upon the arrival of the signal permit Cl$^-$ ions to come into the signal-receiving cells (either neurons or muscle cells), to make them nonresponsive to excitation stimuli. Those insecticides—chlorinated hydrocarbon insecticides, cyclodiene (such as γ-HCH, dieldrin, endosulfan, and toxaphene), and more modern insecticides (such as fipronil)—render the chloride channel inoperative so that chloride ions cannot come into the cells. Cells thus affected fail to receive the inhibitory signal of GABA and therefore cannot counterbalance any excitatory forces. One group of insecticides, avermectin analogues, keep the chloride channel stuck in the open position, an action opposite from that of the excitation-inducing insecticides. These compounds induce long-lasting inhibition of excitation in insects. Insects thus affected by avermectin analogues show diminished activities, nonresponse to stimuli, and slow death through paralysis.

Certainly there are other mechanisms by which normal functions of insects may be affected. The main ones are as follows:

1. Mitochondrial poisons, such as rotenone, which causes respiratory failure.
2. Inhibitors of cuticle formation, via the action of diminil, including the rest of the dibenzoylmethane derivatives, which cause difficulty in molting and maintaining protective shields.
3. Insect hormone mimics such as juvenile hormone analogues that keep affected insects as immature forms (this method is effective against insects that cause damage only as adults, e.g., mosquitoes). Another group is ecdysone analogues, which affect insect development, including molting.
4. Bt toxins, which mainly affect the potassium channel in insect digestive systems.
5. Formamidine analogues, such as chloridimeform, which mimics octopamine, a naturally occurring transmitter/hormone, by acting on its receptor. Octopamine is used by insects and mites to control their behavior (among many of its actions), and therefore chloridimeform analogues are known to modify many behavioral patterns of insects and mites, and thereby protect crops from those pests.

INSECTICIDE RESISTANCE

In 1958, A.W. A. Brown’s landmark publication, *Insecticide Resistance in Arthropods*, established the principle that insects as well as other related invertebrates are capable of developing resistance to insecticides through natural selection. The probability of the development of resistance largely depends on (1) the frequency of the resistance-conferring gene in the given population, (2) the level of selection pressure, (3) the degree to which resistant gene density is diluted by susceptible genes through influx of individuals from untreated areas, and (4) the stability of the resistance gene in the given population. In some cases, once established, resistance genes may persist in the
same locality for many years. A good example may be the pyrethroid resistance of the moth *Helicoverpa armigera* in Australia.

How insects develop resistance to insecticides is a topic that has fascinated many entomologists. Basically, there are two major ways through which insect pests acquire resistance: increased detoxification capabilities and alteration of the insecticide target sites (target sensitivity). The first type of resistance occurs more frequently than the second type, as well as all others. Detoxification of toxic insecticidal chemicals is carried out by specialized enzymes designed to handle all chemicals toxic to insects, not just insecticides. Insects, particularly those feeding on plants that produce naturally large amounts of toxic chemicals, have well-developed detoxification enzymes. There are three major types of detoxification enzymes: (1) broad-spectrum oxidases such as mixed function oxidases catalyzed by cytochrome P450, (2) hydrolyases that break up esters, ethers, and epoxides, and (3) conjugation systems such as glutathione S-transferase, which are mediated to cover up the reactive part of the toxic chemical and further facilitate its removal. Every type of detoxification enzyme has been documented to play a role in the development of some form of resistance against various classes of insecticides.

In determining which type of detoxification enzymes will become the key player in the development of resistance, the most important factor for consideration is the chemical properties of the insecticide. For instance, carbamates and pyrethrins are readily detoxified by mixed function oxidases; therefore, if resistance is reported against these insecticides, one must first look for increased activities of mixed function oxidases in the resistant insects. If higher activity levels are found, the resistance spectrum (i.e., cross-resistance of carbamate-resistant insects to other types of insecticide) is usually wide because mixed function oxidases are capable of detoxifying chemicals of many different types. In contrast, organophosphorus and pyrethroid insecticides are mainly degraded by hydrolyases. Thus, the involvement of an increased hydrolytic enzyme activity may be suspected when insects develop resistance against these chemicals.

A good example of this is malathion resistance. Malathion molecules contain two extra carboxylic acid ethyl ester parts. Malathion-resistant insects always show increased carboxylesterase activity. Esterases of these types are not broad-spectrum enzymes, and therefore malathion resistance is usually specific (i.e., usually the insects resistant to malathion are not resistant to other insecticides). Insecticides with labile halogen, epoxides, methoxy unsaturation, and some aliphatic unsaturation may be degraded through these glutathione-mediated detoxification systems, and hence their elevated presence could be suspected to cause resistance. This scheme is, however, merely a rough guess about the possible mechanism of development of metabolic resistance. Indeed, unexpected and unique resistance mechanisms have been reported to occur in some combinations of insecticides and insects (e.g., DDT resistance in *Drosophila*). The recommended method of identification of the metabolic cause is to co-treat insects with the insecticide and specific inhibitors for each type of metabolic detoxification system, such as piperonyl butoxide for mixed function oxidase and DEF for esterases.

In studies of mechanisms for target insensitivity resistance, mutations occurring in the sodium channel, the GABA receptor, and acetylcholinesterase have been found in insects resistant to DDT/pyrethroids, cyclodiene insecticides, and organophosphorus and carbamate insecticides, respectively. Those resistances are characterized by their specificity (low degrees of cross-resistance) and the general stability of resistance among insect populations in given localities.

**REGULATIONS OF INSECTICIDE USES**

Insecticides, like all other types of pesticide, are highly regulated by governments in all countries. In the United States, the main law governing the use of insecticides is the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), which mandates registration with the U.S. Environmental Protection Agency of all insecticides used in the country. The initial data requirements for successful registration (so-called Tier 1) depend on the extensiveness of the projected use, the levels of acute toxicity of the agent contemplated, its effectiveness as an insect control agent (called “efficacy”), the intended modes of usage, and the availability of background knowledge, among other requirements. Occasionally, experimental use permits are given after this Tier 1 examination/process (e.g., for insect pheromones, which are already known to be almost nontoxic and are to be used only for a specific pest in small areas). Usually, however, registrants are required to go through a much more extensive and rigorous process of registration, data procurement, and evaluation. For example, extensive tests are required for acute, chronic (such as carcinogenicity tests), genetic, pathogenic, reproductive, hormonal, and immune toxicities along with the environmental behavior of chemicals and limited wildlife toxicities. Such registration processes, which must be completed before a new chemical pesticide can be sold in the United States, typically require 7–10 years and roughly $100 million.

Despite the thoroughness of the registration processes, occasionally problems come to the attention of the scientific community or the regulatory agencies. Sometimes, for example, old pesticides are not registered despite the availability of extensive records of their actual use. This is partly the result of the relative ease of the registration process in the past and partly from the absence of the main registrant, who is not economically motivated to reregister the compound because the patents for those chemicals (and thereby the exclusive marketing right) have expired. The second type of problem is due to the failure of the regulatory agency/scientific community to address the special vulnerability of certain groups of human populations or ecosystems. Examples include the lack of toxicological data on infants and embryos, women, and the aged, and science’s incomplete understanding of the hormonal effects of pesticides on humans and wildlife. The third type of problem is caused mostly by unforeseen scientific or technological developments, or unfortunate circumstances that are difficult to predict. The question of the safety of genetically modified crops and the assessment of strategies to study the recently discovered skin-hypersensitizing action of some pesticides serve as examples.

A recent trend is to look at this issue from the consumer’s side. A good example is the enactment of the Food Quality Protection Act (FQPA), which addresses the presence of pesticide residues and other toxic chemicals in food and drinking water. A key part of this regulation is the consideration of children’s health. Here, an extra safety factor of 10× is demanded to accommodate the postulated extra vulnerability of embryos, infants, and developing children. This requirement is enforced unless registrants can provide actual safety data to demonstrate that the susceptibility of these groups to the hazardous effects of the compound is equal to or less than that of adults.

In the end, the toxicological methods of evaluation, including overall risk assessment approaches, address the majority of health concerns. Future improvements are needed, however, to deal with unresolved environmental and human health risks.

Insecticide and Acaricide Resistance

Gregor J. Devine and Ian Denholm
Rothamsted Research

Insecticide resistance is an example of a dynamic evolutionary process in which chance mutations conferring protection against insecticides are selected in pest populations. This article reviews the origins and mechanisms of resistance, the factors that influence its severity, and the current options for combating its detrimental impact on agricultural productivity and human health.

INTRODUCTION

The genetic variation inherent in all populations is the consequence of random mutations within individuals, their recombination through meiosis, and the dispersal of genes between populations (gene flow). This variation is then shaped by the chance events of genetic drift and by the deterministic process of natural selection. The latter phenomenon eliminates alleles (gene variants) that reduce the fitness of an organism and preserves those that are neutral or that increase fitness. In eukaryotes, the phenotypic changes (adaptations) that result from this process are seldom visible over a human lifetime. The development of pesticide resistance by arthropods, however, is a spectacular exception to the rule.

Since the 1940s, synthetic insecticides have been used on an increasing scale to control the insects, mites and ticks that cause immense crop losses and pose major threats to public and animal health. However, because many of the target species have evolved resistance, some of these chemical control programs are failing. At the current time, more than 500 arthropod species have evolved resistance to at least one insecticide class, and a few populations of some of those species are now resistant to all, or almost all, of the available products (Fig. 1).

The evolution of insecticide resistance is an obvious constraint on effective pest management, both of agricultural pests and of vectors of disease. Resistance in Anopheles mosquitoes threatens the sustainability and efficacy of indoor residual spraying and insecticide-treated bednets for malaria control, and annual crop losses in the United States alone, related to insecticide resistance in pests, have been estimated at $1.4 billion. In order to compensate for such reduced control, farmers or spray operators are often driven to increase the concentrations of insecticides used and/or make repeated treatments to the same areas. This strategy, however, simply increases selection for further resistance development. The resulting “pesticide treadmill” in which ever greater quantities of insecticide are used to overcome burgeoning resistance problems undoubtedly contributes to our seeming inability to use insecticides

![FIGURE 1](image-url) DDT was the first insecticide to be used on a global scale. The first case of DDT resistance was recorded in 1946, signaling the beginning of a continuing war of attrition. Over the next 60 years, the number of resistant arthropod species increased rapidly in response to the development and use of insecticides. Horizontal bars denote time over which particular insecticide groups have been used, and dates are the year in which resistance was first documented [Adapted with permission from Georghiou, G. P. (1990). Overview of insecticide resistance. In “Managing Resistance to Agrochemicals” (M. D. Green, H. M. Le Baron, and W. K. Moberg, eds.), pp. 18–14. ACS Symposium Series 421. Copyright (1990) American Chemical Society, Washington, DC.]
judiciously, despite an increasing awareness of their detrimental effects on human health and the environment. Despite numerous initiatives aimed at reducing pesticide use, the acreage over which the developed world applies insecticides has remained stable for over a decade. The United Kingdom alone treats approximately 6 million hectares of land with insecticides each year (reflecting multiple applications to the same areas).

It is proving impossible to combat resistance by simply embarking on a chemical arms race in which redundant and resisted insecticides are replaced by others. The development of a new insecticide takes a decade and costs approximately $180 million. There are consequently few products that are deemed by agrochemical companies to be worth supporting all the way to the market place. Moreover, for those chemicals that are registered, resistance often arises within a few years (and sometimes within a few seasons).

**DIAGNOSIS OF RESISTANCE**

Although a large number of laboratory bioassay methods have been developed for detecting and characterizing resistance, most of these are limited to defining phenotypes and provide little or no information on the underlying genes or mechanisms. Thus, although bioassays remain the indispensable mainstay of most large-scale resistance monitoring programs, much attention is being paid to developing more incisive techniques that not only offer greater precision and turnover rates but also diagnose the type of mechanism(s) present and, whenever possible, the genotypes of resistant insects. A variety of approaches are being adopted for this purpose, including electrophoretic or immunological detection of resistance-causing enzymes, kinetic and end-point assays for quantifying the activity of enzymes or their inhibition by insecticides, and DNA-based diagnostics for mutant resistance alleles. An increased understanding of the insect genome has, in the past decade, allowed researchers to design microarrays (sets of cloned DNA molecules) that contain large numbers of coding regions associated with resistance. These microarrays can be used to probe insects for the incidence and expression of resistance alleles and are a powerful tool for the incrimination and diagnosis of resistance mechanisms.

The sensitivity of some of these techniques is exemplified by work on the green peach aphid, *Myzus persicae*. In Northern Europe, this insect possesses three coexisting resistance mechanisms: an overproduced carboxylesterase conferring resistance to organophosphates, a modified acetylcholinesterase (MACE) conferring resistance to certain carbamates, and target-site resistance [i.e., knockdown resistance (*kd*)] to pyrethroids. It is now possible to diagnose all three mechanisms in individual aphids by using an immunoassay for the overproduced esterase and molecular diagnostics for the MACE and *kd* alleles. The combined use of these techniques against field populations provides up-to-date information on the incidence of the mechanisms, serves to inform growers of potential control problems, and assists with developing optimal strategies for the management of *M. persicae*.

**EXTENT OF RESISTANCE**

In some insects, resistance extends only to a few closely related compounds in a single chemical class. It may be very weak or restricted to a small part of the insects’ geographical range. At the other extreme, some populations of widespread pests, such as the yellow fever mosquito (*Aedes aegypti*), the diamondback moth (*Plutella xylostella*), the Colorado potato beetle (*Leptinotarsa decemlineata*), and the sweet potato whitefly (*Bemisia tabaci*) now resist most or all of the insecticides available for their control.

The most extensively used insecticide classes are the organochlorines, organophosphates, carbamates, and pyrethroids. These four insecticide classes accounted for 70% of all insecticide use globally in the year 2000 and have generally been the most seriously compromised by resistance. Many principles relating to the origin and evolution of resistance can be illustrated solely by referring to these fast-acting neurotoxins. In recent years, however, there has also been a worrying increase in resistance to more novel insecticides. These include compounds attacking the developmental pathways of arthropods (e.g., chitin synthesis inhibitors), their respiratory processes [e.g., mitochondrial electron transport inhibiting (METI) acaricides], their digestive systems (e.g., *Bacillus thuringiensis* (Bt) endotoxins), as well as newer neurotoxins (e.g., neonicotinoids, spinosyns, and indoxacarb). Neonicotinoids were introduced in the mid-1990s, and are currently the fastest growing class of insecticides worldwide. Although resistance has been slow to develop, mutations that render their target site (the nicotinic acetylcholine receptor) less susceptible and enzymes conferring enhanced detoxification are now being reported in an increasing range of pests.

**ORIGINS AND BREADTH OF RESISTANCE**

Insecticides are not mutagenic at their field application rates and are not the causative agents of insecticide resistance. Rather they act to select favorable mutations inherent in the population to which they are applied. Some attempts to estimate the rates at which resistant mutations occur have been made. The treatment of blowflies (*Lucilia cuprina*) with a chemical mutagen resulted in the production of a dieldrin-resistant target-site mutation in less than one per million individuals, and less empirical measures of mutation rates suggest an underlying figure of anywhere between $10^{-2}$ and $10^{-4}$, undoubtedly dependent on the resistance mechanism involved.

Some studies have found the incidence of resistant mutations to be worryingly high. A recessive allele conferring resistance to Bt toxins in unselected populations of the tobacco budworm, *Heliothis virescens*, was estimated to be present in about one in every thousand individuals in some areas of North America. Sixteen in every hundred insects (a frequency of 0.16) were found to carry a Bt-resistant recessive allele in unselected populations of the pink bollworm, *Pectinophora gossypiella*, in Arizona cotton fields. Mutations conferring resistance to some Bt toxins seem common, even in species that have never been exposed. Frequencies of 0.003 are reported for a recessive allele conferring resistance to the Cry3A toxin in the beetle *Chrysomela tremulae* and to Cry2A in unexposed *Helicoverpa armigera* populations. Despite this, Bt cotton (engineered to express Bt toxins) remains effective in the control of pest species, suggesting that such estimates need to be interpreted carefully. A recent study on ancient museum specimens of the sheep blowfly from Australia showed that a mutated esterase that confers resistance to the organophosphate malathion was already common in the population long before the introduction of this insecticide.

Resistant mutations seldom confer protection to just a single toxin. Most commonly, they exhibit differing levels of resistance to a range of related and unrelated insecticides. In its strictest sense, the term cross-resistance refers to the ability of a single mechanism to confer resistance to several insecticides simultaneously. A more complex situation is that of multiple resistance, reflecting the coexistence of two or more resistance mechanisms, each with its own specific cross-resistance characteristics. Disentangling cross-resistance from multiple resistance, even at the phenotypic level, is one of the most challenging aspects of resistance research.
Cross-resistance patterns are inherently difficult to predict in advance because mechanisms based on both increased detoxification and altered target sites can differ substantially in their specificity. The most commonly encountered patterns of cross-resistance tend to be limited to compounds in the same chemical class. However, even these patterns can be very idiosyncratic. For example, organophosphate resistance based on increased detoxification or target-site alteration can be broadly ranging across this group or highly specific to a few chemicals with particular structural similarities. The breadth of target-site resistance to pyrethroids in houseflies is also dependent on the resistance allele present. The kdr allele itself affects almost all compounds in this class to a similar extent (~10-fold resistance), whereas resistance due to the more potent super-kdr allele is highly dependent on the alcohol component of pyrethroid molecules, ranging from about 10-fold to virtual immunity. Cross-resistance between insecticide classes is even harder to anticipate, especially for broad-spectrum detoxification systems whose specificity depends not on insecticides having the same mode of action but on the occurrence of common structural features that bind with detoxifying enzymes.

Empirical approaches for distinguishing between cross-resistance and multiple resistance include repeated backcrossing of resistant populations to fully susceptible ones, to establish whether resistance to two chemicals cosegregates consistently, and reciprocal selection experiments, whereby populations selected for resistance to one chemical are examined for a correlated change in response to another. If available, biochemical or molecular diagnostics for specific resistance genes can assist considerably with tracking the outcome of genetic crossovers or with assigning cross-resistance patterns to particular mechanisms.

MECHANISMS OF RESISTANCE AND THEIR HOMOLOGY

Depending on the mechanism involved, resistance has been shown to arise through structural alterations of genes encoding target-site proteins or detoxifying enzymes, or through processes affecting gene expression (e.g., amplification or altered transcription). Examples of the former include the following.

- Enhanced metabolism of insecticides by cytochrome P<sub>450</sub> monooxygenases can potentially confer resistance to most chemical classes. Much of the evidence for this mechanism in the past was indirect, based on the ability of monooxygenase inhibitors to reduce the magnitude of resistance when used in combination with insecticides in bioassays. More recently, information from genome sequences such as that of the fruit fly Drosophila has been used to probe for differences in the expression of individual members of large gene families such as P<sub>450</sub>.8.

- Enhanced activity of glutathione S-transferases (GSTs) is considered to be potentially important in resistance to some classes of insecticide, including organophosphates. Like monooxygenases, GSTs exist in numerous molecular forms with distinct properties, making the identification of enzymes associated with resistance very challenging.

- Enhanced hydrolysis or sequestration by esterases (e.g., carboxylesterases) capable of binding to and cleaving ester bonds undoubtedly plays an important role in resistance to organophosphates and pyrethroids. Biochemically, this is the best-characterized detoxification mechanism. Sometimes (e.g., for mosquitoes, blowflies, and M. persicae), the esterases have been identified and sequenced at the molecular level. Resistance caused by increased esterase activity can arise through a qualitative change in an enzyme, improving its hydrolytic capacity, or (as in mosquitoes and aphids) a quantitative change in the titer of a particular enzyme that already exists in susceptible insects.

The following examples appear to show that although some adaptations to the environment are unpredictable (e.g., the modifications of the forelimbs for flight are very different in birds, bats, and pterodactyls), the opportunities for insects to modify or reduce binding of insecticides, hence to develop target-site-based resistance mechanisms, are very limited indeed. It is likely that most of the mutations capable of conferring resistance do not allow the organism to retain normal functioning of the nervous system, and are therefore lethal and cannot be selected.

- Pyrethroids act primarily by binding to and blocking the voltage-gated sodium channel of nerve membranes. Knockdown resistance, or insensitivity of this target site, is now unequivocally attributed to structural modifications in a sodium channel protein. The same amino acid substitution (leucine 1014 to phenylalanine) in a sodium channel protein confers a “basal” kdr phenotype in a range of species including house flies, cockroaches, the green peach aphid, the diamondback moth, and a mosquito (Anopheles gambiae). This phenotype may subsequently be enhanced (to “super-kdr” resistance) by further mutations that also recur between species.

- γ-aminobutyric acid (GABA) receptors are targets for several insecticide classes including cyclodiennes (a subclass of the organochlorines), avermectins, and firombils. The primary mechanism of resistance to cyclodiennes and firombils involves modification of a particular GABA receptor subunit, resulting in substantial target-site insensitivity to these insecticides. The target-site mechanism of cyclodiene resistance has been attributed to the same amino acid substitution (alanine 302 to serine) in the GABA receptor of several species of diverse taxonomic origin including Drosophila, several beetles, a mosquito (A. aegypti), a whitefly (B. tabaci), and a cockroach (Blatella germanica). When susceptible individuals of the sheep blowfly (L. cuprina) were exposed to the mutagen ethyl methanesulfonate (EMS), and their progeny screened for resistance to dieldrin (a cyclodiene), surviving insects exhibited an alanine-to-serine amino acid substitution in the GABA receptor identical to that found in nature.

- Organophosphates and carbamates exert their toxicity by inhibiting the enzyme acetylcholinesterase (AChE), thereby impairing the transmission of nerve impulses across cholinergic synapses. Mutant forms of AChE showing reduced inhibition by these insecticides have been demonstrated in several insect and mite species. Biochemical and molecular analyses of insecticide-insensitive AChE have shown that pests may possess several different mutant forms of this enzyme with contrasting insensitivity profiles, thereby conferring distinct patterns of resistance to these two insecticide classes. Some of these resistance mechanisms are illustrated schematically in Fig. 2.

SPREAD OF RESISTANCE GENES

The recurrence of specific resistance mutations within and between taxa begs another question: have such mutations arisen repeatedly within the same species, or have they appeared on a limited number of occasions and subsequently spread through migration and/or human agency? Although there is molecular evidence for some resistance genes having several independent origins in the same species (e.g., for target-site resistance to cyclodiennes in the red
As an evolutionary trait, insecticide resistance is unusual in that we can identify the main selection pressure with ease, but the rate at which resistance develops is governed by numerous biotic and abiotic factors. These include the genetics and ecology of the pests and their resistance mechanisms, and the operational factors that relate to the chemical itself and to its application. To manage resistance effectively, an assessment of genetic, ecological, and operational risk is required. Although this can be done empirically on a species-by-species basis, one of the great challenges of the future is to understand why some species seem to have a greater tendency to become resistant than others.

Genetic Influences

To predict how quickly resistance will become established, it is necessary to understand how resistant alleles affect the survival of phenotypes in the field. For example, the dominance of resistance genes exerts a major influence on selection rates. In laboratory bioassays evaluating the relative survival of susceptible homozygotes (SS), heterozygotes (RS), and resistance homozygotes (RR) over several insecticide concentrations, RS individuals usually respond in an intermediate manner. In the field, however, dominance is dependent on the concentration of insecticide applied and its uniformity over space and time. Even when the initial concentration is sufficient to kill RS individuals (rendering resistance effectively recessive), upon weathering or decay of residues, this genotype may later show increased survival, with resistance becoming functionally dominant in expression. When resistance genes are still rare, hence mainly present in heterozygous condition, this sequence can have a profound effect in accelerating the selection of resistance genes to economically damaging frequencies.

The diverse mating systems of insects also influence the rate at which resistance evolves. Although most research has focused on outcrossing diploid species (typified by members of the Lepidoptera, Coleoptera, and Diptera), systems based on haplodiploidy and parthenogenesis also occur among key agricultural pests. In haplodiploid systems, males are usually produced uniparentally from unfertilized, haploid eggs, and females are produced biparentally from fertilized, diploid eggs. The primary consequence of this arrangement (exemplified by whitewoves, spider mites, and phytophagous thrips) is that resistance genes are exposed to selection from the outset in the hemizygous (haploid) males, irrespective of intrinsic dominance or recessiveness. Whether a resistance gene is dominant, semidominant, or recessive, resistance can develop at a similar rate.

Most species of aphid undergo periods of parthenogenesis (in which eggs develop and give rise to live offspring in the absence of a paternal genetic contribution) promoting the selection of clones with the highest levels of resistance and/or the most damaging combination of resistance mechanisms. In fully anholocyclic (asexual) populations, such as those of *M. persicae* in northern Europe, the influence of parthenogenesis has led to strong and persistent associations between resistance mechanisms within clonal lineages.

Ecological Influences

Fecundity and generation times have a huge bearing on the evolution of resistance in a population. The greater the number of individuals, and the faster they reproduce and attain maturity, the higher the likelihood that a favorable mutation will occur and be maintained in the population. Faster growth and higher population numbers will increase the likelihood that a favorable mutation will occur and be maintained in the population. Faster growth and higher population numbers will affect the size of a pest population and therefore the need for and frequency of insecticide treatment.

The dispersal capabilities of pests can also act as primary determinants of resistance development. Movement of pests between untreated and treated parts of their range may delay the evolution of resistance because of the diluting effect of susceptible immigrants. Conversely, large-scale movement can also accelerate the spread of resistance genes across geographical barriers.

**FIGURE 2** Schematic diagram of a nerve synapse showing examples of insecticide resistance mechanisms: (1) changes in the structure of the sodium channel confer kdr or super-kdr target-site resistance to pyrethroids; (2) modified AChE is no longer bound by organophosphates and remains available to break down acetylcholine molecules after neurotransmission across the synapse; (3) detoxifying enzymes degrade or sequester insecticides before they reach their targets in the nervous system.
resistance by transferring resistance alleles between localities. An example of how dispersal is key to the development of resistance management strategies relates to the control of two major cotton bollworm species (Lepidoptera: Noctuidae) in Australia. One (H. armigera) is endemic to Australia with a wider range of native, non-crop hosts. Historically, H. armigera has proved an almost intractable problem, rapidly developing resistance to many insecticide classes. Conversely, H. punctigera, an equally important cotton pest, has remained susceptible to all insecticide classes, probably because its greater host range (and long-range dispersal between these hosts) results in the maintenance of a large pool of unselected, susceptible individuals, which dilute any resistant mutations that arise.

Operational Influences

Operational factors are at human discretion and can be manipulated to influence selection rates. Factors exerting a major influence in this respect include the rate, method, and frequency of applications, their biological persistence, and whether insecticides are used singly or as mixtures of active ingredients.

Equating operational factors with selection is often difficult, because without detailed knowledge of the mechanisms present it is impossible to test many of the assumptions on which genetic models of resistance are based. If resistance alleles are present, the only entirely nonselecting insecticide doses will be ones sufficiently high to overpower all individuals, regardless of their genetic composition, or ones so low that they kill no insects at all. The latter is obviously a trivial option. Prospects of achieving the former depend critically on the potency and dominance of resistance genes present. A pragmatic solution to this dilemma is to set application doses as far above the tolerance range of homozygous, susceptible individuals as economic and environmental constraints permit, in the hope that any heterozygotes that do arise will be effectively controlled. However, this approach will obviously be ineffective if resistance turns out to be more common than suspected (resulting in the presence of homozygous resistant individuals) or if resistance alleles exhibit an unexpectedly high degree of dominance (and heterozygotes are therefore phenotypically resistant). Unless a high proportion of insects escape exposure altogether, the consequence could then be very rapid and effective selection for homozygous resistant populations.

In practice, concerns about optimizing dose rates to avoid resistance are secondary to those related to the application process itself. Delivery systems and/or habitats promoting uneven or inadequate coverage will generally be more prone to select for resistance, because, under these circumstances, pests are likely to encounter suboptimal doses of toxins that will permit survival of heterozygous individuals.

The timing of insecticide applications relative to the life cycle of a pest can also be an important determinant of resistance. Targeting of insecticides against newly hatched larvae, as is generally advocated for bollworm control, not only increases the likelihood of contacting larvae at the most exposed stage in their development but also offers the greatest prospect of retarding resistance by overpowering its expression (the sensitivity of larvae to insecticides declines with increasing size). It may also have the effect of reducing genetic variation and therefore the potential number of resistant mutations. Indeed, it is also possible to impose genetic “bottlenecks” by applying pesticides when populations are already low (e.g., when they are overwintering). Although such a tactic might be beneficial where populations are fully susceptible, if resistant mutations are already present, it might act to increase their frequency.

In theory, the application of two or more unrelated chemicals as insecticide mixtures offers substantial benefits for delaying the selection of resistance. The underlying principle is one of “redundant killing,” whereby any individuals already resistant to one insecticide are killed by simultaneous exposure to another, and vice versa. However, achieving this objective requires that each type of resistance be rare and that both ingredients persist throughout the effective life of an application. Otherwise, one compound will exert greater selection pressure than the other, and the advantage of applying a mixture will be lost.

Fitness of Resistant Individuals

In the absence of insecticidal selection pressure, resistance genes can impose fitness costs on their carriers. Sometimes these costs are quite subtle and difficult to determine. In M. persicae, a reduced response to alarm pheromone (produced as a warning signal by aphids) was associated with both the amplification of a gene that codes for OP resistance and the kdr target-site mutation. In this species, gene amplification was also associated with a decreased propensity to move from senescing leaves to fresh leaves at low temperature and hence reduced overwintering survival. Housefly genotypes possessing the identical kdr mutation were shown to exhibit behavioral differences in comparison with susceptible insects. Resistant individuals showed no positional preference along a temperature gradient while susceptible genotypes exhibited a strong preference for warmer temperatures. Costs such as these can contribute to a decline in the frequency of resistant insects when insecticide pressure is relaxed. However, reduced fitness is by no means an inevitable side effect of acquiring resistance. There are examples of mutations at even highly conserved sites in essential proteins that seemingly exert no effect on the fecundity, development, or survival of their carriers.

COMBATING INSECTICIDE RESISTANCE

Insecticide resistance management (IRM) aims to intervene in the evolutionary process and either overcome resistance or prevent its appearance in the first place. There are several practical, economic, and political constraints on the choice of possible IRM tactics and the precision with which they can be applied:

- The properties of any resistance genes present are often unknown, and knowledge of pest ecology may still be rudimentary.
- It is often necessary to contend with a whole pest complex rather than just a single pest species.
- There may be a very limited number of insecticides available for use in management strategies.
- For highly mobile pests, at least, countermeasures may need to be standardized and synchronized over large areas, sometimes whole countries.
- Resistance is a dynamic phenomenon; that is, any mechanisms already known to exist may change over time.
- To promote compliance with management strategies, the tactics adopted should be as unambiguous, rational, and simple as possible.

A strategy first implemented on Australian cotton in 1983 against H. armigera illustrates many features of large-scale attempts at resistance management. Introduced in response to unexpected, but still localized, outbreaks of pyrethroid resistance in H. armigera, the strategy was based primarily on the concept of insecticide rotation. The threat of pyrethroid resistance was countered by restricting these chemicals to a maximum of three sprays within a prescribed
time period coincident with peak bollworm damage. To diversify the selection pressures being applied, farmers were required to use alternative insecticide classes at other stages of the cropping season. Additional recommendations, including the targeting of insecticides against newly hatched larvae (the most vulnerable life stage), the plowing in of cotton stubble to destroy resistant pupae overwintering in the soil, and the use of trap crops to concentrate pests in particular areas where they could then be controlled by other means (i.e., destructive cultivation of the crop), were major additional components of the program. The result was to delay but not prevent the evolution of resistance to the pyrethroids. These days, pyrethroids remain among the insecticides listed for rotation with organophosphates, carbamates, and a range of newer products that have been introduced since the strategy was first devised. Management of resistance to conventional insecticides remains vital to cotton production alongside tactics for combating pest resistance to transgenic crops expressing Bt toxins (see below).

TRANSGENIC PLANTS

A major innovation in crop protection has been the release of crop plants genetically engineered to express genes for insecticidal Bt toxins derived from the microbe *B. thuringiensis*. Existing toxin genes in Bt cotton and corn are active specifically against certain key lepidopteran pests (especially bollworms and corn borers), and another has been engineered into potatoes to provide protection against the Colorado potato beetle (but due to poor sales, all genetically engineered potato varieties have now been discontinued). The production of Bt non-food crops continues to accelerate. In 2006, 19.0 million hectares were planted with Bt crops and 13.1 million hectares with the stacked traits of Bt and herbicide tolerance. Aside from their commercial prospects, insect-tolerant transgenic crops offer numerous potential benefits to agriculture. By affording constitutive expression of toxins in plant tissues throughout a growing season, the incorporation of Bt genes into crops should reduce dramatically the use of conventional broad-spectrum insecticides against insect pests and therefore environmental contamination. It removes the dependence of pest control on extrinsic factors such as climate and on the efficiency of traditional application methods. However, this high and persistent level of expression also introduces a considerable risk of pests adapting rapidly to resist genetically engineered toxins. To date, there are no substantiated reports of resistance selected directly by exposure to commercial transgenic crops, but resistance to conventional Bt sprays (selected in either the laboratory or the field) has been reported in more than a dozen insect species. Research into the causes and inheritance of such resistance provides valuable insights into the threats facing Bt plants and the efficacy of possible countermeasures. Tactics proposed for sustaining the effectiveness of Bt are more limited in scope than for conventional insecticides because of the long persistence and constitutive expression of engineered toxins and because of the limited diversity of transgenes currently available. Indeed the only prudent and readily implementable tactic currently employable is to ensure that substantial numbers of pests survive in nontransgenic refugia, a strategy dependent on some key assumptions: (1) that resistant mutations are recessive or at least only partially dominant, so that their heterozygous forms can be controlled by the toxins expressed; (2) that refugia will produce enough susceptible insects to ensure that insects carrying resistant alleles do not meet and mate; and (3) that resistant alleles will carry a fitness cost, rendering insects less fit when the selection pressure is removed (e.g., outside the growing season when the insect is dependent on other crops).

As an example of a transgenic crop, the majority of cotton grown in Australia is now engineered to express two Bt toxins (Cry1Ac and Cry2Ab). These toxins are lethal to all field populations of cotton bollworm (*H. armigera*). In order to preserve this susceptibility, each Bt cotton farmer is legally required to grow a refuge crop capable of producing sufficient Bt susceptible *Helicoverpa* moths to dominate mating interactions with survivors emerging from Bt crops. It is hoped that stacking (or pyramiding) these two genes in the same cultivar, in combination with the use of refugia, will result in a far more durable resistance management strategy than has been afforded by the presence of single Bt toxins. It is clearly essential that plants expressing insecticidal transgenes (essentially analogous to conventionally-bred pest-resistant cultivars) be exploited as components of multitactic strategies rather than as a panacea for resistance problems with conventional insecticides.

RESISTANCE IN NONPEST SPECIES

In contrast to the detrimental impact of resistance in pests, the ability of insect predators and parasitoids to develop pesticide resistance could be of enormous benefit to pest management strategies incorporating insecticides. Although pyrethroid and organophosphate resistance has been documented in predatory mites (e.g., *Typhlodromus pyri* in orchards and *Amblyseius womersleyi* in tea fields) and hymenopterous parasitoids (e.g., *Aphyts holoxanthus* in orchards and *Anisopteromalus calandrae* in grain stores), reports of insecticide-resistant beneficial species from the field are far rarer than they are for pest species. Reporting bias aside, the most likely reasons for this are the difficulty in host location when both natural enemy and host are under selection pressure and, in comparison with herbivorous species, the possibility that the enzyme systems of predators and parasites are less well adapted to detoxify xenobiotics.

In general, when resistance does occur in nonpest species, its mechanisms are similar to those exhibited by pest species. Organophosphate resistance in strains of *A. calandrae* has been linked to the presence of carboxylesterase-like enzymes similar to those conferring organophosphate resistance in the aphid *M. persicae*. The expression level of the carboxylesterase-like enzyme in this wasp is approximately 30-fold higher in the resistant strain relative to that in the susceptible strain, and the mechanism seems to have its basis in a single-nucleotide replacement. Organophosphate resistance in strains of the warehouse pirate bug (*Xylocoris flavipes*) has also been linked to the presence of a carboxylesterase. Resistance to this chemical group in the lacewing, *Chrysopa scleastes*, has been attributed to increased AChE activity.

CONCLUDING REMARKS

Research on the topic of insecticide resistance has provided invaluable insights into the origin and nature of adaptations, and these are proving to have broad significance for understanding genetic responses to man-made change in the environment. In many respects, the continuing battle against resistance is as good an example of coevolution as any and is a clear illustration of how such processes influence biological diversity.

It is important to note that the pest management problems posed by the evolution of resistance are not unique to control strategies that use conventional insecticides. Codling moths (*Cydia pomonella*) were recently reported to have evolved up to 100,000-fold resistance to a baculovirus applied as a biological control agent that was widely considered to be much less vulnerable to resistance development. The
utilization of host plant resistance is another case in point. Resistance to insects in crop plants is selected by screening for genes that provide resistance in the laboratory or in field plots, and then inserting those genes into crop strains with other desirable characteristics (through crossing or genetic engineering). At least eight major genes for resistance to the Hessian fly (Mayetiola destructor) have been successively bred into wheat over the past two decades. In each instance, the introductions of new insect-resistant mutations in the plant were rendered useless by the evolution of corresponding protective adaptations in the fly. Another example of such coevolution comes from the use of semiochemical tools for pest control. In many parts of Asia, a synthetic pheromone is used to disrupt mating in a tea tortrix moth (Adoxophyes honmai), the larvae of which can cause severe damage in tea plantations. Researchers in Japan recently reported the evolution of a new biotype of this species that exhibits reduced sensitivity to mating disruption. In this case, resistance may have evolved quickly because the original formulation used did not match the precise blend used by the female. Use of the complete pheromone blend restored efficacy. Such events make it clear that regardless of whether the major strategies for pest management continue to use conventional chemicals, the “arms race” between insect evolution and human ingenuity will continue to present major challenges.

Insectivorous Plants

Lewis J. Feldman
University of California, Berkeley

The term “insectivorous” was used by Charles Darwin to characterize a group of plants that seemed to trap and feed on insects. Since Darwin’s time, observations have revealed that these plants capture and interact with a greater variety of animals, which can include spiders, lizards, sow bugs, tadpoles, and frogs, and judging from some reports, even small mammals such as rats and rabbits. Hence, because of this varied diet, many workers now prefer to describe such plants as carnivorous, rather than solely insectivorous. Yet the interactions between carnivorous plants and animals go beyond the presence of certain creatures as items on a plant’s menu. While it is true that the most spectacular and usually the most obvious activities of carnivorous plants seem to be in the often elaborate mechanisms for capture and digestion of prey; many other (often more subtle) associations occur between these plants and animals. Researchers are just at the beginnings of learning about these other fascinating interactions.

THE CARNIVOROUS HABIT

Plant carnivory is a rarity, occurring in only about 550–600 out of approximately 250,000 plant species. True carnivory has probably evolved a number of times independently. The carnivorous habit is not obligate, and carnivorous plants can grow without an insect meal, depending instead on photosynthesis and minerals supplied from the soil. In general, carnivorous plants grow in sunny areas, and in mineral-deficient, sometimes sandy soils. Often these soils have standing or gently moving water, with any dissolved minerals from the soil being easily carried away by the flowing water. The carnivorous plant habitat is typically low in nitrogen and phosphorus and, as suggested by some reports, in potassium as well. In this sort of habitat, plants that have alternative strategies for obtaining essential minerals are at a competitive advantage. The capture of insects and other animals thus provides carnivorous plants with a supplemental source of essential nutrients.

The carnivorous habit depends on an ability to trap prey. In the vast majority of carnivorous plants, the trap represents a modification of the entire leaf or of structures borne on the leaf. Given this rather straightforward requirement of a trap, it should be easy enough to characterize a plant as carnivorous, or not. However, the picture is not so simple: many plants can trap insects yet are not considered to be carnivorous. What truly distinguishes a plant as carnivorous is not only a trapping ability but also a mechanism to digest prey and to absorb the prey’s nutrients.

It is the specifics of this digestion that have caused some controversy. Some workers consider a plant to be carnivorous only if it has an inherent ability to digest prey—that is, if the plant itself produces enzymes to break down the insect. Other plants, sometimes considered to be semi-carnivorous, are able to trap prey but depend on the
assistance of other organisms, usually, but not always, microbes, to digest the captured insects. However, for this short article, a plant is considered to be carnivorous if it traps and has a means, of its own making or not, for digesting prey.

The trap of a carnivorous plant is a true marvel. Traps can be grouped by whether they are “passive,” with no or slowly moving “parts,” often relying on gravity to aid in capture of the insect, or “active,” exhibiting some sort of usually rapid movement.

PASSIVE TRAPS

Perhaps the most familiar examples of passive traps are the sundews (Drosera) and the pitcher plants (Sarracenia and Darlingtonia in temperate climes and Nepenthes in the tropics). The sundews capture their prey by producing from stalked glands an adhesive, or glue (the drop of “dew”), which captures and holds fast the insect. As the prey struggles, it is covered with the sticky mucilage and, as a consequence, suffocates. The stalked glands then bend in toward the prey; in some species, the entire leaf enfolds the prey. A second type of gland on the leaf secretes digestive enzymes and acids, initiating the breakdown and subsequent absorption of nutrients. Darwin was so enthralled with the sundews that about two-thirds of his book *Insectivorous Plants* is devoted to this group. He notes his surprise at “finding how large a number of insects were caught by the leaves of the common sundew,” and speculates that, “as this plant is extremely common in some districts, the number of insects thus annually slaughtered must be prodigious.”

A fascinating variation on the carnivorous plant passive trap theme is shown by plants that comprise the genus *Roridula*. These plants, considered by some workers not to be truly carnivorous, are native to South Africa and may be near extinction. Individuals in this group have leaves covered with stalked mucilage-secreting glands, which as in the sundews capture and hold fast insects. This is where the carnivorous story would end, were it not for another player, a species of assassin bug, which forms a mutualistic association with *Roridula*. Large numbers of these predaceous bugs may inhabit *Roridula* and are able to traverse the leaves, without themselves being ensnared by the glue. When other insects are captured by the plant, the assassin bugs move to the trapped prey, suck out their liquid contents, and, some time afterward, defecate a nutritious substance that is absorbed by the leaf and nourishes the plant.

The second major group of plants that have passive traps are the pitcher plants. In this group, the leaf becomes variously modified, often into a tube, and develops at the base of the tube a well that must fill with water for the pitcher to function as a trap. The temperate species of pitcher plants (Darlingtonia in the western United States and Sarracenia in eastern North America) (Figs. 1 and 2) are usually terrestrial. In these plants, the leaf lures flying insects by producing nectar, in some plants laced with volatile insect attractants (e.g., enol diacetal monoterpene and/or a series of methyl esters) that sometimes covers the colorful appendages. Crawling insects follow nectar trails running along the outside of the leaf. The nectar trails lead to the mouth of the tube, where the surface is smooth and slippery and from which the insect can easily lose its foothold, thus falling into the watery well. Escape from the well is almost impossible, since the inside wall of the tube leaf is lined with downward-pointing hairs. One would think that flying insects could fly out if they started to fall. To counter this possibility, pitcher plants such as *Darlingtonia* have developed a hooded leaf, transparent and sealed at its top. When an insect tries to leave the leaf, it flies toward light coming through the transparent upper portion of the hood. Since, however, the exit is sealed, eventually the insect becomes so exhausted that it falls into the well. There is some suggestion that pitcher plants may produce a “drug” to confuse the flying insect, and that fluids in the well may contain substances (in *Sarracenia flava*, a toxic alkaloid, conine, [the poison in hemlock]) that is suggested to quiet and stun the fallen insect. In addition to nectar serving as an attractant, the

![Figure 1](image1.png) **FIGURE 1** Habit view of the California pitcher plant (*Darlingtonia californica*) growing in a bog in northern California. The leaf is divided into a hood region and tube region. Digestion occurs in a well of water at the base of the tube.

![Figure 2](image2.png) **FIGURE 2** Eastern pitcher plant (*Sarracenia purpurea*) from Ohio. In this species a hood is absent.
possible development of ultraviolet signaling, as employed by flowers to attract pollinators, may also serve to lure insects to the trap. Many temperate pitcher plants secrete hydrolytic enzymes into the liquid in the well, thereby digesting the insect, whereas other pitcher plants (e.g., *Darlingtonia*) produce none of their own digestive enzymes but instead rely on bacteria to decay the insect. In either model, the digestive enzymes can be quite powerful, with only the hardest parts of insects, such as legs or shells, remaining undigested.

The tropical pitcher plants belong to the genus *Nepenthes* in which the pitcher develops at the end of a leaflike petiole. Given, the complexity and variety of pitchers in *Nepenthes*, it is often difficult, hard to believe that what one is indeed looking at is a leaf. Like their temperate cousins, *Nepenthes* spp. produce nectar to lure prey, which subsequently become intoxicated, lose their foothold, and fall into the trap. *Nepenthes* spp. generally produce climbing stems, thus elevating the pitchers, and perhaps thereby making them more accessible to potential prey.

Species of *Nepenthes*, and likely all carnivorous plants, do not seem to be designed to trap one particular species. An inventory of the traps shows that their diets are ever-changing and can be quite varied. For example, from 10 *Nepenthes* pitchers over a season, Erber found arthropods of 150 identified species, belonging principally to the orders Diptera, Hymenoptera, Collembola, and Acarina, and the families Formicidae and Aphididae. Similar tallies in *Sarracinea* reveal victims of 115 families belonging to 14 orders of insects, including several species of Mollusca. This strategy no doubt ensures some prey, if, for example, a particular insect species is not present one year, or becomes extinct, and also allows the plant to trap a variety of insects over a very long season. Additionally, such variety may be important in supplying a diversity of nutrients.

**ACTIVE TRAPS**

Plants with rapid movement usually first come into mind when carnivorous plants are mentioned. These so-called active traps imprison their prey by a quick movement of all or part of the leaf. Into this group are placed several genera: one well known, the Venus flytrap (*Dionaea*) (Fig. 3) and the others less familiar (e.g., the bladderworts, *Utricularia*) (Fig. 4). It is believed that the rapid movement comes about when the prey makes contact with a triggering mechanism, resulting in the generation of a small electric current and the activation or closure of the trap. As with the passive traps, the lure for the insect is usually some sweet nectar. In the case of the Venus flytrap leaf in which the two halves of the blade are joined along one side, as in an open book, nectar is produced on the inner surface of the leaf (Fig. 3). As an insect wanders along this inner surface collecting nectar, it may contact the trigger hairs, of which there are about two to four on the inner surface of each half-leaf. For the trap to close, either an individual trigger hair “must be touched twice, or two different trigger hairs must be touched sequentially, within a time period that is neither too short (<0.75 s) nor too long (>20 s).” When the hair or hairs are touched within the right time interval, the trap literally snaps shut, though at first, not completely. Initially, small openings remain between the two halves, presumably to allow smaller insects to escape from the trap. When unsuitable prey gain their release, the trap reopens and awaits the main course. But if the insect is unable to escape

![FIGURE 3](image-url) **FIGURE 3** Habit view of the Venus flytrap (*Dionaea* sp.). In this genus the blade is divided into two halves, which are attached along one side. On the inner surfaces of the blade a lure is produced, and here too are located the trigger hairs.

through the small openings and continues to struggle, the trap closes more fully. Subsequently, enzymes are secreted by special gland cells, and the insect is digested over a period of one to two weeks, and its nutrients are absorbed by the leaf. Leaves of the Venus flytrap apparently can be redeployed several times in capturing insects.

Less well known as active trappers but possessing traps more complex than the Venus flytraps are the bladdernots, which grow in wet or periodically wet areas. Bladdernots, the largest genus of carnivorous plants, grow worldwide, on every continent. They develop diminutive, often microscopic traps that cover the leaves (Fig. 4). The size of the trap determines what creatures will enter: paramecia, rotifers, water fleas, worms, and mosquito larvae, for example. As in the Venus flytrap, contact with trigger hairs initiates the trapping mechanism, which involves the opening of a “door” leading to a chamber maintained under a vacuum, a sucking in of the prey, and a rescaling of the trap; all this occurs within 10 to 15 thousandths of a second! With the secretion of enzymes, the prey is digested, usually within hours. There is some speculation that the trap can also lure prey.

OTHER INTERACTIONS BETWEEN CARNIVOROUS PLANTS AND INSECTS

Thus far, plant-insect interactions have been presented in the context of insects serving as prey. But the associations can be much more varied and complex, as seen in the case of the assassin bug and Roridula. Entomologists are now only beginning to appreciate the many other ways in which carnivorous plants and insects/animals interact. Some of the more fascinating examples are found in the pitcher plants, where other animals turn the traps to their own advantage. Spiders often can be found prowling about the mouth of pitchers, then lowering themselves on silken strands to retrieve prey from the pitcher well. In Nepenthes, spiders also use the pitcher for protection from predators. If a predator is detected, the spider will lower itself on a silk thread to the pool and, if necessary, will even hide under the water until danger passes.

Other insects spend part or most of their lives in the wells of pitchers. For example, the pitcher plant mosquito (Wyeomyia smithii) lays its eggs on the moist inner surface of the leaf, or more often, in the pool of liquid. The larvae hatch and feed on detritus from trapped insects, bacteria, and protozoans. As winter approaches, the larvae go into a dormant state and overwinter in the pitcher, exiting the pitcher in the spring as adult mosquitoes. In climates where water freezes, the larvae spend winter frozen in the ice of the pitcher. Interestingly, the liquid that digests the trapped insects seems to have no detrimental effects on the larvae. Fish fly larvae also live in pitchers and, like the mosquito larvae, are not injured by the pitcher’s digestive enzymes because, it is speculated, their bodies produce a protective substance.

One of the most fascinating examples of an association between plant and insect, benefiting the insect, is seen in species of Exyra moths (Noctuidae) that exploit the pitcher leaf to shelter their young. The cycle begins with the female moth entering an open leaf and laying its eggs on the inner wall of the pitcher leaf. When the larval hatch, they move about on silken strands, feeding on the inner wall. As they grow, hence becoming more visible to predators, the larval move to the top of the pitcher, severing vascular strands carrying water to the upper regions of the pitcher leaf, which causes the top of the pitcher leaf to dry, collapse, and fold over the opening. The developing larvae are now shielded from predators. Just before a larva prepares to pupate, it chews a hole in the wall of the leaf. Through this hole, the moth exits the leaf.

Yet another example of an insect exploiting its association with carnivorous plants is the solitary sarracenia wasp (Chlorion harrisi). This insect uses the pitcher as an incubator for its eggs. In preparation for the laying of eggs, the wasp packs into the bottom of the pitcher tube a layer of grass, which is then overlaid with freshly killed grasshoppers or crickets. This process may be repeated several times, resulting in alternating layers of insects and plant materials. Eggs are then laid among the dead insects and the whole construction is covered by another layer of grass. The eggs can now develop protected, and when the young hatch, they have a food supply.

The last example represents what may come closest to a commensal, or symbiotic, association between plant and insect. Certain species of Nepenthes (e.g., N. bicalarate) have enlarged, hollow petioles in which ants take up residence. In return for this “home” (domatia), the ants, it is suggested, protect the plant from predators.

Carnivorous plants grown outdoors probably catch more than enough insects to maintain proper nutrition, whereas plants grown indoors may be fed insects by hand. Interestingly, carnivorous plants are generally not able to digest large non-insect food, such as bits of raw meat, suggesting that some characteristics of the insect may stimulate the plant’s digestive processes.

Finally, note should be made of the apparent conflict between the plant-pollinator and plant-prey systems. Some plants separate spatially, or temporally, the flowers from the traps. But in most cases traps and flowers are produced at the same time. Indeed, in some cases, as in the pitcher plants, the leaves mimic the flower characteristics (Fig. 1). In Pinguicula, plants in bloom increase the prey capture of small visitors, especially thrips and small beetles. Thus, at a cost of some pollination flowering can promote increased vegetative success through prey capture, which usually translates into increased reproductive success. It would seem, therefore that under conditions in which pollinators were not limiting, trapping a portion of the pollinators would not be detrimental.

Insectivorous Vertebrates

Charles R. Crumly
University of California Press, Berkeley

Insects are a part of the diet of a vast array of animals. Indeed, there are almost no animal groups that do not include some representatives that consume insects, incidentally or intentionally, actively or accidentally. Even obligate herbivores consume insects,
Although never in any large number. Several groups of animals are insectivorous as juveniles and shift dietary focus as adults, whereas other groups become insectivorous only as adults.

**DIVERSITY OF INSECTIVORY**

A simple list of the insectivorous terrestrial animals would be lengthy and include many freshwater fishes, most frogs and salamanders, lizards and snakes, and birds and mammals. Because marine ecosystems do not include many insects, the incidence of insectivory among marine invertebrates and vertebrates is much less common. In freshwater fishes, insects are ubiquitous and widely consumed. In streams, for example, 70–90% of the macroinvertebrates are insects, comprising as much as 99% of the numbers of individual organisms and 99% of the biomass. Fishes take advantage of these abundant resources and consume insects from all of the 13 orders of insects with aquatic life stages.

Terrestrial salamanders and almost all frogs, which are often filter feeders or herbivores as larvae, become predominantly insectivorous as adults. Frogs and salamanders that remain aquatic, or become so secondarily, possess a wide array of dietary choices that can include other aquatic life, including (but not limited to) insect adults or larvae.

Lizards, more so than snakes, include insects in the diet. Consumption of insects also occurs in other reptiles such as turtles and juvenile crocodilians. Insect prey selected by lizards is somewhat size dependent: smaller lizards consume more small insects, whereas larger lizards can also consume larger insects. Some lizards that are insectivores as juveniles become more herbivorous as adults. In snakes, smaller insectivores become more carnivorous as they get larger, focusing on other vertebrate prey, especially mammals, frogs, and other snakes. Among some groups of lizards and snakes, specialization for insectivory is a familiar pattern; in these instances, ants and termites are most frequently consumed.

There are many birds that consume insects as a dominant part of the diet. Some of these insectivorous lineages include pipits and wagtails (Motacillidae), bulbuls and allies (Campephagidae, Pycnonotidae, Chloropseidae), waxwings and allies (Ptilogonatidae, Bombycillidae, Dulidae), dippers (Cinclidae), warblers and gnatchatchers (Sylvoridae, Parulidae), flycatchers (Muscicapidae), and titmice, nuthatches, and treecreepers (Paridae, Sittidae, Certhiidae). Many birds capture insect prey in flight, whereas other birds forage in shrubs and trees or on the ground. Some birds specialize by obtaining insect food, grooming large mammals or following behind large mammalian herbivores and foraging on the insects disturbed by large mammal movements.

Mammals include many insectivorous groups, some generalists and others obligate specialists. Most of those that specialize in eating insects eat either ants or termites. Generalized insectivores will eat insects along with other arthropods such as centipedes, millipedes, spiders, and scorpions. Marsupials, bats, primates, rodents, carnivores, and other groups of mammals include insectivorous lineages. Specialized feeding on particular insects, especially ants and termites, occurs among a few frogs, many lizards, and some snakes and has occurred in several different lineages of mammals (see Table I).

**ANATOMICAL SPECIALIZATIONS FOR INSECTIVORY**

Although eating insects is a dominant part of many diets, anatomical and behavioral specializations for insectivory are not as widespread. Many lizards, for example, feed on whatever suitable prey item might be available. Nevertheless, there are several anatomical specializations that seem to assist in the capture of insect prey. Perhaps the most obvious and remarkable trait is a highly projectile tongue. This sort of tongue evolved many times, in many different lineages, and in many different ways. Most frogs have a projectile tongue whose intrinsic muscles attach to the lingual edge of the symphysis of the jaw. The tongue is flipped out of the mouth, in the same way that a catapult works, so that the back of the tongue after it is extruded contacts the prey first. Salamanders have evolved several different types of projectile tongues. One group of lungless salamanders, the plethodontids, uses the hyobranchial skeleton and associated muscles, once used to ventilate lungs, in a tongue protrusion mechanism that is quite spectacular. Contraction of these muscles results in protrusion of the tongue as well as large parts of the mandibular arch, resulting in an extruded tongue that can reach 80% of body length.

Chameleon lizards have an unmatched ability to accurately aim, project, and hit arboreal insect prey. The muscles that chameleons use to accomplish this ballistic feat contract faster than any other vertebrate muscle. Furthermore, the tongue can be accurately projected up to 200% of body length. The tongue has a large tip covered with viscous mucus. A muscle in the large fleshy tip contracts just after the tongue tip strikes a prey item, creating a slight vacuum that assists in prey capture.

Mammals eat insects and the most distant ancestors of mammals may have been insectivores. Generalized features derived from the primitive amniote condition are associated with mammalian feeding,

Note: Not all the taxa that are a part of these lineages eat only ants and/or termites. There are many other lineages not listed that eat insects.
including a longer secondary palate, heterodont dentition, higher metabolic rates, and more active foraging behaviors. Several of these features are reversed in obligate ant- and termite-eating mammals. For example, anteaters, pangolins, and the echidna, numbat, and aardvark possess highly simplified teeth few in number or lack teeth entirely. Some ant and termite specialists have lower metabolic rates, but it is not clear if these rates are retained from a primitive mammalian ancestor or if they are a response to prey that may present chemical challenges to typical mammalian digestive systems. A long, sticky, and protrusive tongue is a common feature among ant- and termite-feeding mammals. Details of tongue anatomy confirm that many of these lineages evolved these specializations independently.

Insect Zoos

Leslie Saul-Gershenz
SaveNature.Org, San Francisco, CA

Insect zoos, exhibits that display live insects and arthropods to the general public, have gained recognition for their broad appeal and enormous educational value. They have demonstrated that insects are interesting to millions of people, not just a select few and draw huge visitation crowds if done well. Insects represent the majority of terrestrial species on earth and display a dazzling diversity of lifestyles, behaviors, and adaptations. The great naturalists Pliny, Fabre, Wallace, Darwin, Belt, and Wheeler possessed a boundless desire to observe living insects in the natural world. The observation of living insects in the field and lab still excites the imagination of naturalists today, and the general public has been increasingly infected with this enthusiasm through exposure to the lives of insects through superb nature films and photography. Insect zoos provide opportunities for positive firsthand observations of live insects to millions of people each year. These exhibits are intended to inspire a desire to learn more, to balance the myths and misrepresentations promoted by the cinema and other commercial media. Insectariums have proven to be enormously popular with the public wherever they appear, whether modest or grand, whether showcasing native or exotic species. Today there are over 100 insect zoo exhibits throughout the world.

INSECT ZOOS DEFINED

The term “insect zoo” has been applied to facilities of many different types. Defined broadly, an insect zoo or insectarium is an exhibit facility dedicated to the display of live insects housed in a separate room, building, or distinct exhibit hall and maintained primarily for public visitation. Insect zoos typically are permanent, year-round facilities that house live insects and related groups of arthropods (arachnids, centipedes, millipedes, and crustaceans) and occasionally representatives of other invertebrate groups. Insect zoos have been built in zoological parks, natural history museums, botanical gardens, county parks, horticultural centers, amusement parks, nature reserves, and universities, and on privately owned land. Interest in their development has increased (excluding the period between the first and second world wars) with growing public interest in biodiversity and the documented success of insect exhibits (Table 1).

Most facilities contain a series of terrariums, where species are displayed in naturalistic mini-environments. A major insectarium is a comprehensive coverage of the class Insecta, representing many different orders such as Coleoptera, Hymenoptera, Orthoptera, and Mantodea. Observation honey bee hives, ant and termite colonies, walkingsticks, katydids, rubber grasshoppers, and assassin bugs are a few examples of typical displays. These facilities can be distinguished from collections of a few species of arthropod housed in a reptile house or aquarium or included in an exhibit that focuses on the interpretation of a particular ecosystem. Many tropical rain forest exhibits today include a few displays of insects, often a leafcutter ant exhibit and a few other invertebrates as nominal representatives of the vast diversity of invertebrates. However, overall these exhibits emphasize the vertebrate fauna of rain forests and present a relatively minor treatment of the subject of invertebrates. Major insectariums typically have between 30 and 100 live displays, exhibiting up to 100 species of arthropods.

A butterfly house or lepidoptery is a type of live insect facility that primarily displays members of the order Lepidoptera, typically in a large walk-through immersion exhibit enclosed in glass or screening, such as the Cockerell Butterfly House in Houston. Some facilities are combinations of both insect zoos and butterfly houses. Year-round walk-through butterfly houses vary in size. The Sophia M. Sachs Butterfly House in Chesterfield, Missouri, covers 511 m², whereas the Penang Butterfly House in Penang, Malaysia, is much larger (1474 m²). Seasonal exhibits are generally smaller. A few facilities, such as the insectarium at the Tama Zoo in Japan, display grasshoppers and aquatic species in walk-through immersion exhibits more typical of butterfly houses.

PURPOSE AND VALUE OF INSECT ZOOS

Live insects are one of the best teaching tools for children and adults alike. Despite an enormous range and intensity of educational, research, and conservation activities, most insectariums and butterfly displays offer some level of educational programming that promotes the appreciation and understanding of insect life. Aside from the actual live exhibits and graphics, these programs take the form of informal presentations, hands-on opportunities to touch live animals, formal classes and lectures from kindergarten to university level, teacher training, field trips, outreach programs, printed educational materials, multimedia materials, Web-based resources, and special events such as insect fairs and film festivals. In addition to these more lofty goals, insects have proven to be enormously popular with the public and thus are used to generate increased visitation and revenue for various types of nonprofit organizations and commercial enterprises.

Basic and applied research is carried out by some facilities, resulting in presentations at conferences and publications in conference proceedings and scientific journals. Several insectariums participate in captive breeding programs for threatened or endangered species such as the American burying beetle, *Nicrophorus americanus*, the Italian ground beetle, *Chrysocarabus olympiae*, the giant wetas, *Deinacrida* spp., and the Lord Howe Island stick insect, *Dryococelus australis* (Fig. 1). For example, London Zoo currently manages six invertebrate conservation programs, involving 38 species. In situ conservation programs are also supported by a number of insectariums and their parent organizations.

Some of the early insectariums began with the immediate goal of raising food for insectivorous zoo animals such as the Tama Zoo’s Insectarium, which opened in its first form in 1961. It was felt that decreases in wild populations of grasshoppers due to widespread use of insecticides required the development of stable food sources. An earlier insectarium at Tokyo’s Toshima-en Amusement Park was developed with the idea of using its live insect residents for making nature films.

### DIVERSITY OF EXHIBIT TECHNIQUES

Facilities that house live insects are as diverse in construction as in the type of sponsoring institution. To face the challenges of exhibiting small, short-lived, seasonally limited, diapausing animals with radically different life stages, major facilities rely heavily on the in-house maintenance of breeding colonies so that the specimens are available year-round. Founder stock is collected from the wild or obtained through exchange or purchase from other insectaries to establish and maintain genetically healthy colonies. In contrast, many butterfly houses rely on independently run breeding facilities, often in the species’ country of origin. Pupae are generally received weekly from various butterfly ranches or farms. Some butterfly houses also have supplemental in-house breeding colonies of selected species of butterflies. Many for-profit butterfly houses maintain breeding populations both for their own display and to sell to other butterfly houses.

Exhibit techniques have not changed much during the 120 years since the opening of the first insect exhibit at the London Zoo.
Insect Zoos

In 1881 (Fig. 2). Even in 1881, informative labels and preserved specimens accompanied live insects. The major change has been the inclusion of interactive techniques and graphics to enhance the interpretive experience of the display. Today, insectariums are really zoo–museum hybrids. Interactive computer modules, microscopes, audio tracks, video loops, models, robotics, and cultural artifacts are now used to enrich and enliven the educational messages. Special displays on topics related to cultural entomology have been included in some facilities such as the Insect Zoo at the San Francisco Zoo, which has produced special exhibits on ancient cricket cages of China, insects as human food, and aquatic insects, fly fishing and fly tying in North America. These techniques combine to address different visitor learning styles, ages, and interests. Some facilities have educational outdoor garden displays to focus attention on native insects and plant interactions, and a few facilities adjoin or are sister organizations to native wildlife reserves.

Most often, insect exhibit facilities are associated with larger institutions. Zoological gardens such as the London Zoo, Cologne Zoo, Berlin Zoo, Tama Zoo, Cincinnati Zoo, San Francisco Zoo, and St Louis Zoo all contain major insectariums. General histories of zoos and aquariums, while focused on vertebrates, can be found in the detailed records of zoo registrars and in edited volumes by Kising, and Hoage and Diess. Natural history museums such as the Smithsonian National Museum of Natural History, the Natural History Museum of Los Angeles County, and the Houston Museum of Natural Science have insect zoos or butterfly houses; the Cecil B. Day Butterfly Center is located within Callaway Gardens in Pine Mountain, Georgia; universities such as Kansas State University, Michigan State University, the University of Joensuu in Finland, and the University of Alberta in Canada all have seasonal butterfly gardens or insect zoos. The Insectarium de Montréal (Canada), the Insectarium of Victoria (Australia), the Butterfly Pavilion and Insect Center (Colorado) are examples of independent stand-alone facilities. Insectariums vary from tax-supported municipal institutions to nonprofit organizations to for-profit corporations. The for-profit businesses such as the Penang Butterfly House in Malaysia, Stratford-Upon-Avon Butterfly Farm in England, Butterfly World in Florida, and the Australian Butterfly Sanctuary in Australia serve as both public exhibits and commercial suppliers. While many are permanent, year-round facilities, the popularity of live insect exhibits (and perhaps the short life span and easy transportability of insects) has allowed for the explosion of temporary or seasonal exhibits, particularly butterfly displays.

**INSECTARIUMS AROUND THE WORLD**

During the 19th century, expanding empires, increased trade, and improved transportation and communication stimulated interest in exotic wildlife. European powers sent expeditions to bring back specimens for potential domestication and commercial use. Illustrated publications on biological subjects appeared, and books recounting the adventures of naturalist explorers allowed the public the vicarious thrill of discovery. With the emergence of modern systematics, the number of described genera rose. This was a fertile time of new discoveries and new theories. Darwin, Wallace, and others pondered the origin of species. From 1828 through 1914, each year an average of two zoological institutions opened throughout the world; the total was 168, with 86 in Europe alone. Themes of metamorphosis and evolution permeated art and literature. The Industrial Revolution transformed commercial production and altered attitudes toward nature as reflected in the diverse philosophies encompassed by the Art Nouveau movement (~1870–1914). Menageries toured, zoological gardens

**FIGURE 1** The Lord Howe Island stick insect *Dryococelus australis* of which both sexes are flightless was thought to have become extinct more than 80 years ago after the supply ship *Mokambo* ran aground in 1918 and rats were released onto the island. In 2001, a National Parks and Wildlife Service survey rediscovered individuals on nearby, almost soilless, Ball’s Pyramid Island and Melbourne Zoo’s Insect Department embarked on a captive breeding program for this very endangered species. Photograph © 2008, courtesy of the Melbourne Zoo.

**FIGURE 2** The London Zoo opened the first major insect exhibit in the world in 1881. This contemporary photograph was made by collector William Hornaday. [From “Zoological Gardens Illustrated” (photograph album), Vol. 1, “London Zoological Gardens.” © Wildlife Conservation Society headquartered at the Bronx Zoo.]
sprang up, and exotic nature became a source of fashionable urban pleasure and scientific study.

**Europe**

**FRANCE** Loisel’s 1912 history of zoos documents the early development of zoos in general and includes some interesting details about a few insect exhibits. In France, the Jardin des Plantes was created in 1793 adjacent to the Musée d’Histoire Naturelle and the Ménagerie d’Observation Zoologique. A chair of Insects and Worms was created, and its first occupant was Jean-Baptiste Lamarck. The Jardin’s mission was exploration to find species of plants and animals for utility or ornament, with instruction of the public as a minor goal. In 1797, the visitors could view silkworms and stroll through the grounds past honey bees, which were housed in a large glass hexagonal structure. In the middle of the 19th century, a disease killed almost all the silkworms in France. In 1860, the Jardin Zoologique d’Acclimatisation was created on the western fringe of Paris to focus on the study of animals of economic utility. New species of silkworm were imported from China and India and kept at the Jardin d’Acclimatization. Two of these species were acclimatized, and a fertile hybrid was produced. French scientist Louis Pasteur, in 1870, rescued the silk industry by discovering that the then epidemic “pebrine disease” of silkworms, now known to be borne by Nosema bombycis, could be prevented through microscopic examination of adult moths and isolation of uninfected stock. These advances set the trend for a more scientific approach to silk production.

In France today, a handful of butterfly houses have appeared as independent facilities. In 2000, a new theme park called Micropolis opened in the town Saint-Léon-en-Lézwon, which was home to the famous French entomologist Jean-Henri Fabre, and another opened in Aveyron, Fabre’s birthplace.

**ENGLAND AND THE NETHERLANDS** In 1828, the Zoological Society of London (London Zoo) opened, and visiting it became a popular recreational pastime. Commercial butterfly farms appeared as early as 1865 in Colchester, England. In 1881, a mere 53 years after its debut, the London Zoo opened the first major public insect house. In what had been a refreshment room, a series of terrariums on tables along the wall and in the center of the room displayed live specimens of silkworms, aquatic insects, and other invertebrates. Display tanks were well labeled, and mounted specimens enhanced the exhibit.

Seventeen years after the opening of London’s insect zoo, in 1898, the Artis Zoo in Amsterdam opened the Insectarium founded by schoolteacher Rudolph A. Polak, who feared that the urban population was becoming alienated from nature. Polak was part of the “Biologisch Reveil” (reveil means wake-up call) movement—to remind people of their connection to the natural world. His goal was to use insects to bring children into close contact with nature, and this tradition is still carried on today at the Artis Zoo. Amazingly, Polak continued to work as a teacher and ran the Insectarium as a volunteer staff person.

In the early 1900s, other insect-viewing opportunities existed as well. In 1900, a businessman operated a butterfly farm in Kent, where he bred various species to sell to collectors, museums, and universities in England and America. In 1908, Londoners could pay 6 pence (equivalent to perhaps $10 today) to visit the storefront menagerie display of an enterprising optician, filled with display cases of live bees and ants. The London Zoo, where the formal display of live insects really began, celebrated the new millennium by creating the Web of Life facility in 1999, boasting 65 live displays, 156 invertebrate species, a room-sized enclosure for desert locusts, Schistocerca gregaria (including a half-buried jeep for atmosphere), and a giant anteater.

Long involvement with the silk industry and an active amateur naturalist community seemed to make England fertile ground for the birth of modern-day butterfly houses. Businessman David Lowe, who created the Guernsey Butterfly Farm in 1977, went on to create seven other facilities in England by 1984. The London Butterfly House in Syon Park opened in 1981, and Stratford-Upon-Avon Butterfly Farm, which followed in 1985, includes an extensive insect zoo exhibit adjoining the free-flight butterfly display. In 1986, there were approximately 40 butterfly houses in England. They number closer to 20 today.

**GERMANY AND EASTERN EUROPE** The Frankfurt Zoo opened its first insect house in 1904 as a seasonal exhibit in the summer (in the winter it was used for storks). In 1957, Frankfurt Zoo built a new large insectarium on top floor above the renovated aquarium. The Zoologischer Garten Köln (Cologne Zoo) opened an insect house in 1905 and maintained it through 1929. A new insectarium was built in 1971, with a butterfly room at its entrance on the first floor of the new aquarium–terrarium, with approximately 60 species maintained in this facility. The Budapest Zoo in Hungary opened its first insect exhibit in 1907 and renovated the vivarium in 1970, exhibiting 68 species. In 2000, a butterfly exhibit was added to the zoo. In 1913, the Berlin Zoo opened a large insect exhibit on the third floor of the new aquarium, as did the Zoologischer Garten Leipzig. The Berlin Zoo’s building, destroyed during World War II, was rebuilt after 1945. The exhibit was renovated again in 1978 through 1983 and maintains over 33 species. An insect section was opened in Gruga Park in Essen in 1956, and in 1970, the Lübbecke Museum in Düsseldorf built a large insect exhibit associated with its aquarium. In 1987, the new Lübbecke Museum and Aquazoo opened an insectarium as the centerpiece of the whole new building. In 1980, the Zoologische Botanische Garten Wilhelma in Stuttgart built an insectarium exhibiting 35 species. The Dortmund Zoo and the Krefeld Zoo built butterfly exhibits in 1991 and 1998, respectively. The Noorder Zoo in the Netherlands, the Zoologicka Zahrada Praha in Czechoslovakia, and the Tiergarten Schönbrunn in Austria also have insect zoo exhibits.

**Asia**

Although no records have been found to document the early exhibition of live insects in China, the Chinese have long had a complex appreciation of the insect world. The development of silkworm culture and silk production, the development of bee culture, the early and extensive use of insects in traditional medicine, and the use of crickets as pets in the T’ang dynasty (618–906) suggest an advanced appreciation of the utility and aesthetics of insect life.

Yajima describes the development of insectariums in Japan. The Insectarium at the Takarazuka Zoological and Botanical Garden opened in 1954 and was expanded in 1967. The Toshimaen Insectarium, at the Toshima-en Amusement Park in Tokyo, opened in the late 1950s. In 1961, Yajima went on to design the first incarnation of the Insectarium at the Tama Zoo. In 1966, Tama Zoo’s Insectarium opened a walk-through grasshopper greenhouse filled with 6000 grasshoppers in addition to a walk-through butterfly house. A firefly building was added in 1975. In 1988, a new insectarium was built at the Tama Zoo, which mixed traditional terrarium-type exhibits with walk-through exhibits without guardrails of Orthoptera, fireflies, butterflies, beetles, ants, and aquatic insects. Insect Ecological Land had a construction cost of over $5 million and increased attendance to the zoo by 20%. At its opening, 94 species were maintained by a staff of 12. As of 1995, there were 30 live insect exhibits in Japan alone.

Other insectariums and butterfly houses can be found throughout Asia. The Penang Butterfly House in Malaysia was founded in
1986. Attached to the butterfly display is an exhibit of Malaysian insects and arthropods. The Fragile Forest exhibit, which opened at the Singapore Zoo in 1998, displays butterflies and other insects. Insect exhibits have opened in Hiroshima, Japan, Sentosa Island, Singapore, and Bangkok, Thailand.

North America

Insectariums developed more slowly in the United States. Although the early entomologist Thomas Say contributed to bringing respect to the science of entomology in the early part of the 19th century, the zoological gardens in the United States remained focused on the display of vertebrates and the natural history museums focused on nonliving exhibits. Interest in representing invertebrate biodiversity, either taxonomically or zoogeographically in these institutions, lagged behind that shown by their European counterparts. Enduring insectariums did not take hold in America until the late 1970s.

However, a number of early successful experiments at both zoos and museums proved extremely popular with the public. The New York Zoological Society Bulletin chronicles several early attempts. Raymond L. Ditmars, Curator of Reptiles at the Bronx Zoo and world-renowned herpetologist, actually began his career in science as an entomologist working as an assistant curator in the Entomology Department at the American Museum of Natural History. Throughout his tenure, he maintained a keen interest in insects. In 1910, under his direction, a live arthropod exhibit consisting of 56 cages and containing silk moths in various life stages, lubber grasshoppers, Herceules beetles, and tarantulas was set up as an experiment. A portion of the moths that emerged from the silk moth collections were mounted and sold as souvenirs by the Bureau of Information in the Lion House. The exhibit was so popular with visitors that plans were made to make it a permanent feature at the zoo. The permanent facility was never built, but Ditmars persevered and in 1940, a Department of Insects was created with Ditmars as curator. Ditmars died in 1942, however, without having brought the plan to fruition. Brayton Eddy, an entomologist for the state of Rhode Island, was hired as the new curator of insects in 1943. Eddy's experience included the development of a seasonal live insect zoo at Goddard State Park in Providence, housed in the first floor of the stately mansion on the property from 1934 to 1937. Then Eddy died unexpectedly in 1950, and again a planned permanent insect exhibit never got started. The new exhibit was to feature local insects and tropical imports sent by Dr William Beebe from his research station in Venezuela.

During the 1930s and 1940s, the Chicago Zoo (later renamed the Brookfield Zoo) was planning and experimenting with its own invertebrate exhibit; construction on the Insect House (also called the Invertebrate House or the Special Exhibit and Demonstration Building) was completed between 1934 and 1938. Grace Olive Riley, acting as curator of reptiles and invertebrates, was succeeded by Robert Snelgier as reptile curator. Snelgier organized the “Animals Without Backbones” exhibit, which ran from 1947 into the early 1950s. Bees, cockroaches, aquatic insects, spiders, scorpions, centipedes, leeches, and other invertebrates were displayed, along with amoebas. Though planned as a permanent feature by Brookfield Zoo’s early designers, the Insect Building was later converted into the zoo’s library. The exhibits developed in the late 19th and early 20th centuries were not very different from the exhibits of today. Glass terrariums with screened lids displayed on tables containing local and exotic insect life were the state of the art in 1881, 1910, the 1940s, 1970s and 1990s.

Worth mentioning is the arthropod exhibit that was included as a permanent feature in the Arizona-Sonoran Desert Museum from its opening date in 1952. Although not large, either in species number or in size of tanks, this collection was innovative in that it included invertebrates in the interpretation of an ecosystem. Then 20 years passed during which the early invertebrate exhibits seem to have vanished from the consciousness of zoo administrators.

Another period of experimentation with short-lived insect exhibitions emerged. An insect zoo was created at the Flushing Meadows Zoo from 1969 to 1970, and another was assembled at the Smithsonian National Museum of Natural History in 1971. The immense popularity of the exhibit at the Smithsonian resulted in the opening of the museum's permanent insect zoo in 1976, in time to greet the International Congress of Entomology, which held its meeting that year in Washington, DC. A natural history museum had now stepped permanently into the world of live insect display, an endeavor formerly restricted to zoological gardens or commercial rearing facilities staffed by persons used to dealing with the challenges and demands of live animals. From the start, the Smithsonian staff interacted with visitors daily with informal hands-on demonstrations, and the species inventory included both local and exotic specimens collected by Smithsonian entomologists in the field.

Cincinnati Zoo followed the Smithsonian in 1978 and opened a new building containing 68 live displays and housing 70–100 species. This facility, the World of the Insect, set a new standard for insectariums in the United States. It also set a new standard for monetary commitment to insect exhibits, with a price tag of $1 million, including the cost of the new stand-alone building, custom-made terrariums, colorful graphics, and educational interactive exhibits borrowed from museum methodology.

The Insect Zoo at the San Francisco Zoo opened in 1979 as a temporary summer exhibit in an unused auditorium building in the children’s zoo section. Zoo attendance instantly increased by 50%, and the collection became a permanent facility, the second largest in the United States for two decades, containing 35 displays and maintaining 70 species.

In the United States, the three permanent insectariums created in the 1970s (at the Smithsonian, the Cincinnati Zoo, and the San Francisco Zoo) were really “arthropod zoos,” with an occasional mollusk, leech, or annelid thrown in. Yet these exhibits became models for many subsequent projects that followed throughout the country. Emphasis was placed on the development of year-round breeding colonies and use of native and exotic species.

The only other invertebrate exhibit to open in the following decade, excluding the butterfly houses, was the Invertebrate Exhibit, which opened in 1987 on the lower floor of the Reptile House of the National Zoo, showing tropical insects alongside marine invertebrates such as cephalopods. A pollinarium exhibit was added in 1996.

The only nonbutterfly insect exhibit to emerge in the 1990s was the Ralph K. Parsons Insect Zoo at the Natural History Museum of Los Angeles County. Modeled at its opening in 1992, it has grown to 40 live displays.

New walk-through butterfly exhibits dominated the late 1980s and early 1990s modeled on free-flight greenhouse exhibits in England. In 1988, the $3 million Cecil B. Day Butterfly Center at Callaway Gardens opened in Georgia. Two for-profit Florida endeavors, Butterfly World and the Butterfly House at Cypress Gardens, opened in 1988 and 1992, respectively. Back in the zoo world, the San Diego Wild Animal Park's Butterfly Encounter debuted in 1993. In 1994, the Houston Museum of Natural Science opened the Cockrell Butterfly Center, a three-story immersion butterfly glasshouse attached to the museum, attracting 700,000 visitors during its first year of operation. A live arthropod exhibit room was later added to this facility. In 1995,
the Butterfly Pavilion and Insect Center became the first stand-alone nonprofit insect facility in the United States.

In the 1990s, at least 20 seasonal butterfly houses emerged, including several supported by universities such as Michigan State University and Kansas State University under the auspices of their respective Departments of Entomology. The insectarium at the St Louis Zoo opened in 2000. Costing $4 million and maintaining 80–100 species in addition to a butterfly display, it became the most important facility to open in over a decade.

Parallel developments have occurred in Canada, but the most notable was the development of the Insectarium de Montréal founded by Georges Brossard in 1990. This $8 million exhibit mixed classic European museum design with multimedia interactive displays and challenged the live animal exhibit community to set a higher standard for the construction of new insectariums to educate the public about insects, which represent 80–95% of the animal species on terrestrial earth.

**Australia**

In Australia, the Melbourne Zoo was the first to get into the invertebrate business by opening a butterfly house in 1985. The Insectarium of Victoria and the Victorian Institute of Invertebrate Sciences opened at Heathcote in 1993, moving in 1998 to Woodend until closing in 2007. They displayed *Astrapogon gouldi*, or the giant yabby or crayfish, one of the largest freshwater invertebrates on earth. Bugs Alive! (Fig. 3) is Melbourne’s newest insect exhibit.

**Latin America and Africa**

Butterfly exhibit houses in Latin America are most commonly derived from commercial butterfly ranching and farming operations. The Butterfly Farm in La Guacima de Alajuela, Costa Rica, founded in 1990, and Sprougta Butterfly Garden in San Jose, Costa Rica, established in 1992, typify these facilities. The Green Hills Butterfly Ranch in Belmopan, Belize, is a display as well as commercial supplier, as is the La Selva Butterfly Farm in Ecuador. The Butterfly World in Klapmuts, South Africa, was opened in 1996.

**Biodiversity Conservation and Insect Exhibits**

Insectariums can play a strong role in conservation education. They can also play a role in the conservation of biodiversity in nature by providing economic opportunities for local populations that are alternatives to destructive resource extraction such as logging, mining, or conversion of forest land to agricultural enterprises such as cocoa, coffee, or oil palm plantations. It is difficult, if not impossible, to conserve natural resources where alternative economic opportunities are limited or absent. In response, as general awareness and concern for loss of tropical forest ecosystems and biodiversity emerged, the government of Papua New Guinea deemed insects a national resource and candidate for economic development. This policy resulted in the establishment of the Insect Farming and Trading Agency (IFTA) in 1988, which runs the 8.9 hectares Shipstern Nature Reserve in Belize. Shipstern also has its own public butterfly house on the reserve grounds.

Approaches to conservation have shifted in the past decade from focusing on single-species protection to ecosystem preservation. In 1987, for example, the Center for Ecosystem Survival, a nonprofit consortium serving zoos, aquariums, museums, and botanical gardens, was created in San Francisco to raise funds for biodiversity conservation through habitat protection, conserving invertebrates and plants as well as vertebrates and other forms of life. In 2008, a total of 138 informal science institutions collaborated in this program and raised over $3.5 million...
for habitat purchase and protection, fueled in part by increased public awareness of the magnitude and importance of insect biodiversity.

Integrated Pest Management
Ronald Prokopy†
University of Massachusetts
Marcos Kogan
Oregon State University

A cross millennia, humans have used a variety of approaches in attempts to maintain pests at tolerable levels. The character of these approaches has evolved over time. Since the late 1960s, an approach termed integrated pest management (IPM) has ascended to dominance internationally. In essence, IPM is a decision-based process involving coordinated use of multiple tactics for optimizing the control of all classes of pests (arthropods, microbial pathogens, vertebrates, weeds) in an ecologically and economically sound manner.

HOW INSECT PESTS ORIGINATE

The manner by which an insect has become a pest influences the strategy used for managing it within an IPM framework. Some species have reached the status of pest because human thresholds for tolerating them have decreased as economic well-being has increased. Other species have become pests as a consequence of the availability of abundant resources for their survival and reproduction; resource concentration in time and space is conducive to rapid buildup of insect populations. Still other species have become pests in regions of their origin when they expanded their host range from comparatively unimportant native hosts to economically important introduced hosts. Finally, some species have become pests almost instantly upon being transported by humans to new locales having favorable resources but devoid of effective natural enemies.

CLASSIFICATION OF INSECT PESTS

For purposes of devising an appropriate IPM strategy, insect pests may be classified as key, secondary, or induced. Key pests are those whose populations, if unmanaged, repeatedly exceed tolerable levels; these are the principal focus of IPM endeavors. Secondary pests are those whose populations occasionally reach intolerable levels; their potential threat is recognized by the very act of devising IPM strategies. Induced pests are those whose populations rarely exceed tolerable levels under natural conditions, but if they become resistant to pesticides or other single-tactic control measures that harm their natural enemies, they can reach outbreak proportions. Usually induced pests return to nonpest status under a true IPM approach.

EVOLUTION OF CONCEPT OF IPM

Through trial and error across centuries, humans gradually came to use tactics such as cultural control, host resistance, and biological control in efforts to protect themselves, livestock, crops, and forests against pests. By the latter half of the 19th century, some pest control strategies that blended these tactics could rightfully be considered to be the precursors of modern IPM strategies. During the 20th century, efforts to maintain pests at tolerable levels became more formalized as they became more intensive; these efforts can be considered as having progressed along the following four pathways.

“Pest control” was the terminology used during the first half of the 20th century to describe the set of actions taken to avoid, attenuate, or delay the impact of pests. Early in the century, inorganic and botanical insecticides gained increasing prominence as a control tactic against pest insects. By the mid-century, use of organosynthetic insecticides supplanted virtually all other tactics in becoming the dominant approach to insect pest control, especially in developed countries.

“Integrated control” surfaced about 1950 in California as a concept of pest control aimed at combining and integrating biological and chemical control. The emergence and eventual popularity of this concept had roots in problems associated with overuse of organosynthetic insecticides, particularly a surge of key, secondary, and induced insecticide-resistant pests and environmental harm caused by insecticides. The publication of Silent Spring by Rachael Carson in 1962 was especially important in spurring widespread interest in the principles of integrated control.

“Pest management” represents a shortened version of “protective population management,” a concept coined in 1964 by Australian ecologists to emphasize direct human interference in maintaining pests at tolerable levels, as opposed to reliance on unmanaged natural abiotic and biotic factors acting on pest populations. The concept of pest management embraced a broader range of pest control tactics than did the concept of integrated control. Until the late 1960s, both these concepts flourished simultaneously in accenting the need to move beyond the use of insecticides as a sole pest control tactic.

“Integrated pest management” originated in 1968 as a contraction of “integrated pest population management,” an expression used first in
1967 by R. F. Smith and R. van den Bosch. Soon afterward, the abbre-
viation “IPM” came into use worldwide for signifying a desirable and
holistic approach to controlling pests. Numerous definitions have been
put forward for IPM, but one that captures the broad and essential el-
ements of many others is the following: IPM is a decision support system
for the selection and use of pest control tactics, singly or harmoniously
coordinated into a management strategy, based on cost–benefit analy-
ses that take into account the interests of and impacts on producers,
society, and the environment. No single definition, however, is likely
to encompass all facets of IPM for all time. IPM has been and likely
will continue to be an evolving concept. For example, a compendium
org/IPMdefi nitions/home.html), listed 67 definitions in the mid-2002.

ECOLOGICAL FOUNDATION OF IPM

Ecology is the study of relationships among organisms and their
environment. Consideration of these relationships usually begins
with focus on individuals or populations of a single species and sub-
sequently broadens to include communities of organisms and, eventu-
ally, ecosystems.

Conceptually, the foundation of IPM is ecological. Ideal IPM
programs are those that fully embrace ecosystem structure and proc-
eses in time and space. In reality, ecological complexity increases
dramatically with each step from population to community to eco-
system. Such complexity challenges the realization of ideal IPM
programs.

One approach that has been taken toward recognition of the eco-
logical foundation of IPM, especially in developing countries, accent-
uates the pest-suppressing properties inherent in natural ecosystems
as primary building blocks for the construct of human-designed eco-
systems. After system construction based on ecological principles, the
intent is to minimize human intervention to the greatest extent pos-
able while still maintaining pest populations within tolerable levels.

Another approach, common in developed countries, takes as its
starting point an existing ecosystem constructed by humans and aims
at reducing negative impact in a succession of steps used in the man-
agement of pests. Such an approach usually commences with a focus
on the ecology of a single-species population and may expand to con-
ideration of structures and processes associated with communities
and ecosystems.

ADVANCING LEVELS OF INTEGRATION IN
IPM IMPLEMENTATION

A hierarchical structure results from the ecological foundation of
IPM that lends itself to viewing IPM as progressing in scope through
a series of ecologically rooted steps. These steps are characterized
by ascending levels of complexity and spatial scale: from focus on a
single-species population in a restricted locale to focus on a commu-
nity of pest and other organisms in a larger area to focus on a whole
ecosystem. Coincident with this ecocentric hierarchy is another step-
wise hierarchy conceived of as a vehicle for measuring progress in
achieving the goals of IPM. This hierarchy comprises a succession of
levels from single-tactic (almost invariably based on pesticide use) to
multitactic measures of pest and habitat management. The steps fur-
ther involve ascending from focus on a single pest species in a single
class of pests (e.g., insects) to multiple pest species across all classes
of pests (insects, microbial pathogens, vertebrates, and weeds). These
distinctive hierarchies can be blended in the form of a continuum of
advancing levels of integration in IPM implementation. Three more
or less distinctive levels along the continuum are described in the fol-
lowing sections (Fig. 1). Degree of success in integration at each level
is shaped not only by ecological processes but also by government
policy, regulatory legislation, social relations, economic forces, and
cultural background that may enhance or constrain progress.

FIRST-LEVEL IPM

In the most basic and also the most widely practiced form of IPM,
emphasis is on monitoring development and/or abundance of a sin-
gle pest species at a single locale (e.g., a household, cow barn, green-
house, cropped field, or woodlot) and using thresholds for deciding
whether to take action. Application of a pesticide is by far the most
common form of action taken under the first-level IPM. Integration
occurs when abundance of natural enemies of the pest in question
also is considered in the decision-making process and when selection
among candidate pesticides involves explicit attention to minimizing
harm to these and other beneficial organisms. This form of IPM has
been characterized by some as “integrated pesticide management.”

Monitoring Pest Development

Because the developmental rate of an arthropod is regulated
largely by temperature, the monitoring of developmental rate for
pest management purposes usually takes the form of measuring
accumulation of heat units above a threshold temperature at which
development begins. At temperatures above these fostering the max-
imal developmental rate, development may decrease. Such decrease
has not been investigated for most pest arthropods and has not yet
played a significant role in making pest management decisions.

The simplest and most prevalent approach to measuring accumu-
lation of heat units above developmental threshold temperature involves
the use of degree-days (DD). For a specific date, the number of accu-
mulated DD equals the average temperature of that date minus the
developmental threshold temperature of the arthropod. Several pro-
cedures have been devised to estimate average daily temperature.
The most common one, albeit somewhat crude, consists simply of averaging

![FIGURE 1 Levels of IPM integration: main targets, ecological scales, and levels of ecological complexity.](image)
the maximum and the minimum ambient temperature of the day. To illustrate the DD approach, if the high and low temperature for a given day were 30°C and 20°C, respectively, with a developmental threshold temperature of 10°C, then 15 DD would have accumulated on that day.

Pest development as monitored by DD accumulation may benefit decision making under first-level IPM in several ways, particularly for optimal timing of management activities. For example, ability to predict when a majority of pest adults is about to emerge from pupae is useful for optimal timing of deployment of traps for monitoring adults. Knowledge about when oviposition is likely to begin and peak can facilitate optimal timing of pesticide application against newly hatched larvae, which often is the stage most vulnerable to pesticide treatment. Sometimes this determination is made in conjunction with date of first capture of adults by traps, known as a “biofix” point for initiation of DD accumulation. The ability to forecast when a majority of larvae or nymphs is at a particular growth stage can aid in optimal timing of sampling their abundance and the abundance of their natural enemies.

### Monitoring Pest Abundance

Ideally, an IPM practitioner would have available a precise count of the number of individuals of an insect pest species present in an area of concern; realistically, obtaining information on absolute densities of pests is prohibitively costly. Therefore, most practitioners rely on imprecise estimates of pest population density obtained by using one or more population sampling techniques. The intent is to capture a more or less consistent, if unknown, proportion of the pest population. Choice of appropriate sampling technique varies considerably according to pest species, its developmental stage, and the crop plant or other habitat where the pest occurs.

For sampling comparatively mobile individuals such as adults, traps using odor and/or visual stimuli are common tools. Odor stimuli usually consist of synthetic equivalents of either attractive sex odors (sex or aggregating pheromones) or attractive food or host odors (kairomones). Visual stimuli normally rely on synthetic mimics of visually attractive sites where feeding, mating, or egg laying occurs.

For sampling less mobile individuals such as larvae, common techniques include visual searching of the target area accompanied by direct counts of detected pests, use of a sweep net (especially effective for sampling individuals on foliage of nonwoody plants), and use of a loose or framed cloth placed beneath vegetation that is shaken or tapped to dislodge pests. Sampling immobile individuals such as eggs, pupae, or nymphs is usually done by visual inspection.

To obtain an acceptably accurate and cost-effective estimate of the size of a pest population by means of one of these techniques, careful attention must be given to the program under which sampling is conducted. Effective sampling programs take into account the daily activity pattern of the target species as well as its characteristic spatial distribution (uniform, random, or clumped). Historically, most programs have incorporated sampling at several or numerous sites in a target area to acquire sufficient representation of the size of a pest population; then researchers have counted the sampled individuals of the target pest. New programs developed for some pests simplify these procedures. Sequential sampling is an approach that optimizes the number of sampling sites needed for classifying a pest population as below or above a density requiring action. Binomial sampling is an approach that classifies an individual species as either present or absent at a sampling site, thereby precluding the need to count all members of that species taken in a sample. Both these simplifying approaches require substantial species-specific background information for their development and use.

The emerging technologies of global positioning systems (GPS) and geographical information systems (GIS) offer unsurpassed capability of aiding in the mapping of site-specific variation in characteristics of areas under consideration for sampling. A GPS uses triangulation of signals from a constellation of satellites to identify the precise location (within a meter) of an area on the earth’s surface. A GIS is a computer program for the mapping and spatial analysis of georeferenced information. GIS capabilities include assemblage, storage, manipulation, retrieval, and graphic display of information about attributes of precise locations identified through GPS. Such information can be exceptionally useful in forming associations between characteristics of a specific locale (e.g., terrain, soil, extent of vegetative growth, microclimate) and density of a population (Fig. 2). For pests, sampling can be directed toward specific sites in which densities are suspected to be the highest.

### Deciding Whether to Take Action

Several approaches have been developed for deciding whether an insect pest population has or has not reached a level requiring intervention, such as an insecticide application. For agricultural purposes, the approach used most often centers on the concept of “economic injury level” (EIL), formalized in 1959 by V. H. Stern, R. F. Smith, R. van den Bosch, and K. S. Hagen and defined by them as the “lowest pest population density that will cause economic damage.” These entomologists also proposed a related concept, which they termed the “economic threshold” (ET), defined as the “pest density at which control measures should be applied to prevent an increasing pest population from reaching the economic injury level” (Fig. 3).

The decision-making concepts of EIL and ET have been fundamental to the development and implementation of first-level IPM, particularly for insect management in agriculture (but less so for...
Ipling program for eggs of tomato fruitworm, below the EIL. M. P. Hoffmann and collaborators developed a sam-

ing desirable commercial or aesthetic traits are beginning to replace
traditional resistance breeding approaches.
derm treatments (e.g., host resistance, biological control, behavioral control), to the greatest extent possible, for the
therapeutic practice of pesticide application. Decision makers must
determine how best to integrate these tactics to achieve long-term suppression of pests within a cost–benefit framework.
Cultural management is purposeful manipulation of the environ-
ment to reduce pest abundance. It is most effective when directed
at the most vulnerable life stage of a pest. Four forms of habitat or
environmental manipulation aimed at controlling pests have been
practiced for centuries in agriculture: crop rotation, timing of plant-
ing or harvest to minimize pest damage, sanitation or elimination of noneconomic resources available for pest reproduction, and poly-
culture, or the interplanting of different crops to diffuse resource concentration. More recent practices include the planting or encour-
gagement of selected types of noneconomic vegetation in the vicinity of
crops or as cover crops to serve as harborage for natural enemies
of pest insects. Analogues of these practices have been developed for
managing insect pests in nonagricultural situations.
Host resistance is any inherited characteristic of a host that less-
eases effects of an attacking pest. For centuries, humans may have
unknowingly or intentionally selected for cultivars of plants or breeds
of animals that are best able to withstand pests. Modern breeding
programs, however, often have placed more emphasis on increasing
yields than on protection against pests. Entomologically, resistant
traits are preadaptive characteristics of a host that reduce its detecta-
bility, acceptance, or nutritional value, or enhance its toxicity to a
pest insect. Molecular genetics techniques that facilitate introduc-
tion of specific pest resistance genes into cultivars or breeds possessing
desirable commercial or aesthetic traits are beginning to replace
traditional resistance breeding approaches.

SECOND-LEVEL IPM
Second-level IPM is intermediate between basic and advanced. It
is receiving increased research attention, but inherent complexi-
ties have greatly limited its effectiveness. Emphasis is on manage-
ment of key pests of all classes and their associated natural enemies
comprising a community (e.g., a village of dwellings, an entire farm,
a wooded area surrounding a village). Emphasis also is on substi-
tuting a variety of comparatively environmentally benign manage-
ment tactics (e.g., cultural management, host resistance, biological
control, behavioral control), to the greatest extent possible, for the

A refinement of the concept of EIL, put forward by L. P. Pedigo
and L. G. Higley, introduces the element of environmental quality
into the decision-making process. Negative effects of insecticides on
natural enemies of pests and on other organisms in the environment
are treated as costs in addition to monetary costs associated with
insecticide application. Quantifying environmental costs has proven
to be challenging and subject to much debate, but progress under
this refined concept of EIL nonetheless has been made.

In 1984, W. L. Sterling advanced the concept of “inaction level,”
which is the density of natural enemies sufficient to maintain a pest
below the EIL. M. P. Hoffman and collaborators developed a sam-
ping program for eggs of tomato fruitworm, Helicoverpa zea, that
permits ready identification and quantification of parasitized eggs in
addition to healthy eggs. If the level of egg parasitism is determined
to be too low to prevent larval numbers from exceeding the EIL, the
lowest adequate rate of a “soft” pesticide (one having least impact
on parasitoids and other nontarget organisms) is recommended. This
approach is an example of application of the inaction level concept
and represents a high degree of first-level IPM implementation.

Area-wide IPM is an expansion of first-level IPM that may rep-
resent a significant transitional step toward second and third levels
of IPM. Under area-wide IPM, the key pest of a crop is targeted
for management by means of the most effective noninsecticidal
approach. For example, the codling moth, Cydia pomonella, is man-
aged in apple and pear orchards by tactics such as the pheromone
mating disruption technique or the sterile insect release method
that impair normal reproduction. Such tactics are implemented over
areas large enough to preclude recolonization by fertile females from
adjacent areas. By reducing the impact of broad-spectrum insectici-
des, natural enemies are preserved and are usually capable of regul-
ating most secondary pests in the crop. As area-wide IPM programs
expand to incorporate multiple pest interactions, they become natu-
ral springboards to higher level integration in IPM systems.

FIGURE 3 Graphs depicting theoretical population fluctuations
of two insect pest species.
In biological control, parasitoids, predators, or pathogens are deployed as natural enemies in the reduction of pest populations. Of the myriad insect species that could become pests, most do not because they are suppressed effectively by naturally occurring populations of biological control agents. Natural levels of biocontrol, however, often are insufficient for IPM purposes. Biological control then takes the form of importing absent natural enemies from other locales (termed importation or classical biocontrol), augmenting existing natural enemies by rearing and then releasing substantial numbers into the target community (termed augmentation), or tailoring management tactics to reduce negative effects on existing natural enemy populations (termed conservation). The latter is the most widely practiced form of biocontrol.

Behavioral control is manipulation of the behavior of pest individuals to prevent them from causing harm or unpleasantness. Because of the expense and technological challenges associated with its use, behavioral control usually is directed only at key pests. Behavioral control may involve use of natural or synthetic chemical or physical stimuli to lure pests to sites where they are killed, or use of such stimuli to disrupt the ability of pests to find or use a potential resource. An ideal form of behavioral control might involve joint use of disruptive and attractive stimuli to achieve maximum effect, but this form is not yet widespread in practice.

Vineyards in parts of Europe and North America represent one of the few areas in which pest management is practiced effectively under the second-level IPM concept. Besides using essential elements of first-level IPM for insect pests, certain practitioners of vineyard IPM in these locations blend host plant resistance with cultural, biological, and behavioral controls for suppression of key pest insects and also use a suite of cultural controls for managing key disease and weed pests. This approach has resulted in marked reduction in pesticide use and greater stability of relationships among organisms comprising vineyard communities.

THIRD-LEVEL IPM

Although many IPM practitioners aspire to implement third-level IPM, the most advanced form remains largely in an embryonic state of development. Emphasis is on using principles and practices of second-level IPM in harmony with all other elements that affect long-term productivity or well-being of an ecosystem. Such elements include sound horticultural or husbandry practices (for agriculture), sound forest management (for silviculture), and sound community health practices (for villages or subunits of cities). Third-level IPM features attention to environmental and societal costs and benefits in the making of pest management decisions. The local ecosystem may be an entity no larger than a community, as considered under second-level IPM, or it could be an entity as extensive as an ecological region. For crops, third-level IPM is roughly synonymous with the concept of integrated crop management. It is not, however, synonymous with organic agriculture, which disallows some materials and practices acceptable under third-level IPM.

Spearheaded by P. E. Kenmore, an approach has been developed for growing rice in developing parts of Asia that reflects many of the tenets of third-level IPM. This approach accentuates societal contribution to the IPM decision-making process. It involves weekly gatherings of small groups of rice farmers, accompanied by experienced pest management personnel, who jointly conduct agroecosystem observations, engage in data analysis, and consider local ecosystem structure, environmental health, and a range of immediate and long-term tactics before making pest management decisions. This process has resulted in dramatic increases in awareness by entire communities of an advanced form of IPM and often dramatic decreases in use of pesticides on rice. It stands in contrast to modes of decision making and levels of popular awareness characteristic of less advanced forms of IPM implementation in many developed countries, where it is commonplace for farmers to make IPM decisions either acting alone or at most interacting with a private consultant, government extension representative, or employee of a pesticide distributor.

IPM AND SUSTAINABLE DEVELOPMENT

In a broad sense, sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs. Sustainable development is rooted in the concept of ecosystem integrity and permeates all facets of human endeavor, whether economic, social, or cultural.

The scope of concerns and practices of third-level IPM as described here corresponds closely to that of sustainable development. Each emphasizes preservation of processes associated with natural ecosystems, long-term well-being of humans as members of communities, economic viability, and deployment of exogenous resources only after careful consideration. For agriculture, concepts underlying third-level IPM can be equated with concepts underlying sustainable agriculture. For both, one can expect concepts to evolve further over time.

Integument

Svend O. Andersen
The Royal Danish Academy of Sciences and Letters

The integument is the external layer of tissue that covers the outer surface of insects and the surfaces of the foregut and hindgut. It is composed of the epidermis, which is a continuous single-layered epithelium, and an underlying thin basal lamina plus the extracellular cuticle that lies on top of the epidermis.

**BASAL LAMINA**

The basal lamina separates the epidermal cells from the hemolymph in the body cavity; it varies in thickness from 0.15 to 0.5μm and is composed of structural proteins including collagens, glycoproteins, and glycosaminoglycans. It is negatively charged and can act as a filter between the hemolymph and the epidermal cells, regulating which molecules gain access to the cells.

**EPIDERMAL CELLS**

The epidermal cells are attached to the basal lamina by hemidesmosomes, which anchor the cell membrane to collagen fibers in the basal lamina. Near their base, the cells are attached to each other by desmosomes; near their apical end, they are attached to each other by a narrow, impermeable zone (the adhering zonule), effectively separating the cuticular compartment from the lateral space between cells. Below the zonule are bands of septate desmosomes, which may be adhesive, and gap junctions through which the cells can communicate chemically with each other by interchange of low-molecular-weight compounds.

The cuticular materials (chitin and proteins) are secreted from the apical surface of the epidermal cells into the subcuticular space, or deposition zone, where they are assembled into an intact cuticle. The apical surface is folded into shorter or longer microvilli, depending on the stage of the molting cycle and the secretory activity of the cells.

**THE MOLTING PROCESS**

The cuticle is a rather inextensible structure, and in order to grow, insects need to shed their old cuticle at intervals after having produced a new one with a larger surface area. The whole process, from breaking the connections between the epidermal cells and the cuticle (ecdysis) to emerging from the remnants of the old cuticle (ecdysis), is called molting. The consecutive steps of the process are controlled by hormones.

The epidermal cells undergo mitotic divisions at the onset of molting, resulting in an increase of cell number and total epidermal surface. To allow the animal to increase in size at molting, the epicuticle deposited above the apical cell surface has a larger area than the previous epicuticle, and the epidermis together with the epicuticle is folded to be accommodated in the space available inside the old cuticle.

Deposition of new cuticle occurs simultaneously with the degradation of the old cuticle. An enzyme mixture, containing proteases, peptidases, chitinases, and glucosidases, is secreted into the space between the old cuticle and the new epicuticle, and the old cuticle is gradually degraded to free amino acids and N-acetylgalcosamine. The degradation products are resorbed by the insect and reused for building proteins and chitin for the new procuticle. Chitin is synthesized by an enzyme complex (chitin-synthetase) located at the top of microvilli on the apical surface of the epidermal cells, and chitin microfibris grow from here into the subcuticular space, the deposition zone. The cuticular proteins are synthesized intracellularly and transported via the Golgi complex to the apical plasma membrane, and are secreted into the subcuticular lumen by exocytosis. The chitin and protein molecules are in some way organized into a macromolecular complex in the deposition zone between cells and cuticle, possibly by a process of self-assembly.

Soon after emerging from the old cuticle (exuvium), the insect expands the new cuticle to a predetermined size, often dependent on the area of the epicuticle. Cuticular deposition of chitin and proteins is resumed and continues for several days after ecdysis, while smaller and larger regions of the new cuticle are hardened (sclerotized) by oxidative incorporation of phenolic compounds into the cuticular matrix. Both sclerotization and post-ecdysial deposition of endocuticle are governed by the neurohormone bursicon.

Secretion of material from the epidermal cells occurs not only at the apical surface. Some of the peptides and proteins synthesized by the cells are exported to the hemocoel via the basolateral membrane system, and others, such as arylphorins, are synthesized in the fat body and secreted into the hemolymph to be taken up by the epidermal cells and incorporated into the cuticle.

**PORE CANALS**

Most cuticles contain pore canals, minute ducts that traverse the cuticle from the apical surface of the epidermal cells to or close to the cuticular surface. When viewed with an electron microscope they may seem empty, but they often contain one or more cuticular filaments composed of wax and lipids. Cytoplasmic processes may extend into the ends of the pore canals during cuticle deposition. The pore canals are generally assumed to be a transport route for lipids and possibly also for sclerotizing agents and proteins to the epicuticle and outer exocuticle.

**SENSE ORGANS**

The integument of insects contains a large number of sensory cell types, involved in transferring information from the environment to the insect. The sensory cells in the epidermis are often connected to specific cuticular structures, forming sense organs of various types, such as contact chemoreceptors (taste), olfactory chemoreceptors (smell), and mechanoreceptors, which register any small distortion of the cuticle caused either by the movements of the animal or by influences from the environment.
OENOCYTES

Oenocytes, a special cell type, often are present between the basal region of the epidermal cells and the basal lamina, or they may adhere to the hemolymphal surface of the basal lamina. Electron microscope studies show that they have a highly developed smooth endoplasmic reticulum, characteristic of cells engaged in hydrocarbon synthesis. Oenocytes synthesize hydrocarbon waxes, which are transferred to the wax layer covering the epicuticle, presumably via the epidermal cells and the procuticular pore canals. It has been suggested that the oenocytes also provide lipids to the epicuticle and to the sclerotized regions of the exocuticle.

INTEGUMENTAL GLANDS

Epidermal glands are present in many types of integument; they often consist of a single cell surrounding a cavity, which functions as a product reservoir and is connected to the cuticular surface by a small duct. Glands of this type are assumed to be responsible for forming and maintaining the cement layer, which after ecdysis is spread as a protective layer on top of the epicuticular wax layer. Other integumental glands produce various chemical defense secretions, which may be forcibly ejected when the insect is disturbed.

Integumental glands may also consist of epidermal cells without a cavity and duct, but with direct contact to the inner surface of the cuticle, through which the secretion passes. Often the secretions of such glands function as pheromones, playing a part in communication between individuals.

COLORATION

The colors of most insects are the result of pigments located in cuticle and epidermis, or they may be physical colors caused by surface structures in the cuticle. Colored material in hemolymph or internal organs can also contribute to the insect’s color if the integument is transparent. Ommochromes, pteridines, carotenoids, bile pigments, melanins, and urates are the most widespread and important of the epidermal pigments. The colored light reflected from such epidermal pigments passes the overlying cuticle before it reaches the eye of the observer, and the observed color is influenced by the amount of colored material present in the cuticle.

Introduction

An introduced species is one that did not achieve its current taxonomic status in some current location. Such species are often called nonindigenous or adventive there. Among nonindigenous species, those carried to the location by humans, either deliberately or inadvertently, are called “introduced species,” whereas those that arrived on their own are termed “immigrant.” However, all nonindigenous species are often colloquially termed “introduced.” “Exotic” and “alien” are sometimes used for all nonindigenous species.

Introduced insects are numerous and generate major ecological and economic impacts by a variety of means. They span most insect orders. Their means of introduction are varied, but most arrive with human help. Only a minority become problematic, and the reasons why a newly arrived species survives or fails to establish a population, and, if established, has or does not have a major effect, are often mysterious. Some problematic introduced species can be eradicated, and several management procedures can adequately control others.

NUMBERS

Introduced species often comprise a substantial fraction of a regional entomofauna. For example, Great Britain has ca. 21,000 native insects and ca. 200 established, introduced ones (comprising ca. 1% of the total). Israel has ca. 15,000 native species and 220 introduced ones (ca. 1.5% of the total). For the contiguous United States, ca. 84,000 native species have been identified, as have 1862 introduced species (ca. 2% of the total). Florida has relatively more introduced species: 11,509 native and 993 introduced (8%). For oceanic islands, the introduced proportion can be much greater. Thus, the Hawaiian Islands have ca. 5400 native insects and 2600 introduced ones (32% introduced), whereas the mid-Atlantic island Tristan da Cunha has 54 native insects and 32 introduced ones (28% introduced). The greater proportions of introduced species on islands probably result more from the mathematics of smaller numbers of native species and relatively larger numbers of attempted introductions than from some inherent invisibility of island communities or stronger “biotic resistance” of continental ones.

SYSTEMATICS

Established introduced insects are not a systematically random group. An order may be over- or underrepresented, reflecting primarily why it was introduced and/or how it arrived. This fact is exemplified in Fig. 1, which depicts the fractions, by order, of insects of
rather than gradually diffusing from a neighboring site. Thus, the monarch butterfly (*Danaus plexippus*) in Australia might not be considered introduced. It arrived around 1870 and established a population, having spread through the Pacific during the 19th century largely unaided by humans. The monarch migrates long distances in its native North America, is an occasional straggler in Europe, and was recorded successively in Hawaii, the Caroline Islands, Tonga, and New Zealand before reaching Australia.

Some insects are introduced deliberately by humans. A few arrive as pets or pet food; recent pet price lists include mantids, walking-sticks, spider wasps, velvet ants, and dung and blister beetles. In Florida in 1989, giant Madagascan hissing cockroaches (*Gromphadorhina portentosa*) became popular as pets; at least some were released to the wild, where they survive. The European honeybee (*Apis mellifera*) has been introduced worldwide for both the production of honey and crop pollination. The Asian silkworm (*Bombyx mori*) has been widely introduced along with its host plant, mulberry, for silk production. Even introductions that fail to establish a commercial industry can nonetheless establish a population. The Asian ailanthus moth (*Samia cynthia*) was brought to the United States in an attempt to found a silk industry on the ailanthus tree. Although the industry founder, the moth remains. The gypsy moth (*Lymantria dispar*) was brought to North America to establish a silk industry; its predictable escape established one of North America’s major pests.

Most deliberate insect introductions are for biological control. Although weeds and insect pests of agriculture are the usual targets, there are others. Thus, the Brazilian ant, *Paratrechina fulva*, was introduced to Colombia to control poisonous snakes, and over 45 dung beetle species were introduced to Australia to break down droppings of introduced livestock (ca. 1/3 established populations). Insects introduced to attack insects are either predators (mainly coccinellid beetles, but including other beetles, hemipterans, and neuropterans) or parasitoids (mostly hymenopterans, but including some dipterans). Insects introduced to control plant pests include primarily flies, beetles, and moths, although others such as bugs and thrips have been employed. The number of insect species introduced for biological control purposes is substantial. For example, of ca. 2600 introduced insect species established in the Hawaiian Islands, ca. 400 were introduced for biological control. Further, about twice as many species introduced there for this purpose perished.

Far more insects are introduced inadvertently than deliberately by humans. Pathways are myriad. Soil ballast was an early predominant mode of entry to North America—many of the first introduced insects were soil beetles from southwestern England. This pathway is less common now, but insects are still carried in rootballs around cultivated plants and soil on heavy equipment. Phytophages, particularly homopterans, dominated introductions to North America in the 19th century with the advent of fast steamships and a proliferation of imported nursery stock, and imported plants are still a major means of introducing insects worldwide. The phylloxera (*Daktulosphaira vitifoliae*) that devastated French vineyards in the 19th century arrived on saplings or cuttings of American vines. Insects can also be carried in water. The yellow fever mosquito (*Aedes aegypti*) probably arrived in colonial America in drinking water casks, whereas the Asian tiger mosquito (*Aedes albopictus*) reached North America in the 1980s in scrap tires from Japan. This is probably the route taken by *Ochlerotatus japonicus*, which arrived in the United States in 1998 and vectors West Nile virus. These latter two mosquitoes have recently been detected in used tires in New Zealand. Wooden packing material

**WHY, WHEN, AND HOW THEY ARE INTRODUCED**

Some introduced insects arrive in new locations on their own and are true immigrants. Any simple range extension could bring a new introduced species in this sense, but we generally restrict introduced status to species arriving at a distant location by a discontinuous dispersal,
brought the Asian longhorned beetle (*Anoplophora glabripennis*) and probably the emerald ash borer (*Agrilus planipennis*) to North America, whereas the European elm bark beetle (*Scolytus multistriatus*) that vectors Dutch elm disease arrived on unpeeled veneer logs of European elm. The growth of international tourism can enhance the rate of insect introduction; in 1992, an Australian tourist returned from South America with a wound containing maggots of the New World screw-worm fly (*Cochliomyia hominivorax*).

**ESTABLISHMENT AND SPREAD**

The great majority of introduced insects do not survive, although only for biological control introductions are there substantial data on failed introductions. For parasitoid species introduced to control insect pests, only about 30% establish populations, whereas for all insects introduced for plant control, the comparable figure is about 60%. Because biocontrol candidates are chosen and often tested for survival in the target environment, one might expect failure rates for inadvertently introduced introductions to be even higher. For most taxa, invasion biologists believe that 5–20% of introduced species establish populations, although many of these may remain for years or in perpetuity near the point of introduction, and a large fraction are restricted to anthropogenous habitats such as human habitations or agricultural fields.

An arriving propagule must be large enough to survive the initial threat of demographic stochasticity—that is, random elimination of so many individuals during the first few generations that the population fails. Data from the biological control literature show that probability of establishment increases with propagule size and number of attempts, but many very small propagules have established large, widespread populations. For example, a single fertilized female of the cochineal insect, *Dactylopius opuntiae*, from Ceylon initiated a large, ongoing population on Mauritius. The European solitary bee, *Lasioglossum leucogenium*, probably colonized North America as a lone singly-mated female; it is now widespread in Canada and parts of the northeastern United States. In Puerto Rico, two females of a bisexual race of the enyrtid wasp, *Hambetonia pseudococcina*, were used to rear 7000 individuals, which were released, established, and quickly spread. For a parthenogenetic species, at least the difficulty of finding a mate is obviated, but demographic stochasticity has other components.

Even assuming an adequate propagule size, the environment, both physical and biotic, must be suitable for a species to survive and spread. Predators, parasites, competitors, and pathogens can eliminate an introduced species or restrict its ambit. For example, the Asian aphelinid wasp parasitoid *Aphyts fisheri*, introduced to California to control California red scale (*Aonidiella aurantii*), failed to establish because of competition from previously introduced *A. melinus* and *A. linguanensis*. Conversely, the absence of natural enemies from its native range is often posited as the reason for the success of some invader, as for the cynipid *Andricus quercuscalicis* into Great Britain. By contrast, the presence of some other species, such as a food plant or a symbiont, might be necessary for an invader to survive. The monarch butterfly would not have survived in Australia but for the prior introduction of its host milkweeds. The physical environment is probably even a more frequent reason an introduced species perishes. For instance, a temperate climate does not augur well for a newly arrived tropical insect.

**IMPACTS**

Quantifying the impact of a new species is an unsolved challenge, but it is safe to say that most introduced species do not generate major impacts. However, some are enormously damaging, whereas others are highly beneficial. The variety of impacts is staggering.

Many introduced insects prey on natives. This activity can be useful, as in biocontrol introductions such as that of the Australian vedalia beetle (*Bodoalia cardinialis*) to attack the cottony cushion scale (*Icerya purchasi*). Predation can also be extremely damaging; on Christmas Island, the introduced crazy ant, *Anoplolepis gracilipes*, has locally devastated populations of the dominant red crab *Gecarcoidea natalis*. Because the crab controls seedling recruitment and litter breakdown, the entire community is affected. Parasites can also be beneficial or harmful. The wasp, *Aphytis melinus*, has effectively controlled California red scale in parts of California. Alternatively, sheep blowfly (*Lucilia cuprina*), introduced to Australia from Africa, caused massive losses. Herbivory can similarly be beneficial or detrimental. The South American flea beetle, *Agrochola hygrophila*, effectively controls alligatorweed in Florida. However, phytophagous insect crop pests impose enormous costs. The alfalfa weevil (*Hypera postica*) caused $800 million in losses in the United States in 1990 alone.

Resource competition is subtler than predation, parasitism, and herbivory, but many introduced insects outcompete natives. The European seven-spotted ladybeetle (*Coccinella septempunctata*), introduced to the United States for control of the Russian wheat aphid (*Diuraphis noxia*), has locally outcompeted several native ladybeetles. European honeybees outcompete the native bee, *Osmia bombylans*, for pollen in the New York State. Introduced insects can even outcompete vertebrates. The introduced wasps *Vespula germanica* and *V. vulgaris* in New Zealand outcompete an endemic parrot for honeydew produced by a scale insect (*Ultracolostoma assinale*) and have locally lowered parrot populations.

Introduced insects can vector or be reservoirs of diseases of humans, domestic animals, cultivated plants, and wild animals and plants. The spread of yellow fever and dengue as the vector mosquito *Aedes aegypti* dispersed throughout the tropics, and of malaria to Brazil with the introduction of its vector *Anopheles gambiae*, are notable examples of human diseases vectored by introduced insects. Cat fleas (*Ctenocephalides felis*) and dog fleas (*C. canis*), introduced to Australia with their hosts, are intermediate hosts for the dog tapeworm (*Dipylidum caninum*). The mosquito, *Culex quinquefasciatus*, was accidentally introduced to the Hawaiian Islands in 1826. Subsequently it vectored avian malaria, introduced with resistant Eurasian songbirds, to susceptible native birds and helps to exclude them from low elevations. The mosquito, *Ochlerotatus japonicus*, transmits West Nile virus to both birds and humans in the northeastern United States. Animal disease vectors may be useful biocontrol introductions. For example, the rabbit flea (*Spilopsyllus cuniculi*), the main vector of myxomatosis in Europe, has been introduced (so far unsuccessfully) in Australia to attempt to boost disease transmission. In the lab, it also transmits calcivirus.

Among plants, Dutch elm disease dispersed to and through North America with the European elm bark beetle (*Scolytus multistriatus*). Beech bark disease spread throughout northeastern North America after the causal fungus was introduced ca. 1890 from Europe with its vector, the beech scale (*Cryptococcus fagisuga*). The California wine industry is plagued by the recent introduction of the glassy-winged sharpshooter (*Homalodisca coagulata*) from the southeastern United States. The sharpshooter spreads an incurable bacterial disease of grape vines, a malady long present but rarely a problem until this vector arrived.

Introduced species often exacerbate one another’s impacts, a process termed “invasive meltdown.” Sometimes this interaction occurs when coevolved mutualists invade a region separately.
In South Florida, over 60 species of ornamental figs were not invasive because their obligatory pollinating wasps were absent. Since the 1970s, three such wasps (Parapristina spp.) have arrived, and three formerly innocuous fig species have begun spreading in natural areas. However, invasive meltdowns need not involve coevolved species. In California citrus orchards, the Argentine ant (Linepithema humile) tends and protects the California red scale, thereby exacerbating its impact. Similarly, in Hawaii, the African big-headed ant (Pheidole megacephala) protects the tropical American gray pineapple mealybug (Dysmicoccus neobrevipes) from coccinellids introduced for biological control.

Relative to the numbers of species introduced, insects rarely cause enormous ecological (as opposed to economic) damage. Introduced species whose impacts ripple through entire communities usually do so by changing the habitat dramatically, and it is mostly plants that do this (by becoming structural dominants or modifying fire regimes) or pathogens that attack dominant plants. Occasionally, mammals can generate an enormous ecosystem impact by trampling or grazing. A recent list of the world’s 100 worst introduced species included 15 insects, but at most one would qualify as having a huge ecosystem-wide impact: the crazy (or long-legged) ant, because it removes the keystone red crab species on Christmas Island. Of the 15, five are ants. In addition to the crazy ant, the Argentine ant, the big-headed ant, the little fire ant (Wasmannia auropunctata), and the red imported fire ant (Solenopsis invicta) all affect other ants greatly, and sometimes other insects, but to date none has had the dramatic impact of certain plants and mammals. Several species among the 15 transmit human diseases (Aedes albopictus and Anopheles quadrimaculatus), and others are agricultural pests, such as the sweet potato whitefly (Bemisia tabaci) and several of the ants. The Formosan termite (Coptotermes formosanus shiraki) has caused enormous damage to housing in New Orleans. With respect to ecosystem-wide damage to natural areas, however, the only members of the list that might qualify, aside from the crazy ant, are the gypsy moth in North America, by virtue of its devastating impact on dominant trees, and the Argentine ant, because it has greatly lowered densities of native seed-carrying ants in the fynbos of South Africa. Other insects may have ecosystemic impacts by removing dominant plants. The beetle transmitting Dutch elm disease has already been noted. The Asian balsam woolly adelgid (Adelges piceae) has eliminated the dominant Fraser fir throughout the high southern Appalachians, and the hemlock woolly adelgid (Adelges tsugae) has killed most hemlocks in much of eastern North America and is spreading to the south and west.

Impacts can occur after a substantial lag period during which an introduced species can appear innocuous. For example, the beetle Chrysolina quadrigemina, introduced to Australia in 1939 to control St John’s wort, seemed to die out but resurfaced and spread in 1942. Such lags are mysterious; they are often attributed to favorable changes in the environment or to evolution of the invader, but evidence for these phenomena is generally lacking. Some introduced insects achieve great numbers and appear to have a major impact, but the population suddenly crashes, again often for reasons poorly understood. After rapid increase and spread, most populations of the European browntail moth (Euproctis chrysorrhoea) crashed in New England and eastern Canada, probably because of parasitism by a tachinid fly (Compsilura concinnata) introduced to control the gypsy moth.

**EVOLUTION**

The conditions under which a species is introduced to a new region [isolation from parent population, small propagule size (usually), and different physical and biotic environment] should conduce to rapid evolution. There has been little study of this phenomenon, but some striking examples have emerged. Drosophila subobscura, introduced to the Americas from the Old World ca. 1880, has spread widely and, by 2000, evolved a cline of increasing total wing length with latitude in North America phenotypically similar to that in its native range. The ichneumonid Bathyplectes curiosus, introduced to the western United States for biological control of introduced alfalfa weevils (Hypera spp.), evolved in less than 10 years to become less susceptible to the encapsulation reaction of its host.

A phenomenon widely reported among introduced vertebrates and plants, particularly in North America and Eurasia, is hybridization with native species, sometimes to the point of a sort of genetic extinction of the latter. Although hybridization is known to have played an important role in insect evolution, hybridization between native and recently introduced insects is rarely if ever reported. This fact may reflect biological differences or simply less genetic study of insects. There are instances of introduced populations hybridizing with one another, most notably the Italian and African strains of the honeybee. The red imported fire ant hybridizes extensively with the previously introduced black imported fire ant (Solenopsis richteri) in Tennessee.

**ERADICATION AND MANAGEMENT**

Eradication is one possible response to an introduced species, particularly if it has not dispersed widely. Many introduced insects have been eradicated, some from substantial areas. Perhaps most impressive is the chemical eradication of the African mosquito Anopheles gambiae from 31,000km² of northeastern Brazil in 1939–1940. The medfly (Ceratitis capitata) was eradicated over 18 months from a 20-county region of Florida by a strict quarantine, destruction of produce and plants, trapping, and insecticide sprays. More recent attempts to eradicate the medfly in both Florida and California may not have been so successful. Although victory has been declared repeatedly, reappearances are frequent and may constitute either new invasions or simply recovery by uneradicated remnant populations.

The development of the sterile male technique in the United States against the New World screw-worm fly gave tremendous impetus to the eradication approach. Release of massive numbers of sterile males so reduced the probability of fruitful mating by females that this species disappeared from the island of Curaçao totally in 1954–1955, and this method greatly aided eradication of this fly from the southeastern United States in 1958–1959. The melon fly (Bactrocera cucurbitae) was eliminated from Rota Island by this method. The male annihilation method, in which males are attracted and destroyed, has also succeeded in eradicating introduced fruitfly populations from islands, including the Oriental fruit fly (Dacus dorsalis) from Rota and Guam and the melon fly from Nauru. Male annihilation followed by release of sterile males eradicated the melon fly from the entire Ryukyu Archipelago. The white-spotted tussock moth (Orgyia thyellina) was eradicated from greater Auckland, New Zealand by pheromone lures plus spraying of Bacillus thuringiensis, while the Australian painted apple moth (Teia anartoides) was eradicated from the same area by use of virgin females in lures, insecticides, B. thuringiensis, and sterile males.

There have also been disastrous failures of expensive eradication campaigns, such as the $200 million attempt to eradicate the red imported fire ant chemically from the southeastern United States, which imposed greater mortality on native insects than on the invader. Quick detection, rapid response, sufficient resources to finish the project, and adequate regulatory power to enforce cooperation have proven to be important for successful eradication.
If eradication fails or is not attempted, chemical and biological control are the two methods most commonly attempted to manage introduced insects. There are successes and failures for both the methods. The nontarget and human health impacts of early-generation insecticides such as DDT are legendary. Although more recent chemicals minimize or eliminate this problem, chemical control frequently is problematic for two main, related reasons. First, insects evolve resistance to chemicals; second, expense can be far too great, especially when amounts used must increase because of resistance. For large natural areas, expense of continued chemical applications can be particularly prohibitive.

Biological control is attractive because the expense of development and deployment is lower, and because, although a host may evolve resistance, the biological control agent itself can evolve countermeasures (as witness *Bathysplectes curculionis*, discussed earlier). There are many striking successes, such as the rescue by the predatory South American coccinellid beetle *Hyperaspis pantherina* of St. Helena’s endemic national tree species from extinction by the South American scale insect *Orthezia insignis*. However, the success rate of biological control is rather low. For instance, for parasitoids introduced for insect control, only 10% have been effective. Further, biocontrol agents can affect nontargets, as has the seven-spotted ladybeetle discussed earlier, and these nontarget impacts can be generated by established biocontrol agents that are not even effective against their targets (about three times as many biocontrol parasitoids establish populations as actually control the target pest). The tachinid fly *Compsilura concinna* has failed to control gypsy moths in North America, but it is believed to be responsible for the decline of several large native moths.

### Island Biogeography

**George K. Roderick and Rosemary G. Gillespie**

*University of California, Berkeley*

Studies of insects have played a major role in the general understanding of the biota of islands, touching on all areas of biogeography, ecology, evolution, and conservation. The notable writings of Darwin and Wallace were influenced heavily by the biological diversity that each witnessed on islands and the processes inferred to underlie that diversity. Rather more recently, studies exploiting the discrete nature of islands have given rise to pervasive organizing theories of community ecology, particularly involving island biogeography. With the advent of accessible molecular genetic tools, research on islands has allowed unique insights into the processes that generate biotic diversity, especially the mechanisms of speciation. Unfortunately, islands are also prime targets for biological invasions, mediated largely by anthropogenic disturbance. The severity of such impacts on island biotas may result from their evolution in isolation, but is certainly compounded by their characteristically small population sizes. Yet, for many islands, extinction among arthropods is largely unknown, although this may be attributable more to lack of knowledge than any innate security that arthropods might possess. Indeed, it is likely that many island arthropods will go extinct before they have been collected and described.

### THEORY OF ISLAND BIOGEOGRAPHY

Larger islands contain more species. MacArthur and Wilson formalized this idea in the 1960s with the development of the Equilibrium Theory of Island Biogeography (ETIB). This theory relates species and area by the formula, \( S = ea^2 \); where \( S \) is species number, \( A \) is area, \( e \) is a constant measuring overall species richness, and \( z \) measures the extent to which increases in area have diminishing returns in terms of species number. Values of \( z \) tend to vary between 0.18 and 0.35; that is, doubling the species number requires increasing the area by a factor of between 7 and 100. The premise of the theory is that the rate of immigration decreases with increasing distance from the source, whereas the rate of extinction decreases with increasing island size. The balance of these processes results in an equilibrium number of species on any one island. As the number of resident species on an island increases, the chance of an unrepresented species arriving on that island decreases and the likelihood of extinction of any one resident species increases. The predictions of the model are that: (1) the number of species on an island should change little once the equilibrium is reached; (2) there should be continual turnover of species, with some becoming extinct and others immigrating; (3) small islands should support fewer species than large islands; and (4) species richness should decline with remoteness of the island because islands farther from the source will have lower rates of immigration.

Rigorous tests of the ETIB have been surprisingly few, and they have supported some aspects of the theory but not others. For example, Simberloff used insecticides to defamine mangrove islands and found that species of insects and spiders accumulated to an equilibrium number. However, contrary to expectation, turnover of species was not randomly distributed among species—particular types of species were likely to colonize or go extinct. In some cases, species numbers have been found to be affected unpredictably by both area and isolation, whereas others have shown that an equilibrium does not exist, or that parameters other than area *per se* may dictate species richness. Such factors include habitat diversity, climatic conditions, island age, and even the status of knowledge concerning the presence of resident species. However, the theory has proven to be remarkably useful and, although it was developed for islands, it has had relevance for the study of many kinds of ecological communities.

**ADAPTIVE RADIATION**

The ETIB assumes that islands are within the geographic distance that a species is likely to disperse, thus maintaining genetic
populations between source and island populations. On islands that are beyond the range within which populations can maintain genetic contact with source populations, one might predict (based on the theory) that few species should be present. But this tends not to happen. Isolated islands that are formed initially without life are often found to have large numbers of closely related species. This phenomenon, where single colonists, isolated genetically from their source population, give rise to a series of species that have diversified ecologically, is termed adaptive radiation, and usually occurs beyond the so-called “radiation zone,” or normal range of dispersal of a given organism. Species that form through adaptive radiation are typically neo-endemics, formed in situ and found nowhere else. Among arthropods, the Hawaiian Islands hold the record in having the largest number of neo-endemics, an extraordinary 98% of the fauna. Important factors involved in adaptive radiation can include founder effects, genetic drift, behavioral isolation, ecological isolation, host-associated isolation, and the presence or absence of competitors, predators, and symbionts, the relative importance of these varying across biological systems. For insects, particularly noted examples of adaptive radiation include: Drosophila flies, which are well known for their diversity of mating behaviors; lineages of crickets that have diversified explosively in song repertoire; sap-feeding planthoppers and psyllids that have proliferated by tracking and switching between plant hosts; and beetles that have formed new species on different substrates. Diversification may follow a predictable pattern, at least in some groups; for example, among Tetragonatha spiders similar ecological sets of species have evolved over and over again on each of the different Hawaiian Islands.

Compared to their hypothetical colonizing ancestors, terrestrial arthropod species on remote oceanic islands are often characterized by a reduction in dispersal ability, including loss or reduction of wings or a reduced tendency to fly or balloon. This effect is most pronounced in species that would have colonized islands passively by wind, including a number of spiders and likely planthoppers and many other insects. Other arthropod species on remote islands, such as beetles in the genus Rhynococcus, likely were never good dispersers and colonized remote islands by hitching rides on vectors such as birds, or on floating mats of vegetation. Regardless of their mode of transport, the species that colonize remote islands are a small sample of the species inhabiting their various continental sources. Island biological communities are therefore unrepresentative of the biotic diversity on continents, a phenomenon accentuated by the frequent proliferation of successful colonists.

DIFFERENT KINDS OF ISLANDS: NEO-ENDEMICS AND PALEO-ENDEMICS

Neo-endemics typically form on isolated islands that have been created de novo, and have abundant empty ecological space into which those few colonists can diversify. Besides Hawaii, other volcanic archipelagoes, including the Marquesas, Societies, and Galapagos in the Pacific and the Canaries in the Atlantic, have provided ideal conditions for the formation of neo-endemics. However, species can also form on fragment islands, formed as a mass of land has broken away from a larger continental region. Examples of such islands include some of the Caribbean islands, and the islands of New Zealand and Madagascar. These islands are formed upon losing connection with a continental source; as they become more isolated, gene flow between island and continental populations is reduced and may become insufficient to overcome genetic divergence. Unlike volcanic islands that form in isolation, starting without any species and accumulating species through time, fragment islands are usually ecologically saturated at the time of separation and tend to lose species through ecological time. Over evolutionary time, the species on these islands may change through a process termed reticulization, with the formation of paleo-endemics, usually without adaptive radiation.

HABITAT ISLANDS

Many of the ideas originally developed for islands in the sea have been extended also to so-called “habitat” islands of a particular habitat type within a matrix of unlike terrain. Most such islands are fragments of habitats that were historically connected, such as remnant trees and forest patches. For habitat islands, as for islands in the sea, ecological and evolutionary processes are governed largely by isolation, time, and the nature of the matrix relative to the dispersal abilities of the organisms in question. Habitat islands, because of their discrete nature and ease of manipulation compared to islands in the sea, have been exploited in the development of many ecological principles including those related to meta-population dynamics and physical design of nature reserves.

CONSERVATION

The biota of islands is often unique—for example, the islands of the Pacific have been designated a biodiversity hotspot. Assessing this diversity, particularly for arthropods, is problematic. The major impediment is a lack of taxonomic understanding of arthropods on many islands, particularly those that are more remote. New species are being collected at a remarkable rate in areas such as French Polynesia, Madagascar, and even the relatively well-studied Canary Islands, New Zealand, Hawaii, and the Galapagos, yet the training of arthropod systematists has lagged behind.

Anthropogenic disturbance has also had its impact, not only in present times but historically, such as witnessed through the colonization of the Pacific by Polynesians several thousands of years ago. In the islands of the Pacific and Indian oceans, new paleoarcheological studies are now documenting what arthropods were present before the arrival of humans. A number of characteristics of arthropod populations on islands, including high local endemism, limited dispersal abilities, and small population sizes, make them particularly vulnerable to both demographic accidents and environmental change. In addition, islands have been impacted heavily by invasive species, many of which are also arthropods. These invasives tend to disperse well and therefore can often recolonize disturbed habitats before indigenous species. The impact has been both direct, such as through the extirpation of species by invasive predatory ants, and indirect, such as through diseases of vertebrates vectored by mosquitoes.

Although islands have long proven themselves as extraordinary laboratories for studying processes associated with the generation of diversity, they are now contributing to our understanding of processes leading to the loss of diversity. For example, studies of invasive species on islands have shown the importance of environmental factors as well as species-specific attributes that facilitate biological invasions and its negative effects. New tools are urgently needed: rapid biodiversity assessment techniques that bypass traditional taxonomic identification will be important in recognizing areas of high conservation priority, as will genetic and ecological approaches that can distinguish native species from those introduced in more recent history.
Isoptera (Termites)

Vernard R. Lewis  
University of California, Berkeley

The ordinal name Isoptera is of Greek origin and refers to the two pairs of straight and very similar wings that termites have as reproductive adults. Termites are small and white to tan or sometimes black. They are sometimes called “white ants” and can be confused with true ants (Hymenoptera). However, a closer look reveals two easily observed, distinguishing features: termites have straight antennae and a broad waist between the thorax and the abdomen, whereas ants have elbowed antennae and a narrow waist. For reproductive forms, termites have four equally sized wings, whereas ants have two pairs of dissimilarly sized wings.

IMPORTANT FAMILIES OF TERMITES

The earliest known fossil termites date to the Cretaceous, about 130 mya. There are >2600 species of termites worldwide. Undoubtedly, more will be recognized with improved methods of discerning cryptic species and after intensive collecting of tropical and remote regions. It has been known for decades that termites are closely related to cockroaches. However, the latest molecular results, albeit controversial, suggest all termite species diversity can be accommodated as a single family within cockroaches (order, Blattodea). The greatest continental termite diversity is in Africa, where there are over 1000 species. Polar continents have none, and North America with 50 species and Europe with 10 species are intermediate in termite diversity.

Development is incomplete metamorphosis containing castes that include nymph, worker, pseudergate, soldier, and several types of reproductives (Figs. 1–3). Nymphs hatch from eggs and molt at least three times before becoming functional workers. Workers are wingless, do not lay eggs, and, except for the family Hodotermitidae, are blind. Worker and pseudergate castes are the most numerous in a colony and conduct all major foraging and nest-building activities. Soldiers defend colonies with fearsome mandibles and/or chemical squirts from a nasus, a frontal projection from their heads. Soldiers cannot feed themselves. Reproductives consist of a royal pair, the original colony founders, but supplementary and replacement reproductives (neotenics) can be generated from workers, nymphs, or other immatures dependent on pheromonal cues from the queen and environmental factors.

Termite families traditionally were categorized as lower or higher. However, this categorization may change soon as newer classification systems are adopted. Lower termites (families Mastotermesidae, Kalotermesidae, Termopsidae, Hodotermitidae, Rhinotermitidae, and Serritermitidae) have symbiotic intestinal protozoa and bacteria. Higher termites (Termitidae) have intestinal bacteria only.

Classically, termite identification at the family and genus level was determined using reproductive adults or soldiers or, in some groups, workers. Today, molecular techniques are gaining importance in the identification process. However, methodological and acceptance hurdles still remain and models that incorporate multiple genes, analyses of sequence codes, representative samples, as well as correlations with traditional and other methods of identification are still needed. All living termites can be divided into seven families as follows.

Further Reading

Isoptera

Mastotermitidae

This family contains the most primitive living termite, *Mastotermes darwiniensis* (Fig. 4), now limited to Northern Australia and Papua New Guinea. In appearance, these termites are light brown, robust, and about 8–10 mm in length. This family is recognized by the presence of an anal lobe in the hind wing of the reproductive adults and five-segmented tarsi. The hind wings are very similar to those of some cockroaches. Like cockroaches, reproductive females also lay egg cases containing up to 24 eggs arranged in two regular rows. Although egg masses contain few eggs, *Mastotermes* has many neotenic reproductives (no primary queen has ever been found in the field), and colonies can reach a population size of millions. Soldiers have powerful mandibles and excrete a toxic brown substance from their buccal cavity that repels intruders.

Kalotermitidae

Members of this family are commonly called “dry-wood termites” for their habit of nesting in wood above the soil level, although exceptions occur. Some dry-wood termites have subterranean habits, whereas others prefer rotten and damp wood. Dry-wood termites are brownish and are considered medium-sized termites, 10–13 mm in length. This family is recognizable by the presence of ocelli and two-segmented cerci in the alate form. There are more than 400 species worldwide. Dry-wood termites are common on most continents. Colonies are moderate in size and contain several thousand individuals, most of which function as workers. The queen lays about a dozen or so eggs per day.

Termopsidae

The damp-wood termites nest in wet and rotting wood, especially fallen logs and stumps in forests. Damp-wood termites were formerly grouped within harvester termites (Hodotermitidae), but now are considered a separate family. Damp-wood termites are among the largest termites, some reaching almost 25 mm in length. Most individuals retain marked developmental plasticity. There are about 20 species and they are limited to forests in the Americas, Eurasia, Africa, and Australia. Egg production per queen is relatively low (<30 per day) and colony size is moderate, up to approximately 10,000.

Hodotermitidae

Members of this grass-harvesting family of 15 species are similar in appearance to damp-wood termites and are quite large (>15 mm in length). Reproductive adults lack ocelli and their cerci have three to eight segments. Modern species are savanna grass feeders and occur in Africa, the Middle East, and India. Queen egg production and colony size are similar to those of damp-wood termites.
Rhinotermitidae

Commonly called subterranean termites, this family typically requires its nest to contact the soil. However, exceptions occur (genera *Coptotermes* and *Reticulitermes*). Most species in this family are recognizable by their reproductive adults and a flat pronotum behind the head of soldiers. The soldiers of some species produce a defensive fluid from a fontanelle gland that is located on their head. Workers and soldiers are small (<5 mm) and are very pale white in color. More than 300 species are recognized. They occur on most continents except in polar and near-polar regions and are serious pests of structures. Queens of some species can produce more than 100 eggs per day, and colonies can number from the tens of thousands to the millions. Some mound-builders and aerial-nesters are found in this family. Aerial-nesting species still maintain contact to the soil for water by runways constructed from soil and saliva.

Serritermitidae

This family is very similar in appearance and closely related to subterranean termites (Rhinotermitidae). It also requires its nest to contact the soil. A single species occurs in South America. Soldiers have serrated teeth along the entire inner margin of the mandibles.

Termitidae

This family contains builders of the great mounds (up to 8 m high) that occur in the tropics, mainly in Asia, Africa, Australia, and South America. There are a few species in North America and none occur in Europe. More than 1800 species have been described, many from Africa. Termitids are distinguished by two prominent teeth on the left mandible of reproductive adults and a saddle-shaped pronotum. The Termitidae have a true worker caste. Workers are very small (<5 mm) and pale or dark in color. Many species have nasute soldiers—these eject anoxic fluid from a horn-shaped nozzle on their heads. Members of this family are some of the most prolific producers of eggs in the animal kingdom. A queen can produce more than 10 million eggs in a single year.

TERMITES AS PESTS

Some termites are destructive feeders and consume homes, other wooden structures, and agricultural crops. In some regions of the world, tunneling by termites damages dams, which then results in flooding. Worldwide, several billion dollars is spent annually for the control and damage caused by termites. In the United States alone, over $1,000 million is spent yearly on termite control and damage repairs. Globally, subterranean termites (Rhinotermitidae: genera *Reticulitermes*, *Coptotermes*, *Heterotermes*, and *Psammotermes*) are the most responsible for the control and damage costs. Dry-wood termites considerably among termite families and species, but occurs most frequently during the rainy season. However, dry-wood termites can swarm during hot days or sometimes on summer evenings. A mated king and queen lose their wings and find a suitable nesting site near or in wood where they construct a small chamber that they enter and seal. The queen soon begins laying eggs, and both the king and the queen feed the young predigested eggs until they are capable of feeding themselves. One worker and nymphs are produced, the king and queen are fed by the workers and cease feeding on wood. The exchange of food among colony members is called trophallaxis. Social insects exchange food in two ways, stomodeal and proctodeal trophallaxis. Termites use the latter method for food and symbiont exchange, mouth to anus. Symbionts are protozoa and bacteria that occur in the hindgut of termites. These microbes help digest cellulose, the major food source for termites.

The reproductive adults have functional eyes, needed for flight and initial finding of nest sites. The blind workers and soldiers live deep in nests, soil, or mounds and do not require vision. They already are in contact with or close to their food source.

Termites can also communicate through chemical, acoustical, and tactile signals. Two termite trail pheromones, (Z,Z,E)-(3,6,8)-dodecatrienol and (E)-6-embrenene, have been identified. These messages are produced in a sternal gland on the underside of the termite’s abdomen. However, other chemical signals, such as those used for alarm and colony recognition, are produced from other glands located throughout their body. Many termite behaviors (e.g., trail following, alarm, and sexual communication) are mediated by pheromones. Soldiers also produce chemicals that are important for colony defense. Colony recognition and colony spacing are thought to be regulated by cuticular hydrocarbons. These waxy compounds are produced over the exterior cuticle of termites and spread throughout the colony. Termites can also communicate danger by “head-banging” of soldiers, in which they tap their heads in galleries to alert their nestmates.

Termites play a major role in recycling wood and plant material, but their tunneling effort also ensures that soils are porous, aerated, and enriched in minerals and nutrients, all of which increase plant growth. For example, termite activity in the desert areas of West and North Africa helps to reclaim soils damaged by overgrazing. Termites are an important food source for many other animals, including reptiles, birds, and mammals. Termite mounds and trees hollowed out by termites provide shelter and breeding sites for birds, mammals, and other insects.

Termites also contribute to atmospheric gases. The most abundant gases produced are carbon dioxide and methane. Both are greenhouse gases, but they are not produced in sufficient quantities to have negative effects on the atmosphere.

The quest for alternative fuels now includes termites. The gut fauna of termites is being mined for molecular sequences that could lead to the efficient conversion of plant sugars into ethanol; the planned future source of power for motorized vehicular transportation.

TERMITES BIOLOGY AND ECOLOGY

Termites live in colonies that are social and can be long-lived. Colonies are composed of castes that conduct all tasks for survival (Figs. 1and 3). Some termite queens are larger than the length of a human thumb and can lay more than 1000 eggs per day. The king is also long-lived and mates intermittently to provide sperm to the queen. Some of the longest living insects are termites; some termite mounds and their queens are thought to be more than 70 years old and Aborigine folklore claims some mounds in Australia are over 200 years old. There are no methods to age a queen.

Termites are herbivores, fungivores (i.e., plant or fungus feeders), and humivores (soil feeders). They feed on cellulose, directly from plants, dead or alive, or indirectly from fungus arising from decaying plant material within mounds. Plants are made of cellulose, a polysaccharide that is composed of glucose units. The traditional view is that termites rely on intestinal gut microorganisms for cellulose digestion. However, there is growing molecular evidence that termites also use their own enzymes for cellulose digestion.

Before mating and starting new colonies, new kings and queens, called alates or swarmers, depart the colony and fly (Fig. 2). They mate after landing on the ground. Swarming behavior varies significantly among termite families and species, but occurs most frequently during the rainy season. However, dry-wood termites can swarm during hot days or sometimes on summer evenings. A mated king and queen lose their wings and find a suitable nesting site near or in wood where they construct a small chamber that they enter and seal. The queen soon begins laying eggs, and both the king and the queen feed the young predigested eggs until they are capable of feeding themselves. One worker and nymphs are produced, the king and queen are fed by the workers and cease feeding on wood. The exchange of food among colony members is called trophallaxis. Social insects exchange food in two ways, stomodeal and proctodeal trophallaxis. Termites use the latter method for food and symbiont exchange, mouth to anus. Symbionts are protozoa and bacteria that occur in the hindgut of termites. These microbes help digest cellulose, the major food source for termites.

The reproductive adults have functional eyes, needed for flight and initial finding of nest sites. The blind workers and soldiers live deep in nests, soil, or mounds and do not require vision. They already are in contact with or close to their food source.

Termites can also communicate through chemical, acoustical, and tactile signals. Two termite trail pheromones, (Z,Z,E)-(3,6,8)-dodecatrienol and (E)-6-embrenene, have been identified. These messages are produced in a sternal gland on the underside of the termite’s abdomen. However, other chemical signals, such as those used for alarm and colony recognition, are produced from other glands located throughout their body. Many termite behaviors (e.g., trail following, alarm, and sexual communication) are mediated by pheromones. Soldiers also produce chemicals that are important for colony defense. Colony recognition and colony spacing are thought to be regulated by cuticular hydrocarbons. These waxy compounds are produced over the exterior cuticle of termites and spread throughout the colony. Termites can also communicate danger by “head-banging” of soldiers, in which they tap their heads in galleries to alert their nestmates.

Termites play a major role in recycling wood and plant material, but their tunneling effort also ensures that soils are porous, aerated, and enriched in minerals and nutrients, all of which improve plant growth. For example, termite activity in the desert areas of West and North Africa helps to reclaim soils damaged by overgrazing. Termites are an important food source for many other animals, including reptiles, birds, and mammals. Termite mounds and trees hollowed out by termites provide shelter and breeding sites for birds, mammals, and other insects.

Termites also contribute to atmospheric gases. The most abundant gases produced are carbon dioxide and methane. Both are greenhouse gases, but they are not produced in sufficient quantities to have negative effects on the atmosphere.

The quest for alternative fuels now includes termites. The gut fauna of termites is being mined for molecular sequences that could lead to the efficient conversion of plant sugars into ethanol; the planned future source of power for motorized vehicular transportation.

TERMITES AS PESTS

Some termites are destructive feeders and consume homes, other wooden structures, and agricultural crops. In some regions of the world, tunneling by termites damages dams, which then results in flooding. Worldwide, several billion dollars is spent annually for the control and repair of damage caused by termites. Dry-wood termites...
TERMITE CONTROL/MANAGEMENT

Before termites in structures can be treated, the extent of the infestation must be assessed. Visual searching and probing of wood are the dominant means of inspection. However, the efficacy of visual searches is questionable, because structures have inaccessible areas. The list is growing for nonvisual detection methods used, including carbon dioxide gas detectors, infrared, microwave, acoustic emission devices, and X-ray, but each of these technologies has some limitations. For subterranean termites, wood-baited monitoring stations can identify the presence and delimit the extent of colonies. Some species of subterranean termite have colonies as large as several million individuals, and these forage over an area of more than 10,000 m². Other termite species have much smaller colonies and forage within areas of only a few square meters. There is considerable debate about the methods and accuracy in reporting termite numbers and foraging behavior.

Termite control is most regulated in North America, Europe, and Australia. However, in many countries controlling termites is achieved by the hand removal of queens and nests, flooding nests, or drenching them with used motor oil. Soil drenches with liquid termiticides injected into the soil beneath the structures to protect foundations with used motor oil. Soil drenches with liquid termiticides injected into the soil beneath the structures to protect foundations and structural wood is the dominant control tactic for subterranean termites for several continents. Chlorinated hydrocarbon insecticides, such as chlordane, have been used extensively for subterranean termite control because of their long persistence, >30 years in the soil. Because of persistence and suspicion of health-related problems, chlordane has been removed from many markets. Chloronicotinyls and phenyl pyrazoles are new compounds marketed for termite control. Also increasingly being marketed are “green” products (plant natural compounds). The use of toxic baits (e.g., containing chitin and metabolic inhibitors) and physical barriers (sand and stainless steel mesh) for controlling subterranean termites are also gaining acceptance. Techniques to prevent infestations of subterranean termites include using wood pressure-treated with oil and water-soluble chemicals. Care has been taken for both remedial and preventative control methods, because reinvasion, budding, and over-looked incipient colonies are frequent. Future innovations for control include use of molecularly altered products and microbes directed against termite colonies.

Surveys of pest control firms in the United States reveal that poor building practices, particularly wood in contact with soil and cracks in concrete foundations, lead to many of the subterranean termite infestations. Experimental efforts have been made to control soil-dwelling termites using biological control agents, such as Argentine ants and nematodes. However, these methods have not yet been proven effective.

Dry-wood termite colonies are usually above soil level in structures, small, and difficult to detect. Treatments include whole-structure applications of fumigants (such as sulfuryl fluoride) and heat. Chemicals (including green products), heat, freezing, microwaves, and electricity are used for localized or spot treatments of dry-wood termites. Portable detection equipment is now commercially available to enhance localized and spot treatments.

Japanese Beetle

David W. Held  
Auburn University

Daniel A. Potter  
University of Kentucky

The Japanese beetle, *Popillia japonica* Newman, is among the most polyphagous of plant-feeding insects. The adults skeletonize the foliage, or feed on the flowers or fruits, of nearly 300 species of wild or cultivated plants. The larvae, or grubs, develop in the soil where they feed on roots of turf and pasture grasses, vegetables, nursery seedlings, and field crops. Hundreds of millions of dollars are spent annually for controlling the adults and grubs, and in state and federal regulatory efforts aimed at limiting the beetle’s rate of spread in the United States and elsewhere.

The Japanese beetle was first discovered in the United States in 1916, near Riverton, NJ. How it was inadvertently transported from its native Japan is not known; however, the grubs may have arrived in soil around the roots of nursery plants. The species is not a major pest in Japan, where suitable grassland habitat is limited and natural enemies keep this beetle in check. The eastern United States, however, provided a favorable climate, with abundant moist turf as habitat for the eggs and larvae, numerous adult food plants and, at that time, no host-specific natural enemies. Therefore, populations increased and spread rapidly. By 2007, the beetle was established in all states east of the Mississippi River except for Florida, and in the central United States as far west as Minnesota, Nebraska, Kansas, and eastern Colorado. It also has spread north into southern Ontario and Quebec, Canada, and is established on Terceira Island (Azores, Portugal) where it escaped from a U.S. air base.

**DESCRIPTION**

Japanese beetles belong to the family Scarabaeidae, subfamily Rutelinae. Adults are broadly oval, 8–11 mm in length, metallic-green, with coppery-brown elytra that do not quite cover the end of the abdomen (Fig. 1A). The abdomen bears five patches of white hairs on either side, and another pair near its tip. Females, which tend to be slightly larger than males, have an elongate, spatula-shaped spur on the foretibia, used for digging. This spur is shorter and pointed in males.

**LIFE CYCLE**

Japanese beetles have a 1-year life cycle in most parts of their range. Adults occur from June to August. Upon emergence from the soil, virgin females emit a volatile sex pheromone that attracts clusters of males. Subsequent matings occur on food plants. The beetles typically feed from the upper surface of leaves, chewing out the tissue between the veins and leaving a lace-like skeleton. Adults also feed on petals of flowers such as roses, and on ripening fruits or berries. Food plants growing in sunny locations are preferred and the beetles usually begin to feed on foliage near the top of a plant, regardless of its height. They often aggregate on particular shoots or plants. This phenomenon results from both sexes being attracted to blends of aromatic volatile compounds released from beetle-damaged leaves. Despite the beetles’ broad host range, some plant species are rarely or never fed upon. Closely related cultivars within species may also differ in susceptibility. Resistance probably results from presence of feeding deterrents (e.g., certain phenolics) or other secondary plant compounds. Certain plants (e.g., geranium: *Pelargonium x hortorum*) are palatable to the beetles but cause paralysis or other toxic effects.

After feeding, gravid females fly to moist turf, pasture, or agricultural fields, where they burrow down to lay small clutches of eggs in the upper 8 cm of soil. Females alternate between feeding and egg-laying; each female may emerge from the soil, fly to host plants, feed, mate again, and return to the soil 15 or more times, laying 40–60 eggs in her lifetime. The pearly white eggs, oval when first laid, swell with soil moisture to a diameter of about 1.5 mm. Larvae hatch in 2–3 weeks, usually by early to mid-August. Larvae feed just below the soil surface, consuming plant roots and organic matter. When grubs are numerous, the root system of turf grasses may be completely severed, such that the turf wilts and dies, and can be pulled from the soil like a loose carpet. Most grubs are third instars by September. About the time of first frost, the grubs move deeper...

June Beetles

Daniel A. Potter
University of Kentucky

David W. Held
Auburn University

June beetles, sometimes called May beetles or June bugs, are heavy-bodied, brownish, plant-feeding scarab beetles (Fig. 1A). Almost all species are nocturnal in their habits. The adults are voracious feeders on leaves of many deciduous trees, shrubs, and some herbaceous plants. Their larvae, called white grubs, develop in the soil, where they feed on plant roots and can be pests of turf and pasture grasses, young nursery stock, corn, small grains, potatoes, strawberries, sugarcane, and other agricultural crops.

June beetles belong to the genus Phyllophaga Harris (formerly Lactosterna) in the family Scarabaeidae, subfamily Melolonthinae. They occur in both the New and Old Worlds. In North America, north of Mexico, about 200 species are known, with many found in the north-central and eastern United States. A species complex occurs in most areas. They also have been reported from South and Central America, the West Indies, eastern and southern Asia, and the islands of the Pacific and Indian Oceans.

DESCRIPTION

June beetles average 12 to more than 25 mm in length, with a cylindrical or oblong body shape, dense hair on the metasternum, and lamellate antennae that end in a three-segmented club that is longer in males than in females. Each tarsal claw bears a small tooth near the middle. Coloration ranges from tan to mahogany to dark chocolate brown. The elytra of some species are hairy, whereas in others, they are nearly smooth. Morphology of the genitalia is the most important taxonomic character used to separate species of June beetles.

Larvae are typical scarab grubs: cream-colored and C-shaped when feeding or at rest, with a brown head capsule, chewing mouthparts, and three pairs of jointed legs (Fig. 1B). The hind part of the abdomen usually appears dark because of ingested food and soil. The ventral surface of the last abdominal segment bears two parallel rows of short spines in a pattern that resembles a zipper. There are three instars. Full-sized grubs of most species are 25–38 mm in length.

LIFE CYCLE

Most June beetles have 2- or 3-year life cycles, although a few species have cycles lasting 1 or 4 years. Adults typically are active from April to June. The beetles emerge after sundown and fly to the tops of trees to feed and mate, returning to the soil before dawn. They are clumsy fliers and are often attracted to outdoor lights. Many species use blends of the methyl esters of two amino acids, L-valine and L-isoleucine, as the female sex pheromone. Mated females fly to turf, pasture, or agricultural fields and burrow down 5–15 cm to lay eggs in the soil. Each female lays 20–50 eggs in her lifetime. Eggs are
Juvenile Hormones

Michael E. Adams
University of California, Riverside

Juvenile hormones (JHs), acting in concert with ecdysteroids, orchestrate the expression of larval-specific genes each time the insect molts to a new stage. These morphogenetic effects include determination of an immature body form and internal organs, hardness and color of the cuticle, and accompanying physiology and behaviors. At the conclusion of larval development, JH levels drop at critical times, allowing ecdysteroids to program expression of pupal and adult characteristics. JHs return in the adult stage, in which they have gonadotropic functions in connection with reproduction. In addition to their morphogenetic and gonadotropic actions, JHs are involved in dormancy and various types of polyphenisms, including caste determination in social insects.

DISCOVERY

The discovery of JHs began in the 1930s, with a series of ingenious experiments conducted by Vincent Wigglesworth that were aimed at elucidating the hormonal control of molting. Trained as a medical doctor, Wigglesworth dedicated his life to basic studies of insect physiology, believing that knowledge gained would hold the keys to controlling insect vector-borne disease and agricultural pests. As a model experimental insect, Wigglesworth chose the Chagas' disease vector *Rhodnius prolixus*, otherwise known as the "kissing bug" because of its habit of sucking blood from the lips of sleeping humans. The choice of *Rhodnius* was inspired because its development is closely timed to its blood meals. This allowed Wigglesworth to precisely determine the physiological stage of the insects to coincide with his experimental manipulations. He found that 3 days after a blood meal, hormones are released into the *Rhodnius* system, stimulating the molt to the next stage. By performing a number of surgical procedures on the bug, Wigglesworth demonstrated the source and timing of hormone release. An advantage of working with insects as experimental animals is that they can survive for long periods without such seemingly vital organs as the brain, a fact that Wigglesworth exploited. He found that decapitation of animals prior to a 3-day critical period led to an arrest in development, even though the animal would remain alive for many months. If the brain was reimplanted, development resumed. He also found that the blood of a normally developing animal could reactivate development in the headless animal. This was achieved via a technique called parabiosis, in which the developmentally arrested animal was joined to the normal one by means of a tube that allowed blood from the two animals to mix. With these experiments, Wigglesworth demonstrated that hormones released from the brain trigger molting. This discovery actually had been made more than a decade earlier by Stefan Kopec, working with gypsy moth, but Wigglesworth's experiments also revealed a new type of hormone, one that influenced the form taken by the animal after each molt.

Wigglesworth fundamentally changed the thinking about insect development, specifically the distinction between regulation of growth and regulation of form by separate hormones. *Rhodnius* passes through five nymphal stages before molting to the adult form. It is easy to distinguish the adults from the nymphs because of differences in pattern and color of the cuticle, as well as the fact that only adults have wings. Wigglesworth found that parabiosis of a fifth (last)-stage nymph with a young nymph prevented the former's metamorphosis to the adult stage. Instead, the animal molted to a sixth-stage nymph, an extra immature stage that never occurs normally. A chemical in the blood of the young insect promoted continued expression of larval characters, and this factor came to be known as the "juvenile hormone." The source of the JH was traced to a pair of small glands behind the brain called the corpora allata (Fig. 1). Surgical removal of the gland did not interfere with molting, but drastically altered the form taken after the molt, causing animals to become precocious adults. Reimplantation of the glands led to the return of larval characters.
While the corpora allata proved to be the sole source of JH, only very small amounts were available from the gland for chemical studies. The short supply of JH greatly constrained experimentation, slowing the process of discovery considerably. A breakthrough came with the discovery of large amounts of JH in abdomens of adult male silk moths by Carroll Williams. Ether extracts produced a dark orange material that he called the golden oil. Such an abundance of JH in a male adult at first was surprising, but already Wigglesworth had noted the essential gonadotropic role of JH associated with reproduction, that is, stimulation of egg and sperm development. The reason for enormous quantities of JH in male adult abdomens is probably its inclusion in spermatophores, which contain sperm together with nutritive and hormonal stores and are provided to the female during mating for fertilization and nutrition of developing eggs. Williams is credited with stimulating the modern era of JH research, by making available enough of the natural hormone to conduct biological experiments on its modes of action in many types of insects. This work also provided quantities of starting material sufficient for the eventual isolation and chemical identification of the hormone, which occurred in the late 1960s and early 1970s.

**CHEMISTRY OF JUVENILE HORMONES**

The JHs are lipophilic sesquiterpenoid derivatives of farnesolic acid. Their chemical nature came into focus in the early 1960s, beginning with observations that farnesoid components of beetle excreta had JH-like activity in bioassays. Although far less potent than the native hormone, these substances, including farnesoic acid and its oxidized form farnesal, were suspected to be JH precursors. Subsequent synthesis of methyl farnesoate with an epoxide at position 10–11 by William Bowers in 1965 gave a highly potent compound. It is indeed ironic that this very same compound was discovered 8 years later to be JH-III, the most ubiquitous of the natural JHs (Fig. 2).

Another interesting prologue to the discovery of the natural JHs was the discovery of a curious “paper factor” by Karel Slama and Carroll Williams in the mid-1960s. Slama had carried insects from his laboratory in Czechoslovakia to the laboratory of Williams at Harvard University for a series of joint experiments. Some weeks after arriving, some insects began to develop extra stages and many died. Nothing of the sort was noticed in Czechoslovakia. It was eventually determined that the paper towels used to line the containers holding the insects contained compounds with JH-like biological activity. The substances were absorbed through the insect cuticle upon contact with the paper towels. The paper factor turned out to be a mixture of terpenoids in the wood pulp from which the paper towels were manufactured. These compounds were found only in American and Canadian balsam fir and not in European trees. One of these substances was chemically identified by Bowers and colleagues as “juvabione” (Fig. 2), which had a structure reminiscent of farnesol.

These studies provided new information on two critical issues of the time. First was the question of JH structure. Observations that farnesoic acid and methyl farnesoate, along with juvabione, possessed JH-like biological activity made it likely that terpenoid chemistry was involved. This guided further attempts to chemically define the natural material(s). The second issue was whether JHs or analogs such as juvabione could be used to produce, as Carroll Williams suggested,
a new class of “third-generation” pesticides. Juvabione constituted a relatively stable terpenoid with potent insecticidal activity and hence stimulated further interest in this novel concept for new insecticides that would be both highly insect-selective and safe for warm-blooded animals.

With this as background, Röller and colleagues isolated sufficient quantities of JH from silk moth abdomens for identification of the first natural JH in 1967. The carbon skeleton was identified as a 15-carbon sesquiterpene substituted at positions 7 and 11 with ethyl groups. Further key structural features were the presence of a methyl ester and an epoxide at carbons 10 and 11, respectively. This landmark achievement was followed rapidly by the discovery of a second JH, also from moths. These molecules were named JH-I and JH-II, respectively, differing only at carbon 7, which was ethylated in JH-I and methylated in JH-II (Fig. 2). These two JHs are most cosmopolitan of JHs, occurring in most insect groups, including the Lepidoptera. Within a few years, a third hormone was identified by a completely different approach. In this instance, corpora allata from the moth Manduca sexta were removed and placed in organ culture containing a radiolabeled methyl donor. 14C-labeled methionine. The corpora allata incorporated the 14C-methyl group into the ester moiety of this JH. This isotope-labeled synthetic product was isolated and identified as JH-III. It is the most cosmopolitan of JHs, occurring in most insect groups, including the Lepidoptera. It has methyl groups at positions 7 and 11 (Fig. 2). Three additional JH structures have been identified: JH-0 and 4-methyl JH from moth eggs and JH-bisepoxide first found in the fruit fly Drosophila and now known to occur in other dipterans as well as ticks (Fig. 2).

The JHs are derived from acetyl CoA and/or propionyl CoA via mevalonic acid and homomevalonic acid in the sterol biosynthetic pathway. The final steps of JH-III biosynthesis go by way of farnesol—farnesoic acid—methyl farnesoate, to which an epoxide is formed at carbons 10–11. Owing to their low aqueous solubility, the JHs are transported through the blood via binding proteins upon their release from the corpora allata. These binding proteins also protect JH from degradative enzymes.

In some insects, the corpora allata synthesize a precursor of the biologically active form of JH, which is converted to the active form in target tissues. For example, silk moth adults produce JH acid in the corpora allata and convert it to JH-I in the accessory glands of the abdomen. It is also known that the ovaries of certain species of mosquito can synthesize JH from precursors under culture conditions. Whether this occurs under natural conditions in vivo has not been demonstrated.

The levels of JH in the blood are regulated through a combination of synthesis and degradation. Synthesis by the corpora allata is promoted by neuropeptides called allatotropins and suppressed by allatostatins. The first allatotropin (Manse-AT) was identified from the moth Manduca sexta. Surprisingly, the peptide proved to be active in the adult stage of this moth, but not in immature stages. Recent evidence however indicates that Manse-AT is active in other insect species, including immature stages. A variety of allatostatins have been characterized. These are neuropeptides synthesized in brain neurons that project to the corpora allata. Their release from nerve endings in the gland inhibits the synthesis of JH. It is also possible that circulating allatostatins help to suppress JH synthesis when appropriate.

The removal of JHs already in the blood, a necessary condition for metamorphosis, occurs through two enzymatic degradation pathways. One is through cleavage of the ester bond by JH esterase, and the other through epoxide destruction by epoxide hydrolases.

**BILOGICAL ACTIONS**

**Morphogenetic Effects**

The presence of JHs in the blood promotes expression of juvenile characters, chief among these being an immature body form or morphology. For insects such as grasshoppers, which undergo incomplete metamorphosis, the effects are not so visible outwardly. The early stages look like miniature adults except for the absence of wings, but they also lack functional reproductive organs. However, for those insects such as flies, moths, and bees, which undergo complete metamorphosis, the effects are extreme. The immature stages are wormlike with no wings, legs, compound eyes, antennae, or other adult structures.

Determination of holometabolous immature or larval body plan by JH represents its morphogenetic action. The decision to develop larval characters during development is made near the end of each larval stage, when ecdysteroid levels increase to initiate the molt. Elevation of ecdysteroids causes a cessation of feeding and a new round of gene expression appropriate for the next stage of development. If JHs are present at this time, genes for larval characters are expressed whereas genes appropriate for pupal or adult characters are repressed. A primary larval character is the type of cuticle secreted by the epidermal cells. Larval cuticle is lighter and more flexible than pupal or adult cuticle, which are characteristics resulting from expression of larval cuticle protein genes that predominate under the influence of JHs. The flexibility of larval cuticle has to do with the absence of cross-linking between proteins and between proteins and chitin, the latter constituting the polysaccharide component of the cuticle. In contrast, pupal and adult cuticles are hard and dark, indicating a high degree of sclerotization and melanization.

Specification of pupal or adult features by JH, or lack thereof, is associated with transient, hormone-sensitive periods during development. It is important to note that the actions of JH depend not only on its presence in the blood, but also on the ability of cellular targets to respond. This latter condition presumably reflects the presence of suitable receptors required to mediate the action of the hormone. It has been observed in many studies that JH responsiveness occurs after priming, which could be associated with expression of receptor genes or other molecules necessary to complete the signaling pathway. For example, in moths, specification of a wandering period in preparation for pupation occurs upon the appearance of ecdysteroid peaks in the complete absence of JH. These “commitment” peaks of ecdysteroid prime the system to respond later in the same stage to elevated JH levels that occur in concert with ecdysteroids, which specify pupal features.

The morphogenetic actions of JH during juvenile stages have historically been inextricably linked with those of ecdysteroids. In this context, the role of JH is to ensure that ecdysteroids program larval phenotype. Nevertheless, JH appears to act alone in promoting the proliferation of imaginal disc tissues, while at the same time suppressing differentiation. The ability of discs to differentiate depends on exposure to ecdysteroids in the absence of JH, which occurs during the last larval instar. Furthermore, intriguing new findings by Truman and colleagues show that JH and nutrient-dependent signals, perhaps insulin-like hormones, regulate the growth and differentiation of imaginal disc primordia. In this way, JH helps to program proper scaling of tissues leading to normal-sized adults.

In many insects, considerable development of the gonads takes place during the larval stages. This is especially true for insects such as the silkworm, Bombyx mori, which does not feed during the adult stage. Within hours of emergence, these animals mate and lay eggs.
The ability to mate and produce viable eggs so soon after emergence means that gonadal development is well along during the larval and pupal stages. JHs promote the development of gonads and gametocytes during the immature stages, but must disappear in order for final developmental steps to be completed. This drop in JH levels just prior to the pupal stage therefore serves both morphogenetic and gonadotropic functions.

**Effects of JH in the Adult Stage**

The decrease in JH levels just prior to metamorphosis is only a temporary condition. The corpora allata are retained in the adult stage, and JH eventually reappears to regulate adult reproductive functions. JH promotes sperm and egg development and hence is said to have “gonadotropic” functions. In the female, JH directly promotes the synthesis of lipo- and glycoproteins in the fat body and their uptake into the developing oocyte. This process, called vitellogenesis, is a complex process of yolk deposition under the control of hormones and nuclear transcription factors. In many insects, JH levels rise and fall in a cyclic fashion as discrete batches of oocytes go through the vitellogenic process.

In other instances, as in some mosquitos, JH exposure leads to “competence” of the fat body to synthesize vitellogenic proteins upon later exposure to ecdysteroids. Likewise, JH exposure is required to induce competence of the ovaries to respond later to peptide hormones from the nervous system, thus stimulating uptake of vitellogenic proteins. In these instances, the gonadotropic actions of JH appear to be priming steps in preparation for ecdysteroid action.

Gonadotropic functions of JH in the male have to do with growth of the sperm. Sperm growth requires JH in many insects. However, maturation from spermatocytes to motile spermatozoa requires a drop in JH. Thus, as observed for oocyte development, JH exerts both positive and negative influences in sperm development.

**Polyphenism and Caste Determination**

Many insects have the remarkable ability to develop into alternate forms as they become adults. These alternate forms together with accompanying physiology and behavior, referred to as polyphenism, do not reflect differences in the genetic makeup of individuals. Rather, they result from a particular pattern of gene expression under hormonal control. Most polyphenisms are controlled by JHs acting at certain sensitive periods during immature development.

Some of the most common instances are caste polyphenisms observed in social insects such as bees, ants, and termites. In these insect societies, larvae can develop into workers, soldiers, or queens, depending on the diet they are raised on and the hormonal levels that result. If bee larvae are reared in a special cell in the hive and depending on the diet they are raised on and the hormonal levels in insect societies, larvae can develop into workers, soldiers, or queens, observed in social insects such as bees, ants, and termites. In these acting at certain sensitive periods during immature development.

In certain ants, development of queens is regulated during embryonic development by JH levels. During postembryonic development, larvae fed a high-protein diet produce large amounts of JH, bringing blood levels to a threshold necessary for specification of soldier phenotype. If larvae are fed a diet lower in protein, JH levels are correspondingly lower and development to worker is specified. The number of soldiers in the colony is also determined by a soldier-inhibiting pheromone, which elevates the JH threshold for soldier specification. Alternative body forms and behaviors in insect colonies provide for cooperative functions between members of the society to serve the greater whole.

Many types of phase polyphenisms occur in nonsocial insects. For example, locusts occur either in solitary or in migratory phases, depending on population density. Differences in both behavior and physiology are characteristic of these phases. Solitary locusts are sedentary, pale green, yellow, or brown, and have short wings and large ovaries. Crowding causes the switch to the gregarious phase, in which individuals are brightly colored, have longer wings and smaller ovaries, and are easily induced to engage in long flights. Both JH and peptide neurosecretory hormones from the brain are involved in the determination of these two phases.

Aphids exhibit at least two different types of phase polyphenism as a response to seasonal conditions: food quality and crowding. In one type, adults switch between winged or apterous (no wings) forms. The other type has to do with the mode of reproduction, either sexual or parthenogenetic. During the longer days of spring and summer, apterous, parthenogenetic females predominate, and JH is involved in specification of these forms. As winter approaches, winged forms are produced, allowing for dispersal. Later, in autumn, males and females mate and lay eggs, which overwinter and hatch in the spring. In this context, body forms and accompanying dispersal or migratory behaviors maximize survival as the season changes.

In summary, JH and other neurosecretory hormones are important determinants of polyphenisms, which result in different body forms, reproductive physiologies, and behaviors in the adult stage. It is emphasized that such variability of form and function is not the result of genetic differences between individuals, which would be classified as polymorphisms. Rather, insects have the enormous potential to change form in response to environmental conditions through hormonal control mechanisms. Depending on the needs of a social colony, or changes of season and in food availability, the complex endocrinology of insects enables them to assume various alter egos to enhance success and survival.

**Behavioral Effects of JH**

The presence or absence of JHs has profound effects on behavior, some of which have been mentioned in the preceding text. Throughout the stages of immature development, JHs program gene expression in the nervous system for the expression of behaviors appropriate for juvenile life, including, for example, locomotion, host or prey seeking, feeding, and silk spinning. From the point of view of behavior, the larva is an animal completely different from its later adult form.

In moths, the disappearance of JH at the end of the last instar allows ecdysteroids to program new behaviors appropriate for metamorphosis. Insects stop feeding, void their guts, and engage in wandering behaviors to locate a suitable pupation site. Once this is accomplished, a series of behaviors leads to silk spinning for cocoon construction.

Upon becoming adults, female mosquitos initiate the search for a blood meal and become sexually receptive to males only after release of JH into the blood. In milkweed bugs, JH levels are influenced by day length, temperature, and food quality. Under short day lengths, JH levels drop and insects engage in migratory behavior immediately after molting to the adult stage. However, long days and warm conditions lead to high JH levels, whereby flight is inhibited and reproduction ensues.

Grasshopper females that have had corpora allata removed rebuff male sexual advances until JH is reintroduced by injection.
Juvenile Hormones

In crickets, the male sings a species-specific calling song to attract the female for mating. The female responsiveness to this song is enhanced by elevated JH levels. These examples serve to illustrate the dramatic effects that JH has on the behavior of insects, effects that are specific and appropriate for each particular life stage.

Dormancy—Diapause

Insects are able to enter prolonged states of dormancy referred to as diapause, allowing them to survive freezing and low food supplies during the winter. Diapause can occur at any stage (egg, larva, pupa, or adult) and is triggered by decreasing day length, low temperatures, decreased food or food quality, or a combination of these factors. The insect response to these environmental factors is mediated by a variety of hormones, depending on the stage and species.

Adult diapause is largely synchronous with reproductive diapause. Beetles, butterflies, and flies enter a reproductive diapause when the brain inhibits synthesis of JHs by the corpora allata. The lack of JHs leads to both physiological and behavioral changes, including cessation of vitellogenesis, loss of flight muscle, increasing stores of lipid in the fat body, burying, and construction of hibernacula (over-wintering chambers). Implantation of corpora allata or injection of JHs reverses reproductive diapause.

JH involvement in larval diapause also has been documented. The southwestern corn borer Diatraea grandiosella enters diapause during the last instar when JH levels are depressed but are still high enough to inhibit development to the pupal stage. The animal spins a hibernaculum, exhibits a light pigmentation, and actually undergoes several "stationary" molts. Diapause in this stage lasts as long as JH levels remain elevated.

MOLECULAR BASIS OF ACTION

It is presumed that JHs exert their effects through receptor activation. Until recently it was a curious and surprising fact that, almost 70 years after the biological activity of JH was described by Wigglesworth, no definitive JH receptors had been identified. There are now tantalizing indications that candidate JH receptors are coming into greater focus. One of these involves a nuclear receptor called ultraspiracle, or USP, a protein that regulates gene expression by forming a dimer complex with ecdysteroid receptors. The complex then binds to regulatory sequences on genes to turn them on or off. Grace Jones and Alan Sharp have demonstrated that JHs bind specifically to USP, although the affinity for this binding is lower than is generally expected for hormone–receptor interactions. It is proposed that JH binding to USP may influence how it interacts with ecdysteroid receptors to regulate gene expression. The influence of JH and USP on EcR actions would seem to be a very plausible scenario for joint actions of JH and ecdysteroids, but further work is needed before USP can be confirmed as a JH receptor.

Although early accounts of JHs focused on their uniqueness with respect to insect biology, the elusiveness of JH receptors has prompted a closer look at possible similarities between signaling mechanisms common to insects and mammals. Indeed, the chemical structure of JHs resembles those of retinoids and farnesoids, both of which function in mammalian nuclear signaling by activating retinoic acid receptors, retinoid X receptors, and the farnesoid X receptor. JH and farnesoids are capable of activating some of these receptors, and some retinoids are known to have JH-like activity. It also has been observed that vertebrate thyroid hormones mimic some of the actions of JHs. Efforts are under way to identify receptors homologous to their mammalian counterparts as possible JH receptors.

Recently, promising new genetic approaches have been employed in searches for JH receptors. A strain of fruit flies has been identified that is resistant to the toxic actions of methoprene, an insecticidal JH analog (see next section for details). The resistant flies have a defect in a gene that encodes MET, a protein related to the vertebrate aryl hydrocarbon receptor (AHR), which, upon binding to a diverse range of hydrocarbons and xenobiotics, activates a battery of genes involved in their metabolism. If the MET protein has properties similar to AHR, this might help explain why many synthetic chemicals such as fenoxycarb and pyriproxifen have very potent JH-like effects, but bear little obvious structural similarity to natural JHs. Paradoxically, fly lines carrying the defective MET gene show no developmental problems, which would be expected if JH signaling is compromised. This has caused considerable doubt about the possible role of MET as a JH receptor. However, recent work by Marek Jindra and colleagues has shown that silencing of the MET ortholog in the red flour beetle, Tribolium castaneum, not only confers resistance to methoprene but also leads to developmental problems consistent with defects in JH signaling. Further work is needed to fully characterize this promising new candidate JH receptor.

JUVENILE HORMONES AND INSECT CONTROL

The discovery of JHs in the late 1960s by Röller and others stimulated a period of great excitement regarding the concept of third-generation pesticides foreseen by Carroll Williams in the early 1960s. It was known that JHs and related substances such as juvabione could disrupt insect development with lethal effects. Likewise, surgical removal of the corpora allata led to precocious metamorphosis, also with lethal effects. It therefore seemed that insect hormones or their analogs could be synthesized and used to accomplish a form of “birth control” for insects.

This idea occurred to Carl Djerassi and Alejandro Zaffaroni, two former colleagues at the Syntex Corporation, who were involved in synthesis of the progestin norethindrone that led to the oral contraceptives for humans. They formed a new company called Zoecon, a name chosen to denote “animal control” through the use of hormones and related chemical analogs. Their principal objective was to develop insect hormones for use as birth control agents specific for this group of animals. Chemists at Zoecon soon produced analogs of JH called “juvenoids” that were much more stable and could penetrate the cuticle. One of the first of these analogs to be granted a registration from the Environmental Protection Agency was methoprene (Fig. 3), a compound with outstanding biological activity against mosquitoes, fleas, and biting flies. By mimicking JH, methoprene prevents treated insects from completing metamorphosis, and insects die during the pupal stage. Other juvenoids such as hydroprene (Fig. 3) are more effective against insects with incomplete metamorphosis, such as cockroaches. Treated cockroaches actually reach the adult stage, but the presence of juvenoid during the transition to the adult results in only a partial adult phenotype in which many adult features are abnormal. For instance, the gonads are not fully developed, leading to sterility, and wrinkled wings are an obvious morphological defect.

Subsequent efforts by several agrochemical companies have generated a variety of juvenoids, many with potent JH-like biological activity but with aryl rings substituted for isoprenoid units and without obvious similarities to natural JHs. These include fenoxycarb and pyriproxifen (Fig. 3). Juvenoids have proved to be commercially successful for
insects that are pests in the adult stage. However, because they do not control insects in the immature stages, they have not proved useful for large-scale agricultural pest control. For this purpose, JH antagonists are needed for induction of precocious metamorphosis. So far, that goal remains as elusive as the search for the JH receptor.

Ladybugs
Michael E.N. Majerus
University of Cambridge

Ladybugs are one of the most familiar groups of insects. These beetles have received attention in both pure and applied areas of biological research. In some senses they are typical insects, having regular life cycles comprising egg, larval, pupal, and adult stages. However, close scrutiny of the behavior and habits of ladybugs has revealed a variety of fascinating evolutionary and ecological features, including color pattern polymorphism, extreme promiscuity, cannibalism, sexually transmitted diseases, and biased sex ratios, some of which seem to be contrary to theoretical expectation. Here the basic biology of ladybugs and some of these conundrums are considered. In addition, the roles of ladybugs as biocontrol agents are briefly discussed.

As a group, the ladybugs are the most popular of beetles. The bright colors of many species and their reputation of being beneficial, because many species eat plant pests, are at the root of this popularity. In many parts of the world ladybugs are named after religious figures and are revered, often being considered harbingers of good fortune. Indeed, the common English language name for this family of beetles derives from the Virgin Mary. Ladybirds are “Our Lady’s birds.”

DESCRIPTION

Ladybugs are beetles of the family Coccinellidae. This family consists of over 5000 described species of small- to medium-sized, oval, oblong oval, or hemispherical beetles. The dorsal surface is convex and the ventral surface is flat. The forewings, or elytra, are strong and are often brightly colored, sporting two or more strongly contrasting colors in a bold pattern. Not all species are red with black spots. Almost every color of the rainbow is found as the predominant color of some species of ladybug. These ground colors are usually allied to a second color, which differs starkly from the first, particularly with respect to tone. Thus, ladybugs may be red and black, or yellow and black, or black and white, or dark blue and orange, and so on. Sometimes the spots are replaced with stripes or a checkered pattern. The elytra cover the membranous flight wings, which are folded away when the beetle is not in flight.

THE LADYBUG LIFE CYCLE

Ladybugs through the Year

The life cycle of ladybugs has four stages: egg, larva, pupa, and adult. The length and timing of the different stages varies greatly with geographic region. Mating usually occurs when food is available, and eggs are laid in the vicinity of larval food. In contrast to many other insects, the two feeding stages (larvae and adults) usually have the same diet. In regions with winter and summer seasons, reproduction usually occurs in late spring and early summer. In some climates, reproduction can continue throughout the summer, with several generations being produced. However, in places with hot summers, some ladybugs have a dormant period (or estivation) in the hottest months, sometimes having a second period of reproduction in the fall. The winter is generally unfavorable for ladybug reproduction, and ladybugs usually pass the winter as dormant adults. In wet/dry seasonal climates, particularly in the tropics, many ladybugs are dormant through the dry season, beginning to reproduce at the start of the wet season when food becomes more readily available.

The rate of development of ladybugs, like that of other insects, depends largely on ambient temperature. In a species such as Adalia bipunctata in a temperate climate, the egg stage lasts from about 4 to 8 days; larvae feed for about 3 weeks. When they stop feeding, they form a humped prepupa and shed the final larval skin about 24 h later to produce a pupa that is attached to the substrate at its posterior. The pupal stage lasts 7–10 days. When the adult emerges, the elytra are pale yellow and unpatterned. Hemolymph is pumped into the elytra and flight wings to expand them, and the color patterns develop over the next day or two. Adult ladybugs live for up to a year.

The eggs of many species of ladybugs are bright yellow and are laid upright in batches (Fig. 1) in the vicinity of food. Newly hatched

larvae habitually eat any remaining eggs in their clutch and then disperse to find food. For many species, this food comprises small sapsucking insects such as aphids or coccids. However, some species feed on fungi, while others are true vegetarians, eating the foliage of plants. The larvae (Fig. 2) are usually elongate, and the ratio of leg length to body length is variable, being correlated to diet. The pupa (Fig. 3) is usually formed on the host plant. Both larvae and pupae may be brightly colored and patterned.

**LADYBUG COLOR PATTERNS**

**Warning Colors and Chemical Defense**

The bright, eye-catching color patterns of most ladybugs are their first line of defense against many predators. The bold markings of one bright color set on a background of another contrasting color provide a memorable image that warns potential predators that ladybugs have hidden defenses, being foul smelling and evil tasting.

The chemical defenses of ladybugs involve a range of chemicals: alkaloids, histamines, cardiac glucosides, quinolenes, and pyrazines, some of which are synthesized by the beetles while others are sequestered from food.

Anyone who has picked up a ladybug a little roughly will have noticed that they often secrete a yellow fluid. This behavior, called reflex bleeding, is part of their defense. The fluid is filtered hemolymph and is exuded through pores in the leg joint (Fig. 4), whence it runs along grooves to form small droplets at the edge of the pronotum and elytra. This “reflex blood” contains a cocktail of volatile chemicals that have a strong and acrid scent to deter naive predators.

Many species of ladybug share the same basic color combinations, red with black spots or yellow with black spots being the most common. From an evolutionary perspective, the similarities between many species are beneficial to all. The reasoning is simply that the more chemically defended species share the same color pattern, the
smaller the number of individuals of each species likely to be harmed by naive predators as the latter learn to associate a particular color pattern combination with unpalatability. This type of resemblance, involving a complex of species that resemble one another and are all unpalatable, is known as Müllerian mimicry.

Most of the generalist ladybugs have fairly simple patterns of just two strikingly different colors. However, some of the habitat specialists have more complex coloration. For example, some of the reed-bed specialists, such as *Anisosticta novemdecimpunctata*, have the ability to change color during their adult life. Through the fall and winter these ladybugs are beige with black spots and are well camouflaged between the old browning reed leaves where they overwinter. In spring, when the ladybugs move to new green reeds to feed and reproduce, their elytra become flushed with red pigment, thus giving the ladybugs a warning pattern. The conifer specialist, *Harmonia quadripunctata*, manages this trick of changing from a camouflage to a warning color pattern in another way. When active on pine needles, its streaked pink to red ground color with black spots is obviously a warning pattern. However, when resting, this ladybug habitually sits on the reddish pine buds where its color pattern acts very effectively as camouflage.

**Polymorphism**

Some ladybug species have variable color patterns, with distinct color forms occurring together as genetic polymorphisms. Thus, for example, in many parts of Asia several different forms of *Harmonia axyridis* can be found. The different forms are controlled genetically, with the inheritance of most depending on differences in just one gene. The existence of these genetic polymorphisms is surprising because the theory of warning coloration leads to the expectation that all members of the species will look the same. Considerable research time has been expended on this evolutionary conundrum, particularly in *A. bipunctata*, which has some forms that are mainly red with black spots and other forms that are black with red spots (Fig. 5). The factors implicated in the evolution and maintenance of the forms of this species include different levels of activity (black surfaces warm up more rapidly than red ones), sexual selection by female choice (some females have a genetic preference to mate with melanic rather than nonmelanic males), and different levels of unpalatability to different predators. A fully convincing explanation for these polymorphisms has yet to be found.

**FIGURE 5** Melanic and nonmelanic forms of *Adalia bipunctata*.

**REPRODUCTIVE BIOLOGY**

**Promiscuity**

The reproductive biology of ladybugs raises several evolutionary problems. Both male and female ladybugs are highly promiscuous. Theoretically, females that produce large and energetically expensive germ cells should mate only often enough to ensure high fertilization rates. This theoretical limitation reflects the energetic and temporal costs of copulation and the possibility of contracting sexually transmitted diseases. Yet females of *A. bipunctata* mate about 10 times as often as they need to fertilize all their eggs. Research suggests that this is an evolved response to high levels of genetic incompatibility between the eggs and sperm of many females and males. Females can store sperm from several males in their spermathecae. By mating promiscuously, females increase the probability that some of the sperm they are carrying are genetically compatible with their eggs.

**Female Mate Choice**

The study of the reproductive biology of ladybugs has an important place in evolutionary biology, for one of Darwin’s mechanisms of evolution was first demonstrated on a ladybug. In addition to natural selection, Darwin argued that some characteristics of some organisms were the result of sexual selection through either male competition or female choice of mates. That females may have a genetically controlled preference to mate with males of a particular genetic type was first demonstrated in *A. bipunctata*, over a hundred years after the theory was first proposed. In brief, it was shown that some females carry a single gene that is expressed as a preference to mate with melanic rather than nonmelanic males, irrespective of their own color. Subsequently, mating preferences were shown to exist in other species of ladybug.

**Apparent Waste of Sperm**

Male ladybugs also present some interesting problems. In a single copulation, for example, a male *A. bipunctata* can transfer to a female up to three sperm packages, or spermatophores. The spermatheca of a female can store about 18,000 sperm. An average spermatophore contains about 14,000 sperm. Therefore, a male that transfers three spermatophores passes more than twice the number of sperm a female can contain. This apparent waste is difficult to comprehend. Possibly by transferring an excess of sperm, the male is indulging in a coarse type of sperm competition, in which sperm in the female’s spermatheca from previous matings are flushed out.

**Consequences of Promiscuity: Sexually Transmitted Diseases**

Not only do both sexes of many species mate many times, but the duration of each copulation is considerable, lasting several hours in many species. This promiscuity has had one obvious consequence: some species of ladybug are infected by sexually transmitted diseases. Such diseases are generally rare in invertebrates, yet both sexually transmitted mites and fungi infect ladybugs. The mite *Coccipolipus hippodamiae*, which appears to specialize on ladybugs, lives under the elytra, with its mouthparts embedded into the elytra, from which it sucks hemolymph. Mite larvae emerging from eggs produced by the adult females move to the posterior end of their host before crossing onto a new host when the ladybug copulates. Female ladybirds are rendered effectively sterile about 3 weeks after becoming infected with this mite; infected females continue to lay
eggs, but the eggs fail to hatch. A sexually transmitted fungus (in the Laboulbeniales) also occurs but does not have any strong adverse effects on the ladybugs.

CANNIBALISM
Ladybugs indulge in cannibalism. Both adults and larvae will resort to eating conspecifics and sometimes other species, particularly when other food is scarce. The most vulnerable individuals are those that either are immobile (eggs, eclosing larvae, prepupae, pupae) or have a soft exoskeleton (recently eclosed larvae, newly formed pupae, newly emerged adults). Aphidophagous species tend to be more prone to cannibalism than those with other diets, largely because of the ephemeral nature of their prey and because they are more prone to large fluctuations in population density.

MALE-KILLING BACTERIA AND LADYBUG SEX RATIOS
The population sex ratio of the majority of sexually reproducing organisms is close to 1:1; selection will normally promote the production of the rarer sex, so that the stable strategy is for sex ratio equality. Female-biased sex ratios were first recorded in the ladybug *A. bipunctata* in the 1940s. Some females were found to produce only female offspring. The trait was inherited maternally. Subsequent research has shown that male embryos die in the egg as a result of the action of bacteria such as Wolbachia. These male-killing bacteria live in the cytoplasm of cells and are transmitted from infected mothers to their eggs. Although the bacteria in male eggs die when they kill their host, they benefit clonally identical copies of themselves in their host’s siblings, which consume the dead male eggs. The additional resources gained by these neonate female larvae increase their fitness and hence that of the bacteria that they carry. Bacteria of five different clades cause male-killing in ladybugs.

PEST CONTROL
The benefits of allowing ladybugs to eat plant pests have long been recognized. Their importance in controlling aphids on hops in England was noted as early as 1815. For over a hundred years, many attempts have been made to use ladybugs as biological control agents of plant pests such as aphids and coccids. The first reported attempt, and still one of the most successful, was the introduction into California of an Australian ladybug, *Rodolia cardinalis*, to control the cottony cushion scale, *Icerya purchasi*, in 1888/1889. This project, costing just $1500, saw an almost immediate return because of the ephemeral nature of their prey and because they are more prone to large fluctuations in population density.

**FIGURE 6** Intraguild predation: *H. axyridis* larvae eating a *Coccinella septempunctata* larva.
The term “larva” is currently used for all immatures that are not eggs, pupae, or adults. When larva is used in this comprehensive sense, the subcategories include exopterygote larva (for Hemimetabola, which have the wingpads developing externally) and endopterygote larva (for Holometabola, which have the wings developing internally as histoblasts in the larva, becoming external wingpads in the pupal stage).

Larvae occur in a great diversity of sizes, shapes, and colors. Colorful ones almost always live in exposed habitats where their colors and shapes offer cryptic concealment or where their bright colors and spines warn potential predators that they are not to be eaten. Larvae that live in concealed habitats are nearly always combinations of white, gray, black, or brown.

Instar has been conventionally defined as the stage the larva is in between molts. Stadium is defined as the interval of time between molts. Others contend that the instar is properly defined as the stage the larva is in between apolysis (separation of the old cuticle) and the molt to the next stage, and a pharate (next-stage) larva would be present before the next molt.

There are some general terms used for types of holometabolous larvae that have broad usage. Campodeiform larvae (Fig. 1) are somewhat flattened and have an elongate body, thoracic legs that are well developed, a head that is directed forward, no abdominal prolegs, and antennae and cerci that are usually conspicuous. This larval type is common in the Coleoptera (beetles), Megaloptera (dobsonflies and fishflies), Neuroptera (lacewings and antlions), and Raphidioptera (snakeflies).

Elateriform larvae (Fig. 2A) are somewhat similar to campodeiform larvae, but their body is more elongate, subcylindrical, and more heavily sclerotized. This type is common in the Elateridae (click beetles) and other Coleoptera.

Scarabaeiform larvae (Fig. 3) have a C-shaped, whitish body, a dark head, and well-developed thoracic legs. White grubs (Coleoptera: Scarabaeidae) are the best example.

Erichiform larvae are caterpillar-like and have a cylindrical body and well-developed thoracic legs, and prolegs are present. This type is common in the Lepidoptera (butterflies and moths), Mecoptera (scorpionflies), and Hymenoptera (sawflies only).
Vermiform larvae (Fig. 2B) are “wormlike.” This is an ill-defined term, but it is generally applied to an elongate, legless larva with or without a conspicuous head. Maggots (Fig. 4) are the larvae of higher Diptera. Their shape is peg-like and tapering toward the anterior end. They are legless, have a greatly reduced head (no head capsule), and have conspicuous mouthhook(s). The posterior end bears a pair of conspicuous spiracles.

Grub (Fig. 5) is an imprecise term that is often applied to “comma-shaped” larvae with or without legs or having greatly reduced legs. This term is commonly applied to weevil larvae and other Coleoptera larvae and to many larvae of the higher Hymenoptera (ants, bees, and wasps) that often have reduced or inconspicuous heads and appendages.

Learning
Daniel R. Papaj
University of Arizona

A butterfly learns to search for the shape of its preferred host plant’s leaves and, contemporaneously, for the color of preferred nectar sources. A parasitoid wasp learns color, pattern, and odor components of its insect host’s microhabitat. A grasshopper avoids feeding on a plant associated with a recent digestive malaise. An emerging adult paper wasp imprints on odor cues in its nest, using the odors to distinguish nestmates from nonnestmates. A male damselfly learns to recognize andromorphs (male-mimicking females) as females. A fly improves its depth perception with experience. A bee memorizes a sequence of visual landmarks between its nest and a patch of flowers, as well as the distance between landmarks. All of these are examples of learning, a phenomenon that is ubiquitous throughout the animal kingdom and, as these examples illustrate, well represented within insects. In fact, learning has been documented in all major insect orders. While best studied in the context of foraging for food or oviposition sites, evidence of learning has also been obtained in relation to water consumption, mate finding and choice, territoriality, predator avoidance, dispersal, migration, kin recognition, and thermoregulation.

Learning Characterized
Characteristics
Learning eludes an easy, satisfying definition, but the following characteristics constitute a useful guide. Learning involves an
enduring change in behavior with experience, the change usually progressing gradually with continued experience to some asymptote. Learned behavior is often modified by novel experiences, and effects of experience eventually wane if not reinforced.

**Associative vs. Nonassociative Learning**

Learning can be categorized as nonassociative or associative. Nonassociative learning includes habituation and sensitization. Habituation involves the waning of a response to a stimulus upon repeated presentation of that stimulus. Alternately, repeated presentation of a stimulus sometimes enhances a response to that stimulus and often to related stimuli, a process termed sensitization. Associative learning involves pairing a stimulus with another stimulus, or with a motor pattern, such that the response to the first stimulus is altered as a consequence of the pairing. Associative learning is typically evaluated in two kinds of paradigms: classical (Pavlovian) conditioning and instrumental conditioning.

**CLASSICAL AND INSTRUMENTAL CONDITIONING**

In classical conditioning, an unconditioned stimulus (US) that elicits an unconditioned response is paired in time and space with a novel stimulus, the conditioned stimulus (CS). As a consequence of the pairing, the CS subsequently elicits a conditioned response. Both appetitive and aversive forms of classical conditioning have been documented in insects. Most of what we know about classical conditioning in insects has involved classical conditioning of the proboscis extension reflex (PER), principally in honey bees.

A case for associative learning is strengthened by evidence of discrimination learning. Discrimination learning (sometimes called differential conditioning) controls for effects of sensitization to a CS by means of an operant conditioning paradigm called discrimination learning. If learning is associative, response to the CS and A only is heightened, relative to controls. Discrimination learning is well documented in bees, hymenopterous parasitoids, moths, butterflies, cockroaches, and fruit flies. A case for associative learning is similarly supported if learning is restricted to forward pairing. In forward pairing, the CS is presented shortly before the US, whereas, in backward pairing, the CS is presented shortly after the US. Insects, like vertebrates, show strong learning in forward-pairing regimes but little or no learning in backward-pairing or random-pairing regimes.

In instrumental conditioning (roughly equivalent to operant conditioning), presentation of a reinforcing stimulus is contingent upon the insect’s own motor actions. For example, an entirely novel motor pattern can be generated through a process of trial and error, as when a bee or butterfly learns how to extract nectar from a flower. A standard operant conditioning paradigm in the laboratory requires a tethered orthopteran to move its leg in response to an electric shock, heat, or access to food. A headless roach learns such a task, demonstrating that conditioning can occur at the level of ganglia.

Learning a given task in nature probably involves a combination of stimulus–stimulus and stimulus–response associations. When an insect pollinator learns nectar-extraction routines for different flowers, for example, it simultaneously learns identifying features of each type of flower, allowing the appropriate motor routine to be expressed on the appropriate flower.

**MISCELLANEOUS TYPES** Various forms of associative learning beyond the basic types have special meaning to students of learning. Food aversion learning, strongly implicated in work on vespid wasps, grasshoppers, mantids, and caterpillars, involves avoidance of food stimuli associated with a digestive malaise. Food aversion learning is noteworthy because an aversion can form even when a long period of time (hours) passes between ingestion of a food and the resulting illness.

Spatial learning is an important component of insect navigation. Commonly traversed routes are learned during homing by ants, bees, and wasps, and traplining is learned by bees and butterflies. Honey bees may additionally possess a topographically organized landscape memory that allows them to navigate along a novel route. Spatial learning is useful in contexts other than movement of the whole organism; for instance, bees learn to discriminate textures with their antennae and use such learning to evaluate the microtexture of flower petals.

One form of learning of significance in vertebrates that has not been documented to date in insects is observational learning, in which a subject imitates the motor actions of a demonstrator. Nevertheless, social interactions do influence what insects learn. Honey bees and bumble bees, for example, evaluate floral scents borne by returning foragers and forage selectively for those scents.

**LEARNING PROCESSES**

Many associative learning processes that have been described for vertebrates have also been shown in insects. The following list of selected processes is derived mainly from work on honey bees, unless otherwise noted.

Generalization refers to an animal’s tendency to respond to stimuli that were not reinforced but that are related to a reinforced stimulus (A+) along some perceptual dimension. Moths and honey bees have been shown to generalize odors according to similarities in functional groups and carbon-chain length.

Blocking occurs when an animal that first learns to respond to a stimulus (A+), and is then reinforced on A and a novel stimulus, B, presented together ([A+B]+), subsequently fails to show a heightened response to B alone, relative to controls. Learning of stimulus B has been blocked by coupling with the previously learned stimulus A. Blocking illustrates that temporal pairing between a CS and a US is not sufficient for associative learning to take place; rather, a new CS must convey new information in order to be learned. Where blocking is a robust phenomenon in vertebrates, studies of blocking in bees and fruit flies have yielded mixed results. Where blocking has been demonstrated, it seems to be restricted to intramodal stimuli (e.g., odor blocking in honey bees).

Overshadowing occurs when an animal reinforced on a compound of stimuli A and B ([AB]+) shows little response to B alone, relative to when reinforced on B alone (B+). As with blocking, overshadowing illustrates that temporal pairing between a CS and a US is not sufficient for associative learning to take place.

Sensory preconditioning occurs when an insect presented simultaneously with two stimuli in the absence of reinforcement ([AB]−), then reinforced on one stimulus (A+), subsequently shows a heightened response not only to A but also to B. During exposure to [AB], the insect learns that A and B belong together. Observed in Drosophila fruit flies and honey bees, sensory preconditioning illustrates that a stimulus does not have to be paired directly with a US in order for an association between the stimulus and the US to form.
Second-order conditioning refers to the capacity for a stimulus, once conditioned, to serve as a US in the conditioning of another stimulus. Second-order conditioning may play a major role in learning complex mixtures of stimuli, such as odor blends.

Patterning is evaluated by reinforcing two stimuli in turn (A +, then B+) and then explicitly not reinforcing a compound of those stimuli ([AB]−). Under this protocol, PER odor conditioning in bees shows “negative patterning,” responses being greater to individual odors than to the compound. This result can be explained only if the insect treats the compound [AB] as a unit and relates it to the absence of reinforcement. Such learning is referred to as configurational learning.

Rule extraction has been demonstrated with the use of delayed matching-to-sample tasks in which honey bees are required to respond to a stimulus that matches a sample stimulus recently experienced. Bees not only solve the task but also transfer the matching to stimuli not previously reinforced. For example, bees trained to match a color can subsequently match patterns of lines and, remarkably, bees trained to match an odor can subsequently match colors too. Such results have been interpreted to mean that insects can form a concept of “sameness.” When trained in a delayed non-matching-to-sample task in which they must choose the stimulus that does not match the sample, bees again perform well and make similar transfers, showing a grasp of a “difference” relation. Bees also learn to extract bilateral symmetry from a series of rewarded patterns and subsequently transfer that extraction to evaluation of novel patterns.

MEMORY

Associative memory in insects, as in vertebrates and other animals, is time-dependent and phasic. Recent work on fruit flies and honey bees suggests as many as five memory phases: (1) an early and (2) a late form of short-term memory [sSTM and lSTM], (3) a mid-term memory [MTM], and two forms of long-term memory (in honey bees, characterized as (4) an early form [eLTM] and (5) a late form [ILTM]; in Drosophila, characterized as (4) an anesthetic-resistant form and (5) a parallel, susceptible form). STM forms immediately upon association, is short-lived (seconds to minutes), and is relatively easily erased by conflicting information or treatment by cooling or shock. eSTM is characterized by a relatively nonspecific appetitive arousal and is highly susceptible to interference by new, conflicting information or by cooling. lSTM is more stable, is more specific, and takes longer to form than eSTM. The transition from STM to MTM after a single learning trial requires several minutes. MTM is more resistant to interference than STM, requiring hours to decay.

LTM takes longer still to form than either STM or MTM, involves longer lasting changes (hours to weeks), and is relatively resistant to interference. In bees, formation of LTM requires multiple learning trials. LTM is highly context-specific; landmarks learned by bees around their feeder, for example, may be entirely ignored when presented at a novel location. eLTM and ILTM have been distinguished in terms of the effects of inhibiting protein synthesis: synthesis inhibition after 24 h degrades memory, whereas inhibition after 3 days does not. Effects of inhibition depend on the time between learning trials, with closely spaced trials (termed “massed trials”) resulting in memory that is independent of protein synthesis.

The underlying processes involved in memory formation are beginning to be revealed. In honey bees, a “value” neuron, the VUMm, of the subesophageal ganglion, which fires in response to sucrose stimulation, is proposed to be part of the US pathway. In PER odor conditioning studies, artificial depolarization of the VUMm neuron just following presentation of an odor generates a conditioned response to the odor. The VUMm neuron, which uses octopamine as a neurotransmitter, converges on two brain neuropils, the antennal lobe and the mushroom bodies. Consistent with these observations, olfactory memories can be established by odor-coupled injection of octopamine into either the antennal lobe or the mushroom bodies. The pattern of octopamine effects suggests that antennal lobe processes may relate more to eSTM, whereas mushroom body processes may relate more to lSTM and LTM.

To what degree these findings pertain only to honey bees or only to odor learning is uncertain. Analysis of Drosophila mutants suggests that the mushroom bodies are important for odor learning but dispensable for visual or tactile learning. Studies of locusts have indicated effects of feeding experience on diet choice that resemble discrimination learning, but are based on an entirely novel mechanism. This taste-feedback mechanism involves adjustments in the level of sensitivity to nutrients in the hemolymph.

FUNCTION OF LEARNING

In a sense, the function of associative learning is obvious. Animals learn by association to orient toward stimuli predicting positively rewarding resources (such as sugar, pollen, food plant, hosts) and away from stimuli predicting negatively rewarding events (shock, heat, toxins, predators). Likewise, habituation is a means for reducing energy-wasteful, time-consuming responses to meaningless stimuli. In either case, however, learning is needed only if the appropriate responses cannot be predicted without benefit of experience, else an insect could respond (or not respond) innately. Even in an unpredictable environment, whether learning yields higher fitness than innate behavior depends on the relative costs of learning. A robust assessment of costs and benefits of learning has proved elusive, perhaps in part because individual fitness in nature is especially difficult to measure in Drosophila and honey bees, the systems in which learning processes and mechanisms have been best studied.

ADAPTATION, CONSTRAINT, AND LEARNING

Limits to Learning and Memory

Of interest to behavioral ecologists is the degree to which learned behavior reflects adaptation by natural selection versus constraints on selection. Generalization (see above), for example, may seem at first to reflect a constraint on learning, but conceivably represents an adaptive mechanism of imprecision. A pollinator, for example, that responded only to the precise odor blend emitted by the first rewarding flower encountered might never visit another flower, owing to among-flower variation in the blend.

A classic case study of limits on learning and memory in nature that interested Darwin himself concerns the tendency for bees, butterflies, and other pollinators to show greater fidelity to one or a few floral species than expected based on the profitabilities of those species. According to one point of view, this so-called floral constancy is dictated by limits on the acquisition, retention, and/or retrieval of stored information about the floral resource.

That foraging success in insects is limited in terms of acquisition and retention seems unlikely at the level of LTM. LTM in insects, as mentioned above, is extraordinarily durable and the amount of information that can be maintained in LTM, as currently understood, is extremely impressive. Butterflies can learn visual cues in two foraging modes (nectar collection and oviposition) simultaneously, showing meaningful responses in each instance in just a single trial. Bees can be trained to distinguish multiple rewarded stimuli from multiple...
unrewarded ones and to link features of eight or more different flower species to the time of day at which nectar is available. These features include flower color, odor, pattern, and microtexture. In addition, a bee learns the location, profitability, and visual landscape associated with a rewarding patch of flowers, as well as the route between hive and patch and, in conjunction with the sun compass used to navigate, even the pattern of movement of the sun through the sky.

Retention at the level of LTM is similarly impressive. Bees have been shown to retain LTM without reinforcement for several weeks, a period of time comparable to average worker life expectancy. In Tribolium beetles and Drosophila, there is evidence that memory formed in the larval stage persists through metamorphosis.

If pollinators are limited at all in memory, it may be at the level of STM. As noted above, STM is particularly vulnerable to conflicting information; this fact may make it difficult for a bee once fixed on a flower type to switch to a novel one. Alternatively, the key to floral constancy may lie in the retrieval of stored information, specifically a constraint on the minimum time required to activate information stored in LTM and a limited capacity to activate multiple memories at once (together, limits on what for vertebrates has been referred to as working memory).

Learning and Memory as Products of Adaptation

An alternative, albeit not mutually exclusive, view holds that natural selection generates an adaptive balance between activation and suppression of memory, tuning that balance finely to the specific ecological requirements of a given species. For example, floral constancy might conceivably permit workers in a colony to partition floral resources efficiently, in which case the properties of learning and memory that contribute to constancy would be viewed as adaptive. It has even been proposed that memory dynamics in bees are tightly matched to foraging activity rhythms as well as the spatial patterning of the floral resource.

Abundant propositions as to adaptive specialization in learning have been made, especially from a comparative standpoint: “Insects of a given species should be prepared to learn particularly well those stimuli relevant to that species’ needs.” “Social insects should learn better than solitary ones (owing to the demands of a complex and unpredictable social environment).” “Generalist insects should learn better than specialists.” For none of these propositions is there compelling evidence, nor will there be until better descriptions are made of learning in an ecological context, learning protocols are brought closer in rigor to those employed in comparative psychology, and more insect species are evaluated.

For now, the primary comparison to be made is a comparison between learning in insects and in vertebrates. Here, the pattern is one of shared features. Despite significant phylogenetic distance between insects and vertebrates, and despite substantial differences in their underlying physiology, there is a remarkable congruence in the diversity and form of learning processes in these taxa (see above). The similarities may reflect shared ancestry, evolutionary convergence, or both. A finding of evolutionary convergence would imply that certain universal, yet to be clearly defined functional principles govern the evolution of learning and memory processes.

Legs

Peter H. Adler
Clemson University

One of the most generally known and oft-repeated facts about insects is that they possess three pairs of legs, one pair each on the prothorax, mesothorax, and metathorax. Indeed, this condition is in the fundamental ground plan of insects and is amply represented in the fossil record. The condition inspired Latreille’s taxon Hexapoda (Greek hexa, six, and poda, foot). Exceptions to the hexapodous condition are found in the apodons, or legless, insects that have secondarily lost their legs, typically as a result of selection for an obligatory parasitic or sedentary existence.

The six-legged condition is derived from an ancestral arrangement in which legs occurred on each body segment and bore the same number of segments, each with an inner and outer articulated branch (endite and exite, respectively). Over more than 500 million years of evolution, the multibranched (multiramous), serially uniform legs became modified in the insectan lineage into the characteristic mouthparts, antennae, thoracic legs, and various abdominal appendages, such as genitalia and cerci, while usually becoming lost on other abdominal segments. Further evolution of the six-legged condition in the insectan lineage has resulted in an enormous diversity of structure and function. This structural and functional diversity of legs, along with evolution of the first pairs of exits into wings, without the loss of legs—a condition unique to insects—undoubtedly has been a key factor in the numerical success of insects and their representation in nearly every habitat on the planet. The exquisite diversity in leg structure plays an important role in the taxonomy and classification of insects.

STRUCTURE

In the classic textbook interpretation, the insectan leg has six well-sclerotized segments, arranged proximal to distal: the coxa, trochanter, femur, tibia, tarsus, and pretarsus. A more fundamental

Legs
and complete segmentation scheme, based largely on the work of Jarmila Kukalova-Peck and Edward L. Smith, involves 11 segments and facilitates the recognition of homologies in legs and leg-derived appendages (e.g., mouthparts and genitalia) among all arthropods. These segments include the epicnemial (present, e.g., as the wing articulation on the thorax of winged insects), subepicnemial (embedded in pleural membrane as the pleuron), coxa, trochanter, femur (typically fused either with the trochanter or femur), patella (fused with the tibia), tibia, basitarsus, eutarsus (often subdivided), and pretarsus. A more modern interpretation of the free thoracic leg of extant insects, beginning with the coxa, therefore, recognizes nine segments, which are the classic six, plus a femur, patella, and basitarsus, the latter three visible in only some taxa. The limb appendage of insects that is least changed from the ancestral arthropod condition is the maxilla of jumping bristletails (Archaeognatha), which retained 10 fully articulated segments, two endites, and two exites.

Each segment in the insectan leg, unless secondarily fused or lost, is independently moveable by muscles inserted on its base. Thus, subdivisions of the eutarsus, marked by flexible cuticle but without corresponding internal muscles, are not true segments; these subdivisions are referred to as tarsomeres. The areas of flexion between segments are joints, and the well-sclerotized contact points in the joints are the condyles. The various joints contribute to the mechanical efficiency of the leg. The articulation between the coxa and the body, for example, allows the leg to move forward and rearward, whereas that between the coxa and the trochanter allows the leg to be depressed at the beginning, and lifted at the end, of the backstroke.

Leg joints are of two types. Monocondylic joints have a single point of articulation, somewhat like a ball-and-socket joint, and usually are situated dorsally. They allow considerable freedom of movement and are characteristic of the legs of larval insects. Dicondylic joints have an anterior and a posterior condyle, or a dorsal and ventral condyle in the case of the trochantero-femoral joint. They typically limit movement to that of a hinge. Adult legs usually have dicondylic joints, although the tibiotarsal joint is often monocondylic.

The coxa (plural coxae) is typically short and stout. It is set in a coxal cavity and articulates with the thorax at the coxal process of the prosoma. Quite often, it also articulates with the thoracic trochanter and sternum, somewhat restricting its movement. To withstand the forces of movement, the coxa is strengthened by a ringlike basicostal sulcus that sets off a basal sclerite, the basicoxite. Internally, the basicostal sulcus is expressed as a ridge, the basicosta, that provides for muscle attachment. Posterior to the point of articulation, the basicoxite is called the meron and in insects such as adult Neuroptera and Lepidoptera, it can be quite large. In higher Diptera, the meron is detached from the coxa and forms a plate in the mesothoracic pleuron. In some insects, an additional external groove, the coxal sulcus, divides the coxa lengthwise.

The trochanter is small and freely moveable in a vertical direction on the coxa, but it is often more or less fused with the femur plus femur. In the larvae and adults of numerous fossil insects and in extant Odonata, the trochanter and femur are distinct segments.

The femur (plural femora) is usually the largest and strongest segment of the leg. It is typically fused to the femur in the legs of most winged insects, but in extant Hymenoptera, the two segments are separated by a deep groove. The size of the femur is related to the mass of the extensor muscles within it, varying from a small, thick segment in larval insects to an enormous segment in the hind leg of jumping Orthoptera. The femur often is equipped with spines and other cuticular modifications, especially in predatory insects.

The tibia (plural tibiae) usually is fused to the patella (plural patellae) and is typically long and slender in adult insects. In the legs of Odonata and Ephemeroptera, however, the patella is separated from the tibia by an oblique groove. Proximally, the patella is bent slightly toward the femur, allowing the shaft of the tibia to be flexed against the femur for more locomotory power in insects such as grasshoppers. The tibia often bears spines for grooming or for engaging the substrate to aid locomotion. Many insects also have apical or subapical movable spurs on their tibiae.

The tarsus (plural tarsi) is a fused, secondary segment in holometabolous larvae and primitive hexapods such as Protura and some Collembola. In collemboles, the tarsus and tibia are fused into a single tibiotarsus. In most insects, a separate segment, the basitarsus, is present and the eutarsus is subdivided into two or four tarsomeres. The ventral surface of the basitarsus and eutarsus often bears pads called tarsal pulvilli that aid movement on smooth surfaces and are especially well developed in some Orthoptera. Thus, the subdivided, flexible eutarsus, in combination with the sharp, curved claws of the pretarsus, superbly adapts insects for climbing. The basitarsus and eutarsus are well endowed with sensory hairs and chemoreceptors. The ventral surface often has a secretory epithelium that produces a wax, possibly for waterproofing, inhibiting the uptake of undesirable water-soluble compounds, or preventing entrapment in surface films.

The pretarsus, also called the acropod or posttarsus, arises from the distal end of the eutarsus. In the Protura, Collembola, and larvae of many holometabolous insects, the pretarsus is a simple, claw-like segment. Typically, however, the pretarsus of insects bears a pair of hollow claws (ungues) and various sclerites and lobes. A sclerotized, basal unguitaractor plate articulates with the eutarsus into which the plate is partly invaginated. The muscles that flex the claws are inserted on a process of this plate. The claws articulate with the unguifer, a median process at the distal end of the eutarsus. A saclike, hollow lobe, the arolium, arises between the claws. In adult Diptera, other than crane flies, an arolium is absent. Instead, a padlike lobe called the pulvillus (plural pulvilli) arises from an auxiliary plate (auxilia) beneath the base of each claw, while an unpaired, lobelike or bristlelike process, the empodium, stems medially from the unguitaractor plate. The pretarsal pads and lobes have adhesive setae (tenent hairs) that allow the insect to climb and hold onto smooth surfaces.

Variation in structure, and hence function, can be found among the three pairs of legs within an individual, as well as between larvae and adults, between males and females, and among taxa. The thoracic legs of many larval insects are serially uniform or sometimes lacking. The legs of adults often vary in structure among the three pairs, although even adults of some insects (e.g., some male Coccidae, Psychidae, and Strepsiptera) are devoid of legs. The variation among the three pairs of legs in adults often is associated with acquisition of food, courtship, and mating. Among the hemimetabolous groups, many Hemiptera–Heteroptera recover a tarsomere in the final molt.

Sexual dimorphism in leg structure is prevalent. The reduced forelegs of nymphaid butterflies have short tarsomeres in females but lack all segments beyond the tibia in males. The forelegs of male Ephemeroptera are typically elongated and used to grasp the female. The slender, elongate legs of crane flies are even longer in males than in females for species in which a guarding male stands over the female during oviposition (Fig. 1); in some crane flies the distalmost tarsomere is prehensile in males and used for holding females. The hind femora of the males of many Coreidae are enlarged for intrasexual fighting. The pulvilli beneath the claws of some flies, such as Tachinidae, are considerably larger in males than in females.
FUNCTION

The majority of insectan legs are either elongate, slender, and designed for walking and climbing or cursorial, that is, adapted for running, as in the cockroach (Fig. 2A). During walking, the legs form alternating triangles of support, with the fore and hind legs of one side and the middle leg of the opposite side contacting the substrate as the other three legs move forward. Various modifications allow the legs to be used in other forms of locomotion. Enlarged hind legs of many Orthoptera, fleas, and other insects are saltatorial, meaning they are designed for jumping. The jump of insects such as fleas is aided by a rubberlike protein called resilin in the cuticle that stores and subsequently releases energy for the jump. Powerful, spadelike forelegs of mole crickets, scarab beetles, burrowing mayflies, and other insects are fossorial, or adapted for digging and rapid burrowing (Fig. 2B). Flattened, fringed legs of aquatic insects such as dytiscid and gyrinid beetles and notonectid backswimmers serve as oars for paddling or swimming (natatorial legs), while long legs with hydrophobic tarsal hairs and antitepalic claws, as in water striders (Gerridae), are for skating on the surface of water. The legs of some insects, although well developed, have lost their locomotory function. The spiny legs of Odonata, for example, are designed for perching or seizing and holding prey captured while the dragonfly is in flight; the legs are ineffectual for walking.

Although typically regarded as agents of locomotion, the legs also have assumed additional, or altogether different, functions. Often, function can be inferred from structure; for example, the thickened, spinose legs of many insects signify a predacious mode of life. Raptorial legs (Fig. 3A), that is, those designed to seize prey, have arisen independently in many insectan lineages. Any of the three pairs of thoracic legs can be raptorial, but the trait is most often expressed in the forelegs (e.g., in Mantodea and Reduviidae) and less frequently in the middle legs (e.g., in some Empididae) and hind legs (e.g., in some Mecoptera).

Legs also play a defensive role, aiding escape by running, jumping, burrowing, and swimming, as well as by kicking and slashing. The spines on the legs of many insects deter predators and competitors and can inflict considerable damage. Insects such as stink bugs and treehoppers deliver powerful kicks at parasitoids and predators that attempt to attack their young. Autotomy, or the loss of legs at predetermined points of weakness, often at the level of the trochanter, occurs in insects such as crane flies, leaving a predator with only a leg in its clutches as the insect escapes. Legs, whether lost through autotomy or accident, can be regenerated to various degrees in some insects, most famously in walking sticks, if one or more molts follow the amputation.

All legs are equipped with an extensive arrangement of sensory structures that allow the insect to feel, hear, and taste. Chemoreceptors, which are especially prevalent on the basitarsus and eutarsus, provide sensory input on environmental substances and can be used to determine the acceptability of food, ovipositional substrates, and perhaps mates. Mechanoreceptors, most often in the form of hair organs, but also campaniform, chordotonal, and plate organs, provide sensory information on position, movement, and vibrations borne by air and substrate.

In many insects, the legs are used in sound production. Familiar examples include the shorthorned grasshoppers, which have a stridulatory mechanism on the hind femur, involving a series of pegs—the scraper—that is rubbed across a ridged wing vein. Some larval hydropsychid caddisflies have a scraper on the prothoracic femur that is rubbed against a file on the venter of the head. Legs also can be used to produce sound for intraspecific communication by drumming them against a substrate, as in some Orthoptera.

**FIGURE 1** Long legs allow male crane flies (*Dactylolabis montana*) to stand guard over ovipositing females they have recently inseminated. [Illustration from Adler and Adler (1991) with kind permission of Springer Science and Business Media.]

**FIGURE 2** (A) Cursorial foreleg of the Madeira cockroach (*Leucophaea maderae*). (Illustration by T. S. Vshivkova.) (B) Fossorial foreleg of the northern mole cricket (*Neocurtilla hexadactyla*). (Illustration by T. S. Vshivkova.)
To maintain hygiene, insects spend considerable time grooming their body and appendages. Grooming typically is effected by various leg structures, such as cuticular combs (ctenidia), setal brushes, grooves, and notches. The cleaning setae on the foretibia of certain heteropterans are mirror images of the arrangement of antennal setae. The hind leg of honey bees is specially modified to groom pollen from the plumose hairs of the body (Fig. 3B). Combs on the inner surface of the hind basitarsus remove the pollen from the body hairs and pass it to the pollen press between the tibia and the basitarsus. Closure of the press forces the pollen into the pollen basket (corbicula), which is housed in the enlarged tibia. Flies that feed on the blood of birds typically have a thumblike lobe at the base of each of their talonlike claws that helps them grasp feather barbules. Grasping is common during mating, and especially the males of many insects have legs designed to secure and hold their mates. Adhesion to objects such as mates and prey can be achieved with suction disks on the legs. Male dytiscid beetles have a flattened, dislikelike arrangement on each foreleg that is formed of the basitarsus and the succeeding two tarsomeres; all three structures bear minute suction cups ventrally that can be applied to the elytra of the female.

The colors and patterns of legs vary from subtle to stark, although their function is often poorly understood. Long-legged insects such as certain crane flies (Ptychopteridae) and some mosquitoes have banded legs that might render the insect less conspicuous through disruptive coloration. Other configurations of pattern and color play a role in camouflage, courtship, and mimicry. In flies such as some Syrphidae and Micropezidae, the forelegs resemble the antennae of aculeate Hymenoptera, reinforcing the remarkable overall resemblance of fly to wasp. Other functions ascribed to legs are often highly specialized. In the Embidina, the basitarsus of each foreleg houses multiple silk glands, and each gland is connected to a seta with an apical pore through which the silk is extruded. The inflated basitarsus of each leg in phantom crane flies contains a tracheal sac, aiding buoyancy during the driftlike flight. Some flies have specialized areas on their legs, particularly on the tibia, that possibly produce pheromones. Insects such as Chironomidae seem to use the legs much as a second set of antennae. In Protura, which lack antennae, the forelegs probably have assumed an antennal (i.e., sensory) function.

Further Reading

Moths and butterflies make up the order Lepidoptera, and they are among the most familiar and easily recognized insects. The Lepidoptera is defined as a monophyletic lineage by a suite of more than 20 derived features, the most obvious of which are the scales and proboscis. The scales are modified, flattened hairs that cover the body and wings, shingle-like, and are the source of the extraordinary variety of color patterns typical of these insects. In all but the most primitive forms, feeding by adults is accomplished by pumping in liquid via a tubular proboscis (haustellum), which usually is elongate and coiled under the head. The sister group of Lepidoptera, the Trichoptera (caddisflies), lack this development of mouthparts and the covering of scales and possess caudal cerci on the abdomen, which are not present in Lepidoptera.

Like other holometabolous insects, lepidopterans pass through egg, larval, pupal, and adult stages. Mating and egg deposition are carried out by the adult moths and butterflies. Within the eggs, embryos develop to fully formed larvae. The larvae, commonly called caterpillars, feed and grow, which is accomplished by a series of stages (instars). At maturity they transform to pupae, usually within silken cocoons spun by the larvae, although many species pupate without a cocoon. Metamorphosis to the adult occurs during the pupal stage, and the fully developed adult breaks the pupal shell to emerge. Adults of most species feed, but they do not grow. Diapause, an arrested state of development, may occur in any of these stages, prolonging life and enabling the insect to bypass seasons that are unsuitable for growth and reproduction.

The Lepidoptera is one of the two or three largest orders of insects, with an estimated 160,000 named species. Based on specimens in collections and extrapolating from recent studies of Central American moths, we believe that fewer than one-half of the known species have been named by taxonomists; even in North America, an estimated one-third of the fauna is undescribed. Thus, a realistic projection of the total world Lepidoptera species number is not possible, but certainly it exceeds 350,000 and may be much larger. Much of this diversity can be attributed to the radiation of species in association with flowering plants. Lepidoptera represent the single most diverse lineage of organisms to have evolved primarily dependent upon angiosperm plants, and their numbers exceed those of the other major plant-feeding insects, Heteroptera, Homoptera, and Coleoptera (Chrysomeloidea and Curculionoidea). Figure 1 depicts the hypothesized evolutionary lineages and lists currently recognized superfamilies of Lepidoptera.

**MORPHOLOGY**

**Adult**

The body framework (Fig. 2) consists of a hardened (sclerotized) exoskeleton made up of a head capsule with appendages; three fused thoracic segments, each with legs, and two pairs of wings, on the middle (mesothoracic) and third (metathoracic) segments; and an abdomen, which has 10 segments, is less sclerotized than the thorax, and is movable by intersegmental membranes. Complex genital structures of external origin arise from abdominal segments A8–10, and often there are accessory structures (pouches, glands, hair brushes) associated with sound reception, courtship, or other functions.
HEAD Structures include paired simple eyes (ocelli) and scaleless, raised spots (chaetosema), which are unique to Lepidoptera, although one or both are lost in many taxa (Figs. 2–4). There is enormous variation in the form of the antennae, often between the sexes of a species, being filiform or with the flagellar segments variously enlarged or branched. Antennae of butterflies are enlarged distally, forming apical clubs, while those of moths are not, although some moths have distally enlarged antennae that are tapered or hooked to the tip. The mouthparts of the most primitive moth families retain functional mandibles as in their mecopteroid ancestors, but in the majority of moths the mandibles are lost, and the maxillary galeae are elongate and joined to form a tubular proboscis (haustellum) with musculature that enables it to be coiled under the head when not being used to suck nectar from flowers or other fluids into the digestive tract by a pumping action. The maxillary palpi consist of one to five segments and in primitive moths are conspicuous, often folded. The labial palpi are more prominent in most Lepidoptera and vary in curvature and length, but they are not folded.

THORAX The pro-, meso-, and metathorax are fused, each consisting of a series of nonmovable sclerites (Fig. 2). In primitive groups the meso- and metathorax and their wings are similar in size, but in derived families the mesothorax is larger and has more powerful musculature, and the forewing has more rigid vein structure, especially on the leading edge. In the largest superfamily, Noctuoidea, the metathorax is modified posteriorly into a pair of tympanal organs. The tibia of the foreleg has an articulated epiphysis on the inner surface, a uniquely derived feature in Lepidoptera, usually with a comb of stout setae, that is used to clean the antennae and proboscis by drawing them through the gap between the comb and the tibia. The wings are tiny and soft at eclosion from the pupa, then rapidly expand by circulation of blood pumped into the flaccid veins, causing them to extend, stretching the wing membranes to full size, after which they rapidly harden, with the membranes pressed closely together, and the system of tubular veins provides structure. Homologies of the six vein systems are discernible across all families of Lepidoptera, and the configuration of veins has been used extensively in classification. In the most primitive moths the forewing (FW) and hind wing (HW) are similar in shape and wing venation (homoneurous) (Fig. 5), while the more derived groups have lost parts of the vein systems and have fewer remaining in the HW than in the FW (heteroneurous) (Fig. 6). There are various wing-coupling mechanisms by which the FW and HW are linked to facilitate flight. Primitive homoneurous moths have an enlarged lobe at the base of the FW (jugum) that folds under the HW when the insect is at rest but extends over the HW in flight, which does not couple the wings efficiently. Most moths have the HW frenulum that hooks under the FW retinaculum, the development of which varies among taxa and between the sexes of many species.
In a few groups (e.g., Psychidae, Lymantriidae) females of many species are flightless, having very reduced wings (brachypterous), or are apterous and may not even shed the pupal skin. Brachyptery has evolved many times independently, such as in high montane and winter-active species of various families in Europe, North America, and Australia. Both sexes are flightless in species of several families on remote southern oceanic islands and in one species of Scythrididae that occurs only on windswept coastal sand dunes in California.

**ABDOMEN** The abdomen has segments A7–10 or A8–10 modified to form external parts of the genitalia; the sternum of A1 in homoneurous families is small and is lost in other Lepidoptera. Articulation of the thorax and abdomen in derived families is accomplished by musculature attached to sclerotized struts (apodemes) that project from abdominal sternite 2. There are paired tympanal organs at the base of the abdomen in Pyraloidea and Geometroidea. Various male glandular organs associated with courtship occur on the abdomen in several families. Usually these are developed as expandable hair brushes or tufts, or as thin-walled, eversible sacs (coremata), from the intersegmental membrane at the base of the genitalia or on other segments.

The genitalia of Lepidoptera are highly complex and provide the basis for taxonomic species discrimination in most families and often generic or family-defining characteristics. In the male (Fig. 7) the valvae, which are thought to provide clasping stability during mating, usually are large, more or less covering the other structures in repose, and usually are densely setate on the inner surface, scaled exteriorly, and the most visible part of the genitalia externally. The phallus, which is separately articulated and passes through the dia-phragma, is sclerotized and contains the membranous vesica, the intromittent organ. The vesica often is armed with cornuti, which sometimes are deciduous and deposited in the female. Sperm are transported from the corpus bursae through the ductus seminalis to the bulla seminalis and ultimately to the oviduct. The musculature that controls the ovipositor and papillae anales, often involving extension and telescoping the abdomen, as well as the copulatory aperture, is inserted on the posterior and anterior apophyses.

**INTERNAL ANATOMY** Lepidoptera possess the same fundamental internal systems for breathing, blood circulation, digestion, excretion, central nerves, and endocrine functions as do other holometabolous insects (see Diptera, Coleoptera, Hymenoptera, Neuroptera articles).

**Egg**

With few exceptions, female Lepidoptera produce eggs that are deposited externally after fertilization in the oviduct (Figs. 9 and 10). Moth and butterfly eggs vary enormously in size, shape, surface sculpture, and arrangement during oviposition. Within lineages such as families, larger species produce larger eggs, but depending upon the family, the sizes and numbers differ greatly. For example, females of heptalids, including some of the largest moths in the world, produce vast numbers of tiny eggs (20,000–30,000 or more by
a single female) that are broadcast in the habitat. Conversely some small moths and butterflies produce few, relatively large eggs.

The shell (chorion) is soft during development and quickly hardens after oviposition, assuming a regular form consistent for the species and often characteristic for genera or families. The chorion may be smooth or strengthened by raised longitudinal ribs or transverse ridges or both. At one end there is a tiny pore (micropyle), through which the sperm enters, surrounded by a rosette of radiating lines or ridges. Two types of egg form are defined, those laid horizontally, with the micropyle at one end, which are usually more or less flat, and those that are upright, with the micropyle at the top. Flat eggs are prevalent in the more ancestral lineages, microlepidoptera, while most derived groups, larger moths and butterflies, have upright eggs with more rigid and ornamented chorion. Eggs of either type are laid singly or in groups; flat eggs are sometimes deposited shingle-like, with the micropylar ends protruding partway over the preceding row (Fig. 9), while upright eggs are arranged side by side, like rows of miniature barrels (Fig. 10). Usually the eggs are glued to the substrate by a secretion of the female accessory (colleterial) glands, applied within the oviduct, sometimes forming a thick, paint-like covering to egg masses. Eggs may be covered with debris collected by the female or hairs or scales from her abdomen or wings or may be surrounded by fences of upright scales, but lepidopteran eggs are not tended or guarded by the adults.

Embryonic development is related to temperature, proceeding more rapidly under warmer conditions, but the rate is physiologically and hormonally controlled in many instances. It requires 7–14 days in most Lepidoptera but may be delayed for many weeks or months in species that overwinter in the egg stage.

**Larva**

The head (Figs. 12 and 14) is sclerotized, usually rounded (flattened in leaf-mining species, Fig. 11), with large lateral lobes, each bearing an ellipse of usually six simple eyes (stemmata) ventrolaterally...
and systematically arranged primary setae and are joined by a median suture, which is flanked by two narrow adfrontal sclerites. The mouthparts may be directed downward (hypognathous) or forward (prognathous). The labium is weak but carries a spinneret behind the mouthparts ventrally, which distributes the silk produced by modified salivary glands. The thorax has spiracles on the meso- and metathoracic segments, except in some aquatic pyraloids that have external gills. The abdomen usually has spiracles on segments A1–8, restricted to segments A1–3 or absent in some aquatic pyraloids. There are paired, ventral, fleshy, and nonsegmented leglike organs on all segments in the most primitive moths, while on others they are restricted to segments A3–6 (ventral prolegs) and 10 (anal prolegs), equipped with circles or bands of tiny hooks (crotchets) that aid in grasping and walking. The prolegs are fewer in Geometridae (Fig. 13) and some other groups and are lost in some borers (e.g., Prodoxidae), leaf miners (e.g., Eriocraniidae, Nepticulidae), and sand-dwelling larvae (a few Noctuidae). In some groups, A10 has a musculated anal fork used to flip frass away from the larval shelter.

There are sensory setae on the head and body integument, and the homology of their primary arrangements (chaetotaxy) (Fig. 15) can be compared in all but the few most primitive families. Their patterns have been valuable to understanding evolutionary trends and to identification of larvae, although the primary arrangement is lost or replaced by numerous secondary setae in many taxa, at least in later instars. The adfrontal sutures, arrangement of stemmata, and crotchet-bearing abdominal prolegs distinguish Lepidoptera from other insect larvae.

Pupa

The head, thorax, and abdomen of the pupa resemble those of the adult and can be recognized externally (Fig. 16). The mandibles of the most primitive families are functional and used to cut open the cocoon preceding eclosion of the adult. In other moths the head is sometimes provided with a beak or other armature that assists in the eclosion process. The appendages of the head and thorax are each encased in cuticle and in most Lepidoptera are fused to the venter of the body, with the wing cases wrapped around, adjacent to the antennae and mouthparts. Abdominal segments A7–10 are fused. In the more ancestral families some of the other segments are movable (Fig. 16A), usually provided with backwardly directed spines or spurs, and the pupa wriggles forward to protrude from the cocoon or burrow just before moth eclosion. Gelechioidea and derived moths (Obectomera, Fig. 1) and butterflies are obect, with fused abdominal segments (Fig. 16B and 16C). They remain in place, and adult eclosion occurs along a silken track or other means prepared by the larva or directly from the pupa, in butterflies and some moth groups that do not spin cocoons. Many species have a cremaster, a hook setae at the tip of the abdomen that anchor the pupa inside the cocoon or at the terminus of a silk emergence track, enabling pressure from the emerging adult to break the pupal shell. Others lack the cremaster but are held within a tight cocoon, in an earthen cell, or by a silk girdle. The integument is soft, smooth, and green or whitish when first formed but soon hardens and turns brown in most Lepidoptera. Those that pupate exposed, including butterflies, Pierophoridae, and some Gelechioidea, are mottled green or brownish and often have prominent spines or ridges that aid in camouflage.

**FIGURE 16** Pupae of ditrysian moths, ventral aspect. (A) Tortricidae, with abdominal segments A4–7 movable, enabling pupal movement forward at emergence. (B) Ethmiidae, with pupal movement restricted to flexible segments A5–6, and the pupa remains in place at emergence, a characteristic of Gelechioidea. BIOLOGY

Success of Lepidoptera populations is dependent upon several factors in the climatic and biotic environment, interrelated with the insects’ behavior. First, larval foods, and for most species adult nourishment, must be available. Climatic conditions suitable for mating and oviposition, larval feeding, and pupation are necessary. Females must find appropriate places for deposition of eggs. Larvae must sense proper foods, eat, molt, grow, and pupate. Pupae need to avoid desiccation and other factors that might prevent successful adult eclosion. Finally, egg, larval, and pupal parasites and predators have to combine to take all but two of the offspring of each female (whose eggs may number 200–600 or more) that survive physical dangers, but on average they cannot exceed that, in order to maintain stable population levels.

Adult Behavior

Males usually begin emergence and peak in numbers a few days ahead of females. Both are sexually mature upon eclosion, and males of nearly all moths are attracted by chemical signals (pheromones) emitted by “calling” females. Hence, in most Lepidoptera mating takes place soon after female eclosion, and she has mature eggs ready to be fertilized and deposited within the first 24 h. Mate seeking involves primarily visual cues in most butterflies, although there may be short-range pheromones produced by one or both sexes that mitigate courtship. Males, and females too in most species, mate more than once. It is assumed that sperm precedence prevails, wherein the most recent male’s sperm is effective.

Adults of both sexes of most Lepidoptera feed and in confinement die quickly if water is not available. Feeding on honey-enriched fluids extends the life of some moths and increases fecundity. Most macromoths and butterflies feed at flowers, imbibing nectar, whereas most microsotis do not and apparently gain nourishment from extrafloral nectaries, sap flows, and honeydew secreted by aphids or other Homoptera. Exceptions occur in diurnal microlepidoptera (e.g., Adelidae, Sesidae, Heliodinidae, Scythrididae, Plutellidae, and Tortricidae, but not nocturnal species of the latter three families), which visit flowers, often other than the larval hosts. The mouthparts are nonfunctional in a few families (e.g., Lasiocampidae, Lymantriidae) and in specialized species such as winter-active Geometridae and Ethmiidae, and females possess mature eggs upon eclosion.

Host-plant selection is made primarily by the female, which seeks by chemical and tactile cues the proper substrate or habitat for oviposition. This choice is made by instinct, inherited genetically, and the newly hatched larvae also require specific stimuli, detected by chemoreceptors on the antennae and mouthparts; in host-specific species, they starve if the proper plant is not available, ignoring plants or synthetic diets that are quite acceptable and sufficient for nourishment of generalist species.

Most butterflies and moths live only a few days, until mating and egg laying are accomplished, but some are active for several weeks, or they may overwinter as adults and become active on warm days. Some adult microlepidoptera enter a prereproductive state lasting through summer and winter, followed by mating and oviposition in early spring.

Larval Development

The newly formed larva, or caterpillar, first bites its way out of the eggshell, leaving a crescentic slit or ragged hole at the micropylar end. Some species then eat the reminder of the eggshell. All growth
takes place during the larval stages, so caterpillars consume enough nutrients to carry through cocoon formation, pupation, and metamorphosis to the adult. It must be sufficient for the moth or butterfly to move to its first feeding or, in species with nonfeeding adults, enough to provide for complete egg development of the next generation. To accommodate growth, the larva molts its skin (cuticle) several times, through successively larger stages (instars). Most Lepidoptera undergo five or six instars, but many larvae that feed on detritus or dry plant material undergo indeterminate numbers of instars.

Silk is produced by paired labial glands. It is composed of two proteins secreted in a viscous fluid in two strands, which consolidate as they leave the spinneret and contact the air. Its functions are many: first instars of many species are dispersed by air currents on silk strands; many or most species lay down a silk line as they move, enabling them to cling to substrates; silk is used by most external-feeding micromoths to form shelters in foliage or other food sources, and some construct portable cases from which they feed; others line tunnels with silk in fruits, stems, roots, or soil from which they forage to feed. Finally, silk is used in cocoon formation preceding pupation, within the larval shelter or gallery or separately, sometimes as a characteristically shaped structure.

Larval habits vary widely and often are quite specific for a family, genus, or species. These include leaf mining, in which a larva spends its entire life within a leaf, and the depth and form of the mines are consistent such that the moth family or genus often is recognizable from the mine (Figs. 17–22). Other types of internal feeding include stem mining; boring in seeds, stems, and roots (Figs. 25 and 26); or feeding in galls developed by plants, stimulated by the larvae (Figs. 27 and 28). Many external-feeding caterpillars avoid adverse conditions by seeking shelter in leaf litter at the base of the plant or in tunnels during the day and emerge at night to feed, when temperatures are cooler, humidity is higher, and diurnal predators are not active. Many macro moth and butterfly larvae remain exposed, motionless, protected by cryptic coloration, body form, and behavior (Figs. 29–32), or even camouflaged by a coat of flower bits or debris that collect on hooked body setae. Larvae of a few genera live gregariously in silken tents that shield them from climatic extremes (Fig. 33). Many others are protected from vertebrate predators by toxic chemicals they sequester, and advertise their presence by bright colors (aposematic) (Fig. 34).

The duration of larval development varies greatly with the feeding and life cycle types, even within families and genera. The time required to reach maturity also is dependent upon temperature within species, such as between seasonal generations. Most Lepidoptera grow slowly in early instars, increasing in size much more rapidly in later instars, particularly the last. Growth after eclosion from the egg to maturity usually takes 30–50 days, but sometimes is more rapid, as few as 18 or 19 days. Larval life can extend much longer, particularly in species that enter quiescent phases at lower temperatures, intermittently feeding when warmer, or in detritus feeders, which can simply wait long periods when food

is not suitable. Such species may live 100–140 days before pupation, and those that enter obligate diapause, usually as first or last instar, typically spend 9 or 10 months as inactive larvae in addition to their feeding and growth period.

Larval Foods

The nutritional requirements of many caterpillars are generally similar. Synthetic diets that contain the same basic elements, casein, sucrose, salt, cellulose, wheat acids, and vitamins, incorporated in an agar base, are successfully used for rearing many species (Pterophoridae, Lasiocampidae, Psychidae, Xylorictidae), mosses (some Crambidae), or ferns (unrelated species, mainly on oceanic islands). A few Lepidoptera are predaceous on scale insects or other Homoptera or in ant nests. A Hawaiian geometrid moth (*Eupithecia*) is predaceous on adult flies, which it catches by seizing the fly with elongate prolegs. Other members of the worldwide genus *Eupithecia* are plant feeders.

Virtually every kind of flowering plant is eaten by one or more species of caterpillar. Food preferences vary enormously among families; they are summarized in the accounts of the major families that follow. Nearly all internal feeders, such as leafminers, stem and root borers, and gall inducers, and most other microlepidoptera are specialists on a few related plants, whereas perhaps half or more of external-feeding macromoth species are generalists within habitats, such as ground-dwelling cutworms feeding on low-growing herbaceous plants or shrub- and tree-feeding species. Most butterfly species are specialists.

Pupal Development

The duration of pupation during which metamorphosis to the adult occurs varies with temperature, usually requiring about 10–12 days, but many species require several weeks or hibernate as pupae, often for 10 months or more.

Pupal movement is an important adaptation in primitive moths and basal Dityrysia. The pupa moves forward just preceding adult eclosion and either anchors by the cremaster to silk or wedges in the emergence aperture, which is prepared by the larva to be slightly narrower than the pupal abdomen. This movement is aided by rows of dorsal, backwardly projecting spines. Gelechioidea and the Ob lectomera (Figs. 1, 16B, 16C) have independently derived fusion of abdominal segments that restricts movement, enabling turning within the cocoon but not forward movement, and the adult emerges directly from the pupation site. Pupae respond to tactile stimuli, including potential predators and probing by a parasitoid wasp ovipositor, by turning or wriggling. Some moth pupae have special structures on the abdomen that produce clicking or rattling sounds when the wriggling abdomen strikes the walls of the pupal cells or parchment-like cocoon, or sounds are produced by rubbing fine pegs or rasp-like surfaces on adjacent segments. Such sounds may aid in pupal defense.

Life Cycle

Most Lepidoptera in temperate climates undergo a single annual generation (univoltine), although many have two discrete seasonal broods (bivoltine), and some produce continuous generations as long as favorable temperature conditions prevail (multivoltine). Diapause, a state of arrested development regulated by hormones, controls the life-cycle pattern and enables populations to survive during unfavorable times (winter, dry season, etc.) when necessary resources are not available. Diapause may be the single most important adaptation leading to species radiation of Lepidoptera in northern climates and high mountains, in the world’s deserts and tropical dry season habitats, and in other places where insects could not grow and reproduce continuously. In Lepidoptera, diapause occurs primarily in fungi (Polyporaceae) or are detritivores on the ground, under bark of dead tree limbs, or in abandoned insect and spider nests or feed on animal products in mammal burrows, bird nests, or scats, and a few can digest wool. Many species feed on fallen leaves, notably Oecophoridae and Tortricidae on *Eucalyptus* (Myrtaceae) in Australia, and several groups of Noctuidae in wet forest habitats. Some Lepidoptera specialize on lichens (lithosine Arctiidae, some Psychidae and Xylorictidae), mosses (some Crambidae), or ferns (unrelated species, mainly on oceanic islands). A few Lepidoptera are predaceous on scale insects or other Homoptera or in ant nests. A Hawaiian geometrid moth (*Eupithecia*) is predaceous on adult flies, which it catches by seizing the fly with elongate prolegs. Other members of the worldwide genus *Eupithecia* are plant feeders.
eggs, in first or last instars, in pupae, or as a reproductive delay in adults, depending on the species. In Mediterranean climates, larval feeding typically occurs in spring when foliation peaks, and diapause lasts through the dry season in summer and hibernation in winter. Some species estivate in diapause as prepupal larvae or pupae, fly in autumn, and then hibernate as adults or eggs. Multivoltine species enter diapause at the end of the growing season, often triggered by decreasing day length, or the larvae simply wait in a quiescent state, feeding slowly on warm days through winter, and metamorphose, and adults eclose with warmer temperature in spring.

Most tropical Lepidoptera are too poorly documented to estimate the proportion of multivoltine to other life-cycle patterns. Some species migrate from wet regions to dry forest habitats at the beginning of the rainy season to take advantage of the newly available resources, but others undergo diapause through the dry season.

Many Lepidoptera are capable of maintaining the diapause to a second or later season if appropriate climatic conditions do not occur. This happens as a regular phenomenon in species adapted to seed feeding on plants with biennial crops such as conifers or sporadically in species that depend upon resources that are limited to a specific season but are erratic in abundance, such as flowering and fruiting by desert plants. Numerous prepupal larvae of yucca moths specific season but are erratic in abundance, such as flowering and fruiting by desert plants. Numerous prepupal larvae of yucca moths specific season but are erratic in abundance, such as flowering and fruiting by desert plants.

**SIGNIFICANCE IN NATURAL AND HUMAN COMMUNITIES**

The major role of Lepidoptera in natural communities is primary consumer of plants. Moths and butterflies make up the largest single evolutionary lineage adapted to depend upon living plants, in terms of species numbers and, in many communities, in biomass as well. Females of most species produce 200–600 eggs within a few days, vastly more in some species (1000–30,000), releasing a potentially enormous load of caterpillars onto particular plant species or plant groups such as herbs or woody shrubs and trees. Therefore, an important food resource is available for specialized parasitoid wasps and flies, general invertebrate predators such as spiders, mites, ants, and social wasps, and vertebrate predators, especially birds. There have been estimates of 80,000 caterpillars of several species feeding on a single oak tree and many times that number during outbreaks of single species that defoliate forest trees. Thus caterpillars comprise a major component of biological communities, affecting foraging by birds, buildup of yellow jacket colonies, and insect disease epidemics. A secondary role as decomposers also is filled by Lepidoptera. Tineidae, several groups of Gelechioidae (particularly Oecophoridae in Australia), and some Noctuidae and other moths are detritivores and assist in reducing fallen leaves and fruit, fungi, and animal products (hair, feathers, predator scats) to humus. Finally, a few species are secondary consumers, predaceous on scale insects or other Homoptera in natural communities.

Lepidoptera larvae damage plants grown for human use (food, lumber, cotton, garden ornamentals) and our stored products (grain, flour, nuts, woolen clothes and carpets). Most agricultural damage occurs because monoculture crops are grown in places distant from the natural enemies of the pest species, which themselves usually have been introduced by human activities to a new region. Wide-scale insecticide suppression of pest species has further increased problems because local parasites and invertebrate predators are eliminated, and the pest species become resistant to the insecticides by selection for survivors of repeated treatments. Similarly, pests of stored food and wool products have been transported worldwide by human activities. Lepidoptera probably are the most important insect group as plant defoliators (e.g., spruce budworm, the economically most important insect in Canada; larch budworm in Europe) and they cause huge losses by damage to fruits (e.g., codling moth, the “worm” in apples), corn (corn earworm, European corn borer), potatoes (potato tuberworm), cotton (pink bollworm), and many other crops and garden plants. They are a major problem in stored meal, grain, and nuts (Angoumois grain moth, Indian meal moth, Mediterranean flour moth) and woolen products (casemaking clothes moth, webbing clothes moth, tapestry moth, and others). Still others infest bee nests, eating the combs (greater and lesser wax moths).

Conversely, some moths are believed to play significant roles in pollination in natural communities, especially Sphingidae and Noctuidae, and they may aid in crop pollination in some instances. Several Lepidoptera have been purposefully introduced to act as biological control agents against noxious plants. Notable examples include a pyralid, the cactus moth, from Argentina used to successfully suppress millions of acres of introduced prickly pear cactus in Australia; an arctiid, the cinnabar moth from Europe, on tansy ragwort in the Pacific states of North America; and several Mexican species against lantana in Hawaii.

**FOSSIL RECORD AND EVOLUTION**

A widely accepted phylogenetic hypothesis of relationships among lepidopteran evolutionary lineages, based on morphological characteristics in living forms, primarily of the adults, is shown in Fig. 1. The problem in such analysis is that we do not know what kinds of species might have preceded and interceded with the primitive extant lineages, each of which is now represented by one or a few relict genera that have divergent larval features not shared with other Lepidoptera. Moreover, the fossil record is of little use in revealing clues to “missing links,” and the preservation usually fails to provide information on critical characteristics, particularly those of the larvae and pupae.

**Fossil Record**

There are fossils of Triassic age assigned to Trichoptera (caddis-flies), the presumed sister group of Lepidoptera, and so branching of the two lineages could have occurred in the early Mesozoic (Fig. 35). The earliest fossil recognized as lepidopteran is a small-scaled wing from the Lower Jurassic of Dorset, England. It was placed in a separate family, Archaeolepidae, suggested as a sister group to the Micropterigidae, but without characters known that might establish its relationships. Four genera were described from Upper Jurassic tuffs from Russia. Among these, two were assigned to Micropterigidae and two to Glossata and Ditrysia, but only one of them, Protolepis, possesses visible mouthpart structures. They were interpreted as a siphon formed of maxillary galeae, which would imply existence of Glossata, 20–30 mya, prior to the radiation of angiosperm plants during the early Cretaceous. That interpretation has been questioned, the structures possibly being maxillary palpi, and therefore the fossil may represent an extinct lineage of Aglossata. By the early Cretaceous there are well preserved Micropterigidae and an incurvariid (Heteroneura) in amber, and by the late Cretaceous several kinds of leaf mines representing modern families and host-plant associations, both heteroneuran (Nepticulidae) and ditrysian (Phyllonorycteridae, Gracillariidae), as well as a ditrysian larval head capsule of a free-living form such as Tineidae. That is,
the fundamental clades of Lepidoptera are all represented before the beginning of the Tertiary. Hence, although Lepidoptera is the most recently evolved major insect order, its radiation was relatively rapid, paralleling that of the angiosperms, the major lineages having evolved between ca. 140 and 90 mya.

**Ecological Scenario**

Questions remain concerning the origins of angiosperm feeding in basal lepidopteran lineages that led to major radiations of Lepidoptera. The ground-dwelling larvae of Micropterigidae are generalists, either detritivores or fungivores in leaf litter or feeding on low-growing green plants in moist habitats, including bryophytes and soft angiosperm leaves. Similar habits occur in Exoporia (Mnesarchaeidae and Hepialidae: The ovis- pore and gonopore are separate, connected by an external groove for sperm transfer; the larvae have differentiated prolegs on abdominal segments A3–6 and A10, with circles of crotchets; and silk is used for various activities, not just cocoon formation, the ancestral condition in Lepidoptera. Functional pupal mandibles are lost and there is no piercing ovipositor. Differentiated size, shape, and venation between fore- and hind wings appear in the Heteroneura. The thoracic legs, crotchett-bearing larval prolegs, and silk webbing are lost by larvae of Nepticuloidae, which are severely modified for leaf mining. An independently derived piercing ovipositor occurs in Incurvarioida, some of which have secondarily legless larvae.

The last fundamental change, leading to the Ditrysia, is the internal system for storage and transfer of sperm from the gonopore to oviduct. Evidently this had evolved by the mid-Cretaceous, when larval mines of Gracillarioidea appear in the fossil record. The most successful lineages, in terms of extant diversity, Pyraloidea, Geometroidea, and Noctuoidea, which are defined by independently derived tympanic organs, presumably originated coincident with radiation of the bats during the late Paleocene and early Eocene. The earliest butterfly fossils also date from late Paleocene–Eocene times.

**Morphological Evolution**

Major changes in morphological adaptation in adult feeding, oviposition mode, wing structure, and larval locomotion are indicated by Figs. 1 and 35. The relict moths of ancient lineages (Micropterigidae, Agathiphagidae, Heterobathmiidae) share features of ancestral mecopteroids, functional mandibles in adults and pupae, similar fore- and hind wings with complete venation, and a single female genital aperture. However, larvae of their extant species differ greatly from one another, each adapted for a particular lifestyle. Micropterigid larvae are free-living ground dwellers in moist environments, with well-developed thoracic legs, no crotchett-bearing abdominal prolegs, and fluid-filled chambers in the cuticle. Agathiphagids are legless borers in primitive gymnosperm seeds with reduced head sclerotization and sutures and few stemmata. Heterobathmiids are flattened leafminers of southern beech, having a prognathous head with prominent adfrontal ridges, as well as seven stemmata laterally and thoracic legs with large, subdivided trochanters (unique in Lepidoptera), but no abdominal prolegs.

Adult Glossata (Eriocraniidae and all subsequent lineages) lack functional mandibles and feed by a proboscis formed of the maxillary galeae. Basal glosstalian lineages have a piercing ovipositor and retain functional mandibles in the pupa, used to cut the cocoon at eclosion. The larvae have a spinneret. Several derived features occur beginning with the Exoporia (Mnesarchaeidae and Hepialidae): The ovis- pore and gonopore are separate, connected by an external groove for sperm transfer; the larvae have differentiated prolegs on abdominal segments A3–6 and A10, with circles of crotchets; and silk is used for various activities, not just cocoon formation, the ancestral condition in Lepidoptera. Functional pupal mandibles are lost and there is no piercing ovipositor. Differentiated size, shape, and venation between fore- and hind wings appear in the Heteroneura. The thoracic legs, crotchett-bearing larval prolegs, and silk webbing are lost by larvae of Nepticuloidae, which are severely modified for leaf mining. An independently derived piercing ovipositor occurs in Incurvarioida, some of which have secondarily legless larvae.

The last fundamental change, leading to the Ditrysia, is the internal system for storage and transfer of sperm from the gonopore to oviduct. Evidently this had evolved by the mid-Cretaceous, when larval mines of Gracillarioidea appear in the fossil record. The most successful lineages, in terms of extant diversity, Pyraloidea, Geometroidea, and Noctuoidea, which are defined by independently derived tympanic organs, presumably originated coincident with radiation of the bats during the late Paleocene and early Eocene. The earliest butterfly fossils also date from late Paleocene–Eocene times.
Repeated shifts to angiosperm feeding (Fig. 36) may have been fac-
least twice) and endophagous larval feeding accompanied by numer-
scenario, there were independent origins of a piercing ovipositor (at
ultative, as it is in extant micropterigids, and multiple adaptations to
be postulated for exoporians and again for Tineidae. In either sce-
there were independent origins of a piercing ovipositor (at

tative, as it is in extant micropterigids, and multiple adaptations to
endophagy imply parallel evolutionary trends, a more parsimonious
be postulated for exoporians and again for Tineidae. In either sce-
there were independent origins of a piercing ovipositor (at

one evolutionary lineage, or clade, the Ditrysia. In

classified as relict, morphologically dissimilar groups. All the
more derived moths and butterflies, more than 98% of the described
species, comprise one evolutionary lineage, or clade, the Ditrysia. In
recent decades, much progress has been made in detailed analyses of
the relationships of the primitive groups, aided by discoveries of new
taxa and previously unknown larvae and pupae. Phylogenetic analy-
ses have shown the primitive lineages to be paraphyletic with respect
to the rest of the Lepidoptera (Fig. 1), and consequently, the use of
suborders and other ranks between order and superfamy has been
abandoned by lepidopterists. In contrast, we continue to recognize
the obligate categories (family, genus, species) for purposes of names
and communication across related lineages. Historically, the family
has been the common denominator level for communication among
entomologists, including for Lepidoptera, but in recent decades
there has been a proliferation of both family and superfamy divi-
sions such that the superfamy has become a commonly used and
understood rank for lepidopterists. Recent authors have treated
more than 120 families of Lepidoptera, and there is considerable dis-
crepancy between analyses within some of the 45–48 superfamilies.
Morphological and biological traits of the larger, worldwide super-
families and families are summarized in the text that follows.

** Primitive Lineages **

** ZEUGLOPTERA—MICROPTERIGOIDEA ** Micropterig-
gi dae are the most primitive lepidopterans, living fossils. There are
micropterigids recognizable as modern genera preserved in amber
dating back to dinosaur times in the early Cretaceous (125 mya).
Adults (Fig. 37) are small (FW length 3–6 mm), often colorful, with
metallic sheens of bronze or purple and yellow forewing markings,
usually active in the daytime. They are characterized by numer-
ous ancestral traits not shared by other moths, most notably reten-
tion of functional mandibles, which are used to feed on pollen of
various trees in Europe, more primitive plants, sedges, Winteraceae,
and fern spores in New Caledonia and Madagascar. A more complete,
Mecoptera-like wing venation led to proposal of this group as a
separate order, the Zeugloptera, but overall evidence indicates the
combined Zeugloptera + other Lepidoptera as a sister group to the
caddisflies (Trichoptera). The larvae are wholly unlike caterpillars of
other Lepidoptera; they are plump, somewhat hexagonal in cross sec-
tion, with long antennae and short thoracic legs, and they lack the
abdominal prolegs with crotchets typical of most Lepidoptera. The
larvae live in moist leaf litter among mosses or in rotting wood, habi-
tats with high moisture conditions; the cuticle has specializations
unique among arthropods, with exo- and endocuticle separated by
a fluid-filled space leading via pores to chambers in the exocuticle,
overlaid by sticky pellicle to which particles of debris adhere. The
pattern of primary setae on the body is unlike that of other moth lar-
vae. Larvae of some species feed on liverworts, but most micropterig-
ids are generalists, feeding on detritus, fungal hyphae, or angiosperm
leaves. About 120 species are known worldwide, in a disjunct, relict-
ual distribution pattern. More than half the named species are in the
genus *Micropteryx* in the Palearctic region, while only 2 are known in
North America ( *Epinaurtinaria* ); there is a greater diversity of genera
in the Orient and southwest Pacific, particularly New Zealand, eastern
Australia, and New Caledonia, which has about 50 species.

There are two other families of Aglossata: the Agathiphagidae
(two species), caddisfly-like moths whose larvae are legless borers in
the seed of primitive gymnosperms ( *Agathis* ) in Australia and south
Pacific Islands, and Heterobathmiidae (nine species), which are simi-
lar moths to micropterigids but their larvae are leafminers in south-
ern beech (Notofagus) in Chile and Argentina.

** GLOSSATA—HOMONEURA ** The majority of Lepidoptera
comprise the Glossata, the monophyly of which is well supported
by a suite of derived characters. The most obvious traits that distin-
guish glossatans are the adult mouthparts: the mandibles are non-
functional and maxillary galeae elongated, forming a proboscis that is
cooled in repose, accompanied by reduction of the head capsule and
its cuticular thickening associated with mandibular musculature.
The basal lineages retain ancestral features of the wings: similarly shaped
fore- and hind wings with relatively complete venation (homoneur-
onous) and the jugal lobe at the base of the forewing. Females in these
families have a flattened, sclerotized abdominal apex with serrate
edges, forming a “saw,” which is everted to cut into host-plant leaves
to deposit the eggs.
FIGURES 37–64  Adults and larvae of microlepidoptera. Micropterigoidea: (37) Epinartyria pardella (Micropterigidae) (California). Incurvarioidea: (38) C. arbutiella (Heliozelidae) ovipositing into leaf of A. menziesii (California); (39) Adela septentrionella (Adeliidae) ovipositing into buds of Holodiscus discolor (California); (40) Greta reticulata (Prodoxidae), ovipositing into bud of Sanicula (California); (41) Tegeticula maculata (Prodoxidae) ovipositing into ovary of Yucca whipplei (California). Tineoidea: (42) Tinea pellionella (Tineidae) (Texas); (43) Larval cases of T. pellionella on wool fabric (Texas). Gracillarioidea: (44) Caloptilia reticulata (Gracillariidae) (California). Yponomeutoidea: (45) Atteva punctella (Yponomeutidae) nectaring (Illinois); (46) Ypsolopha maculatella (Plutellidae) nectaring at flower of Asteraceae, whereas the larval host is Ephedra (California). Gelechioidea: (47) Anteostricha species (Stenomatidae) (Illinois); (48) Ethmia arctostaphylella (Ethmiidae), bird dropping-like resting posture on Eriodictyon, the larval host (California); (49) Larva of Ethmia deiliiella (Ethmiidae), which feeds on Cordia (Costa Rica); (50) Arottrara longissina (Scythrididae) nectaring at flowers of Senecio, whereas the larval host is Lycium (California); (51) Esperia sulphurella (Oecophoridae, Oecophorinae) (California); (52) Callimima lophoptera (Oecophorinae) (Australia); (53) Coleophora species (Coleophorinae) (California); (54) Holcocera species (Blastobasidae) (California); (55) Telphusa latifasciella (Gelechiidae) (Illinois). Choreutoidea: (56) Tebenna gemmula (Choreutidae) nectaring at flowers of Achillea, whereas the larval host is Wpethia (California). Sesioidea: (57) S. sequoiae (Sesiidae) (California); (58) Castnia species (Castniidae) (French Guiana). Cossoidea: (59) Acossus species (Cossoidea) (California). Tortricoidea: (60) Argyrotaenia citrina (Tortricidae, Tortricinae) (California); (61) Synnoma lynosyrana (Tortricidae, Tortricinae), flightless female in calling posture on Chrysanthemum, the larval host plant (California); (62) Pseudatetria leopardana (Tortricidae, Chiladonitidae), a diurnal and presumed distasteful species (Costa Rica). Alucitoidae: (63) Alucita species (Alucitidae) (Colorado). Pterophoroidea: (64) Platypsyllinae species (Pterophoridae) (Costa Rica). (Photographs by: I. Common, 52; C. Covell, 58; R. Coville, 45, 47, 51, 53, 55, 56, 57, 60, 64; H. Daly, 50; J. Hafernik, 42, 43, 59; P. Opler, 62, 63; J. Powell, 38, 39, 40, 41, 44, 46, 48, 49, 61; D. Wagner, 37.)
Eriocranioida Eriocraniidae form a Holarctic counterpart to the South American Heterobathmiidae, resembling them superficially as adults and larvae, mining primarily in birch and oak (Fagales) in early spring. Adults are small moths (FW length 4–6.5 mm) with relatively narrow wings covered by iridescent, simple scales and hairs, often golden with purplish markings. Most are diurnal and fly in early spring just as the host trees are beginning to leaf out. The larvae are legless miners in newly expanded leaves, forming “baggvay” full-depth mines. They mature quickly and enter the soil for pupation, and the mines dry and deteriorate after the leaf hardens. The pupae are mandibulate, and the emerging pharate adult uses the mandibles to cut through the cocoon and reach the soil surface the following spring. Larval foods are birch (Betulaceae), oak (Fagaceae), and other Fagales, or Rosaceae (1 species). There are about 20 species assigned to 5 genera, with about half the species in Europe and Asia and half in North America.

A related family, Acanthopteroctetidae, with two species in the western United States, formerly was included in the Eriocranioida, has been given superfamily status based on its more derived type of scales and first thoracic spiracle. The larvae of one species are miners in Rhamnaceae.

EXOPORIA Within the homoneurous Glossata, two superfamilies comprise the Exoporia, the Mnesarchaeoidea (15 species), a relict group of small, eriocraniid-like moths in New Zealand, and the worldwide Hepialoidea. Monophyly of the two is established by the unique configuration of the female genital system, which is shared by and interpreted as homologous in these otherwise quite dissimilar moths. The copulatory orifice is separate from the ovipore, but there is no internal connection between the two. Sperm is transferred via a groove in the body wall below the ovipore.

Hepialoidea The Hepialoidea is the most successful of the Homoneura and more primitive lineages in terms of extant diversity. The superfamily is characterized by having reduced mouthparts, with the proboscis absent or short and evidently nonfunctional. Hepialidae are large moths, even enormous in some genera, well represented on all nonpolar continents. Four other hephialid families, Anomosetidae, Neotheoridae, Palaeosetidae, and Prototheoridae, are Southern Hemisphere relicts represented by one to a few species and are smaller moths.

Adults of the Hepialidae are large to very large (FW 10–120 mm), including some of the largest Lepidoptera in the world, Trichophasius in South America and Zelotypia in Australia, with a 10-in. wing span, and often beautifully colored in greens and pinks. The females carry enormous numbers of eggs—one female of Trictena in Australia laid 29,000 eggs and had another 15,000 in her ovaries when dissected—and therefore are bulky, heavy-bodied creatures, surpassing in weight the largest sphingid and saturniid moths. Hepialid males form groups, or leks, that fly together at dusk, as a ritual of courtship behavior; especially suggestive of the common name “ghost moths” is one European species that has white forewings and forms ghostlike clouds. The larvae are elongate, cylindrical, with fully developed thoracic legs and abdominal prolegs that bear rings of crochets. They have primary setae distributed in patterns that are homologous with those of ditrysian larvae, and they lack secondary setae. Hepialid larvae are concealed feeders, living in silken galleries in leaf litter and grasslands, in tunnels in roots or trunks, feeding indiscriminately on pteridophyte, gymnosperm, or angiosperm plants. Early instars of some species feed on decaying wood and fungi associated with it, and then bore into tree trunks in later instars. There are about 550 named species in 50+ genera worldwide, best developed in Australia and Africa.

HETERONEURA—MONOTRYSIA All the remaining Lepidoptera have different fore- and hind wing shapes and venation, with reduced radial system in the hind wing, and the hind wing usually is smaller. They possess a frenulum–retinaculum wing-coupling mechanism, and they have lost the first abdominal sternite. The five most basal superfamilies of the Heteroneura retain the ancestral monotelic female reproductive system, but they share no derived characteristics that would unite them as monophyletic. The three most diverse of these are Nepticuloidea, Incurvarioida, and Tischerioidea.

Nepticuloidea These are tiny moths whose larvae are leaf and stem miners. Specialization on diverse flowering plants has led this group to become the most speciose of the primitive Lepidoptera.

Nepticulidae Adult nepticulids include the smallest Lepidoptera (FW length 1.5–4.5 mm), characterized by having the basal antennal segment (scape) usually greatly enlarged, forming a cap over the upper half of the relatively large eye. The head is rough-scaled, and the mouthparts are primitive, with long, folded maxillary palpi, and rudimentary proboscis with galeae not joined, used to lap up moisture and honeydew secreted by aphids. The FW is relatively broad with long scale fringes. The larvae are legless, obligate leafminers, typically forming a serpentine track beginning just below the egg cemented to the leaf surface, gradually enlarging to a full-depth tube or irregular blotch (Fig. 17). At maturity the larvae cuts a crescentic slit in the upper cuticle and drops to the ground to form a tough silken cocoon. Larval foods usually are mature leaves of woody plants, although a few larvae mine stems or cause petiole galls. Individual species are specialists, using more than 40 families of angiosperms, primarily Fagaceae and Rosaceae in the Holarctic; some species groups are specialists on one plant family, such as Anacardiaceae, Polygonaceae, or Fabaceae. There are nearly 800 described species, placed in 11 genera, occurring in all nonpolar regions. No accurate estimate is available, but the total named includes fewer than 10% of the species in tropical regions and probably less than half the North American species.

A related family, Opostegidae (100+ species), are slightly larger moths (FW 1.8–8.3 mm), with enormous eye caps, completely obscuring the eyes from a frontal view. The FW is relatively broad, white with sparse black markings, and the apexes often are strongly bent upward. The larvae are leafminers in Rutaceae and cambium miners in stems and fruit of Betulaceae, Rhamnaceae, Polygonaceae, Saxifragaceae in the Holarctic, and Fagaceae in Chile.

Tischerioidea Tischeriidae adults are very small (FW 2.7–5.5 mm), with lanceolate wings of white, gray, or yellow. They are nocturnal with large eyes and when at rest they perch with the head appressed to the substrate and tail end lifted at a 45° angle. The larvae are slightly flattened leafminers with thoracic legs reduced to two vestigial segments or ambulatory calli, abdominal prolegs rudimentary with crochets (Fig. 11). The linear or blotch mines are characterized by a heavily silk-lined nest within which the larva retreats when not feeding; the mines have been recorded from nine angiosperm families, most commonly Fagaceae, Rosaceae, and Asteraceae, more diverse on the last than is true of other lepidopterous miners. This group is primarily Holarctic, with about 80 described species in one genus, a few of which are in the Neotropical, Ethiopian, and Indo-Malayan regions, none in Australia and Oceania.
Incurvarioida  These are tiny to small moths having diverse biologies, but females all have a piercing ovipositor specialized for inserting the eggs into plant tissue, often the ovules or young seed. There are six families, Cecidoidae (seven species, gall inducers in South America and Africa), Crinopterigidae (one Mediterranean species, a larval case bearer with habits similar to some coleophorids), and four that are diverse and widespread: Heliozelidae, Incurvariidae, Adelidae, and Prodoxidae.

Heliozelidae  Species of this family occur worldwide but because of their minute size and diurnal habits they are rarely seen and many more species are known from the characteristic abandoned larval mines than there are named. Adults (Fig. 38) are tiny to small (FW 1.7–7.0 mm), typically with iridescent, metallic-appearing scaling. The eyes are small, characteristic of diurnal microlepidoptera. The larvae are flattened, usually legless leaf miners, having a thorax with paired ventral and dorsal movable calii; abdominal prolegs are absent. Early instars form a short, serpentine mine, and then enlarge it to a full-depth blotch (Fig. 18). The last instar constructs a portable case by cutting lenticular disks from the upper and lower epidermis and joining them with silk, giving rise to the common name “shield.” The last instar constructs a portable case to a full-depth blotch (Fig. 18). The last instar constructs a portable case by cutting lenticular disks from the upper and lower epidermis and joining them with silk, giving rise to the common name “shield.” The last instar constructs a portable case by cutting lenticular disks from the upper and lower epidermis and joining them with silk, giving rise to the common name “shield.”

Incurvariidae  Adults are small (FW 3.5–9 mm), with rough head scaling, relatively small eyes, and proboscis short, half the palpi length; maxillary palpi are elongate and folded. They are somber moths with dark, monochromatic wings, sometimes iridescent brown, bronze, or bluish. The larvae are moderately flattened, with well-developed thoracic legs and reduced abdominal prolegs. Early instars form blotch mines; later the larvae cut through the upper and lower epidermis to remove oval sections, which they sew together to form a case. Larvae of a few genera remain in the mines throughout development, in experimental trials. Holarctic Lamproniinae and Adelinae mainly Palearctic and Prodoxinae largely Nearctic, Prodoxus species have

Prodoxidae  Heliozelidae

TINEOIDEA  The tineoids are generally recognized as the most ancestral living group of the Ditrysia. Most tineoids have erect, roughened head scaling and elongate, five-segmented maxillary palp that are folded, usually longer than the labial palp, which have lateral bristles, while the hastellum has short, unconnected galeae, used to lap up surface moisture from detritus or fungi. Females of most specie possess elongate apophyses of segments A9 and 10 that anchor musculature, enabling the ovipositor to be telescoped outward to inject the eggs into crevices or other niches in the host plant.
habitat. Five families are regarded as comprising the superfam-
ily, two of which are worldwide and more species rich, Tineidae and
Psychidae. The others are smaller families of restricted distribution,
Eriococidae (70+ species) in the Mediterranean region and southern
Africa to Australia and Taiwan, Acrolophidae (280 species) in the
Neotropical and Nearctic regions, and Arrenophanidae (30 spe-
cies), Neotropical.

Tineidae (Fig. 42) are slender, small to moderately large moths
(FW length 2.5–25 mm), usually shining brown, tan, or whitish, with
FW patterns of black on pale or yellow on dark. Tineids are most
easily recognized by the rough head vestiture and the short (or
absent) proboscis. They lack bipectination of the male antennae,
characteristic of other tineoid families. The larvae are slender with
integument usually lacking color pattern, often living within silken
 tubes or portable cases (Fig. 43). All instars have well-developed
thoracic legs and abdominal prolegs with a single circle of crotchets.
Larval foods—Tineids do not feed on flowering plants; they mostly
are generalist detritivores or fungivores, and members of some
subfamilies tend to be specialists on animal products such as fur or
feathers (e.g., Tineinae). Some are capable of digesting wool, includ-
ing several cosmopolitan species that feed on woolen clothes and
other manmade products. Others are primarily fungus-feeders (e.g.,
Scardiniinae, Nemapogoninae), especially in sporophores of the wood-
rot fungi (Polyporaceae) or wood permeated by the hyphae, sometimes
quite specialized in host preference. Fungivory or detritivory pre-
sumably was the ground plan for the family and therefore for the
Ditrysia. Larvipary, wherein eggs mature and first instars emerge
within an enlarged oviduct in the female, is known in numerous
Andean and Indo-Australian Tineinae. Many fewer eggs are pro-
duced than by tineids with conventional reproductive systems. There
are more than 3000 described species worldwide, probably less than
half the number known in collections, especially in tropical regions.
These are assigned to more than 300 genera in 15 subfamilies.

Psychidae The common name “bagworms” applies to psy-
chids because the larvae live in portable cases constructed from
silk, plastered with debris or symmetrically arranged pieces of host
plants (Fig. 25). Adults are small and slender to rather large and
heavy bodied (FW length 4–28 mm). Males are fully winged, while
females of some species may be fully winged, short-winged, wing-
less, or even larviform and never leave the larval case. Some species
are female only (parthenogenetic) or bisexual only in some popula-
tions. The head vestiture is roughened, with long, slender scales
directed forward, and the antennae often are strongly bipectinate
in males, particularly in species with flightless females, but are fil-
iform in both sexes of species having winged females. Nearly all psy-
chids are gray or brown without color patterns. Psychid larvae are
stout compared to tineids, with the head and thorax larger and more
heavily sclerotized than the posteriorly tapered abdomen and vari-
osly pigmented. The thoracic legs are well developed and are used
to pull the cases along on the host plant, while the abdominal prolegs
are reduced. Bagworms feed on lichens, grasses, conifer foliage, or
leaves of angiosperm trees and shrubs, sometimes as specialists but
often as generalists. At maturity the larva attaches the case to a sub-
strate and then inverts itself and pupates in the case with the head
ward toward the distal (older) end, whence the moth emerges. There
are nearly 1000 described species from all faunal regions, about 85% in
the Old World. Psychids are generally better studied than most mi-
crolepidopterans, owing to their fascinating behavior, biologies,
and genetic complexity associated with the larviform females and parthe-
nogenesis in five unrelated genera.

GRACILLARIOIDEA This is the major clade of Lepidoptera
adapted for larval mining in leaves (Figs. 19–21). Gracillarioids
primarily mine woody trees, shrubs, and vines of angiosperms and
conifers. The larvae are obligate leaf-, stem-, or fruit-miners in early
instars; in many genera larvae leave the mines to feed exposed or
in webs externally. The adults lack the tineoid lateral bristles of the
labial palpi, have a smoothly scaled frons, and usually have a well-
developed, elongate, coiled proboscis.

Gracillariidae Adults (Fig. 44) are nocturnal, often are
brightly colored, with the FW patterned in metallic orange, bronze,
purple, or yellow. They are small, slender moths (FW 2–10 mm)
with a head with smooth scaling directed forward over the front and
tufts of erect scales on the crown in Lithocolletinae; the antennae
are 0.8 times to much longer than the FW and filiform. The HW is
laceolate with scale fringe broader than the wing. The larval char-
acteristically are hypermetamorphic with more than one form in suc-
cessive instars; early instars are modified for mining, flattened with
legs reduced or lacking, transforming in the third or later instar to
cylindrical caterpillars, with chewing mouthparts and fully developed
legs. They use silk to buckle the mine into a tentlike shelter or feed
externally, often folding a leaf into a tightly closed shelter in which
they graze. In some genera a variously modified, nonfeeding instar
spins the cocoon. Pupation occurs outside the mine in most genera.
Nearly all gracillariids are specialists on one or a few closely related
plants, typically woody angiosperms, including more than 80 plant
families. More than 2000 species have been described from all major
faunal regions, assigned to about 75 genera, and certainly a much
greater number remain to be defined, especially in tropical forests.

Phyllocnistidae Adults are tiny, slender moths (FW 2–3 mm)
with long antennae, often with shining white or silvery FW, delicately
banded with gray and rust distally; HW are laceolate with a much
broader fringe. The larvae are flat with legs reduced to stumps, mouth-
parts highly modified for sap feeding; they create extremely long,
meandering or regularly zigzag, subcutaneous mines (Fig. 21), often
in new, still-soft leaves, causing them to curl conspicuously. More than
20 angiosperm families have been recorded as larval hosts, but many
others in Central America are used, judging from the ubiquitous
mines, probably all made by undescribed species. Phyllocnistid mines
are described from mid-Cretaceous (97 mya) Magnoliidaceae, the earliest
known ditrysian leaf mining. Fewer than 100 species are described, a
small fragment of the fauna; mines are found on more kinds of plants
at one lowland forest locality in Costa Rica than there are named New
World species.

Bucculaticidae Adults are tiny to small moths (FW 2.5–7 mm),
most easily recognized by their elongate frons and large, erect tuft
of scales on the vertex. The appendages are short, antennae 0.6–0.9
times the FW length. The wings are laceolate, FW often with tufts
of upraised scales. Larvae are hypermetamorphic; they are legless
leaf miners in the first two instars and later have well-developed
legs, feeding externally as exposed grazers. Bucculaticrid species are
host-plant specialists, with more than 20 angiosperm plant families
recorded, Asteraceae and Fagaceae dominant in the Holartic; many
species use Cupressaceae. There are about 250 described species,
distributed on all continents except New Zealand, most numerous in
the Holartic.

YPONOMEUTOIDEA This superfamily includes a heteroge-
neous conglomeration of dissimilar microlepidopterans that are
grouped by default, that is, the nonapoditrysian Ditrysia that
have nonmotile pupae and lack the scaled proboscis typical of Gelechioidae.

**Yponomeutidae** Adults are slender moths with elongate FW, ranging from tiny (FW 3.2–6.8 mm), metallic golden, purple, or gray and white nocturnal *Argyresthia* to larger (FW 9–15 mm) and brightly colored, diurnal moths in *Atteva* (Fig. 45) and the white ermine moths in *Yponomeuta*. Larvae of typical yponomeutines live communally in extensive webs on trees and shrubs, sometimes causing economic damage to fruit trees; those of some *Zelleria* damage growing tips of conifers. Larvae of *Argyresthia* are miners in angiosperm buds or conifer foliage. Most species are specific to one or a few plants; *Argyresthiinae* feed on at least 13 gymnosperm and dicot families, with more than 40% of recorded species on conifers, including 25% of *Plutella* feeders in concealed shelters on diverse angiosperms (16 families), predominately Myrtaceae in the Southern Hemisphere and Fagales in the Neartic. More than 30 genera and 1200 species are named, 90% from the Neotropical region, where many are not yet described. This group and the Ethmiidae tend to be mutually exclusive on a broad geographical scale. Stenomatids are species rich in the southwestern United States and Mexico.

**GELECHIOIDEA** This is the largest superfamily of micromoths by far, and because vast numbers of species remain undescribed, Gelechioidae may surpass Noctuoidea as the most diverse group of Lepidoptera. For example, even in North America only about one-third of the species known in collections are named, and a total of 4400 species is projected, 1000 more than Noctuoidea. In tropical regions the inventory is imponderably incomplete—more than 1100 species of Gelechioidae have been counted at one rainforest reserve in Costa Rica, comprising 20% of all Lepidoptera believed to occur there, the majority unnamed. In Australia, gelechioids are estimated to make up about 40% of the Lepidoptera species.

Gelechioids all have overlapping scales on the dorsal surface of the haustellum, up to half its length, and most have a smooth-scaled head, four-segmented maxillary palp, and upward curved labial palp with the third segment long and acute. FW are narrow to lanceolate, with a flared terminal fringe. Large pleural lobes enclose the male genitalia in ypsolophids but are small and narrow in philetellids. These are typically nocturnal moths with yellow, brown, or gray FW, often with linear markings. The diamondback moth (*Plutella xylostella*), a ubiquitous pest of cabbage, cauliflower, and other plants of the mustard family, is the best-known philetellid. The larvae are slender, tapered toward both ends, often with elongate abdominal prolegs, and pale green with unpatterned integument, and they live in slight webs as external feeders. Pupation occurs in large-meshed, open cocoons (*Plutella* group) or dense, envelope-like cocoons (*Ypsolophia* group). Most *Plutella* feed on Brassicaceae, the only moth lineage adapted to do so, while members of this family group as a whole use 50+ families of angiosperms, rarely monocots, and a few gymnosperms, including Ephedraceae and Cupressaceae. Nearly 300 described species are assigned to one or the other of these families, but the systematics relationships and descriptive inventory are incompletely known, especially in Southern Hemisphere faunas.

**Glyphipterigidae** are small (FW usually 3.2–10 mm), diurnal moths with a smooth-scaled head and prorect or decumbent, slightly upcurved labial palp, often metallic gray; the FW have metallic markings and parallel, white chevron marks from costa and dorsal margin. The last abdominal tergum is greatly enlarged, forming a hood over the genitalia. The larvae are borers in seed, flowering stems, terminal buds, or leaves, primarily in sedges and rushes (Cyperaceae, Juncaceae), less commonly in grasses, and rarely in dicots, including Crassulaceae. Nearly 400 species are described in 20+ genera. The family is cosmopolitan and well represented in temperate, Palearctic, Nearctic, and Australian regions, including New Zealand.

**Heliodinidae** Adults are tiny, diurnal moths (FW mostly 3.2–5 mm; rarely to 8 mm), resplendent in shining metallic body and wing scaling, often red or orange with raised silver or lead-colored spots. Adults of many species hold the hind legs aloft when perched, which has been regarded as characteristic of heliodinids, but not all of them do so. Larvae are unpigmented, grab-like, and host specific as leafminers or stem or seed borers, or a few feed externally in flowers and fruit. This is the only lepidopteran family to specialize on Caryophyllales (90% of the known hosts), especially Nyctaginaceae. About 75 species are described worldwide, but the majority occur in the southwestern United States and Mexico.

**Elachistid Assemblage** This group of taxa is defined by having modified abdominal articulation in the pupa, lateral condyles, on A5–6 and A6–7, that prevent lateral movement (Fig. 16B), although those of *Elachistidae* s. str. are polymorphic and questionably homologous. The first three groups have been treated as families or subfamilies of Oecophoridae or Elachistidae. They are broad-winged moths with strongly curved labial palp, often exceeding the top of the head (e.g., Fig. 4).

**Stenomatidae** Adults (Fig. 47) are small- to moderate-sized (FW 5–25 mm), with rectangular to nearly oval FW. The valvae of male genitalia have setae with prominent, multilobed apices. The male antennae usually have long cilia. Larvae of only a small proportion of described species are known; they are relatively stout caterpillars, often with heavily pigmented integument. They are external feeders in concealed shelters on diverse angiosperms (16+ families), predominately Myrtaceae in the Southern Hemisphere and Fagales in the Neartic. More than 30 genera and 1200 species are named, 90% from the Neotropical region, where many are not yet described. This group and the Ethmiidae tend to be mutually exclusive on a broad geographical scale. Stenomatids are species rich in the southwestern United States and lowland wet forests of Central America and northern South America, while ethmiids are speciose in arid parts of western North America and thorn forest regions of Mexico, Central America, and the Antilles.

**Ethmiidae** Adults (Fig. 48) are small moths (FW mostly 4–16 mm, rarely 24 mm), having elongate, narrow FW, often dark with a sinuate pale band along the dorsal edge that renders a bird-dropping appearance when the moth rests, or white with black spotting, superficially resembling *Yponomeuta*, and some tropical species are colorful. Most are nocturnal, but some high montane species are diurnal, as are a group of species in the southwestern Neartic that fly in early spring, adapted to use annual plants. The family is characterized by a strongly recurved basal part of the phallus, secondary SV setae of the larva, and two separately derived pupal-anchoring mechanisms, either development of “anal legs,” ventral, setiferous, forward-directed...
extensions of the ninth segment (Fig. 16B) or grasping of the exuvial head capsule or cocoon silk between abdominal segments A6 and 7. Diapause occurs in the pupal stage, and development can be delayed several years, an adaptation to unpredictable, arid habitats. About 80% of the species for which the often colorful larvae (Fig. 49) are known feed on Boraginales (Boraginaceae, Ehretiaceae, Hydrophyllaceae). About 300 species are named worldwide, with the greatest richness in areas of seasonal drought, especially microphyllous thorn forests of the northern Neotropical Region. This group is better studied than most micromoths, excepting the African fauna, and most species in collections are described.

**Depressariidae** Adults are small (FW 7–16 mm) and resemble the two preceding groups, with FW usually rectangular and labial palpi slender and strongly curved upward, lacking the multilobed setae of the valvae, the strongly recurved phallobase, and special pupal-anchoring mechanisms that characterize stenomatids and ethmids. The larvae mostly are leaf tiers but some bore into stems or seed, using at least 17 families of dicots, with strong specialization on Apiaceae and Asteraceae in the Holartic. More than 600 species are described, assigned to 80+ genera, occurring in all major faunal realms and best represented in north temperate and tropical regions.

**Elachistidae** Adults are tiny (FW 2.5–6.5 mm) with narrow wings; the HW fringe is much wider, and FW are usually white or black with white markings. The labial palpi are slender, strongly curved upward. The larvae are flattened, with head prognathous and recessed into the first body segment and legs short, adapted for mining. *Elachista* typically mine monocots (Poaceae, Cyperaceae, Juncaceae), while other species are miners in a few dicot families. There are about 250 described species worldwide, but they are mainly Holartic.

**Xyloxyctid Assemblage** The remaining families of Gelechioidea lack modified lateral articulation on the abdominal segments of the pupa but otherwise are not defined as a lineage by a derived feature.

**Xyloxyctidae** Adults are small to moderately large (FW 10–33 mm), nocturnal moths, often brightly colored, shining white or yellow patterned with black or brown, and relatively heavy bodied, having spiniform setae on the posterior part of abdominal terga 2–6. The labial palpi usually are long, strongly curved, and slender. Larvae are robust caterpillars with a bordered submranal plate and secondary SV setae on abdominal segments A3–6. They form silken tubes or shelters in lichens, on bark, or among foliage. Some species feed in bark or tunnel in bark or stems and drag leaves back to the gallery at night. Larval foods are lichens, living angiosperm plants (20+ families), about half the known species on Myrtaceae and Proteaceae, or dead eucalypts. More than 500 described species are assigned to 60+ genera, in Africa, the Indo-Australian region, and Polynesia, with the greatest numbers in Australia.

**Scythrididae** are tiny to small (FW 3–12 mm), stiletto-shaped moths with narrow wings that wrap around the body, rendering a tapered appearance from thorax to wing tips (Fig. 50). Most are somber colored, gray or brown, with darker or white FW markings, the nocturnal species tending to be white or pale gray with larger eyes, while diurnal scythrids are mostly dark brown with small eyes and visit flowers for nectar. The male genitalia display an astonishing array of forms, from a relatively unmodified gelenchioid plan in most nocturnal species to an extremely reduced and modified by fusion, often asymmetrical form that defies interpretation of homologies of the structures, mostly in diurnal forms. A remarkable species on coastal sand dunes in California, *Areniscythris brachypteris*, is flightless in both sexes, has greatly enlarged hind legs that enable it to leap 20 times or more its body length, and buries itself at night. The larvae are slender, with a small head, tapered toward both ends, usually without integumental markings but with sclerotized rings around setae SD1 on the abdomen. The head capsule has a submental pit in most genera, at least in early instars, which with the setal rings indicates relationship to Blastobasidae. Most species live in frail webs and feed on growing tips of herbaceous plants; some are leaffminers in early instars. At least 20 families of angiosperms are hosts, mostly dicots, with Cistaceae and Asteraceae prevalent in the Paleartic; larvae of a few species eat lichens, mosses, grasses, or cacti. There are 700+ described species in 26 genera, with vast numbers awaiting study and naming (e.g., 90% of the North American fauna). Worldwide but most numerous in arid and seasonal drought areas such as the southwestern Nearctic, these moths are rare or lacking in wet tropical habitats.

**Oecophoridae** (s. str). As now defined this is a worldwide assemblage of dissimilar moths, with a tremendous radiation of forms in Australia. Adults (Figs. 51 and 52) are small (FW 4–23 mm) with narrow to broad wings, mostly dull colored in Holartic genera but wildly variable and colorful in Australia, where the FW are patterned in yellow, rose, rust, and browns. The abdominal terga are usually without spiniform setal bands. The larvae are cylindrical, with head often darkly sclerotized, sometimes with reduced numbers of stemmata and integument usually not pigmented; the thoracic legs and abdominal prolegs are well developed. Most feed on dead plant material, leaf litter, and other vegetative refuse, and the rich fauna in Australia depends mainly on *Eucalyptus* (Myrtaceae), with about 60% feeding on fallen leaves and 25% on living foliage. There are more than 3000 described species in 500+ genera worldwide; this is the dominant group in Australia, with 2200+ named species in 340 genera and a projected 35–40% of the Lepidoptera fauna. Several species are cosmopolitan household moths whose larvae feed in stored meal, potted plant humus, etc.

**Coleophoridae** are tiny to small (FW 3.5–13 mm), very slender moths with lanceolate wings (Fig. 53); the HW fringe is much wider than the wing. Usually these moths have rather long, nearly straight labial palpi that project forward, often slightly drooping. Paired patches of spiniform setae on the abdominal terga define their relationship with the Momphinae, which are tiny, stout moths with thick, diverging, upward-turned palpi. Mostly dull colored, yellowish, white, gray, or brownish, the FW often have linear, pale, or dark streaks. The larvae are slender, with very reduced abdominal prolegs in Coleophorinae, which are leafminers in the first instar and then live in a portable case constructed of silk covered with sand grains or pieces of plant material (Fig. 24); they feed by mining outward from the affixed case, forming characteristic, round mines with a central hole, as they move from spot to spot. Larvae of Momphinae are more stout, are grub-like, and feed within growing tips, stems, or galls they cause. Coleophorinae feed on more than 30 plant families, including conifers (rare); monocots, especially Juncaceae; and diverse dicots. Momphinae specialize on Onagraceae (70% of host records), the only Lepidopteran group to do so. More than 1100 species are described, with an estimated 500 unnamed species known in the Nearctic; they exist worldwide but are mainly Holartic and are absent from Neotropical rainforests.

**Blastobasidae** Adults (Fig. 54) are small (FW 4–15 mm), nocturnal moths with narrow wings and a short abdomen that bears a conspicuous, transverse row of stout, rust-colored or black, spiniform
setae on each segment dorsally. The labial palpi are usually short, strongly curved upward, and appressed to the head. Blastobasids are uniformly dull colored, usually gray, having FW with whitish or black steaks, sometimes tan or yellowish. The larvae are slender, cylindrical, often with heavily pigmented integument, a labium with a submental pit, and SD1 setae usually with sclerotized rings. Larval foods—the larvae are mainly scavengers, living in a wide variety of situations such as abandoned nests of insects, galleries of stem and root borers, and detritus associated with aphid and scale insect colonies, occasionally eating living insects, and a few species feed on living plant material. Owing to their consistently drab appearance and uniform genitalia structures, this family has been neglected in systematics studies. Worldwide, but more diverse in the Nearctic and Neotropical regions, there are 500+ described species and possibly 5–10 times that many awaiting study.

**Cosmopterigidae** This is a diverse group not defined by any uniquely derived characteristic. The adults are tiny to small (FW 3–13 mm), slender with lanceolate or somewhat broad wings, lacking a gnathos, and having a strongly hooked aedeagus. The larvae are morphologically most similar to Gelechiidae. Habits are diverse, most of these insects are internal feeders, leafminers or bud, stem, bark, or root borers, sometimes causing gall formation by the host plant. Hence they tend to be stout with short legs, without secondary setae and little integumental pigmentation. More than 25 families of angiosperms are hosts. Typical cosmopterigines are leafminers, *Cosmopterix* often in monocots; others are seed feeders, and many are scavengers, in and under old bark, dead stems, etc., and in ferns and palms, especially on oceanic islands. Larvae of *Euclenemis* are preaceous on scale insects. Worldwide, there are 1650 described species in 100+ genera. The genus *Hypomnemis* in Hawaii is the most famous example, with an estimated 450 mostly unnamed species that occupy diverse larval niches, including living plants, in dead wood or stems, on lichens, some feeding from a portable case, and in freshwater and littoral habitats, analogous to the Galapagos finches, but with a vastly more species-rich insular radiation.

**Gelechiidae** One of the major families of micromoths, especially in temperate latitudes, the adults are most easily recognized by the hind wing shape, with the terminal margin indented below the acute apex. Adults (Fig. 35) are tiny to small (FW 3–12 mm, a few tropical species to 18 mm). The great majority are nocturnal, somber colored, brown, gray, or black, but some are colorfully patterned. The larvae usually form concealed shelters in new growing tips of trees and shrubs, but many are leafminers at least in early instars, or stem and root borers, and a few live in plant galls they cause (Fig. 27). Some feed in seeds or dead plant materials, while a broad diversity of living gymnosperms and angiosperms (80+ families) are used. A few feed on ferns or mosses, especially on oceanic islands. There are more than 4500 named species placed in 500+ genera and unknown numbers of undescribed species (e.g., estimated 60% of the North American species). These moths are most diverse in temperate zone areas, including deserts and other seasonally arid habitats. Several are important agricultural insects, including the pink bollworm (*Pectinophora gossypiella*), a threat to cotton growers worldwide; Angoumois grain moth (*Sitotroga cerealella*), which feeds in stored grains; potato tuber moth (*Platholytinae opercula*); and many conifer needle miners.

**Apodityrysa** All the more derived Lepidoptera are grouped in the Apodityrya by possession of shortened apodemes on the second abdominal sternum that have enlarged bases, contrasted with the more ancestral state, continuations of longitudinal costae (venulae) of the sternal plate. Several superfamilies comprising the non-obtectomeran Apodityrya retain the ancestral movable and spined abdominal segments in the pupa, which moves forward to protrude from the shelter, facilitating the moth’s eclosion. The more derived superfamilies of this lineage, the Obtectomera (the pyraloids and macromoths), have nonmotile pupae.

**Choreutoidea** The family Choreutidae is a small group of phenotypically similar moths that have a scaled proboscis, an independent development from the Gelechiidae and Pyraloidea, and deposit upright eggs. The adults (Fig. 56) are small (FW 2–9 mm), diurnal, with broad wings, which they twitch in a characteristic fashion as they strut jerkily about on host-plant leaves. The male antennae usually have long ventral setae. Choreutids are mostly dark colored, with black or brown wings marked by metallic gray, white, or silver-white; some tropical species are orange, with harlequin patterns. The larvae are slender with elongate abdominal prolegs, living externally in slight webs, from which they graze on leaf surfaces. Larval foods include diverse dicot angiosperms (17+ families), concentrating on Moraceae in tropical regions, Fabaceae, Urticaceae, and Asteraceae in the Holarctic. About 400 species are described worldwide, with many undescribed tropical species.

**Sesioidae** This superfamily consists of three families, Brauchidae, Sesiidae, and Castniidae, the adults of which are markedly dissimilar in appearance and behavior; their proposed relationship is based on subtle features: the eye is more strongly pigmented anteriorly, they have large patagia, and the larvae have an unusual crotchett arrangement, two transverse, unioridial rows.

**Sesiidae** These moths are wasplike (Fig. 57), with FW basally narrow and relatively short HW, usually lacking scales except along the veins and distal margin. The wings are tightly coupled, with the posterior margin of the FW bent down, engaging with the upcurved costal margin of the HW, and both have rows of stiff scales that interlock, in addition to the normal frenulum and retinaculum. Sesiids are small to moderately large and heavy bodied (FW length 5–28 mm), diurnal or crepuscular, and almost all species resemble wasps or bees, often startlingly so. This involves not only clear wings and a colorful, banded abdomen, but the legs are modified with tufts, even to the extent of having yellow-tipped scales resembling pollen carried by bees. *Alcathoe* are black with bright orange wings, and the males have a long, slender, scaled process from the tip of the abdomen, which in flight resembles the trailing leg posture of tarantula hawks (*Pompilidae, Pepsis*). Sesiids often visit flowers with quick, darting flights. The larvae (Fig. 25) are borers in stems, bark, and roots; they are stout, with heavily sclerotized head and mandibles and unpigmented integument. Larval foods include 40+ families of flowering plants, including conifers but not monocots. There are more than 1100 described species in 120 genera, speciose in both temperate and tropical regions. Sesiidae may be the most completely known of any microlepidoptera. Many species are agricultural pests, borers in stems of berry and squash vines, fruit trees, and conifer trunks.

**Castniidae** are primarily tropical, large (FW 24–190 mm), strong-flying, diurnal moths that have broad, often colorful wings, and the antennae are swollen distally, so they resemble butterflies (Fig. 58). The antennal tip is abruptly narrowed and bears a tuft of long hairs, features shared with Sesiidae. Some species are crepuscular and occasionally come to lights. Larvae are stout, cylindrical, with short legs and a head retractable into the thorax. They feed in plant stems or form tunnels in soil and feed on subterranean plant parts. The larval life requires 4.5 months to 2 years. All confirmed feeding
records are for monocots, and several species are pests of sugarcane, banana, or oil palm. There are about 180 species, placed in 33 genera. The distribution suggests a Gondwanan origin, with the subfamily Tasciniinae in Southeast Asia, the sister group of Castniinae in Central and South America and Australia. Castniids occur in tropical, subtropical, and warm temperate regions and are lacking from most of the Holartic, southern South America, Tasmania, and New Zealand.

Cossioidea

Cossidae  Goat moths are small to large, hawk moth-like, robust moths (Fig. 59) (FW 4–70 mm, rarely to 125 mm), having short, usually bipectinate antennae in the male; the proboscis is not functional, reduced to a small triangular lobe; labial palpi are three-segmented, short, and upturned. The wing venation is more primitive than in related superfamilies, with the median vein complete and branched within the cell. Cossids typically are nocturnal, drab, mostly gray with black striae; a few have brown or orange patches. The eggs usually are laid in groups in crevices or under bark and may be produced in vast numbers, 18,000 counted for one species in Australia. First instars disperse and bore into branches or trunks of living shrubs or trees, sometimes living gregariously; later instars are stout, cylindrical, with secondary setae, with setal pattern and crotchet arrangements similar to those of Cossidae, usually with little or no integumental pigmentation other than the setal pinacula. Larvae of most Chiladanotinae and Olethreutinae feed as borers in stems (Fig. 26), roots, buds, or seeds, and most are specialists in host-plant selection. Larvae of a few species are miners in leaves (Fig. 22) or conifer needles or cause plant galls (Fig. 28). By contrast, nearly all Tortricinae are external feeders, often polyphagous, that form leaf rolls or other shelters in foliage, but species of Cochylini bore into buds and stems. Pupation usually occurs in the larval shelter or gallery, although some drop to the ground to pupate, especially those that diapause over winter as pupae or prepupal larvae in the Holartic. External feeders of all three subfamilies possess an “anal fork,” used to flip frass away from the larval shelter. An enormous array of plants serve as hosts. A few small tribes (two genera) are specialists, for example, Baetritini on monocots. About 8500 described species are placed in 720+ genera, and incalculable numbers are unnamed in tropical regions—for example, 70–80% of recently studied species of Neotropical tortricines have been previously unnamed. Rich faunas occur in all biogeographic regions. In addition to the spruce budworms, important economic Tortricinae include the light brown apple moth (Epiphyas postvittana) in Australia and fruittree leafroller (Archips argyrospilus) in North America, while Olethreutinae include the codling moth (Cydia pomonella), pea moth (C. nigricana), larch and spruce budworms (Zieraphera), several seed and cone borers (Cydia), and pine tip borers (Rhyacia-nia) in the Holartic.

Zygaenoidea

This is a conglomeration of families of very different appearing moths and larvae. All share two features, larval head retractile into thorax and second abdominal spiracle of the pupa covered by wings. The mouthparts are vestigial in all the families treated here except Zygaenidae. The larvae are stout with the ventral surface slug-like, having short prolegs or suckers, often resembling caterpillars of lycanid butterflies. Feeding habits vary, including predators of Homoptera or ants. Defensive secretions containing cyanoglycosides are produced by some zygaenoids. Some families have been intensively studied because of their interesting larval habits, reproductive behavior, or chemical ecology. Taxonomists define 12 families, most of them small, with fewer than 50 species and limited to one geographical region.

Epipypipodida

Adults are small (FW 4–10 mm), FW triangular, HW round, blackish or gray, rarely with white or orange HW. The antennae are bipectinate in both sexes, more broadly in the male. The moths are crepuscular or nocturnal but rarely come to lights. Females produce large numbers of eggs, up to 3000 in one African species, that are deposited on foliage of a plant frequented by the planthopper hosts. The larvae are hypermetamorphic, with first instar triungulin-like, slender, tapering posteriorly with long thoracic legs and ventral ambulatory setae. The first instar seeks the host, attaches by means of silk, and transforms to a grub-like larva, which may feed on secretions produced by the homopteran, and the host remains active. The larva is covered by wax secreted by glands in its integument. Pupation occurs away from the host in a dense cocoon impregnated with wax. Epipypipids feed on body fluids and secretions of fulgoroid leaffoppers of several families. There are about 40 described species assigned to nine genera, occurring in pantropical and warm temperate regions.

The Australian family Cyclotornidae (12 species) are similar to the Epipypipidae with an even more bizarre life cycle. Females deposit large numbers of eggs (1400 counted for one female) on vegetation infested with cicadellid leaf hoppers or Psyllidae (Homoptera). The active first instars follow Iridomyrmex ant trails leading to the homopterans. After feeding, the moth larva leaves and
molds into a brightly colored, flat, broadened, scalelike larva, which curls its abdomen upward to expose the anus where a secretion is produced that is much sought after by the ants. The cyclotornid is seized by an ant and carried back to the nest, where it feeds on ant larvae and pupae.

**Limacodidae** Adults (Fig. 65) are small- to medium-sized (FW 6–35 mm), mostly nocturnal moths with a stout body, relatively short, broad wings, and densely scaled head and body. The antennae are bipectinate in male, often to about half the length of the body. Mostly brightly colored, in yellow, tan, browns, these moths assume a characteristic resting posture, with the body held at an acute angle to the substrate. Larvae are hypermetamorphic, with first instar, which often is nonfeeding, oval, flat, and bearing rows of large spines that are not homologous with basic setal patterns of other Lepidoptera. Later instars (Fig. 66) are lycaenid-like in form, lack abdominal prolegs, and often have ventral suckers on segments A1–7 that adhere to the foliage, aided by a fluid secreted over the cuticle, and they move slug-like by peristaltic waves passing along the sole-like venter. Different species exhibit a great variety of body form, smooth, sometimes with gelatinous warts, with protuberances, spines, and hairs, some of which are stinging (nettle caterpillars), or densely hairy. Later instars often are green, but in stinging species they are brightly colored. The fecal pellets are characteristically cup-shaped. The cocoon, which usually is hard, incorporating calcium oxalate that is secreted by the prepupal larva, has a circular, dehiscent lid. A variety of dicot trees and shrubs serve as larval hosts, with many species polyphagous, and some feed on monocots, including coconut, banana, rice, sugarcane, and other economically important plants. There are more than 1000 described species, occurring in all zoogeographical regions, with greatest numbers in the tropics.

The sister family to the Limacodidae, the Dalceridae (40 species), is limited to the Neotropical region. Adults (Fig. 67) are small moths (FW 6.5–24 mm), white, yellow, or orange, with broad, rounded wings and hairy bodies, similar to epiyopids and limacodids in having vestigial proboscis and small labial palpi; the antennae are bipectinate, more broadly in males. The larva (Fig. 68) has a brush-like spinneret, dorsum and sides with gelatinous humps secreted from glandular setae, venter with transverse cuticle, thoracic legs short, prolegs not developed, and crotchets absent in early instars, appearing in the final two.

**Megalopygidae** Adults (Fig. 69) are also similar to Limacodidae but generally larger (FW 11–28 mm) and relatively heavy-bodied, with FW markings often brightly colored and elaborately patterned and scales hairlike, cleft, or tripartite. The larvae (Fig. 70) are super- ficially similar to some limacodids, but with three rows of spined protuberances (scoli) bearing variable development of typically urticating setae, sometimes beneath tufts of long, silky hairs like a fur coat (puss caterpillars), with the unusual complement of seven pairs of prolegs, those of A2 and A7 lacking crotchets. Pupation occurs in a tough, tapered cocoon blended into a branch. There are about 260 species, primarily Neotropical, with several genera ranging into the United States. The small subfamilies Somabrachyinae, in the Mediterranean region and Africa, and the Neotropical Aidinae are sometimes separated as families.

**Zygaenidae** comprise a worldwide group of distantly related moths exhibiting a large number of remarkable specializations. Nearly all are diurnal and many are slow-flying and brightly colored (aposematic) (Fig. 71) and are avoided by birds and other predators because both adults and larvae biosynthesize cyanoglucosides. They are able to release hydrocyanic acid by enzymatic breakdown of the cyanoglucosides. This has enabled many to take part in complex mimicry relationships. Moreover, adults and larvae are unusually resistant to cyanide, and naive collectors are startled to see a moth survive for half an hour in a potent vial that kills other moths in seconds. Adults are small to large (FW 5–50+ mm), with head and labial palpi smooth scaled, and they commonly visit flowers for nectar. The antennae are often thick and either clubbed in both sexes or bipectinate in males and narrowly bipectinate or filiform in females. Glands located between the eyes and the base of the proboscis produce a whitish or yellow liquid or foam when the moth is disturbed. They are often metallic colored, particularly vivid in European Zygaena, in bright red and metallic blues. The eggs are deposited in rows, clusters, or overlapping patches and sometimes covered with scales from a special abdominal hair tuft, which in some Australian genera are urticating. The larvae are stout and broad, with the head usually retractile under the extended prothorax; the body is roughened and covered with dense secondary setae. Larval foods include numerous plant families, although the species are mostly host specific. European zygaenines specialize on Celastraceae, cyanogenic Fabaceae, and noncyanogenic Apiaceae; some Australian Propriolinae rely on Dilleniaceae, Myrtaceaee, or Vitaceae, and the last is used by some Neartic species. About 1000 species are described, and the family is relatively well studied owing to the colorful forms, diurnal habits, and mimicry associated with the chemical ecology.

**Alucitoidea**

**Alucitidae** The many-plume moths are so called because the wings are deeply cleft, so each wing has six fringed, plume-like segments (Fig. 63). The family was classified with the true plume moths (Pterophoridae) from which the alucitids differ by having discrete bands of spines on some or all of abdominal terga 2–7 and a relatively unspecialized pupa formed in a cocoon. Adults are small (FW 3–13 mm), slender moths that are unmistakable by their wing structure, but in two tropical genera with the largest members of the family, the wings are divided only a short distance. The antennae are filiform, proboscis is well developed, and labial palpi are usually fairly long, porrect or upcurved. Most are gray or brown, delicately banded with tan or white. They are nocturnal and collapse the wing plumes when at rest, holding them out from the body so as to resemble narrow-winged pyralids, but when active they strut about with the wings fully expanded, like miniature peacocks. The larvae are borers in flower buds, shoots, or in galls; the body is stout with short legs with short setae on inconspicuous bases. Pupation occurs in the larval shelter or in leaf litter in a cocoon. Larval hosts include at least eight dicot families, especially Caprifoliaceae in the Holarctic and Bignoniaceae and Bubiaeae in Australia and tropical regions; one species is a coffee pest in Africa. There are about 130 species described and likely there are many more in tropical regions.

**Pterophoroidea**

**Pterophoridae** The plume moths are recognizable by their deeply cleft wings in all but the most ancestral genera. They lack pro- boscis scaling and abdominal tympana, the hind tibia is 2 or more times the length of the femur, and abdominal terga 2 and 3 are elongated. Adults (Fig. 64) are small (FW 4–18 mm), with long and slender bodies, legs, and wings; FW is cleft for about 0.25–0.33 its length and the HW deeply twice-cleft in most species. When at rest, the plumes are overlaid and rolled under the leading edge of the FW, resembling sticks held out from the body. They usually are nocturnal and dull colored, tan, brown, or gray with paler and darker markings; although a few are colorful members of tropical mimicry complexes. The larvae (Fig. 29) typically are elongate and cylindrical with long
FIGURES 65–92  

Adults and larvae of zygaenoid, pyraloid, and macro moths. 

Zygaenoidea: (65) Parasa indeterminata (Limacodidae) (New Jersey); (66) Larva of Isa textula (Limacodidae) (Maryland); (67) Dalcerides ingenita (Dalceridae) (Arizona); (68) larva of D. ingenita (Dalceridae) (Arizona); (69) Trosia retocens (Megalopygidae) (Amazonas); (70) larva of Monoleuca semifascia (Megalopygidae) (New Jersey); (71) Zygæna ephialtes (Zygæniidae), pair in copulo (France). 

Pyraloidea: (72) Petrophila confusalis (Crambidae, Nymphulinae) (California); (73) Pyraustinae species (Crambidae) nectaring at composite flower, whereas the larval host is a grass (Arizona). 

Geometroidea: (75) Urania fulgens (Uraniidae) (Ecuador); (76) Dichorda illustraria (Geometridae) (California); (77) Neoterpes edwardsata (Geometridae) (California); (78) flightless female of Tescalsia giulianiata (Geometridae), a winter moth (California). 

Bombycoidea: (79) Phyllodesma species (Lasiocampidae) (California); (80) Bombyx mori (Bombycidae), pair in copulo of the commercial silk moth; (81) Eacles species (Saturniidae, Citheroniinae) (Costa Rica); (82) Hemileuca eglanterina (Saturniidae, Hemileucinae), a diurnal species, female ovipositing (California); (83) Argeena vaenas (Saturniidae, Saturniinae) (Malaysia); (84) Smerinthus cerisyi (Sphingidae) in predator avoidance posture (Utah); (85) Hemaris senta (Sphingidae), a diurnal bumble bee mimic (California). 

Noctuoidea: (86) Clostera apicalis (Notodontidae) (California); (87) Phryganidia californica (Notodontidae, Dioptinae); (88) larva of P. californica, the California oak moth; (89) Lymantria dispar (Lymantriidae), mating pair of the notorious gypsy moth (Russia); (90) Orgyia vetusta (Lymantriidae), wingless female tussock moth (California); (91) larvae of O. vetusta; (92) Horama panthelon (Arctiidae) (Texas). 

(Photographs by: E. Buckner, 71; R. Cardé, 89; C. Covell, 75, 83, R. Coville, 72, 73, 76, 77, 79, 80, 81, 86, 87, 88, 90; J. Hafernik, 74; C. Hanson, 67; L. Penland, 65, 68; J. Powell, 78, 84, 91; D. Rubinoff, 82, 85, 92; J. Ruffin, 66, 70; K. Sandved, 69.)
prolegs. Most are external feeders on foliage and usually have dense setae that may be forked, clubbed, or glandular, secreting a sticky fluid. Some species are borers in stems and have short setae, even a strongly sclerotized and shield with two stout hornlike processes resembling the urogomphi of coleopteran wood borers. The pupae are strongly spinous or setose and either are formed in the galleries or affixed to host-plant stems or debris by the anal cremaster to a silk pad, fully exposed, and they can bend and curl over by their movable abdomen. More than 20 dicot families are recorded as larval hosts, principally Asteraceae, usually herbs, but not monocots. The larvae of *Buckleria* in Europe are remarkable for feeding on sundews (*Drosophyllum*); principally Asteraceae, usually herbs, but not monocots. The larvae of *Buckleria* in Europe are remarkable for feeding on sundews (*Drosophyllum*); the larvae usually are stout and cylindrical, with relative- ly short legs and setae; the body typically is unpigmented, although some species are well patterned, even brightly colored. Almost all are ground dwellers feeding primarily on grasses or as stem borers in various monocots; Schoenobiinae are borers in marsh grasses; Cybaloniinae and Evergestiinae specialize on Brassicaceae and Capparidaceae; Midliinae are borers in Arecaceae; Musotimiinae larvae feed on ferns, a rare niche for Lepidoptera; many Odontinae are leafminers or flower, bud, and stem borers, on diverse dicots; and Pyraustinae, which make up 65% of the known species of Crambidae, are mostly webworms but some borers, in an enormous variety of monocots and dicots, pest species of many crops, including corn, bananas, palms, pasture grasses, cucurbits, tomatoes and other solanaceous fruits, coffee and other tropical trees, garden mints, and conifers. Scopariinae are specialists on mosses and lycopers, tunneling in the roots and stems, and on ferns, or on seed-bearing vascular plants. Nymphulinae larvae are aquatic, living either in ponds on vascular plants, often in cases, or in rapid streams, usually under webs on rocks and feeding on algae. Larvae either breathe through open spiracles, living in air-filled cases or stems, or absorb dissolved oxygen through tracheal gills. Pupae are formed in cases in chambers within the plants or in gas-permeable cocoons and breathe through the spiracles. In the Palearctic *Acenteria* (Schoenobiinae), females are wingless, enter the water, and are parthenogenetic until a bisexual generation of winged adults late in the season. More than 11,500 species are described, nearly 90% of which are members of Nymphulinae, Crambinae, or Pyraustinae.

**Geometroidea** This group includes five families, Drepanidae, Epicepeidae, Sematuridae, Uraniiidae, and Geometridae, although they have been separated as two or three superfamilies by some authors, based primarily on the structure of the larval mandibles and tympanal organs. Geometrids typically are broad-winged, with slender bodies, small to large moths (FW 5–78 mm); they have abdominal tympana of structures different from those of pyraloids and lack scaling of the proboscis. Larvae of Uraniiidae have well-developed abdominal prolegs, while most Drepanidae and Geometridae have some of the prolegs vestigial or absent.

**Drepanidae** Adults have internal abdominal tympana unlike any other Lepidoptera, associated with the dorsal–ventral sclerites that connect tegum 1 with sternum 2, opening dorsally. Adults are medium- to large-sized (FW 8–31 mm), broad winged and geometrid-like in typical Drepaninae, often with the FW apex produced or curved; Thyatirinae are stout bodied and noctuid-like. The antennae usually...
are short, lamellate or bipectinate to the tip for most of the length, sometimes filiform. The larvae have few secondary setae or rarely numerous but very short setae, sometimes with an eversible vesicle just above the prothoracic coxa in Drepaninae, often with notodontid-like protuberances in Thyatirinae; anal prolegs are usually vestigial but those of A3–A6 are well developed, and the anal shield is conspicuously elongated. At least 20 families of diverse dicots and one monocot (Zingiberaceae) are hosts; some Holarctic species are generalists. More than 650 species are described in 120+ genera, mostly in the Holarctic and Oriental regions; Drepaninae are absent in the Neotropics. A few species are pests of coffee.

**UranIIDae** This family is defined by the sexual dimorphism of the tympanal organs, which are on the lateral, posterior part of tergum A2 in males and on the lateral part of sternum A2 in females. Adults (Fig. 75) are small to large (FW 7–78 mm), broad winged, usually with a relatively slender body; wings are often resplendent in brilliant, iridescent colors; HW veins are sometimes produced into one or several shallow tail-like butterfly-like tails. Most are nocturnal, but three tropical genera are day flying, including *Urania*, some species of which are famous for their massive migratory flights, involving thousands of the spectacularly colored moths. Epipleminae are smaller, nocturnal, and dull colored; they rest with the FW extended and rolled, HW appressed to the body. The antennae are filiform, lamellate, or pectinate, sometimes thickened preapically. The larvae are more or less bare, with few secondary setae, occasionally with spatulate setae, and prolegs are well developed. Larval foods are recorded in about a dozen dicot families, including specialization on Oleaceae, Asclepiadaceae, and Euphorbiaceae (all known larvae of Uraniinae feed on euphorbs), unusual for Lepidoptera and likely sources of distasteful qualities, and many species appear to be aposematic. Worldwidely, these moths are primarily pantropical; around 700 described species are assigned to 90 genera.

Sematuridae are tropical, similar superficially to Uranidae, often brightly colored with HW tails, but adults lack abdominal tympana, and the antennae usually are distally thickened, like those of skipper butterflies.

**Geometridae** This is one of the three most speciose families of Lepidoptera. Adults (Figs. 76–78) are small to large (FW 5–55 mm), typically with broad wings and slender body and abdomen with basal tympanal organs in deep, ventrolateral cavities. The great majority of geometrids are nocturnal and rest by day with the wings outspread, with cryptic resemblance to tree bark, lichens, green or fallen, brown leaves, often ornate with lines simulating leaf veins or spots resembling necrotic or eaten areas of foliage. Some genera hold the wings upright, butterfly-style, and their undersides are cryptically colored. Some geometrids are day flying, including early spring species in the Holarctic or mimetic species in tropical regions. A few species that are winter moths or occur at high elevations have flightless females (Fig. 78), and these have the mouthparts and tympana reduced or vestigial. The larvae usually have prolegs of segments A3–A5 reduced or absent (Fig. 13), so the caterpillar walks by advancing in measured, looping steps, from which both the family name and the common name (inchworms) are derived. They are bare but with a variety of colors, protuberances, ornate body forms, and behavior; most are exposed feeders that depend upon cryptic resemblance to flowers, leaves, twigs, etc., to avoid predators (Fig. 30). Most species are general feeders on trees or shrubs. Owing to their worldwide species richness, an enormous variety of gymnosperms and angiosperms are eaten. At least 21,000 species and 1500 genera have been described, and no doubt many remain unnamed, especially in tropical regions. Several species are defoliators of hardwoods or conifers (e.g., spring and fall cankerworms, *Paleacrita vernata* and *Alsophila pometaria*, and the hemlock looper, *Lambdina fiscellaria,* in North America), but geometrids are not a major pest group.

**Bombycoidea** These are macromoths that have no thoracic or abdominal tympana. The group is distinguished by deep clefs between the prescutum and the mesoscutum of the mesothorax. There are 12 families, including 4 worldwide groups summarized here that are sometimes treated as superfamilies: Lasiocampidae, Bombycidae, Saturniidae, and Sphingidae. Other bombycoids are Mimallonidae, a mostly Neotropical family with 200 species; Anthelidae, a small Indo-Australian group; Eupterotidae, worldwide with 300 species; Endromidae, Mirinidae (Palearctic), and Carthaeidae (Australian), each with 1 or 2 species; and 2 small Eurasian and African families related to Sphingidae, Lemoniidae and Brahmaeidae.

**Lasiocampidae** Adults (Fig. 79) are small to large (FW 9–80 mm) with moderately broad wings and stout bodies. The eyes usually have fine hairs between the facets; mouthparts are absent or vestigial; antennae are bipectinate to the tip in both sexes; labial palpi are pectinate, the first segment with a scaleless patch bearing sensory setae, unique in Lepidoptera. The wings have interlocking tiny setae but no retinaculum and frenulum. Lasiocampids are nocturnal, but males of a few species are primarily diurnal, mostly somber-colored moths, browns and tan. The female often is much larger than the male, with a stout abdomen having a fully developed complement of eggs upon emergence, sometimes deposited in a single large mass. The larvae do not have the fore coxae fused as in other bombycoids. The body is covered with dense, often long, unbranched secondary setae and frequently is brightly colored. Larvae of some genera are gregarious (e.g., *Holarchic Malacosoma*, tent caterpillars, Fig. 33), and some have urticating hairs that produce a skin rash in humans. Pupation occurs in a dense, parchment-like cocoon. Larval foods are diverse, mainly trees and woody shrubs, Betulaceae, Fagaceae, and Salicaceae in the Holarctic; low-growing Asteraceae, Brassicaceae, and grasses in Africa; and predominantly Myrtaceae in Australia but also mistletoes (*Santalaceae*). Some species are polyphagous. There are about 1500 named species, in 150 genera, occurring worldwide, mostly in the tropics; they are absent from New Zealand.

**Bombycidae** Including Apateolidae of recent authors, this family is defined by a few subtle skeletal features and by short pupal galeae that fail to reach the foreleg apices. Adults are small- to medium-sized (FW 9–28 mm), nocturnal with broad wings, which usually are held outward from the body when at rest. The mouthparts are vestigial. The antennae are bipectinate nearly to the tip in both sexes, and the thorax and legs are clothed in long, hairlike scales. Larvae are similar to lasiocampids, but the secondary setae are either short and minute or long in Apateolidae. The fore coxae are separate (Apateolidae) or fused. Segment A5 has a middorsal scolus except in Apateolidae. Larval foods are largely Bignoniaceae, Symplocaceae, Moraceae, and Theaceae—some species are reported to defoliate commercial tea. There are about 350 species referred to 40 genera, worldwide except in Europe, best represented in the Oriental and Neotropical regions. The silk moth (*Bombyx mori*, Fig. 80) is the most well-known species; it has been domesticated for centuries and is not known in the wild, its adults no longer capable of flight.

**Saturniidae** The emperor or giant silk moths include many of the world’s most spectacular moths. They are medium- to very-large-sized (FW 14–130+ mm), broad winged with highly variable
color patterns (Figs. 81–83), often with eyespots with concentric rings (hence the family name), which presumably act as a defense mechanism against predators of the sluggish moths, many of which must warm themselves by pumping the abdomen before they can fly. Most genera are nocturnal, some mating only during early morning hours, while species of a few genera are diurnal (e.g., *Hemileuca* in North America, buck moths, Fig. 82). The proboscis and maxillary palpi are rudimentary or absent. The male antennae are bi- or quadripectinate, those of the female filiform to quadripectinate. The male FW is usually produced apically, while the hind margin of the HW sometimes has short to very long tails. The larvae are stout with a prominent, smooth head and body protuberances that often are branched; secondary setae are numerous but small, mostly on the ventral half of body and prolegs. The scoli of some genera bear poisonous spines that cause nettle-like stings in humans, and females of some species coat the eggs with urticating hairs that cause dermatitis. Abdominal segment A8 usually has a middorsal horn or scolus. Pupation occurs in a strong, sometimes double-walled silken cocoon that may be covered with plant fragments or in the soil without a cocoon. Many saturniids are polyphagous, and an enormous array of plant hosts are recorded—90 genera in 48 plant families recorded for one species of *Atteca*—but some are specialized feeders. There are about 1500 described species in 165 genera, occurring worldwide except at the highest latitudes, most abundant in moderate to high-elevation habitats, richest in the Neotropical region, particularly the South American Andes.

**Sphingidae** Sphinxs or hawk moths are among the largest, most easily recognized, and best known Lepidoptera. Adults (Figs. 84 and 85) are medium- to very-large-sized (FW 16–90 mm), having a stout body with the abdomen typically tapering posteriorly. The FW is narrow and HW relatively short, its hind margin produced, angulate at the tip of veins 1A + 2A, emarginate beyond. The antennae are distinctive, usually lamellate ventrally or bi- to quadripectinate, tapering toward the apex, which is upturned or hooked; males with two rows of long sensillae that meet dorsally; shorter and filiform in females. The proboscis is usually well developed and coiled; labial palp is often quite short. The abdomen is densely covered with long, slender scales and sometimes dorsal scale tufts at the base. The tips of the tubial spurs are serrated. These are mostly dull-colored, tan, brown, or gray motifs, but many tropical doliopes are diurnal and brightly colored, involved in mimicry complexes. The larval body is stout, nearly bare, sometimes with long secondary setae, often possessing one or more protuberances, a modified body form (Fig. 31), a median knob or horn on A9, or anal prolegs modified into slender, single or double caudal processes (stenopods). All larvae except Diopitinae have two MD setae above the spiracle on abdominal segments, whereas other noctuids have only one. Late instars have a smooth mandibular cutting edge, derived from the serrat ancestral state in other noctuids. When disturbed, some species emit formic acid or ketones from a cervical gland (adenosoma). Many have various cryptic colors correlated with modified body forms, but others are brightly colored and aposematic, especially Diopitinae (Fig. 88). Larval foods include a wide diversity of dicot angiosperms, mainly woody shrubs and trees, and a few feed on grasses. Many specialize on plants containing toxic substances, including Anacardiaceae, Apocynaceae, Aristolochiaceae, Fabaceae, Passifloraceae, and Violaceae. There are more than 2500 described species, distributed worldwide except in New Zealand and the Pacific Islands and particularly rich in the Neotropics. A few are occasional defoliators of orchard or forest trees.

**Noctuoidea** This is the largest superfamily by far, with more than 7200 genera proposed for nearly 60,000 species, about 40% of all described Lepidoptera. As such, there is a tremendous variety of form, size, color, morphology, and behavior in both larvae and adults. Four major, cosmopolitan families are recognized, Notodontidae, Lymantriidae, Arctiidae, and Noctuidae, from which several regional lineages have been split as families by some authors. Monophyly of Noctuoidea is unequivocally based on complex metathoracic tympanic organs and associated abdominal structures. The tympana are assumed to have evolved in response to bat echolocation, and many species have been observed to engage in bat avoidance behavior upon receipt of their sounds. Tympana may also receive mating signals, especially in Arctiidae.

**Notodontidae** With Thaumetopoeidae and Dioptidae included as subfamilies, this is a large and diverse family. Adults (Figs. 86 and 87) are medium- to large-sized (FW 16–50+ mm), typically with relatively long FW and stout body that extends 2 or more times the width of the HW. The head often has scale tufts or crests; antennae are usually bipectinate to the tip in the male, filiform or sometimes bipectinate in the female. Proboscis is usually well developed and coiled; labial palpi are often quite short. The abdomen is densely covered with long, slender scales and sometimes dorsal scale tufts at the base. The tips of the tubial spurs are serrated. These are mostly dull-colored, tan, brown, or gray motifs, but many tropical doliopes are diurnal and brightly colored, involved in mimicry complexes. The larval body is stout, nearly bare, sometimes with long secondary setae, often possessing one or more protuberances, a modified body form (Fig. 31), a median knob or horn on A9, or anal prolegs modified into slender, single or double caudal processes (stenopods). All larvae except Diopitinae have two MD setae above the spiracle on abdominal segments, whereas other noctuids have only one. Late instars have a smooth mandibular cutting edge, derived from the serrat ancestral state in other noctuids. When disturbed, some species emit formic acid or ketones from a cervical gland (adenosoma). Many have various cryptic colors correlated with modified body forms, but others are brightly colored and aposematic, especially Diopitinae (Fig. 88). Larval foods include a wide diversity of dicot angiosperms, mainly woody shrubs and trees, and a few feed on grasses. Many specialize on plants containing toxic substances, including Anacardiaceae, Apocynaceae, Aristolochiaceae, Fabaceae, Passifloraceae, and Violaceae. There are more than 2500 described species, distributed worldwide except in New Zealand and the Pacific Islands and particularly rich in the Neotropics. A few are occasional defoliators of orchard or forest trees.

**Lymantriidae** The tussock moths are so called because larvae of many have thick tufts of erect secondary setae on the dorsum, like those of a toothbrush (Fig. 91). Adults are small to moderately large (FW 7–45 mm), nocturnal, usually dull-colored moths, mostly brown or yellow; they are usually broad winged and densely hairy; the FW is triangular, HW rounded, hidden under the FW at rest, with the wings appressed to the substrate and the densely hairy forelegs extended in front of the head. Females of some genera are flightless, their wings vestigial (Fig. 90). Antennae of males and usually females are bipectinate to tip. The proboscis is vestigial or absent. Females have a large, abdominal tuft of deciduous scales used to cover the egg masses. Males of many genera possess a tymbal organ, a pair of finely corrugated pockets on A3. The larval integument often is brightly colored, with hair tufts from verrucae, but the body form is not strongly modified as in notodontids. Lymantriid larvae all possess a middorsal, eversible gland, often yellow or red, on segment A6 and usually another on A7. The larval hairs of *Euproctis* in Australia
and some other genera are hollow, barbed, and urticating and cause a severe skin rash in humans. The body hairs are woven into the cocoons and often retrieved by the emerging female and redeposited on the egg masses and then used by first instars, which feed in protected aggregations. Many lymantriids are polyphagous, frequently on arborescent shrubs or trees, and a broad array of plants is eaten. Applicable generic radiations feed on flowers and fruit of low herbs and grasses, and many Asian and African species feed on algae, fungi, and detritus. There are more than 2500 species placed in 360 genera, distributed in all geographic regions, reaching their greatest development in the Old World tropics. Many species in several genera are forest defoliators in Europe, North America, and Indo-Australian tropics, the most notorious being the Palearctic gypsy moth (Lymantria dispar, Fig. 89), which was introduced into North America in the late 1800s.

**Arctiidae** The tiger moth family includes Ctenuchidae and Pericopidae, formerly treated as families, which now are interpreted as artificial groupings. There are three subfamilies, Lithosiinae, Synthominae, and Arctiinae, all characterized by a pair of dorsal, eversible, single or branched pheromone glands from the terminal abdominal segment in the females. In addition, many arctiines and lathosiines have metathoracic tymbal organs in both sexes. Sound is produced by contraction of muscles that deform ridges on the tymbals rapidly to produce bursts of ultrasonic clicks, stimulated by tactile cues or in response to hunting signals of bats. Many species of all three subfamilies have prothoracic glands from which a liquid is extruded containing acetyleholines and histamines and probably pyroges, the odor of which is believed to signal distasteful or toxic properties to predators. Adults (Figs. 92 and 93) are small to moderately large (FW 5–50 mm), usually brightly colored with a myriad of patterns, predominately orange, red, and black, often aposmotic, advertising their toxic qualities and involved in mimicry complexes, or they resemble wasps, with mostly scaleless wings. Females of some species have a large tuft of abdominal scales used to mix with or cover egg masses. Most arctiids are nocturnal and come to lights, even many tropical species with elaborate Hymenoptera resemblances. Some genera are strictly diurnal, such as North American Ctenuchida and Gnaphalidae and Lycomorphidae that accompany aggregations of lyceid beetles they mimic. Larvae of many arctiids have dense secondary setae over the body (woolly bears, Fig. 94), but setae are sparse in some arctiids, especially Lithosisinae. The body form is typically cylindrical with a full complement of prolegs; most are rapid crawlers and can move great distances in search of food or pupation sites. Lathosiinae possess an enlarged basal malar area of the mandibles, used to macerate algae and lichens, which are the principal foods (rarely liverworts and mosses). Some Synthominae also feed on algae and lichens, many are scavengers or fungivores, and some feed on flowers, especially Asteraceae, or grasses. Arctiinae are polyphagous plant feeders or specialize on one of a variety of angiosperms, some genera on latex-producing plants (Apocynaceae, Euphorbiaceae, Moraceae) or those with toxins (Asteraceae, Boraginaceae). More than 6000 species are described in 750+ genera, occurring worldwide, particularly rich in tropical regions. Tropical lathosiines are poorly studied, and there are numerous undescribed species.

**Noctuidae** This is the largest family of Lepidoptera, with more than 35,000 species grouped into about 30 subfamilies, many of which have been regarded as families, including Pantheinae and Nolinae, by recent authors. The composition and classification of most of these subfamilies is debatable, with critical larval characteristics unknown for most genera. Members of this vast lineage do not share a distinguishing derived feature; they possess the wing venation and tympanal form of advanced noctuids, retain a well-developed proboscis, and lack the eversible abdominal gland present in larval Lymantriidae and the eversible pheromone glands of arctiid females. Adults (Figs. 95–97) are small to very large (FW 4–140 mm), including Thy-sania agrippina in Central America, with the world’s largest insect wing expanse, exceeding 10 in. The FW is triangular to narrow and the HW broad, usually folding fanlike under the FW when at rest. The body is relatively heavy, the thorax having powerful musculature in most noctuids, and many of these moths migrate long distances. The head has long scales, sometimes forming erect tufts or a conical projection in front; the proboscis is long and coiled, its tip armed with thorns for piercing fruit in some genera. Wing coupling is accomplished by frenulum–retnaculum, usually a single bristle in males, two or three finer bristles in females. The abdomen often has eversible coremata or tufts or pouches of specialized scales. Most noctuids are nocturnal and somber colored, with the FW cryptic against bark or leaf litter when the moths are at rest during the daytime. Some have brightly colored HW that are flashed when the insect is disturbed, presumably having a startle effect on would-be predators (e.g., Catochela, underwings, Fig. 96). Other Catochelinae hold the wings out flat at rest, with the HW cryptically colored, matching the FW. Some noctuids are diurnal and brightly colored, like flowers they visit, while many high-latitude and montane species are diurnal and dark colored. The larvae typically are cylindrical robust caterpillars, bare with only primary setae (cutworms). Those of some Catochelinae have lateral fringes that appress to the substrate, eliminating shadows (Fig. 32). Acronictinae, Pantheinae, and Nolinae have various secondary setae, sometimes in rows or as tufts on verrucae similar to the arctiids. The prolegs are reduced in some subfamilies, with those of segments A3–5 nonfunctional (semioomers), especially in sedentary species that feed on herbs. Noctuids feed on all kinds of plants, probably nearly every gymnosperm and angiosperm family. Many are polyphagous, foraging on low-growing plants at night, while others are specialists on one or a few plants, including those with toxic chemicals or latex, such as Anacardiaceae, Apocynaceae, Asclepiadaceae, Euphorbiaceae, Moraceae, Urticaceae, and Vitaceae, as well as grasses and sedges, Liliaceae and Amaryllidaceae. Several groups feed on fallen leaves or in plant detritus (e.g., Hypenodinae) or on algae, lichens, and fungal-ridden plant matter. Several species are predaceous on scale insects or feed on detritus in spiderwebs or mammal nests. Many are important economically worldwide, especially polyphagous cutworms and armyworms (e.g., Agrotis, Autographa, Trichoplusia, Heliothis, Pseudalita), eating soybean, sugarcane, cereal, legume, rice, and other field crops. There are more than 35,000 named species in 4200+ genera, worldwide, occurring from high elevations above timberline to low deserts and especially numerous in tropical regions.

**Hedyloidea** Hedyliids are peculiar moths that superficially resemble geometrids, with which they were classified until recently proposed as the ancestral butterfly lineage. The hypothesis is based on 10 characteristics: metathoracic aorta configuration, six features of the adult skeletal structure, an upright egg, larval anal comb, and pupal girdle. None, however, is unique or universal for all members of either Hedyloidea or Papilionoidea to affirm their monophyly. Probably these resemblances evolved independently, as they are not present consistently in ancestral members of the respective butterfly lineages. Adults (Fig. 98) are nocturnal, medium-sized (FW 16–32 mm), with broad, semitranslucent wings, weakly scaled in patterns of gray or brownish and white. Wings coupled by a retinaculum and frenulum with a single bristle in the male, weak bristles

Powell, 94, 101, 103, 104, 107, 108, 110, 112, 113, 114, 116; unknown, 93.)
in the female, typical of most ditrysian moths. The resting posture is characteristic, with the thorax titled so the HW nearly touch the substrate, and the slender abdomen is raised above them. The head is small, eyes are large, proboscis is well developed, labial palpi are ascending. The antennae are usually filiform, bipectinate in a few species, lacking the apical club of butterflies. There are small, tympanal-like structures at the base of the FW, similar to those of some Nymphalidae, and there are no abdominal tympana that would link hedylids with Geometridae. The forelegs of males are reduced and not used for walking, like nymphalid butterflies. The egg is pierid-like, upright, spindle-shaped, and ribbed. The larval head is bizarre with elongate, trifid, barbed horns, similar to some nymphalids; the body is smooth and slender, and the last abdominal segment is bifid, somewhat like some notodontid moths and satyrine butterflies. The pupa is exposed, anchored by a silken girdle, similar to Pieridae and some Papilionidae. Recorded larval foods are Euphorbiaceae, Malpighiaceae, Malvaceae, and Sterculiaceae. There are about 40 species, all in the genus Macrosoma, restricted to the Central and South American tropics, Cuba, and Trinidad.

Hesperioidea Hesperioidea includes six subfamilies, and the giant skippers, formerly accorded family status (Megathymidae), have been relegated to a subset of the subfamily Hesperiinae by recent authors. Adults (Figs. 99–101) are small to moderately large (FW 8–35 mm), stout bodied with powerful thoracic musculature; they are called skippers because of their quick, darting flights. The third axillary sclerite at the FW base is unusually wide and forms an irregular Y-shaped structure for muscle attachment, a defining character for Hesperiidae. The HW has an area of very small, specialized scales at the base of R + Sc, also not found in other Lepidoptera. Skippers typically perch with the wings outspread (Pyrginae, Fig. 100) or hold the HW out horizontally and the FW upright, slightly cocked open (Hesperinae, Fig. 101), or they close both wings above the body like other butterflies, especially when taking nectar. The head is broader than the thorax, with the antennae widely separated and enlarged distally into a club with its tip (apiculus) attenuated and curved. The flagellum is strongly bent at the club in Pyrrhopogynae. The proboscis is well developed, and nearly all species feed at flowers, bird droppings, or other nutrient sources. Most skippers are rather drab, predominantly tan, brown, gray, or black, but many tropical species are colorful. The larval head is prominent (Fig. 102), frequently with protruding lobes, separated from the body by a constricted “neck” in all but the Megathymin group, a unique condition in Lepidoptera. In megathyminids the head is narrower than the thorax, and the pupa moves in the larval tunnel, protruding at adult eclosion, a unique reversal among Obstectomera. The terminal body segment has an anal comb, analogous to that of some moths, used to flip frass from the larval shelter, sometimes remarkable distances. Trapetinae in Australia feed on monocots, mainly Xanthorrhoeaceae, Poaceae, and Cyperaceae, as do Hesperiinae, mostly on grasses. Coelidae of the Old World tropics, Pyrrhopogynae in the New World, and Pyrginae specialize on dicots, with more than 50 plant families recorded, and a few feed on monocots. About 3500 species are described in 500+ genera, and many species complexes in tropical regions are not thoroughly studied. Hesperiidae are distributed worldwide except in New Zealand, with greatest richness in the Neotropical region.

Papilionoidea To most people butterflies are among the most conspicuous and recognizable insects. Their diurnal behavior, esthetic beauty, and limited species numbers render them favorite subjects for beginning naturalists and amateur collectors and teaching insect metamorphosis to primary school children. Moreover, butterflies have been of special significance to biologists, in studies of geographical distribution patterns, chemical defenses and mimicry, migration, genetics and population biology, and host–plant relationships. In recent decades they have become poster children in conservation efforts. Butterflies are vastly better studied than most moths, but they are negligible in insect biodiversity, making up fewer than 0.1% of all insect species and 9% of described Lepidoptera (likely less than 4%, were moths equally well cataloged). Several adult skeletal features define members of this superfamily as monophyletic, and the antennae have apical clubs, without an apiculus like that of Hesperiidae and not subapically broadened as in sphingid, castniid, and sesiid moths. Systematists recognize four families of butterflies: Papilionidae, Pieridae, Lycaenidae (including riodinids), and Nymphalidae (including lythids, satyrids, and danids). There are an estimated 14,000 species, a total that is greatly inflated relative to moths and other insects, because they are more thoroughly studied, with a propensity by the industrious specialists to accord species status to geographically disjunct populations that differ in color patterns and size but not morphologically or by molecular analysis.

Papilionidae The swallowtail family is one of the most easily recognizable of Lepidoptera, one whose phylogeny is well supported, based on several wing venation and skeletal features and the eversible gland of the larval prothorax (osmeterium). Adults (Fig. 103) are medium- to very-large-sized (FW 14–105 mm), including the largest butterflies (birdwings of the Indo-Australian region); wings are broad, with the FW triangulate and the HW rounded, and often with one or more veins extended into “tails.” Most are brightly colored, often aposematic, warning of their distasteful properties, and many swallowtails are models in mimicry complexes; some are polymorphic, with several forms each with different corresponding mimics, often nymphaids. Swallowtails are strong fliers and have been recorded dispersing several miles from a point of origin. Some tropical species engage in mass migrations. The larvae (Figs. 34 and 104) are plump, often ornate with filaments or protuberances. They appear bare but usually have numerous tiny secondary setae. They live exposed on foliage, inactive by day, and depend upon cryptic coloration for protection, often resembling bird droppings in early instars and then graduating to foliage or flower colors, as they grow, or they are aposematic, brightly colored (Fig. 34). The osmeterium is hornlike, forked, usually bright pink or orange, and everted to emit a foul aroma intended to ward off predators. The caterpillars feed on a wide variety of dicot angiosperms, including several groups on Aristolochiaceae and others on Magnoliaceae, Apiales, Rutaceae, Lauraceae, and other plants not used by most Lepidoptera. There are about 600 species in 26 genera, with virtually all the world’s species described, distributed worldwide, with Parnassinae in high latitudes and elevations of the Holarctic and Papilioninae mostly subtropical and tropical and with their greatest richness in the Old World tropics.

Pieridae The whites and sulfurs make up a well-established, monophyletic family, based on several characters: the presence of pterin pigments in the wing scales; the foretarsi with inner claw subequal in length to the outer; whereas the inner is much shorter in other butterflies; and wing venation and thoracic skeletal features. Adults (Fig. 105) are small- to medium-sized (FW 11–48 mm), broad winged, mostly white, yellow, or orange, with some tropical species brightly colored, containing flavone pigments, mimicking other butterflies (e.g., South American Dismorphiinae). Most pierids display sexual dimorphism in color patterns, sometimes to the extreme, and many have marked seasonal variation. Remarkable mass migrations by some tropical pierids occur, often moving from seasonally dry to...
Lepidoptera

wet habitats. Larvae are slender caterpillars, relatively uniform in structure, without protuberances, and covered with short secondary setae, and each segment is divided superficially into six annulets. They are mainly green, including the head, or spotted with yellow and blue in species that feed in flowers. Some species possess an anal comb. Tropical Discomorphinae feed on legumes, as do some Collidiinae, while most Pierinae specialize on Brassicaceae, Capparidaceae, Loranthaceae, or Santalaceae. The American genus Neophasia feeds on pines. Several species have achieved important pest status, particularly the cabbage white (Pieris rapae), which was introduced from Europe into North America in the 1880s, feeding on cabbage and other crucifer crops, and species of Colias, feeding on alfalfa. More than 1000 species in 75 genera have been described, including probably nearly all the world’s species. This group is cosmopolitan except in New Zealand and the Pacific Islands, with greatest development in the tropics. Species range to the extreme limits of Lepidoptera habitats, Colias to 83° N latitude and Baltia to 5000 m (16,350 ft) in the Himalayas and several genera to similar elevations in the Andes.

Lycaenidae The coppers (Fig. 106), hairstreaks (Fig. 107), blues (Fig. 108), and metalmarks (Fig. 110) together form a diverse butterfly family, with a remarkable array of larval biologies. Inclusion of the metalmarks (Riodininae) is debatable because they have several uniquely derived traits and because they have foreleg morphology and function that resemble those of Nymphalidae. However, exclusion of the riodinids leaves the remainder of the Lycaenidae an incomplete lineage (paraphyletic). Adults (Figs. 106–108, 110) are mostly small (FW 6–25 mm; Neotropical Eusmaeus and African Liphyra reach 35 mm) and the upper surface of their wings is usually brightly colored, entirely or patterned, in blue, orange, or red, often brilliantly metallic, especially in the males, while the undersides, which are exposed when the butterfly is inactive and the wings are held together above the body, tend to be more cryptic, gray, brown, or green. The wings are relatively broad, the FW usually triangular and the HW rounded; most hairstreaks and a few blues have one or more slender filaments arising from the hind margin, often preceded by a colorful eyespot on the underside. During perching the wings are moved alternately, giving an impression of antennal movements, a behavior thought to deflect predator attack to the HW rather than to the head and thorax. Metalmarks exhibit a bewildering array of wing forms and color patterns, especially in tropical species, resembling diverse kinds of butterflies and moths. Lycaenid antennal bases are adjacent to and usually indenting the eyes. In Riodininae the antennae usually are long, more than half the FW length, and the forelegs are atrophied in males. The antennae are shorter and the male forelegs functional in other lycaenids. Lycaenid larvae are peculiar caterpillars, shaped like a sowbug, with the body segments broadened laterally and the small head retractable and hidden under the thorax; they are usually covered with short secondary setae, giving a velvety appearance (Fig. 109). Species that live in association with ants are bare, and Riodininae usually have long secondary setae. All lack eversible prothoracic glands. Species that live in association with ants are bare, and Riodininae usually have long secondary setae. All lack eversible prothoracic glands. 

Nymphalidae This is a large and diverse family that includes the typical Nymphalinae (brush-footed butterflies, admirals, checkerspots, Fig. 111), Libytheinae (snout butterflies), Satyrinae (wood nymphs, ringlets, Fig. 112), Heliconinae (long wings, fritillaries, Fig. 113), Morphinae (morpho and owl butterflies, Fig. 116), and Danainae (milkweed and glasswing butterflies, Fig. 115). All possess three longitudinal ridges (carinae) on the ventral surface of the antennae that are unique in Lepidoptera, and the forelegs of males are reduced or modified (less so in Libytheinae), usually lacking claws and nonfunctional for walking. Adults are small to very large (FW usually 10–50 mm, ranging to 75 mm in tropical Morpho and Caligo), mostly broad winged except in Heliconinae, and usually brightly colored, often with orange, black, and white dominating, but mostly brown and tan in Satyrinae. Many tropical nymphalids are involved in mimicry complexes, either as models (Danainae, Heliconiinae) or as mimics of them or other distasteful butterflies and moths and/or they benefit in both roles. Glasswing butterflies (Ithomini) live primarily in deep shade of tropical forests and have sparsely scaled areas or transparent wings, with subtle color patterns, while owl butterflies fly at dusk. They, morphos, and satyrines have conspicuous eyelike spots near the margins of the wing undersides, presumably confusing would-be predators or diverting their attacks from the body. The larvae are cylindrical caterpillars with full complement of abdominal prolegs (Fig. 114), but there are diverse modifications, e.g., densely spined or with dorsal projections (verrucae) that are spinose (Nymphalinae), smooth with filaments (Danainae), smooth with bifid caudal segment (Satyrinae), pubescent with hair tufts and usually bifid caudally (Morphinae). The pupa hangs head downward, attached by a cremaster, without a silken girdle. The larvae feed on a diverse array of flowering plants, with considerable specialization within subfamilies: Morphinae and Satyrinae almost exclusively on monocots, including Arecaceae, Bromeliadaceae, Heliconiaceae, and Musaceae (a few species are pests on bananas) in the tropics, mostly Poaceae and Cyperaceae in the Holartic, with 2 genera on Selaginellaceae; other nymphalids eat mostly dicot angiosperms, often specializing on plants with toxic chemicals (e.g., Heliconiinae on Flacourtiaceae, Passifloraceae, Urticaceae, Violaceae) or latex-producing plants (Danainae on Apocynaceae, Asclepiadaceae, Moraceae). About 6500 described species are placed in 630 genera, occurring worldwide, ranging from Arctic–Alpine Boloria in the Holartic to extremely rich tropical faunas in most subfamilies, several of which are not represented in New Zealand.

Lice, Human

(Pediculus and Pthirus)

Terri L. Meinking
Global Health Associates of Miami (GHAM)

Lice are wingless, bloodsucking insects that belong to the order Phthiraptera. Although there are currently 4000 species of lice recognized, only 560 species suck blood and feed on mammals. Lice are very host specific; therefore human lice cannot be transmitted to or from other mammals. There are only three species of lice that infest humans: *Pediculus humanus humanus*, the body or “clothing” louse; *Pediculus h. capitis*, the head louse (Fig. 1) and *Pthirus* (or *Phthirus*) *pubis*, the crab or “pubic” louse (Fig. 3).

**BIOLOGY**

Lice, like all other insects, have six legs. They are hemimetabolic in development, meaning that they do not go through a complete metamorphosis like mosquitoes or fleas. There are three nymphal or “instar” stages that all look like a miniature adult. Within 7–12 days after eggs (nits) are laid, nymphs hatch, which will molt three times before becoming adults.
Within a few hours of hatching, the nymph must find a human blood meal or it will die of starvation and dehydration. At all stages, lice have a very tough, leathery cuticle capable of considerable expansion after feeding, usually taking in blood meals up to one-third of their own body weight every few hours. Regular feedings occur every 4–6 hours with head and crab lice, although body lice can survive for days without a blood meal. Several feedings occur between the shed of each chitinous exoskeleton or cuticle. The first, second, and third nymphal stages last 3–4 days each. It is not until the final molt that the sex can be determined. Females are usually 20% larger than males of the same species, as well as longer, wider, and rounder, with the posterior portion of the female terminating in an invaginated V-shape (Fig. 1). Gender identification is more difficult with Phthirius than with Pediculus.

Within 2 days of molting the female will feed several times, copulate, and begin laying an average of 3–6 eggs per day, with body lice laying more and crab lice laying fewer eggs. The female louse attaches the nits to hairs or fibers (in the case of body lice) by secreting a glue for which there is no solvent (Fig. 2). The life span of a louse from hatching through adult is 30–42 days.

**HABITAT/Epidemiology**

*Pediculus h. humanus*

The body louse lives in clothing or bedding and travels to the host only to feed. The nits are laid on the clothing fibers, especially in the seams and collars. This is truly an infestation of individuals who are unable to wash themselves or their clothing. Infestations with the body louse occur more commonly in individuals crowded together because of war, natural disaster, refugee status, or, in cooler climates, homelessness. They give all lice a "bad name" because people associate all lice with poor hygiene; however, this is the only human louse associated with lack of cleanliness.

*Pediculus h. capitis*

The head louse likes a clean healthy head and is found commonly on children 3–11 years of age. The nits are laid on the hair, usually close to the scalp for warmth. Head lice are primarily transmitted by head-to-head contact, which is more frequent in younger children; however, older siblings, parents, childcare workers, and teachers may also be infested. Sharing of brushes, combs, hats, helmets, and other headgear and hair accessories also can result in transmission.

*Phthirus pubis*

The crab louse (Fig. 3) prefers the pubic and perianal areas, but contrary to older literature, can also be found on the beard, mustache, scalp, axillae, eyebrows and eyelashes, or any hairy part of the body. Unlike head lice, which tend to be somewhat particular, crab lice are found in all levels of society, and are generally transmitted by sexual contact. HIV-positive and immunocompromised individuals are more difficult to treat. Adult crab lice can remain alive off of the host for at least 36 hours therefore, transmission by infested towels and bedding is more common than originally thought.

**Disease Transmission**

*Pediculus h. humanus*

Disease transmission primarily occurs as a result of contact with infested lice fecal pellets. The body louse is capable of transmitting the following diseases: epidemic typhus (caused by *Rickettsia prowazeki*), murine typhus (caused by *R. typhi*), trench fever (caused by *Bartonella quintana*), and relapsing fever (caused by *Borreli recurrentis*).

*Pediculus h. capitis* and *Phthirus pubis*

Head lice and crab lice are capable of transmitting group A *Streptococcus pyogenes* and *Staphylococcus aureus*. Neither head nor crab lice have been studied as transmitters of blood-borne diseases, but this is an area of current interest.

**Treatment**

*Pediculus h. humanus*

Over-the-counter lice treatments that contain 1% permethrin or natural pyrethrin products can be used, but resistance has been reported in the United States and other countries. Prescription malathion lotion and oral ivermectin are the most effective treatments. Lindane products should not be used because of toxicity and resistance.

*Phthirus pubis*

Although head lice products may be used on crab lice, the most effective treatment is 5% permethrin cream or oral ivermectin. All hairy areas of the body should be treated, including the scalp.

*Phthiriasis palpebrarum*

Since topical treatments should not be used around the eyes, crab lice of the eyelashes should be treated with petroleum jelly, which suffocates lice and eggs and lubricates the lashes, making nit removal easier.

Locusts

R.F. Chapman†
University of Arizona

Locusts are medium- to large-sized grasshopper-like insects that form swarms of hundreds of millions of individuals with the potential to migrate long distances in the tropics and subtropics. Locusts differ from grasshoppers in their responses to crowding. Locusts behave as solitary insects immediately after hatching or when maintained in isolation, but if they are forcibly crowded for as little as 6 h they subsequently tend to group together, or exhibit gregarious behavior. In contrast, if grasshoppers are kept in a crowd they usually remain as solitary insects and show no tendency to come together. A few grasshopper species, however, do have some tendency to gregarize when forcibly grouped, although this does not occur naturally. Thus, there is no absolute distinction between a “grasshopper” and a “locust.”

Locusts do not comprise a single taxonomic group. Rather, they occur in three subfamilies of Acrididae, the Cyrtacanthacridinae, Oedipodinae, and Gomphocerinae. Even within a genus, some species exhibit the swarming habits of locusts, while others lack the habit and never swarm. This is most obvious in the genus Schistocerca, where a majority of the American species are non-swarming, and Dociostaurus, with many nonswarming species in Asia. Locusta migratoria, which extends from Australia and eastern Asia to Europe and West Africa, has a number of subspecies, which differ in their propensity to swarm. The species usually regarded as locusts and their distributions are given in Table 1.

In addition to the behavioral change, locusts exhibit a marked color change when crowded. In isolation they are often green or exhibit a more or less uniform color matching that of the background; crowded locusts, however, exhibit a striking black and yellow or orange coloration in the nymphal stages. These changes, however, are not peculiar to locusts; similar changes are shown by some grasshoppers. The proportions of different parts of the body also differ between locusts reared in isolation and those reared in crowds. The most striking difference occurs in the migratory locust, where insects reared in isolation have a strongly crested pronotum (upper surface of the first thoracic segment), but in crowded insects the upper surface of the pronotum is saddle shaped.

PHASE THEORY OF LOCUSTS

Locusts do not swarm continuously; periods of swarming may last for several years but are separated by times when no swarms are reported (i.e., recession periods). The mystery of their apparent disappearance during recession periods was solved for L. migratoria by B. P. Uvarov in a paper published in 1921. He proposed the phase theory of locusts, suggesting that during recession periods the insects exist in a form that differs phenotypically and behaviorally from swarming locusts. He referred to these two forms as the “solitary” (later called “solitarious”) and “gregarious” phases. Locusta in the solitarious phase had, until that time, been placed in a different genus, Pachytylus. Subsequent work showed that similar phases occur in the other locust species. Solitarious locusts are typically cryptically colored, relatively inactive as nymphs (but not necessarily as adults; see later), and live in isolation. Gregarious locusts are conspicuous, with contrasting colors; they form bands (as larvae) or swarms (as adults), and are usually highly mobile. The change from one form to another does not occur in a regular manner, but is dependent on environmental conditions. For example, a period of grouping may increase the tendency of nymphs to group (i.e., to become gregarious), but if they then become isolated again they will tend to lose these characteristics. Consequently, there is no regularity in the timing of outbreaks when swarms occur.

PHASE CHANGE IN THE FIELD

During recessions between outbreaks, solitarious locusts may be very widely distributed, but sometimes these insects are very uncommon. The transformation from solitarious to gregarious involves several discrete phenomena that were first recognized by J. S. Kennedy. Outbreaks are initiated by conditions that favor successful breeding.

†Deceased May 2, 2003.
leading to an increase in the population size. Then the population becomes concentrated in particular areas as other parts become uninhabitable. This leads to aggregation in which the previously isolated individuals are forced into intimate contact with one another. Finally, in the process of gregarization, the behavior and physiology of the insects is changed, and they now tend to aggregate spontaneously. Concentration, aggregation, and gregarization are generally dependent on a drying out of the habitat following good breeding conditions.

Population increases may occur in any part of the distribution area of the insects, but swarming of most species seems to originate only in what are called outbreak areas. The peculiarity of these areas is that only here do the conditions for population increase, concentration, and aggregation coexist. The migratory locust has only a single outbreak area in Africa, even though the species is widespread and often common in many parts of the continent. This outbreak area is the delta of the middle River Niger in Mali. The area is unique because, in addition to local rain, it receives considerable moisture from precipitation on the mountains of Senegal, the source of the Niger. From the mountains, the river runs inland to a low-lying area in Mali, where it branches to form a delta before flowing southwest through Nigeria to the Atlantic Ocean. The combined effects of rain and river flooding in the delta region produce an extended growing period for vegetation and so enable the locusts to have as many as four generations within a year, whereas elsewhere in Africa the species usually has only two. As a result, huge population increases can occur. However, as the floodplains dry out, suitable areas of vegetation become increasingly restricted, and the insects are first concentrated and then aggregated into smaller areas, where gregarization occurs. Biogeographical analysis of the occurrence of swarms during the last great outbreak of the migratory locust, which lasted from 1930 until 1940, shows clearly that the plague originated from the single outbreak area and spread progressively over Africa south of the Sahara.

The red locust, in southern Africa, unlike the migratory locust, has only a single annual generation. It has several outbreak areas in Tanzania and Zambia that, like the middle Niger, are floodplains. The red locust outbreak areas, however, have either no or very limited outflow of water. As a result, the water that accumulates and sometimes forms a lake has become salty over time. Nymphal development coincides with the rainy season, when extensive flooding produces lush, tall grasslands in which the locusts feed. As the vegetation dies, its distribution becomes more limited, perhaps as a consequence of increasingly saline conditions in the slightly lower parts of the floodplain and as the area of vegetation becomes more restricted, the locusts become concentrated, with the potential to give rise to swarms.

The desert locust differs from these species in that swarms arise in different places depending on the success of breeding and vegetation changes; there is no evidence of any single outbreak area from which the plagues of the 20th century originated.

MIGRATION

Locust swarms fly during the day and, if they are flying close to the ground, often tend to stream in one direction. This is still true at any one position within a high-flying swarm; in the swarm as a whole, however, the orientation of these streams is random. This would rapidly cause the swarm to disperse except that upon reaching the edge of the swarm, individuals turn back into it. It is not known what stimuli produce this behavior, but vision, sound, or even smell may be involved. Because the locusts within the swarm are, effectively, randomly oriented, the swarm itself has no directional movement and is carried downwind. The rate of displacement of swarms flying close to the ground is less than the airspeed because the insects tend to land at intervals, taking off again as the rest of the swarm passes. In high-flying swarms, however, this is not possible. The locusts may be carried on thermals as high as 3000 m above the ground, and then the swarms are displaced downwind at about the speed of the wind. If the winds are light and variable, swarm displacement is negligible. With sustained winds, however, displacements over hundreds or even thousands of kilometers can occur. This behavior is one of the factors enabling the desert locust to survive in some of the most arid regions on earth, the Sahara and Arabian deserts. Downwind displacement takes the insects to areas of wind convergence, where rain is most likely to occur, if it occurs at all, so that the chances of the insects breeding and producing viable offspring are greatly increased. Because wind patterns are not completely reliable, however, this strategy is not always effective. As a result, swarms of desert locusts in West Africa are sometimes carried out into the Atlantic or north to western Europe. The most spectacular recorded flight occurred in October 1958, when huge swarms were carried right across the Atlantic, with large numbers reaching the Caribbean and the northern coasts of South America, a distance of about 6000 km from the insects’ source in West Africa.

The bulk of the work leading to our current understanding of swarm behavior was carried out by R. C. Rainey and Z. Waloff, working on the desert locust in the 1950s and 1960s. The assumption is that swarms of other locusts behave in the same way, although the other species do not generally form such massive swarms and are much less well studied.

It is also known that adults of the solitarious phases of at least some locust species migrate, but they do so at night. Evidence for night migration by solitarious individuals exists for Anacridium spp., L. migratoria migratorioides (the African subspecies), Locustana pardalina, and S. gregaria. Nomadacris septemfasciata, on the other hand, appears to be sedentary in the solitarious phase. In this respect, locusts are similar to tropical grasshoppers, many of which are sedentary, whereas a few are known to make extensive night migrations. These solitary migrants, unlike day-flying swarms, deliberately climb to relatively high altitudes (200–500 m above the ground) and then may maintain flight for some hours, although probably a majority of flights are relatively short. In the case of L. m. migratorioides, regular flights occur within the floodplains of the outbreak area and from them to the surrounding semi-arid country, where breeding may occur. Return migrations to the floodplains also occur, and this strategy moves populations with the Inter-Tropical convergence, along which rain is likely. These flights are sometimes downwind, but there is also some evidence from radar observations that the insects can maintain a particular heading despite shifts in wind direction. These seasonal movements make an important contribution to the survival of the insects. Night flights by the Australian plague locust, Chortoicetes terminifera, are also well documented, but these generally are of shorter range.

CONTROL OF PHASE

The physiology of phase change is not yet fully understood. It has been known for some time that grouping can be induced in isolated nymphs by touching individuals with fine wires dangling from a rotating circle, indicating that it is primarily physical contact with other locusts that initiates gregarization. More recent work has
shown that touching the hind femora is more effective than touching other parts of the body. Presumably, the effects are registered by mechanoreceptors on the femora, leading to a change in the nervous system that alters the insect’s behavior toward gregariousness. It is very likely, though not yet proved, that this sequence involves neuro-modulators. A peptide hormone that enters the hemolymph via the corpora cardiaca induces the dark coloration of gregarious nymphs.

Pheromones play a part in the maintenance of gregarization. A number of experiments indicate that gregarious locusts of both sexes produce a gregarization pheromone. In adult desert locusts, benzaldehyde, veratrole, guaiacol, phenol, and phenylacetonitrile are its major components. This pheromone enhances the tendency to group as well as having some effect on color change. Solitary locusts do not produce the full suite of compounds in comparable concentrations. It has been shown that the chemicals are produced from plant material ingested by the locusts and that bacteria are responsible for their production. Locusts reared on axenic (microbe-free) diets do not produce the pheromone. Mature males in the gregarious phase of both the desert and migratory locusts produce from epidermal glands a pheromone that accelerates maturation of insects of either sex. The major component of this pheromone in the desert locust is phenylacetonitrile. Its effect under natural conditions is, presumably, to tend to synchronize oviposition by the individuals in a swarm, which increases the likelihood that the first-stage nymphs, when they hatch, will be present in large numbers and so will be likely to interact with each other and gregarize. A chemical produced in the accessory glands of gregarious females of the desert locust promotes gregarious behavior and coloration in the nymphs hatching from the eggs; solitary females do not produce the chemical. The chemical is contained in the frothy material that forms a plug above the egg mass and that is interpolated in spaces between the eggs. There is thus a marked intergenerational effect of phase with gregarious females producing offspring that already have some characteristics of gregarious individuals.

**EVOLUTION OF SWARMING BEHAVIOR**

It was once thought that the contrasting coloration of gregarious nymphs was likely to have a function in promoting gregarious behavior, but experimental evidence does not support this. Recent studies with the desert locust show that when the locusts feed on plants containing deterrent chemicals, such as the alkaloid hyoscyamine, predaceous lizards rapidly learn to avoid individuals with gregarious coloration but do not avoid solitarily colored nymphs even when they have eaten the same food. Other plants in the desert areas that are the habitat of *S. gregaria* also contain potentially noxious compounds, and it may be that the gregarious coloration results from selection for warning coloration. This, in turn, may have led to gregarious behavior, since aposematic insects commonly group together. Whether similar arguments can be applied to other locust species is not known.

The tendency to migrate is clearly an adaptation to living in arid habitats, enabling the insects to colonize new areas before the initial food supply is totally depleted. This is most clearly seen in the desert locust. Because some grasshoppers in these same habitats exhibit annual migrations, and some solitary locusts are also known to migrate, it must be supposed that swarm migrations arose from these individual movements. This, however, involved a switch from nighttime migration within the insects’ boundary layer, where flight can be directed by the insect, to daytime flight that is often outside the boundary layer and displacement is largely determined by the wind.

Magnetic Sense

John Klotz
University of California, Riverside

Rudolf Jander
University of Kansas, Lawrence

Experimental evidence for magnetic field sensitivity has been reported in insects belonging to various orders, including Isoptera (termites), Diptera (flies), Coleoptera (beetles), Hymenoptera (ants and bees), and Lepidoptera (moths and butterflies). There is evidence that a few insect species obtain directional information from geomagnetic fields for compass orientation. Two alternative properties of the local geomagnetic vector could serve this purpose. Like a number of birds, animals either make use of the direction in which the dip angle points (“inclination compass”) regardless of the field’s polarity or sense the local declination and polarity (“polarity compass”). Which of these alternatives pertains to insects has not been identified definitively, though one favored hypothesis is based on the detection of magnetic fields using particles of magnetite.

Magnetic compass orientation can be useful for insects in the context of home range (topographic) orientation and during long-distance migration, especially in the absence of visual compass cues. Both honey bees building combs in darkness and blind termites building oriented mounds appear to use magnetoreception for aligning their structures. On the other hand, it is difficult to imagine how an insect could make adaptive use of sensing the absolute strength of the local geomagnetic field.

MAGNETIC COMPASS ORIENTATION

Multiple directional orientation or compass orientation to artificially induced magnetic fields has been shown in several species. The insects always responded to changes in the magnetic field’s declination, which implies sensing of magnetic polarity. In contrast, a geomagnetic inclination compass, as used by some migrating birds, has not been demonstrated for any insect.

Home Range Orientation in Social Insects

The magnetic sense of insects and its adaptive importance have been most thoroughly investigated in social insects such as ants, bees, and termites that require highly developed orientation skills to find and then communicate to their nestmates the location of resources within their home ranges. Much is known about how ants and bees use visual cues such as the sun, polarized light, the moon, and landmarks for spatial orientation. For most navigating insects, the primacy of visual cues must be taken into account in experiments designed to investigate magnetic field orientation. Indeed, an insect’s competence in magnetic field orientation may be hidden if more salient cues such as light are present. However, termite workers and soldiers, which have poor vision at best, rely more on nonvisual cues.

THE GEOMAGNETIC FIELD AS A BACKUP CUE FOR ANTS

Experiments with naturally foraging weaver ants, Oecophylla smaragdina, revealed that their sense of direction is stronger and more accurate under clear skies than under overcast skies. In addition, when ants were tested for orientation indoors after displacement from their outdoor foraging trail, those exposed to overcast conditions maintained the correct trail heading but others exposed to clear skies did not. The difference in response indicated the ants’ use of a nonvisual cue that is overridden by celestial cues if they are present. Support for this hypothesis came with further experiments showing that ants trailing in dim, diffuse light reversed their heading when exposed to an artificially induced magnetic field with polarity opposite that of the geomagnetic field. Wood ants, Formica rufa, have also been shown to use magnetic field orientation when directional light cues are unavailable. These experiments with two species of ants suggest a hierarchically organized orientation system designed so that the primary light compass is more efficient than the magnetic compass, which serves as a backup when directional light cues are absent.

MAGNETIC DIRECTION AS A REFERENCE FOR LANDMARK LEARNING IN HONEY BEES

In flight, the honey bee, Apis mellifera, also uses a magnetic compass in home range orientation. Foraging bees approaching the vicinity of their “target” learn the precise location of resources with respect to surrounding landmarks so they can return to the same place in the future. The most popular hypothesis assumes fast “snapshot”-like recall of near-target constellations of landmarks. The returning bee finds the target location by matching the current perception of landmarks with the “snapshot memories” of them. While learning the spatial relations of landmarks, bees face in a preferred compass direction, using directional light and the geomagnetic field. Honey bees trained in an artificial field with polarity reversed to the geomagnetic field face landmarks in the opposite direction. Hence, their magnetic compass may provide directional information as a frame of reference for the memorized landmarks.

A MAGNETIC CUE FOR HOMING TERMITES

All termites are social insects that have evolved a different set of adaptations for home range orientation. Termites are specialized for foraging underground and in enclosed spaces. The eyesight of workers and soldiers either has regressed or has been lost completely. All foraging termites depend heavily on pheromone trails for finding their way back home. However, as in ants, such trails do not provide any cue that helps to discriminate between the outward and homeward direction. The geomagnetic field could provide such a cue. This has indeed been demonstrated in the blind African grass-harvesting Trinervitermes geminatus (Termitidae: Nasutitermitinae) which, unlike the majority of termite species, is an open-air forager. Homing orientation in returning workers is substantially disturbed by distortions of the geomagnetic field due to weak bar magnets. Whether geomagnetic field orientation is widespread among termites is still an open question.
Migration in Moths and Butterflies

Long-distance compass migration has evolved in relatively few species of insects as an adaptation for dispersal and for coping with seasonal climatic changes. Examples are found among dragonflies (Anisoptera), true bugs (Heteroptera: e.g., the large milkweed bug Oncopeltus fasciatus), and moths and butterflies (Lepidoptera). The implied geographic orientation mechanism could, plausibly, make use of magnetic compass orientation, especially during nocturnal migration and migration under dense overcast.

The most spectacular example of geographic orientation in insects is the massive annual fall migration of the monarch butterfly, Danaus plexippus. Eastern North American populations of monarchs migrate over 3000 km to winter in the mountains of Mexico. Experimental evidence substantiates their use of a sun compass for geographic orientation, and some experiments suggest their use of a magnetic compass as well.

For years entomologists have speculated about magnetic compass orientation in migrating monarch butterflies. The first supportive evidence came in field experiments: migratory butterflies were exposed to a brief pulse of an induced magnetic field 15,000 times the intensity of the geomagnetic field, whereupon the treated butterflies were released and tracked to determine their direction of flight. Two control groups of butterflies were also tested. One of the control groups received the same treatment as the experimental group except for the magnetic pulse. The other group received no treatment and was composed of naturally occurring butterflies migrating through the test area. Both control groups of butterflies kept their normal migratory flight direction to the southwest, but directional headings of the magnetically treated group were randomly distributed, indicating disorientation. Because these experiments were conducted on clear days, however, the sun was also available as a cue. Thus conflicting information from the butterflies’ sun and magnetic compasses may have caused the insects’ disorientation.

OTHER EFFECTS OF MAGNETIC FIELDS ON THE ORIENTATION BEHAVIOR OF INSECTS

Some of the earliest and most detailed studies of magnetic field sensitivity were also conducted with social insects. Once again the honey bee was the focus of intense research, but this time the investigators studied its communication behavior. To recruit and guide nestmates to a newly discovered resource, a honey bee performs a dance indicating to her followers the direction and distance of the resource from the hive. The dance is usually performed in darkness on a comb’s vertical surface. The flight direction to the resource in reference to the sun is transposed by the bee to the direction of her dance with respect to gravity on the comb. If the resource is in the direction of the sun, the dance is directed upward; if away from the sun, downward; and if in other locations, at various angles to the vertical. Small systematic errors in the directional component of this dance are correlated with daily fluctuations in intensity of the geomagnetic field. These errors disappear when the bees dance in an artificial magnetic field that compensates for the earth’s field.

When honey bees are forced to dance on a horizontal surface in the dark, their dances become aligned with the cardinal and intercardinal axes of the geomagnetic field. This response intensifies when the magnetic field is artificially enhanced and disappears when the field is canceled.

Evidence also suggests that honey bees use magnetic fields in nest construction. Bees that are transferred to a new hive construct combs that are oriented in approximately the same magnetic direction as those in their old hive. In one study, bees built abnormal combs when they were exposed to magnets during construction.

Among the most spectacular and magnificent termite mounds are those of Amitermes meridionalis (Termitidae: Amitermintinae) in tropical Australia near the town of Darwin (Fig. 1). These massive tombstone-like black structures reach up to 4 m in height, and their long horizontal axes align near perfectly north–south. Similar but less perfectly oriented and shaped mounds are constructed by A. lauren- sis on the Cape York Peninsula of Australia. It is more than tempting to refer to these mound builders as “magnetic termites.”

Indeed some good evidence supports this label. If a strong, permanent magnet is buried underground where a new colony starts to build, the resulting structure is misshapen and lacks clear orientation.

In addition to nest alignment, numerous studies have identified insects that align the body axis to magnetic fields. Resting termites, flies, and honey bees adopt positions aligned with the cardinal axes of a magnetic field.

Finally, orientation transfer sometimes occurs from light orientation to magnetic compass orientation. When a yellow mealworm moves away from a light source, it remembers its current magnetic compass bearing. If the directional light is turned off, the course direction is maintained with the help of the remembered magnetic compass bearing.

POSSIBLE SENSORY MECHANISMS

Several hypotheses have been proposed to explain how animals sense magnetic fields. There is circumstantial but no definitive evidence in insects for two such sensory mechanisms. One type of mechanism could be based on the magnetic sensitivity of some chemical or photochemical reactions. If such reactions are linked to light reception in the eye, then changing the wavelength of ambient visible light could alter the directional orientation to the geomagnetic field. Such effects have been observed in male Drosophila melanogaster (Diptera) as well as in some birds. A second mechanism could be based on the interaction between the geomagnetic field and intracellular, submicroscopic magnetite particles that have been found in some insects, including ants, honey bees, and monarch butterflies.
Malaria

William K. Reisen
University of California, Davis

Specialized Terms

Plasmodium Genus (Order Coccidiida, Family Plasmodiidae) contains more than 100 species of blood parasites of vertebrates, of which Plasmodium malariae, P. vivax, P. falciparum, and P. ovoce cause malaria disease in humans.

Anopheles A genus of mosquitoes (Order Diptera, Family Culicidae) that contains 422 species, of which 40 may be involved in the transmission of human Plasmodium.

sporozoites Infective stage of the malaria parasite for the human host, inoculated with saliva by Anopheles females during blood feeding

gametocytes Infective haploid blood stage of the malaria parasite acquired by mosquitoes during blood feeding. Sexual union of micro- and macrogametes occurs in the midgut of the definitive mosquito host.

vectorial capacity The epidemiological efficiency of Anopheles host species in transmitting malaria parasites, expressed as new infections per infection per day, based on mathematical relationships among mosquito daily survival, blood meal host selection and feeding frequency, and susceptibility to parasite infection.

malaria paroxysm A clinical attack of malaria in human host, associated with the liberation of parasites from the red blood cells, featuring cold (shivering, lasting <1h), hot (fever as high as 41°C, 2–6h), and sweating (fever breaks, temperature drops rapidly to or below normal) stages.

Malaria is a pyrogenic (fever-producing) disease caused by infection with one of four species of parasitic protozoa in the genus Plasmodium and is the most important arthropod-transmitted pathogen in the world today, in terms of numbers of cases, deaths, and economic burden. Acquired from the bite of an infective Anopheles mosquito or from infected blood products, malarial parasites continue to suppress development in Africa and parts of Asia, and are emerging as a critical health issue in tropical Central and South America. Anthropogenic environmental changes associated with subsistence agriculture have enhanced epidemiological receptivity and endemicity in the New World. Expanding and rapid global commerce and travel provide an effective conduit for malaria parasites to be re-introduced into currently malaria-free areas.

HISTORY AND DISCOVERY

There is little doubt that there has been a long evolutionary association between humans and malaria. The ascent of the human species and their dispersal from the African center of origin into Europe and Asia most likely was accompanied by host-specific and co-evolved species of plasmodia. Vitax malaria possibly accompanied early Asian voyagers to the New World across the Pacific Ocean, whereas falciparum malaria probably was introduced into the New World from Africa with the post-Columbus slave trade.

Malarial disease has impacted human health throughout recorded history. References to seasonal intermittent fevers abound in the earliest Assyrian, Chinese, and Indian religious and medical writings; however, it was not until the 5th century B.C. that Hippocrates related the distribution of cases to specific seasons and residence near marshes. Malaria has altered the course of human history by afflicting political, scientific, and religious leaders as well as decimating invading armies. The Romans associated marshes with intermittent fevers and attempted to reduce their occurrence through swamp drainage. The term “malaria” was derived from the Italian “mal aria” (bad air), drawing from the association between foul-smelling marsh gases and the occurrence of this disease. In the 1600s, powders from the bark of the Peruvian “Quina-quina” tree (now known as quinine) were discovered in South America and shown to be therapeutic against certain seasonal fevers. Shortages of these natural medicinal powders and the resulting impact of malaria on military campaigns during World War I stimulated research to develop antimalarial drugs and resulted in the formulation of atebrin in 1930 and chloroquine in 1934. Although marshes, mosquitoes, poor living conditions, and malaria were associated repeatedly throughout history, it was not until 1880 that Laveran first observed parasites in the blood of fever patients and 1897 that Ross found malarial parasites in an Anopheles mosquito that previously had fed on a malaria patient. The following year, Ross worked out the complex life cycle of the malaria parasite using a Culex mosquito-sparrow malaria model. Shortly afterward Grassi and colleagues elucidated the life cycle of the human parasite and with Manson demonstrated that protection from mosquito bites provided protection from infection.
The now-confirmed relationship between malarial infection and mosquitoes led to expanded control efforts by chemically treating or reducing surface water where larval mosquitoes occurred. In 1936, the insectical properties of DDT were discovered by Muller and Weisman. DDT spraying was used in the successful eradication of introduced *Anopheles gambiae* mosquitoes from Brazil in 1939–1940 and Egypt in 1942–1945. These successes and the eradication of malaria from the USA by spraying the inside walls of houses with DDT set the stage for the 14th World Health Assembly to adopt a global malaria eradication strategy that was implemented by the World Health Organization from 1957 through 1969. However, failure to sustain the efforts and funding after initial success, disregard for the magnitude of the malaria problem in Africa, and the onset of insecticide resistance in several of key vector species resulted in a global collapse of this effort that was followed by a general resurgence of malaria throughout tropical regions of the world. In 1992, the World Health Organization again selected malaria as the target disease for a global initiative to improve human health, and in 1998 launched the new “Roll Back Malaria” campaign to reduce malaria by 50% by the year 2010. Subsequent financial support by the U.S. Government under President Bush and the Bill and Melinda Gates Foundation has brought established and new technology into this campaign. Only time will determine if the human host finally will rid itself of the circumtropical malaria burden.

**PARASITES AND LIFE CYCLE**

Four species of human *Plasmodium* may be identified, in part, by clinical symptoms such as the pattern of fever and chills (Table 1), morphology, and staining characteristics of the parasite within red blood cells, antigenic properties determined by serology, or genetic sequence. The *Plasmodium* life cycle is complex (Fig. 1). The female *Anopheles* becomes infected when gametocytes are ingested during blood feeding. Sexual union of gametocytes occurs in the mosquito midgut, after which the resulting ookinete penetrates the midgut wall and forms an oocyst. After asexual reproduction, the oocyst ruptures and the motile sporozoites make their way to the salivary glands. Humans become infected during blood feeding by the infective mosquito host when sporozoites are exectorpated with mosquito saliva into the wound created by the mosquito bite. After entry into the circulatory system of the human host, sporozoites rapidly enter the liver where asexual reproduction occurs. Liberation of parasites from the liver may occur rapidly or be delayed, depending upon the species and strain of parasite (Table 1). Once in the blood stream, parasites rapidly enter red blood cells where they multiply sexually. The synchronous liberation of parasites from the red blood cells results in rhythmic paroxysms characteristic of malarial disease. As the infection progresses, haploid gametocytes are formed in the peripheral blood stream from where they are ingested by blood-feeding mosquitoes, thereby completing the life cycle.

**MOSQUITO VECTORS**

Only female mosquitoes in the genus *Anopheles* serve as definitive hosts for the four species of human malarial parasites. Of these, species in the subgenus *Cellia* account for most of the current global transmission and include members of the *Anopheles gambiae* complex (*gambiae, arabiensis*) and *An. funestus* in sub-Saharan Africa, and the *An. culicifacies* complex, *An. fluviatilis* complex, *An. stephensi*, and *An. minimus* in Asia. Historically, the *An. maculipennis* complex was important in the Mediterranean and Europe, whereas species in other subgenera such as *An. darlingi* and *An. albifarlis* have been responsible for the resurgence of malaria in South America.

**EPIDEMIOLOGY AND DISEASE**

Malaria remains a critical health problem of global proportions, causing an estimated 300–500 million clinical cases and more than one million deaths annually. It is a health problem of crisis proportions and a severe economic burden in 107 countries inhabited by 3 billion people (roughly 40% of the world population). The temporal concordance between crop growing and malaria transmission seasons frequently results in a serious loss of agricultural productivity. The distribution of malaria in time and space and the efficiency of transmission are limited by temperature requirements for the

development of the *Plasmodium* parasites within their poikilothermic *Anopheles* hosts and the abundance, bionomics, and behavior of the different *Anopheles* vectors. *P. vivax* can develop at temperatures as low as 14.5°C and is found at more colder latitudes and higher elevations than *P. falciparum* that requires temperatures above 16°C (Fig. 2). In addition to ambient temperature, transmission efficiency depends almost entirely on *Anopheles* bionomics expressed as vectorial capacity; species that are long-lived, rapidly develop parasites, and feed frequently on humans are the most efficient transmitters of malaria parasites.

The incubation period between infection and clinical illness varies among malarial species and strains, being shortest in *P. falciparum* and as long as 9 months in some northern strains of *P. vivax* (Table I). Illness is characterized by the malarial paroxysm and, if untreated, increases in severity as the number of parasites multiply logarithmically. Typical complications include anemia and splenomegaly. In *P. falciparum* infection, changes in the structure of infected red blood cells create congestion and blockages within the circulatory system, causing coma (brain hemorrhages), jaundice, and “black-water fever” with the passing of black urine (liver failure, nephritis), and severe dysentery (dehydration, renal failure). Infection during pregnancy frequently leads to abortion, stillbirths, and neonatal mortality. Some liver stages of *P. vivax* and *P. ovale* remain dormant and, if untreated, may relapse many years after the initial infection.

Infection imparts transient immunity that is maintained in endemic areas by almost constant re-infection. In hyperendemic areas, morbidity and mortality are highest among the non-immune, including travelers, infants, and pregnant women. Adults in these areas tolerate chronic infections and present a constant source of gametocytes for mosquito infection. Malaria mortality has selected for resistant and semi-resistant phenotypes from the genome of affected human populations, leading to the evolution and persistence of traits such as sickle
cell anemia and Duffy blood group antigen that alter the structure and surface of red blood cells making them resistant to parasite infection.

TREATMENT AND CONTROL

Treatment has emphasized the use of chemical derivatives of the quinoline ring, originally found in quinine and present in chloroquine and primaquine. Primaquine has the important feature of destroying the liver stages of \textit{vivax} and \textit{ovale}, thereby eliminating relapses and chronic sources of parasite re-introduction. Resistance has led to the development of alternative drugs including proguanil, mefloquin, pyrimethamine, and sulphonamide; however, in some areas of Southeast Asia treatment of patients infected with multiple drug-resistant strains must revert to quinine with tetracycline. Extracts from plants in the genus \textit{Artemisia} represent a new class of drugs from Asia that now are used for treatment in areas with widespread drug-resistant malaria.

Historically, public health efforts targeting eradication have combined active case detection and treatment with adult mosquito abatement. Active case detection has emphasized complete village-level surveys, the presumptive treatment of fever cases with chloroquine, and verification of malaria infection by slide examination. Residual house spraying with DDT and later malathion targeted indoor resting and verifi cation of malaria infection by slide examination. Residual surveys, the presumptive treatment of fever cases with chloroquine, have led to the development of alternative drugs including proguanil, mefloquin, pyrimethamine, and sulphonamide; however, in some areas of Southeast Asia treatment of patients infected with multiple drug-resistant strains must revert to quinine with tetracycline. Extracts from plants in the genus \textit{Artemisia} represent a new class of drugs from Asia that now are used for treatment in areas with widespread drug-resistant malaria.

In addition to research to improve and expand the arsenal of drugs for patient therapy and the distribution of impregnated bednets and curtains, two new control approaches currently are being investigated: (1) vaccination (protection that probably will be of short duration and is expected within 7–10 years) and (2) genetic manipulation of vector competence in \textit{Anopheles} (species-specific, costly, and untried). These research thrusts have been facilitated by the complete sequencing of the \textit{P. falciparum} and the \textit{An. gambiae} genomes that should enhance the understanding of transmission and provide new targets for intervention.

Success of malaria intervention in developing countries most likely will continue to be hindered by inadequate control delivery systems, political unrest, and the low socio-economic level of most rural populations that cannot sustain intervention. In the modern era, successes in malaria control typically have accompanied advances in education, economic well-being, and medical delivery systems that have led to sustainable programs.

in this suborder. The most important family (about 80% of all named species) is Mantidae, consisting of 21 subfamilies and 263 genera so far identified. This family contains some of the most abundant and widely distributed species on earth including the Chinese (Tenodera aridifolia sinensis) and European (Mantis religiosa) mantids that occur widely in the temperate zones of Europe, Asia, and North America.

Three families in Mantodea are well represented in the Old World in addition to Mantidae: Amorphoscelididae (two subfamilies found widely distributed in Africa and Australia), Empusidae (eight genera in Africa and Asia), and Eremiaphilidae (two genera of ground-dwelling desert species in Africa and Asia). Another tropical family, Hymenopodidae, contains three subfamilies that include some relatively rare and spectacular flower mimics such as Hymenopus coronatus (Asia) and Pseudocreobotra ocellata (Africa).

The remaining three families of Mantodea are less diverse tropical groups: Mantoididae, (with a single neotropical genus, Mantoida), Chaeteessidae (with only one neotropical genus, Chaeteessa), and the most primitive family in the order, Metallyticidae (with a single Malaysian genus, Metallyticus, named for their characteristic metallic coloration).

**NEUROPHYSIOLOGY AND BEHAVIOR**

The interaction between neurophysiology and behavior has been the object of a number of studies, including the role of binocular vision in estimating distance, hearing of ultrasound and its possible use for avoidance of bat predation, and behaviors associated with defense, sex, and prey capture. Mantids are capable of integrating much detailed information from their environment and have exhibited an astonishingly sophisticated array of responses to stimuli.

Sexual behavior varies among species, but in general females attract males through a combination of airborne sex pheromones and visual cues (Fig. 1). In many species, females either cannot or do not fly, and so males find females by flying upwind to follow the pheromonal concentration gradient. This places males at risk of predation because they are more apparent to birds while in flight. When a male finds a female, he incurs even greater jeopardy from his intended mate, depending on her hunger level. Sometimes males are simply captured and eaten before they have a chance to mate, but unless the female is very hungry, he usually is able to mount her. However, a hungry female may decapitate and partially consume a male during copulation without interrupting the transfer of sperm. This behavior, more commonly observed in the confines of laboratory cages than in nature, was once interpreted as “adaptive suicide” by the male, on the presumption that natural selection would favor investing both his sperm and his bodily nutrients in the next generation before he dies. However, this assumes that the victim is guaranteed paternity, is not simply a food item for a female that has already been fertilized by a previous suitor. A more parsimonious explanation is that a female attracts males for nutrition as well as for sperm at the end of the growing season, when alternate prey are becoming scarce and she has to gain significant body mass to produce viable eggs. Males have no choice in the matter, because they cannot discern which pheromone-emitting females already have been inseminated.

**ECOLOGY**

The population biology of temperate mantids is chiefly influenced by food, temperature, and rainfall. Even under the best weather conditions, most individuals within a cohort starve soon after hatching in the spring, and if the weather during the growing season is unusually cool or dry, maturation can be delayed until it is too late to complete the life cycle and lay eggs to overwinter. Global warming is predicted to move the habitable latitudes for temperate species poleward, perhaps faster than they can disperse through natural means, leading to the prediction that some species of mantids (and of other temperate zone insects as well) may face regional, if not global, extinction. The population biology of tropical species is poorly studied, but presumably the relative lack of seasonality close to the equator is likely to mean that biological factors such as competition, parasitism, and predation are more important to survival than weather.

Most predators are generalists with respect to prey choice, and this is especially true for praying mantids, which are capable of feeding on three trophic levels (tritrophic). Their prey includes other predators (including cannibalization of each other) in addition to herbivores, and at least one species has been shown to feed on pollen as a supplement to prey. The fact that all of these processes may be occurring simultaneously, and can interfere with one another, complicates interpretation of the ecological role (niche) of these predators in the structure and function of ecosystems.

Experimental studies have demonstrated that mantids have both direct (prey reduction) and indirect (prey enhancement) effects, because competition with, or predation on, other predators may reduce the total effect that predators have on other prey. The magnitude of a predator’s impact on its prey, measured by a metric known as interaction strength, varies widely among prey types in field experiments so far performed with praying mantids. One study...
reported that the presence of juvenile mantids causes spiders that are small enough to be eaten by them to emigrate from experimental plots set up in the field. Another field study showed that under natural conditions mantids can instigate a trophic cascade (top-down effect) whereby productivity of grass is enhanced when mantids eat herbivores. This might suggest that mantids would be good predators for biological control of crop or flower pests. However, mantids eat many arthropods that are beneficial to plants, including pollinators such as bees and butterflies, and predators such as wasps and spiders. There are as yet no published data demonstrating that mantids are beneficial to garden plants.

**Mantophasmatodea**

Klaus-Dieter Klass and Christin Grossmann, *Museum für Tierkunde, Dresden, Germany*

Mantophasmatodea are hemimetabolous, wingless pterygotan insects, 11–25 mm in length, found in Africa. Unique features for this order are a peculiar morphology of the antenna, an upwardly angled course of the subgenal sulcus on the head, a dorsal process on the tarsi, and a medioventral projection on the male subgenital plate. Discovered in 2001, the Mantophasmatodea are the most recently described order of insects.

**SYSTEMATICS AND DISTRIBUTION**

So far there are 16 described extant species of Mantophasmatodea (in addition to several undescribed ones), which have been assigned to 10 genera. *Austrophasma*, *Hemilophosha*, *Lebathophosha*, *Karophosha*, and *Namaqaphosha* are found in South Africa and together form a monophyletic clade. *Mantophasma* (Fig. 1), *Sclerophosha*, *Praedatophasma*, and *Tyrranophosha* occur in Namibia; the two latter genera are conspicuously spinose and closely related. *Tanzaniaphosma* occurs much further north, in Tanzania, and might be the sister group of the remaining extant taxa. South African and Namibian genera and species show a high degree of endemism. Two fossil taxa were found in (European!) Baltic amber from the Eocene (about 45 mya): *Adicophasma* and *Raptophosha*, which resemble extant mantophasmatodeans. The assignment of another Baltic-amber fossil, *Ensiferophosha*, to Mantophasmatodea requires stronger evidence. *Juramantophasma* from the Jurassic of China is the oldest known mantophasmatodean.

**ANATOMY**

The hypognathous head lacks ocelli and bears orthopteroid mouthparts. The antennae show a unique structure: they have 14 basiflagellomeres and 7 distiflagellomeres, which differ in their width, shape, and equipment with sensilla; the first and sixth distiflagellomeres each bear a tiny distal gland. The subgenual sulcus is strongly angled upward, and the tentorial pit is located in the upper part of the angle. The epistomal sulcus is lacking.

In the abdomen, both tergum I and coxosternum I are free from the metathorax. The small spiracles lie in the pleural membrane and have a muscular closing device. In the male (Fig. 2B and 2C), coxosternum IX forms a subgenital lobe with a median spatulate process (spp in Fig. 2B) but without styli. The phallopores (male genitalia) are simply structured and almost symmetrical in *Tanzaniaphosha* (Fig. 2C), but very asymmetrical and complicated, with several sclerites, tendons, and projections, in the other species. Behind them lies a transverse, asymmetrically produced sclerite (vomeroid), which articulates upon tergum X. The female (Fig. 2D) has a short subgenital lobe formed by parts of coxosternum VIII. The genital opening lies above it on segment VIII. The ovipositor comprises claw-like gonoplates (third valves), blunt gonapophyses VIII (first valves), and gonapophyses IX (second valves) fused with the gonoplates and interlocked with the gonapophyses VIII. The one-segmented cerci are elongate, slightly asymmetrical claspers in the male but short cones in the female (Fig. 2B–D).

The foregut has a large proventriculus (gizzard) armed with weak sclerites that terminate posteriorly in three successive whorls of lobes. Midgut caeca are a pair of short and wide lateral pouches. In the nerve cord, abdominal ganglion VII is free from the terminal ganglion including neuromeres VIII and the following.
Mantophasmatodea are assigned to the Pterygota by their lack of a noncuticular trunk endoskeleton and of the lateral parts of abdominal tergum XI, and to the Pterygota–Neoptera by the valve-like gonoplacs lacking styli and the presence of apodemes on the abdominal spiracles. Beyond that, their phylogenetic position is unclear. The connecting bands in the flagellum of the spermatozoa (between axoneme and mitochondrial derivatives) support a clade comprising Grylloblattodea, Orthoptera, Dictyoptera, and Mantophasmatodea. Promising candidates as the sister group of Mantophasmatodea are the Phasmida (mitochondrial gene sequences), Grylloblattodea (nuclear gene sequences), and Dictyoptera (male genitalia, histology of antennal vessels). A close relationship between Mantophasmatodea and Grylloblattodea has also been advocated based on characters shared with the same Mesozoic taxa; however, this is not very convincing, because only few superficial characters can be observed in the respective fossils.

**HABITATS AND LIFE HISTORY FEATURES**

Mantophasmatodea prey on other insects, which they catch by means of their strong, spinose fore- and midlegs. They are found in moderately humid to very dry habitats, where they live on small bushes or in the tussocks of grass-like plants (Poaceae, Restionaceae). Both males and females drum on the substrate, the males using the process of the subgenital plate; this likely serves for communication. For copulation, which may last for several days, the male jumps on the female. The females produce egg pods, which include some 10–16 eggs embedded in a matrix of sand and gland secretions. Nymphs hatch at the beginning of the rainy season and become mature after five nymphal instars.

**Marine Insects**

**Lanna Cheng**

*Scripps Institution of Oceanography*

Although insects are undoubtedly the most common animals on land, very few species appear to live in the sea. However, they are actually rather well represented in diverse coastal marine or saline habitats. A marine insect is any insect that spends at least part of its life cycle in the marine environment, which includes any habitat...
from the upper intertidal to the open ocean. Among the 30 or so recognized insect orders, marine members occur in more than one-half of them (Table I). The most important species are found in Collembola, Heteroptera, Homoptera, Coleoptera, and Diptera. There are also many species of Mallophaga (biting lice) and Anoplura (sucking lice) whose hosts live in or on the sea (mammals or seabirds). A Web page on marine insects, www.unm.edu/marineinsects, is available.

**HABITATS**

Marine habitats can be divided either by salinity or by their position relative to the tidal level. Three types of saline habitats are generally accepted, based on their salt content (in parts per thousand): brackish (0.5–32), sea (34–37), and inland saline (0.5–250). Marine biologists, on the other hand, have traditionally divided coastal habitats into various zones according to their coverage by seawater or exposure to the sun. Three major zones are recognized: supralittoral (covered only during highest spring tides), littoral or intertidal (covered regularly between high and low tides), and sublittoral (never exposed even during the lowest low tides). An additional important habitat for marine insects is the pelagic zone, which comprises the open ocean far from the shore.

The majority of marine insects occur in the intertidal zones, which can be further categorized by the types of vegetation associated with them, for example seagrasses and rushes (Spartina and Juncus), seaweeds (green, blue-green, brown, or red), mangroves (Rhizophora, Avicennia, Bruguiera, and Sonneratia), or other higher plants (Xylocarpus and Acanthus). The salinity of water in the various intertidal habitats tends to be variable or brackish. Larvae of several marine chironomids (Diptera) live among submerged vegetation in the sublittoral zone, which may include various green plants (Enhalus, Halophila, and Halodule) and algae (Halimeda and Corallina).

The occurrences of various insect orders in different marine habitats are given in Table I. Five habitat categories are used in this table: pelagic, coastal, intertidal, mangrove, and salt marsh. Brackish-water habitats are commonly associated with mangroves in the tropics but with salt marshes in temperate regions.

**TAXONOMIC GROUPS**

**Apterygota**

Among the five known orders, marine members are found only in Collembola, Microcoryphia, and Thysanura. There are few marine thysanurans. The genus *Petrosius* has several marine species living on rocky shores in Europe, whereas species of *Neowachilis* can be found living under rocks or in crevices in the upper intertidal in California and probably elsewhere in North America. Some species in at least six families of Collembola (Onychiuridae, Hypogastruridae, Necuridae, Isotomidae, Ennomobryidae, and Arteletidae) live in various intertidal habitats. The best studied and most widely distributed is *Anurida maritima* (Necuridae), commonly found in rocky upper-intertidal zones or salt marshes. It lives in crevices among rocks and comes out to feed at low tide when the habitat is exposed. It is able to withstand submergence under seawater during high tide for periods up to 4 h by surrounding itself with an air bubble that acts as a compressible gas gill. Its orientation rhythm is endogenous and synchronized with the tides. These animals are usually negatively phototactic (i.e., going away from light), but between 2 and 7 h after low tide a large proportion of the population becomes positively phototactic (i.e., going toward light). Brightness of the horizon appears to be the main cue for the animals to move toward higher ground, where they seek shelter after foraging at low tide. When population densities become too high for any given crevice, these collembolans emerge and allow themselves to be dispersed at high tide by currents. They may then become stranded on the beach. Not infrequently huge aggregations consisting of millions of collembolans can be seen washed up on beaches in various parts of the world.

**Heteroptera**

This is one of the most important orders in the marine environment, with nine families represented. Four families are semiaquatic and live at the water surface, five are shore dwellers, and only one, the Corixidae, is truly aquatic.

**FAMILY GERRIDAE**

This family is represented by several species in the Corixidae, which are thought to be the main group of marine insects. The Corixidae are frequently found in rocky and sandy intertidal areas, where they feed on small crustaceans and mollusks.

Note: P, pelagic; C, coastal; I, intertidal; M, mangrove; S, saltmarsh; +, present; -, absent or no data; * only habitats of hosts marine. From Cheng and Frank (1990).
subfamilies (Halobatinae, Trepobatinae, and Rhagadotarsinae), five genera (Asclepios, Halobates, Stenobates, Rheumatometroides, and Rheumatobates), and over 60 species. They can be found in various habitats ranging from near-shore mangrove streams, intertidal reefs, coastal lagoons, bays and estuaries, to the open ocean. The majority of the species are found in the Indo-Pacific region. The best studied genus in terms of taxonomy, distribution, ecology, phylogeny, and evolution is Halobates (Fig. 1). This genus is almost exclusively marine and contains 45 described species, including 5 that live a wholly pelagic life on the ocean surface. Although no living Halobates are known from the Mediterranean, a fossil species was described from an Eocene deposit (45 mya) in Verona, Italy.

**FAMILY HERMATOBATIDAE** This is a monotypic, exclusively marine family with eight recognized species, all except one being found in the Indo-Pacific. These unique bugs are associated exclusively with intertidal rocks or coral rubble, where they hide in crevices during high tide and come out to feed at low tide. However, some must remain active at the sea surface because individuals have been caught in net tows offshore or with light during the night at high tide.

**FAMILY CORIXIDAE** This is the only truly aquatic heteropteran family to be found in saline environments. Although about 60 species belonging to 12 genera have been reported from saline waters, most of them normally occur in freshwater habitats but are able to tolerate saline conditions. Many species are common in inland saline lakes, but only a few are found there predominantly. *Trichocorixa verticalis*, the most widely distributed species, is commonly found in salt marsh pools, but specimens have occasionally been captured in plankton tows near shore. It is most tolerant of salinity changes and has been found to live and even to breed in ponds with a salinity approaching saturation (>300 ppt). Unlike most marine Gerrids, which are wingless and flightless, adult corixids are winged and often disperse by flight.

**SALDIDAE AND OTHER SHORE BUGS** Five families of shore bugs (Saldidae, Gelastocoridae, Ochteridae, Omaniiidae, and Aphelocheiridae) have representatives in marine environments. The most important family is Saldidae, which has at least 15 genera with more than 50 marine species worldwide. Most live in salt marshes. Winged forms occur in most shore bugs, and some species are rather strong fliers.

**Homoptera**

The Homoptera are rather poorly represented in the marine environment. In the Aphididae the best studied are *Pemphigus* spp., which feed on the roots of the salt marsh Aster in Britain and probably elsewhere in Europe. Several species of herbivorous homopterans (Delphacidae, Issidae, Cicadellidae, and Cicadidae) feed and breed in seagrass beds in tidal salt marshes. *Prokelisia marginata* (Delphacidae) is confined to beds of the seagrass *Spartina alterniflora* along the Atlantic coast of North America.

**Coleoptera**

Representatives of more than 20 families of beetles are found in marine environments, but none are truly aquatic. Most of the species occur in the intertidal zones among sand, rocks, algae, or wrack. Some are found in brackish waters, salt marshes, or sand dunes. The most important marine families are Staphylinidae, Carabidae, Curculionidae, and Tenebrionidae.

**FAMILY STAPHYLINIDAE** This is the most important family, with more than 300 marine species. The genus *Cafius* is exclusively marine, with about 50 species. They are generally found on beaches associated with wrack (piles of stranded seaweeds), where they feed (as predators) and breed. The genus *Bledius*, with well over 400 species, has about 10% occupying marine habitats. Unlike most other staphylinids, they are not predatory. Females lay eggs in burrows and guard them from fungal attack and predation (a presocial behavior). The narrow openings of burrows of *B. spectabilis* have been shown to prevent flooding by tides. Adults and larvae of some other *Bledius* species dwell in inland salt flats. *Bryothis*, a genus of at least 24 species of small beetles, is exclusively marine.
OTHER FAMILIES  Tiger beetles (Carabidae, subfamily Cicindelinae) include about 2300 species that occupy mainly terrestrial habitats. Adults of a few Cicindela species are common on sandy seashores and invade the intertidal areas during low tide. These predatory beetles run very fast and are difficult to catch. Females lay eggs in burrows where the larvae, after hatching, may remain for one or more years in the larval stage. Females of certain Cicindela species have been found to choose soils with specific salinity or shade conditions for laying eggs. In Okinawa the larvae of Cicindela yua-sai okinancens can be found on mud-lobster mounds which may be inundated at spring high tide. Larvae were observed to plug burrow entrances before high tide and to open them after the tide has receded, a behavior that may be governed by an endogenous biological clock.

Some genera of Cureionidae are known exclusively from driftwood or stranded seaweed on beaches, where they breed and the larvae develop. Beetles in several other families (Chrysomelidae, Cerambycidae, Cureionidae) are pests of tropical mangrove trees, feeding on flower buds, leaves, or bark and in some instances causing considerable damage.

**Trichoptera**

Caddisflies are predominantly freshwater insects, but several families breed in brackish water. The Chathamidae are exclusively marine and are known only from New Zealand and Australia. The four species belong to two genera, Chathamia and Philanisus. The adults are winged and can be found flying among intertidal rock pools. Eggs of the most widely distributed species, *P. plebeius*, have been found in the coelomic cavity of intertidal starfish and among coralline algal turf. The larvae use bits of coralline algae to construct their tubes (Fig. 2). They feed on various intertidal algae that may remain submerged at high tide.

**Diptera**

In addition to salt marsh mosquitoes (Culicidae), biting midges (Ceratopogonidae), horse flies, and deer flies (Tabanidae), some of which are of great medical and/or economic importance, many other dipterans are found in various saline habitats. Almost all adult flies are winged, but the larvae of many species are truly aquatic and may remain submerged throughout their entire larval lives. The most commonly encountered nonbiting beach insects are probably seaweed flies belonging to at least five families (Coelopidae, Dryomyzidae, Muscidae, Borboridae, and Anthomyiidae). They are all associated with wrack or cast seaweeds where the adults feed and breed, and their life cycles tend to be synchronized with the tidal rhythm. Members of the predatory family Canaceidae are exclusively marine and occur in the intertidal zone. Some of the most common invertebrates of inland salt lakes are brine flies in the family Ephydridae. Millions of these flies can sometimes be seen clustering along the lake shores, where they provide abundant food for shore birds.

**Orthoptera**

Grasshoppers and crickets are not commonly associated with marine habitats. However, at least four genera in the subfamily Nemobiinae (Family Trigonidiidae) are marine. Members of *Apteronemobius* can be found in mangrove forests. These mangrove crickets are all completely wingless. Males of *A. asahinai* have antennae that are almost three times as long as their body. They may use chemical communication instead of stridulation to attract females.

**Lepidoptera**

Except for caterpillars that feed on mangrove leaves, very few lepidopterans are known in marine habitats. However, a species of *Tatobotys* (Crambidae: Pyraustinae) has recently been reported from intertidal habitats in Okinawa. Larvae of *T. aurantiais* were found to feed on the intertidal red alga *Bostrychia tenella*. Adult moths are nocturnal and can be found hiding in caves during daytime.

**Other Orders**

Other insect orders are represented in the marine environments by only a few species, for example the earwig *Anisolabis*...
Mating Behaviors

Darryl T. Gwynne
University of Toronto

Mating behavior is typically viewed as comprising all events from pair formation through courtship to the final breakup of the mating pair. In most pterygote insects, sperm transfer is achieved through copulation. In contrast, in most apterygotes, including both Insecta (Archaeognatha and Thysanura) and Ellipura (Collembola, Protura, and Diplura), sperm transfer is indirect; the spermatophore is placed on the substrate and is picked up by the female either following a period of courtship or with the pair making no contact at all. This article focuses on events occurring after the male and female have made physical contact; pair formation in insects is covered elsewhere. The main theme here is the function and adaptive significance of mating behaviors, that is, how mating behavior increases reproductive fitness such as by increasing the number of offspring produced.

There is a vast amount of published information on the mating behaviors of insects. These behaviors have traditionally been viewed as relatively invariant within species. However, it is now evident that insect mating can show a great deal of adaptive variation and flexibility. As an introduction to this variation, consider the wide range of mating behaviors by insects that use carrion, a resource that can attract both males and females and thus serves as a location for mating. The complexity and plasticity of mating behavior observed in carrion insects easily rival those of other animals, including vertebrates. Indeed, Shakespeare’s Romeo felt that “more courtship lives in carrion-flies than Romeo.”

One courting carrion fly is attracted to the dry hide and bones of large old carrion sources, the main larval food for the species. The fly Procylia xanthostoma (Piophilidae) shows a remarkably complex courtship that can last for over 15 min (see Fig. 1 for another example). A courting male approaches the female while stepping rapidly from side to side and striking his abdomen downward. Males

FIGURE 1 A fly similar to piophilids in exhibiting complex male courtship is the otitid, Physiphora demundata. The male first taps the male with a foreleg (A), then raises a middle leg (B), and turns and presents his abdomen to the female, who extends her proboscis to touch his abdomen (C). This can be followed by the female backing up in a spiral path, appearing to pull the male backwards (D). (Reproduced, with permission, from Alcock and Pyle (1979) Z. Tierpsychol. 49, 354.)
can repeat these vigorous movements and vary the degree to which they display. If the female stops moving, the male stops courting, orients, and then slowly creeps toward her, occasionally repeating earlier parts of his routine. Individual males vary greatly in the vigor and length of the courtship display and this may represent variation in a signal of male genetic quality used by females to select mates that increase the fitness of her offspring (Table I, Nos. 5 and 6).

Courtship by males of another temperate-zone carrion fly also appears to mediate female discrimination among males. Females of the fly *Dryomyza anilis* (Dryomyzidae) lay eggs on small carrion items such as dead fish. For this fly, courtship on the carrion occurs after copulation. A single courtship sequence consists of the male’s genital claspers tapping vigorously on the female’s external genitalia and then lifting and releasing her abdomen. Males vary in the number of genital tapping sequences performed and the number of sequences correlates with greater fertilization success. Bouts of tapping are followed by oviposition during which the male guards his mate from rivals. A male’s success in fertilization is apparently achieved by the female biasing the distribution of sperm within her sperm storage organs (see Box 1). A similar influence on the success of courting male red flour beetles (*Tribolium castaneum*: Tenebrionidae) comes from a display in which the male rubs the female’s elytra.

In a beetle that buries carrion, considerable variation occurs in reproductive behavior after the sexes have paired up and mated. A male and a female of the beetle *Nicrophorus defodiens* (Silphidae) cooperate both to defend a mouse-sized carcass from intrusions by other *Nicrophorus* and to bury the carrion in an underground chamber where it becomes food for the pair’s offspring. However, the behavior of the sexes is quite different after interment of a rat-sized carcass, one large enough to support more offspring than can be produced by the initial pair. Here, conflict between the pair becomes evident when the male produces a pheromone to attract additional females. The male’s signal causes his resident mate to try and thwart this signaling by mounting and biting the male (Table I, No. 8). Conflict stems from a potential sexual difference in success on larger carrion. On a larger food resource, the male stands to gain substantially from the increased number of larvae he fathers when mating several females, whereas his first mate can expect only decreased fitness owing to increased larval competition.

Sexual conflict and flexibility in mating behavior are also apparent in the postmating interactions of a neotropical rove beetle, *Leistotrophus versicolor* (Staphylinidae). Male and female *L. versicolor* are attracted to carrion (and occasionally dung) not as an ovi-position site but as a place to prey on flies. After a pair copulates, the male can be observed to attack and bite his mate, often running after her for up to half a meter. However, this behavior occurs only when there are a number of rival males present. Male aggression appears to serve in driving the female away from the carrion, thus preventing her from mating with other males (Table I, No. 8). An alternative possibility is that aggression toward females is a form of postcopulatory courtship (see Box 1 and Table I, No. 6).

### SEXUAL CONFLICT DURING MATING

These episodes of insect mating reveal how Darwinian selection theory can be used to understand variation in behavior. The basic underlying assumption of this theory is that individuals behave in such a way as to yield the greatest number of surviving progeny (fitness). This theoretical insight argues that courtship and copulation should be a purely cooperative venture only when the fitness interests of the sexes are completely aligned. Cooperation in courtship was the prevailing view among biologists at one time, in part because courtship was thought to synchronize mating events (Table I, No. 2). In contrast to this view, much research indicates that the sexes are often in conflict. Sexual conflict is expected to be common when the reproductive interests of male and female are at odds (Table I, No. 8).
Box 1  A Broader View of Courtship: The Concept of “Cryptic” Sexual Selection

Sexual selection, typically greater on males than females, is selection in the context of competition for more mates or the best mates. This form of selection explains many sexual dimorphisms, from peacock tails to elaborate cockroach genitalia. Competitive males typically maximize the number of surviving offspring. Therefore male success is best estimated as fertilization success rather than success in mating many females. Thus, both direct competition between males and female discrimination should not end at copulation. The full development of this insight has coincided with the advent of a number of molecular-genetics methods to assign paternity. In insects the potential for paternity competition is high because females typically mate with more than one male and store their long-lived sperm in specialized organs. Indeed, males have been found to possess adaptations that incapacitate, physically displace, or remove rival ejaculates, examples being copulatory movements in dragonflies, such as *Calopteryx maculata*, in which penis brushes remove virtually all rival sperm from the female sperm storage organs. In fact, male insects can enhance fertilization success even after sperm transfer has occurred. For example, males are known to transfer charity-enforcing chemicals to females or substances that cause the females to increase the rate of laying eggs. Commonly, mechanisms that bias fertilization success are under female control and so are often cases of female discrimination, a phenomenon that can be revealed by experimentally removing “male-control” effects on the paternity of offspring. Female adaptations include fertilization biases caused by moving favored ejaculates. Also, in species with “fast ejaculate stored is the first to be used” mechanisms, females mating high-quality males (representing genetic quality in species with no paternal care, Table I, No. 6) can simply increase the rate of egg laying (e.g., *Oecanthus* tree crickets and *Hyllobittacus* scorpionflies) or differentially allocate more resources to these eggs, thereby increasing offspring fitness (no examples from insects, but this is known in birds). Finally, the consequences of these “cryptic” sexual selection mechanisms are: (i) a male’s courtship that signals his quality, that is, genital copulatory displays (Table I, Nos. 5 and 6), can occur at any point during mating until the female oviposits (thus making courtship synchronous with mating) and (ii) the Darwinian division between primary (e.g., penes and testes) and secondary (e.g., the peacock’s tail) sexual structures is blurred: male structures such as dragonfly penis brushes and large testes that are adapted to deliver large numbers of gametes into the sperm competition lottery are probably sexually selected devices. The vast diversity and complexity of insect genitalia may result from these processes: species with multiple-mating females are known to have more complex male genitalia than species in which females mate only once.

Conversely, cooperation is expected in any case in which male and female interests are similar. For example, interactions between a pair of burying beetles are mainly cooperative after they have interred a mouse-sized carcass. In contrast, when a larger carcass is buried, conflict is evident because, unlike the situation with small carcasses, the male has an opportunity to increase his reproductive success by attracting additional mates, whereas any added larvae from such matings probably decrease the initial success of the female. The latter situation exemplifies a type of sexual conflict expected in the reproductive activities of animals because of a sexual difference in reproductive strategy: males typically maximize the number of females mated so as to maximize fertilization success, whereas females maximize fecundity and offspring quality. This sexual difference also causes conflict when already-mated females are harassed by promiscuously mating males. Examples come from the precopulatory struggles often observed in insects. A well-studied case involves water striders (Heteroptera: Gerridae). When a male uses forelegs and genitalia to secure a female for copulation, a vigorous struggle ensues during which the female attempts to dislodge him. Superfluous matings can be costly to females in terms of increased predation risk (Box 2) and energetic cost. To reduce such costs, female *Gerris incognitus* have evolved upcurved abdominal spines that appear to function in thwarting male mating attempts. Another possible purpose for precopulatory struggles is that they test male quality (Table I, No. 6; see also the example of seaweed flies considered under “Genetic Quality and Mate Choice”).

Precopulatory struggles appear to be a result of sexual conflict in species in which males feed their mates, because females pay a cost if the size of their meal is reduced in any way. Thus at the end of mating, a male and female scorpionfly (Mecoptera: Bittacidae) can both be seen to pull on the prey offering (Fig. 2). Conflict comes from male attempts to recover the prey in order to conserve food for copulations with other mates and the female maximizing how long she feeds on the prey. Conflict in some mate-feeding insects is particularly evident in the struggle between the sexes when a male attempts to force a copulation without providing the beneficial meal to his mate. To overcome female resistance, males of both panorpid scorpionflies and haglid orthopterans have specialized abdominal organs that function in holding onto females during forced matings. A widespread form of sexual conflict arises from multiple mating by a female, which increases her success while compromising her mate’s confidence of paternity. This conflict is evident when male rove beetles and tree weta *Hemideina crassidentata* (Orthoptera: Anostostomatidae) drive their mates away from rivals. Striking examples also occur in male adaptations that not only enforce chastity in the female but also reduce her survival. Examples include toxic chemicals in the seminal fluid of fruit flies, *Drosophila melanogaster* (Drosophilidae), and damaging...
from males—their spermatophore nutrients. The degree of choosiness shown by a sex should also be influenced by variation in the quality of the sex being chosen. Members of a sex are expected to be choosy if variation in the quality of potential mating partners is high.

**SIGNS TO MATES DURING MATING**

**Material Benefits and Mate Choice**

Rejection of a mate (usually of males by females) is only one of the explanations for the failure of a pair to mate successfully. Other causes of breakup of pairs are certain changes in the physical environment and a threat of harm from predators (see Box 2) or rival males. A number of studies have ruled out these alternatives and have thus shown that certain mating behaviors function in choosing mates, for example individuals noted to move between signaling or swarming members of the opposite sex before mating with one of them and individuals pulling away from their mates after the mating sequence has begun.

As predicted by theory, female choice of mates is more widespread than male choice. Some of the clearest examples of mate choice come from species in which females obtain material benefits from males (Table I, Nos. 5a and 5b). One case involves scorpionflies (family Bittacidae), of which females attracted to males presenting food gifts of prey will make tarsal contact with the offering (Fig. 2) and reject males presenting small prey. Female scorpionflies also discriminate against such males by breaking off copulation prematurely. Only a male that transfers a large prey will complete copulation by supplying both a full complement of sperm and clastidy-inducing substances.

Most cases of male choice in insects appear to involve the acquisition of material benefits from large females, specifically the large number or size of eggs possessed by heavyweights. This has been noted in a number of insects, including tettigoniid orthopterans, cerambycid and brentid beetles, and empidid flies. There are very few cases of males choosing female displays. Indeed, despite instances of sexual selection on females, there are few examples of female ornaments, even in cases where the mating roles are reversed. One hypothesis for this is that investment in elaborate displays probably trades off with reduced fecundity. Consequently selection on males to mate with the most fecund individuals led to avoidance of ornamented females. There are, however, ornamented females in certain empidid flies. For example, female *Rhampomyia longicauda* displays inflated abdomens and fringed legs to choosy males while flying in all-female swarms during twilight. Poor light conditions may have selected for ornaments as an indicator of female size and thus fecundity. Less likely is the hypothesis that these ornaments advertise genetic quality. As noted earlier, male choice is expected when the mating roles are reversed or when there is a high degree of variance in the quality of females. Examples of the former include male Mormon crickets (*Anabrus simplex*; Tettigoniidae) pulling away from mounted lightweight females—apparently after weighing them—and male empidid flies choosing large, fecund individuals from within all-female swarms. In contrast to male mate choice in role-reversed systems, male choice that evolves in response to a high variance in female quality typically is often found with a high degree of male–male competition, that is, sexual selection on males. Indeed, male choice in this situation can be caused by sexual selection among males to mate with the highest quality females. An example of male choice when females vary in quality includes winter moths, *Operophthera brumata* (Lepidoptera, Geometridae), and red flour beetles. Finally, local population variation in the primary sex ratio can affect the likelihood of male choice; a scarcity of males is associated with a higher degree of male choice in red milkweed beetles, *Tetraopes tetrophthalmus* (Cerambycidae); and in a

**FIGURE 2** Sexual conflict behavior in insects can be seen in mating struggles between a male and a female. Here a pair of scorpionflies, *Hylobittacus similis*, are using their hind tarsi in a tug-of-war over a nuptial prey (a blowfly) item captured by the male.
Genetic Quality and Mate Choice

In theory, females are expected to show choice to obtain indirect benefits, that is, benefits that enhance the genetic quality of offspring. Female Dryomyza flies appear to do this by biasing fertilization after evaluating male copulatory courtship. But what sorts of indirect benefits do choosing females obtain? In yellow dung flies, Scathophaga stercoraria (Scathophagidae), females can favor the stored sperm from males with genotypes likely to enhance offspring growth. One allele in males is better when larvae feed in shaded dungpats (where the environment is relatively stable) and another is better in the sun (where temperature fluctuates greatly between day and night). In other insects, the cue to a male’s genetic quality is consistent. For example, following a courtship consisting of wing-flicking and pheromone displays, older females of Colias butterflies (Pieridae) show mating preferences for genotypes that fly well and are long-lived. Male and female calopterygid dragonflies also act using wing displays and the size of wing spots. The latter is a sexually dimorphic trait in European Calopteryx splendens and is correlated with several aspects of male quality, including the level of immunocompetence, developmental stability, and resistance to gut parasites. In a dipteran, the seaweed fly, Coelopa frigida (Coelopidae), mating interactions involve prolonged premating struggles in which a mounted male can be dislodged as a result of kicking and shaking by the female. Such struggles favor matings with large males and this female bias enhances the genetic fitness of her offspring: progeny of large males tend to be heterozygous for a chromosomal inversion that increases offspring viability. However, female choice in this system may be maintained by more than good-genes sexual selection. Females carrying the inversion genotype show a strong preference for large males. Genes for preference thus appear to be linked with genes for the male display trait, suggesting a form of female-choice sexual selection, termed “runaway” or “Fisherian” sexual selection (after the originator of this idea, R. A. Fisher), in which mothers gain by producing “sexy sons,” those that are highly attractive to females.

Mating Preferences for the Correct Species

One result of the expected rapid evolutionary change from runaway sexual selection may be speciation through behavioral isolation. Speciation results when there is sufficient between-population divergence in the female preference and the linked male display that a side effect of intraspecific mating preferences is discrimination against males from other populations (see also Box 1). This “effect” hypothesis for species discrimination differs from the hypothesis that certain female mating preferences have evolved to function in avoiding costly interactions with other species. An example of the latter involves the fruit flies Drosophila pseudoobscura and D. persimilis, in which hybrid matings result in decreased reproductive success because sons are sterile. Female Drosophila assess the wing-vibration displays of males, and D. pseudoobscura females collected from areas where the two species co-occur (sympathy) reject courting D. persimilis males more frequently than females collected from areas with no species overlap (allopatry). This result was not the result of differences in courtship by the males with the two types of females. These findings indicate that female discrimination against heterospecific male courtship has been reinforced in areas where maladaptive hybridization is likely to occur.

A high degree of discrimination against courtship by heterospecific individuals in sympathy has also been noted in Calopteryx dragonflies in which both sexes display patterned wings in precopulatory courtship. Compared with areas of allopatry, male C. aequa- bilis females, and mate preferences during courtship appear to have reinforced wing-pattern differences between the species. For example, in a north–south transect in eastern North America, the proportion of pigmented wing area of both sexes is greater in areas of sympathy than in areas of allopatry.

Signals to Rivals During Mating

In another North American calopterygid, Hetaerina americana, variation in wing-spot displays reflects an evolutionary history of competition between males; males with larger wing spots are more successful in defending mating territories than males with smaller spots. As males with experimentally enhanced spots suffer a cost (increased mortality), these signal patterns appear to have evolved as honest indicators of fighting ability. These signal indicators may convey to rivals information about male ability displayed during wing-waving directed at females. Other behaviors taking place during mating appear to function in a competitive context (Table I, No. 7). For example, males of the carrion beetle mentioned previously (L. versicolor) will occasionally mimic female behavior during interactions with potential mates (Fig. 3). Pseudofemale behavior reflects a remarkable plasticity in the way the male beetles obtain matings. The most profitable way to gain access to females is to fight to defend the carcass that attracts them. However, males can obtain some matings subversively by mimicking female behavior and thus avoiding costly fighting. This form of behavior is conditional on the relative size difference between opponents: a male will engage a smaller male in a fight but will switch to pseudofemale behavior if a subsequent rival is larger. There are other mating behaviors that appear to reflect male–male competitive interactions. For example, after attracting females, males of some singing insects switch from song to a more reclusive signal such as substrate vibration, apparently as a way of avoiding courtship behavior that attracts rivals.

Homosexual Behavior and Mating Mistakes

A male L. versicolor beetle can be duped into courting a small female-mimicking rival (Fig. 3) and there are a few other examples, such as in some butterflies and dragonflies, of homosexual mating mistakes when certain males adaptively resemble females. Homosexual mounting can also occur among insects of which the males have not evolved to mimic females. This male behavior is widespread in animals and appears to be simply an effect of poor sex recognition; strong selection on males to mate frequently causes them to mount any object that resembles a female. Examples of mating mistakes can even include inanimate objects, such as in the case of Julidomorpha bakewelli, an Australian buprestid beetle, the males of which attempt to copulate with beer bottles with a coloration and reflection pattern resembling the female’s elytra (Fig. 4).

Poor sex recognition appears to be the explanation of why males of another beetle, Diaprepes abbreviatus, mount conspecific males. A difference between this species and others, however, is that males also perform homosexual mountings. In this case, however, mounting appears to be an adaptive reproductive strategy rather than a mating mistake. Laboratory experiments with this species reveal that a
CONCLUSIONS

Observations of insect mating behaviors reveal a great diversity, some of which is a result of plasticity within species. The examples discussed here show how an understanding of the function of both inter- and intraspecific variation in mating behaviors can be gained by examining the consequences of behavior for the reproductive success of the mating male and female. Functions of insect mating that were proposed before the widespread use of the “selectionist” approach (Table I, Nos. 1 and 2) can be subsumed into this framework. For example, movements involved in delivering sperm are undoubtedly subject to sexual selection. And any observations of synchronized courtship in a species inevitably lead to the question of how such synchrony enhances the reproductive success of the male and female. There is a wealth of behavioral diversity for future research, including apterygote insects, a virtually unstudied group and one of great interest because many species lack copulation.

mounted pair of females attracts males. In fact, large males attempt to mate more often with paired females than with single large or small females. As both the mounting and the mounted females had similar probabilities of copulating with the attracted male, it appears that the mounted pair mimics a heterosexual pair in order to incite the attraction of large, competitive (i.e., high-quality) males.

FIGURE 3 A male staphylinid beetle, L. versicolor, can avoid being chased by a rival from the carrion source by mimicking female behavior. The mimic male turns and presents his abdomen to the approaching rival, which antennates the abdominal tip and taps it with his head. Copulation (bottom) is the only stage of a heterosexual encounter that is not represented in these homosexual encounters (because the mimic male breaks up the encounter by walking away). Mechanoreception
(Touch, Sensillar Structure)

Andrew S. French, Päivi H. Torkkeli
Dalhousie University, Halifax, Nova Scotia

Specialized Terms

coupling A term for processes and structures that convey mechanical events in the environment to the sensitive plasma membrane of a mechanosensory neuron.

coding The creation of a train of action potentials from a sensory receptor potential.

collopale A “sense rod,” or minute rod-like structure around the distal end of a sensory neuron.

transduction The conversion of mechanical displacement at a nerve cell membrane into a receptor current that changes the membrane potential.

tubular body A microtubule-based structure found in the distal sensory dendrites of many mechanoreceptor neurons.

Mechanoreception is the sense that allows insects to detect their external and internal mechanical environments, including physical orientation, acceleration, vibration, sound, and displacement. The integument and internal organs contain a wide variety of mechanoreceptors. Prominent receptors, such as surface hairs that mediate touch, or auditory organs, have been studied extensively, but many other physiological functions also depend on mechanosensory signals.

Arthropod mechanoreceptors are divided into two morphological groups: Type I, or cuticular, and Type II, or multipolar. Type I are ciliated receptors, associated with the cuticle, and have their nerve cell bodies in the peripheral, close to the sensory endings. They can be subdivided into three major groups (Fig. 1). Hair-like receptors are found on the outer surface in a variety of shapes and sizes, from long, thin hairs to short pegs and scales. A sensory neuron is closely apposed to the base of the hair, and its dendrite contains microtubules ending in a structure called the tubular body. It is assumed that movement of the hair compresses the ending, with the tubular body perhaps providing a rigid structure against which the compression can work. Hair receptors can contain additional sensory neurons, such as chemoreceptor neurons in taste hairs. Campaniform (bell-shaped) sensilla are also found on the outer surface, particularly in compact groups near the joints, where they detect stress in the cuticle. Stress moves the bell inward, compressing the dendritic tip containing the tubular body. Chordotonal receptors are generally found further beneath the integument, although they can be connected to the integument by attachment structures. They serve several functions, including hearing and joint movement detection. They often lack tubular bodies but all have dense scolopales surrounding the dendrites and often have multiple mechanosensory neurons.

Type II mechanoreceptors are nonciliated neurons, whose central cell bodies have many fine dendritic endings, each of which is apparently mechanosensitive but lacks the detailed structures seen in Type I receptors. Type II receptors are found in many internal structures, predominantly associated with mesodermal tissues, including the musculature, where they detect muscle tension.

Studies of mechanoreceptor morphology have used many techniques, including light microscopy, scanning and transmission electron microscopy, and immunohistochemistry. Receptor electrophysiology has been studied by three basic methods: (1) Extracellular recordings observe the receptor currents flowing along the axon. (2) Epithelial recordings measure the current flowing through the relatively low resistance of the thin socket tissue or through a cut hair. (3) Intracellular recordings give direct measurements of membrane potentials and currents. Important evidence applicable to insect mechanoreceptors has been obtained from similar structures in arachnids and crustaceans.

Mechanosensation is commonly viewed as a three-stage process in which a mechanical event is first coupled to the receptor cell membrane by mechanical structures, then transduced into a receptor current at the cell membrane, and finally encoded into action potentials for transmission of information to the central nervous system (CNS).

DEVELOPMENT OF MECHANORECEPTORS

Type I sensory neurons are surrounded by specialized sheath cells of varying numbers and names, although the terms trichogen (hair-forming) and tormogen (sheath-forming) are commonly used for the innermost two layers of sheath cells. Development of these cells has been well characterized in several species, but especially in Drosophila external bristles, where many of the genes involved have been identified. A single sensory organ precursor cell divides to give two different secondary precursors, IIA and IIB. IIA divides to form one trichogen and one tormogen cell. IIB gives rise to the neuron, another sheath cell, and sometimes an additional glial cell. The neuron then forms an axon that grows into the CNS. A variety of other noncellular structures, including sheaths, are also found, particularly in dendritic regions. The development of Type II receptors is less well understood.

MECHANICAL COMPONENTS

Extracellular tissues, often with elaborate structures, surround the sensory cells. These structures modify the spatial and temporal
sensitivities of the receptors, and are often designed to interact with the outside environment or other parts of the animal, such as cercal hairs detecting air movements or hair plates detecting joint rotation. External structures usually allow detection of mechanical events at some distance from the sensory cell, but make the displacement at the receptor cell membrane smaller than the original movement. Estimates of this attenuation suggest that threshold movements at the cell membrane leading to sensation are in the range 1–5 nm.

**TRANSDUCTION AND ENCODING**

Mechanically activated ion channels, probably located at the tips of the sensory dendrites, transduce the mechanical stimulus into a receptor current. These transducer channels are permeable to potassium ions, which are more concentrated in the receptor lymph space. The molecular identity of transducer channels is unknown, but there is evidence for both the transient receptor potential (TRP) and acid-sensitive (ASIC) channel families. Mechanotransduction currents are very sensitive to temperature, with activation energy values of 12–22 kcal mol⁻¹.

Current flowing through the channels causes a receptor potential that is encoded into action potentials using several different sodium and potassium currents. Action potentials propagate into the central nervous system along axons in nerve roots of the segmental ganglia. Afferent axons have a size range of 1–20 μm and conduction velocities are typically 1–5 m s⁻¹. Information is transmitted from mechanoreceptor axons into the central nervous system via cholinergic synapses.

**CENTRAL, PERIPHERAL, AND HUMORAL MODULATION**

Many mechanoreceptors receive GABAergic inhibitory efferent innervation close to the output synapses of their axon terminals. This presynaptic innervation modulates afferent mechanoreceptor information. Some mechanosensory neurons are also modulated by efferent innervation in the periphery and by circulating chemicals such as biogenic amines, of which octopamine has been most thoroughly studied. Octopamine directly excites spider mechanoreceptors in the periphery, but the evidence is less clear in insects.

The extent and functions of peripheral modulation in insects remain to be seen. It is the latest in a series of surprises about the complexity of insect mechanotransduction, but probably not the last.

**Mecoptera**

*(Scorpionflies, Hangingflies)*

George W. Byers
University of Kansas

Mecoptera (scorpionflies, hangingflies, and others) are holometabolous insects in which the head is characterized by a downward projecting rostrum or beak, at the end of which are chewing mouthparts. They are usually slender bodied and have four long, narrow wings that are membranous and often marked with dark bands, spots, or darkening along the numerous crossveins. There are exceptions, however. A few species are brachypterous or wingless; species in family Boreidae have hardened, highly modified wings, which are nearly oval and scalelike in females, slender and somewhat curved apically in males. The rostrum is not unusually prolonged in species of Nannochoristidae; and the wings of species of Meropoeidae are only about 2.5 times longer than their greatest width. Although Mecoptera are one of the minor orders of insects, with only about 570 living species so far made known, they are of much interest to entomologists. This is largely because fossil Mecoptera are among the oldest remains of insects with complete metamorphosis (of Permian age) and have been regarded by some as ancestral to the more recently evolved and vastly larger orders Diptera and Lepidoptera. Fossil evidence suggests that the Mecoptera were once the larger orders of holometabolous insects. Past diversity, based mainly on wing venation, has led to placement of nearly 400 fossil species in 87 genera in 34 families. Thus, modern Mecoptera are survivors of millions of years of evolutionary development.

**FAMILIES AND GENERA**

Following are the nine families of extant Mecoptera, with the number of genera included in each and the approximate geographical distribution: Panorpidae—3 genera, in Europe, Asia, and North
Mecoptera

America; Panorpodidae—2 genera, in easternmost Asia and North America; Bittacidae—19 genera, in North and South America, Africa, Asia, Australia, and Europe; Boreidae—3 genera, in North America, Asia, and Europe; Choristidae—3 genera, in Australia; Nannochoristidae—2 genera, in Australia, New Zealand, and southern South America; Apteropanorpidae—1 genus, in Australia (Tasmania); Meropidae—2 genera, in North America and southwestern Australia; Eomeropidae (formerly Notiothaumidae)—1 genus, in South America.

Most Mecoptera belong to the families Panorpidae (scorpionflies) and Bittacidae (hangingflies). Scorpionflies are so called because abdominal segments 7 and 8 of the male are slender, and segment 9 is abruptly enlarged and often held above the back, recalling the sting of a scorpion (Fig. 1). The female abdomen tapers to a slender tip. Both male and female hangingflies are slender bodied and, having a single, large (raptorial) claw at the end of each tarsus, are unable to stand on the upper surfaces of leaves but suspend themselves from twigs or edges of leaves (Fig. 2).

ZOOGEOGRAPHY

Mecoptera present a variety of zoogeographical patterns, from highly localized (as in *Notiothauma*, which is endemic in central Chile, or *Apteropanorpa*, found only in Tasmania) to virtually cosmopolitan (as the Bittacidae, which occur in the temperate and tropical parts of six continents). Only Bittacidae have been found in Africa. Some very disjunct occurrences suggest relics of ancient, more widespread ranges (as *Merop* in eastern North America and the very similar *Austromerop* in southwestern Australia; or Nannochoristidae in southeastern Australia, New Zealand, and southern South America).

HABITAT

Broad-leaved, herbaceous plants shaded by trees are the usual habitat of panorpids, bittacids, and most species in the smaller families. Some species, however, are most commonly found in vegetation near forest borders, whereas others occur in somewhat similar but more uniformly shaded habitats well within a forest. Elevation clearly affects the distribution of Mecoptera. Boreidae, for example, reach the adult stage in the cold part of the year (and being darkly colored are most often seen on the surface of snow) and at high elevations and high latitudes have a longer seasonal occurrence than boreids at lower elevations. In Mexico, Bittacidae are usually found at elevations below 1500 m, while Panorpidae occur above that level and up to over 3000 m.

DIET

Both adults and larvae of *Panorp* are scavengers, feeding usually on dead insects, and less often on other dead organisms, including some small vertebrates. Adults occasionally eat pollen and associated parts of flowers; they may even invade the webs of spiders to feed on entangled insects (and are sometimes trapped themselves). Adult Bittacidae (Fig. 2) are predaceous, capturing a variety of insects and occasionally other arthropods by means of the raptorial hind tarsi. Larval bittacids, in contrast, are primarily saprophagous on dead insects but may occasionally feed on mosses. Adults of *Brachypanorpa* (Panorpodidae) have been observed scraping the upper epidermis from leaves of herbaceous plants; their larval diet is not known. There is some evidence that *Notiothauma* (Eomeropidae) is also a plant feeder. Aquatic larvae of Nannochoristidae feed on small larvae of chironomid flies, but nothing is known of the adult diet.
BEHAVIOR

Feeding by adults of some Mecoptera is often associated with mating behavior (Fig. 3). Some male bittacids, for example, capture insects as nuptial gifts, then extrude pheromone-dispersing vesicles between abdominal terga 6–7 and 7–8 to advertise their presence to females in the vicinity. Females seem to make an evaluation of the gift prey, leaving the male if his offering is too small or unpalatable. They may then respond to the pheromone of another male. Males of some Panorpidae, when they have found a good source of food, make known their presence by means of pheromonal vesicles within the enlarged genital segment. When a female is attracted closely enough, the male clamps the costal edge of her forewing in a structure formed by a peg on the anterior fourth abdominal tergum and an overlapping portion of the third (the notal organ); mating then ensues as the female feeds. In other species of Panorpa, the male may build a small column of brownish saliva, gelatinous as it dries, which serves as a nuptial gift in place of a dead insect.

EGGS

Eggs of most Mecoptera are ovoid but approximately equally rounded at the ends. Those of Bittacus species are roughly cuboidal with the flattened surfaces shallowly impressed. The chorion of eggs of some species of Panorpa is smooth, while in others it is coated with a fine network of polygonal cells. In Notiothauma, the chorion is yellowish and granular; in Austromerope, the chorion is smooth. Eggs are ordinarily inserted into preexisting cavities in the soil by females of Panorpa, or in soil or rotten wood by Brachypanorpa. Females of these genera have been observed probing with the extended abdomen for some time before oviposition occurred. Female Bittacidae typically hang from the edge of a leaf and drop their eggs among dead leaves and other plant debris on the ground. Boreids deposit their eggs among the rhizoids of the mosses that will later be a source of food. As the embryonic larva develops and nears the time of hatching, the egg swells noticeably. In Panorpa, the increase is as great as 38%; larval eyes and mandibles become visible through the chorion. Eggs of Bittacus, roughly cuboidal when laid, become subspherical; those of Harpobittacus also become rounded and may double in size.

The egg stage is brief for some species (5–10 days for some American species of Panorpa; 14–16 days for panorpids living above 2250 m in Taiwan; 12–15 days in Chorista). In contrast, there may be an egg diapause, which together with larval development within the egg may last 216–256 days in one North American Bittacus, and up to 290 days in a Japanese Bittacus. Larvae from diapausing eggs of Boreus laid in early winter hatch the following spring.

LARVAE

Larvae of Panorpidae, Bittacidae, and Choristidae are eruciform; that is, they have somewhat the appearance of caterpillars. The head is well sclerotized, as is the dorsum of the prothorax; the legs are nearly conical, their skin largely membranous; and there are subconical prolegs on abdominal segments 1–8. Larval bittacids have paired, elongate, three-branched, fleshy structures on the back of the mesothorax, metathorax, and nine abdominal segments. Panorpids and choristids have setae in most of the corresponding positions. The larvae of Panorpodidae and Boreidae, described as scarabaeiform, lack abdominal prolegs and conspicuous dorsal setae. Larvae of Nannochoristidae are unlike those of the other families, so far as known. They are aquatic, with slender, elongate, almost conical bodies and no prolegs. Their mouthparts are directed forward, not downward as in eruciform larvae.

A striking characteristic of many larval Mecoptera is the presence of compound eyes, whereas larvae of most holometabolous insects have only one or a few simple eyes at each side. The larvae of Panorpodidae and Choristidae have 30 or more ommatidia in each compound eye, while those of the Bittacidae have seven. Boreidae usually have only three, and larvae of Panorpodidae lack eyes altogether. Larvae of Nannochoristidae have eyes with indistinctly formed ommatidia. Because their larvae are so different from the larvae of other families in the order (and because of some characteristics of the adults, such as a short rostrum), the Nannochoristidae have sometimes been considered as a group distinct from other Mecoptera.

Duration of larval life varies with the species involved, with temperature and season, availability of food, and length of prepupal diapause. Under favorable conditions, a larva of Panorpa may pass through three growth stages and become a fourth instar in about a month. During the final larval stage, feeding and growth continue for several days. But then the larva prepares a cavity in the soil, or other material in its habitat, stops feeding and becomes quiescent as it begins the period of prepupal diapause (inactivity) in this cavity. In species of Panorpa that have spring and late-summer generations, prepupal diapause in summer lasts only about 5 weeks, while in overwintering larvae it requires about 6.5–7 months. In nearctic species of Bittacus it lasts about 7 months. The pupal stage is much shorter: 10–21 days in Panorpa, 15–24 days in Bittacus, and 37–40 days in Boreus.

PUPAE

Described as exarate, the pupa has the legs rather loosely drawn up against its ventral surface and the wings tightly folded within their sheaths, which are closely adhered to the body. The prepupal rostrum is shorter than that of the adult and the mandibles larger. Otherwise, the pupal body has generally the form of the adult developing within.
Medical Entomology

John D. Edman
University of California, Davis

Medical entomology is concerned with the impact of insects and related arthropods on the mental and physical health of humans, domestic animals, and wildlife. It is often subdivided into public health entomology and veterinary entomology. These divisions are tenuous since many of the same arthropods cause similar injuries and diseases in both humans and other animals. The history of medical entomology dates from the end of the 19th century, when arthropods were first shown to transmit important human diseases such as filariasis and malaria. Most arthropod-borne diseases are zoontic infections that occur naturally in nonhuman hosts. Malaria, dengue fever, and most forms of filariasis are important exceptions. Household pests such as cockroaches and fleas are sometimes included within medical entomology. When synanthropic flies and cockroaches mechanically contaminate food or other media with infectious organisms, they are clearly of medical importance. Nonetheless, these insects are generally treated in greater depth within the scope of urban entomology.

MEDICAL IMPORTANCE OF ARTHROPODS

Arthropods influence animal health in multiple ways. The most significant impact involves their role as primary vectors and alternate hosts of many devastating infectious disease agents. Parasitic agents transmitted by hematophagous arthropods include filariae, protozoa, bacteria, rickettsiae, and viruses. Arthropods also affect the health of vertebrates directly by triggering altered mental states (delusional parasitosis and entomophobia/arachnophobia), contact allergies, feeding annoyance and blood loss, envenomization, and myiasis.

Each year these arthropod relationships collectively cause the death of millions of humans and bring illness to hundreds of millions more. Their impact is greatest in poor tropical countries where they are one of the major factors limiting animal production, agricultural productivity, economic development, and well-being. Several vector-borne diseases (e.g., plague, malaria, leishmaniasis, yellow fever, and dengue) apparently were transported from the Old World to the Western Hemisphere via the slave trade or ship crews. Related species of insects in the New World were able to successfully maintain and transmit these introduced parasites. In recent years, several native but previously unrecognized arthropod-borne infections, including tick-borne Lyme disease and ehrlichiosis, have been discovered in the United States and elsewhere. Well-known diseases such as dengue and malaria have been reemerging or expanding in many regions of the world. Other diseases such as West Nile fever have recently been introduced into new regions with devastating effects. A combination of population growth, rapid movement of people and other animals, and environmental disruption has contributed to the growing threat posed by vector-borne diseases. Control of these diseases is complicated by the lack of investment in public health and development of drug-resistant parasites and insecticide-resistant vectors.

ORDERS AND FAMILIES OF MEDICAL CONCERN

Phylum Arthropoda contains several classes of invertebrates that have direct medical importance. In addition to insects, these include arachnids (spiders, mites, ticks, and scorpions), millipedes, and centipedes. Some crustaceans (sowbugs and copepods), molluscs (snails), arachnids (oribatid mites), and insects (mainly beetle larvae) are intermediate hosts for parasitic worms.

Orders and families of blood-feeding species are of major medical significance (Table 1). Most but not all of these are involved in the transmission of microparasites. Nonetheless, the simple act of feeding by arthropod ectoparasites can result in blood loss, anemia, stress, discomfort, allergic reactions, and reduced productivity. A few insects are specialized ectoparasites on humans. Bed bugs and kissing bugs are nest parasites and some have permanently invaded human dwellings and feed at night on sleeping people. Humans are also parasitized by three species of sucking lice (i.e., pubic louse, head louse, and body louse), each of which specializes in a different region of the body. Biting flies such as mosquitoes, black flies, deer flies, and biting midges can reach annoyance levels that make outdoor activities nearly impossible, but these hordes normally feed on a wide variety of domestic and wild animals. Only a few biting flies such as the yellow-fever mosquito (Aedes aegypti), the tropical house mosquito (Culex pipiens quinquefasciatus), and some vector species of Anopheles, Simulium, Phlebotomus, and Lutzomyia feed preferentially on humans.

Both insects and arachnids can cause harm because of the venom they contain. Venomous insects are found mainly in the order Hymenoptera within the families Formicidae (ants), Vespidae (yellowjackets and hornets), Mutillidae (velvet ants), and Apidae (honey bees and bumble bees). Some Coleoptera (e.g., Meloidae, Staphylinidae, Chrysomelidae, and Dermentidae) and Lepidoptera (e.g., Noctuidae, Saturniidae, Sphingidae, and Nymphalidae) also produce toxic defensive secretions through specialized glands and urticating hairs or have hemolymph that is toxic to vertebrates if the insect is crushed. These secretions are especially toxic when exposed to mucus or lachrymal glands. Spiders in the genera Loxosceles (recluses), Latrodectus (widows), Atrax (Australian funnel-wombs), Harpactirella (South Africa), Lycosa (Central and South America), and Phoneutria (Brazil) include some of the most highly venomous species. All scorpions have venomous stings and those within the family Buthidae can be fatal to humans. Desert regions of the Americas, the Mediterranean, and northern Africa are home to most of the highly poisonous scorpions. Centipedes also have venomous
Exacerbated this problem especially among the middle and upper classes. Asthma is one of the fastest growing medical problems, particularly among children. Respiratory failure is not an uncommon outcome. Concern over life-threatening multiple stings and allergic reactions (anaphylaxis) to the venom of insects has increased as a result of the introduction and spread of the hybrid of the African honey bee (Apis mellifera adansonii) and the imported fire ant (Solenopsis invicta) in the Western Hemisphere.

Myiasis is a serious problem in animal production, especially in the neotropics where millions of dollars is lost annually due to these tissue-invading flies. These flies are often found within families that include species that normally feed on the decaying tissues of dead or wounded animals, that is, flesh flies in the family Sarcophagidae and blowflies in the family Calliphoridae. Some species of Calliphoridae (and related families) sometimes will facultatively invade living tissues, while others are so restricted to dead tissues that they are used in maggot therapy to clean deep wounds. All members of the four subfamilies of bot flies (Oestrinae, Gasterophilinae, Hypoderminae, and Cuterebrinae of the family Oestridae) are obligate parasites. The torsalo (Dermatobia hominis) is a neotropical dipteran whose eggs are glued to the abdomen of biting flies, and its larvae emerge during blood feeding by the host fly.

DIRECT INJURIES CAUSED BY ARTHROPODS

The various direct effects of arthropods on humans are summarized in Table II. The most common of these is the asthma suffered by millions of people, especially children, who are allergic to the fine airborne particulates generated by insects and mites. These allergens are most often associated with feces or decomposing body parts. The advent of air-conditioning and wall-to-wall carpeting seems to have exacerbated this problem especially among the middle and upper classes. Asthma is one of the fastest growing medical problems, particularly among children. Respiratory failure is not an uncommon outcome. Concern over life-threatening multiple stings and allergic reactions (anaphylaxis) to the venom of insects has increased as a result of the introduction and spread of the hybrid of the African honey bee (Apis mellifera adansonii) and the imported fire ant (Solenopsis invicta) in the Western Hemisphere.

ARBOVIRUS TRANSMISSION OF MICROPARASITES

Vector-borne diseases can be transmitted either biologically or mechanically. In mechanical transmission, vector mouthparts serve as contaminated hypodermic needles since there is no replication or development of the microparasite in the vector; the vector does not serve as an alternate host as in the case of biologically transmitted diseases. For infectious organisms to be mechanically transmitted by arthropods efficiently, they must be abundant in circulating blood or cutaneous tissues and able to survive external exposure. Diseases that are mechanically transmitted by arthropods generally have other transmission mechanisms as well.

Biological transmission takes one of three forms: propagative transmission, which involves the replication of eukaryotic parasites and dissemination to the salivary glands prior to transmission; cyclodevelopmental transmission, which occurs among filarial parasites, in which development of the parasite to the infective stage is required prior to transmission but there is no increase in the number of parasites; or cyclopropagative transmission, which involves both development and multiplication by the parasite as occurs with protozoan parasites such as *Plasmodium, Leishmania,* and *Trypanosoma.*

After the appropriate extrinsic incubation period for replication and/or development of the parasite, the arthropod vector is said to be infective, that is, able to transmit. Infectious agents are passed to the vertebrate host through a number of different routes: (1) transovarially from the female to her offspring or transtadially from one stage to the next, (2) venereally from infected males to uninfected females, (3) through cofeeding when infected and uninfected vectors group feed, or (4) horizontally through (a) infective saliva injected during feeding, (b) regurgitation of parasites blocking the food canal, (c) defecation of infective faeces on the skin, or (d) active escape from the mouthparts and invasion of the skin. In some cases, hosts must assist the transmission process by crushing the infective insect, scratching the contaminated area, and rubbing the eyes. Transmission may be promoted by the physiological or behavioral effect of parasites on the vector. Invasion of host cells or tissues by the parasite can be modulated by host immune responses to the salivary secretions of the vector.

The efficiency of transmission is determined primarily by the "competence" of the arthropod species to support development/replication of the parasite and by the ecology and behavior of the arthropod species. The latter determines the temporal and spatial connection between hosts and potential vectors. Thus, the density, feeding frequency, and host preferences of the vector play critical roles in establishing the vectorial capacity (number of infective bites received daily by a single host) of any given species. Environmental conditions also play an important role.

DISEASES TRANSMITTED BY ARTHROPODS

The major diseases transmitted by arthropods are listed in Table III. Protozoan parasites dominate this list in terms of worldwide importance. Malaria is the single most significant vector-borne disease, with an estimated 300 million people infected annually and over 1 million deaths among young children in Africa alone. It is endemic in most tropical and subtropical regions of the world, where it has been resurging since eradication attempts ended some 30 years ago. It is transmitted byAnopheles mosquitoes and can be successfully treated with drugs if promptly available. Drug resistance is a growing problem. Tsetse-transmitted African trypanosomiasis remains a serious human disease in parts of tropical Africa, but its impact on domestic cattle production is even more severe. Wild bovines are the reservoir of the acute Rhodesian form, and humans and porcines are the reservoir of the chronic Gambian form. American trypanosomiasis is restricted to the mountain regions of tropical America and is often a silent disease that leads to early death. Great efforts are under way to control this zoonotic disease by spraying residual pesticides and by constructing houses with materials that prevent invasion by domesticated kissing bugs. Visceral and cutaneous forms of leishmaniasis affect millions of people and cause significant mortality in Africa, Asia, and South America. The reservoirs for these parasites are dogs, rodents, and a variety of other wild mammals. The cutaneous form also exists in southern Europe and Central America, but disfigurement rather than mortality is usually associated with this form.

Lymphatic filariasis (elephantiasis), transmitted by *Culex quinquefasciatus* and other human-biting mosquitoes, infects many millions of residents throughout the tropics. The long-lived nematode parasites cause debilitation, especially of the lower limbs, but seldom result in death. Onchocerciasis (river blindness), also a filarial infection, is limited to sub-Saharan Africa and some coffee-growing regions in Central and South America. Both of these nematode infections can be prevented by treatment with a new drug, ivermectin. River blindness has been effectively controlled in much of West Africa in recent years through pecticidal elimination of the black fly vectors breeding in streams and the use of anthelmintics to treat the human population. There are a large number of bacterial and rickettsial infections transmitted by arthropods (mainly ticks, fleas, lice, and mites) annually but none compare to the impact of plague and typhus epidemics in earlier times. Some of these, such as tick-borne Lyme disease and ehrlichiosis, have just been recognized within the past 30 years. Lyme

DISEASE AND VECTOR MANAGEMENT

Efforts to develop vaccines for a wide range of vector-borne diseases, including malaria, have been vigorously supported but success has been slow. Antigenic variation in parasites has been a major deterrent. New drugs for treatment of parasitic diseases also are under development, and several important new drugs for treatment of helmint and protozoan parasites have been marketed in recent years. Nonetheless, vector control is often the first line of defense against the transmission of these diseases and, during active epidemics, this is the only option outside of public education. Control of vertebrate reservoir animals has occasionally been practiced for diseases that are maintained by rodents. An early example was control of wild bovine reservoirs in parts of Africa to control trypanosomiasis in humans (sleeping sickness) and cattle (Nagana). Vector control programs are generally based on surveillance systems that monitor and report cases of disease or vector population levels. A variety of tools are available to manage vector populations, including chemical pesticides, biological controls, habitat alteration, and personal protection strategies (e.g., screens, bed nets, and repellents). Currently, genetic control strategies are receiving much attention. Optimal vector control programs utilize integrated vector management strategies and strive to maintain vector populations below the threshold densities required for transmission. Targeting the immature stages of vectors that blood feed and transmit disease only as adults normally is more efficient and cost effective. Lack of public health funds is the major limitation on surveillance and vector control programs, especially in developing countries where these diseases have the greatest impact.

Throughout history, humans have used insects and their products therapeutically. Ingested, injected, or topically applied, insects have been used to treat an assortment of respiratory, gastrointestinal, cardiac, neuromuscular, and infectious diseases. To this day, therapeutic insects are prescribed worldwide. Medicinal maggots and honey bee venom therapy are two commonly prescribed insect-based treatments.

INTRODUCTION AND HISTORICAL OVERVIEW

Many insects are ingested for their medicinal value as well as their nutritional value. Roasted, boiled, or powdered cockroaches (Blattodea: Blattidae) have been ingested by people of many cultures to treat respiratory diseases. Various beetles (Coleoptera) are noted to be useful in the treatment of intestinal diseases. The blister beetle, Lytta vesicatoria (Spanish fly), is the source of cantharidin, a vesicant that was ingested in Europe as an aphrodisiac. Stinkbugs (Heteroptera: Pentatomidae) in China and termites (Isoptera) in India were used for the same function.

Up until a few decades ago, patients with neurosyphilis often were cured with an inoculation of malaria (Plasmodium spp.). The syphilis pathogen (Treponema pallidum) was killed by the recurrent fevers and possibly also other unidentified interactions with the malaria parasites. The malaria was then eradicated with quinine or another species-specific antimalarial agent. Initially, malaria inoculation was achieved by transferring the blood of a malaria-infected neurosyphilitic to a nonparasitized neurosyphilitic. This practice was soon replaced by mosquito-transmitted inoculations. Eventually, syringes replaced mosquitoes as the preferred method of inoculation.

“Caterpillar fungus” (dong chong xia cao) is a Chinese moth larva (Hepialidae: Hepialus obfuscus) infected with an entomopathogenic (insect-killing) fungus, Cordyceps sinensis (Clavicipitales:
Ascomycotina). Ingestion of the caterpillar fungus reportedly strengthens and rejuvenates the body. At a cost of approximately $1000 per kilogram, this tonic achieved international notoriety in 1993 when fungus-drinking Chinese athletes set new world track records. Caterpillar fungus is often prepared as a broth; both the broth and the caterpillar are eaten.

Arthropods have played a role in wound care for centuries. The use of large ant or beetle mandibles for holding together wound edges has been documented in many countries. Honey and spiderwebs both have been used to dress wounds and prevent infection. Maggot therapy—the topical application of specific, disinfected blowfly larvae (especially \textit{Phaenicia}, \textit{Lucilia}, and \textit{Phormia}) to treat infected wounds—is currently practiced in over 35 countries.

**MAGGOT THERAPY**

The practice of maggot therapy is based on observations that wounds naturally infested with maggots (wound myiasis) often are free of infection and debris. For centuries, European military surgeons described how the maggot-laden wounds of soldiers not promptly removed from the battlefield often appeared clean, once the larvae were wiped away. Soldiers’ maggot-infested wounds were observed to heal better than wounds that had not been infested. After his own observations of wound myiasis on the battlefields of World War I, William Baer intentionally placed blowfly larvae into the chronic wounds of his patients at Johns Hopkins and Children’s Hospital in Baltimore. Baer first presented his results in 1929; by 1935, thousands of physicians and surgeons had embraced this practice. Many hospitals maintained their own therapeutic fly colonies; other practitioners obtained maggots from pharmaceutical companies.

Maggot therapy all but disappeared during the 1940s. The reasons for this probably include the development of antibiotics and the refinement of surgical techniques that came about during World War II. Over the next several decades, therapeutic myiasis was performed only rarely, and only as a last resort, in patients who failed to respond to aggressive surgical and antibiotic treatments. But the 1980s brought about the realization that surgery and antibiotics could not cure all wounds. Many microbes were by now resistant to the once omnipotent antimicrobials. In the 1990s, maggot therapy was reintroduced as a treatment for nonhealing wounds, after a series of controlled clinical studies demonstrated better responses to maggot therapy than to conventional medical and surgical treatments (Fig. 1). Today, medical grade larvae are produced by 24 laboratories worldwide, and sent to thousands of centers in over 40 countries for treating wounds (Figs. 2 and 3).

**FIGURE 1** The left foot of a 73-year-old man who was treated for 3 years by orthopedic and podiatric surgery for his chronic foot ulcers: (A) before, (B) during, and (C) 1 year after maggot debridement therapy.

**FIGURE 2** In the United States, medicinal maggots are sold under the brand name \textit{Medical Maggots}™. (Photo courtesy of Monarch Labs, Irvine, CA.)

**FIGURE 3** This facility (insectary) for breeding medicinal maggots produces nearly one million eggs per week. The eggs are disinfected in a separate section of the laboratory, at which point they become an FDA-regulated medical device and are handled according to Good Manufacturing Procedure (GMP) standards of the medical device industry. (Photo courtesy of Monarch Labs, Irvine, CA.)
Maggots effectively treat open wounds by removing dead and infected tissue (debridement), killing bacteria (disinfection), and stimulating the wound to heal. To understand the procedure of maggot therapy, it is necessary to review the natural history of the fly. Many species of blowflies (Calliphoridae) naturally “blow” or lay their eggs on carrion, feces, or the dead (necrotic) tissue of a living host. Upon hatching, the larvae secrete and excrete their digestive enzymes, liquefying the dead organic tissue so that they can ingest it. The larvae will be satiated within 3–7 days (depending on the temperature and abundance of food) and the maggots leave the host to pupate underground or in some other protected area. One to three weeks later, adult flies ecrose (emerge). Therapeutic maggots—blowfly larvae that have been made “germ-free” (disinfected)—are placed on wounds at a density of 5–10 cm⁻². Larvae are retained on the wound for about 48 h in cage-like dressings. After one or more such cycles of treatment, the wound is often free of necrotic tissue and able to accept a skin graft or heal spontaneously. Treatments can be administered in the hospital, clinic, nursing home, or at home.

Maggot therapy has been used to treat pressure ulcers, venous stasis ulcers, diabetic foot ulcers, burns, traumatic wounds, and non-healing postsurgical wounds. Compared with conventional wound therapy, medicinal maggots are credited with more rapid debridement and wound healing. Maggot therapy has reportedly saved numerous limbs from amputation and other surgical procedures. Other advantages of maggot therapy include its simplicity, safety, and relatively low cost. Efforts are underway to isolate the active constituents in the maggots’ secretions, but thus far no isolate has been found to equal the efficacy of the live larvae.

**BEE VENOM THERAPY**

Honey bee (*Apis mellifera*) venom, propolis, royal jelly, beeswax, and honey all are used therapeutically. Medicinal use of any of these products can be considered to be “apitherapy,” but many authorities use the term specifically to denote the clinical use of honey bee venom itself (known more precisely as bee venom therapy). Bee venom therapy has been used successfully to treat rheumatological disorders (rheumatoid and psoriatic arthritis, gout, fibromyalgia), neurological diseases (multiple sclerosis, chronic pain syndromes), immunological diseases (scleroderma, systemic lupus erythematosus), and other chronic illnesses.

Bee venom contains a multitude of polypeptides, enzymes (phospholipase A₂, hyaluronidase), and biologically active amines (histamine, dopamine, and noradrenaline). The mechanisms by which venom exerts its beneficial actions are unknown, but might include an anti-inflammatory effect resulting from alterations seen in pituitary and adrenal gland function, local effects on the nerves and blood vessels, and stimulation of acupuncture-like pathways. A combination of these and other mechanisms may explain the diversity of benefits attributed to venom therapy.

Some therapists administer the treatments in the form of an increasing number of bee stings; other practitioners inject a partially purified extract of the bee venom, in gradually increasing doses. Serious toxic reactions to the venom are uncommon because patients are educated about the signs and symptoms of venom reactions; they are also supervised closely following treatment and are given ready access to medical care after leaving the therapist’s office or apiary.

**Megaloptera**

(Alderflies, Fishflies, Hellgrammites, Dobsonflies)

Norman H. Anderson, Oregon State University

The Megaloptera, which include the alderflies, dobsonflies, fishflies, and hellgrammites, are a small order of neuropterous insects with 328 described species. They are often considered to be the most primitive group of insects with complete metamorphosis. In the fossil record, Megaloptera first occur about 250 mya in the late Permian. The Megaloptera are most closely related to the Raphidioptera (snakeflies) and Neuroptera (lacewings and antlions), although the interordinal relationships between these three groups

Bee Products ■ History of Entomology ■ Venom
Megaloptera are uncertain. Among the major orders, they are most closely related to the Coleoptera (beetles). Larvae of all Megaloptera are aquatic predators. Their association with cool, well-oxygenated waters probably accounts for their greater species diversity in temperate regions than in the tropics. Although they are found throughout the world, the distributions are discontinuous, which is characteristic of a relict fauna.

**DIAGNOSIS AND CLASSIFICATION**

Megaloptera can be distinguished from other orders of insects by the following combination of characters: holometaboly, terrestrial adults and eggs, predaceous aquatic larvae, and exarate terrestrial pupae.

The adults are large, short-lived, and soft-bodied; the head is broad and flattened, with chewing mouthparts, large bulging compound eyes, and long many-segmented antennae; there are two pairs of similar membranous wings, held rooflike over the body, with all major veins present and many cross-veins; the five-segmented tarsi have paired apical claws; and the abdomen has 10 segments, eight pairs of spiracles, and lacks cerci.

The larvae have a well-sclerotized head, with long toothed mandibles, four- or five-segmented antennae, and six lateral stemmata (eyespots); the thorax is sclerotized dorsally, with a quadrate pronotum, meso- and metathoracic spiracles, and elongate five-segmented legs with two tarsal claws; and the abdomen is soft, with seven or eight pairs of lateral filaments, and spiracles on segments 1–8.

The order contains two families, Sialidae and Corydalidae. Sialids, or alderflies, are slow, awkwardly flying insects that range from 10 to 15 mm in length. Their bodies are black, brown, or yellowish orange. The wings are held tentlike over the abdomen so that they bear some resemblance to caddisflies (Trichoptera). The Corydalidae are much larger, 40–75 mm in length. Many species have pale, smoky wings mottled with brown, whereas others are nearly black, with white markings. This family is divided into two distinctive subfamilies: the Corydalinae or dobsonflies (larvae are hellgrammites), and the Chauliodinae or fishflies.

**FAMILY SIALIDAE**

Of the eight genera in the family Sialidae (Figs. 1–3), only the widespread Holarctic genus *Sialis* has received much attention. The life history of *S. lutaria* has been studied extensively in Europe, and the larvae have been used in behavioral and physiological experiments. *Sialis* larvae are found in many habitats, ranging from small springs to large rivers and from ponds to large lakes. They usually occur where the substrate is soft and where dead leaves and other detritus have accumulated. Larvae may dig into the substrates to a depth of several centimeters. Sympatric species may be ecologically segregated based on habitat. For example, in Oregon *S. rotunda* occurs in ponds with a muddy bottom, whereas *S. californica* is usually found in pools or glides of streams. However, the two species can be found together in backwater reaches.

The life cycle takes 1 or 2 years depending on physical and biological conditions. The colder and less productive habitats such as trout streams and mountain lakes lengthen the period of larval life, whereas rapid development occurs in warm, productive habitats such as lowland ponds, warm lakes, and muddy rivers.

Larvae feed nonselectively on small invertebrates such as insect larvae, annelid worms, crustaceans, and mollusks. The prey is seized by the elongate mandibles and forelegs and worked into the mouth.

**FIGURE 2** *Sialis* adult.
with the aid of labrum, maxillae, and labium. Sometimes only the softer abdominal parts of prey are eaten. Cannibalism occurs, especially in high-density situations.

During spring or early summer the final instars move to shallow areas near the shore. They then leave the water and prepare to pupate. The transformation also involves a switch in respiration from using aqueous dissolved oxygen via the gills to intake of atmospheric oxygen through the abdominal and thoracic spiracles. Pupation occurs in an unlined chamber dug 1–10 cm into soil or litter. The adults emerge after a pupal instar of about 2 weeks. Adults are most active during midday. In mating, the male crawls beneath the female's abdomen from the rear and raises his abdomen upward and forward to couple the genitalia. A spermatophore is passed to the female within a few minutes, copulation is terminated, and oviposition occurs within a day.

Adult *Sialis* have biting mouthparts, and some observations suggest that they visit flowers to feed.

The eggs are deposited on a variety of substrates projecting over the water. The underside of overhanging leaves is the most common oviposition site. Egg masses contain 300–900 eggs. There are two distinctive types of egg mass; in one, the long axis of the egg is almost parallel to the substrate, and in the other it is almost upright. The incubation period is about 10 days to 2 weeks. Eggs are sometimes parasitized by tiny *Trichogramma* wasps.

In hatching, the larva pushes its head against the chorion below the micropylar projection. The toothed, V-shaped egg burster then ruptures the chorion, initiating a jagged tear through which the larva emerges. When the larva leaves the egg, a postembryonic molt occurs, and the egg burster and embryonic membrane are left attached to the eggshell. Then the appendages and abdominal filaments are expanded and the larva becomes active. It drops to the water surface, where it is quickly wetted to pass through the surface film, and then swims to the bottom. There are about 10 instars before pupation.
The Chaulioidinae have a wide geographical distribution and occur in a wider range of habitats than do sialisids or corydalids. In the western United States, several genera (e.g., Neohermes, Dysmicohermes, and Protochauliodes) inhabit intermittent streams, whereas others (e.g., Ortheurus) are found in cold, permanent streams and rivers as well as in the adjacent intermittent tributaries. Chauliodes occurs in slow waters, in swamps and ponds, and sometimes in intermittent habitats. These larvae can exploit low-oxygen habitats because the terminal spiracles are on contractile tubes.

The life cycle is also quite variable, with growth and development being temperature and habitat dependent. For example, the life cycle of Neohermes varies from 2–5 years depending on the duration of flow in temporary streams. Estimates of the number of instars range from 9 to 12. Females may have one more larval molt than males to account for their larger size.

Fishfly larvae are generalist predators, but in intermittent habitats they also may be scavengers, feeding on corpses of individuals stranded by receding waters.

Mating occurs in a tail-to-tail position with no display or special mating behavior (but pheromone attraction may be involved in some genera). The male Nigronia backs to the female, the genitalia are clasped, and they remain in copulation for several hours. Spermatophore transfer has not been observed for Nigronia or Corydalus, although it is reported for Sialis.

The final instar of N. serricornis leaves the water to pupate in a shallow cell that is dug into the soil. The exarate pupa is light colored but darkens in the last 2 days before emergence. The pupa is active; it turns in the cell, which helps in maintaining cell structure. Pupae do not feed but can use the sizable mandibles and will bite an object that is placed in contact. The pupal period ranges from 2 to 4 weeks depending on temperature.

Like most megalopterans, Nigronia adults are awkward and weak in flight. They fly throughout the day, with oviposition occurring in the afternoon. Nigronia adults readily take fluids, especially sugar solution and mashed fruit. Adult feeding is needed because some individuals live for 2 weeks.

Reproductive organs in Nigronia are mature at emergence, as is the case with Sialis but unlike Corydalus. A bimodal occurrence in egg deposition demonstrated that after their first oviposition, females waited a week to lay a second mass. Egg masses are composed of one to five layers. Maturation of Nigronia eggs requires 2–3 weeks. Hatching begins with individuals in the uppermost layer and continues to the lower level.

Larvae of fishflies and dobsonflies often have colonies of epizoic attached to the exoskeleton. These growths, which are readily apparent at low magnification, include stalked protozoans, rotifers, and filamentous algae. Phoretic Chironomidae, for example, Plecopteraconclusus donnest, are often found strapped in cases attached to thoracic sternites.

Metabolism

S.N. Thompson

University of California, Riverside

R.K. Suarez

University of California, Santa Barbara

Specialized Terms

glycolysis The principal metabolic pathway responsible for oxidation of carbohydrate (glucose) to pyruvate during cellular respiration.

gluconeogenesis A metabolic pathway responsible for the net synthesis of carbohydrate (glucose) from amino acids, lactate, and glycerol.

respiration The collection of metabolic pathways responsible for the oxidation of glucose, amino acids, and fatty acids, with the production of energy involving an electron transport chain.

lipid A chemically diverse group of molecules that are insoluble in water and other polar solvents.

supercooling The absence of freezing at or below the normal freezing point of water.

metabolome A quantitative metabolite profile associated with a cellular process.
The chemical reactions of cells, linked together in series to form pathways, are collectively referred to as metabolism. Metabolic pathways are interdependent and exquisitely regulated for efficient extraction of energy from fuels and for synthesis of biological molecules. Cellular processes produce unique chemical fingerprints or metabolite profiles, and a complete quantitative set of metabolic intermediates associated with a cellular process is referred to as the metabolome. Metabolomics is the study of changes in the metabolome that may arise from metabolic regulation or alteration in gene expression, or a combination of both mechanisms. Studies of metabolism and metabolomics are subject areas of biochemistry, which also includes the structural chemistry of biological molecules and the chemistry of molecular genetics.

Metabolic studies with insects have focused on the biochemical bases for the unique physiological capabilities of insects and their arthropod relatives. Early studies considered chemical content, individual chemical reactions, respiration, and metabolic rate. Much of this was discussed in Sir V. B. Wigglesworth’s The Principles of Insect Physiology that first appeared in 1939. With advances, other comprehensive reviews appeared, including D. Gilmour’s 1961 The Metabolism of Insects, the 1964 edition of Physiology of Insects and in 1978 The Biochemistry of Insects, both edited by M. Rockstein. More recently, insect metabolism was described in several volumes of Comparative Insect Physiology Biochemistry and Pharmacology, edited by G. A. Kerkut and L. I. Gilbert (1985). A recent update is Comprehensive Molecular Insect Science, edited by L. I. Gilbert, K. Iatrou, and S. Gill (2005), but the coverage of metabolism is restricted.

**INTERMEDIARY METABOLISM**

Insects share with other invertebrates the common pathways of carbohydrate, lipid, and amino acid metabolism. Although much has been presumed based on overt similarities to more extensive studies of mammals and other higher taxa, many aspects of intermediary metabolism have been examined in a number of insects and different insect tissues. Much of intermediary metabolism, including synthesis and storage of carbohydrate and fat, takes place in the fat body.

Metabolism and utilization of the glucose saccharide trehalose as the principal hemolymph or blood sugar is unique to insects and some other invertebrates. First described from an insect by G. R. Wyatt in pupae of the silk moth, Antheraea polyphemus, trehalose, a non-reducing sugar, occurs in many insects at variable but high levels. In lepidopteran insects, trehalose concentrations are commonly between 25 and 100 mM, levels greatly exceeding those of glucose in the blood of mammals. Blood glucose in man typically is about 5 mM, a low value for trehalose in hemolymph. With few exceptions, glucose occurs in insect hemolymph at levels less than 5 mM, and often at less than 1 mM. Trehalose serves multiple functions, as a storage carbohydrate that serves as a fuel for flight and as a cryoprotectant, protecting insects from damage during overwintering in cold climates. The hemolymph level of trehalose plays an important role in regulating carbohydrate intake and maintaining nutritional homeostasis. Levels of trehalose in the hemolymph are maintained by a complex interaction of nutrient intake and metabolism.

Trehalose is synthesized in the fat body from two glycolytic intermediates, glucose-1-phosphate and glucose-6-phosphate. The reactions are catalyzed by trehalose-6-phosphate synthase and trehalose-6-phosphate phosphatase. Sources of glucose for trehalose synthesis include dietary sucrose, glycogen, and gluconeogenesis; dietary sugar being the sole source of glucose under fed conditions. Trehalose formation from glycogen has been described in several insects including the cockroach Periplaneta americana and moth Manduca sexta during starvation. The breakdown of glycogen to glucose is due to activation of the enzyme glycogen phosphorylase and is under endocrine control by a neurohormone released from the corpora cardiaca in the brain. Induction of a “hypertrahalosemic” hormone RNA transcript in the central nervous system of the cockroach, Blaberus discoidalis, in response to starvation was recently demonstrated. Glucose synthesis, followed by trehalose formation, via gluconeogenesis, has only been reported in M. sexta and was induced when larvae were maintained on low carbohydrate diets. Starvation did not induce gluconeogenesis.

Insects obtain energy principally from aerobic respiration, but many species have some capacity for anaerobic energy metabolism when exposed to hypoxic or anoxic conditions. This is best known in aquatic insects such as midge larvae where the fermentation products may include lactate, ethanol, and acetate. The midge Chaoborus crystallinus accumulates succinate, suggesting that this species is able to use anaerobic respiration for ATP production.

**CHEMISTRY AND METABOLISM OF SCLEROTIZATION**

The hardness of cured exocuticle is the result of polymerization due to cross-linking between molecules of the protein sclerotin and/or cross-linking between sclerotin and chitin. Because of the resilience of cuticle, the chemical composition of sclerotin and of the chemistry of the polymerization process was first understood from organochemical analyses of the products resulting from chemical degradation of cuticle. Current knowledge of cuticular structure comes about through non-destructive NMR analysis of intact cuticle. Although sclerotization is principally the result of the reaction of cuticular proteins and chitin with quinones derived from N-acetylglucosamine, the metabolism of sclerotization is complex and sclerotized cuticles vary greatly in their physical and chemical properties because of metabolic variation.

The metabolism principally involves reactions of quinone methide intermediates that produce so-called β-sclerotin, with cross-linkages involving the β carbon of the catecholamine side chain, as well as dehydrodopamine intermediates producing linkages to the benzoyl ring. The metabolism of the quinone and dehydrodopamine intermediates is integrated, such that both the side chain and the ring structure may be involved in an individual cross-linked structure. Phenoloxidases, quinone isomerases, and quinone tautomeras are the principal enzymes involved in this metabolism.

The structure of the cross-linkage between sclerotin and chitin in the pupal cuticle of M. sexta was established through use of solid-state NMR spectroscopy. The structure demonstrates cross-linkage of phenolic and quinone intermediates with the imidazole ring of histidine residues of the protein and the β hydroxyl group on C4 of N-acetylglucosamine units of chitin (Fig. 1).

**CHEMISTRY AND METABOLISM OF PIGMENTS**

The diversity of insect coloration is in large measure because of an abundance of pigments. Combinations of pigments together with effects of light diffraction, refraction, and interference involving various anatomical structures produce the array of exotic colors familiar to insect observers. Many insects synthesize melamines, ommochromes, porphyrins, pteridines, and/or quinones. Other pigments such as flavonoids and carotenoids, although not synthesized, are often sequestered by insects from plants and contribute to coloration. Two pigment groups are notable. Ommochromes, first reported from the eyes of insects, and papiliochromes, a unique group that occur in the bodies and wings of the butterfly family Papillonidae.
FIGURE 1  Structure of the protein–chitin cross-linkage in the pupal cuticle of Manduca sexta (adapted from Schaedler et al., 1987). Protein may be linked through the 1 or 3 nitrogen of the amidizole ring to the 2, 5, or 6 ring carbon of the quinone derivative, and carbon 4, or other carbons of chitin may be linked to phenoxyl carbon 3 or 4 of the quinone.

Ommochromes are polymers of heterocyclic phenoxines, distributed among a variety of different insect tissues, producing yellow, red, and brown coloration. They are synthesized from tryptophan in a metabolic pathway involving kynurenine derivatives. In the compound eye, ommochrome form the principal masking pigments that surround and isolate the individual ommatidia and thus the origin of the name. Several eye-color mutants, described in several insect species, result from the absence of enzymatic function at specific steps in the synthetic pathway. Identification of these steps in Drosophila was one of the early confirmations of A. Garrod’s one gene–one enzyme hypothesis. The ommochrome biosynthetic pathway in the coloration of M. sexta larvae is hormonally regulated.

Papiliochromes are novel white, yellow, and red pigments whose synthesis intersects the well-known metabolic pathways, the melanins and ommochromes. For butterflies of the genus Papilio, the precursors are β alanine, tyrosine, and tryptophan. Papiliochromes accumulate in the wing scales, and their distribution varies with the butterfly species. Recent studies on papiliochrome synthesis demonstrated that, as in the case of sclerotization, quinone methides derived from tyrosine are intermediates. The synthesis involves the non-enzymatic condensation of N-β-alanyldopamine quinone methide with L-kynurenine to produce a mixture of two diasteroisomers of papiliochrome II, a white pigment. Papiliochrome II is a peptide in which the two aromatic rings are linked by a bridge between the aromatic amino group of kynurenine and the catecholamine side chain of norepinephrine derived from the quinone. Papiliochrome synthesis is regulated by the activation of β-alanyldopamine synthase that shifts dopamine derived from tyrosine away from melanin synthesis and into papiliochrome synthesis.

ENERGY METABOLISM DURING FLIGHT

Insect flight muscles are obligately aerobic, deriving energy from O2-dependent substrate oxidation to CO2 and H2O. Small insects in flight achieve the highest known mass-specific rates of aerobic metabolism among animals. Of the estimated one-half million insect species capable of flight, the metabolism of only a few have been subjected to detailed examination. Insect species differ in the extent to which carbohydrates (principally trehalose), fats (mainly diacylglycerol), and proline (an amino acid) are used to fuel flight. The relevant pathways are shown in Fig. 2.

The evolution of fuel use by insect flight muscles remains poorly understood. In some species of locusts and moths, flight is initially fueled by carbohydrate and prolonged flight is accompanied by activation of fatty acid oxidation and inhibition of carbohydrate oxidation. The switch from one fuel to another allows the use of a more energy-dense fuel (fat) while sparing carbohydrate stores and is triggered by adipokinetic hormones. Bees are unable to make use of fats to fuel flight, but instead oxidize carbohydrate, while using proline as a carbon source for augmenting the concentration of Krebs cycle intermediates. Pyruvate carboxylation serves a similar, “anaplerotic” role in these species. Carbohydrate and proline are oxidized simultaneously to support steady-state flight by flies and some beetles, but there is considerable inter-specific variation as to which fuel is used as the primary carbon source. Proline, for example, is the principal flight fuel for a few beetle species, whereas tsetse flies use proline exclusively.

A huge increase in the rate of ATP utilization in muscle occurs during the transition from rest to flight. In species possessing synchronous flight muscles (e.g., locusts, butterflies, and moths), this is the result of increased activities of actomyosin-ATPase, Ca2+-ATPase, and Na+-K+-ATPase. In insects with asynchronous muscles, actomyosin ATPase accounts for most of the ATP hydrolyzed, and the energetic cost of excitation–contraction coupling (involving Ca2+-ATPase and Na+-K+-ATPase) is much lower in comparison with synchronous muscles. Contraction frequencies in asynchronous muscles are not limited by maximum rates of Ca2+ cycling. This advantage, as well as the lower energetic cost of excitation–contraction coupling, may explain why asynchronous muscles, which are unique to insects, are found in 75% of insect species, including flies, beetles, and many species of wasps and bees.

ATPase activities increase upon the initiation of flight, and metabolic control mechanisms activate pathways of substrate catabolism, mitochondrial respiration, and oxidative phosphorylation to maintain ATP concentration and muscle function. Cellular rates of ATP hydrolysis and synthesis in insect flight muscle are so exquisitely matched that ATP concentrations are maintained within narrow limits, despite up to 100-fold increases in the rate of ATP turnover during the transition from rest to flight. The regulatory mechanisms that make possible these large flux changes between rest and flight remain poorly understood. The extremely high, steady-state rates of metabolic flux during flight are made possible by high concentrations of catabolic enzymes in the flight muscles, the operation of some of these enzymes at high fractional velocities, high mitochondrial content, large inner membrane surface areas per unit mitochondrial volume, and unusually high rates of electron flow between respiratory chain enzymes. Evolution has produced no locomotory muscles capable of higher rates of aerobic metabolism than those found in flying insects.

METABOLISM OF COLD HARDINESS

Many insects that exhibit arrested development during periods of cold, or routinely live in cold environments, display a resistance or tolerance to freezing. The phenomenon of supercooling was described for various insects over 100 years ago, and supercooling temperature may approach −50°C. In most cases, low-molecular-weight cryoprotectants, including some amino acids, mannitol, trehalose, sorbitol, and particularly glycerol, accumulate in the hemolymph
and act as antifreeze. Cryoprotectants can reach levels of 20–30% fresh body weight with the level of cryoprotectant inversely related to the supercooling point. In freeze-tolerant species ice-nucleating proteins accumulate.

Among the first studies of cryoprotectant synthesis was a demonstration of glycerol and sorbitol formation from glycogen by diapausing Bombyx mori silkworm eggs. The formation of polyols is an example of anaerobic fermentation. Their synthesis provides cryoprotection, but also maintains redox balance in response to a reduced level of oxidative respiration. Regulation of polyol formation is poorly understood, but cold-induced activation of glycogen phosphorylase is involved. Studies with Eurosta solidaginis fly larvae demonstrate independent control over glycerol and sorbitol formation, and hormonal cues may be important.

In insects that accumulate trehalose for cryoprotection, inhibition of phosphofructokinase has been suggested as the mechanism for shifting metabolism in the direction of sugar formation. A temperature-dependent change in the balance between glucose oxidation by glycolysis and the pentose phosphate pathway may also affect the balance between trehalose, sorbitol, and glycerol.

Metabolomic studies have characterized distinct changes in metabolite profiles associated with cryoprotection and diapause in the fly Sarcophaga crassipalpis. These confirm the accumulation of glyceraldehyde-3-phosphate dehydrogenase and sorbitol during rapid cold hardening (Fig. 3). Additional metabolites are also formed while others exhibit decreased concentration. Although cold hardening and diapause produce distinct metabolite profiles, insects in either of these states accumulate several of the same metabolites.

CONCLUSION

Insects exhibit many unique metabolic characteristics. The brevity of this article only allows discussion of a few select examples. Relatively few investigations have been conducted on molecular-genetic aspects of metabolism and metabolic regulation. Available techniques in cell and molecular biology, including differential display and microarray analysis, offer marvelous opportunities to examine the “transcriptional physiology” of hormonal and nutritional regulation of intermediary metabolism.

Metamorphosis

Frederick W. Stehr
Michigan State University

Metamorphosis means change in form. Most organisms undergo a change in form as they grow from an embryo to an adult. Some changes are radical and the immatures bear little resemblance to the adults; others are more gradual, with the immatures looking very much like the adults.

The term larva has very broad usage in invertebrate zoology, being applied to an assortment of forms (often the dispersive state) in virtually all invertebrate phyla. In Arthropoda other than insects, larvae is most often used for first stages, as it is in the mites and ticks, and for the first-stage hexapod larvae of millipedes, with “nymph” being used for second-stage mites and ticks. However, in continental Europe (especially France) “nymph” refers to a pupa; in English-speaking countries “pupa” is universally used for the stage between the last instar and the adult of insects with complete metamorphosis (Holometabola).

In the insects, larva has been used in different ways, including such diverse forms as the immatures of the most primitive order Protura and of the most advanced order Hymenoptera (sawflies, ants, wasps, and bees). The termites present an interesting problem: some authors use nymph for all juvenile termites, whereas others use larva for those lacking wingpads, and nymph for those having wingpads. This is further complicated because the supplementary reproductives may be wingless or bear wingpads, even though the two forms are functionally equivalent.

The kind of metamorphosis insects undergo is closely related to which of the subclasses a taxon belongs to. In the Apterygota metamorphosis is either anamorphic in the Protura, in which three abdominal segments are added as the individual develops to an adult, or it is ametabolous, in which the number of molts is indefinite and molting may continue throughout life after sexual maturity (Collembola, Diplura, Archeognatha, and Zygentoma).

In the Pterygota there are two fundamental kinds of metamorphosis: the hemimetabola develop through the egg, larva, and adult stages, and the holometabola develop through the egg, larva, pupa, and adult stages. There are also other terms (defined below) that have been used to describe variations in metamorphosis.

LARVAE VS. NYMPHS AND NAIADS

Defining a larva is also necessary because its use has been highly variable in the Insecta. In 1918, Comstock proposed restricting the term larva to juveniles of the holometabolous orders, nymph to the immatures of the hemimetabolous orders, and nymph to the immature of the homoptera.
juveniles of his paurometabolous (nonholometabolous) terrestrial orders, and naiad to the juveniles of his hemimetabolous nonholometabolous aquatic orders (Ephemeroptera, Odonata, and Plecoptera). Because these three aquatic orders have a much greater change in form from the last instar to the adult than the terrestrial hemimetabolous orders, there was some basis for Comstock’s proposal to call them naïads. However, the Ephemeroptera and Odonata are Paleoptera, which cannot fold their wings, whereas the Plecoptera are Neoptera, which can fold their wings over their back, so they are not closely related.

Currently there is a tendency to use larva for all immature insects that are not eggs, pupae, or adults and the term immature insect for not closely related. There is little difficulty in defining an egg or an adult, but naming and defining the instars or stages that may occur between egg and adult can be problematic. Some insects are larviparous, never depositing eggs; some multiply from a single egg by polyembryony, and some are sexually mature as immatures (paedogenesis or neoteny). Nevertheless, all of them undergo a series of molts as they grow. When larva is used in the comprehensive sense, the subcategories “exopterygote larva” (Hemimetabola that have the wingpads developing externally) and “endopterygote larva” (Holometabola that have the wingpads appearing externally in the pupal stage but having developed from internal larval histoblasts) are useful for pterygote immatures. A useful term roughly equivalent to larva in the comprehensive sense is “juvenile,” which can be used as a general term for nonadult larvae of all orders.

KINDS OF METAMORPHOSIS

Below are terms that are currently widely used for different types of metamorphosis. Most species are either holometabolous or hemimetabolous, with more than 85% of them holometabolous and most of the rest hemimetabolous.

Anamorphosis

This term means development with fewer body segments at hatching than when mature, which is found in the Protura, in which three abdominal segments are added anterior to the tail as the individual develops to an adult. Because of this some workers believe proturans are not true insects.

Ametabolous

Ametabolous means development with the major change being an increase in size until sexually mature. The number of molts is indefinite, and molting may continue throughout life; it is found in Apterygota (excluding the Protura).

Simple Metamorphosis

This is a broad term covering all types of metamorphosis except holometabolous.

Holometabolous (Complete, Indirect)

This means development through egg, larva, pupa, and adult. All insects do not fit neatly into Hemimetabola or Holometabola. Some Hemimetabola are intermediate in having one or more nonfeeding stages before the adult instar and in having a last instar that forms into a pupa. For example, in the whiteflies (Homoptera: Aleyrodidae) the first instar is active, but subsequent instars are stationary, resembling and feeding like scale insects, and the last instar stops feeding and becomes a pupa, with the wings developing internally. This could be termed holometabolous, but the homopterans as a whole are certainly hemimetabolous. In the Thysanoptera (thrips), there are two feeding instars followed by two or three nonfeeding instars, the propupa and pupa, which may be contained within a cocoon formed by the last feeding instar. This is certainly closer to Holometabola than to Hemimetabola.

Migration

Hugh Dingle
University of California, Davis

Migration, the major movement behavior of insects, allows them to escape deteriorating habitats, to colonize new areas, or to seek temporary shelter such as overwintering sites. It involves a complex of traits that include development, physiology, morphology, and behavior, and it is a major component of the life histories of many species. These trait complexes or syndromes are adjusted by natural selection in complex ways that increase the fitness and therefore the success of migrants.

MIGRATION AND OTHER MOVEMENTS

The movements characteristic of organisms can be roughly divided into two broad categories, those that are immediately responsive to resources and those that are not (Box 1). Within the category of immediate responses to resources are two further broad types. The first type consists of “station-keeping” responses that serve to keep the organism on its territory or within the home range in which it carries out most of its life functions and spends most of
its time. Included within station-keeping movements are resource-sensitive behaviors crucial for survival. Examples are foraging, territorial behavior, and commuting, which is a periodic, often daily, round trip for resources. Foraging may be for any resource, including food, shelter, or mates; and commuting, which can also be considered to be a form of extended foraging, may involve travel over considerable distances. The commuting trails of leafcutter ants, for example, may extend for hundreds of meters both horizontally along the forest floor and vertically into the canopy. Foraging, commuting, and territorial behaviors are all readily responsive to resources: thus a female butterfly stops searching (foraging) upon encountering a host plant on which to oviposit, and a territorial forest drosophilid fly is bounded by the borders of its leaf display ground.

Box 1 Types of Insect Movement

Migration is a type of movement displayed by insects, but it differs from all other types because migratory insects (and other migrants as well) are unresponsive to suitable resources. There are two broad categories of movements:

I. Movements that are directed by resources and/or home range.
   A. Station keeping: examples are foraging, commuting (periodic, usually daily, movements), and territorial behavior.
   B. Ranging: movement to explore an area, often for a new home range or territory.

II. Movement not directly responsive to a resource or home range: here migration is undistracted movement with cessation primed (thresholds lowered) by the movement itself. Responses to resources are suppressed or suspended.

Ranging movements take organisms on exploratory journeys beyond the current home range and serve to locate a new home range or territory. Like station-keeping movements, ranging movement is a facultative response to resources, and like foraging or commuting, it ceases when a new resource (here in the form of previously unoccupied living space) is encountered. Ranging movements may also extend considerable distances but, like station keeping, still belong in the category of activities that are proximately resource sensitive.

Movement that is not immediately responsive to resources constitutes the distinct sort of behavior that is migration. Taking an organism beyond its current home range and neighboring potential home ranges, migration is physiologically distinct from all other movements. It is so distinct because sensory inputs from resources that would ordinarily cause movement to cease do not stop migration. Thus, a characteristic of migration is that the organism undertaking it is undistracted by and fails to respond to food or mates, otherwise so necessary a part of life functions. Furthermore, migration is usually triggered by environmental cues, such as photoperiod, which forecast habitat change rather than being directly responsive to the change itself (usually a deterioration in the quality or availability of resources). Other characteristics of migration include distinct initiating and terminating behaviors. Many insects climb to the top of a bush or tree branch to take off on migratory flights, behavior they show at no other time. Sensory responses may also change, as in aphids that are sensitive to blue light from the sky during the take-off phase of migratory flight but become increasingly sensitive to yellow light, the characteristic wavelength of young host plants, as migration proceeds. Thus, migration is not defined by the distance traveled or by whether it is a “round trip.” Rather, it is defined in terms of the physiological and behavioral responses to resources; this behavior is true of all organisms, not just insects.

The movement behavior of individuals also has an outcome for the population of which those individuals are a part. This outcome involves displacement for a greater or lesser distance, but at either distance it involves removal from the home range. It can also result in the scattering or dispersal of individuals within the population; thus “dispersal” is a population phenomenon, not an individual movement. Movement can also result in congregation by mutual attraction or aggregation in a habitat. Both tendencies result in a decrease in the mean distance among individuals and contrast with dispersal, which increases mean distances. Note that all the movements just described can contribute to aggregation, congregation, or dispersal, depending on species and ecological circumstance.

Three examples of the sorts of population outcome attributable to migratory behavior occur in locusts, aphids, and moths of the genus Heliothis (and the very similar Helicoverpa). Locusts are a group of grasshopper species that under crowded conditions undergo remarkable behavioral and morphological changes known as phase transformation. In the desert locust, Schistocerca gregaria, perhaps the most extreme example of the phenomenon, crowded nymphs (hoppers) are strikingly black and yellow, whereas isolated individuals are pale brown or green. Crowded adults are larger and display differences in body proportions that readily distinguish them from their isolated counterparts. It is behavior, however, that most distinguishes the two forms. Isolated individuals display no mutual attraction, forage independently, and migrate at night. Crowded individuals show a high degree of mutual attraction and form large swarms that can number in the millions. When a swarm is feeding, locusts at the rear are constantly running out of food, overflying the body of the swarm, and landing at the leading edge. The result is a “rolling” movement across country in extended foraging. If a swarm enters an area with no forage, it may rise in unison and be carried for some distance by the wind. If this happens for a long period or repeatedly, the individuals in the swarm may switch to migratory behavior and cover considerable distances to descend again in regions of fresh plant growth. These aggregated swarms are major pests over much of Africa, occasionally reaching adjacent areas of the Middle East and in several notable instances the New World. The arrival of a swarm can mean that “not any green thing” (Exodus 10:15) is left for human consumption. It is the aggregation and migration that make the desert locust such a notorious pest. It would be much less a pest if its characteristic behavior led to dispersal rather than swarming.

Various species of aphid are also capable of spreading far and wide by migration. In Europe, an extensive monitoring network coordinated by English and French entomologists has mapped the seasonal spread of bean aphid, Aphis fabae. Large concentrations appear first in central France in early to midsummer. The species then spreads westward and northward over succeeding generations so that by late summer the aphid has reached high densities as far north as Scotland. In North America, monitoring of the corn leaf aphid, Rhopalosiphum maidis, has indicated the arrival of large numbers in the cornfields of Illinois. Analysis of weather systems suggests these aphids have come from as far away as Texas and were transported on wind streams. Studies of a number of other insects indicate that the Mississippi Valley is a major spring migration route for wind-transported insects to the agricultural regions of the upper Midwest.
Migration

Heliothis moths breed following rainfall in tropical and subtropical arid regions. If productivity is high on the new vegetation on which they feed, large populations of migrating moths are produced and are carried by winds to agricultural areas. In Australia, moths are transported in spring to wheat- and cotton-growing regions in New South Wales from breeding areas in interior regions of New South Wales and Queensland. The location of rainfall in the interior of Australia is unpredictable from year to year, and considerable effort has gone into locating areas in which rain has fallen, determining whether this precipitation is sufficient to produce large moth populations, and forecasting the arrival of migrating moths in conjunction with weather systems so that necessary control measures can be undertaken and unnecessary ones avoided. In the spring in North America, there is similar breeding of Heliothis moths in northern Mexico and southern Texas and migration northward on winds.

HISTORICAL BACKGROUND

In the 1930s C. B. Williams collected and summarized the available information on insect migration. The two books that resulted were largely responsible for bringing to the attention of entomologists and other biologists the fact that the phenomenon was a common one. Williams focused on large insects such as butterflies and dragonflies, and he adopted the prevailing notion, derived largely from birds, that only round-trip movement could be called migratory. The way entomologists now think about insect migration is primarily the result of the work of four Britons: C. G. Johnson, J. S. Kennedy, T. R. E. Southwood, and L. R. Taylor, beginning around 1960. Johnson and Kennedy stressed that insect movements vary with respect to physiology and function, and their ideas revamped notions concerning the behavioral and life history aspects of migration. Southwood showed that the type of habitat determines the likelihood of migration among insects, and Taylor noted the importance of movement to the dynamics of populations in both time and space. Combined, the work of all four made explicit that migration is a distinct behavior with consequences for populations.

The distinct nature of migratory behavior was precisely outlined by Kennedy in his studies of the flight of the summer parthenogenetic females of A. fabae. He used a flight chamber that allowed him to analyze the responses of free-flying aphids (Box 2). Key aspects of migratory flight that distinguished it from other types of flight were revealed by the flight chamber experiments. The aphids tested were the winged or alate form produced under crowded conditions. The uncrowded wingless females larviposit (bear live young) as soon as they make contact with a suitable host leaf. In contrast, the winged migrants do not larviposit until they have completed at least some flight. Furthermore, landing responses are primed by migratory flight: the longer the flight, the lower the threshold for landing. Finally, there is reciprocal interaction between flight and settling, since settling responses (i.e., probing a leaf to test its suitability and subsequent moving to the underside of the leaf to larviposit) can prime flight if they fail to be completed by attaching via the mouthparts and producing offspring. This flight after incomplete settling may actually be stronger than that occurring at the beginning of migration. Migration thus is qualitatively different from other movement because station-keeping responses such as landing and probing (foraging) are inhibited by flight, but flight also primes them and promotes their later recurrence. Based on the behavior of migrating aphids, Kennedy provided a complete predictive definition of migration, as follows: migratory behavior is persistent and straightened-out movement effected by the animal’s own locomotory exertions or by its active embarkation upon a vehicle; it depends on some temporary inhibition of station-keeping responses, but promotes their eventual disinhibition and recurrence.

Box 2 The Kennedy Flight Chamber

J. S. Kennedy used this device in studies of insect migration. His experiments analyzed the performance of free-flying aphids and their landing and foraging responses. The lever arm can be twisted to shake the aphid off the platform, forcing it to fly, and it can be rotated out of the light and presented to the flying aphid again at will. Host plant leaves of different ages and leaves of different species of plant can be presented to permit investigators to observe variation in landing responses. Free flight is maintained by wind from the top of the chamber, and the wind speed is varied with the butterfly valve, whose setting thus indicates the strength of flight as measured by rate of climb which is balanced by the downward wind speed. [Figure reproduced from Dingle, H. (1996). “Migration: The Biology of Life on the Move.” Used by permission of Oxford University Press, Inc.].

By explicitly focusing on the interaction between growth and reproductive behaviors (station keeping) and migratory behavior, Kennedy put migration firmly in the context of life histories. This context was also emphasized by Johnson, who identified the “oogenesis-flight syndrome” as characteristic of insect migration. Johnson noted that in a high proportion of migratory insects, especially in females, flight is limited to individuals with immature reproductive systems. It thus seemed that migration was based on an interaction between
flight and the maturation of reproduction. Implicit was the assumption that migration and reproduction were alternative physiological states, with trade-offs in the mobilization of energy and materials. Johnson further postulated that this life history syndrome would be mediated by juvenile hormone (JH), a postulate now amply demonstrated (see later: Migratory Syndromes).

The population dynamical aspects of insect migration were assessed by Southwood and Taylor. Southwood placed migration into an ecological and evolutionary context by summarizing evidence that migration is characteristic of insects living in temporary habitats such as seasonal pools or early successional fields. This condition is in contrast to that of insects with more permanent habitats such as forests or large lakes; such insects are nonmigratory and often even wingless. This pattern of migration as a response to transitory environments was later formalized by Southwood in 1977 in the ratio $H/\tau$, where $H$ is the duration of the habitat and $\tau$ the generation time of the insect. The frequency of migration in populations or species increases as the ratio shrinks toward unity, as later nicely demonstrated, for example, in leafhoppers (Homoptera) by Denno and colleagues. Taylor stressed the role of migratory behavior in the spatial dynamics of insect migration. He noted that migrants can disperse or coalesce, depending on whether individuals attract or repel one another and on atmospheric dynamics. This behavior can create a mosaic of insect densities over the landscape. He also initiated the Rothamsted Insect Survey, an array of traps to sample insects in the air, from which data on numbers were taken and analyzed at the Rothamsted Experiment Station near London. This network allowed tracking and forecasting of insect pests such as aphids with major practical implications for insect control.

### THE CAUSES OF MIGRATION

Since Southwood's original statement of the relationship, it has become apparent that the impermanence of habitats is indeed the primary selective force driving insect migration. Much of this impermanence is a function of season, and as with other well-known migrants such as many fish or birds, seasonality is a common factor in insect migrations. Most seasonal migrations are on a relatively small scale, with distances traveled only a few hundreds or thousands of meters, but others cover much greater distances. Examples of short-distance migrations to overwintering diapause sites include the Colorado potato beetle, *Leptinotarsa decemlineata*, several species of common seed-feeding hemipterans, including *Lygus californicus*, a milkweed bug of Europe (in Sweden it often flies to lighthouses to diapause), and several species of lady beetles (Coccinellidae). In some lady beetles migration extends to several kilometers. In California, *Hippodamia convergens*, the convergent lady beetle, overwinters at high altitudes in the Sierra Nevada and migrates to agricultural areas in the Central Valley in March. Beginning in June, offspring of the early spring migrants fly back to intermediate altitudes and form aggregations. There is then a later movement to higher altitudes to overwinter so that the migration to overwintering sites is a two-step process.

Other insect migrants make spectacularly long journeys. The best known of these is that made by the eastern North American population of the monarch butterfly, *Danaus plexippus*, studied extensively by Lincoln Brower and F. A. Urquhart. This butterfly cannot overwinter in the temperate zone, so it must migrate to southern overwintering sites. The short days of autumn cause adult butterflies to enter reproductive diapause, and they undertake a southward journey of 3000 km or more. The majority of the eastern population overwinters en masse in a very few high-altitude protected sites in the Transvolcanic Range of central Mexico, where they arrive in the late autumn. Beginning in February, the aggregations break up, mating occurs, and the butterflies begin to move northward. Identification of the chemical cardenolide “fingerprints” of the milkweeds eaten by monarchs when they are caterpillars and stored in the adults has revealed that the overwintering generation stops and breeds on the spring flush of milkweeds along the coastal plain of the Gulf of Mexico. It is the offspring of these individuals that invade regions farther north beginning in late May and early June. Thus, as with fall California convergent lady beetles, the spring migration is at least a two-step process. A very similar migration pattern occurs in the same region in the large milkweed bug, *Oncopeltus fasciatus*, and it, too, occurs in two stages in the spring.

The migration of western populations of the monarch is more complicated. These populations overwinter in aggregations along the coast of southern California, where winter climatic conditions are similar to the aggregation sites in Mexico. When the aggregations begin to break up, as early as late January, the butterflies move to early sprouting milkweeds in the Coast Ranges and breed there. The next generation moves both to more coastal milkweeds and to milkweeds that grow farther inland as far east as the Rocky Mountains and as far north as the Canadian border, so that as in the eastern populations, the spring migration occurs in two stages over two generations. A very similar pattern occurs in the monarch population introduced into eastern Australia, with overwintering near the coast, a migration inland in the spring, and a return to the coast in the autumn. In more northern parts of the Australian range, there may be year-round breeding in coastal and subcoastal regions.

One way to assess the influence of ephemeral habitats on the evolution of insect migration is to survey across species and populations occurring in different kinds of habitats. In Europe, a number of species and populations of water striders (Hemiptera: Gerridae) occur over an array of habitats, from small, temporary ponds to large lakes and permanent streams to isolated permanent bogs. Species in the more temporary bodies of water have wings and undertake regular migrations to locate their aquatic habitats as they appear and disappear in the landscape. At the opposite extreme in permanent lakes and bogs, there are species that are wingless. Across habitats with varying degrees of permanence are populations and species of water striders with varying proportions of winged and wingless individuals determined primarily environmentally (polyphenisms) where habitat change is predictable, and primarily genetically (polymorphisms) where change is increasingly random with respect to the life cycle.

A second example of the influence of habitat duration on the occurrence of migrants within a fauna occurs in Australian butterflies. Often, latitude predicts the amount of migration that will occur, especially where there is adequate rainfall and seasonal change is largely a function of temperature. In eastern North America, for example, 98% of the variance in the proportion of migratory birds is explained by latitude, with a higher proportion of migrants at northern latitudes. Similarly, in eastern Australia, where the climate is warmer overall but still temperate with adequate rainfall, 72% of the variance in the proportion of butterfly migrants is explained by latitude. The situation is quite different in the dry regions of Australia west of the Great Dividing Range. Here latitude accounts for less than 1% of the variance in proportion of butterfly migrants, and climate variables that indicate rainfall patterns, such as soil moisture, which accounts for about 50% of the variance, are much better indicators of migration. The amount of rainfall is not correlated with latitude, and so latitude does not predict migration. In this dry climate it is the availability of erratic rainfall that counts, and only migrants that can take advantage of the ephemeral flushes of vegetation that follow such rainfall. Thus, as with *Heliothis* moths, migration allows some butterflies to exploit a dry and ephemeral habitat.
MIGRATORY SYNDROMES

Accompanying migratory behavior is a syndrome of traits that act in coordination to increase fitness. These traits vary from enzymes to life history characters and, being influenced by subsets of the same genes, are genetically correlated. At the physiological level, insects (like most other migrant organisms) use fat as fuel, primarily for two reasons. First, fat metabolizes to produce about twice as much energy as carbohydrate or protein; and second, it requires no water for storage (in contrast, storage of 1 g of carbohydrate requires 3 g of water). Insects such as the monarch butterfly and the large milkweed bug shift lipids from yolk formation to fat storage under the influence of the shorter photoperiods of autumn and just prior to migration. The flight muscles of migrants are also adapted to the energetic demands of lengthy flight. Enzymes active in oxidative metabolism, such as citrate synthase, and in fatty acid oxidation, such as β-hydroxyl coenzyme A dehydrogenase, or HOAD, tend to show higher levels of activity in the flight muscle of migrants compared with that shown in nonmigrants. This difference is most apparent where there are wing polymorphisms and migrants have longer wings.

The most important hormone involved with insect migration is JH. It has influence not only on the coordination of the various relationships of the oogenesis-flight syndrome but also has direct effects on migratory flight. In many insect migrants such as the monarch butterfly, short photoperiods result in reduced outputs of JH from the corpus allatum. This reduction in JH output in turn leads to a reduction in ovarian and egg development, which is then accompanied by migratory flight. In several species of migrant insects, prolonging of the prereproductive period by reduced JH titers results in the triggering and maintenance of migratory flight. At the same time it has been demonstrated in several migratory species (such as the large milkweed bug, the convergent lady beetle, and the monarch butterfly) that JH directly stimulates migration. Implants of corpora allata, the source of JH, or topical application of JH or some of its chemical analogues, are effective in increasing flight in migrants. In some insects such as the monarch, adipokinetic hormone (AKH—involved in promoting fat metabolism) also stimulates additional flight. The effects of JH and AKH in the monarch are illustrated in Fig. 1.

Because migratory flight occurs when reproduction is delayed by reduced JH concentrations, it is logical to inquire what level of JH determines migration. This question was answered for the large milkweed bug by M. A. Rankin. She selected for delayed onset of flight, which also resulted in delayed reproduction. Rankin measured JH titers in the blood during the prereproductive period and showed that JH titers were low when there was no flight or reproduction; intermediate titers stimulated flight, and high titers stimulated oogenesis. Thus, if titers rose only to intermediate levels, as might occur under short days, for example, flight but not reproduction would be triggered. These JH titers may also be regulated by JH esterase, the enzyme that breaks down JH. In wing-polytrophic crickets, high concentrations of JH result in short-winged individuals. Artificial selection experiments that increased the frequency of long wings also resulted in increased amounts of JH esterase in the blood and so reduced amounts of JH. Selection also demonstrated that it was possible to change both mean and threshold JH esterase activity. The possible role of JH esterase in fully winged migratory insects remains to be studied.

An additional behavioral aspect of the migratory flights of many insects is the ability to maintain a more or less constant direction during migration. Mostly, this directionality has been studied in butterflies, although some other large insects such as dragonflies and larger Hymenoptera also seem to maintain a constant direction when migrating. The monarch butterfly in eastern North America flies in a steady southward or southwestward direction in the autumn, flight directions that lead to the overwintering sites in central Mexico. In the spring, the migratory flight is to the north. Compilations of observations of several species of Australian butterflies, including the monarch, reveal that the insects fly south or southwest in the spring and north or northeast in the autumn. The apparently migratory flights of a few species occur in the same direction no matter what the season, a phenomenon that has yet to be explained. In Europe migratory flights of the butterfly *Pieris brassicae* are consistent with both season and geography. Autumn migrants from northern Germany fly south or south by southeast, whereas migrants in the south of France fly to the southwest, which takes them to Spain rather than over the Mediterranean. Further experiments have demonstrated that butterflies that have diapaused, as they do during the winter, fly north when they migrate, but those emerging from nondiapause (summer) pupae fly toward the south. Seasonal winds also frequently carry migrating insects in the “correct” direction. Monarch butterflies in eastern North America frequently soar and are carried southward by northerly winds, and simulations of the migration of the large milkweed bug from the same region indicate that a portion of the population reaches southern overwintering areas regardless of whether they orient.

Where the mechanism of orientation has been studied, the evidence suggests that it is a time-compensated sun compass. To use the sun effectively for orientation, organisms must be able to compensate for its daily passage across the sky by reference to a “biological clock.” To demonstrate that an organism is using a time-compensated sun compass, it is necessary to clock-shift it by maintaining it in a daily light cycle that is out of phase with the ambient cycle and then to show that its orientation is displaced by an amount consistent with the clock-shift. A displacement of 6 h, for example, should lead to a directional change of 90°; whether the change is plus or minus depends on the direction of the clock-shift. Experiments with southward-moving monarch butterflies suggest that this pattern is indeed followed. In tropical Panama, two species of migrating pierid butterflies, *Aphrissa statira* and *Phoebis argante*, regularly maintain

**FIGURE 1** Influence of JH and AKH on tethered flight in the monarch butterfly. Flight (%) longer than 30 min is the index of migratory flight. The butterflies received topical application of hormones or the acetone control, and subsequent flight duration was determined. Both hormones, singly or together, increased flight over controls.
a directional flight across Gatun Lake in the Panama Canal. Clock-shift experiments resulted in changes in the direction of orientation that were consistent with a sun compass, even though there was also a component imposed by wind drift. The sophisticated orientation mechanisms of honey bees, ants, and certain other insects incorporating a sun compass, imply that orientation is probably widespread. The future will undoubtedly reveal the presence of a sun compass in other migrants, as well as the presence of other mechanisms, especially in nocturnal migrants. Radar observations indicate that the passage of many species of nocturnal migrants is specific to winds of a certain direction, but the means by which this preference is enforced are unknown.

In addition to behavioral and physiological characters, migration syndromes often include life history traits such as the age at first reproduction and fecundity, particularly in many wing-polymorphic insects. Typically, in these species the short-winged or wingless forms reproduce earlier and display higher fecundities than their long-winged counterparts. This dichotomy is at least in part because of trade-offs between flight and reproduction. The metabolically active flight muscles that accompany long wings and migration are costly to maintain, requiring considerably more maintenance energy than the thoracic musculature of wingless or short-winged individuals. In contrast, the later reproducing individuals, with lower egg production, are often longer lived.

Migration syndromes that include life history traits are the result of underlying genetic mechanisms, as revealed in artificial experiments using the large milkweed bug. Like all flying insects, this migrant can be induced to fly by removing substrate contact. Bugs that are glued at the prothorax to a tether will fly if contact with the tarsi is removed. An individual in the migratory state can fly on the tether for several hours, and the duration of flight can be used as an index of migration. Artificial selection can be used to increase the proportion of individuals making long (or short) flights, with the duration of flights also affected. Selection was used to both increase and decrease the proportion of bugs undertaking long flights. In addition to flight, wing length and fecundity responded to this selective regime. The bugs of the line with a higher proportion of long flights also had longer wings on average, and the females of this line produced more eggs during the first 5 days of reproductive life. This means that the genes influencing flight also influenced wing length and fecundity, most likely via pleiotropic effects. Longer term selection experiments on wing length, which also resulted in higher fecundities and increased flight as wing length increased, suggested that linkage disequilibrium is unlikely. Parallel selection experiments on a population that did not migrate failed to reveal genetic correlations among wing length, flight, and fecundity, indicating that the genetically based syndrome of correlations among these traits is unique to migratory populations. The selection experiments reveal that natural selection has produced an adaptive migratory syndrome that includes wing length and fecundity. Interestingly, the age at first reproduction is unaffected by selection.

The conclusion from the brief survey of insect migration is that this behavior involves more than simply extended movement to escape to a new habitat. Rather, migration is a trait of considerable complexity, requiring knowledge of behavior, development, ecology, physiology, and genetics to provide a full understanding of its evolution and function.

Mimicry
Mathieu Joron
Muséum National d’Histoire Naturelle, Paris, France

Mimicry is the adaptive resemblance in signal between several species in a locality. The most spectacular and intriguing cases are those of accurate resemblance between distantly related animals, such as spiders mimicking ants. Closely related species can also benefit from mutual resemblance, in which case mimicry results from selection against signal divergence.

The vast majority of the hundreds of thousands of insect species are described and identifiable on the basis of morphological characters. This bewildering diversity is, however, ordered because species share characters with their relatives—and one of the taxonomist’s tasks is indeed to recognize, among the shared and divergent characters, a sign of the relatedness of the taxa. Nevertheless, some distantly related species may share a common morphology. Such resemblance may be the result of evolutionary convergence, that is, parallel lifestyles leading to the selection of similar morphological structures; in this case, resemblance per se is not under selection. On the contrary, when a character is taken as a signal between individuals, one species may benefit from bearing the same signal as the one already used by another species; then selection acts directly to favor increased resemblance.

AN INTERACTION BETWEEN THREE PROTAGONISTS
The Discovery of Mimicry and the Development of Evolutionary Hypotheses

Mimicry in insects has been a puzzle for entomologists long before the Darwinian concept of natural selection, but the explanations for mimicry are tightly linked to the development of evolutionary thinking. While he was traveling in the Amazon with Alfred
Mimicry

Russel Wallace in 1842, British entomologist Henry Walter Bates noted that distantly related butterfly species bore the same wing color pattern. Moreover, these communities of species changed their shared pattern in concert across localities. Among these species were the very abundant Ithomiinae (called Danaoid Heliconiidae then, now a subfamily in the Nymphalidae) and rarer Dismorphiinae (called Leptalidae then, now a subfamily in the Pieridae). Bates, as a pioneer evolutionist (but after Darwin published his On the Origin of Species), developed an adaptive explanation for the resemblance. Hypothesizing that ithomines were inedible to most predators, he proposed that the edible pierids would benefit from being mistaken for their defended counterparts and would thus be selected to resemble them. Edward B. Poulton later named this kind of mimicry after him as Batesian mimicry, when an edible species mimics a distasteful one.

Bates also realized that some apparently inedible ithomiine species in the genus Naopeogenes seemed to mimic other inedible Ithomiinae. He proposed that, in fact, rare species, whatever their palatability, should benefit from resembling defended common species. It was, however, more difficult to understand the resemblance of abundant and distasteful Melitaea, Mechanitis (Ithomiinae), Lycorea (Danainae), and some Heliconius (Heliconiinae) from Peru and Colombia, so he assumed the resemblance was the result of some inorganic or environmental factors. In 1879, German naturalist Fritz Müller was the first to develop a mathematical demonstration that two unpalatable prey could benefit from mutual resemblance. He understood that, if the community of predators had to kill a certain (fixed) number of prey to learn to avoid them, two indistinguishable distasteful species would together suffer this mortality and both reduce their death rate per unit time. Müller actually showed that this benefit was biased in favor of the rarer species, to a factor equal to the square of the ratio of the species’ abundance. Therefore, unequal population sizes translate into even more unequal, although still mutual, benefits: Müllerian mimicry, thus defined, could be beneficial for both species, and perhaps also for the predators, in contrast to parasitic Batesian mimicry.

Mimicry: An Interaction between Senders and Receivers

Mimicry typically involves at least three protagonists, two senders and one receiver, with the receiver judging the resemblance of the signals from the two senders (Fig. 1). Obviously, both the senders and the receiver should be found in the same locality for the mimicry to be possible, although time lags or geographic separation between senders may be plausible if receivers have a long-term associative memory and/or migrate. In a habitat, many senders will converge on the same signal, thereby forming what is called a mimicry complex, or mimicry ring. Signals may involve different sensory modalities, depending on the receiver’s sensory ecology: static visual signals (e.g., warning color patterns in butterflies, recognizable body shapes in ants), motion (flight behaviors), acoustic signals (clicking in many arctic moths), olfactory/chemical signals (pheromones or the so-called cuticular hydrocarbon profiles by which social Hymenoptera recognize one another), or tactile signals (used by brood parasites of ants to be allowed to enter their nests). Signaling is indeed often multimodal.

Apparent complications may arise when, for example, one of the senders is also the receiver. For example, a predator may mimic the appearance of its prey when approaching it (aggressive mimicry in some spiders or chemical/tactile mimicry for brood parasites); the prey is thus fooled by the predator via its own conspecific signal. The two senders can also be the same species. This is sometimes the case in chemical-sequestering phytophagous insects when unpalatability varies among individuals in the same population (e.g., Danaus gilippus in Florida), leading to so-called automimicry of palatable toward unpalatable individuals in the same species. Similarly, male Hymenoptera do not have the defenses that females have.

However, the present article is not organized around these classificatory distinctions, which are based on subtle differences in the identities of senders and receivers or ecological situations. Instead, it highlights the important evolutionary dynamics that arise from whether receivers are expected to try to discriminate or generalize on the senders’ signals or, in other words, from senders sending honest compared to dishonest signals. This should bring into perspective some of the main and still unresolved puzzles in mimicry theory, such as the rise and maintenance of diversity in mimicry signals. Most examples are chosen from the butterfly genera that represent today’s best known mimetic organisms, such as Papilio and Heliconius; indeed, our knowledge of the ecology and genetics of mimicry in these genera is unequaled by any other group of insects.

FREQUENCY-DEPENDENT POPULATION PROCESSES

Batesian Mimicry and Negative Frequency Dependence

THEORY AND CONSEQUENCES In Batesian mimicry, one of the sender species, the mimic, sends a dishonest signal to deceive the receiver—for example, a predator. It is thought that deception is possible only if the receiver has previously inherited or acquired knowledge about this signal. There is ample evidence that (1) vertebrate predators (birds, lizards) can learn to recognize distasteful prey, (2) they can be deceived by mimicry, and (3) mimics gain from the resemblance. The most famous Batesian mimic is probably the viceroy butterfly, Limenitis archippus, which mimics the monarch Danaus plexippus, although this relationship is now questioned (because
viceroy can be unpalatable. Hoverflies (Diptera: Syrphidae), diurnal moths (Sesiidae, Sphingidae), striped beetles (Cerambycidae), or crane flies (Tipulidae) are well-known Batesian mimics of wasps and bees (Fig. 2).

FIGURE 2 Batesian mimicry. The day-flying moth Synanthedon tipuliformis (Sesiidae) (top) is a Batesian mimic of stinging wasps in Europe. The resemblance is very accurate, and the moth is very rare compared to its wasp models, so that it is not often observed. Similarly, but in a totally different group, the beetle Clytus arietis (bottom) mimics wasps and is sometimes seen on blossoms. These two examples illustrate how the same general appearance can be achieved by morphological changes of totally different nature in different groups of insects. (Photographs copyright 1998–2002 Hania Arentsen and Hans Arentsen, reproduced, with permission, from The Garden Safari, http://www.gardensafari.net.)

Clearly, the efficiency of the deception is directly linked to the probability that predators have knowledge of the prey. It thus depends on the ratio of models and mimics in the population of prey (Fig. 1). As in host–parasite systems, the fitness of Batesian (“parasitic”) mimics therefore depends negatively on their proportion in the prey community. Negative frequency dependence, the selective advantage to rare forms, is thought to be a strong force favoring and maintaining diversity in many ecological situations in nature. In Batesian mimics, any new (or rare) mutant resembling another protected model will be favored, leading to a balanced polymorphism between the two mimetic forms. Negative frequency dependence also predicts that the local number of Batesian species should be dependent on the abundance of the model(s).

Many, but by no means all, Batesian mimics are indeed polymorphic. Among the most famous is the African swallowtail P. dardanus, which may have three co-occurring forms that mimic different species of the Danainae genus Amauris. Hypolimnas misippus (Nymphalidae) is another African butterfly that has four forms mimetic of D. chrysippus. In South America, the swallowtail Eurytides lisithous has up to three forms that mimic the co-occurring Parides species (Papilionidae), whereas in Southeast Asia the famous Papilio memnon also mimics three or more different papilionid models. In the Diptera, the Old World hoverflies Volucella bombylans and Merodon equestris are examples of polymorphic species mimicking bumble bees.

EVIDENCE FOR NEGATIVE FREQUENCY DEPENDENCE

Although experimental demonstration that Batesian polymorphisms stem from negative frequency dependence is still lacking, there is a lot of evidence for negative frequency dependence itself. A first line of evidence comes from the observation of patterns of abundance of models and mimics in nature. For example, the North American butterfly Battus philenor is known to be unpalatable to most birds and is believed to act as model for a number of edible mimics in the “black” mimicry ring. In one of them, P. glaucus, females are found as a mimetic and a nonmimetic (male-like) form, and the proportion of the mimetic form tends to be higher where its model B. philenor is more abundant. Similarly, the resemblance of the mimic P. troilus to B. philenor is higher where the latter is abundant. These give an overall pattern of mimics’ occurrence consistent with negative frequency dependence. Moreover, field experiments directly showed a strong selective advantage to mimetic vs. nonmimetic Callosamnia promethea day-flying moths, another Batesian mimic of B. philenor.

Experimental approaches give more insight into the mechanisms involved in frequency dependence. In experiments, captive or wild predators can be tested with a variety of artificial or real prey, and the mimic/model proportions can be experimentally changed to explore how it affects the prey’s survival. Traditional experiments were carried out in the 1970s with mealworms or pastry baits colored with food dyes, and/or dipped in quinine to make them distasteful, and exposed to garden birds in suburban Britain. Such experiments do suggest that a rare mimic has an advantage over a common one if the “model” is slightly distasteful, which demonstrates frequency-dependent selection. However, if the “models” were made very distasteful, the advantage of being rare decreased and eventually vanished. Laboratory experiments can also be used to search for evidence of frequency dependence, while avoiding potential confounding effects of field experiments. Experiments with captive great tits as predators showed that the mortality of both mimics and models depended on the frequency of the model and that both models and mimics survived better when mimics were fewer.

These experiments tell us that the intensity of frequency-dependent selection in mimics is highly dependent on the palatability of the models. To see its selective advantage decrease, the palatable mimic must become very common, or the model must be not very distasteful. This suggests there is some kind of effective “equivalence” between relative numbers of prey encountered and their relative levels of toxicity.
Mimicry

Positive Frequency Dependence in Müllerian Mimicry

THEORY: THE DISADVANTAGE OF RARE FORMS

Warning signals, or aposematism, evolve because prey bearing signals that predators associate better with unprofitability (e.g., harmful prey) survive better. The evolution of warning signals brings some apparent paradoxes that are not treated in that entry. However, there is plenty of evidence that aposematic prey are easily learned and subsequently avoided by vertebrate predators. Both the warning prey and the learning predator benefit from a correct interpretation of the signal. Under such an “honest signaling” framework, rare or new variants within a prey population should not be recognized as distasteful and should suffer higher predation (Fig. 1). This selection against rare forms translates into positive frequency-dependent selection: rare mutants are removed, leading to monomorphism in all populations.

Because predators select only on prey appearance, the selective pressure does not stop at the species boundary: several protected prey species may be selected to use the same warning signal, that is, become Müllerian mimics. Although the phenomenon is not necessarily symmetrical, two or several defended species should all benefit

**FIGURE 3** Six butterfly mimicry rings from eastern Peru. The mimicry rings (groups of mimetic species) presented here are dominated by butterflies in the Ithomiinae and occur in the forests around the city of Tarapoto. Following G. W. Beccaloni’s nomenclature, these mimicry rings are Tiger (1–16), Melanic tiger (17–21), Large transparent (22–24), Small transparent (25 and 26), Small yellow (27–31), and Orange-tip (32–34) mimicry rings. At least 5 other mimicry rings can be recognized involving Heliconiinae and/or Ithomiinae in this area, which brings the total to at least 11 mimicry rings for these two butterfly subfamilies. Many more species, not featured here, belong to these mimicry rings, particularly Ithomiines and especially in the Small transparent group. The Tiger mimicry ring involves a lot of species and the size distribution is almost continuous from small to very big. This may be because as more and more Müllerian mimics join the mimicry ring, predators might generalize more, and the selection for close resemblance could be somewhat relaxed. Note that some day-flying moths (6, 17, 22, 27) participate in these mimicry rings, probably as Müllerian mimics (they reflex-bleed bitter hemolymph when handled). Butterflies 13–16 and 31 are supposed to be Batesian mimics as they belong to palatable groups within their families. See more species belonging to these mimicry rings in Figs. 4 and 5. All butterflies are Nymphalidae: Ithomiinae, except 1–3 (Nymphalidae: Heliconiinae), 14 (Nymphalidae: Melitaeinae), 16 (Nymphalidae: Charaxinae), 15 (Papilionidae), 13 and 31 (Pieridae: Dismorphiinae), 34 (Riodinidae), and 6, 17, and 22 (Arctiidae: Pericopinae). Scientific names: 1, Eueides isabella; 2, Heliconius pardalinus; 3, H. hecale; 4, Melinaea menophilus; 5, Tithorea harmonia; 6, Chetone histriona; 7, Neopogenes larina; 8, Mechanitis lysimnia; 9, Mec. polymnia; 10, Mec. mazaeus plagifera sp.; 11, Ceratinia tutia; 12, Hypothyris cantobrica; 13, Dismorphia amphiona; 14, Eresia sp.; 15, Pierouras zagreus; 16, Consul fabius; 17, Chetone histriona; 18, Mel. mareaus; 19, Hypocascada anchiela; 20, Hypot. mansuetus; 21, Mec. mazaeus deceptris; 22, Natophyon heliconides; 23, Methona confusa; 24, Godysis zavaleta; 25, Greta andromica; 26, Pseudoscada florula; 27, Notodontid moth; 28, Aeria eurimedia; 29, Ithomia salapia; 30, Scada sp.; 31, Moschoneura sp.; 32, Hypus. illinissa; 33, Hypoleria sarepta; 34, Stalachtis euterpe. Scale bar, 2 cm.
from sharing a warning signal, which reduces their per capita predation rate. As more and more individuals join in the mimicry ring, the protection given by the signal becomes stronger. Therefore, the direct, and naïve, prediction is that all unpalatable prey of a similar size in a habitat should converge into a mimicry ring.

**EVIDENCE FOR THE FREQUENCY-DEPENDENT BENEFITS OF MÜLLERIAN MIMICRY** Although comparative and/or biogeographical studies give strong support to the theory, the first convincing experimental evidence came from pastry-bait experiments with garden birds that tend to attack rare distasteful baits more often than common ones. Recently, laboratory experiments also showed strong selection against new rare warningly colored prey items. However, field evidence with free-living prey is crucial for a validation of these results. In one experiment, J. Mallet reciprocally transplanted *Heliconius erato* individuals between populations in which *H. erato* have different wing patterns, thus effectively releasing rare “mutant” and “control” butterflies into the host populations. A strong selective advantage of about 50% was calculated for the commoner form. More recently, to avoid the potential pathology of color patterns being adaptations to local habitat conditions in addition to mimicry, D. D. Kapan used a similar reciprocal release-recapture technique but used polymorphic populations of the butterfly *H. cydno*. In this species, two morphs coexist but participate in two different mimicry rings that differ in relative abundance in different locations in Ecuador. Life expectancy was 12 days for the locally common forms and only 2 days for the locally uncommon forms. These field data give unequivocal evidence for strong selection against rare forms in these Müllerian species.

**CONSEQUENCES AND CHALLENGES** Strong purifying selection now seems well supported by theoretical, comparative, and experimental evidence. To evolve a new pattern, a toxic prey would have to pass an apparently impassable initial disadvantage, survive a transient polymorphism, and win the aposematic competition with alternative warning signals. It is therefore no surprise that most distasteful Müllerian mimics are indeed monomorphic in local populations (Fig. 3) and that polymorphisms are usually restricted to narrow hybrid zones between color-pattern races. In *H. erato*, in which two color races abut, frequency-dependent selection maintains a sharp boundary, alternative forms being positively reinforced on either side of a steep cline. Many species join Müllerian mimicry rings, which itself represents interspecific evidence for strong frequency-dependent selection.

However, in contrast with such extremely conservative forces, diversity is present at all levels in mimicry (Fig. 3). At a macroevolutionary level, aposematic and mimetic groups typically undergo rapid mimetic radiations into numerous species and races differing in color pattern, like heliconiine butterflies or pyrrhocorid red bugs. At the community level, many radically different mimicry rings coexist in the same habitat (e.g., five or six coexisting rings just within the *Heliconius* of Costa Rica, at least seven or eight rings just within the Ithomiinae of the Peruvian Amazon—Fig. 3). At the biogeographical level, many aposematic species show a bewildering diversification in more or less sharply defined mimetic races. Finally, at the population level, several chemically defended species show mimetic polymorphism. For instance, the bumble bee *Bombus rufocinctus* has two mimetic forms in North America, the burnet moth *Zygaena ephialtes* has two sympatric forms in Italy, the African monarch *D. chrysippus* has four main color forms coexisting in large areas in East Africa, and the Amazonian *H. numata* shows the most astounding polymorphic mimicry with up to 7–10 forms in the Andean foothills. In each of these cases, the different forms closely match the different local mimicry rings (Fig. 4).

**FIGURE 4** Polymorphic Müllerian mimicry. The Amazonian butterfly *H. numata* (Nymphalidae: Heliconiinae—right column) is a Müllerian mimic in a variety of tiger-pattern mimicry rings. Each population (here around the city of Tarapoto in Eastern Peru) is polymorphic and up to seven forms may coexist, each being an exceptionally accurate mimic of species in the genus *Melinaea* (Nymphalidae: Ithomiinae—left column). Spatial variation in selection pressure is probably what maintains the polymorphism, by a balance between local selection for mimicry of the commonest *Melinaea* species and movement of individuals (gene flow) between neighboring localities selected for different wing patterns. From top to bottom (left column): *Melinaea ludovica ludovica*, *Mel. sat-evis cydon*, *Mel. maraes mothis*, *Mel. maraes phasiana*, *Mel. menophilus ssp. nov.*, *Mel. menophilus hicetas*, and *Mel. maraes mothis*. (Right column) *H. numata* forms *silvana*, *elegans*, *aurora*, *arcuella*, *tarapotensis*, *timaeus*, and *bicoloratus*. Scale bar, 2 cm.
This rampant diversity does not question the existence of frequency dependence itself, but the details of how purifying selection may or may not prevent the evolution of diversity. It may also question the validity of the two classical categories of protective mimicry (Batesian and Müllerian) and the existence of a sharp divide between them along the spectrum of prey palatability. Explaining these unexpected cases is therefore central to our understanding of signal evolution in distasteful insects.

The Palatability Spectrum and Predator Psychology

MODELS OF MIMICRY EVOLUTION Case studies and experiments on mimicry are practically difficult, time consuming, and inform us only on potential processes in particular cases. They are thus not always very informative as to which processes are generally important in the evolution of mimetic diversity. For these reasons, mathematical models simulating mimicry evolution have been widely used. Models of mimicry evolution have been traditionally of two different types: "evolutionary dynamics" models have concentrated on trait evolution in the prey populations, underestimating the effects of the details of predator behavior; "receiver psychology" models have concentrated on the effect of predator cognitive abilities in driving the costs and benefits to mimetic prey, but largely ignored evolutionary processes in the prey populations, particularly frequency or density dependence. The second category of models are those that apparently pose a threat to the validity of the Batesian/Müllerian distinction, and M. P. Speed even coined the new term "quasi-Batesian mimicry" for the strange, though possibly common, intermediate dynamics that his model highlighted.

The main discrepancies lie in the way predators are thought to respond to prey palatability and density. Speed's models assumed that predators attack a fixed fraction of a prey in a population, irrespective of their total number (linear frequency dependence), and that this fraction depends on the palatability of the species. In a mixture of prey of differing palatability, the resulting fraction killed would be intermediate between the fractions lost in each prey in the absence of mimicry, leading to one prey species benefiting and the other suffering from mimicry. This view, however, leads to the strange prediction that as more mildly unpalatable prey are present, the attacked fraction (per unit time) can increase. In contrast, J. Mallet and M. Joron argued that predators are unlikely to be sensitive to frequency per se and should instead need only to attack a fixed number of prey before learning, making the "attack fraction" a decreasing function of the total number of prey bearing the pattern. This should lead to a strongly nonlinear, effectively hyperbolic frequency dependence. The attacked fraction (per unit time) should always decrease when the total number (and therefore the density) of unpalatable prey increases, whatever be their relative unpalatability.

The debate is still very much active, and decisive data are surprisingly scarce. In an experiment with pastry baits and wild passerines, Speed showed that the attack fraction of a mimetic pair was indeed intermediate between that of either "species" alone. Furthermore, birds seemed to learn only to a certain extent; that is, they never completely stopped attacking the unpalatable items. Despite some potential problems in the experimental design (especially, the artificially high prey density in a time of scarce prey density), these data remain a puzzle and may hint at more complex learning processes than a pure number-dependent dose response. More decisive evidence came from L. Lindström's study, in which novel toxic prey were introduced into a great tit's foraging arena at varying frequencies (=densities in this setting). Although the total number of attacked toxic prey increased with their initial frequency, the attack fraction decreased. Her data support the validity of nonlinear frequency dependence, although the idea of a strictly fixed number of prey killed could be an oversimplification. Absolute numbers of prey attacked may increase with warning signal density, but proportion will inevitably decrease, which should lead to a traditional Batesian–Müllerian distinction. More recently, in an experiment where the total number of signaling prey individuals was allowed to increase with the addition of a mimetic species, thereby approaching more natural conditions for the evolution of mimicry, Speed's group provided long-awaited evidence that mimicry unpalatable prey of varying strength benefited mutually from the mimicry due to an increased density of the signal in the prey population. The mutual benefits may, however, be modulated by the availability of alternative prey to predators in the habitat, as this and theoretical models have suggested. It appears optimal foraging, in which predators tune their discrimination abilities to the availability of prey and their palatability distribution, should be taken into account to understand the interplay between density-dependence and the unpalatability spectrum in the evolution of mimicry.

More intriguing prospects have come from the recent discovery by J. Skelhorn that the benefits of mimicry tend to be enhanced when mimics use different types of chemical defenses for protection. Although the mechanisms underlying this are unknown, the potential consequences for speciation and the community ecology of insect species assemblages may be large if selection facilitates the recruitment of distantly related mimics more easily than close relatives.

THE STRENGTH OF THE SELECTION Müller's number-dependent model also leads to a prediction that has hitherto been largely overlooked. At low densities, selection should act strongly against any transient polymorphism, but at higher densities, selection quickly becomes weak at intermediate form frequencies. This leads to effective neutrality of polymorphism once it is established in abundant species. Kapan's field experiments, in which H. cydno were released at varying density, showed precisely this trend. Polymorphism could therefore be nonadaptive but very weakly selected against by predators.

Numerical Mimicry and Density-Dependent Processes

The studies of J. Allen and his collaborators, and others, show that prey selection by predators can be frequency dependent in palatable, cryptic prey, that is, even in the absence of mimicry of unprofitable prey. This is probably caused, in part, from predators using search images when foraging. For instance, at low densities of a particular kind (palatable) prey, predators usually prey on the more common form, which corresponds to their search image, imposing a negative frequency dependence. Cryptic prey may be globally numerous in a habitat, but because they are camouflaged, their apparent density to predators is bound to be low. This leads to the diversification of cryptic patterns, and perhaps the selection of plastic (partly environmentally induced) color-pattern genetic control, in prey. In contrast, at high density, predators usually prey on the odd phenotypes preferentially, even among perfectly palatable prey, effectively leading to a positive frequency-dependent selection on morphology.

Gregarious palatable prey that are at locally high density and that presumably rely on predator satiation to escape predation, might then be selected for mutual resemblance. Such a prey might be called warningly colored, whereas the appearance itself is not protective. This idea led to the supposition that several prey species that co-occur at unusually high densities, like mud-puddling butterflies or schooling fishes,
might evolve “numerical” or “arithmetic” mimicry by simple frequency-dependent predation unrelated to unprofitability. Prey traits like color, shape, and especially locomotor behavior are therefore thought to be under purifying selection in mixed-species aggregations. This attractive idea remains largely untested in insects, although R. B. Srygley proposed the pair of bright orange butterflies *Dryas julia* (Heliconiinae) and *Marpesia petreus* (Nymphalinae) as a potential candidate.

**Female-Limited Mimicry**

Some of the most spectacular and best studied cases of Batesian polymorphism are found in swallowtails, and in some species only the female is mimetic (see an example in Fig. 5). This peculiar tendency to sex-specific polymorphism seems to be restricted to butterflies (Papilionidae and Pieridae), and virtually no other case of sex-limited mimicry seems to be reported for other insects (except for male-limited mimicry in some moths). Female-limited mimicry was often viewed as a result of negative frequency dependence: if mimicry is restricted to one sex, the effective mimetic population size is only about half that of a nondimorphic species, reducing deleterious effects of parasitism onto the warning signal. But this group-selection argument cannot in itself explain why females tend to become mimetic more often than males and why mechanisms arise that restrict the mimicry to one sex. However, more proximal, individual-selection arguments are not lacking. First, mimicry may be more beneficial to one sex than to the other. For instance, female butterflies have a less agile flight because of egg load and a more “predictable” flight when searching oviposition sites, and they suffer higher rates of attacks by visual predators. Second, male wing patterns can be constrained by sexual selection, via either female choice or male-male interactions; males could not evolve Batesian mimicry without losing mating opportunities. In experiments with North American swallowtails (of which only females mimic *B. philenor*), male *P. glaucus* painted with the mimetic pattern had a lower mating success than normal yellow males; similarly, painted *P. polyxenes* males had a lower success in male-male fights and therefore held lower-quality territories around hilltops. In these insects, the wing coloration appears to bear signals directed either to conspecific males or to predators, which creates a potential conflict leading to sex-limited polymorphism. It is interesting to note that *Papilio* and *Eurytides* species that mimic *Parides* (Papilionidae) in South America do not exhibit female-limited mimicry; different modes of sexual selection (e.g., absence of territoriality) may operate in the forest understory habitat. In a different ecological setting, diurnal males of the North American silkmoth *C. promethea* are exposed to visual predators, and mimicry of *B. philenor* is limited to males; female *Callosamia* fly at night and benefit more by crypsis during the day.

**MIMICRY AND THE EVOLUTION OF SIGNAL FORM**

**Resemblance and Homology**

Mimicry can arise as soon as the signal is effectively copied, that is, as soon as superficial resemblance is attained. Therefore, mimics usually bear characters similar to those of their models, but these are often clearly nonhomologous in terms of genes and mechanisms of development. For instance, red spots near the base of the wing in *P. memnon* mimic the spots on the bodies of their models. The translucency and iridescence of distasteful Ithomiinae clearing butterflies is mimicked by white raylets in dioprine and pyralid day-flying moths and provide the same impression in motion. Similarly, the black-wing patterning of some flies seems to mimic the superposition of wings over the abdomen in their wasp models. Therefore, mimics from distant phylogenetic groups are certainly under very different functional and developmental constraints to create a mimetic impression. Selection will retain the first characters that suddenly increase overall similarity. The initial step made may therefore strongly influence the route selected to achieve mimicry.

**The Genetics of Mimicry: Polymorphisms and Supergene Evolution**

**THE DEBATE** The genetical study of the evolution of mimicry was first dominated by a debate between gradualists (Fisher) and mutationists (Goldschmidt). Goldschmidt proposed that “systemic” mutations could affect the whole wing pattern of butterflies in one step and that models and mimics, although not using the same genes, were using at least the same developmental pathways. Because this view could not account for the obvious nonhomologies, like those pointed out above, Fisher and others claimed that mimicry was achieved by slow microevolutionary steps and the gradual accumulation of resemblance alleles.

Decisive steps toward a resolution of the debate came principally from the study, by C. Clarke and P. Sheppard in the 1960s, of Batesian butterfly mimics in which color pattern is easy to define and analyze and gene effects are straightforward to identify. Polymorphic mimics, particularly *Papilio* species, of which different forms could be crossed by breeding experiments (including hand pairing), were particularly useful. It appeared that color pattern is mainly inherited at one or few major loci, affecting the whole pattern. From rare

**FIGURE 5** Female-limited mimicry in *Perrhybris pyrrha* (Pieridae), Eastern Peru. The female (top) is a Batesian mimic of the tiger-patterned Ithomiines and Heliconines (see Fig. 3), while the male (bottom) has retained a typical pierid white coloration. Scale bar, 2 cm.
recombinants, it could be shown that these loci were in fact supergenes, that is, arrays of tightly linked small-effect genes. Several additional unlinked “modifier” loci were also shown to increase resemblance via interaction and epistasis with the supergene. Goldschmidt’s ideas seemed refuted.

However, although supergenes seem to be a necessary condition for the evolution of polymorphism (otherwise numerous nonmimetic, unift recombinants would be produced), how they evolve is another issue. Theoretical models suggested that supergenes could not be achieved by simple gradual reduction in recombination. In the absence of spatial variation in selection pressures, tighter linkage cannot evolve by small steps via Fisherian gradual evolution, because good combinations of alleles are immediately broken up by recombination. Instead, gene clusters should preexist the evolution of polymorphism.

**THE TWO-STEP HYPOTHESIS** These results led to a unifying, now widely accepted two-step mechanism of mimicry evolution: (1) mutations at genes of major effect first allow a phenotypic leap achieving an approximate resemblance to a particular model. (2) Once these mutations have increased in the population, resemblance can be enhanced through the gradual selection of epistatic modifiers. This two-step mechanism is supported by three lines of evidence. First, empirical evidence from butterflies suggests the existence of a small number of major-effect genes and numerous small-effect modifiers. In fact some of these genes of major effect could even include a series of regulatory upstream elements and transcription factors, now known to be involved in the development of butterfly color patterns. Pigment pathway genes and scale maturation regulators can also have very dramatic effects on the color patterns. Second, population genetics and dynamics models support the prediction that a major phenotypic jump is necessary to cross the deep fitness valleys in a rugged fitness landscape, after which gradual, Fisherian evolution may proceed to enhance resemblance. Finally, experiments show that birds associate cryptic patterns with edibility and generalize those in such a way that only profoundly deviant prey are treated as separate cases by the birds and memorized as warning patterns when appropriate. These experiments also indicate that increased resemblance is still significantly advantageous in imperfect mimics, supporting the second step of the two-step scenario.

**LARGESSE OF THE GENOME** Another, but not exclusive, route to supergenes for mimicry is called largesse of the genome, put forward by J. R. G. Turner. Under this scenario, it is believed that the modification of a trait can be achieved by so many different genes that some of them will inevitably happen to be linked. Among the many possible combinations of loci, selection could simply sieve out the ones that involve linked genes. This hypothesis is particularly likely for loss-of-function phenotypes that can be achieved by mutating any step in the development, like the loss of tail in the African swallowtail *P. dardanus*. Similarly, that different mimetic species use nonhomologous supergenes can be viewed as indirect evidence for the validity of the largesse of the genome hypothesis in the broad sense.

**SUPERGENES IN MÜLLERIAN IMICS: A PUZZLE** Mullerian mimics being usually polymorphic locally, supergenes are not expected to control wing patterns, and multilocus control was hypothesized to be the norm. This basic prediction has, however, constantly been challenged by *Heliconius* color-pattern genetics, which show that a limited set of genes of large effect and supergenes control most of the racial color-pattern variation. In the polymorphic *H. numata*, one single gene seems to control the entire wing pattern, with as many as seven alleles, each allele bringing resemblance to a specific mimetic pattern (Fig. 4). Tight gene clusters are also found, to a lesser extent, in polymorphic *H. cydno*, in *H. melpomene*, and in *H. erato*. The existence of these supergenes seems puzzling. It is possible that butterfly color patterns in general are under the control of relatively few conserved genes, at least in some lineages, such as developmental regulatory genes involved in eyespot formation.

In toxic prey, strong selection against any new form and the impossibility of gradual color-pattern changes have been theoretically and empirically demonstrated. It follows that, like Batesian mimics, Müllerian mimics seem to need an initial phenotypic leap, perhaps involving multimodal signal modifications, to jump either to an already protected pattern or away from predators’ generalization of cryptic prey. Therefore, it is perhaps no surprise that most exaggerated signal forms studied are under the control of relatively few genes, following the same two-step scenario as in Batesian mimicry. Moreover, switches from one mimetic pattern to another are likely selected only if the new mutant’s mimetic characters are not randomly recombined in its descendants. This imposes another constraint (or “sievel”) on the genetic architecture for new mimetic patterns to be selected out of a transiently polymorphic population. It is therefore remarkable to note that although Batesian and Müllerian evolutionary dynamics are radically different, and are even perhaps engaged in an evolutionary arms race, the evolution of their signals might require a similar (though nonhomologous) genetic predisposition.

Recent comparative mapping, by M. Joron and colleagues, of the genetic architectures in *H. numata* and *H. melpomene* has uncovered a remarkable level of positional genetic homology between those species for the major loci controlling mimicry, despite the fact that *H. numata* and *H. melpomene* cover very different mimetic patterns, and are involved in totally disjunct mimicry rings (see Fig. 4). This suggests that the few genes involved are remarkably flexible in the array of possible phenotypes and that selection for ecological adaptation, as opposed to genetic constraints, is the chief determinant of mimicry diversity.

**Myrmecomorphy**

Ants represent the most abundant group of organisms in most biota and have powerful multimodal defenses such as acid taste, aggressive biting, painful sting, and social defense. For these reasons, foraging ants are generally little subject to predation and act as ideal models in mimicry rings. Many insects and spiders indeed have an altered morphology and resemble ants, a phenomenon called myrmecomorphy. For instance, several salticid spider genera such as *Myrmarachne* or *Synemosyna* are bewilderingly good ant mimics. It is also common to spot ant-like mirid nymphs (Heteroptera) running among leafcutting *Atta* ants or *Eciton morpha* staphlinid beetles among *Eciton* army ant columns. The adaptive significance of ant-like morphology has been the subject of considerable debate. For instance, several ant-like spiders are believed to mimic ants as a trick to approach and prey on their ant models (“aggressive mimicry”); some ant-like bugs use the same trick to approach and prey on ant-attended aphids. However, most ant-like insects are phytophagous, do not prey on foraging ants, and usually mimic the locally abundant ant species. They are therefore good Batesian mimicry candidates. The interesting aspect of ant mimicry is that, although small birds, lizards, or amphibians may be important predators on ant-sized insects, there are grounds to think that arthropod predators with developed visual skills could be the prime receivers selecting for ant mimicry. For instance, wasps in the Pompilidae are known as important predators of jumping spiders, but ignore ants, thus potentially selecting for ant-like morphology and behavior. Jumping spiders themselves are
visual predators hunting insects and also tend to avoid stinging ants as prey. Although the cognitive abilities of arthropods are not well researched, several studies using mantids, assassin bugs Sinea sp., or crab spiders show that they are capable of associative learning and discriminate against ant-like prey. Despite the difference in visual acuity and cognitive abilities between vertebrates and arthropods, it is interesting to note that arthropod predators are likely responsible for visual mimicry that is very accurate to our eyes.

The Importance of Behavior and Motion

Myrmecomorphy highlights a crucial aspect of mimicry: the importance of behavior. Predators integrate many aspects of prey appearance when making a decision of whether to attack, and behavior is an important part of multimodal signals. Ants are characterized by jerky (e.g., Pseudomyrmex spp.) or zigzag (e.g., Crematogaster spp.) movements that their mimics adopt. The rapid movement of antennae is a common feature of ant behavior which mimetic species copy by waving their front legs (e.g., ant-mimicking Salticidae spiders, and spider-wasp-mimicking leaf-footed bugs Coreidae). Because motion considerably enhances visibility, it is hardly surprising that details of the behavior make important identification cues for the predators. For instance, although slow flight in aposomatic butterflies may save energy, slowness itself is certainly recognized as such by predators that can select on extremely minute details of flight unnoticeable to the human eye. R. B. Srygley’s work on locomotor mimicry has shown that the two butterflies H. erato and H. sapho differ in the asymmetry of the upward and downward wing strokes, which their respective (Mullerian) mimics H. melpomene and H. cydno copy accurately in Panama. Batesian mimics usually retain escape behaviors characteristic of their groups; the lazily flying Neotropical butterfly Consul fabius (Nymphalidae: Charaxinae) (see Fig. 3) can start rapid escape flight when detected; ant-mimicking salticid spiders are also usually reluctant to jump unless attacked.

The tendency for predators to generalize the characteristics of palatable prey, on which they actually feed, probably selects aposomatic signals away from these morphologies, and behavioral signals are no exception. Rapid jerky flight is usually characteristic of a tasty prey, a profit that predators have to weigh against the time and energy costs associated with catching the prey. Unconventional behaviors like the flight of Heliconius butterflies or the looping of honey bees make them highly noticeable to predators. This imposes an additional visibility cost on incipient mimic prey; for the resemblance to be selected, such cost has to be offset by a significant reduction in predation. These considerations suggest that mimetic behavioral change probably evolves in much the same way as morphological characters do, that is, a two-step process.

Escape Mimicry

Unpalatability is not the only way to be unprofitable to predators. Fast, efficient escape is another way for prey to teach predators that pursuit is useless and will bring no reward: predators unable to consume the desired prey may associate this frustration with the prey appearance and reduce their attacks on this prey altogether. Even if the prey can be seized, predators probably trade off the energy spent and the (often low) nutritional reward. In several experiments birds were shown to be able to decrease their attack rates when the presented prey would quickly disappear (“escape”) during their attacks, and conspicuousness of the prey tended to enhance the response. Therefore, evasive prey could advertise their escaping abilities by color patterns, which other prey may mimic. At least three kinds of characters may enhance the difficulty of catching an evasive prey: erratic flight (like that of pierids), and maneuverable flight (like that of charaxine butterflies), or high reactivity (like that of syrphid hoverflies). Typically, these escape specialists are all palatable to predators. Some species of the Neotropical butterfly genera Adelpha (subfamily Nymphalinae) and Doxocopa (subfamily Charaxinae) show convergent appearance and exhibit extremely quick escape when slightly disturbed, followed by very fast flight. Their resemblance is hypothesized by R. B. Srygley to be a case of escape mimicry. The poor resemblance of some hoverflies to their purported hymenopteran models has also led to the hypothesis that groups of syrphid species could represent an escape mimicry ring on their own.

Poor Mimicry

At least to our eyes, the model’s color pattern is not always copied very accurately. Many syrphid flies, for instance, are difficult to assign to particular mimicry rings, although they seem to mimic the general appearance of Hymenoptera. The heterogeneity in mimetic accuracy has led biologists to propose adaptive and nonadaptive hypotheses, none of which seems very strongly supported at present. (1) The null hypothesis is that poor mimics are no mimics: many mimicry associations have been claimed on the general appearance of an insect, whereas careful examination of the geographic covariation of purported models and mimics may reveal evidence against them. In the case of inaccurate mimics, this method is not very powerful because the mimetic association itself is hard to define; so such covariation is difficult if not impossible to judge. (2) Another nonadaptive scenario is that accurate mimicry may not always be possible, either because of functional constraints/trade-offs on the modified organs or because of genetic or developmental constraints on the variation available in populations. Mimicry may then asymptotically reach a maximum level of resemblance, contingent on the route followed in the initial stages of the mimetic change. Again, this is theoretically plausible, but difficult to test. (3) Among the adaptive explanations for inaccurate mimicry is the hypothesis that these species are in the initial stages of their mimetic change and that their instantaneous view of evolution doesn’t show us the complete picture. (4) Another adaptive scenario is that predators have biases and perceptions different from those of humans and are likely to generalize more in some directions than in others, leading to the possibility that mimics that look very inaccurate to us are in fact very good mimics for a predator. Generalization is also dependent on the strength of the harmfulness of the models, perhaps allowing lower levels of accuracy. This may be the case for poor mimicry in some hoverflies. The ultimate adaptationist hypothesis is that inaccuracy itself may be beneficial. (5) It could either allow the mimic to benefit from the protection of several different models, perhaps in a heterogeneous environmental context, or—a related hypothesis—create conflict in the predators’ recognition, which may give the mimic more time and chances to escape.

MIMICRY, COMMUNITY ECOLOGY, AND MACROEVOLUTIONARY PATTERNS

Habitat Heterogeneity, Spatial Dynamics, and the Coexistence of Mimicry Rings

The efficiency of a warning pattern depends on the abundance of that pattern in the habitat. Therefore, as new species join a particular mimicry ring, the protection given by the pattern increases, and more species should converge on this best protected pattern.
Ultimately, all species should converge on a single mimicry ring. But nature seems to behave in a totally different way. In any one habitat, particularly in tropical environments, aposematic insects of similar size and shape usually cluster into a number of distinct mimicry complexes or mimicry rings.

**MULTIPLE MIMICRY RINGS IN THE COMMUNITY**

One possibility is that different mimicry rings are found in different microhabitats. If predators do not move between microhabitats, or retain microhabitat-specific information, insect species in different microhabitats could converge on different adaptive peaks. Flight height has been invoked as a possible explanation, following the rainforest stratification paradigm, but evidence from butterflies is rather equivocal. However, host-plant stratification and different nocturnal roosting heights in Neotropical butterflies have received empirical support. Forest maturity and succession stage influence the host-plant composition and may allow the maintenance of multiple mimicry rings in a mosaic habitat.

**MULTIPLE MIMICRY RINGS WITHIN A SPECIES**

If some species are patchily distributed because of their microhabitat requirements, each “subpopulation” may be particularly sensitive to genetic drift and allow the local predators to learn and select a different color pattern in different patches. Once locally stabilized, the new pattern may be hard to remove. Indeed, local positive frequency dependence is both very efficient at stabilizing patterns around fitness peaks and slow at removing already established suboptimal patterns. Any slight difference in microhabitat quality or patchiness of the species involved will increase the local apparent abundance of particular patterns to particular predators, further decreasing the power of selection to achieve ultimate convergence.

This “mosaic mimetic environment” theory can help explain some problematic cases of Müllerian polymorphism. For instance, *Laparus doris* is a Heliconine butterfly (Nymphalidae) that has up to four coexisting forms in some populations, some of which are probably mimetic and others are not. The maintenance of polymorphism in this species could be attributed to its larval and pupal gregariousness (several hundreds of individuals), which results in a patchy distribution of the adults. When hundreds of butterflies suddenly emerge from one single vine, they make up their own local mimetic environment, and the mimetic environment prior to the mass emergence might be effectively neutral to *L. doris*.

If the species composition and the resulting mimetic environment are spatially variable, polymorphism can evolve in microhabitat generalists, with gene flow across these microhabitats. For example, the Amazonian polymorphic species *H. numata* is selected toward different mimetic patterns in different localities that may represent different microhabitats for their more specialized models in the genus *Mellinaea* (subfamily Ithomiinae) (Fig. 4). The balance between local selection and gene flow in a mosaic habitat (and perhaps weak selection against polymorphism as suggested earlier) can therefore maintain a nonadaptive, although widespread, polymorphism in *H. numata*.

**Coevolution in Mimicry**

**EVOLUTIONARY RATES AND THE COEVOLUTIONARY CHASE**

Despite many potential sieves constraining mimicry, several to many edible species can end up mimicking a particular warning pattern in a parasitic way. In such cases, is it possible that a “Batesian-overload” threshold is reached, beyond which the efficiency of the signal is severely lowered? Batesian mimics are indeed parasites of the honest signals of their models, and so the models should escape their mimics by evolving a new warning pattern. However, this escape would be transient because the new pattern would soon attract new Batesian mimics, resulting in an evolutionary arms race, or coevolutionary chase, between the model and its mimics. Some authors suggested that this chase could be a cause of the mimetic diversity in both models and mimics and that cyclical interactions could arise in some cases. However, first, theory has shown that mimics always evolve faster than their models, because they gain a lot more from mimicry than models lose from being mimicked. Any gradual move of the model should be quickly matched by a similar evolution in the mimic. Second, the models, which are the prime educators of local predators, are under strong purifying selection against any new warning pattern. This strong intraspecific conservative force should in the vast majority of cases be stronger than the deleterious effects of being mimicked and preclude pattern change in the models. Coevolutionary changes between Batesian mimics and their models should therefore be stopped in their early stages by a stronger selection for the status quo, and both the models and their mimics should be trapped in the same warning pattern. Only by a phenotypic leap toward an already established warning pattern (Müllerian mimicry) or by crossing a fitness valley thanks to local genetic drift could the model ever escape its mimics.

**MUTUALISM AND COEVOLUTION IN MÜLLERIAN MIMICRY**

In contrast with the unilateral Batesian evolution in which mimics outrun their models, Müllerian mimicry was traditionally thought to involve mutual resemblance of the species involved, as if all had moved toward some halfway phenotype. Of course, Müller himself and others were quick to point out that the mutual benefits were not even, but lopsided, that is, typically the rarer or the less distasteful species would benefit more than the more common or better defended one (respectively). However mutualistic the relation is, coevolution has often been assumed in Müllerian associations, and the protagonists are usually called comimics just because it is difficult to know if one species is driving the association. Coevolution also predicts that geographic divergence and pattern changes should be parallel in both species of comimics, like in the mimetic pair *H. erato* and *H. melpomene* in tropical America, presumably leading to parallel phylogenies. However, DNA sequences from mitochondrial and nuclear genes show distinct phylogenetic topologies in these two species and distinctly nonparallel evolution.

In fact, there are a number of grounds on which to believe that the asymmetrical relationship leads to one-sided signal evolution even in Müllerian mimicry, one species being a mimic and the other a model. First, because of number dependence, mimetic change of a rarer species toward a commoner species will be retained, but the reverse is not true: by mimicry of a less common species, the commoner species would lose the protection of its own ancestral pattern, and a change toward a rarer pattern would be initially disadvantageous. The commoner species is therefore effectively locked in its pattern, and initial changes are only likely in the rarer species. Second, given the selection against nonmimetic intermediates, the mutants in the rarer species will have to be roughly mimetic of their new model to be selected, thus bringing the ultimate shared signal closer to that of the common species. Once this initial step is made by the mimic, there could be gradual “coevolution” to refine the resemblance, but the resulting change in color pattern will inevitably be more pronounced in the mimic, the model remaining more or less unchanged. Because Müllerian pairs are of a mimic-model nature, even with mutual benefits, the prediction for parallel evolution is
therefore not likely to be valid. Indeed, in the mimetic pair H. erato/ H. melpomene, the phylogeography suggests that H. melpomene has radiated onto preexisting H. erato color-pattern races, thus colonizing all color-pattern niches protected by H. erato in South America.

Mimicry, Speciation, and Radiations

Racial boundaries in mimetic butterflies are usually very permeable to genetic exchange, since selection acts primarily on color-pattern genes. However, because clines moving geographically are likely stopped at ecological boundaries, the resulting racial boundaries are likely to rest on ecological gradients. Racial boundaries between mimetic color patterns could therefore be reinforced by adaptation to local ecology on either side of the cline, leading to speciation. Color-pattern diversification could then accelerate speciation by allowing both postmating reproductive isolation, because of a higher mortality of nonmimetic hybrid offspring, and premating isolation if color pattern itself is used as a mating cue by the insect. For these reasons, mimicry has the potential to accelerate speciation. The pattern of mimetic associations in Heliconius butterflies seems indeed to indicate that speciation and mimetic switches are usually coincident: sister species usually differ in their mimetic color pattern. Direct evidence of the role of color pattern in mate choice has been gathered for the sister species pairs H. erato/H. himera and H. melpomene/H. cydno. The first two species are geographically separated across an ecological gradient in the Andes. The second pair is sympatric, although the species also differ in ecological requirements in a patchy distribution. In both pairs, therefore, color-pattern and mimetic switches probably accelerated speciation initiated by ecological adaptation. It is unknown how general this mimicry-based speciation is in mimetic insects but it could be an important consequence of the rampant and apparently easy diversification of mimetic patterns at the intraspecific level. The genetic predisposition of mimetic species to evolve polymorphism—the first stage toward speciation—might explain why mimetic lineages are usually very speciose and undergo rapid radiations, both geographically and phylogenetically.

Mites

Barry M. O’Connor

University of Michigan

Mites comprise the Acari, which are the largest group within the arthropod class Arachnida, with over 48,000 described species. This number is misleading because it is estimated that only between 5% and 10% of all mite species have been formally described. In contrast with other arachnid groups such as spiders and scorpions, mites are distinctive in both their small size (adult body length ranging from 0.1 to 30 mm) and their ecological diversity. Some mites are predators, like almost all other arachnids, but mites may also feed on plants, fungi, or microorganisms or as parasites on or in the bodies of other animals. Mites are among the oldest known groups of arthropods, with a fossil record beginning in the Devonian period.

BODY STRUCTURE

Unlike insects, with bodies divided into head, thorax, and abdomen, the arachnid body is anestrally divided into two functional units, the prosoma (the first six body segments) and the opisthosoma (the remaining segments). The body of a mite is further modified in that these original units are fused. A secondary subdivision separates the first two body segments into a structure termed the gnathosoma, specialized for feeding, and the remainder of the body, termed the idiosoma, containing organs of locomotion, digestion, and reproduction. Most mites show no evidence of external body segmentation, other than the serial appendages. The gnathosoma bears the first two pairs of appendages, the chelicerae, which may retain the ancestral chela, or pincer-like form, or may be highly modified as stylets for piercing and sucking the pedipalps, which may be almost leglike, are strongly modified for grasping prey or attaching to a host or highly reduced. The anterior idiosoma typically bears four pairs of walking legs, the first pair of which may be modified as antenna-like, sensory structures. Legs may also be modified for attaching to a host.
Occasionally legs of males are modified for grasping a female during mating or for intraspecific combat. The mite's body cuticle may be entirely soft, divided into a number of hard, sclerotized plates, or almost entirely sclerotized. In a few mites, crystalline, mineral salts also strengthen the cuticle. Such modifications balance the needs for flexibility in movement and protection from predators. The body surface bears setae, typically hair-like sensory organs, arranged in characteristic patterns in different subgroups of mites. Setae are primarily hair-like, but may take on an incredible variety of shapes, from thick spines, to flat plates, to highly branched, feather-like forms. The pedipalps and legs also bear tactile setae as well as chemosensory structures termed solenidia, which are organs of smell and taste, and other specialized sensilla that are sensitive to infrared radiation. Simple eyes, or ocelli, may be present on the anterior idiosoma, and specialized sensory organs, the trichobothria, on the anterior idiosoma or legs may detect vibrations or electric fields.

Like other arthropods, the inside of a mite's body is a hollow cavity, the hemocoel, in which the internal organs are surrounded by fluid, the hemolymph. Hemolymph distributes food materials and waste products and contains hemocytes, which are the cells that serve as the mite's immune system, but it does not contain oxygen-binding proteins as are found in the blood of vertebrates and some other arthropods. The mite's digestive system is divided into three parts typical of arthropods: foregut, midgut, and hindgut. The midgut may be divided into diverticulae for food storage, particularly in parasitic mites. Some mites lack a connection between the midgut and the hindgut; these mites feed only on fluids and do not defecate. The hindgut in these mites is transformed into an excretory organ for elimination of nitrogenous wastes. Other mites, with entire guts, may have Malpighian tubules, like insects, extending from the junction of the midgut and hindgut as excretory organs. The internal reproductive system typically consists of a single ovary (paired in the Astigmata) in the female and paired testes in the male. Females typically possess a spermatheca for sperm storage after insemination, and both sexes have various accessory glands and ducts to the exterior as part of the system. Tracheal systems for respiration have evolved independently a number of times in the Acari. These open at spiracles, or stigmata, on various parts of the body in different groups. Other mites lack any respiratory system, and gas exchange occurs through the cuticle in these groups.

CLASSIFICATION OF MITES

The classifications of mites used by various authors vary considerably in the number of higher categories recognized and the hierarchical ranking of the various groups. The simplest system, used by Walter and Proctor (1999), recognizes three orders within Acari: Opilioacariformes, Parasitiformes, and Acariformes. The Opilioacariformes, comprising a single family with about 20 species, is considered the most primitive. These mites are relatively large (2–3 mm) and resemble small spiders in their general form, having a leathery cuticle that retains traces of external segmentation. These mites resemble the Parasitiformes in having a tracheal system opening laterally on the body, but they have four pairs of stigmatic openings in contrast to the single opening of the Parasitiformes. Opilioacarids resemble some Acariformes in feeding on solid food particles and bearing a pair of nutella, which are sclerotized food-processing structures located near the ventral apex of the gnathosoma.

The order Parasitiformes is a diverse group comprising 76 families divided among three suborders: Gamasida (or Mesostigmata), Ixodida, and Holothyridia. Compared with the Acariformes, this order is morphologically relatively conservative, with most species retaining the same basic body plan. The Holothyridia includes 3 families and around 30 species of heavily sclerotized, predatory or scavenging mites of tropical regions. The Ixodida, or ticks, includes 3 families and around 850 species exclusively parasitic on vertebrate hosts. The vast majority of parasitiform mites are included in the Gamasida, with 70 families. Most gamasid mites retain the ancestral predatory lifestyle, but the group includes a number of parasites of vertebrates and other arthropods, a few mites which feed on pollen or fungi, and one small group of detritivores capable of feeding on solid food particles.

The order Acariformes is the largest and most diverse group of mites, in terms of both its morphology and its ecological diversity. Hundreds of families are recognized, and over 30,000 species are included. Acariform mites are characterized by the internalization of the basal leg segment, the coxa, leaving the next segment, the trochanter, as the first functional leg segment. Most acariform mites also possess structures termed genital papillae. While associated with the genital region in the postlarval instars, these structures are actually osmoregulatory organs.

The order Acariformes is conveniently divided into two suborders, Trombidiformes (largely equivalent to the Prostigmata of some authors) and Sarcoptiformes (including the Oribatida and Astigmata of some authors). Most trombidiform mites have tracheal systems opening on or near the gnathosoma. Many have strongly modified chelicerae adapted for piercing animal prey, plant tissue, or the skin of a host animal. Sarcoptiform mites ancestrally feed on solid food and have gnathosomal nutella, like the Opilioacariformes. Tracheal systems opening at the leg bases or anterior dorsal idiosoma have evolved independently several times in this group. Sarcoptiform mites are most diverse in soil habitats, but many have adapted to patchy habitats and have developed commensal or parasitic associations with vertebrates and other arthropods (Fig. 1).

Walter and C. Meacham.) (D) Heteromorphic deutonymphs, phoretic on a predatory mite. (Photograph by D. E. Walter.)

LIFE CYCLES, DEVELOPMENT, AND REPRODUCTION

Most mites exhibit a fixed developmental pattern, passing through the same number of instars regardless of how much food is available. The most complete pattern consists of egg, prelarva, larva, ...
protonymph, deutonymph, tritonymph, and adult. The prelarva and larva are distinguished by having only three pairs of legs; the fourth pair is added at the protonymphal molt. Other immature stages are distinguished from each other by a characteristic pattern of additions of leg and body setae. The prelarva is typically a short-lived stage, either passed completely within the egg or, if it actually hatches, having a highly regressive morphology. The few active prelarvae known do not feed and typically begin the molt to the larval stage within hours after hatching from the egg. This life cycle is found in the Opilioacariformes and ancestrally in the Acariformes. Reductions from this number of instars appear in other groups of mites. Within the Parasitiformes, the prelarva is not observed, and the tritonymph is retained only in some Holothyrida. In one family of Ixodida, the Argasidae, the number of nymphal instars is not fixed. Molts take place after each blood meal in these ticks, but the adult morphology develops only when the mite reaches a minimum body size. In many trombidiform mites, the last nymphal instar is suppressed, and in some extreme cases, all immature stages are suppressed and passed within the body of the female mite. After an extreme form of engorgement termed phypsygastru on fungal food or host-insect hemolymph, these females give birth to fully developed adults.

Another developmental pattern observed in the large trombidiform subgroup, the Parasitengona, involves alternation of active and inactive instars. Active stages in this life cycle include the larva, deutonymph, and adult, while the prelarva, protonymph, and tritonymph are morphologically regressive, inactive stages.

Mites exhibit a variety of reproductive strategies and modes of sperm transfer. Ancestrally, mites appear to practice indirect sperm transfer, with males producing and depositing a package of sperm, termed a spermatophore, on the substrate. Females then take the spermatophores into their reproductive tract. This type of reproduction is found in most acariform subgroups, and individuals of the two sexes may or may not be in close contact at the moment of insemination. In known parasitiform groups, males typically use their chelicerae to assist in directly inserting a spermatophore into the female’s primary genital opening (as in Ixodida and primitive Gamasida), or the male chelicerae bear an organ termed the spermatodactyl which is used to transfer sperm from the male’s genital opening into secondarily developed sperm induction pores near the bases of the female’s legs. These paired openings lead to a median spermatheca which is connected directly to the ovary, where fertilization takes place. Direct insemination involving the development of an intromittent organ, the aedeagus in the male, has appeared independently in several groups of acariform mites. Secondary sexual dimorphism typically accompanies direct mating, with males often having modified appendages for holding the female during mating. Many such males also practice precopulatory guarding of immature females, either merely waiting near a juvenile female about to molt or actually attaching to her. This last behavior is taken to an extreme in the sarcoptiform family Chiropedicidae, species of which live on the hairs of mammals, in which immature females are legless and unable to move. They must be found upon hatching by an adult male who uses an elaborate clasping organ to attach to, and carry about, the juvenile female until her legs appear at adult eclosion.

Sex determination mechanisms and reproductive modes also vary widely throughout the Acari. Some mites are diploid in both sexes, with males having either a Y chromosome or no sex chromosome. Other mites are arrhenotokous, in that females are diploid and males haploid. Such males develop from unfertilized eggs. An unusual reproductive mode, termed parahaploidy, is found in some Gamasida. In these mites, fertilization is necessary for egg development, but in males, the paternal genome is inactivated shortly after the first embryonic cell divisions, and adult males are functionally haploid. Finally, thelytoky, or all-female parthenogenesis, is found in many groups of mites. Such mites reproduce clonally, with diploid eggs developing directly into females without fertilization.

**ECOLOGY**

Mites exhibit a breadth of ecological interactions unmatched in any other arthropod group. Mites may be found in all geographic provinces, from tropical rainforests to arctic tundra and rocky outcrops in Antarctica and from desert habitats to the deep ocean trenches. They dominate the microarthropod fauna of the soil where they may be found several meters deep or even in groundwater. They occur in all types of aquatic habitats, including freshwater lakes, streams, seepage areas, and even hot springs. Unlike insects, mites are also quite diverse in marine habitats, ranging from the intertidal zone to the deep trenches.

**Soil Mites**

A single square meter of temperate forest soil may contain upward of 250,000 mites, belonging to a hundred different families. In the litter and upper layers of organic soil, mites play many roles in food webs based on decaying plant materials. Gamasid and some trombidiform mites are the dominant predators in such systems, feeding on nematodes, small annelids, collemboles, other mites, and the eggs of insects. These predatory mites have developed several strategies for prey detection and capture, from active, foraging species in the gamsid families Laelapidae and Parasitidae, and the trombidiform families Raphignathidae and Cunaxidae, to more sedentary species in the trombidiform families Caeculidae and Cheyletidae, with palps or forelegs modified as traps for unwary prey. Most soil-inhabiting mites, however, are detritivores or fungivores, feeding directly on decaying organic materials or on fungi or microorganisms growing upon them. The greatest diversity of detritivores belongs to the sarcoptiform subgroups collectively known as orbital mites. These mites are typically slow moving and may take up to 3 years to complete the life cycle. Adults tend to be well sclerotized as a defense against predators, while soft-bodied juveniles may burrow into substrates to avoid predation. Orbital mites are primarily detritivores, feeding directly on particulate organic material. Others preferentially scrape decaying leaves for their microbial or fungal floras. Despite their numbers, compared with earthworms or other larger soil invertebrates, mites actually process a relatively smaller amount of organic material and are thus of less importance in converting biomass to nutrients again available to plants. However, in terms of the cycling of particular nutrients, notably calcium, mites play an essential role. Mites are also extremely important in the dispersal of bacterial and fungal agents of organic decomposition. Mites feeding on such substrates ingest bacteria or spores that can often pass undigested through the mites’ guts. The movement of the mites through the soil, with the associated deposition of fecal pellets containing decomposer propagules, provides a much more efficient dispersal of these organisms than simple physical processes.

Specialized soil types have specialized mite faunas. Dry, sandy, and nutrient-poor soils typically harbor a fauna of primitive acariform mites that show little morphological change from their Devonian fossil ancestors. This entire community may consist of such living fossils, with this type of nutrient-poor soil likely similar to the original terrestrial environment at the time of the first land-colonizing animals. Another highly specialized fauna of mites inhabits the deeper layers of mineral soils. Because there is little organic material that
filters down to these layers, many of the mites feed directly on the sparse microbial flora or are predators on nematodes that are able to extract nutrients from the limited resources. Deep soil mites tend to be quite small and soft-bodied and may be elongated to allow for movement through very tight spaces between mineral soil particles. Most are effectively aquatic because the deep soils are often saturated, with the interstitial spaces filled with water.

**Mites in Patchy Habitats**

Mites living in large, continuous habitats such as the soil and litter layers generally have limited dispersal capability. Being small and lacking wings, mites would seem to be limited to such habitats. However, mites also form major components of the microarthropod communities associated with patchy habitats, which are those separated by distances greater than mites’ ability to walk. Such mite communities occur in habitats such as decaying logs, dung and manure, carrion, fungal fruiting bodies, nests of insects and vertebrates, and other concentrations of organic matter such as treeholes, sap flows, and other specialized habitats associated with plants.

Common in patchy habitats are specialized gamasid mites in the families Parasitidae, Macrochelidae, Laelapidae, Digastridae, and Uropodidae. These species are typically predators on insect eggs and larvae, particularly those of the Diptera that also frequent patchy habitats, and nematodes. Among the Trombidiformes, species in the subgroup called Heterostigmata are largely associated with patchy habitats, feeding primarily on fungi. The most diverse group of mites in patchy habitats is the saccophytophore subgroup Astigmata, which appears to have had its origin in such associations.

All of these groups, and some others as well, are able to exploit these habitats, which are generally unavailable to most mites, through a specialized dispersal mode termed phoresy. Phoresy involves one organism utilizing another, larger organism to facilitate its dispersal. In all of the mentioned groups of mites, one life stage is typically specialized for phoretic dispersal on an insect, myriapod, crustacean, or mammal host. Gamasid mites disperse either as inseminated females or as deutonymphs, which is the final juvenile stage in this group. Female laelapid and macrochelid mites typically attach to insect carriers by grasping host setae or other structures with their chelicerae. Parasitid and digamasellid mites disperse as deutonymphs, often in the space under the elytra of beetles, and may roam freely over the insect’s body. In the Uropodidae, the deutonymph is often specialized for dispersal and may attach to the host by secreting a sticky substance from posterior ventral glands. This material is drawn into a stalk that hardens in air and connects the mite to its host.

Heterostigmatid mites disperse as adult females, with many species exhibiting a polymorphism in this stage. Nondispersing females have normally developed anterior legs and are not attracted to insect or mammal hosts. Dispersing females, or phoretomorphs, have very enlarged forelegs with a grasping claw that allows attachment onto insect setae or other structures with their chelicerae. Parasitid and digamasellid mites disperse as deutonymphs, often in the space under the elytra of beetles, and may roam freely over the insect’s body. These mites wander on the substrate or aquatic vegetation, but many species have morphological adaptations for active swimming. These include anterior displacement of the leg bases for squeezing through the spaces between rock and sand particles, and have mouth parts that can insert into the substrate. Many astigmatid mites inhabit naturally occurring patches of organic material such as decaying wood or mushrooms and disperse on any insects that frequent the habitat. Others have developed closer associations with particular insects, notably nest-building bees, wasps, ants, and termites, and depend on these insects not only for dispersal but also for creation of the habitat in which the mites live. Still other astigmatid mites have adapted to the nests of vertebrates, with many species inhabiting mammal nests specialized for phoretic dispersal on the mammalian host itself. Species living in birds’ nests still disperse on nest-inhabiting insects such as beetles and fleas.

A few of these phoretic associations between mites and insects have become mutualistic, with mites providing either “cleaning services” or “pest control” for their hosts. Some species of Old World carpenter bees may carry several species of mites on their bodies. The astigmatid mites in these communities are kleptoparasites, feeding on the provisions intended for the bee’s offspring. A female bee may also carry trombidiform mites in the genus Cheletophyes (family Cheyletidae) in specialized pouches, termed acarinarium, on the thorax. These mites are obligate predators of the astigmatid mites. The same female bee may also have a large acarinarium in the anterior part of the abdomen, carrying large (2–3 mm) gamasid mites in the genus Dinogamasus (family Laelapidae). These mites have modified chelicerae that scrape the cuticle of the bee larva and remove potentially pathogenic microorganisms and fungal spores as well as cuticular exudates. Some astigmatid mites in the family Histiostomatidae are mutualists in the nests of swim bees (family Halictidae). Feeding stages of the mites have highly modified chelicerae for filter feeding. These mites wander over the nectar and pollen provisions, straining potentially harmful microorganisms. Deutonymphal mites ride in a rudimentary acarinarium on the propodeum or anterior gaster of the female bees.

**Aquatic Mites**

A number of different groups of mites have successfully colonized and diversified in aquatic habitats. The most diverse of these, with over 40 families, and 5000 species, is a group within the trombidiform subgroup Parasitengona that is termed Hydracarina or, more simply, water mites. This lineage is characterized by the enlargement or multiplication of the genital papillae (often termed acetabula in this group), acariform organs of osmoregulation that allow these mites to maintain ionic balance in hypoosmotic freshwater environments. The parasitengone life cycle is unusual, with its alternation of active and inactive stages, and in most terrestrial and aquatic species, the larva is parasitic, typically on an adult, flying insect. This parasitic larva not only acquires nutrients by feeding on its host, but also is able to disperse over some distance while on the host. The deutonymph and adult stages are typically active predators on other arthropods or their eggs. Water mites are primarily inhabitants of freshwater habitats including temporary ponds, permanent ponds and lakes, streams and rivers, and interstitial waters. One family of water mites, the Pontarachnidae, has invaded marine, intertidal waters and has lost the genital papillae, while another, the Thermacaridae, is restricted to hot springs and capable of surviving temperatures close to 50°C. Mites in standing waters may crawl about on the substrate or aquatic vegetation, but many species have morphological adaptations for active swimming. These include anterior displacement of the leg bases and long setae, termed swimming hairs, on the legs. These mites actively seek and capture aquatic crustaceans and small insect larvae. Mites inhabiting running waters are typically smaller, with flattened bodies, robust legs, and often sclerotized plates on the body. These mites crawl on and in the substrate, feeding on the eggs of aquatic insects and other microinvertebrates. Some of these mites are specialized predators of the eggs of the same insect species used as hosts by their larvae. Some stream-inhabiting species live deep in the interstitial waters, often having quite elongate bodies for squeezing through the spaces between rock and sand.
particles. Many water mites are brightly colored, either retaining the red color common among the ancestral, terrestrial Parasitengona or becoming a cryptic blue or green. Some water mites have modified the ancestral parasitengone life cycle by producing fewer, larger eggs. Larvae hatching from these eggs transform to deutonymphs without feeding or dispersing on a host.

Another relatively large group of aquatic mites forms a separate trombidiform lineage, the family Halacaridae. These mites are most diverse in marine habitats, with most species found in intertidal waters. Some halacarids, however, have been collected in abyssal depths up to 7000 m. Feeding ecology of halacarids varies, with some species retaining the ancestral predatory behavior, while others feed on algae or as parasites on crustaceans, echinoderms, or cnidarians. Some halacarids have reinvaded freshwater habitats, presumably via groundwater connections. Such mites are often collected from well water, and a number of species are restricted to freshwater habitats.

Other groups of mites contain aquatic taxa, but none has diversified to the extent seen in the water mites and Halacaridae. Mites in the orbiviratid family Hydrozetidae are often collected on aquatic vegetation, while those in the family Trimalaconothridae occur in the substrates of ponds and streams. The sacorform type group Astigmata includes the family Hyadesiidae, all species of which live in marine, intertidal habitats. These mites are unusual among the Astigmata in living in more or less continuous habitats, and they have lost the dispersing deutonymph from the life cycle. Some species in the family Algoraphagidae live in brackish waters, and one is known from a fast-flowing river. Other Astigmata live in temporary aquatic habitats, such as water-filled treeholes and other phytotelmata, or water-filled plant cavities, such as pitcher plants, bromeliads, the leaf axils of aroids, and the flower bracts of heliconias and related plants. These species still retain the phoretic deutonymph that disperses on an insect host. Relatively few gamasid mites have become aquatic, but some species in the family Ascidae live in phytotelm habitats or regularly flooded swamp or flood-plain soils. Some of these have a modified cuticle around their respiratory openings that functions as a plastron, holding a bubble of air against the spiracle when the mite is submerged.

**Mites on Plants**

Unlike all other arachnid groups, several groups of mites have evolved the ability to feed on living plant tissue. Most species belong to one of several lineages of Trombidiformes, each of which has independently evolved this capability, but all share the modification of the chelicerae into piercing styles. One lineage, the superfamilies Tetranychoidae, contains the spider mites and their relatives. Spider mites (family Tetranychidae) are so named because some species utilize silk in constructing webbing on leaves or pads for oviposition and also for dispersal via ballooning much in the manner of some spiders. Silk production is not unique to this group, however, because it is also found in related trombidiform groups not associated with plants. Tetranychoid mites have elongate cheliceral styles that pierce leaf or root tissue and feed on cell contents or on interstitial fluids. Most species are relatively host specific and do little damage, but some, such as the two-spotted spider mite, *Tetranychus urticae*, are polyphagous and are serious pests of agricultural crops, particularly herbaceous annuals, such as beans, and fruit trees. Another tetranychoid group, the false spider mites, or flat mites (family Tenuipalpidae), also includes serious agricultural pests.

A second lineage of plant-feeding mites, the Eriophyoidea, contains extremely tiny species with a highly modified body form. These elongate, worm-like mites have only two pairs of legs at the anterior end of the body, but possess a sucker at the posterior end and move inchworm fashion over plant surfaces. All are obligate plant feeders, using their short styles to pierce individual cells. Most species are highly host specific, and a single plant species may harbor many species in this group, most of which simply wander over the leaf surfaces. Large populations of such mites may cause loss of color in leaves, leading to the common name rust mites. Another common name, gall mite, refers to the ability of some species to induce characteristic galls on leaves, buds, stems, flowers, or fruits of their host plants. Salivary chemicals mimic certain plant growth hormones and induce the formation of galls in which the mites live. Simple erineum galls form when epidermal cells produce elongate hair-like growths upon which the mites feed. Pouch galls are like erineum but actually form into elongate cavities within which the mites live. Mite-induced proliferation of wooly tissue causes “witches’ brooms” on trees. Although rusting and gall formation are often unsightly and may affect fruit set in orchard crops, the most important effects of eriophyoid mites on agricultural systems are as vectors of viral pathogens such as wheat streak mosaic virus. On the other hand, other, highly host-specific, eriophyoid mites have been used as virus vectors in the biological control of weeds.

Other plant-feeding mites occur in the families Penthleidae, including the redlegged earth mite, *Hilotydeus destructor*, a serious pest of grasses and herbaceous plants in the Southern Hemisphere, and Tarsonomidae. This last family includes such serious agricultural pests as the broad mite, *Polyphagotarsonemus latus*, which, true to its scientific name, is a polyphagous pest of many agricultural crops.

Other mites living on plants are beneficial as predators of phytophagous mites. Chief among these are species in the gamasid family Phytoseiidae. These mites range from generalist to specialist predators, often attacking economically important species of spider mites, flat mites, and eriophyoids. Several species of Phytoseiidae are commercially marketed for biological control of these pests.

**Parasitic Mites**

A great many lineages of mites contain parasites of vertebrate and invertebrate animals, some of which are of importance in human and veterinary medicine. Most important of these is the Ixodida, the ticks, but the Gamasida contains a diversity of parasites of reptiles, birds, mammals, insects, myriapods, and crustaceans, most of which belong to the mite superfamily Dermanyssoidae. Among the vertebrate parasites, several different types of parasitism occur. The simplest of these is facultative parasitism, in which typically nest-inhabiting predators may feed opportunistically from a wound on a bird or small mammal host. Other nest-inhabiting mites are obligate parasites, but get on the host only to feed. Notable among these are the northern fowl mite, *Ornithonyssus sylviarum* (family Macronyssidae), and the chicken mite, *Dermanyssus gallinae* (family Dermanyssidae), both of which parasitize a variety of wild birds and domestic poultry and will bite people. Many of these mites have chelicerae modified for piercing and sucking blood or tissue fluid. Finally, some gamasids have become permanent parasites, spending all their time on the host’s body. These may have enlarged claws or spurs on the body for holding onto the host. Several different groups of dermanyssoid mites have become endoparasites, living in the respiratory tract of snakes, birds, and some mammals, notably dogs and seals. Some species in the family Rhinonyssidae can cause respiratory distress in cage birds. Other endoparasites inhabit the ear canals of ungulates such as cattle and goats. Some parasitic gamasids act as vectors of bacterial, viral, and protozoan pathogens to their normal hosts, but only one, the dermanyssid *Liponyssoides sanguineus*, acts as a vector for a bacterial pathogen from mice to humans, causing the disease known as rickettsialpox.
Other dermanyssoid mites are parasitic on arthropods, with the most important being the honey bee parasite, Varroa destructor (family Laelapidae). This mite is responsible for the worldwide decline in populations of the European honey bee, Apis mellifera. The mites feed on hemolymph of bee larvae, causing the adult bee that develops to have aborted wings that prevent the bee from foraging. Buildup of mites in a bee colony causes its destruction over time. This mite became a pest after colonizing A. mellifera from its ancestral host, the Asian honey bee, A. cerana. In the normal host, this mite is not pathogenic to the colony because populations do not reach damaging levels.

Several groups of trombiculiform mites have become parasitic, the largest of which is the Parasitengona. This group includes the water mites discussed above, but also a number of terrestrial groups. Larvae of most species parasitize insects, in which they may reduce fecundity or longevity. Larvae of one family, the Trombiculidae, or chiggers, parasitize vertebrate hosts. All groups of terrestrial vertebrates may serve as hosts for this very large group of parasites. Most of the over 5000 described species are known only from their parasitic larval stage. Chiggers feed on tissue fluid and lysed host tissue. On most hosts, they appear not to affect the host negatively, but species biting humans induce an immune reaction that not only causes the death of the chigger, but also causes a relatively long-lasting, itchy lesion. Different species of chiggers have achieved “pest” status in various parts of the world. Most are merely irritants to human hosts, but some species in the genus Leptotrombidium, ranging from Japan and Korea, west to Pakistan, and south to northern Australia, act as vectors of a serious bacterial pathogen from rats to humans. The disease, termed scrub typhus or tsutsugamushi disease, can be fatal if untreated. A chigger is able to vector to the pathogen, the bacterium, Orientia tsutsugamushi, despite parasitizing only a single host in its lifetime, because the pathogen remains in the mite’s body and enters the eggs of the female mite. Thus, larval chiggers are capable of transmitting the pathogen at hatching.

Another diverse group of trombiculiform parasites is included in the superfamily Cheyletoidea. Different families in this group parasitize reptiles, birds, and mammals, with the family Demodicidae containing two species specifically parasitic on humans. Demodex folliculorum, an elongate, worm-like mite, inhabits the hair follicles of the face and occasionally other body regions, whereas D. brevis lives in the sebaceous, or sweat, glands in the skin. Although heavy infestations have been linked to acne rosacea, most people harbor these mites with no discernable effect. Other demodics can be more pathogenic in the normal host, such as D. canis in dogs and D. bovis in cattle. The former can cause a mange condition, with hair loss and irritated skin, especially in puppies, while the latter causes large nodules full of mites to form in the skin. Species in other cheyletoid families parasitize birds, living on the skin, in feather follicles, or inside feather quills. One interesting group in the family Cheyletidae lives within feather quills but feeds as predators on other quill-inhabiting mites.

The trombiculiform lineage Heterostigmata includes many parasitic species in the family Hypoderatidae with bird hosts, enter either the hair follicles or the subcutaneous tissue of their host. Despite lacking a mouth and functional gut, these deutonymphs engorge, with some Hypoderatidae increasing their body volume up to 1000-fold. The mode of nutrient acquisition in these parasites is unknown, but some are able to complete the remaining, free-living part of the life cycle in the host’s nest without additional food.

Other groups of astigmatid mites have become permanent parasites of birds or mammals, eliminating the deutonymph from the life cycle. Among mammal hosts, these mites are most diverse on marsupials, rodents, insectivores, primates, and bats, with relatively few occurring on carnivores or ungulates. Most are relatively nonpathogenic, feeding primarily on sebaceous materials on the hair shafts. Others, however, can cause problems for their hosts.

Species in the family Psoroptidae live on the host’s skin or in the ears and feed by abrading the skin with their chelicerae and imbiling tissue fluids. These mites irritate the skin and cause itching. Several species of psoroptic mites occur on domestic animals, notably the carnivore ear mite, Otodectes cynotis, common in cats and dogs, and the scab mites in the genera Psoroptes and Chorioptes in horses, cattle, sheep, and others. The sheep scab mite, Psoroptes ovis, particularly causes economic damage by causing loss of wool.

Probably most important among parasitic astigmatid mites are species in the family Sarcoptidae. Commonly known as mange mites, species in several genera can parasitize humans and domestic animals. Naturally most diverse on marsupials, bats, primates, and rodents, several species have been able to colonize new hosts. Sarcoptes scabei is ancestrally a parasite of humans, causing the skin disease scabies. Like other sarcoptids, these mites burrow into the superficial layers of the skin. In healthy humans, this disease is an itchy annoyance, but in immune-compromised individuals, a serious condition known as crusted scabies can develop in which the patient may harbor millions of mites in large, crusty lesions all over the body. Sarcoptes scabei has also been able to colonize many domestic animals, notably dogs, pigs, cattle, camels, and others, in which the disease known as sarcoptic mange can be fatal due to the large mite populations and secondary bacterial infections.

Many other astigmatid mites parasitize birds, in which, again, most do not cause harm. Feather mites may be very diverse on an individual bird, with one parrot species known to harbor almost 40 species. Like their fur mite counterparts on mammals, these mites feed on skin oils and do not harm the host. Others, however, may parasitize the feather follicles, skin, or respiratory tract. Skin-inhabiting species in the family Knemidokoptidae can be quite pathogenic in domestic poultry, cage birds, and wild species. Endoparasitic species in the family Cytoditidae live in the air sacs and can cause respiratory distress in poultry.

**IMPORTANCE OF MITES**

As indicated above, there are a number of instances in which mites are important to humans. Many species are serious pests of agricultural crops, either through direct damage or indirectly as vectors of plant pathogens. Other species are parasitic on domestic animals and cause losses in meat, egg, and fiber production. Others, such as the human scabies mite, are direct agents of human disease or, as in the case of chiggers and ticks, vectors of pathogens. Other mites may affect humans by infesting stored food products. Many species of Astigmata are known as stored-product mites because they have moved from their ancestral rodent nest habitats into human food stores. Such mites may also cause damage in animal feed by causing allergic reactions in livestock and are also known to cause...
Molting

Lynn M. Riddiford
University of Washington

Molting is the process of producing a new cuticle and the subsequent shedding (or ecdysis) of the old cuticle. This molt is orchestrated by a series of hormones so that it can be triggered by both internal and external cues.

THE MOLTING PROCESS
Cuticle Production

The cuticle is the outer covering of the insect and is its exoskeleton to which the muscles are attached (Fig. 1). The outermost layer is called the epicuticle; under this is the exocuticle followed by the endocuticle. In some systems, the exo- and endocuticle are classed together as the procuticle. In some insects, only the exo- and endocuticle are deposited before ecdysis, with the endocuticle following ecdysis, whereas in others, some endocuticle may be deposited before ecdysis. The epicuticle is composed of only protein, whereas the exo- and endocuticle contain both chitin and protein in varying proportions depending on the type of cuticle, that is, whether rigid or flexible. Chitin is a polymer of N-acetylglucosamine and can be cross-linked to the protein components of the cuticle in a process called sclerotization or hardening, which usually occurs in the exocuticle just after the shedding of the old cuticle and expansion of the new cuticle. After sclerotization the insect is able to move, feed, fly, etc. The rigid parts of the cuticle are then set and cannot be expanded, whereas flexible cuticle may expand either by a simple unfolding of the new epicuticle or in response to hormonal signals. When the epicuticle has completely unfolded, further expansion is impossible and the larva must molt in order to grow further. Molting is also necessary at the end of larval life for metamorphosis.

The epicuticle is a single cell layer that produces the cuticle that lies above it (Fig. 1). During the intermolt period, the epicuticle actively deposits lamellate endocuticle, especially in those regions where the cuticle is extensible. The chitin and protein are secreted as plaques at the tips of the microvilli at the apical surface of the epidermal cells. Above the plaques in the extracellular space, the cuticle arises by self-assembly of the chitin microfibrils and the secreted proteins. As the larva grows, the epidermal cells underneath the extensible cuticle also grow. During this cell growth, there is DNA synthesis and the epidermal cells may become polyploid (i.e., >2n). In the case of a soft-bodied insect such as the larva of the tobacco hornworm, Manduca sexta, the epicuticle is deposited in folds to allow for growth during the succeeding intermolt period during which time the epicuticle then unfolds. In this instance, the underlying endocuticle expands via a series of apical expansion points created by the deposition by the epidermal cell of vertical chitin microfilaments during the first day after ecdysis. To accommodate these two processes that must occur at the same time, an unstructured layer is deposited between the epicuticle and the lamellate procuticle.

At the onset of the molt, the epidermal cells detach from the overlying cuticle and go through a burst of RNA synthesis including that of ribosomal RNA. At this time, the cells (including those that are polyploid) may divide. Endocuticle synthesis ceases and is followed

![Diagram of the relationship of the epidermis (EPID) to the overlying cuticle that it produces. by secretion of inactive proteolytic and chitinolytic enzymes, and other proteins, to form the “molting gel” that fills the space between the old cuticle and the apical border of the epidermis. Later activation of these enzymes at the end of the molt leads to digestion of the old endocuticle. Other cellular events preparatory to the deposition of the new cuticle, such as cellular shape changes that prefigure the surface conformation, also occur. Then, cuticulin is deposited first at the tips of the plasma membrane plaques followed by deposition between the plaques to form a complete layer. Under this layer the epicuticle precursors (lipid, protein, and polyphenols) are secreted and self-assemble on the inner face of the cuticulin layer. The whole structure is then stabilized by the action of phenoloxidases that cross-link the polyphenols and the proteins. Subsequently, the apical membrane of the epidermal cells withdraws from the patterned surface and begins to form the procuticle, beginning with the exocuticle.

**Digestion and Ecdysis of the Old Cuticle**

During most of the formation of the new cuticle, the old cuticle remains intact and the muscles remain attached to this cuticle to allow the insect to move. At the end of the molt shortly before ecdysis, specific proteases are secreted into the molting gel to clip off a part of the inactive chitinases and proteases to render these enzymes active. These enzymes work together to digest both the protein and the chitin in the old endocuticle down to its component amino acids and N-acetylglucoaminic sugars. This molting fluid is then resorbed into the hemolymph for its components to be recycled for production of the next cuticle or for other uses. Resorption is thought to occur in one of two ways, either back through the new cuticle and the epidermis or through the gut via swallowing and uptake in the hindgut.

Near the end of molting fluid resorption, the insect begins the process of shedding the old cuticle or ecdysis. This shedding occurs in a stereotyped sequence of behaviors. The preecdysis behavior is characterized by a series of coordinated movements that serve to loosen the muscle attachments to the old cuticle. This phase is followed by ecdysis behavior itself, which often is a series of peristaltic waves that travel from posterior to anterior and cause the animal to rupture the old cuticle anteriorly and to escape headfirst. The cuticle opens at ecdysial sutures that are areas of the old cuticle lacking exocuticle so that all but the epicuticle has been digested. In insects with rigid head capsules such as lepidopteran caterpillars, the head capsule has slipped down over the forming mandibles early in the molt to allow the formation of a larger head capsule. At the time of ecdysis, the old head capsule separates from the remainder of the old cuticle and falls off as the new larva walks out of its old cuticle.

At the time of ecdysis, a waterproofing cement layer is deposited on top of the epicuticle by the secretion of dermal glands known as Verson’s glands (Fig. 1). This layer is spread over the surface by the movements of the animal under the old cuticle as it sheds its old cuticle. In some cases, a waxy layer is secreted on top of this layer in the first few days after ecdysis for further prevention of desiccation. This secretion occurs through the pore canals that traverse the cuticle from the epidermal cell to the surface of the cuticle (Fig. 1).

**Postecdysial Expansion and Sclerotization**

After ecdysis the animal fills its tracheae with air and also swallows air in order to expand the new larger cuticle. When it attains its final size, the new cuticle hardens and may also darken (tan) to varying degrees depending on whether the cuticle is to be flexible or rigid. In many insects there is a preecdysial tanning and hardening of certain key structures such as the mandibles or the crochets on the abdominal prolegs of caterpillars used for grasping.

Sclerotization is the process of hardening the exocuticle by cross-linking the proteins together and the proteins with chitin to form a stabilized structure suitable for an exoskeleton that anchors the muscles to allow movement. The primary cross-linking agents are N-acetyldopamine and N-β-alanyldopamine. The latter is found in tan cuticles such as those of many lepidopteran pupae. Both compounds are derived from the amino acid tyrosine through a series of enzymatic steps of which the key enzymes are phenoloxidase for conversion of tyrosine to dopa and dopa decarboxylase for conversion of dopa to dopamine.

**HORMONAL CONTROL OF MOLTING**

**Prothoracicotropic Hormone and Ecdysone**

The molt is initiated by the release of prothoracicotropic hormone (PTTH), a neuropeptide, from the brain (Fig. 2). In Lepidoptera there are only two pairs of neurosecretory cells that make and release PTTH (Fig. 2). These cells send their axons out to the corpora cardiaca (or corpora allata in Lepidoptera) where they terminate and store the PTTH in vesicles until either internal or external environmental signals stimulate the cells to fire action potentials that cause release of their vesicular contents. In the blood-sucking bug Rhodnius prolixus, Vincent B. Wigglesworth in his classic studies of the insect endocrine system showed that the blood meal is the signal for PTTH release. Distention of the abdomen by the blood is relayed to the brain by stretch receptors. In many larvae such as the large milkweed bug Oncopeltus fasciatus, and M. sexta, size determines the time of PTTH release although the sensory pathway utilized has not been determined. In Manduca, the time of day at which the larva attains critical size is also important because PTTH can be released.
Molting

only during a particular time period during the night called a gate. Thus, if the larva attains critical size after the gate closes, PTTH is not released until the gate opens the following night. During the intervening time the larva continues to feed and grow and so will be larger than one that attained critical size during the open gate period and immediately released PTTH. Thus, the brain can integrate the sensory input from both the internal and the external environments and direct the time of molting.

PTTH acts on the prothoracic glands to cause the synthesis and secretion of the steroid hormone α-ecdysone into the hemolymph. α-Ecdysone (E) is converted to 20-hydroxyecdysone (20E) (Fig. 2) by the fat body, the Malpighian tubules, and sometimes other tissues. During the rise of the ecdysteroids for molting, one observes that E appears first in the hemolymph (blood) followed by 20E and later 20,26-dihydroxyecdysone (20,26E). 20E is the main component at the peak of the titer, and 20,26E is the primary ecdysteroid at the end of the molt.

Both E and 20E play a role in molting, with E being important in early cellular changes in the initiation of the molt, such as proliferation, and 20E necessary for the differentiative changes. Experiments with tissues in culture show that low levels of 20E can mimic the early predifferentiative changes caused by E, whereas high levels of E are unable to cause the differentiative events caused by 20E. Although high 20E initiates the deposition of the cuticulin and epicuticle, procuticle consisting of chitin and protein can be deposited only when the 20E levels in the hemolymph have declined. Experiments both with imaginal discs (precursors of adult structures found in larvae of moths and flies) and with Manduca abdominal epidermis in culture have shown that in the continuous presence of 20E, neither chitin nor the exo- and endocuticular proteins are deposited, although the epicuticle can be. To form a new cuticle in vitro, tissues taken during the intermolt period must first be exposed to 20E for a time commensurate with their exposure during the molt, and then they must be transferred to hormone-free medium. Although 20,26E is present for a long time during the decline of ecdysteroids at the end of the molt, so far no role has been found for it either in the timing of events that occur at the end of the molt, such as the production of new endocuticle or of dopamine, or in any aspect of ecdysis behavior. Therefore, at the present time, 20,26E is still considered to be an inactive metabolite of 20E.

Juvenile Hormone

Juvenile hormone (JH) is a sesquiterpenoid produced by the corpora allata (Fig. 2) and is present throughout nymphal and larval life in all insects. Its primary action is to prevent metamorphosis in response to ecdysone at the time of the molt as first demonstrated by V. B. Wigglesworth with Rhodnius and Carroll Williams in the wild silk moth Hyalophora cecropia. Consequently, Williams called it the status quo hormone.

At the beginning of or during the final nymphal or larval stage, the corpora allata cease production of JH, and JH in the hemolymph declines to undetectable levels. When ecdysone next rises, it causes metamorphosis. In most insects metamorphosis of the epidermis consists of switches in developmental programs from nymph to adult or from larva to pupa to adult. This switch is prevented, whereas the late puffs do not. In the early 1960s these findings led Peter Karlson to suggest that ecdysone acted directly on genes to regulate their activity, a hypothesis that has since been proven true for all steroid hormones. Based on the precise timing of the effects on puffing seen after the addition of 20E to the salivary glands, Michael Ashburner suggested in 1974 that ecdysone acted by directly activating the early genes that produced mRNA to make proteins that in turn activated the late genes and inhibited the early genes. This “Ashburner cascade” was essentially confirmed in the 1990s when the genes involved were isolated and their products identified. The following is the modern version of ecdysone action.

Ecdysone enters the cell and goes to the nucleus where it combines with the ecdysone receptor (EcR), a protein in the nuclear receptor superfamily that has the characteristic structure seen in Fig. 3 (top). The DNA binding domain (C in Fig. 3) consists of 66 amino acids and contains two cysteine–cysteine “zinc fingers” by which the zinc is held coordinately by the four cysteines. The first zinc finger is involved in binding to the DNA, whereas the second is necessary for stabilizing that binding by protein–protein interactions. The ligand-binding domain (E in Fig. 3) has a pocket that binds the ecdysone and on so doing the molecule changes its shape and may interact with coactivator proteins. The N-terminal A/B domain (Fig. 3) is also important for interactions with other proteins that are necessary to activate a gene. Normally the EcR forms a heterodimer with ultraspiracle (USP), another member of the nuclear receptor family. This heterodimer binds to the DNA at a particular sequence called the
ecdysonic-response element in the gene promoter (a region usually but not always upstream of the gene that is necessary to turn the gene on and off) (Fig. 3, bottom). In the absence of hormone, the EcR/USP heterodimer keeps the gene suppressed; then when ecdysone appears and binds to EcR, the gene may be activated.

Most of the early genes activated by ecdysone encode transcription factors, proteins that bind to DNA in promoter regions and may activate or inactivate transcription of those genes. In the ecdysone cascade, these transcription factors activate the late genes, which are either general or tissue-specific genes that are involved in the molting process for a particular tissue. They also inactivate the early genes and the intermoln genes such as those for endocuticle synthesis in the epidermis. In addition, these early transcription factors are important in the regulation of the so-called delayed early genes that encode transcription factors and are activated by ecdysone but require protein synthesis for their full activation. All of these early and delayed early factors require continuous exposure to ecdysone for their continued transcription, but may be present for differing periods of time depending on the dynamics of their inhibition by the various ecdysone-induced factors. The few early genes that do not encode transcription factors instead encode proteins that are likely critical to the molting process, such as a calcium-binding protein, an ATP-binding cassette membrane transporter, and a protein in imaginal discs important for the cell shape changes that occur at metamorphosis.

The coordination of events such as endocuticle synthesis and later dopamine production that occur during the decline of the ecdysteroid titers is also dependent on ecdysone-regulated transcription factors. These factors appear only after exposure to 20E followed by its removal. One can show that the timing of this appearance varies among the factors in a sequence similar to that seen in the animal and is presumably dependent on the levels of both 20E and the various inhibitory transcription factors that 20E has induced.

JH has been found to inhibit the appearance of a set of ecdysone-induced transcription factors named the broad complex (BR-C) in the epidermis during larval molts. In both Manduca and Drosophila the BR-C factors appear in this tissue at the time of pupal commitment and are also present during pupal cuticle synthesis. In

**Hormonal Control of Ecdysis: ETH, EH, and CCAP**

The molt culminates in the shedding of the old cuticle during ecdysis, which is followed by the expansion of the new cuticle and then its hardening and often darkening or tanning. A cascade of small peptide hormones that are released after the new cuticle is formed and the ecdysone titer has declined below a threshold level initiates ecdysis. This cascade has been studied in detail by James Truman and co-workers and by Dushan Zitnan. The precise nature of the signal that initiates this cascade is not yet understood, but at a certain time near or at the end of molting fluid resorption, the epitracheal glands just below the spiracles (the openings of the tracheae to the outside air) release a small peptide, ecdysis-triggering hormone (ETH) (Figs. 2 and 4). ETH enters the central nervous system (CNS) and initiates a sequence of behaviors called the pre-ecdysis behavior that serves to loosen the muscle attachments from the old cuticle. ETH also acts on a set of neurosecretory cells in the ventromedial region of the brain to cause the release of eclosion hormone (EH) both into the ventral nervous system and into the hemolymph from their endings in the proctodeal nerve along the hindgut (Fig. 4). In the ventral nervous system, EH activates a network of neurons that contain crustacean cardioactive peptide (CCAP) (so named because it was first isolated from the crab in which it increases the beating of the heart) (Fig. 4). In response to EH release within the CNS, CCAP is released both into the CNS and into the hemolymph via the neurons’ endings in the perivisceral organ (PVO) (Fig. 2). The action of CCAP in the CNS is to trigger the ecdysis behavior that allows the animal to shed its old cuticle. Some of these neurons also apparently contain and release bursicon, the tanning hormone (see below), into the hemolymph at the same time as they release CCAP.

In moths and flies, the sequences of the preecdysis and ecdysis behaviors are found to be stereotyped programs that once initiated by the hormone in question run their course. This behavior can even be seen in the isolated nervous system in the absence of sensory feedback, indicating a preprogrammed network that has only to be triggered by an external signal. The absence of ecdysone is necessary for this system to function since ecdysone suppresses the release of ETH from the epitracheal glands, thereby preventing this cascade of peptides. Ecdysone also decreases the excitability of the EH cells. EH release also is controlled by photoperiod in many species so that its release, like that of PTTH, can occur only during a certain gate during the day. A good example of this control was shown by the classical studies of Truman on the eclosion (adult ecdysis) of two species of wild silk moth, H. cecropia and Atheraea pernyi (Fig. 5). H. cecropia normally emerges in the morning and A. pernyi emerges.
emerged in the morning in a coordinated manner. Thus, EH release from the implanted brain occurs at the time of day dictated by the donor brain, indicating that both detection of the photoperiod signals and the clock that determines the timing of EH release are located in the brain. Also, these studies indicated that EH is necessary for the coordination of eclosion behavior. Specific destruction of the EH-releasing cells in *Drosophila* brains in the embryo and early larva resulted in about half the animals being unable to complete the larval molts, whereas the remaining flies emerged in an uncoordinated manner, again indicating that EH is necessary for behavioral coordination.

In the hemolymph EH acts back on the epitracheal glands in a positive feedback to cause further release of EH so that within a few minutes, both the ETH and the EH cells are depleted of their stored peptides. EH also causes the filling of the new tracheae with air and the Verson’s glands to release their waterproofing products over the surface of the animal as the insect is shedding its old cuticle.

**Hormonal Control of Cuticular Expansion and Hardening: Bursicon, CCAP**

After ecdysis the insect expands the new cuticle, then the cuticle hardens. Both CCAP and bursicon released from the PVOs into the hemolymph are involved. CCAP stimulates an increase in heart rate that is associated with the expansion of the new cuticle.

Bursicon is thought to initiate both of the above processes. For example, *Rickets* mutants in *Drosophila* lack the putative bursicon receptor eclyse but show no wing expansion or other expansion behaviors and do not harden their cuticle. Bursicon is a large protein that is synthesized by various neurosecretory cells within the CNS (Fig. 2) but has not yet been chemically characterized. It is thought to act via cyclic AMP in the epidermal cell to trigger the cross-linking activities of N-acetyldopamine and N-3,3-αanlyldopamine that cause sclerotization and tanning. Its plasticizing role in cuticular expansion has not been well studied.

Monarchs

Lincoln P. Brower
Sweet Briar College

The monarch butterfly (Danaus plexippus, Nymphalidae) belongs to the tropical subfamily Danainae, the members of which are called milkweed butterflies because their larval host plants occur mainly in the milkweed family, Asclepiadaceae. With the exception of the monarch, most of the 157 known Danainae species are limited to tropical regions in Malaysia, Africa, South America, and the Greater Antilles. The adults of several species exhibit both short-distance migrations during the dry and wet seasons and social clustering behavior. This suggests that the long-distance migration and overwintering-aggregation behavior of the monarch butterfly in North America was evolutionarily elaborated from an ancient (pleisiomorphic) character of the taxon.

During the late Cenozoic, the milkweed genus Asclepias underwent an adaptive radiation that produced 108 species in temperate North America, ranging from Mexico to the boreal forests of Canada and from the Atlantic to the Pacific coasts. As the climate alternated between hot and cold periods during the Pleistocene, the North American flora periodically advanced and retreated. The author hypothesizes that the monarch tracked the geographic expansion and retraction of its milkweed hosts and in the process refined its inherited ancestral ability to move between habitats. Because the monarch cannot tolerate temperate zone winters, natural selection would have favored those individuals that moved southward as summer waned. As time passed, the migration syndrome gradually evolved to become increasingly sophisticated, ending in the present round-trip migration, one of the most complex in the animal kingdom (Fig. 1a and 1b).

UNPALATABILITY AND MIMICRY

C. V. Riley, the most famous 19th century entomologist in North America, proposed in 1871 that the monarch was distasteful and advertised its unpalatability with its conspicuous behavior and its spotted pattern of bright orange, black, and white. Time has proven him correct and a remarkable coevolutionary interaction of the monarch with the North American Asclepias species resulted in great refinements of the monarch’s chemical defense. Milkweeds synthesize differing arrays and amounts of vertebrate heart poisons, known as cardenolides. These are bitter-tasting chemicals that cause severe vomiting when ingested. Monarch larvae are insensitive to these molecules and, as they feed on the milkweeds, they sequester and store them in their bodies. The poisons are passed on into the chrysalis and then to the adults in sufficient amounts to sicken vertebrate predators, especially birds and mice. Laboratory experiments with blue jays (Cyanocitta cristata) have shown that some monarchs are so toxic that once a bird has eaten one, the noxious experience is so intense that the bird not only refuses monarchs in future encounters, but may actually retch at the sight of another (Fig. 2a and 2b).

Riley also proposed that the unrelated viceroy butterfly (Limenitis archippus) had evolved through natural selection to mimic the color pattern of the monarch. The viceroy was originally considered palatable and a so-called Batesian mimic, but recent studies suggest that it is also unpalatable. Therefore the monarch and viceroy have most likely converged on a common warning color pattern and are Müllerian mimics. However, the situation is more complex because some milkweeds lack cardenolides. As a result, monarch larvae that feed on nontoxic milkweeds produce palatable butterflies, whereas those that feed on toxic species produce unpalatables. This discovery gave rise to the concept of automimicry, in which palatable members of a species are identical in appearance to, but are protected by their unpalatable relatives. Thus, in the wild, monarchs exhibit a “palatability spectrum,” with the result that mixed populations of monarchs and viceroys may simultaneously exhibit Batesian mimicry, Müllerian mimicry, and automimicry.

THE EASTERN AND WESTERN MIGRATORY POPULATIONS

Monarchs that breed west of the Rocky Mountains have been known since the mid-19th century to migrate during the fall from their breeding areas to numerous overwintering sites along the coast of California, the most famous of which is in Pacific Grove on the Monterey Peninsula. Almost certainly attracted to each other by visual and pheromone signals, the butterflies aggregate from mid-October through February in spectacularly dense clusters on the live branches of Monterey pines, cypress, and eucalyptus. As spring advances, the surviving monarchs mate and migrate inland, where the females seek out the spring flush of milkweeds on which they lay singly up to 400 eggs before they die.

It was long suspected that the much larger eastern population of monarchs—those that breed during the summer in a 2.6 million km² area east of the Rocky Mountains—migrates to Mexico. Fred and Norah Urquhart at the University of Toronto developed a wing-tagging program involving hundreds of collaborating amateurs that...
Finally led one of their associates, Kenneth Brugger, to discover the first overwintering site in Mexico on January 2, 1975. Subsequent searching by Lincoln Brower, William Calvert, and their Mexican colleagues located overwintering sites on 12 separate mountain ranges within a 30 × 60 km area of central Mexico (Fig. 3). Unlike the coastal overwintering sites in California, the overwintering areas in Mexico all occur above 3200 m altitude in a coniferous oyamel fir–pine ecosystem. This is a very limited ecosystem in the Transverse Neovolcanic Belt of mountains that run across Mexico, just south of the Tropic of Cancer.

**THE MEXICO OVERWINTERING PHENOMENON**

The numbers of butterflies in the Mexican overwintering colonies are astounding large (Fig. 4). Early research, based on mark, release, and recapture studies in California, suggested that the butterfly densities in Mexico are 10 times greater and led to an estimate of 10 million monarchs per hectare (2.47 acres) of forest. However, a catastrophic winter storm in January 2002 killed so many butterflies...
Monarchs

(656 one sample had more than 50,000 dead butterflies in a single square meter!) that the revised density estimate is now at least five times this. In other words, the fir and pine trees are festooned with 50 million monarchs per hectare. So far the maximum combined area occupied by all known colonies is about 20 ha, a total of at least 1 billion monarchs. The extraordinary beauty and mystery of the densely aggregated cluster of monarchs in these colonies is now well known. They represent one of the greatest biological wonders on this planet.

The extreme unpalatability of monarchs was probably one factor that allowed the species to elaborate the extremely dense winter aggregation behavior. Were they not chemically protected, the aggregations—an enormous potential food supply—would be exploited by vertebrate predators. In fact, field studies have shown that most, but not all, species of birds and mice in the overwintering areas in both California and Mexico avoid eating monarchs. However, in Mexico, orioles and grosbeaks have broken through the chemical protection and killed an average of 15,000 monarchs per day in one colony, that is, more than a million butterflies during the overwintering season. Again, the old adage holds that no protection, no matter how sophisticated, can ever be perfect.

Because various milkweed species fed upon by monarch larvae synthesize arrays of chemically distinct cardenolides, it is possible to extract the molecules from the butterflies and by thin-layer chromatography to obtain a chemical fingerprint that indicates which species of milkweed each monarch ate when it was a caterpillar. Using this technique, Brower and his colleagues determined that individual monarchs that have survived the winter in Mexico remigrate in the spring to the Gulf coastal states where they lay their eggs and then die. The ensuing new spring generation then continues the migration northward into the Great Lakes region and establishes the first summer generation.

By July, the first summer generation of monarchs disperses east to the Atlantic coast and west to the Rocky Mountains and produces at least one more generation of adults. By mid-August, shortening daylength and colder nights reduce juvenile hormone production in the

(FIGURE 3) Locations of 12 mountain massifs on which monarch butterfly overwintering occurs in the oyamel–pine forest ecosystem of central Mexico, about 120 km west of Mexico City. The total area shown is approximately 11,700 km². The five shaded polygons are overwintering areas protected by presidential decree in 1986 (16,100 ha). The unshaded polygons are seven additional overwintering areas that currently are not protected. [From Brower et al., (2002), with permission of Odyssey Press.]

THE MULTIGENERATIONAL MIGRATION SYNDROME

Because various milkweed species fed upon by monarch larvae synthesize arrays of chemically distinct cardenolides, it is possible to extract the molecules from the butterflies and by thin-layer chromatography to obtain a chemical fingerprint that indicates which species of milkweed each monarch ate when it was a caterpillar. Using this technique, Brower and his colleagues determined that individual monarchs that have survived the winter in Mexico remigrate in the spring to the Gulf coastal states where they lay their eggs and then die. The ensuing new spring generation then continues the migration northward into the Great Lakes region and establishes the first summer generation.

By July, the first summer generation of monarchs disperses east to the Atlantic coast and west to the Rocky Mountains and produces at least one more generation of adults. By mid-August, shortening daylength and colder nights reduce juvenile hormone production in
the final summer generation. This prevents gonadal maturation and the butterflies become gregarious and begin their fall migration to Mexico. As shown by Gibo, these migrants are adept at using thermal lift and tail winds. As dusk approaches, the butterflies drift down and aggregate on trees where they spend the night. When the winds blow from the south, the butterflies interrupt their migration and seek out fields of flowers and assiduously drink nectar. They convert the sugar in the nectar into lipid and store it in their abdominal fat bodies. By the time the migrants reach central Texas, they have increased their lipid content by 500%. This reserve is crucial both to sustain them over their 5 months' overwintering period and to fuel the subsequent 1 month's spring remigration.

**UNRESOLVED QUESTIONS**

The individual monarchs of the last summer generation are genetically programmed to perform this migration to central Mexico in the fall, to survive the winter, and then to remigrate to the southern United States in the spring. Thus adult monarchs born in the Toronto area in August and returning to central Texas the following April traverse a distance of more than 5000 km. Their ability to find their way through deserts and mountain passes, to compensate for wind drift, and finally to locate the very small areas in Mexico that they have never before encountered remains a mystery. It will probably be solved when satellites can monitor electronic tags placed on individual butterflies.

The migratory orientation of individual monarchs shifts from south in the fall to north in the spring. How they maintain a particular course is poorly understood. While recent evidence casts doubt on the possibility that they may use magnetic orientation, there is strong evidence that sun compass orientation is involved. A complementary hypothesis is that monarch individuals have an internal clock that ticks away in all life stages and shifts the potential angle of the migration direction 1° per day throughout the year. Thus, at the spring equinox, the monarchs head out of their Mexican overwintering areas on a due north course (0°). The new spring generation, about 45 days later, heads northeastward toward the Great Lakes (45°), and the next generation that is produced about 90 days after the spring equinox heads due east (90°). By the fall equinox (September 21), their heading would be 180°, that is, due south, changing to southwesterly as they migrate southward and finally reach the overwintering areas in November and December (Fig. 5).

Another unresolved question is the degree to which the eastern and western North American migratory populations are geographically isolated from each other. Molecular evidence suggests little differentiation, and it is possible that the western population is derived from and ultimately dependent on monarchs that get displaced westward by occasional strong northwesterly winds during the spring remigration from Mexico. Until the natural interchange between the eastern and the western populations is better understood, it seems prudent to avoid experimental and frivolous commercial transfers between them.

**MIGRATION AND OVERWINTERING: ENDANGERED BIOLOGICAL PHENOMENA**

The overwintering monarchs in Mexico are highly adapted to the oyamel fir–pine forest ecosystem. The forest provides a microclimatic envelope that protects the butterflies during the five winter months and allows them to remain in reproductive dormancy until the northern milkweed flora resurges in the spring. The high altitude and low latitude selected by the butterflies combine to provide a microclimate beneath the forest canopy that is generally wet enough to prevent the butterflies from desiccating, warm enough to preserve their lipid reserves. However, their overwintering can be precarious.

Anderson and Brower determined that adult monarchs can tolerate temperatures to about −8°C if they are dry, but when wetted by rain and exposed to the night sky they lose most of their natural freezing resistance. They concluded that an intact forest serves both as a blanket and as an umbrella for the overwintering monarchs and that removal of even a single large tree exposes and jeopardizes thousands of monarchs during winter storms. Unfortunately this warning was realized in January 2002 when a severe northern cold front penetrated the overwintering region. The ensuing storm soaked and then froze more than a quarter of a billion butterflies in the Chincua and Campanario colonies. The severity of this kill was exacerbated by the fact that the surrounding forests have been thinned and severely fragmented, and despite three presidential decrees supposedly protecting the overwintering forests, extensive legal and illegal logging is accelerating throughout the region.

Monarchs are also becoming rapidly imperiled in their eastern breeding range by industrialized agriculture that is eliminating

**FIGURE 5** The rotational orientation hypothesis holds that all generations of monarch butterflies are migratory and that their orientation shifts clockwise at a rate of 1° per day throughout the year. The number of generations produced in each annual cycle varies from three to five and is temperature dependent. The spring equinox apparently triggers the northward remigration from Mexico. As time proceeds, the hypothesis holds that the orientation of subsequent generations shifts as shown, with some degree of scattering in each successive geographic displacement. Once the last generation has reached the overwintering sites, their migratory activity is repressed, but their orientation clock is assumed to continue running. By the time the cycle is complete at the new spring equinox, the overwintered butterflies are primed to migrate due north. [Reproduced from Brower (1996), with permission of the Journal of Experimental Biology.]
mosquitoes and nectar sources. An assay based on hydrogen and carbon isotope ratios that vary systematically with respect to the geographic origin of the monarch's Asclepias syriaca food plants has determined that the major area of summer breeding in the United States coincides with the corn belt that has replaced the former grassland ecosystem in the midwestern United States. This has ominous implications because of the genetic engineering of crops to be resistant to herbicides. Massive and increasingly sophisticated herbicide spraying is killing the principal milkweed food plant of the monarch (A. syriaca) as well as most of the native flora over tens of thousands of hectares. Thus monarchs are losing both their larval food resources and their access to the diversity of flowers that provide critical nectar resources.

Because of these combined pressures on the breeding, migratory, and overwintering habitats, the migration of the monarch butterfly in North America has become an endangered biological phenomenon. The remarkable syndrome manifested by the monarch butterfly is too great a cultural and scientific treasure to allow these rampantly destructive processes to continue. Time is rapidly running out.

Mosquitoes

Bruce F. Eldridge
University of California, Davis

Mosquitoes are small flying insects and are related to other members of the order Diptera, the “two-winged flies.” The immature stages of larvae are aquatic and live in stagnant water sources in every biogeographic region of the world. Adult female mosquitoes of most species feed on blood of vertebrates, including humans, and this habit has resulted in great economic and public health significance for this group of insects.

There are well over 3000 species and subspecies of mosquitoes in the world. They occur in a variety of habitats, ranging from deserts at or below sea level to high mountain meadows at elevations of 3000 m or more. Adult mosquitoes are terrestrial flying insects; immature stages are aquatic. Larvae and pupae of the various species can be found in ponds, ditches, puddles, swamps, marshes, water-filled rot holes of trees, rock pools, axils of plants, pools of melted snow, water in discarded tires, tin cans, and other artificial containers. Some species are most active in the warmest part of the year, whereas others are adapted to cool temperatures. Many species of mosquitoes are rarely encountered and seldom pose a threat to the health or well-being of humans and domestic animals. However, other species are abundant, frequently encountered, and readily attack people, their pets, and their livestock. Some of these species transmit microbial organisms that cause malaria and encephalitis, and other severe diseases of humans and other vertebrates. Mosquitoes are also commonly used as research objects in a wide range of biological studies.

CLASSIFICATION AND IDENTIFICATION

Mosquitoes are classified into three subfamilies, each with different characteristics in all of their life cycle stages. The species of importance from the standpoint of public health are contained in the subfamilies Anophelinae (referred to as anophelines) and Culicinae (referred to as culicines). Females of species in a third subfamily, Toxorhynchitinae, lack mouthparts adapted for sucking blood from vertebrates. The larvae of this subfamily are predaceous on other aquatic organisms and have been proposed as biological control agents of mosquito larvae.

Common genera of the Culicinae include Culex, Aedes, Psorophora, Mansonia, Haemagogus, Sabethes, Coquilletidia, and Culiseta. Most species in the Anophelinae are contained in the genus...
Anopheles. The subfamily Toxorhynchitinae contains only the genus Toxorhynchites.

Mosquito adults are small flying midge-like insects. Most female mosquitoes can be differentiated from similar insects by the presence of a long slender proboscis that is adapted for piercing skin and sucking blood, and long slender wings that are covered with small scales (Figs. 1 and 2A). Male mosquitoes have scale-covered wings, but their proboscises are adapted for sucking plant juices and other sources of sugars (Fig. 2B). Most male mosquitoes can also be differentiated from females of the same species by their generally smaller size and by the presence of much longer and hairier maxillary palps.

The immature stages of mosquitoes, the larvae (Fig. 3) and pupae (Fig. 4), vary in color from yellowish tan to black. Most mosquito larvae have a distinctive siphon, or air tube, at the rear of their bodies (Fig. 3B), but some species lack this tube (Fig. 3A).

Culicine larvae have an air tube extending from the posterior section of their body and in most species hang at rest from water surfaces at an angle of approximately 45°. Larvae of Coquillettidia and Mansonia have air tubes adapted for piercing submerged plants to obtain air for breathing. They are rarely found at water surfaces. Anopheline larvae lack an air tube and consequently rest parallel to water surfaces.

Culicine adult females have proboscises developed for piercing the skin of vertebrates and sucking their blood. While feeding, their bodies are usually arranged somewhat parallel to the skin surface of their hosts. Anopheline adult females also have proboscises adapted for piercing vertebrate skin, but they orient themselves at about a 45° angle while blood feeding.
The eggs of mosquitoes also vary (Fig. 5). Females of culicine species deposit single eggs (*Aedes, Psorophora*), boat-shaped rafts of 100 or more eggs (*Culex, Culiseta*), or clusters of eggs attached to floating plants (*Mansonia, Coquilletidia*). Anopheline eggs are also laid singly, but have elaborate floats extending to the sides of the eggs. Anopheline eggs are often found in clusters on water surfaces, forming interesting geometric patterns. *Toxorhynchites* eggs are also laid singly, usually on water surfaces.

**LIFE CYCLE**

**Egg Stage**

The egg-laying habits of female mosquitoes vary widely from species to species. Some female mosquitoes lay eggs on water surfaces (*e.g.*, *Anopheles*); others lay single eggs on moist soil (*e.g.*, *Aedes*). From eggs deposited on water surfaces, larvae usually hatch within a day or so, but eggs laid on soil surfaces do not hatch until the surfaces are flooded, which may occur months, or even years, later. The environmental cues female mosquitoes use to find suitable sites for oviposition remain only partially known. Color, moisture, and volatile chemical stimulants appear to play a role in certain species. Efforts to explain the occurrence of various mosquito species in different aquatic habitats based strictly on oviposition cues have been unsuccessful.

**Larval Stages**

Small larvae that are nearly invisible to the naked eye hatch from eggs. Larvae molt three times to become fourth-stage larvae. Several days later, this larval form molts again to become a pupa. The time required for development of the larval stages depends on several factors, the most important of which is water temperature. Availability of food and larval density are also other factors. Water temperature and food are inversely related to time of development, whereas larval density is directly related.

Most mosquito species have larvae that are restricted to freshwater. However, larvae of a few species can develop under other conditions, for example, brackish or saltwater or water polluted with organic solids. Species with larvae adapted to saltwater can maintain osmotic pressure within their bodies by drinking substantial amounts of water and by removing ions from their hemolymph through their Malpighian tubules and rectum. Generally, saline species can also develop in freshwater, but do not compete well with freshwater species. The inverse is not true and consequently, various kinds of water usually have a characteristic mosquito fauna.

**Adults**

Adult mosquitoes emerge 1–2 days after the appearance of pupae, with males emerging first. In the summer, the entire life cycle, from egg to adult, may be completed in 10 days or less. Females feed on vertebrate blood for the development of eggs. This behavior by females is the single most important characteristic of mosquitoes from the human standpoint. Blood feeding in insects is believed to have evolved several times independently from ancestral forms adapted for sucking plant juices or for preying on other insects. The means by which female mosquitoes locate suitable hosts for blood feeding has been studied for many years, but there are still many unknown features to this behavior. The best explanation is that females are attracted by warmth, moisture, and carbon dioxide from hosts, but other factors are involved. Several studies have suggested that substances such as lactic acid, a component of human sweat, also serve as attractants.

Ordinarily, a female mosquito cannot develop a batch of eggs unless she has taken a blood meal to obtain nourishment for ovarian development. However, some strains or individuals of several species can develop eggs without a blood meal, which is called autogeny. The nourishment for egg development is carried over from the larval stages, and consequently, only the first batch of eggs can develop in this way. The usual situation in which a blood meal is required for the development of all batches of eggs in an individual female is called anautogeny.

Some mosquitoes take blood only from certain groups of vertebrate animals. For example, *Culex pipiens*, the northern house mosquito, feeds almost entirely on birds. *Aedes sierrensis*, the western treehole mosquito, feeds only on mammals. *C. tarsalis*, the encephalitis mosquito, feeds on birds and mammals (this dual host preference is one characteristic of an effective vector of disease pathogens). In the past, this relative host specificity has been called host preference. However, this term is not appropriate, because it ignores availability of hosts, host defensive behavior, and other factors unrelated to the mosquitoes themselves. The blood-feeding drive is controlled by neurohormones and can be induced artificially by treatment with juvenile hormone or one of its analogs. This hormonal influence is the reason why mosquitoes that have recently had a blood meal and are developing a batch of eggs do not usually seek another blood meal. However, multiple blood meals (more than one blood meal in a single gonotrophic cycle) do occur at times in nature in some species.

Blood feeding by mosquitoes is a complex process. It is facilitated by the injection of saliva into the feeding wound of the vertebrate host. Saliva comes from organs in the thorax of mosquitoes called salivary glands. Saliva may contain a variety of substances, including chemicals that reduce clotting of vertebrate blood. Digestion of a blood meal usually takes 2–3 days, depending on the ambient temperature. The uptake of blood is accomplished by the action of muscular pumps in the head of female mosquitoes. Blood travels through the digestive tract of the mosquito into a structure called the midgut. After blood reaches the midgut it is soon surrounded by a thin sheath, the peritrophic membrane, which is secreted by cells at the front of the midgut. Digestion of the blood takes place within this structure.
Seasonal Development

Some species of mosquito have but a single generation per year (univoltine), whereas others have many (multivoltine), depending upon the length of the season favoring the activity of the adult stages. To avoid seasons of the year not favorable to adult activity (usually the winter), mosquitoes may have some kind of diapause mechanism. In *Aedes* and related genera, the diapause mechanism usually involves the egg stage. In temperate and subarctic zone *Aedes*, populations may survive winters as desiccation-resistant eggs, sometimes under the surface of snow or along river flood plains. The larvae then hatch in the spring after the eggs are flooded from melted snow or after flooding of the riverbanks.

*Culex* and *Anopheles* females usually survive unfavorable periods as diapausing or quiescent adult females. Male mosquitoes usually do not survive unfavorable periods, so it is necessary for insemination to occur before the onset of diapause.

Some mosquito species survive unfavorable periods as diapausing larvae (e.g., species of *Aedes, Anopheles, Culiseta*). Diapause can be variable in some species, depending upon the latitude at which they occur, with diapause occurring in the larval stage at warmer latitudes and in the egg stage at cooler ones.

There is considerable variation in the environmental and physiological control of diapause. In nearly all diapausing mosquitoes studied, diapause is triggered by exposure of one or more of the life cycle stages to daylength. In *Culex* species, and other mosquitoes that overwinter as adults, exposure of late-stage larvae and of pupae to short daily photophases occurring in autumn results in diapause in adult females. This diapause is manifested by lowered activity levels, inhibition of blood-feeding drive, and the arrest of follicle development in ovaries. In some *Aedes* species, the short autumn days experienced by females result in deposition of eggs that are in a diapause state. The larvae in these eggs do not hatch until after a period of exposure to near-freezing temperatures lasting several months. In other species of *Aedes*, diapause results from exposure of the eggs themselves to short daylengths. Still other *Aedes* species have larvae that enter diapause triggered by their exposure to short daylengths.

As with other aspects of reproduction and development, diapause is controlled directly by neurohormones. Diapause can be induced in most diapausing species by exposure to juvenile hormone or one of its analogs.

Many tropical and subtropical species, such as *A. aegypti*, the yellow-fever mosquito, do not have a diapause mechanism. Still other tropical species have mechanisms for avoidance of hot, dry seasons, but these mechanisms have been little studied.

**PUBLIC HEALTH AND VETERINARY IMPORTANCE**

As discussed earlier, female mosquitoes of nearly all species require blood from vertebrate animals to develop their eggs, and many species bite people, their pets, and livestock for this purpose. The most important result of this behavior is the transmission of microorganisms that cause diseases such as malaria, filariasis, yellow fever, and dengue. These and other mosquito-borne diseases can have serious and sometimes fatal consequences in people. These diseases can also have an impact on livestock, pets, and wildlife. Even when no infectious disease pathogens are transmitted by mosquitoes, they can be a serious health problem to people and livestock. Biting of people by mosquitoes can result in secondary infections, allergic reactions, pain, irritation, redness, and itching. Mosquito biting in beef cattle can result in reduction in weight gains and in dairy cows, reduction in milk production.

The interactions between mosquito hosts and the pathogens they transmit are highly variable. Three basic types of transmission mechanisms are involved: (1) propagative transmission, in which the pathogen multiplies within the mosquito but does not undergo any changes in developmental form; (2) developmental transmission, in which the pathogen undergoes developmental changes but does not multiply; and (3) propagative-developmental transmission (also called cyclodevelopmental transmission), in which the pathogen multiplies and undergoes changes in developmental forms. Transmission of the yellow-fever virus by the yellow-fever mosquito is an example of propagative transmission. The virus is taken up by a female mosquito from a viremic host during blood feeding, multiplies many times, and eventually infects the salivary glands of the host. When the female mosquito takes another blood meal, she may infect a new host by the injection of saliva.

Some pathogens are transmitted to the offspring of female mosquitoes via infected eggs. This type of transmission is known as transovarial transmission.

Filarial worms, the cause of the disease filariasis (a type of which is called elephantiasis) in humans and other vertebrates, are transmitted by developmental transmission. In this example, very small immature forms of the worms, called microfilariae, occur in the blood of infected vertebrate hosts and are taken up by female mosquitoes in a blood meal. Within the mosquito, the microfilariae molt several times until they eventually become infectious larvae. These larvae migrate down the proboscis of the mosquito and enter the feeding wound caused by the mosquito during a subsequent blood feeding. Within the vertebrate host, these larvae may eventually develop into adult male and female worms that mate and produce microfilariae. It is the presence of large numbers of adult worms that results in the symptoms of filariasis.

Malarial parasites have a very complex life cycle, involving both multiplication of parasites and development of life cycle stages. Anopheline mosquitoes are the vectors of human malaria, and because the sexual stages and fertilization occur within mosquitoes, by definition they are the definitive hosts. Parasite forms called microgametocytes (male sex cells) and macrogametocytes (female sex cells) occur in the peripheral blood of humans and are taken up by mosquitoes. Fertilization of the female cells by the male cells occurs within the gut of the vector mosquito. After several life cycle changes, and multiplication of forms within cysts on the gut wall, forms of the parasite called sporozoites enter salivary glands of the mosquito and infect new hosts during blood feeding.

There are hundreds of types of microorganisms that are transmitted by mosquitoes to vertebrates that result in diseases. A few are extremely important worldwide because of their high incidence and the severity of their symptoms in humans.

Malaria is one of the most important diseases in the world. Several hundred million people are infected with malarial parasites, resulting in over 2 million fatalities annually, mostly in tropical countries in Africa and Asia. Malaria is especially serious in pregnant women and young children. Typically, more than a million children die every year from this disease. The economic development of a number of tropical countries is badly hindered by malaria because of the burden of chronic malaria infections in working-age men and women.

The virus disease known as dengue, transmitted mostly by the yellow-fever mosquito, is a rapidly expanding problem in the world and is now considered second in importance only to malaria among mosquito-borne diseases. The increase in global human travel resulting from expanded rapid air transportation has been paralleled by the increase in the number of viral strains causing dengue and the
increase in the number of cases of a particularly serious form of the disease called dengue hemorrhagic fever. This form of the disease is most serious in children and is a significant cause of mortality.

Filaria is a general term applied to infection of vertebrate animals by many different species of parasitic worms belonging to the superfamily Filaroidea. A form of mosquito-borne filariasis is caused by lymphatic filariasis because this infection can cause impairment of the lymphatic system. Lymphatic filariasis is a chronic disease that can lead to the well-known disfigurement of humans called elephantiasis. Another type of filariasis called dog heartworm occurs in dogs, other canids (e.g., wolves and coyotes), and felids (e.g., domestic cats). Heavy infections can result in large buildups of adult worms in the cardiopulmonary system and can be fatal.

Yellow fever, a virus disease, has virtually disappeared from the United States because of the availability of an extremely effective vaccine. This vaccine may provide lifelong immunity from a single inoculation. Unfortunately, the availability of the vaccine is limited on a worldwide basis and there are many unvaccinated people living in tropical countries. Periodic epidemics caused by viruses. Some of these viral diseases, such as Japanese encephalitis, La Crosse encephalitis, West Nile fever, Ross River disease, and Rift Valley fever, affect large numbers of people in parts of the world where they occur.

CONTROL OF MOSQUITOES

In most industrialized nations, mosquito control is done by government-supported agencies that are either components of health agencies or separate agencies organized specifically for that purpose. In the United States, states that have the most serious mosquito problems (e.g., New Jersey, Florida, Texas, Louisiana, California) have many such agencies. Some are small and have responsibility for mosquito abatement in a few square kilometers, whereas the activities of others may encompass one or more entire counties. However, even in states that have many mosquito abatement districts, many people live in areas with no organized mosquito control. In undeveloped areas of the world, organized mosquito control is rare except for scattered programs aimed at specific diseases such as malaria.

Most organized mosquito control is accomplished by searching out mosquito larvae in standing water and then treating the water with some kind of material that kills the larvae. Modern materials are highly specific for mosquitoes and ordinarily have little or no effect on other organisms. One such material is a bacterial product called Bti (Bacillus thuringiensis israelensis) which produces a toxin that kills only larvae of mosquitoes, black flies, and certain midges. Mosquito abatement agencies may also apply chemical pesticides to kill adult mosquitoes, but ordinarily only when adult populations become so high that they cause extreme annoyance to many people or when the threat of disease transmission to people is high. Therefore, the most common method for this is known as ultralow volume (ULV). This approach involves using special equipment to spray extremely small volumes of small particles of highly concentrated insecticides. When used properly, it is a safe and highly specific method of mosquito control.

Control of irrigation water in agricultural areas to avoid excess runoff is an important mosquito control method, but in recent years elimination of small bodies of water that can serve as wildlife habitat has ceased to be a mosquito control option.

In the first half of the past century, elimination of bodies of temporary and permanent water (swamps, marshes, vernal pools) was an accepted form of mosquito control. Recent years have seen the realization that such habitats are valuable and irreplaceable components of the environment and that a variety of activities have resulted in the permanent loss of many of these wetland habitats. This loss has resulted in the development of mosquito management strategies that are more ecologically sound. Considerable research has been conducted on management strategies that enhance wetland habitats while minimizing problems from mosquito breeding.

Biological Control

A method that is a preferred alternative to chemical control is the use of live organisms to control mosquitoes, either by predation or by infection. Mosquitofish (the common guppy) have been used for many years for this purpose, often with effective results. However, because mosquitofish are generalist predators, they must be used with great care to avoid damage to other aquatic organisms. Many other forms of biological control for mosquitoes have been tried, including other types of fishes, fungi, bacteria, nematode worms, flat worms, protozoan parasites, and predaceous insects (including some mosquitoes). Some of these organisms have been effective under special circumstances, but few of them have been adopted widely. Microbial organisms such as Bti and Bacillus sphaericus may be considered biological control agents, and these are used to great advantage in a variety of aquatic habitats.

Insecticides

At one time there were dozens of insecticides available for killing both adults and immature stages of mosquitoes. However, because of economics, primarily the costs involved in developing, testing, and registering new materials, and the development of resistance to insecticides by mosquitoes, the number of available materials is now down to a handful. A class of insecticides known as insect growth regulators has been highly effective and specific for mosquitoes, but the development of resistance to even these materials has clouded the future of these so-called third-generation pesticides. The best hope for circumventing resistance to pesticides is the use of a combination of approaches referred to as pesticide resistance management. Frequent testing for susceptibility in mosquito populations, alternation of pesticides, and avoidance of methods that result in the persistence of low dosages of pesticides are examples of this approach. Insecticide resistance is under genetic control, and the goal of insecticide resistance management is preservation of genes in mosquitoes associated with susceptibility.

Protection from Mosquito Bites

People living in areas lacking organized mosquito control must protect themselves from bites of mosquitoes by using a variety of strategies. Probably the most effective method of personal protection from mosquito bites is to avoid places where mosquito densities are high and to avoid being out-of-doors at times of the day when mosquito activity is at its highest. In mountainous areas, most species of mosquitoes bite during the morning and afternoon, and often, they do not bite at all during periods of darkness. In low-elevation areas, some mosquitoes tend to bite at night, whereas others bite
during the day. The species of mosquito present in a given area varies from place to place, and it is necessary to learn the activity patterns of the mosquitoes present to develop avoidance strategies.

If exposure to biting mosquitoes cannot be avoided, there are several ways to minimize discomfort. The most important of these is to reduce exposed skin surfaces by wearing hats, long trousers or slacks, and long-sleeved shirts or blouses. Some mosquitoes bite through light clothing, but the number of bites received is definitely reduced if most areas are covered. When mosquito densities become very high, application of a mosquito repellent may be needed to avoid bites. For many years the only really effective repellents on the market were those containing the material DEET (N,N-diethyl-meta-toluamide). However, in recent years newer materials have been discovered that are equally effective, and there are now alternatives available to DEET-based repellents. Skin repellents have some drawbacks. After application, they are effective for only a few hours. Factors such as wind, high temperature, high humidity, and sweating can reduce time of effectiveness even further. When applying skin repellents, the material must be thoroughly applied to all exposed skin, including behind the ears. In recent years, longer-lasting repellent formulations have been developed by the incorporation of various additives such as lotions and polymers.

Many people have tried gadgets such as ultrasonic emitters, electric grids, aromatic plants, and even vitamins for mosquito protection. Research has shown that most such methods are of little or no value in repelling mosquitoes, but such devices continue to appear on the market. In some areas of the world incense coils are sold for protection. Research has shown that most such methods are of little or no value in repelling mosquitoes, but such devices continue to appear on the market.

Bednets can provide excellent protection from mosquito bites at night if used properly. The use of bednets treated with insecticides has been shown to afford excellent protection from attack by malaria mosquitoes. Insecticide-treated window and door nets also have been proven to help reduce mosquitoborne diseases in endemic areas. When they are available, vaccines may protect humans from mosquitoborne disease (e.g., yellow fever) and prophylactic drugs may be used to avoid some diseases (e.g., malaria).

MOSQUITOES AS SUBJECTS OF RESEARCH

Mosquitoes have been studied for their role as vectors of diseases of humans and other animals for well over a century. However, they have also been popular test animals for research on fundamental biological processes, both in the laboratory and in the field. Because mosquitoes occur in so many habitats all over the world, they present opportunities for a wide variety of ecological studies such as predator–prey interactions involving larvae. Further, many species can be colonized in laboratories. Because of their short life cycle intervals (many species can complete an entire life cycle from egg to adult in 7–10 days), large numbers of live mosquitoes can be produced for studies of physiological and biochemical processes common to many types of invertebrate animals. A. aegypti and C. pipiens are two species that can be colonized readily and have been studied extensively both for their importance as disease pathogen vectors and as test animals for biological phenomena. Genomics (the field of study involving the determination of the sequence of the entire genome of an organism) is an exciting new field that has great promise in understanding disease processes and their prevention and control. The genomic sequence has been determined for A. aegypti and C. pipiens, as well as for the important malaria vector Anopheles gambiae. Other arthropod species of medical importance, such as ticks and tsetse, are already the subject of genomics analysis. Fine-scale genetic studies of important mosquito disease vectors also open the door to the possibility of altering their genetic makeup, resulting in transgenic individuals with lethal traits or diminished vector capacity.

Mouthparts

R.F. Chapman†

University of Arizona

The mouthparts of insects are structures surrounding the mouth that are involved in the mechanics of feeding and processing and manipulating the food so that it can be ingested. Although functionally equivalent to the jaws of vertebrates, they lie outside the mouth, not within a buccal cavity. Good basic accounts of insect mouthpart structure are to be found in most textbooks of entomology. The aim of this article is to supplement these basic accounts by briefly considering some of the variations associated with different feeding habits and different types of food. It also gives some information on the functioning of the mouthparts.

BITING AND CHEWING INSECTS

Insect mouthparts are derived from the appendages of four of the segments forming the insect head. They surround the mouth

†Deceased May 2, 2003.
and are external to it, unlike the condition in vertebrates in which the teeth are within the oral cavity. The basic segmental character of the mouthparts is most apparent in insects that bite off fragments of food and then chew it before ingesting it (Fig. 1). Insects that do this are said to be “mandibulate” because the mandibles are relatively unmodified compared with those of fluid-feeding insects (see below). These are also commonly called biting mouthparts, although there is some risk of confusion with blood-sucking insects, such as mosquitoes, which bite! In this article the latter are distinguished as “piercing.” The mandibulate arrangement occurs in the primatively wingless insects (Apterygota), in the cockroaches and grasshoppers and their allies, in larval and adult beetles (Coleoptera) and most Hymenoptera, and in caterpillars (larval Lepidoptera), among the more advanced groups of insects.

**FIGURE 1** A lateral view of the head of a grasshopper showing the segmental arrangement of the mouthparts: labrum, mandible, maxilla, and labium. Arrows show the points of articulation (condyles) with the head capsule. The mandible has two condyles (dicondylic), the maxilla only one, and the labium one on each side. [Modified after Snodgrass (1935). “Principles of Insect Morphology,” McGraw-Hill].

Immediately in front of the mouth is the labrum formed from the fusion of the appendages on either side of the labral segment. It comprises a flat sclerotized plate of cuticle continuous with the cuticle of the front of the head (clypeus). Its inner side (toward the mouth) is known as the epipharynx, and it is formed from membranous cuticle-bearing tracts of noninnervated hairs, all pointing toward the mouth. In grasshoppers, and probably in other insects with similar mouthparts, the hairs are easily wetted, whereas the other parts of the cuticle are water repellent. The hydrophilic hairs may serve to direct the flow of fluid from the food toward the mouth and also to groups of contact chemoreceptors (taste receptors) that occur just outside the mouth. Contact chemoreceptors also often occur along the distal edge of the labrum. At rest, the labrum presses back on the mandibles, which are immediately behind it, being held in this position by a rubber-like protein, called resilin, in its connection with the clypeus.

The mandibles, one on each side, are hinged to the head capsule by one or two condyles. Archaeognatha have only one condyle (monocondylic), whereas Thysanura and all mandibulate pterygote insects have two (dicondylic). The change from one to two condyles represents a considerable evolutionary advance because it gives the mandibles a much firmer base and so facilitates feeding on hard materials. The mandibles of the two sides swing transversely to meet below or in front of the mouth, depending on the orientation of the head, and are opened and closed by a pair of muscles, one inserted on either side of the axis of mandibular attachment at the condyles. The opener muscle is called the abductor, whereas the closer is the adductor. The latter is the larger of the two because it provides the force necessary to bite into or through material. Both muscles arise on the cuticle at the top of the head and, in grasshoppers and caterpillars, the head capsule grows bigger to accommodate the increased size of the adductor muscle if the insect feeds on tough food.

The two mandibles are asymmetrical so that where they meet in the midline the cusps on the biting surface of the two sides fit between each other (Fig. 2). These cusps are extremely hard. In addition to being sclerotized like the hard cuticle elsewhere in the body, their cuticle contains zinc or manganese or, occasionally, iron, which are assumed to contribute to the hardness. The form of the biting cusps varies from species to species in relation to feeding habits in a way that, superficially, is comparable with the adaptations in the jaws of mammals. Predaceous tetttigoniids, for example, have a sharply pointed cusp distally and powerful blade-like cusps more proximally that have some resemblance to the canine and carnassial teeth of carnivorous mammals and presumably serve similar functions of grasping and tearing the prey. Among grasshoppers, species feeding on soft, broad-leaved plants have small, sharply pointed cusps that cut the food into very small fragments. Grass feeders, on the other hand, have very long, chisel-edged incisor cusps distally with short, flattened molar cusps proximally, which can superficially be compared with the chisel-shaped incisors and grinding molars of mammalian herbivores. Other insects also exhibit food-related modifications of the mandibles. The cusps become worn down with use, especially if the insect is feeding on hard foods, and there is some evidence that this wearing down reduces the rate of food intake. The cusps can be renewed only at a molt, when new cuticle is formed.

**FIGURE 2** Mandibulate mouthparts. Mandibles, seen from in front with the labrum removed, of grasshoppers with different feeding habits. Notice that the mandibles of the two sides are asymmetrical. (A) A grasshopper that feeds on soft, broad-leaved plants. (B) A grasshopper that feeds on grasses. [Reproduced, with permission, from Iseley, F. B. (1944). Correlation between mandibular morphology and food specificity in grasshoppers. *Ann. Entomol. Soc. Am.* 37, 47–67.]

In insects eating food that requires special treatment during ingestion, the mandibles may become highly modified. An example occurs in the larvae of pergine sawflies (Fig. 3). These Australian insects feed on *Eucalyptus* and related trees, the leaves of which are rich in essential oils. The insects sequester the oils in a diverticulum of the foregut and use them for defense. The mandibles are apparently adapted for separating the oils from the leaf tissue. Sticking out from the center...
of the mandible is a structure called the scopa mandibularis. It is covered by rows of pointed setae and these, perhaps by scraping and shredding the leaves, seem to be involved in extracting the oils.

In the midline, immediately behind the mouth and probably also derived from the mandibular segment, is the hypopharynx. This structure is a lobe of mostly membranous cuticle but with rods of sclerotized cuticle to which muscles are attached. Like the epipharynx, it bears tracts of hairs pointing toward the mouth and these hairs probably help to move food toward the mouth as the hypopharynx is moved by its muscles.

Behind the mandibles are the maxillae, one on each side of the head. Each maxilla articulates with the head capsule by a single condyle so that it is extremely mobile. This high degree of movement allows the maxillae to manipulate food between the mandibles and move it toward the mouth. The lacinae at the distal ends of the maxillae are especially important for this and they are usually curved and pointed with the tip hardened like the mandibles. The maxillary palps are leg-like structures often with three to five segments and they have an important sensory function. At the tip of each palp is an array of contact chemoreceptors; in a large grasshopper there may be as many as 400 chemosensilla on the tip of each palp. These receptors have an important role in food selection. Grasshoppers drum on a leaf surface with the palps before accepting or rejecting it as food, and they continue to drum at intervals during feeding. Chemoreceptors are also present on the galea, a distal lobe of the maxilla immediately lateral to the lacinae.

The labium is essentially similar in structure to the maxillae but with the appendages of the two sides fused together in the midline behind the hypopharynx. There is a single articulation with the head capsule on each side, which allows the labium to swing beneath the head in the vertical plane of the body. It provides a scoop that prevents food from spreading backward from between the mandibles. As with the maxilla there are two terminal extensions on each side, known as the glossa and paraglossa. There is also a leg-like labial palp with chemoreceptors at the tip.

The labium is uniquely developed in larvae of dragonflies and damselsflies, forming their prey capture equipment. The form is basically similar to the labium of other insects except that the basal parts are lengthened and the palps are claw-like. It is sometimes called a labial mask because the distal parts cover the lower part of the face when the labium is folded beneath the head. The mask can be suddenly extended by hemolymph pressure, enabling the larva to capture prey a little distance in front of it without moving its body.

FLUID-FEEDING INSECTS

Many insects feed on liquid food and their mouthparts are modified to form a tube through which fluid can be drawn into the mouth and, often, another tube through which saliva is injected into the food so that it is digested to some extent before being ingested. In most fluid-feeding insects the basic segmental arrangement and appendicular form of the mouthparts are no longer obvious, but some predaceous larvae that feed on the body fluids of their hosts are mandibulate, with mandibles resembling those of insects feeding on solid food. These are larvae of lacewings and ant lions (Neuroptera), glowworms (Lampyridae), and dytiscid beetles. In all of them, the mandibles are sickle shaped with a groove along the inner edge. In the beetles, the two sides of the groove arch over to meet, or almost meet, so that a tube is formed. In ant lions, the lacina of the maxilla is also sickle shaped and it fits in the mandibular groove to form an enclosed canal. These insects can pump the fluid contents of their prey into the foregut through the tubes.

In other fluid-feeding insects, the basic segmental arrangement of the mouthparts is not apparent and in many insects the mouthparts themselves are drawn out into long, slender structures called styllets. The food and salivary canals are formed in different ways in different insect groups. In Hemiptera, both canals are formed between the stiltiform maxillae, which interlock by a tongue-and-groove mechanism that permits them to slide lengthwise with respect to each other but prevents them from coming apart (Fig. 4). They are supported in a groove along the anterior margin of the elongate labium, which is often referred to as the rostrum. The food canal is formed between the maxillary galeae in Lepidoptera, but here the two sides are linked by a series of cuticular hooks and plates that hold the two sides together while allowing them to coil up beneath the head when not in use (Fig. 5). This device makes it possible for some lepidopterans to have an extremely long tongue, which would not be possible if the insect were unable to...
The stylets of aphids and coccids are very flexible and usually follow intercellular pathways that may be quite tortuous.

The watery saliva of aphids contains a pectinase that degrades the pectin, which is present on a surface, but other fluid-feeding insects obtain their food from within plants or other animals and so must pierce the host tissues. The stylets of aphids and coccids are very flexible and can penetrate the plant. The stylets are within the cell wall, which is surrounded by a sheath of solidified saliva that is produced as they penetrate the plant. The stylets are within the cell wall, which is seen in its normal form at lower left. [Reproduced, with permission from Elsevier Science.]

FIGURE 4 Piercing and sucking mouthparts of a hemipteran. Electron micrograph of a transverse section through part of the stylet bundle of an aphid within a leaf. Notice how the maxillary stylets interlock to form the food canal and the salivary canal. The stylets are surrounded by a sheath of solidified saliva that is produced as they penetrate the plant. The stylets are within the cell wall, which is seen in its normal form at lower left. [Reproduced, with permission from Elsevier Science.]

The ventral surface of each labellum is invaginated to form a series of pseudotracheae. These pumps in the head and give the channels an appearance that is superficially like that of tracheae and so they are called pseudotracheae. The labellum, with the pseudotracheae, enables the fly to draw fluids from a relatively large surface. The channels open to the exterior via a narrow groove that is closed off during feeding except for occasional openings through which fluid can pass freely. Fleas have the food (blood) channel between a highly developed epipharynx and the two maxillae. There are two salivary canals, one in each maxilla.

The mouthparts of bees are unusual among the fluid-feeding insects. They retain normal mandibles that are used for wax and pollen manipulation, but are not involved in nectar feeding. The other mouthparts retain some semblance of the appearance in biting and chewing insects, but are elongate. The two glossae (parts of the labium) are fused together to form an elongate tongue with an open gutter posteriorly. The glossal tongue is surrounded by the lengthened and flattened galeae (of the maxillae) and labial palps. The food canal is formed by the space between the glossal tongue and the other components.

Lepidoptera, bees, and some flies feed from fluids, often nectar, that is present on a surface, but other fluid-feeding insects obtain their food from within plants or other animals and so must pierce the host tissues before being able to feed. This is true of all Hemiptera, fleas, and some flies. In Hemiptera, the mandibular stylets are the main piercing structures. The relatively stout labium does not enter the wound, but folds up beneath the insect as the mandibles and maxillae penetrate deeper into the host tissues. The stylets of aphids and coccids are very flexible and usually follow intercellular pathways that may be quite tortuous. The watery saliva of aphids contains a pectinase that degrades the pectin of the cell walls and facilitates movement of the stylets.

Among blood-sucking flies, the maxillae are the primary piercing organs of female mosquitoes (Fig. 7). They have recurred teeth...
distally that probably anchor the stylets in position in the wound so that when the retractor muscles contract they pull down toward the host skin, pushing the labrum into the wound at the same time. Male mosquitoes do not feed on blood and, in many species, the piercing stylets are greatly reduced. Horse flies and deer flies (Tabanidae) have a completely different mechanism. Their somewhat elongate mandibles are articulated to the head capsule so that they move transversely, like the mandibles of biting and chewing insects. This scissor-like motion cuts through the skin of the host and the labrum and maxillae are forced into the wound. The labium does not enter the wound and blood is taken directly into the food canal on the inner side of the labrum. For example, compare Fig. 8B, which depicts the rasps and spines on the inside of the labellar lobe and pointing downward, with Fig. 8C, in which they are on the outside and pointing upward. Contact chemoreceptors are also exposed as the teeth are moved around the tip of the labellar lobes so that they are in a position to detect blood as the host’s capillaries are damaged.

Once the insect starts to feed, the properties of the fluid and dimensions of the food canal affect the rate of uptake and so the rate of nutrient intake. The more viscous a fluid, the more slowly it flows, so that although nectar containing high concentrations of sugars has more nutrients per unit volume, it also is taken up more slowly than a more dilute solution. The flow rate is also negatively correlated with the length of the proboscis, but positively correlated with the diameter of the food canal; the greater the diameter of the canal, the faster the fluid flows.

Movement of fluid into the gut is affected by three factors: the hydrostatic pressure of the fluid in the host organism, capillarity, and muscular activity. If the fluid is under high pressure, simply piercing the vessel containing it is sufficient for the fluid to be forced out, just as water gushes out from a burst water main. Phloem, the fluid carrying sugars and amino acids away from photosynthetic tissues to other parts of a plant, is under such positive pressure, up to 1 MPa, and, consequently, phloem-feeding insects, such as most aphids, have simply to penetrate a sieve tube and the phloem is forced through the food canal and into the gut. If the stylets are cut experimentally, phloem continues to ooze out, and this oozing provides a method for obtaining samples of phloem. Although vertebrate blood is under
pressure, pressure in the blood capillaries is probably too low to play a major part in forcing blood into the insect's gut.

Xylem, in contrast to phloem, is under high negative pressure which may exceed ~1 MPa. Xylem is the fluid imbibed by the roots of plants and drawn upward through xylem vessels as a result of water loss (transpiration) from the leaves. Consequently, insects that feed on xylem require a powerful pump to overcome this negative pressure and draw the fluid into the mouth. Cicadas have a highly developed cibarial pump made obvious externally by the inflated clypeus. The cibarium is the space between the mouthparts, outside the mouth. In fluid-feeding insects, this space forms a continuum between the mouthparts and the mouth. Blood-sucking insects such as mosquitoes also have a cibarial pump, but it is less well developed than the pharyngeal pump formed by the first part of the foregut.

The importance of capillarity in insect feeding is not well understood. Insect cuticle, in general, tends to be water repellent but, if the cuticle lining the food canal in the mouthparts is wettable, capillarity might be important. In honey bees, when the glossal tongue is dipped into nectar, the fluid adheres to it, being held in place by hairs that project from the surface of the tongue. The glossa is drawn in and out between the folds of the galeae and labial palps and it is probable that capillarity is important in drawing the fluid toward the mouth.

**Movies, Insects in**

May R. Berenbaum, Richard J. Leskosky

*University of Illinois*

The ubiquity of insects and the frequency of their interactions with humans virtually ensure that they will feature prominently in cultural contexts. Throughout history, insects have conspicuously appeared in a range of visual media, including painting, sculpture, printing, and engraving. Thus, with the advent of film in the late-19th century, insects were depicted in some of the earliest efforts; since then, they have made appearances in virtually every form of this modern medium. As the 21st century begins, insect images are common in film and television, and their role in cinema is firmly established. In fact, their impact on culture has been so pronounced that references to insect movies even serve on occasion as punch lines in jokes and cartoons, and the expressions “big bug film” and “insect fear film” are widely recognized.

**THE TAXONOMY OF CINEMA**

What constitutes an insect in cinema is not necessarily consistent with scientific standards. In the taxonomy of cinema, any jointed-legged, segmented organism with an exoskeleton is likely to be classified as an insect, irrespective of how many legs or how few antennae it possesses. For example, in *Sherlock Holmes and the Spider Woman*, Holmes identifies a spider (used by the Spider Woman to dispatch her victims) as *Lycosa carnitorea* from the Obongo River in Africa, the “deadliest insect known to science”; in actuality, spiders are classified as arachnids and not as insects. Taxonomic categories are also ill defined in cinema; in the film...
Tarantula, for example, the artificial-nutrient-enhanced giant spider is identified as being “from a species called Arachnida—a tarantula, to be exact.” The taxon Arachnida is not a species; rather, it is a class, containing thousands of species. In Mimic, the eminent entomologist Dr. Gates, mentor of a young scientist engaged in genetic engineering experiments with cockroaches, makes reference to the “Phylum Insecta.” Again, “Insecta” is the name of the taxonomic unit called a “class”; the phylum to which insects belong is Arthropoda.

Insect morphology in the movies reflects the relatively sketchy familiarity most filmmakers have with entomological reality. As is the case for real-life insects, most movie insects have six legs, whereas movie arachnids often have eight. In general, movie insects also have the three characteristic body regions—head, thorax, and abdomen—that differentiate them from other arthropods. Even at the ordinal level, many morphological features are depicted with some degree of accuracy. Movie mantids can have raptorial forelegs (e.g., The Deadly Mantis), and movie lepidopterans (e.g., Mothra, the giant moth that attacked Tokyo in a series of Japanese films from the 1960s) possess scales. Large flat objects of the size of pie plates scattered around the countryside (eventually identified as oversized scales) provide evidence of an enormous moth in The Blood Beast Terror.

Other aspects of insect anatomy, however, are not so accurately portrayed. Compound eyes are cause for some confusion; many films present an “insect-eye” view of a particular scene (usually a victim-to-be) through a filter lens, to simulate what is imagined to be the image created by compound eyes (e.g., in Empire of the Ants). In reality, these images appear to insects to be more like mosaics than repeated images. In Monster from Green Hell, the compound eyes of the cosmic wasps roll in their sockets; real compound eyes are incapable of such motion. Antennae are also poorly understood anatomical features; on occasion, movie arachnids are equipped with a pair, even though antennae are lacking in real-life arachnids (e.g., the 1973 animated Charlotte’s Web). Not surprisingly, mouthparts (whose intricacies in real insects are rarely visible to the naked eye) in movie arthropods often bear little resemblance to real arthropod mouthparts.

Insect physiology in movies often bears only a passing resemblance to the physiology of real arthropods. According to Dr. Elliot Jacobs, the entomologist in Blue Monkey who assists in attempting to control an outbreak of genetically engineered mutant cockroaches in a hospital, “Insects aren’t like humans or animals. They’re 80% water and muscle. They have very few internal organs.” A recurring conceit in insect films is the violation of the constraint imposed by the ratio of surface area to volume—movie arthropods routinely grow to enormous size without suffering the limitations of tracheal respiration or ecysis and sclerotization experienced by real-life arthropods. Nonetheless, there are physiological attributes of film arthropods that are reproduced with some degree of fidelity. Insect pheromones are hotly featured in a number of films (although they are not always identified as such; in The Bees they’re called “pheromones”). In Empire of the Ants, for example, giant ants use pheromones to enslave the local human population and to compel the humans to operate a sugar factory for them. The explanation provided for the response is that a pheromone “causes an obligatory response—did you hear that? Obligatory. It’s a mind-bending substance that forces obedience….” Although they have long been documented to exist in a wide range of organisms (including humans), pheromones rarely appear in science fiction films outside an entomological context.

As is the case with insect physiology and morphology, insect ecology takes on different dimensions in the movies. Life cycles are orthodox and generally dramatically abbreviated by entomological standards. In Mosquito, for example mutated mosquitoes, the offspring of normal mosquitoes that had consumed the blood of aliens in a crash-landed UFO, have a life cycle consisting only of egg and adult stages. In Ticks, full-grown ticks ecloge from what seems to be a cocoon. Population dynamics differ as well. A number of movie arthropods seem to have a population size of one (as evidenced by the titles—e.g., Tarantula, The Deadly Mantis), and reproduction does not seem to occur (at least over the 2-h span of the movie). At the other extreme, populations often build up to enormous sizes without depletion of any apparent food source. Bees blacken the sky in The Bees and The Swarm in a remarkably short period of time with no superabundance of nectar sources in evidence. It must be assumed that food utilization efficiencies of virtually all film arthropods are far higher than they are in real life because arthropods in films, giant or otherwise, rarely produce any frass (e.g., in Beginning of the End, giant grasshoppers consume several tons of wheat in a 3-month period with little or no frass to show for it). In Starship Troopers, it is unclear what the giant arthropods living on a planet that is bereft of other life-forms eat to attain their large size. However, because they are alien arachnids, terrestrial biological standards may not necessarily be applicable.

Insect behavior in big bug films is often biologically mystifying. Screen insect predators and herbivores alike almost invariably announce their presence with an ear-piercing stridulating sound (e.g., Them, The Deadly Mantis, Beginning of the End, Empire of the Ants); in reality, such behavior would alert prey to danger and elicit escape or defensive behavior (which, on the part of humans in many films, involves machine guns and bazooka fire directed at the insect). For example, in Beginning of the End, a television newscaster updates viewers in Chicago on the Illinois National Guard’s efforts against hordes of gigantic radiation-induced mutant grasshoppers descending on the city, reassuring them that “the one advantage our forces hold over the enemy is that they ALWAYS reveal their intention to attack. Before every attack the locusts send forth this warning in the form of a high-pitched screech. Now, this screech increases in intensity until it reaches ear-shattering proportions. And it’s when this screech reaches its full intensity that the locust attacks.” Such maladaptive behavior is unlikely to persist in nature.

**INSECTS IN ANIMATED FILMS**

Until the mid-20th century, insect representation in cinema was restricted largely to animated films. The small size of insects presented challenges to the standard equipment of the time that could not be met without either a disproportionate increase in cost or a decrease in visual quality. In animated films, however, technical limitations could be avoided; to create the illusion of a close-up, the animator can simply draw a larger image. In animated films, one or two frames are exposed at a time, and between exposures small changes are introduced; for example, one drawing may be substituted for another slightly different drawing or a puppet or clay model slightly repositioned. When the film is projected at normal speed, the image appears to move. An insect may even have inspired one film pioneer to become one of the first animators. Segundo de Chomon, a Spanish filmmaker of the late 19th and early 20th centuries, allegedly conceived of the animation process while shooting intertitles for a silent film and noticing that a fly, included on the footage exposed a frame at a time, appeared to move in a jerky fashion when the film was projected.

This is not to say that insects were not a challenge to animators. Because of their many moving body parts—six legs, two antennae, and from two to four moving wings—many animators simplified their drawing by reducing appendages. Thus, in animated films, insects may be depicted with four instead of six legs and spiders with six instead
of eight. The first appearance of an insect in an animated cartoon was in a 1910 film by Winsor McCay titled How a Mosquito Works—the second American animated cartoon. Although McCay accurately portrayed his mosquitoes with six legs and two wings, in contrast with later animated films featuring insects with reduced appendages, even this early film contains many of the other conventions typically found in insect cartoons—an adversarial relationship between humans and insects, as well as the depiction of insect mouthparts as tools. McCay showed the film in vaudeville houses to large crowds and later returned in insects, as well as the depiction of insect mouthparts as tools. McCay showed the film in vaudeville houses to large crowds and later returned to the use of insect characters with his 1921 film Bug Vaudeville.

Another very early example of puppet animation was provided by entomologist-turned-animator Wladislaw Starewicz. In attempting to film the mating behavior of stag beetles, Starewicz discovered that the hot lights used to illuminate his subjects caused them to stop moving altogether; accordingly, he killed and dismembered the beetles and wired their appendages back onto their carcasses, painstakingly repositioning them for sequential shots in the short film The Fight of the Stag Beetles. That film and its fictionalized sequel, Beautiful Lucanida or the Bloody Fight of the Horned and the Whiskered, proved to be quite popular with audiences. Starewicz expanded his efforts, eventually abandoning real insects and constructing puppets de novo for his later films with more complex plots (as in Revenge of the Kinematograph Cameraman, a story of love and betrayal among a variety of insect species).

Arguably the most well-known animated arthropod was Jiminy Cricket, who initially appeared in a supporting role in the 1940 Walt Disney feature Pinocchio. Disney animators used a talking cricket, a minor character that appeared in the original Pinocchio story by Carlo Collodi, to unify disparate elements within the film. The character proved to be popular as a “voice of conscience” and appeared in several series of subsequent short subjects and educational films. Jiminy exemplifies the liberties taken with insect morphology by animators; although early sketches depicted the character with more insect-like features, the final film version, with its two arms and two legs, eyes with pupils, and morning coat and vest, resembles a dapper elf more than any arthropod.

Computer animation developed at a rapid pace during the 1980s and has proved particularly well suited to depicting insects. Modern methods of computer-generated imagery (CGI) have become particularly effective at creating shiny metallic surfaces and at joining slender rodlike structures to larger volumes—precisely suited to depict an insect’s exoskeleton and multiple appendages. The first computer- animated insect was Wally-Bee, in the 1984 short film from Pixar titled The Adventures of Andre and Wally-Bee; this film was the first computer-animated short film with a plot line. That CGI offers technological advantages over traditional animation is not to say that it has resulted in more realistic animated insects. A Bug’s Life (1998) from Disney/Pixar continued to depict insects with anthropomorphized faces and four limbs to ensure audience empathy with the characters; the DreamWorks film AntZ (1998) gave its ants six legs but provided them with similarly humanized faces and raised the head and thorax into a vertical position, making them look like tiny centaurs. CGI is not limited to what is basically caricature, however; the otherwise live-action Joe’s Apartment (1996) featured hundreds of computer-rendered cockroaches which were indistinguishable from the real thing, except for their ability to sing and dance.

INSECTS IN FEATURE FILMS

Big Bug Films

Frequent appearances by insects in live-action films are a relatively recent phenomenon in the history of film. For many years, the technical challenges of filming very small, largely untrainable, fast-moving creatures was a disincentive for incorporating them into films. The pioneering efforts of special-effects genius Willis O’Brien, starting in the 1930s, and of his protégé Ray Harryhausen, as well as technical advances in the production of film stock and traveling matte techniques, gradually made the incorporation of insect images in film economically attractive, or at least reasonable. Moreover, competition for audiences, particularly with the rise of television, led the major film studios to increase investment in hitherto minor genres, such as science fiction. With bigger budgets, more elaborate effects became feasible.

The year 1954 was a watershed year; Them! was released by Warner Brothers Studios, featuring giant ants mutated by exposure to atomic testing in the Arizona desert (Fig. 1). The film, tapping into widespread fears of atomic power in the aftermath of World War II,
was an enormous success, grossing more money for the studio that year than any other and winning an Academy Award for special effects. Its success is understandable in retrospect: its use of large mechanical models was innovative and dramatic, its screenplay was tight and well written, it featured several big-name actors of the era, and its subtext about invasion disrupting the fabric of American life played well to American fears of communist powers.

The “big bug films” inspired by the success of Them! were by and large lesser efforts. Many of these were the work of director/producer Bert I. Gordon, who made so many films with big animals that he was known as “Mr. Big” (a reference as well to his initials—B.I.G.); his big bug films included Beginning of the End (1957), featuring giant radiation-induced grasshoppers threatening to destroy Chicago, and Empire of the Ants (1977), about giant radioactive-waste-induced ants threatening a real estate development in Florida. Other notable titles of the 1950s in the “big bug” genre (Table I) include Tarantula, The Deadly Mantis, The Black Scorpion, Monster from Green Hell, and Earth vs the Spider. The Japanese film industry did not embrace this genre until the 1960s but made up for the slow start in volume; the first Japanese big bug film, Mothra, featuring a giant radiation-induced moth, was released in 1962 and was followed by four sequels, in which Mothra appeared with other “big” science fiction stars such as Godzilla and Rodan.

Transformation/Metamorphosis Films

Metamorphosis is a characteristic of a substantial proportion of movie arthropods, although the film version is often at variance with reality. The transformation most frequently depicted in films is insect to human or human to insect, generally involving some form of exchange of body fluids—“Drosophila serum” in the case of She Devil (which allows the patient to transform herself at will from brumette to blonde), “spider hormones” in Mesa of Lost Women, “royal jelly” in Wasp Woman, and “DNA” in the 1986 remake of The Fly.

Insects most likely appear frequently in films involving metamorphosis because of the shock value—the transformation of a human into a life-form radically different in appearance. Generally, transformations of humans into other animal forms in films involve magic or re-creation (The Shaggy Dog, The Shaggy D.A., Oh, Heavenly Dog, Lucky Dog) or genetic predisposition (Teen Wolf and its sequels, The Howling and Cat People) rather than mediation by hormones (with the exception of the early films of Bela Lugosi, including The Ape Man and Return of the Ape Man, which involve serum exchanges between humans and apes).

In the 1980s, insect fear films acquired a new life with the release of David Cronenberg’s The Fly. Although as scientifically as inaccurate as earlier efforts with respect to surface area/volume rules, it was generally regarded by critics as an artistic success, thematically depicting physical transformation leading to mental and emotional change. Although The Fly II (directed by Chris Walas, special-effects artist on the earlier film) was not embraced as enthusiastically by critics, it nonetheless was perceived as more than just a horror film, with allegorical elements relating the physical and emotional changes of adolescence with the metamorphic transformation of the protagonist. Despite the presence of redeeming intellectual content in these films, these films attracted considerable attention for their graphic special effects, far surpassing earlier efforts.

In 1983, the first report of successful genetic transformation of an insect (Drosophila melanogaster) was published, and by 1987 genetically engineered insects (specifically, mutant killer cockroaches) made their first appearance in a science fiction film, in the otherwise unremarkable film The Nest. Genetic engineering techniques advanced more quickly on screen than in real life; by 1997, in Mimic, the young entomologist Susan Tyler (Mira Sorvino) is able to incorporate termite and mantid DNA into cockroaches, with the goal of creating a “Judas bug” to bring contagion to the cockroach vectors of a human illness but instead unleashes a plague of 6-foot-tall people-eating cockroaches in the subway system of New York City. In Spiders, unspecified alien DNA is incorporated into the titular arthropods to wreak havoc in a secret government laboratory.

“Social” Insect Films: Small Size, Large Numbers

One of the largest orders of real-life arthropods, the Hymenoptera, is in fact the most frequently depicted in insect fear films. There may be several reasons for this proportional similarity. For example, bees are relatively easily manipulated for the camera in comparison with other insects, can be produced commercially, and can be reared in enormous numbers with comparative ease. Perhaps an even more important factor, however, is their familiarity to the audience. Encounters with bees, ants, and wasps are part of the normal course of life for most moviegoers. Such an explanation also can account for the proliferation of films involving cockroaches, although these, too, share the practical advantage of ease of rearing in enormous numbers and affordability.

Films using footage of real insects engaging in more or less normal insect behaviors rose to prominence in the 1970s and included such efforts as Phase IV, featuring documentary-quality footage of ants, and Bug, featuring Madagascar hissing cockroaches (albeit engaged in some unusual behaviors, such as spelling out death threats with their bodies on the wall of a house). The appearance of African “killer” bees on a container ship in San Francisco harbor in 1974 may have inspired filmmakers to capitalize on a real threat—the introduction of African honey bees whose heightened aggression can cause problems for pets, livestock, and humans. The films proved popular with filmmakers in part because audience members enter the theater with at least passing familiarity with the film’s antagonists (in contrast with giant arthropods). As well, bees can be controlled chemically—by pheromones—to cluster or land in a particular spot and so are more easily manipulated for special effects. Five films were made about killer bee invasions between 1974 and 1978 (Table I), although none of them was particularly successful at the box office (despite, in the case of the 1978 film The Swarm, a screenplay by renewed science fiction writer Arthur Herzog and a cast with such Academy Award-caliber actors as Henry Fonda and Michael Caine).

In many of the films featuring large numbers of small insects, ecological disruption is a recurring theme. Biomagnification, accumulation of toxins up a food chain, is the focus of Kingdom of the Spiders; tarantulas take over a town and start consuming livestock because “DDT” destroyed the food chain and deprived them of their normal prey. Other films depicting altered food web dynamics as a result of pollution (radioactive and/or toxic waste) include Skeeters and Empire of the Ants. In Ticks, fertilizers and other chemicals used by illegal marijuana growers are encountered by ticks, which grow to enormous size and terrorize a group of inner-city teens in the woods on a wilderness survival trip.

Another ecological phenomenon of concern both in the movies and in real life is the accidental introduction of alien species (although in the movies these are more likely to be real aliens, from outer space, not just a foreign country). Arachnophobia depicts the fictional consequences of the accidental introduction of a South American

*Made-for-television movie.
spider species to the Pacific Northwest. The many killer bee movies pointedly make reference to the dangers of accidental importation of strains of bees into new habitats (although in *The Bees* their introduction is no accident; greedy cosmetics magnates import killer bees in the hope of producing large amounts of profitable royal jelly).

## INSECTS IN DOCUMENTARY FILMS

Although educational shorts for school and extension markets often deal with entomological topics, documentary filmmaking, which combines information and art, has tended to skirt insect subjects. For a long time, documentary filmmakers faced many of the same challenges faced by feature filmmakers with an interest in insects. Only in the latter half of the 20th century did developments in technology permit the capture of small moving objects (such as insects) on film in a compelling and effective manner. Yet another obstacle, particularly problematic for documentary filmmakers, was audience interest; whereas audiences could accept insects bent on destruction of the human race in science fiction or horror films, they generally showed considerably less interest in the accurate depiction of the lives of real-life insects. Animal documentary filmmakers have long had to accept the fact that audiences prefer drama to accuracy in depictions of nature. Walt Disney, with his groundbreaking *True Life Adventure* nature films made between 1948 and 1970, relied in many of his nature films on personification and anthropomorphism to make the animal subjects of studio films more appealing to audiences.

Arguably the first “documentary” films involving insects were the pioneering efforts of F. Percy Smith, who in 1912 created films aimed at illustrating the physical prowess of the common house fly. Smith enclosed a fly inside a dark box equipped with a thin glass door at one end; the door in turn had a small opening into which was fitted a toothed wheel that was free to rotate. The fly, orienting to the light entering through the glass door at one end of the box, would move toward the light; when it encountered the glass door obstructing its escape, it was struck on the head by a tooth in the wheel which rotated as a consequence of the fly’s movements. Eventually, via conditioning, the fly simply walked up the wheel, which would rotate, creating a treadmill and providing the photographer an opportunity to film the fly walking in place. Smith modified his approach to film flies outside the box, tethered in place, and in this way was able to obtain footage of them seemingly juggling dumbbells, corks, bits of vegetables, other flies, and sundry other objects. When the film was released, newspaper reports accredited the cinematographer with the ability to train house flies as others do circus animals.

Audience reluctance to accept insects for their own sake is the explanation for the peculiar framing device used in the first big-budget feature-length documentary about insects, *The Hellstrom Chronicle*. This film was originally conceived as a straightforward documentary and featured what was at the time state-of-the-art macrophotography that provided startling and dramatic close-ups of its arthropod subjects. The extraordinary inventiveness of cinematographer Ken Middleham led to spectacular images of insects engaged in a wide range of behaviors. However, the studio heads were unconvinced that a documentary about insects could bring in an audience and insisted on adding to the film a fictional storyline, about an academic, Dr. Nils Hellstrom (Lawrence Pressman), denied tenure because of his insistence that insects were bent on human destruction. As a result, the hybrid film was a commercial success as well as an artistic success of sorts (earning a Grand Prix de Technique award at the 1971 Cannes Film Festival for its remarkable images), although it was panned by critics, in part because of its sensationalistic tone.

A general awakening of the American public to environmental issues in the 1970s did little to inspire interest in insect biology, and insect documentaries have been few and far between since *The Hellstrom Chronicle*. Insects figured peripherally in the documentary *Cane Toads: An Unnatural History*, directed and written by Mark Lewis, and first shown in 1988. The cane toad *Bufo marinus* was deliberately introduced into North Queensland, Australia in 1935 to control *Lepidodermum albolirium* (a beetle larva) and its relatives. Although the cane toads were ineffectual biocontrol agents, they were exceptionally effective colonizers and they now populate much of Queensland, northern New South Wales, and eastern Northern Territory, wreaking ecological and environmental havoc. The history of this ill-conceived biocontrol effort and its consequences are the subject of the documentary.

*Microcosmos* (1996) is similar to *The Hellstrom Chronicle* in that its success was due largely to quantum improvements in capturing insect images and behavior on film. Filmmakers Claude Nuridsany and Marie Perennou spent 15 years researching, 2 years designing equipment (including inventing a remote-controlled helicopter for aerial shots), 3 years shooting, and 6 months editing a masterpiece of insect cinematography. Yet the concept underlying the film was quite novel. Instead of a “supernatural” film involving insects, the filmmakers settled on the idea of telling the story of a single summer day (albeit in reality filmed over a much longer period of time) in a field in the countryside of Aveyron, France (where they lived and worked). Their goal was to depict insects and other small creatures not as “small bloodthirsty robots” but rather as individuals with unique abilities. Instead of narration, there was a simple introduction, 40 words, spoken by actress Kristin Scott Thomas. *Microcosmos* was well received by critics (although it failed to win a nomination for best documentary at the Academy Awards), and it performed respectfully at the box office. Although some notable entomologists bemoaned the absence of voiceover and the loss of an opportunity to educate the public about the insect lives captured on film, the extraordinary images depicted on screen will likely set the standard for excellence in insect documentary filmmaking for years to come.

## INSECT WRANGLERS AND SPECIAL EFFECTS

Because handling insects and other arthropods and eliciting appropriate behaviors from them on cue is beyond the experience and training of most directors, these responsibilities are frequently delegated to a specialized crew member known in the profession as an “insect wrangler” or “bug wrangler.” Since the early 1960s, only a handful of individuals have engaged in this occupation in a conspicuous way. Some insect wranglers specialize in handling a narrow range of taxa. Norman Gary has been a bee wrangler for more than a quarter-century. Currently an emeritus professor at University of California at Davis, he served as a faculty member in bee biology from 1962 to 1994. His research interests have been in the area of bee behavior, and he has written or coauthored over 100 publications on bees. Since 1966, he has been a consultant for legal, industrial, film, and television productions about bees. His ingenuity in developing methods for manipulating bees and their behavior has led him to develop methods of narcotizing queens to facilitate instrumental

Another individual with an affinity for a particular taxon is Ray Mendez, who worked as an entomologist at the American Museum of Natural History in New York. Mendez, along with colleague David Brody, provided over 20,000 cockroaches for the film Creepshow in 1982; in 1996 Mendez wrangled 5000 live cockroaches and provided advice on animated and puppet cockroaches for the film Joe's Apartment. Mendez is also an authority on naked mole rats and was featured in the documentary Fast, Cheap and Out of Control.

Steven R. Kutcher, a consulting entomologist in Arcadia, California, and part-time biology instructor at West Los Angeles College, is notable for the range of arthropods with which he has worked. Kutcher obtained a bachelor's degree in entomology at University of California at Davis and a master's degree in biology with an emphasis on insect behavior and ecology at California State University, Long Beach. Since 1976 he has been involved in arthropod wrangling for many movies and commercials. He has worked with a variety of arthropods, including spiders, yellowjackets, cockroaches, mealworms, grasshoppers, and several species of butterflies. Among his film credits are Extremities, Exorcist II: The Heretic, Arachnophobia, Race the Sun, Jurassic Park, and Spiderman. His unusual vocation has made him the focus of more than 100 print articles, and in 1990 his work was the subject of a short documentary by National Geographic.

**INSECT FEAR FILM FESTIVALS**

The idea of using insects in movies as a means of entomological outreach apparently dates back to the origins of the annual Insect Fear Film Festival at the University of Illinois at Urbana-Champaign. The first festival, brainchild of then assistant professor of entomology May Berenbaum, was held in March 1984. The goal of the festival has been to recruit audiences with insect fear films and then use the films as a means for highlighting popular misconceptions about insects. At each festival, two or three feature-length films are shown, interspersed with animated shorts. Before the festival begins, and between films, the audience is invited to see and handle a variety of live as well as pinned specimens. Generally, the festivals are organized around themes, which have included, among others, noninsect arthropods, orthopterans, social insects, cockroaches, flies, alien arthropods, and mosquitoes. The 20th festival featured three films by Bert I. Gordon and the 25th festival featured films by Simon Smith; both directors actually attended the festivals.

Other events that have been held in conjunction with the festival included a thematically relevant blood drive, held in cooperation with Community Blood Services of Champaign, for the 1999 mosquito film festival. Attendance at these festivals can exceed 1000. Over the years, the festival has been featured in a wide range of media throughout the world.

Other insect fear film festivals *per se* are few in number; Iowa State University has conducted an Insect Horror Film Festival since 1985, and Washington State University has hosted its Insect Cinema Cult Classics festival since 1990. Insect films, however, have been elements of insect expo and public outreach efforts in many venues, including museums, science centers, and universities across the country.

There is one legitimate insect film festival in the traditional sense, in which films are submitted in competition and are judged and awarded prizes. FIFI, organized by l‘Office pour les Insectes et leur Environment du Languedoc-Roussillon (OPIE LR) and the the Regional Natural Park of Narbonne and the city of Narbonne, France, is a biennial international film festival dedicated to insects and other small animals. The FIFI, in its seventh session in 2007, is the result of a partnership with the Institute for Research and Development, the French National Center for Scientific Research (CNRS), the National Institute of Agronomic Research (INRA), the City of Sciences and Industry and the National Museum of Natural History (Paris), and the Agronomic University of Gembloux (Belgium). Its stated objectives are to increase the sensitivity of the media and the public to the ecological importance of continental invertebrates and to encourage and promote the making of films or videos dedicated to insects.

**FUTURE OF INSECTS IN CINEMA**

With the continuing development of computer-generated imaging (CGI) and the explosion of such outlets for films as cable stations, satellite television, DVD and video markets, the future of insects and other arthropods in the movies looks secured. Arthropods will certainly continue to be objects of distaste and unease for audiences throughout the world and so will remain staples of horror films and sci-fi adventures. Moreover, CGI and developments in macrophotography ensure that insect images on screen will become increasingly sophisticated, although scriptwriting will doubtless remain as resolutely unrealistic as it has since the earliest days of insects in cinema.

Muscle is the excitable, contractile tissue of animals that is responsible for movement and behavior. Although there is great variability in structure and performance among different insect muscles, many basic features of biochemical composition, ultrastructural organization, and contractile performance are common among insect muscles and indeed are similar between muscles of insects and those of vertebrates.

**Muscle Structure and Ultrastructure**

**Muscle Fibers and Fiber Bundles**

The skeletal muscles of insects are bundles of elongate, multinucleate cells called muscle fibers. The fibers attach at each end to the exoskeleton. The muscles typically span joints of the exoskeleton and, when active, cause bending of the joint or stabilization of the joint against external forces. Skeletal muscles are the muscles of behavior, the muscles involved in posture and locomotion. In addition to skeletal muscles, insects contain visceral muscles that cause movement of the gut, Malpighian tubules, and parts of the reproductive system; there are also cardiac muscles that cause contraction of tissue sheets and vessels associated with the circulatory system. The visceral and cardiac muscle cells are typically small, spindle shaped, and with a single nucleus.

An individual insect contains many morphologically identifiable skeletal muscles. The large number of muscles is a consequence of the segmental organization of insects and the serial replication of parts associated with segmentation. Each of the wing-bearing segments of a cockroach contains about 50 separate muscles, an abdominal segment a somewhat smaller number. In a classic anatomical study, Lyonet, in 1762, noted that the larva of the goat moth, *Cosus*, contains three times the number of anatomically distinct skeletal muscles as does a human!

In most insect muscles the fibers lie parallel to one another, and when the muscle contracts, it shortens along the long axis of the fiber bundle. Such muscles are spoken of as being parallel-fibered muscles (Fig. 1, left). In some muscles, in particular peripheral leg muscles, the fibers attach obliquely at one of their ends onto an internal, cuticular extension called an apodeme (Fig. 1, right). When these muscles are activated, the muscle as a whole shortens along the axis of the apodeme, oblique to the fiber axis. The oblique insertion of fibers onto the apodeme is reminiscent of the oblique junction between lateral filaments and the main shaft of a feather, hence muscles with an oblique fiber arrangement are called pinnate (L. *pinna* = feather). The force that a muscle can generate increases with increasing cross-sectional area. The pinnate arrangement of muscles increases the effective cross-sectional area and hence the force that the muscle can produce.

**Filaments and Fibrils**

Muscle shortening in insects as in other animals results from sliding movement between interdigitating thick and thin filaments contained within the muscle fibers. The force of contraction is a shearing force developed between these filaments. The thick filaments are made up largely of the protein myosin, the thin filaments of the protein actin. A single thick filament is composed of many individual myosin molecules and, similarly, a thin filament contains many actin molecules. Projections of the myosin molecules from the thick filaments toward the thin filaments, called cross-bridges, are the sites of interaction between the two and are the force generators for contraction.

The thick and thin filaments are grouped into longitudinal bundles called fibrils. The filaments within a fibril are grouped precisely, both longitudinally and transversely (Figs. 2 and 3). The thin filaments attach to and project from both sides of transverse structures called Z disks. The Z disks occur regularly along the length of the fibril. The interval from one Z disk to the next is called a sarcomere. The thick filaments lay side by side in the middle of the sarcomere. The sarcomere lengths in fibrils of fast muscles such as flight muscles are 2–4 μm; those in leg muscles, body wall muscles, and visceral muscles tend to be longer, up to 7–10 μm. The regular longitudinal arrangement of Z disks, thin filaments, and thick filaments creates a striped pattern along the length of a fibril (Figs. 2 and 3). The most obvious components of the striped pattern are (1) the Z disks; (2) the A bands, corresponding to that part of a sarcomere containing thick filaments; and (3) the I bands, corresponding to that part of a sarcomere without thick filaments. When a muscle shortens, the thin filaments slide toward the center of the sarcomere and the I bands become shorter. Because of their transverse banding pattern, muscles in insects (and skeletal muscle in vertebrates, which have a similar organization) are described as being striated muscles. The visceral muscles of insects are similar in function to vertebrate smooth muscles and in many ways similar in physiology as well. But although vertebrate smooth muscles lack...

**FIGURE 1** Muscle with parallel fibers (left) and one with pinnate fibers (right). The parallel-fibered muscle is the mesothoracic dorsal longitudinal flight muscle of the tettigonid *Neoconocephalus robustus*. [Modified from Stokes, Josephson and Price (1975). *J. Exp. Zool.* 194, 379–407.] The dark structure coursing across the muscle surface is the motor nerve that innervates the muscle. The pinnately fibered muscle is the metathoracic extensor tibia of the cricket *Telogryllus oceanicus*. [Modified from Donaldson and Josephson (1981). *J. Comp. Neurol.* 196, 735–742.] Abbreviations: N, motor nerve; Tr, trachea; A, apodeme.
striations, the visceral muscles of insects, like the skeletal muscles, are striated.

The thick filaments of insect muscles, and of vertebrate striated muscles, occur in a regular, hexagonal array. In vertebrate muscles a thick filament is surrounded by six thin filaments, each of which lies at the midpoint between three adjacent thick filaments (Fig. 4), and the overall ratio of thin-to-thick filaments is 2:1. In fast muscles of insects, for example flight muscles, there are also six thin filaments surrounding each thick filament, but these occur at the midpoint between two thick filaments and the thin-to-thick ratio is 3:1. In slower insect muscles, such as body wall muscles, the usual pattern is for each thick filament to be surrounded by a circle of up to 12 thin filaments.

The fibrils of insect muscles occur in two basic patterns, cylindrical and radial–lamellar (Figs. 3 and 5). In muscles with cylindrical fibrils the bundles of filaments forming the fibrils occur as elongate cylinders that are often polygonal in cross section. In radial–lamellar fibers the fibrils are ribbon-shaped structures arranged radially about the center of the fiber.

**Other Components**

The cellular components of muscle fibers seen in electron micrographs fall into four functional groups. First are those structures directly involved in the generation of force and mechanical power.

**FIGURE 2** Origin of the transverse striations in skeletal muscle. The upper electron micrograph is a longitudinal section of a somewhat stretched fiber from the mesothoracic dorsal longitudinal muscle of the tettigoniid *Neoconocephalus ensiger*. The scale bar represents 1 μm. Abbreviations: M, mitochondrion; I, I band; Z, Z disk; A, A band.

**FIGURE 3** Structural organization of a fiber from an insect fast muscle. The drawing is based on electron micrographs from a tettigoniid singing muscle. The fibrils here are radial–lamellar. Abbreviations: A, A band; I, I band; M, mitochondrion; SR, sarcoplasmic reticulum; T, transverse tubule; Z, Z disk. [Modified from Josephson (1975)].

**FIGURE 4** Organization of thick and thin filaments as seen in cross sections of fibers from (A) a vertebrate skeletal muscle, (B) a fast insect muscle, and (C) a slow insect muscle.

**FIGURE 5** Transverse electron microscope sections through (A) a fiber with radial–lamellar fibrils (a flight muscle of the tettigoniid *Euconocephalus nasutus*) and (B) a fiber with columnar fibrils (from the tympanal muscle of the cicada *Abiecta curvicosta*). The scale bars indicate 1 μm. Abbreviations: M, mitochondrion; F, fibril; Tr, intracellular tracheole.
These structures are the thick and thin filaments that collectively form the fibrils. Second are those components involved in the control of contraction. The most obvious structures involved in the control of contraction are the transverse tubular system (T tubules) and the sarcoplasmic reticulum (SR). The T tubules are membrane-bound tubular structures oriented perpendicular to the fiber axis. The membrane of a T tubule is continuous with the surface membrane of the fiber, and the T tubule can be regarded as an inwardly directed extension of the surface membrane. In most insect muscles there are two tubules per sarcomere, lying in the overlap areas between thick and thin filaments (Fig. 3), but in the fibers of some muscles there is a single, centrally located T tubule per sarcomere. Within the fiber the T tubules make specialized junctions with the SR, which is an internally closed, membrane-bound compartment within the fiber. The function of the T tubules and SR is considered further below. Other elements involved in the control of contraction are the surface membrane of the muscle fibers and membrane specializations at the sites at which nerve processes contact muscle fibers. Third are the structural elements of the metabolic power supply. These are the mitochondria, which provide ATP, and glycogen granules. ATP is the immediate energy source for contraction; glycogen is a stored fuel for cellular metabolism. It would be appropriate to include among the elements involved in metabolic power the tracheoles, the terminal portions of the gas-exchange system that ramify throughout muscle fibers, even though topologically tracheoles are external to and not really part of the muscle fibers. Fourth are the structures involved in long-term maintenance of muscle, specifically the many nuclei of the fibers.

The relative abundance of different cellular components in muscle is tightly correlated with the functional capacity of the muscle fibers. SR and T tubules are particularly abundant in muscles that can produce brief contractions, that is, in muscles in which the contractile apparatus can be rapidly activated and inactivated. Muscles capable of sustained activity at high power output are particularly well supplied with mitochondria and tracheolar endings. Mitochondria make up 30–40% of the muscle volume in wing muscle of active fliers and in sound-producing muscles that are active continuously and at high frequency. Such muscles are often pink, because of the cytochromes in the abundant mitochondria. It should be noted that hypertrophy of mitochondria, and of T tubules and SR, is at the expense of myofibrillar volume, so fast and fatigue-resistant muscles are likely to be relatively weak.

Muscle Attachments

Skeletal muscles attach to the cuticle of the exoskeleton through specialized epidermal cells. The muscle fibers are joined to these cells by specialized junctions called desmosomes. The terminal sarcomeres of the fibrils lack a final Z disk; instead, the thin filaments are attached to the muscle portion of the terminal desmosome through a band of what have been called junctional filaments. Visceral muscles are frequently joined to one another by desmosomes, and cardiac muscle fibers are joined by structures resembling the intercalary disks of vertebrate cardiac muscle.

INNERVATION AND ACTIVATION

There is an electrical potential across the surface membrane of a living, resting muscle fiber; the interior of the fiber is typically 30–70 mV electrically negative with respect to the extracellular solution. Nerve cells in the central nervous system send out long processes (motor axons) to the muscle fibers where they make specialized contacts termed synapses. A motor axon makes many synaptic contacts along the length of each muscle fiber that it innervates (multiterminal innervation), and a single muscle fiber may receive inputs from more than one motor axon (polynervous innervation). Impulses initiated in the central nervous system travel along the motor axons and cause the release of specific chemical signals (transmitters) from the motor axon terminals at the synapses. The transmitter released from the terminals of most motor axons leads to a reduction (depolarization) in the transmembrane potential of the muscle fiber in the vicinity of the nerve terminal. Muscle fiber depolarization initiates contraction of the fiber. Motor axons that depolarize muscle fibers and cause muscle contraction are called excitatory axons. Some axons, termed inhibitory axons, release transmitters that stabilize the transmembrane potential of the muscle fiber or even make it greater, thus antagonizing excitatory inputs. In addition to excitatory and inhibitory neural inputs, many muscles receive inputs from modulatory motor neurons, activity that releases chemicals that modify muscle performance, for example, increasing muscle force and work output or speeding relaxation.

Insects, like other arthropods, manage their muscles using relatively few motor neurons. Some major muscles, for example tymbal muscles of cicadas, are innervated by a single motor neuron. Many muscles receive two to four motor neurons. The largest number of motor neurons yet described for an insect muscle is 16, to the flexor muscle in the leg of a locust.

The processes linking membrane depolarization and contractile activation have been little studied in insect muscles, but the ultrastructure, biochemistry, and contractile performance of insect muscle are so similar to those of the far better studied frog, cat, and rodent muscles that one can predict with confidence that the basic principles worked out for vertebrate muscles apply to insects as well. The expected scheme is as follows. Membrane depolarization spreads inwardly into the fiber along the T tubules. Depolarization of the T tubules, which are coupled to the SR through specialized junctions, leads to release of calcium from the SR. Released calcium reversibly binds to regulatory sites in the fibrils, turning on the contractile machinery. Relaxation occurs as the SR takes up the released calcium and reduces the calcium concentration in the cytoplasm below that needed for contractile activity.

MUSCLE MECHANICS

Muscle Force and Muscle Length

The muscle contraction initiated by a single stimulus, or by a single impulse in an innervating motor neuron, is termed a twitch; that evoked by repetitive input at a frequency high enough to maintain full activation of the muscle is termed a tetanus. A response in which a stimulated muscle develops force while held at constant length is called an isometric contraction. The isometric force generated by a muscle stimulated to contract in a tetanus is maximal at about the normal muscle length in the insect body and declines at longer and shorter lengths. The decline in force with increasing muscle length beyond the optimum is thought to be caused by a reduction in the overlap between the thick and the thin filaments and therefore in the number of myosin cross-bridges that can interact with the actin filaments. The decrease in force at short muscle lengths is probably a consequence of the thick filaments running into and being impeded by the Z disks, of collision of thin filaments in the middle of the sarcomere, and, at still shorter lengths, of overlap of thin filaments with
portions of thick filaments of inappropriate polarity on the far side of the center of the sarcomere.

Some muscles in insects and elsewhere can shorten to a small fraction of their resting length, a response termed supercontraction. The capacity for supercontraction appears to involve modifications in the structure of the Z disk such that there is not a collision between the Z disks and the thick filaments at short muscle lengths. In the supercontracting muscles that have been examined, the Z disk becomes perforate at short muscle lengths and the thick filaments slide through the spaces in the disks.

The posterior, intersegmental, abdominal muscles of female locusts are of particular interest for the wide range of lengths over which they can operate. During oviposition, appendages on the end of the abdomen dig and pull the posterior abdomen down into a relatively deep hole. The intersegmental muscles become stretched to about nine times their resting length. During this stretch, called superextension, the Z disks become broken up into discontinuous, nonaligned elements to which the thin filaments are attached. Muscle contractility is not lost, and contraction of intersegmental muscles returns the abdomen to its normal length following oviposition. The latter part of the recovery may be supercontraction, for in the resting state the posterior intersegmental muscles are normally supercontracted, with thick filaments protruding through gaps in the Z disks.

**Force, Shortening Velocity, and Power**

There is an inverse relationship between the force on a muscle and the velocity with which it can shorten, a relationship conveniently expressed in a force–velocity plot (Fig. 6). To facilitate comparison of muscles of differing size, force in a force–velocity plot is usually expressed as stress (force per unit cross-sectional area) and shortening velocity as strain rate (shortening velocity per unit muscle length). Two points on a force–velocity plot are frequently used to characterize a muscle’s contractile properties: the maximum isometric stress of the muscle (Fmax, the intercept of the curve with the 0 velocity axis) and the maximum shortening velocity (Vmax, the intercept of the curve with the 0 force axis). Values for the maximum force in insect muscles are generally 5–35 N cm⁻² (N, Newton; 1 N is approximately the downward force exerted by a mass of 100 g in the gravitational field at the earth’s surface). The few available measurements of the maximum shortening velocity for insect muscles, all from fast muscles, are on the order of 3–15 lengths/s.

The product of force and shortening velocity has dimensions of force × distance per time (work per time) and is the rate of doing work, that is, the mechanical power output. The product of stress (force per area) and strain rate (shortening distance per second per unit muscle length) is the mechanical power per unit volume of muscle, which is readily convertible to power output per unit muscle mass. Thus each point on a force–velocity plot (or a plot of stress against strain rate) represents a power output. The power predicted from a force–velocity curve is the instantaneous power output. The peak instantaneous power is substantially greater than the sustainable power available during repetitive, cyclic contraction has been determined for several synchronous insect muscles using the work loop approach, in which the muscle is subjected to length changes simulating those during normal activity and stimulated phasically during the length cycles. A plot of muscle force against muscle length for a full cycle produces a loop, the area of which is the net work output of the muscle for that cycle. The product of work per cycle and cycle frequency is the power output. The mechanical
power available from synchronous flight muscles of several locusts and katydids and of a moth measured in this way ranges from 50 to 120 W kg\(^{-1}\) at normal operating temperature.

### Asynchronous and Synchronous Muscles

Most insect muscles are like vertebrate skeletal muscles in that each contraction is initiated by depolarization of muscle fibers, and there is a 1:1 relationship between muscle electrical activity and muscle contraction. Such muscles may be termed synchronous muscles, reflecting the congruence between electrical and mechanical activities. The major flight muscles in several insect groups are different in that there is no synchrony between electrical and mechanical events. These muscles are known as asynchronous muscles. Neural input and fiber depolarization are needed to activate an asynchronous muscle, but when it is activated an asynchronous muscle can contract in an oscillatory manner if it is attached to a mechanically resonant load. The resonant loads for the flight muscles are the wings, which may be regarded as small, somewhat dampened tuning forks. The frequency of the oscillatory contraction is the mechanically resonant frequency of the load, which is greater than the neural input frequency required to keep the muscle fully activated. The contraction frequency of asynchronous wing muscles during flight is typically 3–10 times higher than the neural input frequency in each of the motor neurons activating the muscle. The main singing muscles in some but not all cicadas are asynchronous muscles; the resonant load here is the cuticular tymbal to which the muscle is attached and whose inward movement produces the sound pulses.

The features of asynchronous muscle that allow oscillatory contraction are stretch activation and shortening deactivation. When allowed to shorten rapidly an asynchronous muscle becomes deactivated, and while deactivated it can be stretched out to its original length, developing less force than it did while shortening. Stretching the muscle, in turn, reacts it. Because of shortening deactivation, less work is required to restretch an asynchronous muscle than is produced by the muscle during shortening, and there is net work output when the muscle undergoes a shortening–lengthening cycle. It is this net work that is available to drive the wings and power flight.

Asynchronous muscles occur in several of the most successful insect groups. They power flight in beetles, flies, bees, and wasps and many of the true bugs. The distribution of asynchronous muscles among insect taxa suggests that this mode of muscle control has evolved independently as many as 7–10 times. It is likely that asynchronous muscle has been favored by evolution because it is more powerful and more efficient than is synchronous muscle for operation at the high frequencies characteristic of insect flight. It is more powerful, in part, because asynchronous control does not demand rapidity in the rate at which muscle is turned on and off by neural input. High-frequency contraction is achieved without hypertrophy of the SR, leaving more room in muscle fibers for fibrils, which are the power-producing component. It is more efficient because a relatively low-frequency neural input is needed to maintain full activation, which reduces the amount of calcium that is released and rebound during activity and the associated metabolic costs of calcium cycling.

### Are Insect Muscles Unusual as Motors?

In the minds of many people, insects are extraordinary athletes. One sometimes hears it said that if a person were as strong as an insect, he or she could carry enormous weights or leap over tall buildings. Such assertions are largely based on incorrect application of principles of scaling. Consider, for example, jumping ability. A 1-g locust can develop enough power to lift its 1-g mass to a height of about 1 m. A 70-kg person can develop enough power in a jump to lift his or her 70 kg to a height of 1 m. The work done is 1 g m for the locust, 70 kg m for the person, and the power required per mass of animal is the same.

The most often studied and certainly the most completely analyzed muscle for any animal is the frog sartorius muscle. The most complete body of information on contractile properties for an insect muscle is probably for the wing muscles of locusts, both *Schistocerca gregaria* and *S. americana*. The frog sartorius muscle is not the strongest or the fastest vertebrate muscle known, but it is a good representative of a fast vertebrate muscle. Similarly locust flight muscles are neither the strongest nor the fastest insect muscles, but they are reasonable representatives of fast insect muscles. Some of the contractile properties of frog and locust muscle are tabulated in Table I. The vertebrate muscle and the insect muscle are surprisingly similar in many of their contractile properties. The muscles of insects share the same capacities and are subject to the same limitations as are muscles elsewhere throughout the animal kingdom.

#### Table I

| Contractile Properties of a Locust Flight Muscle (Metathoracic Second Tergocoxal Muscle of *S. americana*) and the Frog Sartorius Muscle |
|---|---|---|---|
| **Locust** | **Frog** |
| Twitch time course (ms) | 20 | 21 |
| Rise time | 39 | 52 |
| Onset to 50% relaxation | 17 | 5 |
| Tension (N cm\(^{-2}\)) | 30 | 25 |
| Maximum shortening velocity (length s\(^{-1}\)) | 4.1 | 6.4 |
| Power (W kg\(^{-1}\)) | 150 | 250 |
| Peak instantaneous | 48 | 50 |

Insect collections are often oversimplified as either a precious and essential, rapidly developing treasure or a musty, dusty, moribund assemblage of archaic specimens. Those who now prefer the latter characterization have not been paying attention. Entomological collections and their curators are experiencing a steady, if not spectacular, evolution in the way collections operate, and perhaps the best is yet to come.

The term “insect collections” is often loosely used, and these collections usually contain other arthropods, including arachnids (e.g., spiders, mites), myriapods (e.g., centipedes, millipedes), and terrestrial crustaceans (e.g., sowbugs and pillbugs, amphipods). So most entomological collections are actually arthropod collections.

Collections of insects and related arthropods constitute an enormous resource for biological information and are an irreplaceable tapestry documenting Earth’s entomological natural history. The numbers of specimens in collections are staggering, as is the amount of work yet to be accomplished just describing and cataloging millions of new species. Despite the revolutionary changes energizing these collections, still daunting are the myriads of problems, particularly financial, that continue to debilitate many collections’ operations.

SCOPE OF THE WORLD’S INSECT COLLECTIONS

Insects are the largest, most diverse group of organisms in the world. Over 900,000 species have been described, and current estimates on the number still without names range as high as 30 million. That theoretical number is based on work in the New World tropics. However, more recent work testing that hypothesis, including the Old World tropics and measuring host specificity, now suggests a more modest but still astounding 4–6 million unnamed species. Reflecting the number of species potentially involved, insect collections maintain a large number of specimens. Based on numbers and extrapolations primarily from Arnett, Samuelson, and Nishida and adjusted for the last 8 years using an annual growth rate of 2% (average over a 20-year period), there are conservatively 724 million specimens in entomological collections worldwide. This figure does not include the unknown number of specimens in private collections, nor does it include a significant number of unprocessed specimens. In 1991 Miller reported the numbers of specimens for entomological collections in the United States and Canada and also included figures on unprocessed specimens (i.e., backlog). In 1976 reports indicated that 26% of specimens were reported unprocessed, increasing to 28% in 1981 and 30% in 1986. If these percentages are extrapolated worldwide and added to the processed specimens, there may be nearly a billion arthropod specimens housed in entomological collections.

As might be expected, a great many collections house the rather large number of specimens that have been amassed. The insects and spider collections of one Web site (http://www.bishopmuseum.org/bishop/ento/codens-inst.html) list 904 institutional or organizational insect collections. Despite the plethora of collections, the largest house a disproportionate number of the specimens. Table I lists the largest entomological collections, that is, those reporting over five million specimens in their holdings. The largest collections are found in Europe, North America, Australia, and New Zealand. The collections’ locations are likely influenced by the historical origins of insect collections, centers for entomological research, cultural interests, and economic restrictions. These collections do not coincide geographically with the regions of highest insect biodiversity, which tend to be in the tropics.

The total number of specimens may appear excessive given the number of species described, but the total figure includes many undescribed species. Also, long series are required to study and account for the morphological, geographic, and seasonal variability within a species. The specimens are also widely spread throughout many collections, enabling multiple centers for study and providing insurance against loss of species representation in case of natural or man-made disaster.

BEGINNINGS OF INSECT COLLECTIONS

The beginnings of insect collections are lost in unrecorded history. The Chinese used silkworms as early as 4700 B.C., honey bees by the 5th century, and scale insects by the 13th century. A treatise describing insects and their pharmaceutical properties had been published in China by at least A.D. 200. Cuneiform texts found in Mesopotamia dating to earlier than 669–626 B.C. contain systematically arranged names of insects. Aristotle (384–322 B.C.) studied insects and taught entomology. In A.D. 77 Pliny produced an encyclopedia that included entries on insects. Insect collections were no doubt made during antiquity, but no record of them has been found.

The early periods saw interest in insects primarily for their practical use or as pests. European explorations in the 15th and 16th centuries opened up shipping lanes for commerce and trade. The explorers and adventurers brought back hordes of items including insect novelties, piquing the interest of many. The first entomological collections were included in the cabinets of “curiosities” assembled by wealthy Renaissance families to show to friends and associates. These cabinets were to eventually lead to modern natural history museums.

The first compound microscopes were made by Hans and Zacharias Jansen in Holland in 1590. This major technological advance, coupled with the improvements made by Antony van Leeuwenhoek in the late 1600s, permitted the observation of tiny insects and their minute parts, advancing their study.

As the number of curiosity cabinets continued to grow in the 16th and 17th centuries, a means to organize their contents became necessary. John Ray (1628–1705) attempted a classification of insects in 1705, which was published posthumously in 1710. Carolus Linnaeus (Carl von Linné) (1707–1778) published the first edition of his Systema Naturae in 1735, and the 10th edition, published in 1758, became the basis for modern insect classification.

\textsuperscript{b}Collections reporting over five million specimens; does not include large Russian collections such as Leningrad whose holdings are not available.

\textsuperscript{c}In 1993 Arnett, Samuelsen, and Nishida reported an estimate of 100 million. However, this is generally considered to be in error, hence the more conservative figure provided here.

**SOURCES OF EARLY SPECIMENS**

Linnaeus surrounded himself with students not only to carry on his work but also to provide specimens for study. Linnaeus was particularly interested in obtaining species of practical use, and he arranged for his students to go on voyages and encouraged them to send material from their travels. From 1744 to 1796, students sent back to Linnaeus and his associates material not only from Europe but from the Middle East, Africa, India, Asia, South America, Africa, and the Pacific (Cook’s first two voyages).

Some of these students of Linnaeus eventually produced works of their own: for example, Fredrik Hasselquist’s \textit{Iter Palaestinum eller Resa til Heliga Landet} in 1762 and Pehr Forsskål’s \textit{Descriptiones animalium} in 1775. Other Linnaean students, for example, Johann Christian Fabricius (1745–1808), were extremely productive in discovering and describing new species, continuing the Linnaean traditions and fostering this era of cataloging.

Wealthy scholars and others amassed large collections that eventually wound up in institutional collections. Catherine the Great started Peter Simon Pallas on collecting and exploring travels throughout the Russian Empire between 1767 and 1810. A. M. F. J. Palisot de Beauvois described insects from Africa and America collected on his own travels from 1781 to 1797. Guillaume Antoine Olivier, sent on expedition to Turkey, Asia Minor, Persia, Egypt and the Mediterranean islands (1792–1798), later became a patron for other naturalists. Pierre François Marie Auguste Dejean (1780–1845), a soldier of fortune, collected in Austria and by exchange or purchase amassed the greatest collection of beetles in the world at that time. Thomas Say (1787–1834), the father of American entomology was appointed naturalist for Long’s expeditions to the Far West and visited the Rocky Mountains and the sources of the St. Peters River in 1823. Victor Ivanovich Motschulsky (1810–1871) was a Russian military officer who traveled through Europe, the Caucasus, Siberia, the Kirghiz steppes, Egypt, India, the United States, and Panama. Thomas de Gray, Lord Walsingham (1843–1919), was an English nobleman wealthy enough to travel extensively (United States, North Africa, Europe) and also purchase specimens.

The 19th century was a fertile time for voyages and expeditions. Alexander von Humboldt visited the Spanish colonies of the...
American tropics between 1799 and 1804. Otto von Kotzebue sailed around the world from 1815 to 1818. On board was J. Friedrich von Eschscholtz who collected in California, Hawaii, the Philippines, Brazil, Chile, and other places. On a later voyage, again with Kotzebue, Eschscholtz amassed a large collection from the tropics, California, and Sitka (Alaska). Other important voyages for entomological specimens included those of the Astrolabe (1826–1829), the Astrolabe and the Zelee (1837–1840), the Swedish frigate Eugenie (1851–1853), and the Austrian frigate Notara (1857–1859). The U.S. Exploring Expedition (1838–1842) visited Madeira, Brazil, Chile, California, Oregon, Pacific Islands (including Hawaii, Australia, the Philippines, and Singapore), South Africa, and St. Helena. Sources of entomological collections mirrored the spread of empire and the pursuit of national interests.

Rather than circumnavigating, some targeted specific locations. For example, Henry Walter Bates spent the years 1851–1870 in South America, mostly in the Amazon, collecting and sending material back to England. Giacomo Doria (1840–1913), who founded the Genoa Museum, funded expeditions to areas particularly rich in insect diversity (Africa, Southeast Asia, New Guinea, Indian Ocean islands). Others such as Lionel Walter Rothschild (1868–1937) focused on specific groups. Lord Rothschild concentrated on butterflies and moths and funded expeditions to the far corners of the world; in 50 years’ time he amassed the greatest personal collection ever (including 2.25 million butterflies and moths).

The amount of material grew exponentially, and as the Linnaean system became entrenched, secure and centrally located places to store the reference collections and unprocessed materials were sought.

DEVELOPMENT OF FORMAL COLLECTIONS

The first natural history museum probably was that of Conrad Gessner a scholar of mid-16th-century Zurich. Very few present-day natural history museums were established before the mid-18th century. The Muséum National d’Histoire Naturelle in Paris was established in 1635 and was the first natural history museum established in the form we recognize today. Others were the Staatliches Museum für Tierkunde in Dresden established in 1650, the Zoologicheskii Institut Zoologicheskii Muzei in Leningrad in 1727, the Zoologiska Museet in Lund in 1735, the Naturhistorisches Museum in Austria in 1748, and the British Museum in 1753. Scientific academies, beginning with the Accademia dei Lincei in Rome in 1603, fostered and often housed early collections. The Royal Society in London was founded in 1662, and the Académie Royale des Sciences of Paris in 1666. The Academy of Natural Sciences in Philadelphia, founded in 1812, is the oldest North American academy. The academies were later augmented by natural history societies that often performed similar functions. The First Aurelian Society (early insect collectors were known as “Aurelians”) was founded in London in 1745. The Entomological Society of Philadelphia, established in 1859, was the first American entomological society.

The great explosion of natural history museums occurred in the latter part of 18th century and into the 19th century, with the continuation of exploration and collecting. Coincidentally, this proliferation of museum collections coincided with the earliest use of persistent poisons such as arsenic to protect biological specimens from damage by the pests that had destroyed many earlier collections (a Western discovery, but the Chinese had written about the use of arsenic and mercury for control of human parasites in A.D. 200–200). Perhaps the concentration of the entomological collections in temperate Europe and North America was a result not only of European influence but also of the climate, which likely was less favorable to potential pests of museum specimens than in the warmer regions of the world.

Growth continued through the 20th century with the exception of periods of global conflict. The 19th and 20th centuries saw increasing participation of institutions and government in organizing and funding expeditions. Expatriates and professionals on foreign assignment were also great sources of collections. The 20th century later saw a focus on regional faunas, opportunistic trips, and taxon-based initiatives. Institutions became less involved with collecting efforts and individuals increased their efforts, particularly to aid their research goals. Toward the end of the 1900s, cooperative efforts returned as the cost of fieldwork increased. Large national inventories such as the Instituto Nacional de Biodiversidad (INBio) established in 1989 in Costa Rica were undertaken, and ATBIs (all taxa biological inventories) were begun to inventory areas with a combination of high biodiversity and high threat of loss due to that biodiversity.

As the great expeditions filled the collections’ coffers and the continuous additions provided more than enough work for taxonomists, collections also needed technological support to improve storage and retrieval capabilities.

TECHNOLOGICAL ADVANCES IN METHODOLOGIES USED BY COLLECTIONS

Technological advances, from the microscope to finding effective pesticides, had and still have a profound influence on the development of entomological collections. Although the basic methods of collections and specimen preparation have not changed radically, new innovations usually made the process quicker, more efficient, and more inclusive. Steady changes have taken place in the past three decades, and in retrospect, a major revolution has occurred.

Many innovations have been implemented, including the use of glass-topped drawers for specimen storage rather than just simple boxes. It is likely that insects were placed in containers to take advantage of the efficacy of pesticides by maintaining the specimens in a closed environment. Dried specimens are still prepared with pins, and paper labels are affixed to the pin beneath the specimen. However, the materials used have been much improved. Insect pins are of higher quality and are less likely to corrode.

Along with the advances in technology, the last few decades have seen a concerted effort to introduce materials conservation techniques into collections management. Recent advances in storage technology in insect collections include the development of the unit tray system. This is a system of totes or drawers made of cardboard and with a material that functions as a pinning base at the bottom of the box. This innovation permits the rapid rearrangement of the collections as new studies modify the organization of a group. Placing like elements in a single unit tray (e.g., specimens of a species all collected in one area) also permits the use of a header card, or tray identifier, that permits rapid recognition and retrieval of information. The material first selected for tray bottoms was cork. Within several decades, however, cork was found to be unacceptable because its acidic nature affected the pins and labels and even perhaps the specimens. A new material was searched for, and most collections have settled on a cross-linked polyethylene product that is inert and pliable.

In the late 19th century, new methods helped streamline the paper-making process. Unfortunately, the new papers are slightly more acidic and tended to break down faster, with the ironic result that older 17th-and 18th-century labels are more permanent. Labels have changed in both substance and content. Some early collections were not labeled...
at all to show the origin of specimens. As systematic work progressed and some species were found to be restricted in their distribution, labels were added. These labels were laboriously handwritten in ink and often would indicate only a country, an island, or a region. As even more species of insects were discovered, classifications became larger, and more specimens were collected, labels became more specific, adding ecological data, collecting information, and details of the collecting locality. With the development of GPS (global positioning systems), collecting location coordinates are routinely added to label data.

Hand-printed labels gave way to mass-printed forms. Typesetting took time, and so photoreduction methods were used to speed the process. Since the 1980s, the desktop computer has become a mainstay in collections work. Initial efforts to use the computer to generate labels were restricted to providing printed copies since the early printers did not have a font size small enough to fit all the necessary information onto the tiny specimen labels. As laserwriters developed, collections personnel began experimenting with producing labels on them. The first efforts were encouraging until it was discovered that the toner (laser cartridge “ink”) did not stick to the paper used for labels in fluid (ethanol) collections. At this time, inkjet printers seem to be a useful alternative.

The last two examples serve to show why collections often embrace technology slowly. Yet despite the pitfalls inherent in adopting new technologies, most collections today are in much better shape for long-term survival than they were before. Other advances in storage and maintenance include new or retrofitted buildings for many collections, use of climate control to reduce fluctuations in temperature and humidity, and installation of compactor storage systems to make better use of space and improve access to collections. Repellents used in collections that are potential human health risks, such as naphthalene (usage introduced in the late 19th century) and paradichlorobenzene, are being replaced with freezing procedures and integrated pest management monitoring techniques such as sticky traps to intercept possible problems sooner.

Collecting methods have improved and can easily overwhelm the preparation capabilities of most present-day collection staffs. Mass collecting techniques took a great leap forward with the invention of a flight intercept trap by René Malaise in 1937 (prototyped in 1933). The Malaise trap is a tent-like structure placed in a position to intercept flying insects and have them self-collect in strategically placed containers. Today’s arsenal of passive traps includes yellow pan traps, pitfall traps, Berlese samplers, and innumerable other specialty traps and methods, including modifications of the original Malaise trap. For those unwilling to wait for their specimens to come to them, proprietary devices (e.g., D-Vac) allow vacuuming of vegetation. Even more efficient is the use of pyrethrum fog to assemble vast quantities of specimens from tree canopies.

As collections techniques evolved, methods of studying and interpreting species have influenced collections also.

**CHANGING ROLES OF COLLECTIONS**

Modern entomological collections are rooted in Linnaean classification. The century following Linnaeus was devoted to describing and cataloging the massive amount of material gathered, but there were too many species and not enough taxonomists. Other disciplines began studies of arthropods, and many researchers had to develop taxonomic expertise on their own to have names for the organisms they were studying.

Around the mid-19th century, large-scale agriculture and expanding horticultural efforts underscored the importance of insects as pests and opened up an entirely new area for collections, namely, the role of identifying insect pests and establishing the authenticity of such identification. The use of parasitoid and predatory insects for biological control began a new type of biological exploration, sending professional entomologists around the world to find control agents which were subsequently reared and released. Governments established sections of entomology in agricultural divisions and often associated them with national collections such as the U.S. Department of Agriculture and the Smithsonian Institution or the Commonwealth Agricultural Bureaux and the British Museum of Natural History.

Between 1897 and 1900, Ronald Ross and Patrick Manson discovered and experimentally proved that mosquitoes act as vectors in transmitting malaria, launching yet another era in collections development: the collection and study of medically important arthropods. Identification and research units were often established within military units or centers, such as the Walter Reed Army Medical Center in the United States.

Evolutionary biology has had a profound influence on the development of insect collections. Both Charles Darwin and Alfred Russel Wallace had been influenced by insects when they proposed their theory of natural selection in 1858. Further evidence for evolution was sought within insects, enhancing collections in the process. In the past 50 years, areas such as genetics, population ecology, and even bioprospecting have used existing insect collections and developed additional collections as adjuncts to their research. Insect collections have provided support for unexpected areas such as medical forensics. Within the last two decades, molecular biology has been asserting its influence on entomological collections, similarly using available specimens and gathering more, making use of DNA evidence to establish better understanding of species relationships.

New approaches to taxonomic studies have appeared in the decades since 1980. Phenetics (sometimes referred to as numerical taxonomy) bases classifications on overall similarities. Cladistics places emphasis for classification on branching points of a phylogeny. Evolutionary taxonomy adds degree of similarity to evolutionary origin. The advent of computers has helped the establishment of these systems by facilitating the manipulation of data. Ernst Mayr perhaps summed up the current status in insect classification best: “Taxonomy has been more active, more in ferment, in the last 50 years, than ever before in its history.” Today these words are even more applicable.

As these new sciences developed, positions in classical taxonomy dropped steadily, many workers transferred to the newer “cutting edge” sciences. An increase in efforts to stimulate appreciation of entomology was one of the responses to the perceived loss of positions and funding.

**COLLECTIONS ON DISPLAY**

Early collections were displayed in their entirety. In 1864 John Edward Gray of the British Museum proposed to store the collections away from public view, and Richard Owen eventually produced an “index collection” that became the model for display of collections specimens. This began the period of exhibit collections, with only a small portion of the material placed on view and the remaining material devoted to research. With little variation, this was the extent of entomological specimen exhibition for the next century.

Toward the latter half of the 20th century, new entomological exhibits with educational themes began appearing in an effort to interest the public. As operating costs rose and income stagnated, museums began adding an entertainment component to their exhibits in hopes of attracting more visitors, and to this end they allied
themselves more closely with educational institutions. Exhibitors and collections staff quickly discovered that people respond positively to the display of live arthropods.

In 1976 the first insect zoos (e.g., Smithsonian Insect Zoo) appeared in North America. These living exhibits were extremely successful, spawning dozens of replicates. The first butterfly house debuted in 1976 on the British island of Guernsey; over a hundred soon followed throughout the world. Determining the exact number of living insect exhibits throughout the world is difficult because many zoological parks have an insect component that is not readily apparent. Both conventional and insect zoos have live specimens on display, but whereas the older style zoos maintain special enclosures and habitats for the animals, butterfly houses permit visitors to walk through the enclosure. These two innovations sparked a flurry of activity in arthropod husbandry. An indication of the popularity of collections staff quickly discovered that people respond positively to the display of live arthropods.

In 1976 the first insect zoos (e.g., Smithsonian Insect Zoo) appeared in North America. These living exhibits were extremely successful, spawning dozens of replicates. The first butterfly house debuted in 1976 on the British island of Guernsey; over a hundred soon followed throughout the world. Both conventional and insect zoos have live specimens on display, but whereas the older style zoos maintain special enclosures and habitats for the animals, butterfly houses permit visitors to walk through the enclosure. These two innovations sparked a flurry of activity in arthropod husbandry. An indication of the popularity of living collections just in North America is the number (328) of organizations represented at the year 2000 Invertebrates in Captivity Conference sponsored by SASI (Sonoran Arthropod Studies Institute).

**SHIFTING FUNDING**

As museums began appearing in the late 1700s and 1800s, funding for collections shifted from the province of wealthy patrons, who were largely replaced by institutions supported by government or public funds. As governments centralized and became more active, particularly in the areas of medicine and agriculture, funding support shifted. Beginning in the late 1800s, agriculture became a major source of economic support, and indeed, modern land grant college collections owe their existence to agricultural funding. Today most large museums in the United States survive on a mix of revenue from endowment, gifts, income from visitors, grants from government or private sources, and direct support from government. In the rest of the world, funding for collections more likely comes from government sources, with less dependence on private sources. Traditional sources of funding such as agriculture or military research have waned recently, as has government spending in general. Though it is likely that funding sources such as biodiversity or conservation have not yet realized their full potential, many insect collections are now seeking supporting funds from private foundations as well as continued support from customary sources such as the National Science Foundation.

**FUTURE OF ENTOMOLOGICAL COLLECTIONS**

Inventory of the world’s biodiversity is far from complete, and present work is being accomplished in the face of extraordinarily high rates of extinction. Despite the large holdings presently in collections, many more species probably have not been collected yet, or even discovered. Financing for large-scale inventory projects has been minimal at best. However, a revival of taxonomy is under way, with funding coming from more diverse sources than before and with entomological collections reasserting their roles. Interest remains in endangered species and interest in alien species and their impact is growing rapidly.

Collections have always been in the information business. Specimens are about data, and collections are in the business of brokering information and storing and retrieving data. Present information technologies are revolutionizing data-sharing capabilities, and many collections are furiously converting their older information retrieval systems (card files, specimen data, etc.) into electronic systems that can be used internally and shared internationally. Bioinformatics tools such as electronic catalogs [e.g., Biosystematic Database of World Diptera (http://www.sel.barc.usda.gov/diptera/biosys.htm) or Orthoptera Species File Online (http://viceroy.eeb.uconn.edu/Orthoptera)] are rapidly coming online. Large clearing-houses for biological information such as the National Biological Information Infrastructure (NBII) are available on the World Wide Web.

The global availability of this information will provide more opportunities for cooperative ventures and at the very least will make the process of scientific inquiry a lot less time-consuming and less costly. Perhaps even more intriguing is the potential to overlay information from other disciplines—for example, adding geographic capabilities to enhance understanding of species distributions, or plant data to further understand host associations—and provide a historical perspective to boot. Ambitious systems such as Species 2000 and the Global Biodiversity Information Facility will permit this type of knowledge synthesis and interoperability. Perhaps an opportunity to better understand human impact on the world’s ecosystems from an arthropod perspective is finally at hand. This is an exciting time for insect museums.

Neosomy

Frank J. Radovsky
Oregon State University

Neosomy in an arthropod is a remarkable enlargement or formation of new external structure, or both, resulting from the secretion of new cuticle unrelated to a molt, during an active instar or in the adult. It is distinct from the more modest addition of cuticle that contributes to intermolt growth of many immature insects (notably larvae of Endopterygota) and that can be detected in some adult insects. Neosomy usually is associated with symbiosis and often with tachygenesis. Physogastry has been used overlappingly, but this term etymologically indicates abdominal swelling, and it usually has been defined as distension and not in relation to cuticular growth.

EXAMPLES

Neosomy is widely present in the Acari, including some parasitic larval mites and all stages (larva, nymph, adult female) of hard ticks (Ixodidae). Female ixodid ticks generally increase in volume about 100 times or more, after first doubling cuticular thickness during the prolonged time they are attached to the host. In the chigger genus *Vatacarus* taken from the lungs of sea snakes, larval volume increases 1500 times or more and neosomules (the new external structures) form as papillae that aid wormlike movement. All feeding is larval, and the adult casts larval and nymphal exuviae together when it emerges. In the Crustacea, some ectoparasitic copepods are neosomatic.

Neosomy is seen in adults, primarily females, of some holometabolic insects. *Tunga penetrans* (Fig. 1A) in mammals, including humans, grows until only the head is visible anteriorly on a globular body, but this is more moderate than most *Tunga* neosomes (see below). Flies in the genus *Ascodipteron* in bats develop much as *Tungia* does.

Some termite- and ant-associated beetles and flies are neosomatic. Social parasites among staphylinid beetles mimic termites in order to be accepted by the colony. The termite-mimicking cuticle that grows from the abdomen of an initially normal-looking adult beetle has paired "legs" and "antennae" (Fig. 1B). Neosomatic cuticle usually grows in soft areas between sclerites, but it may also involve sclerotized parts in these beetles. Many queen termites, sometimes >12.5 cm in length, and some queen ants are neosomatic.

**FIGURE 1** Female neosome, lateral view (scale bar, 1 mm). (A) *T. penetrans*, with part of head visible on left [Reproduced with permission from Audy et al. (1972).]. (B) *Coatonachthodes ovambolan- dicus* [Reproduced with permission from Kistner (1979).].

*Tunga monositus*, embedded in the skin of rodent ear pinnae, grows >1000 times until it no longer has any surface resemblance to a flea (Fig. 2A–G); addition of cuticle is centered in the second abdominal segment.

**FUNCTIONAL SIGNIFICANCE**

Combination of neosomy with symbiosis results from the abundance of food provided by a host or host colony. Neosomy in a termite or ant queen suggests that, although the association is intraspecific and hence not symbiotic, the queen's relation to the colony as a whole parallels symbiosis functionally. A female ixodid tick or a queen termite, for example, has unusual access to food and produces many eggs compared with related groups.

Tachygenesis has a comparable effect in sheltering the species from risks. *T. penetrans* has two rather than the usual three instars of fleas. The more advanced *T. monositus* does not feed as a larva, and all stages except the female in the host are sheltered in a rodent burrow, nonfeeding, and quiescent (except the larva spinning its cocoon and the male mating). The mimicry in termite-associated beetles presumably could not be achieved other than by neosomy.

**FIGURE 2** Development of female *T. monositus* (photographs by author). (A) Before feeding, 0.9 mm long. (B) Neosome removed after 3–4 days in host, dorsolateral, 1.5 mm long. (C) Neosome, 10 days, lateral, head left, 2 mm long. (D) Neosome, 20 days, oviparous, anterior, head hidden by abdominal lobes, up to 5.5 mm. (E) Same, posterior. (F) Neosome, 21 days, section of feeding area, papilla of host tissue 0.2 mm wide, flanked by abdominal lobes. (G) Neosome largely under skin of lab mouse pinna, 21 days, 6 mm.

Neotropical African Bees

Orley R. Taylor

University of Kansas

Neotropical African bees are derived from an intentional introduction of bees from South Africa into Brazil. These bees are famous for their stinging behavior and they are known as “killer” or “Africanized” bees in the media.

The introduction from South Africa into Brazil of a subspecies of the common honey bee, Apis mellifera, resulted in a spectacular biological invasion that has had profound effects on agriculture, beekeeping, and human and animal health. Establishment of the African bees led to hybridization with bees of European subspecies maintained by beekeepers for honey production and pollination. The resulting apiary bees became extremely defensive, and honey production declined as beekeepers abandoned beekeeping. Stinging incidents that resulted in human and animal deaths soon led the press and the public to refer to these invaders as “killer bees.” The perception that the feral African-derived bees were of hybrid origin led to the term “Africanized bees,” which is a misnomer.

PREVIOUS INTRODUCTIONS

Honey bees (A. mellifera) are native to the Old World, and all honey bees present in the Americas are descendants of bees introduced from Europe, Africa, and the Middle East. Managed honey bees in the Americas are derived from at least five introduced European honey bee (EHB) subspecies belonging to two major lineages of A. mellifera (west European bees, A. mellifera and iberica; eastern European bees, A. m. ligustica, carnica, and caucasica). These temperate subspecies are notably successful in other temperate regions (e.g., Australia) and have been used with some success in tropical areas. However, they are not well adapted to tropical conditions and did not establish large self-sustaining feral populations in the tropics as they have done in subtropical and temperate regions. In many tropical areas, European bees would not persist without human assistance and, in most habitats (with the exception of regions with pronounced dry seasons) honey production was marginal. In 1956, to improve honey production in Brazil, Warwick Kerr intentionally introduced to Brazil A. m. scutellata, a subspecies belonging to the African lineage of A. mellifera. The introduced subspecies became established in southern Brazil in early 1957 and, because this bee was well adapted to tropical conditions, a large feral population soon developed and began to spread at rates of 100–300 miles per year. No other invading species has expanded so rapidly into new habitats.

DEFENSIVE BEHAVIOR

The Neotropical African honey bees (AHBs) are well known for their defensive behavior, and the deaths of hundreds, perhaps thousands, of people (and certainly thousands of domestic animals) have been attributed to these insects. These bees are not always defensive, but under certain conditions they will attack people and animals near their nests in massive numbers, inflicting hundreds and even thousands of stings. The venom (per bee) of AHBs is less toxic than that of EHBs; nevertheless, human victims of massive stinging require immediate medical attention to minimize lysis of blood cells, breakdown of muscle tissue, and kidney damage, which can result in acute kidney and multiple organ failure.

IMPACT ON BEEKEEPING

Beekeepers accustomed to dealing with relatively gentle and manageable EHBs were unable to adapt to the defensive behavior as AHBs advanced through the Americas, and many abandoned beekeeping. Honey production declined and many countries became honey importers rather than exporters. For example, in the Yucatan peninsula of Mexico, an area of intense beekeeping with both EHBs and native stingless bees (Melipona and Trigona), both types of beekeeping declined precipitously following the arrival of AHBs. In much of the Americas, as new beekeepers adapted to AHBs, beekeeping and honey production recovered, most notably in Brazil. AHBs are now used for honey production in many areas of the Americas where EHBs were ineffective, and it appears that Kerr’s goal of improving honey production in the New World tropics will be realized.

DIFFERENCES BETWEEN AHBs AND EHBs

Honey bee subspecies from tropical and temperate regions have evolved adaptations that are suitable for their respective environments. AHBs are smaller, and they have higher metabolic rates, more rapid development, reduced longevity, smaller nest sizes, greater brood production, and lower honey storage than EHBs. These traits combine to limit the ability of AHBs to overwinter in areas where the interval between first and last frost is longer than 3.5 months. In contrast, feral EHBs can exist in areas where this winter interval is 6 months. Adaptations to tropical conditions that give AHBs advantages include higher rates of swarming (reproduction) and the ability to abandon the nest (abscond) and move to new habitats under unfavorable conditions. Also affording AHBs a distinct competitive advantage in the tropics is these insects’ abilities to find pollen and nectar, to increase their brood production under conditions in which EHBs are unable to do so, and to mount an intense nest defense that repels predators.
HYBRIDIZATION AND GENETIC DIFFERENCES

When two formerly isolated species or populations come into secondary contact there are four possible outcomes: coexistence with complete reproductive isolation, replacement of one population by the other, fusion of the two populations and complete mixing of the two gene pools (sometimes referred to as “dilution”), and establishment of a more or less permanent hybrid zone. The first scenario, coexistence with reproductive isolation between these biotypes, has not developed anywhere in the Americas. The second scenario seems to be the rule in nonmanaged populations: African-derived bees establish large feral populations and replace any resident European feral honey bees.

Gene flow between neotropical AHBs and EHBs seems to be strongly asymmetrical. AHBs have maintained their genetic integrity, in spite of hybridizing with EHBs, as they have expanded their distribution. Even after 45 years of interaction with EHBs, these bees are indistinguishable in behavior and so similar genetically to bees in the Transvaal of South Africa that it is more appropriate to refer to them as Neotropical African bees or as African-derived bees rather than Africanized bees. Low acquisition of EHB traits into the AHB population can be attributed to pre- and postzygotic isolating mechanisms (i.e., mate selection, queen developmental time, and hybrid dysfunc- tion). For example, AHB queens mate predominantly with AHB drones even in the presence of large numbers of EHB drones. When AHB queens are inseminated with semen from drones of both types, the AHB queen progeny develops faster than the hybrids, assuring that in most cases the next queen would be an AHB rather than hybrid.

Colonies from backcrosses of F1 hybrid queens to either parental genotype have unusual metabolic patterns, low honey storage, and high rates of mortality. This finding suggests possible incompatibility of the nuclear and mitochondrial genomes of these biotypes. EHBs, in contrast, rapidly become Africanized, and nearly all traces of the EHB nuclear and mitochondrial genome disappear from the feral bee populations following the arrival of AHBs. Disappearance of the European traits seems to result from a lack of prereproductive isolation, which results in extensive mating by EHB queens with AHB drones. This is followed by a pattern of queen development that favors hybrid rather than EHB queens. Matings by these F1 queens to AHB drones results in colonies with low fitness and the eventual loss of EHB mitochondrial DNA from the population. Displacement of EHBs therefore seems to result, in part, in a type of “genetic capture” in which one form, A. m. scutellata, eliminates the others by hybridizing with their females. The genetic and population consequences of the interactions between A. m. scutellata and A. mellifera subspecies from Europe suggest that A. m. scutellata deserves the status of a semispecies.

HYBRID ZONES

A hybrid zone formed at the southern limit of AHBs in northern Argentina in the late 1960s and early 1970s. Although many anticipated that a similar zone would form in the United States, this has not happened. Coincident with the arrival of AHBs in the United States, the mite, Varroa destructor, an introduced brood parasite from Asia that kills EHB colonies, spread rapidly throughout the country eliminating feral EHB colonies. At present, feral EHBs, which usually are escaped swarms from managed apiaries, are transitory and persist only for a short time; this precludes the formation of a persistent hybrid zone. In Argentina, it is likely that Varroa, which arrived after the formation of the hybrid zone, has changed the dynamic of the interaction of both types of bee as well.

FUTURE

In the future, the only significant feral bee populations in the United States will consist of AHBs in the southwestern states and possibly Florida, until or unless EHBs acquire sufficient tolerance of Varroa mites to once again establish feral populations (Fig. 1). AHBs will not become more European through hybridization or selection and move further north. Barriers to gene flow into the AHB genome, coupled with selection against any AHBs with EHB genes that make them susceptible to Varroa mites, assures the continuation of a nearly separate Neotropical African bee genome. AHBs have many useful attributes but hesitancy on the part of beekeepers to work with these bees, partly because of familiarity with EHBs but also because of concerns of legal issues should their bees be linked to stinging incidents, will keep American beekeepers from adapting this bee to apiculture.
Nest Building

Robert L. Jeanne
University of Wisconsin

Insects manipulate their environment for a variety of purposes: to trap prey, attract mates, and provide shelter from the elements and protection from predators and parasites. Nests are a special category of environmental manipulation. A nest may be defined as any modification of the environment by adult insects that provides shelter for the rearing of their offspring. In most nest-building insects, the nests are simple excavations or small constructions that provide temporary shelter and/or food for their young. The female of the leaf roller, *Deporaus betulae* (Attelabidae), cuts across a leaf along a precise trajectory, then rolls the leaf into a tube, inside of which she lays her eggs. The larvae feed on the inner layers of the leaf roll, while being protected by the outer layers. The dung beetles (Scarabaeidae) excavate nests in the ground and provision them with balls of dung rolled to the site. Some of the carrion beetles (Silphidae) form the body of a dead mouse or other small mammal into a ball, drop it into an excavated chamber, then lay eggs on it. In some species, the female remains in the nest and feeds the young larvae by regurgitation until they are large enough to feed on the carrion directly.

**Coleoptera**

A number of beetles manipulate the environment so as to provide shelter and/or food for their young. The female of the leaf roller, *Deporaus betulae* (Attelabidae), cuts across a leaf along a precise trajectory, then rolls the leaf into a tube, inside of which she lays her eggs. The larvae feed on the inner layers of the leaf roll, while being protected by the outer layers. The dung beetles (Scarabaeidae) excavate nests in the ground and provision them with balls of dung rolled to the site. Some of the carrion beetles (Silphidae) form the body of a dead mouse or other small mammal into a ball, drop it into an excavated chamber, then lay eggs on it. In some species, the female remains in the nest and feeds the young larvae by regurgitation until they are large enough to feed on the carrion directly.

**Embiiidina**

Both sexes of webspinners, adults as well as nympha, produce silk from the swollen metatarsal glands in the forelegs, which they use to spin a network of galleries on tree trunks or in leaf litter. Not only do the galleries serve as a center for brood-rearing, but they also provide a shelter within which the family of webspinners grazes on bark, dead leaves, moss, or lichens.

**Isoptera**

All the termites are eusocial (reproductive division of labor, cooperation in brood care, and overlap of at least two generations capable of contributing labor to the colony) and all live in nests. In the more primitive species, the colony nests in the wood source it feeds on. Such “single-site nesting” is exemplified by the small colonies formed by species of Termopsidae, most genera of Kalotermitidae, and the less-derived members of Rhinotermitidae. The colony spends its entire life in its log, the nest consisting simply of the irregular galleries excavated by the feeding termites. The “higher” termites, belonging to the family Termitidae and others, have evolved the ability to nest independently of their food source, in the soil or arboreally. Dissolving the identity between food source and nest freed these species to evolve larger colony size and to exploit a wider range of cellulose sources, including wood fragments of all sizes, grass, seeds, leaf litter, and humus.

**Hymenoptera**

Nesting behavior in the Hymenoptera is limited to three superfamilies: Sphecoidea, Vespoidae, and Apoidea. The ancestors of nest-building aculeates were non-nesting parasitoids of other arthropods. Nesting behavior probably got its start when a female parasitoid dragged her paralyzed prey into a crudely excavated nest in the ground and laid an egg on it, much as some sphecoids do today. Many of the solitary sphecoids and vespoids (sand wasps, digger wasps, spider wasps) excavate a subterranean nest and stock it with one or more paralyzed prey, on which an egg is laid; others (mud daubers, potter wasps) construct aerial nests of mud. A few sphecids nest in hollow stems or other natural cavities. Except for the parasitic “cuckoo bees,” all bees (Apoidea) make nests. Most are solitary, the female excavating a nest in the ground or using hollow stems or other natural cavities. Carpenter bees excavate...
burrows in solid wood. Some solitary bees construct nests of resin or a mixture of resin and pebbles, leaf pulp, or mud on rocks, stems, or leaves.

Eusocial behavior has arisen in all three superfamilies. Nesting behavior, a prerequisite, was already established well in advance of the numerous origins of eusociality in these taxa. In the ants (Formicidae) and bees (Apidae), the evolution of eusocial behavior occurred in subterranean nests, while in the wasps (Sphecidae, Vespidae) it took place in constructed, aerial nests of naked brood cells. In each group, as social life became more elaborate, nests increased in size and complexity and adapted to new nesting sites. Although many species of ants nest in the ground, many others, especially in the tropics, construct arboreal nests or nest intimately with plants. Many of the eusocial bees construct their nests in cavities, whereas others construct aerial nests, either with combs exposed or enclosed in a heavy involucrum. With larger colony size in the wasps came the evolution of protective nest envelopes and/or the move to cavities in the soil or in trees.

NEST-BUILDING BEHAVIOR

**Materials and Tools**

For the majority of social species that excavate nests in soil or wood, the nest consists merely of the cavity left after the removal of material. In contrast, constructed nests, which have evolved in all four eusocial groups, require a combination of exogenous structural material and adhesive to bind the particles of material together. Various materials are used: termites use soil or wood particles cemented together with saliva and/or fecal material. Ants use wood or other vegetable fiber or mud. *Lasius fuliginosus*, for example, fills its nest cavity with an irregular carton meshwork glued together with honeydew. The matrix is strengthened by the network of hyphae of a symbiotic fungus. Social wasps (Vespidae) are known as “paper wasps” because familiar species use wood pulp as a structural material, although many tropical species use plant hair and some even use mud. The fibers are chewed and mixed with a proteinaceous secretion of the labial gland that dries into a plastic-like matrix, giving the finished carton strength and a modicum of water repellency. Wasps that build exposed, pedicellate combs construct the pedicel primarily of this secretion, giving it toughness and a dark, shiny appearance (Fig. 1). Honey bees are unusual in using wax, secreted by wax glands on the abdomen, rather than collected material to construct their brood and storage cells. Other social bees also use wax, but mix it with exogenous materials, including pollen, plant resins (propolis), vegetable material, mud, or even feces. *Microstigmus* wasps (Sphecidae) produce silk from glands at the tip of the abdomen and use this to glue together the leaf pubescence from which their delicate nests are sculpted. Weaver ants (*Oecophylla* spp.) sew living leaves together with strands of larval silk to create multiple arboreal nesting chambers in which the young are reared.

In all nest-building insects the mandibles are chisel and trowel, the primary tools used to excavate, collect, carry, and mix materials and shape them into the nest. In paper wasps, there is evidence that mandibular morphology has evolved along with changes in nesting material. Other tools are important in a few species: sand wasps use the legs to kick excavated sand out of the burrow, and paper wasps use the forelegs to help manipulate wads of nest material during chewing and mixing with oral secretion. Sensory feedback is critical for precision construction. Wasps use the antennae as calipers to control the size of brood cells in the comb. Honey bees measure brood cell diameter with the prothoracic tarsi and sense the thickness of wax in the cell walls via pressure receptors on the antennae.

**FIGURE 1** Newly founded nest of the social wasp, *Mischocyttarus dreessenii*, from Brazil. The founding female is shown wiping an ant-repelling secretion (the gland opens at the base of the terminal abdominal sternite) onto the pedicel of the nest, where it reduces the likelihood that ants will discover the comb of brood cells while the queen is away on a foraging trip. (Reprinted, with permission, from R. L. Jeanne, Chemical defense of brood by a social wasp. *Science* 168, 1465–1466. Copyright 1970 American Association for the Advancement of Science.)

**Information Sources**

The information required to construct the nest ultimately resides in the genome of individuals, not as a blueprint of the finished nest, but as a set of one or more kinds of construction acts combined with a set of decision rules. The decision rules determine the location and orientation of material added in relation to environmental cues that include gravity, the current structure of the nest, and the location and state of brood and food stores in the nest. It is the interaction of innate rules of behavior and feedback from external cues that results in the species-typical form of the nest.

The simplest nests of solitary species are constructed by following a linear (nonbranching) sequence of steps. A sand wasp digging her nest, for example, need only decide when to switch from extending the burrow to excavating a brood cell. In contrast, nonlinearity characterizes the construction behavior of all social insects. Rather than following a programmed linear sequence, workers make choices among several types of building behavior according to the current state of construction of the nest. Thus, a *Polistes* wasp can use her load of pulp to thicken the pedicel, lengthen a brood cell, initiate
bees expand the combs in the hive when there is a strong nectar flow; others it occurs in bouts separated by periods of no growth. Honey growth is continuous throughout the life in the colony, whereas in date colony growth. In some species, such as yellowjacket wasps, and wasps.

A similar arrangement is also seen in the nests of termites (Fig. 2). The entrance to the nest cavity (or a hive box) is secured by guard bees against intrusion by predators and parasites. A similar arrangement is also seen in the nests of termites (Fig. 2) and wasps.

Most social insects are able to expand their nests to accommodate colony growth. In some species, such as yellowjacket wasps, growth is continuous throughout the life in the colony, whereas in others it occurs in bouts separated by periods of no growth. Honey bees expand the combs in the hive when there is a strong nectar flow coupled with a shortage of honey storage cells. In ants and termites, nest expansion may occur opportunistically after rains soften the soil.

**FUNCTIONS OF NESTS**

Social Functions

The nest is the information center of the colony. It is here that information is communicated about resource supply and demand and about the status of the queen. The nest itself is involved in the distribution of information about colony membership. Each colony has a unique mix of chemicals that labels every individual as belonging to that colony. This “colony odor” resides on the cuticle of each individual as well as in the nest material, and it has been shown for wasps and honey bees that newly emerging workers learn to recognize their colony odor from the nest.

Food Storage

Bumble bees construct specialized wax pots in which they store honey and pollen during periods of good foraging. Stingless bees and honey bees store pollen and enough honey to sustain the adult population through the unfavorable season. The “honey wasps” (Brachygastra spp.) of the Neotropics also store large amounts of honey in their brood cells for the same purpose. Many other species of social wasps store enough honey as droplets in empty brood cells to get the colony through several days of poor foraging. Desert seed-harvester ants stockpile seeds in chambers in their nests, and honey ants (Myrmecocystus and others) store large amounts of honey in the crops of specialized workers called repletes. The fungus ants and higher termites in the subfamily Macrotermitinae (Termitidae) grow specialized fungus as food in chambers in their nests (Fig. 2).

Defense

Nests often incorporate or accommodate some means of defense against natural enemies. The broods of small, newly initiated colonies are especially vulnerable when the founding queen must leave the nest to forage. Wasps in the genera Polistes and Mischocyttarus...
sustain their uncovered combs from a narrow, tough pedicel, which
they coat with an ant-repelling secretion produced by an exocrine
gland at the base of the terminal sternite (Fig. 1). Among the swarm-
founding wasps of the tropics are several species that surround the
access to the nest with “ant traps” made of carton bristles several
millimeters long, each tipped with a sticky droplet.

Bees and wasps that nest in cavities or construct protective outer
covers reduce access by ants and parasitoids to a narrow entrance
that can be guarded by a few defending workers. Some stingless bees
cover the entrance tube with sticky propolis as a barrier against ants,
whereas others pull the soft, waxy tube closed each night. The outer
layer of the involucrum of arboreal nests of *Trigona cornixa* and
*T. spinipes* is thin and easily broken by an intruder, allowing defending
bees to swarm out through passageways in the tough, inner layer and
launch an attack.

Homeostasis

Social species that form small colonies can exert little control
over temperature, humidity, or atmospheric gas concentration in the
nest, but some compensate by placing their nests in favorable micro-
habitats. By building their nests where sun-warmed air collects, such
as under eaves on the sunny sides of outbuildings, *Polistes* wasps at
higher latitudes achieve shorter egg-to-adult development times than
they would at ambient temperatures.

By virtue of a larger metabolizing biomass and lower nest sur-
face/volume ratios, social species with larger colonies are better able
to regulate nest conditions, and nest architecture is often adapted to
enhancing homeostatic control. Large colonies produce considerable
amounts of metabolic heat, raising nest core temperature well above
ambient. Thick nest-cavity walls or insulating envelope reduce the
loss of this heat to the environment. By combining metabolic heating
with evaporative cooling, honey bees can regulate the temperature in
the core of the nest to within half a degree of 35°C, even if the out-
side temperature is many degrees lower or higher. The multiple lay-
ers of paper envelope of yellowjacket wasps (*Vespula*) enclose dense
air spaces that insulate the nest against heat loss, enabling the colony
to maintain the nest temperature well above ambient.

Subterranean-nesting termites and ants have less control over the temperature in the chambers of their nests, but they can construct
the nest to take advantage of solar heating. Some ground-nesting
ants of temperate regions excavate chambers under flat rocks lying
on sunny ground. As the rock warms in the sun during the day, heat is
conducted downward to the ground below. By moving the brood
up into these warm but moist chambers during the day, the ants
accelerate the development of their immatures. At night, as the rock
loses its heat, the brood is moved down to relatively warmer cham-
bers deeper in the soil.

Some ants in higher latitudes build honeycombed mounds of soil
or plant detritus. In some of the *Formica* species these can be over
2 m in height. The sun warms the mound to several degrees above
ambient, and the colony incubates pupae by moving them up into
chambers in the mound during the day.

The most spectacular examples of homeostatic control of nest
conditions are the large epigal (aboveground) mounds built by ter-
mites in the savannas of the tropics. Homeostatic mechanisms vary
across species, habitat, season, and even time of day. One example
is *Macrotermes bellicosus*, found on the savannas of western Africa,
whose colonies can reach 2 million workers living inside large, cathe-
dral-like towers that are 3 m or more in height. Air circulation within
the mound during the day in the dry season is shown in Fig. 2.

Neuropeptides

Miriam Altstein

*Agricultural Research Organization,*

*the Volcani Center, Israel*

Neuropeptides (Nps) are bioactive peptides of neuronal origin,
found throughout the animal kingdom, forming a most struc-
turally and functionally diverse group of compounds. Nps
have been well conserved during the course of evolution, indicating
their major role as regulators of physiological processes. Nps are extra-
cellular chemical messengers that act as circulating neurohormones,
as local co-transmitters or as neuromodulators, and in the hierarchy
of entities that regulate endogenous biochemical control functions,
the Np messengers rank the highest, regulating almost every aspect of
life. The original definition of Nps covered small molecules (less than
50 amino acids) of a peptidic nature, synthesized in specialized nerve
cells, known as neurosecretory cells (NSCs), most of which are located
in the cerebral ganglia (brain), and are released from their axon ter-
minals, either into the intracellular space of an adjacent cell (nerve,
endocrine, or non-endocrine) or into the circulatory system. Those
released into intracellular spaces affect proximal effector sites; those
that enter the general circulation reach peripheral organs, where their
activity can be manifested either directly by activation of a distal target organ or indirectly via signals to non-neuronal internal secretory glands. In recent years, it became apparent that Nps are also synthesized in neuronal cells that are not NSCs as well as in non-neuronal cells, and the Np concept has been widened to include peptides that serve to integrate the brain and other tissues for the maintenance of normal physiology, homeostasis, and behavioral patterns.

In insects, Nps regulate a long list of physiological and behavioral processes during development, reproduction, and senescence, and they maintain growth, homeostasis, osmoregulation, water balance, metabolism, and visceral activities. In the past two decades, many insect Nps have been identified, the basic principles of their action (e.g., biosynthesis, processing, release, transport, activation of the target cell, and degradation) have been revealed, and their roles in the physiology of organisms have been determined by means of genome sequencing, peptidomics, gene microarrays, receptor characterization, and targeted gene interference, all combined with physiological, electrophysiological, and behavioral analysis. This article describes the current knowledge of the structure of the insect neuroendocrine system, the distribution of insect Nps and their receptors, and lists the various Np families and their diverse functions.

**NP RESEARCH IN A HISTORICAL PERSPECTIVE**

The concept of neuroendocrine control dates back to the beginning of the 20th century when Stephan Kopeček first suggested that metamorphosis in insects is regulated by brain factors that are released into the hemolymph. Further progress in the field came from the studies of Berta and Ernst Scharrer who introduced the basic concepts of neurosecretion and NSCs, and described the similarities between the retrocerebral complex in insects and the hypothalamic–hypophysial system in vertebrates. Although neurosecretion was first observed in insects, invertebrate Np research has lagged behind vertebrate studies, mainly because of low availability of biological material and the lack of sensitive techniques for isolation, sequencing, and lack of sensitive techniques for isolation and sequencing of peptides. The development of chemical, biochemical, and genetic engineering technologies, as well as the growing awareness of the major role Nps play in the physiology of organisms, stimulated active interest in insect Np studies, and indeed, in 1975 Starratt and Brown released their pioneering publication announcing the initial determination of a primary structure of the insect Np, proctolin.

Since then, over 150 insect Nps have been identified, most of which have been isolated from the fruit fly, *Drosophila melanogaster*, cockroaches (e.g., *Leucophaea maderae*, *Periplaneta americana*), locusts (e.g., *Locusta migratoria* and *Schistocerca gregaria*), moths (e.g., *Manduca sexta*, *Bombyx mori*, and various Heliothine species), and mosquitoes (e.g., *Anopheles gambiæ* and *Aedes aegypti*).

A variety of methods have been employed to identify the structures and to localize and study the mode of action of Nps. The first insect Nps were identified (prior to the genomic/proteomic era) by “classical” methods, namely, isolation and Edman degradation sequencing, and their putative functions were tested in different in vivo and in vitro bioassays. This approach was applied mainly to functionally identified Nps. Later on, Np primary sequences were predicted, based on their cloned genes, and localization studies were carried out using immunohistochemical and in situ hybridization techniques. In parallel, Np receptors, obtained from fractionated cell membranes have been studied by means of specific binding assays, but only a few (less than five) had been characterized before the late 1990s.

In the past few years, research on insect Nps has seen several major advances that have accelerated our familiarization with their structures and functions. One of the most important of these advances was the sequencing of several insect genomes (e.g., *D. melanogaster*, *Apis mellifera*, *B. mori*, *A. gambiæ*, and *A. aegypti*), which provided information about Np precursor genes: information that formed the basis for predicting and identifying many more Nps. Currently, 30–40 genes encoding Np precursors have been predicted in each species. The genomic information also extended our knowledge on Np receptor genes (G-protein-coupled receptors, GPCRs), Np prohormone processing enzymes, and several other genes that encode proteins which play a role in the regulation of cell-specific Np expression, thus providing us with great resources for gaining a better and deeper insight into Np functions in insects. More recently, mass spectrometry (MS) followed by sequence determination, was employed for Np identification and localization. This method enabled analysis of Nps (in the femtovol level or less) in the hemolymph, in tissue extracts and single cells by matrix-associated laser desorption/ionization (MALDI) MS and examination of neuronal homogenates by electrospray ionization (ESI) techniques. A variety of MS-based approaches (direct tissue MS or MS in combination with laser capture microdissection) have accelerated the rapid and accurate identification of predicted Nps in small amounts of tissues, and even in single neurons, and have led to both identification and localization of hundreds of new Nps in a single step.

Currently, Np studies focus on: re-screening of genome databases with novel search algorithms (database mining) to enable putative GPCRs or prohormone sequences to be identified and then cloned from any nascent, unidentified genome; MS probing of tissue extracts for confirmation of predicted sequences; MS analysis of single neurons, in conjunction with immunocytochemistry (ICC) for localization and determination of the anatomical organization of Nps inside and outside the insect’s central nervous system (CNS); molecular manipulations at the Np gene level, for determination of the functional role of a given Np; and development of cell-based and/or cell-free recombinant GPCR-binding assays to determine the mode of action of a given Np at the cellular level, to discover orphan receptors ligands, and to screen libraries (chemical, phage display, and natural compounds) for discovery of Np agonists and antagonists. Special attention is paid to the role insect Nps play as potential targets for pest management and as a basis for development of insect-control agents by means of rational/structural design approaches.

**ANATOMY OF THE NEUROENDOCRINE SYSTEM IN INSECTS**

The cellular distribution of Nps and their anatomical neurochemical organization in insects have been studied mainly by morphological methods such as ICC and retrograde nerve filling and, in several cases, by *in situ* hybridization. Recently, with the introduction of a variety of MS techniques, mass spectrometric analyses have been employed in conjunction with the above methods to identify Nps and their possible co-localization in single identified neurons of neurohema organs. The studies revealed great diversity among insects in the distribution patterns of the various Nps, with diverse degrees of complexity in the various peptidergic circuits. Insect Nps are found in NSCs, interneurons, and endocrine cells. The vast majority of known insect Nps are found in NSCs that terminate in the brain–subesophageal ganglion (SOG)–corpora cardiaca–corpora allata complex (Fig. 1). This complex comprises six clusters of NSCs: a pair of medial NSCs that originate in the pars intercerebralis (PI), a pair of
lateral NSCs that originate in the protocerebral region of the brain, and a pair of NSC that originate in the SOG. These six clusters form axon bundles termed nervi corporis cardiaci (NCC); NCC1, NCC2, and NCC3, respectively. Each of the nerve bundles terminates in a pair of retrocerebral neurohemal glands, termed corpora cardiaca (CC). The nerve terminals form the storage lobe of the CC through which Nps are released into the circulatory system. Additional neuroendocrine (intrinsic) cells are present in another lobe of the CC glands (the glandular lobe), which is the site of synthesis and release of other Nps. Two additional clusters of NSCs, which originate in the SOG, extend axons that form the nervi corporis allati 1 (NCA1), which terminate in another pair of endocrine glands (of non-nervous tissue origin), termed corpora allata (CA), and form another neurohemal region. Another pair of dorsolateral NSCs that originate in the PI region of the brain extend axons that terminate in the CA. The CC and CA are adjacent glands, partially fused with the ventral wall of the aorta, which enables release of the Nps that are synthesized in the neuroglandular cells, as well as those from the brain/SOG nerve terminals, into the circulatory system.

Studies carried out in a variety of insects (the fruit fly D. melanogaster, the desert locust S. gregaria, the cockroach P. americana, and the moth M. sexta) revealed that many Nps are also found in a large variety of interneuronal cell types scattered in all areas of the brain, and that most Nps are expressed in at least a few intersegmental neurons throughout the length of the ventral nerve cord. Np-containing cells have also been reported in visceral organs such as the gut, oviduct, accessory glands, and even hemocytes.

Another much smaller neuroendocrine structure comprises the segmentally arranged perisymphatic organs (PSOs); it serves as the storage and release site of Nps produced by neurons in the thoracic and abdominal ganglia of the ventral nerve cord. Most of the Nps that have been detected in the PSO are not homologous with those found in the retrocerebral complex. Another neuroendocrine structure is the epitracheal system; it consists of segmentally arranged nerve cells located at the trachea, near the spiracles that form the epitracheal glands (EGs). The system produces two blood-borne Nps that trigger pre-ecdysis and ecdysis behavior: pre-ecdysis-triggering hormone (PETH) and ecdysis-triggering hormone (ETH). Other NSCs are distributed throughout the insect body: throughout the CNS, in the sympathetic nervous system and the peripheral nervous system, on the aorta, and at the ampullae of the antennal heart. Most of these release sites are situated in well-circulated regions of the body. A detailed review on insect Np localization was presented by Nässel and Homberg.

### NP FAMILIES

Accumulation of information on the primary structures of insect Nps led to synthesis of many peptides, which together with the availability of a large variety of bioassays enabled studies of their structure–activity relationship (SAR) and their arrangement into either structurally homologous peptide families or by their functions. Categorization of Nps into “functional families” was usually based on their main action or the one for which a given Np was best known. The major groups of Nps involved in development, reproduction, homeostasis, metabolism, myotropic activity, and coloration are listed below. Some peptides are involved in several functions and are, thus, listed in more than one category.

#### Developmental Nps

The main Nps in this category are the allatotropins/allatostatins, which stimulate/inhibit synthesis of juvenile hormones by the CA; PETH, ETH, crustacean cardioactive peptide (CGAP), and eclosion hormone (EH), which are involved in controlling pre-ecdysis and ecdysis behavior; and prothoracotropic hormone (PTTH), which stimulates molting by initiating biosynthesis and release of ecdysone by the prothoracic gland and diapause hormone that arrests development in eggs.

#### Reproductive Nps

This family includes the ovary maturating peptide (OMP) and egg development neurosecretory hormone (EDNH), which stimulate egg development; oostatic hormone (OH), which inhibits maturation of ovaries; trypsin modulatory oostatic factor (TMOF), which regulates egg development by modulating trypsin biosynthesis in the gut; neuroparsin which affects gonad activity; PTTH, which...
and their peptides has been introduced. This approach was summa-
native approach for Np categorization, based on Np precursor genes

tological characteristics) has been presented by Gäde and by Gäde and

peptide. A detailed review of the structural, biochemical, and physi-
activity may be regulated in a given insect species by more than one
insect species or in several different ones; and a given biological
gene duplication occurred resulting in the presence of more than
one Np form (isoform) in a given species (e.g., AKH, PBN) belong to families that are known to occur only in arthropods. These
studies also revealed that a few peptides (e.g., proctolin and CCAP)
belong to “one-member” families, whereas others are members of large families (e.g., the PK/PBN family). Moreover, for some Nps
gene duplication occurred resulting in the presence of more than
one Np form (isoform) in a given species (e.g., AKH, allatostatins,
and myopectinins and myoinhibitory peptides (e.g., allatostatin and myosuppressin).

Chromatotropic and Circadian Nps

Members of this family include melanization and reddish colora-
tion hormone (MRCH), pigment dispersing hormone/parasite hormone (PDH/ PDH), and corazonin, a cardioactive peptide that exhibits dark pig-
mentation properties.

Most of the above-mentioned insect Nps have been character-
zized, their amino acid sequences have been determined, and their
cDNA and genes have been cloned from various insect species. The
analysis of the structures and modes of action of major Np families of insects has revealed that some peptides (e.g., AKH, PBN) belong to families that are known to occur only in arthropods. These
studies also revealed that a few peptides (e.g., proctolin and CCAP)
belong to “one-member” families, whereas others are members of large families (e.g., the PK/PBN family). Moreover, for some Nps
gene duplication occurred resulting in the presence of more than
one Np form (isoform) in a given species (e.g., AKH, allatostatins,
and myopectinins and myoinhibitory peptides). Many Nps are multi-
functional and elicit more than one biological response in a single
insect species or in several different ones; and a given biological
activity may be regulated in a given insect species by more than one
peptide. A detailed review of the structural, biochemical, and physi-
ological characterization of insect Nps (based on structural and func-
tional characteristics) has been presented by Gade and by Gade and Marco. Recently, with the availability of the genomic data, an alter-
native approach for Np categorization, based on Np precursor genes
and their peptides has been introduced. This approach was summa-
rized by Altstein and Nässel.

NOMENCLATURE

The nomenclature of insect NPs is usually based on two primary characteristics: the Np source, which is indicated by the first two let-
ters of the genus name (with the first letter capitalized) and the first
letter of the species name and the first reported or the major biolog-
ic function. For example, a peptide isolated from Helicoverpa zea
which was first reported to have a pheromone-active property, would
be designated Hez-PBN. A detailed explanation of insect peptide
nomenclature was presented by Raina and Gade.

Homeostatic/Metabolic Nps

This group includes the adipokinetic/hypertrehalosemic peptides (AKH/HT) that regulate carbohydrate and lipid metabolism,
and bombyxin and other insulin-related peptides that control fat,
and carboxylation, and protein metabolism. Additional members of the family are the diuretic and antidiuretic hormone peptides and the
ion-transporting peptides (ITP), which are involved in osmoregula-
ration, regulation of Malpighian tubule activity, and water balances.

Myotropic Nps

This family is one of the largest Nps families in insects; it regulates the contractile activity of visceral and/or skeletal muscles. The family
includes peptides such as proctolin, CCAP, FMRFamide-related
peptides, myokinins, sulfinkins, pyrokinins, tachykinins short and
long neuropeptide F (NPF), nyotropins and myoinhibitory peptides
(e.g., allatostatin and myosuppressin).

Chromatotropic and Circadian Nps

Members of this family include melanization and reddish colora-
tion hormone (MRCH), pigment dispersing hormone/parasite hormone (PDH/ PDH), and corazonin, a cardioactive peptide that exhibits dark pig-
mentation properties.

Most of the above-mentioned insect Nps have been character-
zized, their amino acid sequences have been determined, and their cDNA and genes have been cloned from various insect species. The
analysis of the structures and modes of action of major Np families of insects has revealed that some peptides (e.g., AKH, PBN) belong to families that are known to occur only in arthropods. These
studies also revealed that a few peptides (e.g., proctolin and CCAP)
belong to “one-member” families, whereas others are members of large families (e.g., the PK/PBN family). Moreover, for some Nps
gene duplication occurred resulting in the presence of more than
one Np form (isoform) in a given species (e.g., AKH, allatostatins,
and myopectinins and myoinhibitory peptides). Many Nps are multi-
functional and elicit more than one biological response in a single
insect species or in several different ones; and a given biological
activity may be regulated in a given insect species by more than one
peptide. A detailed review of the structural, biochemical, and physi-
ological characterization of insect Nps (based on structural and func-
tional characteristics) has been presented by Gade and by Gade and Marco. Recently, with the availability of the genomic data, an alter-
native approach for Np categorization, based on Np precursor genes
and their peptides has been introduced. This approach was summa-
rized by Altstein and Nässel.

NOMENCLATURE

The nomenclature of insect NPs is usually based on two primary characteristics: the Np source, which is indicated by the first two let-
ters of the genus name (with the first letter capitalized) and the first
letter of the species name and the first reported or the major biolog-
ic function. For example, a peptide isolated from Helicoverpa zea
which was first reported to have a pheromone-active property, would
be designated Hez-PBN. A detailed explanation of insect peptide
nomenclature was presented by Raina and Gade.

CELLULAR AND MOLECULAR ASPECTS
OF NP ACTIVITY

The cellular and molecular components of Np activity include biosynthesis, release, transport, activation of the target cell, and inac-
tivation of the Np to terminate its action. Np gene expression is regu-
lated by a complex series of factors that are controlled by other Nps
and neurotransmitters. The Nps are synthesized as large precursor polypeptide chains (termed prohormones) that include a signal
sequence which is removed by an endopeptidase during translation.
The remaining protein, the prohormone, is transported to the Golgi
apparatus, where it is packed into secretory vesicles in which it is fur-
ther processed proteolytically into smaller fragments by prohormone-
converting enzymes. Precursors can encode multiple bioactive Nps
within a single molecule, including replicates of an individual peptide
or single copies of numerous peptides. During the transit through the
Golgi network, the precursors may be subject to post-translational modifications such as glycosylation, phosphorylation, sulfation, or
hydroxylation. Secretory vesicles containing Nps accumulate at NSC
terminals and are secreted by a regulatory secretory pathway (usu-
ally in a Ca2+-dependent manner). Unlike neurotransmitters, Nps
are not recycled at the nerve terminals but are newly synthesized in the
cell body. Following secretion (either to the circulatory system via
neurohemal organs, or to the intracellular space of adjacent cells) the
Nps reach their target organ, where they activate their target cells
by binding to cell-surface proteins (termed receptors) and exciting
second-messenger systems, thus eliciting a variety of cellular
responses. At the end of the activation, Nps dissociate from the recep-
tor and are rapidly inactivated by peptidases present in the plasma,
in the intercellular space, or in the target cell membrane. All the above
events are common to all Nps, regardless of their origin or biological
function. Strand has provided a detailed summary of these processes.

NP RECEPTORS

Nps activate cellular processes via GPCRs, which are seven trans-
membrane domain proteins (7TM) that sense molecules outside the
cell and activate internal signal transduction pathways and, ultimately,
cellular responses. Prior to the determination of insect genomes,
receptors were isolated from the relevant tissue and characterized bio-
chemically and pharmacologically. This approach has led to the char-
acterization of a dozen different receptors from a variety of tissues in
diverse insects: locust hindgut proctolin receptor; Blaberus craniifer
fore- and hindgut proctolin receptor; M. sexta Malpighian tubules
diuretic hormone receptor and fat body AKH receptor; Diploptera
punctata brain and midgut allatostatin receptors; B. mori ovarian
cell bombyxin receptor; locust oviduct FLRFamide receptor; cricket
Malpighian tubule achatakinin receptor; locust and flesh fly tachyki-
nin receptors; A. aegypti Malpighian tubule leucokinin receptor; and
Heliothis peltigera pheromone gland pyrokinin/PBN receptor. Two of
the above receptors were cloned (diuretic hormone and tachyki-
nin). An outburst of studies on insect Np receptor cloning occurred in
the late 1990s, when databases of various gene banks, and especially
that of the Berkeley Drosophila Genome Project, became available
to the scientific community. In less than 4 years eight novel insect
Np receptors have been cloned by means of a variety of approaches.
Some receptors (the cattle tick Boophilus microplus leucokinin recep-
tor and the D. melanogaster tachykinin and neuropeptide Y recep-
tors) were cloned by PCR with primers based on the 7TM domain
common motifs. Other approaches included screening cDNA and
genomic libraries with sequences homologous to mammalian recep-
tors (e.g., Drosophila growth hormone receptor, and allatostatin-1

694 Neuropeptides
and -2 receptors) or receptors of related families isolated from other insects (e.g., *Drosophila* and stable fly tachykinin receptor, *P. americana* allatostatin receptor). The field received an even greater boost with the completion in 2000 of the *Drosophila* genome sequence and subsequently of those of other insects. Within a few years, 48 Np receptor genes that represent the vast majority, perhaps all, of the peptide GPCRs encoded by the fly genome have been predicted and, to date, nearly 30 *D. melanogaster* GPCRs have been characterized with respect to their preferred peptide ligands. Peptides from other insects, too, have been identified, and recently knowledge on *D. melanogaster* GPCRs was used to annotate 35 Np GPCRs in the recently sequenced genome of the honey bee, *A. mellifera*. A detailed summary was presented by Hauser et al.

**SUMMARY AND FUTURE PROSPECTS**

The combination of the above novel approaches (e.g., MS, large-scale peptidomic studies, genome sequence analysis, and targeted mutagenesis of Np genes) with the more classical immunochemical, biochemical, and cytochemical approaches, together with *in vitro* studies of characterization of peptide GPCRs and analysis of their distributions in various insects has provided us with a great source of information and has significantly advanced our understanding of Np signaling. Further studies along these lines, combined with comparative experimental studies, based on information from annotated genomes of multiple insect species should be pursued in order to achieve identification and structural and functional characterization of some orphan receptors and predicted Nps, which should lead to evaluation of the functional role of Np isoforms in the organism, and enable study of the various downstream secondary messenger pathways all of which can be expected to further improve our insight into the various aspects of Np signaling. Altstein has recently summarized a novel approach to the exploitation of this avenue.

In addition to their position as prime objectives in advancing our understanding of the physiology of insects, Nps and their receptors are also targets for the development of novel insect-control strategies based on interference with their activity by means of receptor-specific agonists or antagonists. The use of Nps as a basis for insecticide design made great progress in the past decade because of the vast input of novel information on GPCRs, Np genes, and their sequences. This information provides a basis for development of insect-control agents based on rational/structural design. This field is still in its infancy and, although this strategic approach has been used to develop a few vertebrate Np agonists and antagonists, the technology has not yet been optimized. Thus, new approaches to the generation of Np agonists/antagonists and to their further conversion into insecticide prototype compounds with specific desired features need to be developed. Once these strategies are devised, it should be possible to implement them with a variety of Nps in order to tailor highly potent insect-control agents.

**Neuroptera (Lacewings, Antlions)**

Catherine A. Tauber, Maurice J. Tauber, *Cornell University, Ithaca, NY*

Gilberto S. Albuquerque

*Universidade Estadual do Norte Fluminense, Campos dos Goytacazes, Rio de Janeiro, Brazil*

The Neuroptera, also known as Planipennia, is one of the oldest insect orders with complete metamorphosis. With ~6000 species distributed among 17 families, the order is relatively small. It includes the green and brown lacewings, antlions, owlflies, dustywings, mantidflies, and allies. Its members occupy a wide variety of habitats and display an array of life styles. Because of their lacy and colorful wings, delicate bodies, and fascinating biology, neuropteran adults attract the attention of both biologists and laypersons (see Fig. 1).

**FIGURE 1** Neuropteran adult in the family Crocidae. Note the colorful forewings, long slender hind wings, and delicate body. (Photograph by E. S. Ross, California Academy of Sciences.)
Neuropteran larvae are much less noticeable than adults and have received less attention. Unlike the adults, which may or may not take prey, almost all neuropteran larvae are predacious. Several families (primarily Chrysopidae, Hemerobiidae, and Coniopterygidae) are useful in the natural, biological, and integrated control of many economically significant insect pests. But, despite their actual and potential importance, they have received less emphasis than other groups, such as the predacious lady beetles.

The name "Neuroptera"—from the Greek words "neuron" meaning “sinew, tendon” and “pteron” meaning “wing”—refers to the neithelike arrangement of veins and cross veins in the wings. The term comes from an old usage of the word “nervation”, meaning "strengthening by sinews". It did not refer to nerves, as often suggested.

**CHARACTERISTICS**

Neuropteran adults are soft-bodied and have four membranous wings of similar size, structure, and venation; the wings are held roof-like over the body while the insect is at rest (Fig. 2). Branches of the veins are generally bifurcated at the wing margins. Adults have chewing mouthparts, large compound eyes located laterally on the head, and multiarticulate antennae that are usually filiform (thread-like) or moniliform (with bead-like segments). Except for one family (Osmylidae), adults lack ocelli. The mesothorax and metathorax are similar in structure, and the cylindrical abdomen lacks cerci.

Neuropteran larvae differ markedly from adults. Larval mandibles and maxillae are usually elongate, slender, and modified for sucking; maxillary palpi are absent. The larval thorax bears walking legs, and the one-segmented tarsus usually ends in two claws that function in locomotion. The terminal adhesive disks of the abdomen also aid locomotion. Like the adult, the larva lacks abdominal cerci.

Neuropteran larvae spin silken cocoons within which they metamorphose. Pupae are decticious; that is, they have strong mandibles that are used to cut open the cocoon. After exiting from the cocoon, the exarate pupae are capable of limited locomotion before they molt to the adult stage; their legs and unexpanded wings are free from the body, and the abdomen is moveable.

Most Neuroptera studied have XXXY sex determination. However, their sex chromosomes may display an unusual type of pairing ("distance pairing"), in which the chromosomes do not align to form bivalents during meiosis; rather, they are pulled from within the spindle to stabilized positions at the poles. This form of meiosis and other cytological features are shared with Raphidioptera. In many neuropteran taxa, meiosis occurs early in development, for example, during the last instar or the pupal stage. In these taxa, adult males have degenerate testes, and mature sperm bundles are stored within the seminal vesicles.

**FOSSIL RECORD AND GEOGRAPHIC DISTRIBUTION**

Although the fossil record of the Neuroptera is fragmentary, ancient (extinct) neuropterans have been traced back reliably to the Late Permian of Eurasia. The affinities of these archaic forms to modern taxa are undetermined; they seem to be a stem group. Other early neuropteran fossils appear in the mid-Mesozoic; these specimens, some of which are assigned to the extinct family Permithonidae, have a primitive wing structure and their affinities with modern neuropterans are unknown. The largest recorded neuropteran, a psychopsid-like lacewing (in the family Kalligrammatidae) with a wingspan of 24 cm and large conspicuous "eyespots" on the wings, existed in the Jurassic. Fossils from the Jurassic are also known for extant families from both suborders (Myrmeleontiformia: psychopsids, nymphiids; Hemerobiiformia: polystoechotids, osmylids, chrysopids, hemerobiids, and coniopterygids). Creataceous amber includes specimens from an array of modern families, including Berothidae, Mantispidae, and Osmylidae, among others, and the diverse Neuroptera found within Baltic amber (Eocene) can be placed within modern families.

Today, the order Neuroptera is distributed worldwide, except for Antarctica. Europe, North America, and Asia have rich neuropteran faunas as do southern Africa, South America, and Australia. Australia may have the broadest diversity; it lacks representatives from only two families (Dilaridae and Polystoechotidae) and most of the presumed archaic families are represented there (e.g., Nevrotidae, Sisyridae, Ithonidae). In contrast, New Zealand and the South Pacific islands have only meager neuropteran faunas. Remarkably, Hawaii appears unique in being the only island group to have evolved complexes of endemic species (Hemerobiidae and Chrysopidae).

**EVOLUTIONARY RELATIONSHIPS WITH OTHER ORDERS**

Taken together, the three orders, Megaloptera (dobraflies, alderflies), Raphidioptera (snakeflies), and Neuroptera, (Neuroptera sensu stricto, Planipennia) (lacewings, antlions, dustywings, and allies) form the superorder Neuropteroidea. Because of its ancient fossil record, the generalized body structure of its larvae and adults, and its exarate pupae, Neuropteroidea is considered to be among the most primitive taxa within the Holometabola (insects with complete metamorphosis, Endopterygota). Significant morphological and molecular evidence indicates that this superorder is a monophyletic grouping and in a sister relationship with the Coleoptera.

A number of synapomorphic (shared, relatively derived or specialized) characteristics distinguish the Neuroptera as a monophyletic order that is separate from Megaloptera and Raphidioptera. Notably, most of these distinguishing features occur in the larvae. For example, megalopteran and raphidiopteran larvae have biting-chewing mouthparts, the mouth opens anteriorly, and the cervix has a single, unarticulated, ribbon-like sclerite. In contrast, the mouthparts of neuropteran larvae are suctorials and consist of elongate and pointed mandibles and maxillae whose adjacent grooved surfaces
form a feeding tube. The mouth, instead of opening anteriorly, connects to the feeding tubes at the sides of the head, and the larva has an articulated, neck-like cervix.

Other larval characteristics distinguish the Neuroptera from the other two neuropteran orders. Neuropteran larvae do not have contiguous intestinal tracts. Rather, the midgut and hindgut remain separate until pupation. As the larvae feed, waste accumulates in the midgut. Only after metamorphosis, when the midgut and hindgut become connected, do the newly emerged adults expel the feces as a meconial pellet. Neuropteran larvae use the hindgut and associated structures (Malphigian tubules) to produce silken cocoons in which the larvae metamorphose to exarate, decticous pupae. In contrast, megalopteran and raphidiopteran larvae have contiguous intestines, and they do not form cocoons or spin silk; rather, they metamorphose within earthen chambers or wooden cells. Like the Neuroptera, their pupae are exarate and decticous.

Recent phylogenetic studies have examined the relationships among the three neuropteran orders; these studies used comparative data from male and female genital structures, larval head and mouth-part structure, and the molecular structure of several nuclear and mitochondrial genes. Although not without limitations, the preponderance of current evidence indicates a dichotomy between Raphidioptera and Neuroptera (Megaloptera + Neuroptera) and a relatively well-supported sister relationship between Megaloptera and Neuroptera (Fig. 3).

**EVOLUTIONARY RELATIONSHIPS WITHIN NEUROPTERA**

The order Neuroptera encompasses 17 families that currently fall into 3 suborders: Nevrorthiformia, Myrmeleontiformia, and Hemerobiiformia. Two of the three suborders, Nevrorthiformia and Myrmeleontiformia, are well supported by morphological and molecular data, and current evidence indicates that an aquatic larval life style, typified by the Nevrorthiformia, was the primitive neuropteran condition (Fig. 3). However, the data are contradictory regarding the phylogenetic history of the two hemerobiiform families with aquatic/semiaquatic larvae—the Sisyridae and Osmylidae. Current molecular evidence can be interpreted as consistent with the retention of a primitive aquatic state in these two families, whereas morphological data from the larvae are consistent with the secondary acquisition of aquatic/semiaquatic life styles. The debate continues.

Order Neuroptera (=Neuroptera sensu stricto, Planipennia)

Suborder Nevrorthiformia (=Nevrorthiformia, a mispelling)
Family Nevrorthidae (=Neurorhidae, a mispelling) (12 species)
Suborder Myrmeleontiformia
Family Psychopsidae (silky lacewings) (~26 species)
Family Neopteridae (spoon-winged lacewings) (~100 species)
Family Crocidae (thread-winged lacewings) (~50 species)
Family Nymphidae (including Myiodactylidae of some authors)
Family Myrmeleontidae (including Stilbopterygidae of some authors) (split-footed lacewings) (~35 species)
Family Sisyridae (spongillafl ees) (~50 species)
Family Chrysopidae (green lacewings) (~1,200 species)
Family Hemerobiidae (brown lacewings) (~550 species)

Suborder Hemerobiiformia
Family Ithonidae (including Rapismatidae of some authors)
(subfamily Inocelliinae) (35 species)
Family Polydactylidae (giant lacewings) (4 species)
Family Osmyliidae (split-footed lacewings) (~160 species)
Family Sisyridae (spongillafl ees) (~50 species)
Family Chrysopidae (green lacewings) (~1,200 species)
Family Hemerobiidae (brown lacewings) (~550 species)

Family Coniopterygidae (including Bruchesieridae of some authors) (dustywings) (~450 species)
Family Dilaridae (dustywings) (~65 species)
Family Mantispidae (mantidflies) (~400 species)
Family Berothidae (including Rhachiberothidae of some authors)
Family Coniopterygidae (dustywings) (~115 species)

**SUBORDER NEVRORTHIFORMIA**

The Nevrorthiformia contains a single, very small family, Nevrorthidae. This family shares several characteristics with the Megaloptera and is considered basal among the Neuroptera: for example, its aquatic larvae retain some megalopteran-like head structures (e.g., well-developed gula), and they have Malphigian tubules that lie free distally (i.e., without cryptonephry). Thus, the Nevrorthiformia emerges as the basal neuropteran suborder.

Among the Neuroptera, a terrestrial life style without cryptonephry is considered plesiomorphic (primitive); this life style is typical of all Raphidiopterans. The evolution of an aquatic larva (without

![FIGURE 3](image-url) One of several cladograms depicting the phylogenetic relationships within Neuroptera (modified from Haring and Aspöck, 2004). Note the sister relationship between Neuroptera and Megaloptera, the separation of three neuropteran suborders, and the relationships of the families within the suborders. (1) Nevrorthiformia; (2) Hemerobiiformia; (3) Myrmeleontiformia. The black circle indicates the evolution of a terrestrial life style; the open circle indicates the evolutionary reversal from a terrestrial life style to an aquatic or semiaquatic one. A “maxillary” larval head is the major apomorphy that typifies the Hemerobiiformia.
Neuroptera

cryptonephry) is considered a synapomorphy that may support a sister relationship between the megalopteran and neuropteran lineages. According to this interpretation, the aquatic life style (without cryptonephry) was retained in the Nevrothiformia, whereas a reversal to the terrestrial life style and the acquisition of cryptonephry (i.e., all but two Malphigian tubules are fused to the hindgut) characterize the remainder of the Neuroptera (the Myrmeleontiformia and Hemerobiiformia). The only exception is found in Sisyridae, which falls within the Hemerobiiformia; here, the partial expression of cryptonephry (all but one Malphigian tubule are free of the gut) may be regarded as an evolutionary reversal associated with the secondary evolution of an aquatic larva. The single remaining fused Malphigian tubule may be evidence of the ancestral cryptonephry. The semiaquatic Osmylus larvae are also unique; they have five fused and two free Malphigian tubules.

Nevrothidae

Twelve nevrothid species are described from three distinctive and geographically separated genera—one each from the Mediterranean region, eastern Asia, and Australia. Nevrothid adults are small (forewing length 6–10 mm) and delicate (Fig. 4). Although they resemble sisyrids, they have unique, defining characteristics in the larval head structure and male and female genitalia.

Nevrothid larvae, like sisyrid larvae, occur in aquatic habitats, but morphologically they are very distinct. For example, unlike sisyrids, they lack abdominal gills and their mouthparts are robust and curved inward (not needle-like) (Fig. 5).

Little is known about the biology or behavior of nevrothid adults or larvae. Larvae of a southern European species have been collected on the stony bottoms of cold, swiftly moving mountain streams; those of an Australian species are believed to live in moist litter. Adults are usually found near streams or in wet, forested areas.

SUBORDER MYRMELEONTIFORMIA

Although its constituent members have been altered over the years, the suborder Myrmeleontiformia has long been recognized as a valid grouping. Currently, it is composed of six families: Psychopsidae, Nemopteridae, Crocidae, Nymphidae, Myrmeleontidae, and Ascalaphidae.

Adults are morphologically diverse and present few clearly defined synapomorphies, but the larvae of the six families share many defining morphological and biological characteristics. Primary among these are a head capsule with a highly sclerotized tentorium and a prementum that resembles a segment of the labial palp. Generally, myrmeleontiform larvae ambush, rather than pursue their prey, and the head capsules and jaws are modified to form a “trap”-like mechanism that can close very swiftly. Their long, robust, inwardly curved mandibles are frequently toothed mesally and constricted basally. The maxillae are lance-like, and the head capsule is robust, quadrate, or cordate (Fig. 6). The body form is short, broad, and powerful. The antennae are short and have only 10–12 segments, with a thick scape and a narrow distal portion. There are two tarsal claws and the empodium is absent (except from psychopsid larvae).

Within the Myrmeleontiformia, the Nymphidae, Myrmeleontidae, and Ascalaphidae form a relatively well-defined group, within which the Myrmeleontidae and Ascalaphidae are very closely related and appear to have a sister relationship. In fact, there are no unequivocal criteria for separating owlfies and antlions because most of the distinguishing traits are shared by some members of the other family. Nevertheless, in the vast majority of myrmeleontid and ascalaphid species throughout the world, adults and larvae exhibit the suite of characters that are typical of one family or the other; so, it is prudent to retain the two families until a thorough cladistic analysis is completed.

Opinions differ as to whether the Psychopsidae is the basal group of the Myrmeleontiformia or has a sister relationship with the Nemopteridae and Crocidae. Detailed studies of additional species from all three families may help resolve this issue.

Psychopsidae (Silky Lacewings)

The Psychopsidae is a small family of ~26 species within five genera. Adults are large, attractive, and moth-like insects (forewing length 10–35 mm). The family is restricted to Sub-Saharan Africa, Southeast Asia, and Australia. Historically, they were much more broadly distributed; fossils have been found in North America, Europe, Asia, and Australia.

Very little is known about psychopsid biology. Eggs are unstalked and attached to the substrate. They are laid singly or in groups on the bark of trees, and they are covered with a secretion that may be derived from plant material, but whose origin is unknown. Larvae of Australian species are found under loose bark (Fig. 6A). There are three instars and the life cycle may take two years. The cocoon has two layers of silk. Adults have been collected in river valleys.

Nemopteridae (Spoon-Winged or Ribbon-Winged Lacewings)

Until recently, this small family of ~100 species included species now comprising the Crocidae. Both groups are extraordinary looking lacewings that are easily distinguished by their remarkably elongate and narrow hindwings, and by a very short metathorax. Nevertheless, there are morphological and ecological differences between the two groups that are consistent with family status. Externally, nemopterid adults are distinguished from crocid adults by their large size (forewing length 13–35 mm) and hindwings that are ribbon-like, with or without dilation, but with distinct dark areas. Nemopterid larvae are myrmeleontid-like (Fig. 6B). In contrast, adults of Crocidae have smaller bodies and their hindwings are thread-like (Fig. 1), white, and rarely with dark shading. Crocid larvae are very unusual, especially in the elongation and sclerotization of the cervix (Fig. 6C and 6D).

The Nemopteridae occurs in the arid and desert zones of the southern borders of the West Palearctic and West Oriental regions, and in dry areas of the Neotropical, Afrotropical, and Australian regions. The world's richest nemopterid fauna is concentrated in southern Africa (>60% of the species). The fossil record indicates that this group was widespread and diverse in North America prior to the Oligocene.

Although nemopterid larvae have not been collected in ant nests, myrmecophily is strongly suspected. Nemopterid eggs are unstalked, small, spherical, or ovoid, and laid singly in the sand or soil. They have a micropyle and an oviruptor (an internal, toothed structure that tears open the chorion during hatching), but the surface of the chorion is smooth and seems to lack the aeropyles that are present.
on crocid eggs. The eggs may be very hard and lack adhesives, and it is believed that they are introduced into ant colonies by foraging granivorous ants.

Apparently, the larvae avoid detection by ants through chemical mimicry and by attaching sand to their bodies. Young larvae may burrow into the sand. Mature third instars become very rotund and their movement is slow and ungainly. Ants appear to be the main food and it is thought that toxic materials are injected into prey, because prey becomes immobilized quickly after being attacked. Larvae can withstand long periods (up to several months) without food, and they require few prey items to complete their development. They may have very low rates of metabolism. Pupation occurs within a silken cocoon.

Adults are mostly crepuscular or nocturnal, and they feed on pollen. The modified hind wings appear to have defensive and sexual functions. For example, they provide camouflage and crypsis or give the illusion of greater size, and they may bear modified setae that have a role in courtship. Like myrmeleontid males, some nemopterid males also have membranous sacs (between tergites 5 and 6) that may emit pheromones. The elongated rostrum probably functions in collecting pollen and nectar. Adults occur during a brief period of the year, perhaps in synchrony with the ephemeral burst of flowers.

**Crocididae (Thread-Winged Lacewings)**

This small family of ~50 species was traditionally included within the Nemopteridae (see above). The two families share elongate hindwings, but crocids are distinguished by the thread-like hindwings, as well as several larval characteristics. The distribution of Crocididae overlaps that of the Nemopteridae: arid and desert zones on the southern borders of the West Palearctic and West Oriental regions and dry areas from the Neotropical, Afrotropical, and Australian regions. Crocid adults are medium to large-sized (forewing length 7–15 mm).

Crocid eggs differ markedly from those of nemopterids; both are unstalked, but crocid eggs have a sponge-like micropyle, the chorion has aeropyles, and no oviruptor is present. The larvae of some crocid species have exceptionally long cervical regions (Fig. 6C); these species are frequently associated with caves or dwellings. Species that have a shorter cervix usually live in detritus, under rocks or in crevices (Fig. 6D). Crocid larvae are largely “sit and wait” predators; some species may pursue prey. In both cases, they can survive for long periods without food, but little is known of the larval diet. Pupation occurs within a silken cocoon that incorporates sand or debris externally. Adults are either crepuscular or diurnal, and they may feed on pollen and/or nectar. Apparently, the hindwings have sensory and stabilizing functions, which enable the lacewings to detect vertical and horizontal surfaces and to fly in confined spaces, such as caves. They may also function in attracting mates and during courtship.

**Nymphidae (Split-Footed Lacewings)**

This small neuropteran family is restricted to the Australian region (Australia, New Guinea, and nearby islands); it contains ~35 species in seven genera. Currently the Nymphidae includes two well-defined lineages, the subfamilies Myiodactylinae and Nymphinae. Nymphid adults are large (forewing length 18 to >40 mm). They may resemble myrmeleontids, but they have long, slender antennae.

Nymphid eggs are laid on slender, filamentous stalks. In Myiodactylinae, the stalks are either pendant or looped, so that the egg contacts the substrate. In Nymphinae, the eggs are arranged in intricate patterns (Fig. 7). In both subfamilies, the stalk may be coated with beads of liquid that may serve nutritional and/or defensive functions. Myiodactyline larvae are very flat, and the margins of their bodies have long seti (Fig. 6E); they are green and arbo-real, and they rest on the surface of leaves with the jaws at an angle of ~180°. Nymphline larvae (Fig. 6F) live in litter or on the bark of trees where they are camouflaged by the debris they carry or by the markings on the body. Cocoons probably are spun in sand. Adults of one species form large aggregations, but the function (e.g., mating, defense) of the aggregations is not known. Some species occur in association with acacias. Adults produce an odor from eversible abdominal glands and copulation involves enlarged and elaborate male terminalia that presumably have a grasping function.

**Myrmeleontidae (Antlions, Doodlebugs)**

With ~2100 species in 300 genera, the antlions constitute the largest neuropteran family. Members of this family have intrigued naturalists from the earliest times; W. M. Wheeler provided imaginative accounts in his 1930 book, _Demons of the Dust_. Most people know antlions because the larvae of some species have pit-building habits. In truth, both the name “antlion” and the assumption that all antlions construct pits are misleading; myrmeleontid larvae do not feed exclusively on ants and most do not construct pits. Adults are slender bodied and medium to large-sized (forewing length 10–70 mm).

Four subfamilies of Myrmeleontidae are generally recognized: Myrmeleoninae, Falparinae, Acanthachilinae, and Stilbopteryginae (formerly a separate family, Stilbopterygidae). Larval morphological (Fig. 6G and 6H) and biological characteristics are crucial in the classification of the family, especially at the tribal level but also for many genera.

This family has a worldwide distribution, notably in the arid and semiarid areas of subtropical and tropical regions of Africa, Australia, Asia, and the Americas. Myrmeleontids inhabit open woodlands, scrub grasslands, and dry sandy areas. Efforts have been made in South Africa to assess the taxonomic richness of the large fauna and to help conserve it.

Myrmeleontid eggs are unstalked and relatively large; they are laid singly in open areas or tree holes, under bushes, in caves, under rock overhangings, or in areas sheltered by buildings. The eggs are covered with a glandular secretion that facilitates adhesion of sand or soil particles, and they lack an oviruptor.

The larvae of most species appear to be “sit and wait” predators. In most taxa they live beneath the soil surface, on trees, in tree holes, under stones, or in debris. Larvae in a very small number of genera construct pits in sand or soil that entrap prey. For a few species, the
Neuroptera

interactions of pit architecture, pit location, prey availability, and larval growth have been studied extensively.

The larvae of some myrmeleontid species can travel quickly over the surface of the sand; others have slow, creeping movements or fast backward movements under the sand. These behavioral patterns are aided by the forward-directed terminal segments (fused tibia–tarsus) of the hindlegs, and they have led to the common name, “doodlebugs.” Ingestion is accomplished by the injection of digestive enzymes from the midgut into the prey, followed, after several minutes, by sucking. The regurgitated gastric juice is not mixed with the contents of the crop or the midgut. Instead, it appears to be extruded from the space between the peritrophic membrane and the epithelium of the midgut; then contractions of the crop’s muscular system transport the fluid forward through a fold in the wall of the crop.

Larvae pass through three instars. In some species, larval development can be protracted over several years depending upon the availability of prey; overwintering occurs in the larval stage. Univoltine or semivoltine life cycles are influenced by photoperiodic and thermal responses during early and late larval stages; pupal size may also be important in determining the number of generations per year. Larvae generally spin a single-walled cocoon; a double-walled cocoon occurs in one unusual South American species.

Adults are largely nocturnal and presumed predacious. Their flight resembles that of damselflies. Sexual communication involves the extrusion of “hair pencils” and abdominal glands or sacs on the male (analogous to those found in lepidopteran males), as well as the release of volatile substances from thoracic glands in both males and females.

Ascalaphidae (Owlflies)
The owlflies constitute a medium-sized neuropteran family of ~430 species assigned to 65 genera. Adults are distinguished from myrmeleontid adults by their long, clubbed antennae. There are three subfamilies: one with bisected eyes (Ascalaphinae) and two with entire eyes: Haplologeniinae and Albardinae. The subfamily Albardinae consists of a single, very unusual, large-bodied Brazilian species.
The two major subfamilies (Ascalaphinae and Haplologeniinae) are widely distributed in the warm regions of the world, but the Haplologeniinae only occurs in Australia. Ascalaphids inhabit grasslands and warm dry woodlands. Most species are nocturnal or crepuscular, but some Eurasian species are diurnal and have pigmented wings that resemble those of butterflies. Adults are relatively large (forewing length 15–60 mm).

Clusters of 20 to 75 large, unstalked eggs are laid on twigs in spirals or rows. Individual eggs are reported to have two micropyles, but lack an ovispositor. Females of many species place small, modified eggs (repagula) on or around egg batches; these repagula reportedly have defensive and nutritional functions—they serve to divert or repel predators and/or provide food for newly hatched larvae. The two major subfamilies in the New World possess this habit, but it is absent from Old World and Australian ascalaphids.

Newly hatched larvae often remain together near the egg cluster for a week or more before dispersing. Larvae are either terrestrial (in the soil or litter) or arboreal (on leaves or tree trunks), and most appear to be “sit and wait” predators (Fig. 61). Characteristically, the larvae hold their jaws open at very wide angles; some New World species resemble nymphids in being able to open their jaws beyond 270°. Larvae can take relatively large prey, and when a larva contacts prey, its jaws can close very rapidly. Considerable evidence shows that the larvae paralyze their prey with toxins from the midgut, not from glands. As with other myrmeleontiform families, there are three instars.

Larvae of some species that live in the soil or sand, camouflage themselves with sand grains or debris. Such behavior shares features with the “camouflaging” behavior of chrysopid larvae, but ascalaphid larvae use their flexible foretarsi, rather than the jaws, to place material on their dorsa. A thick mat of tangled threads anchors the debris to the dorsal surface.

Second and third instars resist starvation well, and development may extend to one or two years. Because ascalaphid adults occur at specific times of the year, diapause probably intervenes in some larval stages. Photoperiod or other factors may serve to regulate the occurrence of diapause, but the responses and mechanisms have not been studied. Pupation occurs within silken cocoons that are spun on the ground or on trees; sometimes they incorporate sand or debris.

Adults remain motionless in a characteristic head-downward position for most of the day; flight is restricted to a relatively short period around dusk and is preceded by ~10 min of muscle-warming via wing vibration. Compared to other neuropterans, ascalaphids have strong and agile flight, similar to that of dragonflies. Adults feed on large numbers of flying insects (e.g., caddisflies); prey capture and mating occur on the wing.

SUBORDER HEMEROBIIFORMIA

The Hemerobiiformia contains ten well defined families with diverse life styles and physical structure (Fig. 8). Its monophyly is open to question, and phylogenetic relationships among the families are largely unresolved. Studies of the larvae indicate that the members of the suborder share a number of distinguishing characteristics. For example, larval head capsules have the following synapomorphies: posteroventral region that is composed primarily of the maxillae, cardines that are elongate, and cervical regions that are cushion-like. Thus, monophyly of the Hemerobiiformia and its sister relationship with the Myrmeleontiformia have some support. However, recent molecular and adult morphological data conflict with these conclusions. The new data are consistent with a sequence of evolutionary splitting events that yielded the Nevrorthidae, Sisyridae, and Osmylidae, respectively. The adult morphological data suggest that these events were followed by the separation of two lineages—one that includes the Coniopterygidae + the dilarid-like families and another encompassing the remainder of the hemerobiiform families + the Myrmeleontiformia.

Ithonidae and Polystoechotidae consistently appear as sister taxa within the Hemerobiiformia. The larvae of both of these families are unique among the Neuroptera in that they feed by sucking on plant tissues. Some authors give family status to Rapismia (Rapismatidae). However, the ithonid genus Adamsiana has adult morphological features that are intermediate between the Ithonidae and Rapismia, and we include both genera in the Ithonidae while awaiting discovery of the larvae and molecular analysis of the two genera.

Relationships among the remaining hemerobiiform families, all of which are carnivorous in the larval stages, are controversial. The dilarid lineage [Dilaridae, Mantispidae, and Berothidae (including Rhabcherothinae)] is strongly supported by larval and adult morphology, but contradicted by molecular data. According to the larval morphological data, the Chrysopidae and Osmylidae form a sister group, although the evidence for this relationship is not strong. A sister relationship between the Chrysopidae and Hemerobiidae is supported by both molecular data and adult morphology. Further comparative studies of these ancient holometabolous families are needed.
Ithonidae (Moth Lacewings)

This very small family includes ~32 species in six genera: three from Australia, one from southeastern Asia, and two in the southwestern United States, Mexico, and Central America. Adults are large and moth-like (forewing length 15–30 mm); they exhibit a variety of plesiomorphic, but few apomorphic characters. The larvae are subterranean and scarabaeiform: their abdomens are large and swollen, legs are short and fossorial, and the short mandibles curve inward and slightly upward (Fig. 8A). The maxillae are broad and robust; the mandibles are narrow. Eyes are absent.

Little is known about ithonid biology. Unstalked eggs are laid singly in the soil, where their sticky surface accumulates soil and sand particles. The larvae of one species in Australia are associated with the roots of *Eucalyptus* trees and a North American species occurs near creosote bushes. The specific food sources of these larvae (plant, mycorrhizae or other fungi, or associated herbivores) are not known. In one Australian species, five instars have been demonstrated, an unusual trait among neuropterans, which characteristically have three instars. Larval development may take two or more years; pupation occurs within silken cocoons in the soil. Apparently, mature larvae undergo diapause; adults emerge synchronously in large numbers, usually following a period of rainfall. Males emerge first and form aggregations that attract females; adults live for only a few days.

Polystoechotidae (Giant Lacewings)

The Polystoechotidae constitutes an extremely small family (4 species) of large-bodied lacewings with long wings (forewing length 15–40 mm) (Fig. 9). The adults resemble ithonids, but polystoechotids are larger, their wing venation is more complex, and there are genital differences. This family is restricted to the New World.

Eggs are like those of ithonids: large, unstalked, and covered with sticky material. Only the first instar of *Polystoechotes* has been described. Unlike the scarabaeiform ithonid larvae, this larva is hemerobiid-like; it is elongate and has relatively long legs, a short multisegmented antenna, and robust jaws (Fig. 8B). Little is known
about polystoechotid biology; phytophagy is suspected but not confirmed. It is noteworthy that populations of one of the species in North America have declined greatly since the 1900s. Thus, lack of knowledge concerning this family is especially unfortunate.

**Osmylidae**

Osmylidae is a family of ~160 species in eight poorly defined subfamilies. Their systematics needs considerable reassessment.

Osmylids are slender, moderate-sized lacewings (forewing length 15–30 mm), with broad pigmented wings. The family is distributed over much of the Old World; five subfamilies occur in Australia and two in South America. Osmylids have not been found in North America.

Knowledge of osmylid biology is sparse. Elongate, knobbed, unstalked eggs are laid with their sides attached to foliage. Larvae live under stones or at the water–land interface near streams or under the loose bark of trees. Osmylid larvae have long slender stylets like those found in sisyrids (and berothids) (Fig. 8D), but unlike sisyrids, they lack gills and breathe through thoracic and abdominal spiracles.

**Sisyridae (Spongillaflies)**

The Sisyridae constitutes a small, but cosmopolitan family that contains ~50 species in four genera: *Climacia*, which is restricted to the New World; *Sisyla*, which is cosmopolitan; and *Sisyrida* and *Sisyrella*, which are small Australian and Asian genera. It is the only hemerobiiform family with truly aquatic larvae. Sisyrid larvae are believed to feed exclusively on freshwater sponges, and they are unique among the Neuroptera in having segmented abdominal gills that function in breathing (Fig. 8H). Adults are dull in color and relatively small (forewing length 4–10 mm). They closely resemble brown lacewings, but the simple, open venation of the forewing and the branching pattern of the radial sector distinguish them.

The sessile eggs of sisyrids are laid singly or in groups on objects that overhang water. A flat layer of silk covers the eggs. Hatching is aided by an oviruptor, and subsequently the neonate larvae walk or drop to the water where they find and enter a sponge colony.

Sisyrid larvae probe sponges with their long, flexible mouthparts (Fig. 8G). Although they have six Malphigian tubules, only one is attached distally to the rectum, a condition that is probably associated with the aquatic life style. After feeding and development, the mature larvae swim to the shore, attach to objects close to the water, and spin double-layered cocoons within which they pupate. Adults forage on nectar, pollen, algae, fungi, aphids, and mites.

![FIGURE 9](image9.png) An adult of *Platystoechotes* from California (Polystoechotidae). These insects are rarely seen. (Photograph by E. S. Ross, California Academy of Sciences.)

**Chrysopidae (Green Lacewings)**

Chrysopidae, with its ~1200 recognized species, is one of the two large families of Neuroptera, second only to the Myrmeleontidae. The larvae of many chrysopid species feed on insect and mite pests of agricultural crops or horticultural plantings, and because of their value in biological control, chrysopids are the most frequently studied of the Neuroptera.

Adults are medium-sized to large, delicate insects with four subequal wings (forewing length 6–35 mm) and relatively long, filiform antennae. In most species the adults are green with large golden eyes, but some species have black, brown, or reddish adults (Fig. 10). Larvae vary in shape and habits; some are voracious, active, and more-or-less generalist predators, with sleek, fusiform bodies (thus the name “aphis-lions”) (Fig. 8C). Others are slow-moving, cryptic, trash-carrying predators with bulbous bodies, elaborate tubercles, and long, hooked setae; they are usually associated with specific types of ant-tended prey. Still others live in ant nests where they feed on the inhabitants; they have rotund, bulbous bodies, greatly shortened appendages, and a dense covering of stiff, hooked setae that hold protective trash on the body.

Currently, the Chrysopidae comprises three subfamilies (Nothochrysinae, Apochrysinae, and Chrysopinae); all three are only weakly supported by molecular data and only the first is well defined on the basis of adult and larval characters. Systematic and comparative biological studies are needed to clarify the taxonomy and phylogenetic relationships of the chrysopid taxa and also to facilitate their use in biological control.

Given the wide range of morphological and behavioral variation among chrysopid larvae, it is clear that inclusion of all life stages is crucial for advancing the systematics of the family. Recent studies of previously unknown larvae have led to changes in the tribal assignments and the recognition of new Neotropical genera. However, except for the European and Japanese faunae where larvae of approximately 80% of the species are described, the world’s chrysopid larvae are poorly known.

The Nothochrysinae includes only nine extant genera; it is believed to be the basal chrysopid lineage, but molecular data have not confirmed this opinion. Defining characteristics occur in the adult and larval stages; however, larvae from very few genera are known. Apochrysinae may be monophyletic, but more supporting
data are needed. The larvae of one apochrysine species have been described, but distinguishing subfamilial traits were not apparent. The subfamily contains the largest and visually most spectacular green lacewings; its ~13 genera are based largely on somewhat variable characters in wing venation. Biological studies are needed.

The large subfamily Chrysopinae encompasses over 97% of the known chrysopid species; it includes ~60 genera distributed among four tribes, at least two of which are poorly defined and probably not monophyletic. The tribe Chrysopini is the largest and least well known; it contains almost all of the lacewings of economic importance.

As a group, the Chrysopidae is cosmopolitan; similarly, all of the subfamilies are widely distributed. Nevertheless, many of the genera have limited geographic distributions. For example, among the Apochrysinae, two genera occur only in Africa, four in the Neotropics, six in the Oriental region or Australia, and one in the eastern Paleartic. Most genera of Nothochrysiniae are endemic to small geographic ranges; many species are known solely from a very few specimens. The genera within Chrysopinae range from cosmopolitan to narrowly endemic.

Typically, chrysopid eggs are laid at the end of long stalks, either singly, in groups, or in clusters with the stalks loosely or tightly intertwined. The egg stalks can be naked or they may bear oily droplets; the droplets contain nutrients or defensive substances that protect the egg or the newly hatched larva from natural enemies.

Larvae of some chrysopid species have fairly large prey ranges; they may feed on homopterans, lepidopteran eggs or larvae, and a variety of soft-bodied arthropods. But, contrary to popular lore, some species have evolved a very strong association with a particular type of prey. In Chrysopa, prey specialization can be restricted to a single species of prey and is based on a suite of intrinsic and extrinsic factors, including maternal oviposition behavior, egg size, larval morphology and behavior, phenotypic plasticity in life-history traits, responses to natural enemies that are associated with specific prey, and phenology. Studies indicate that prey association, such as that in Chrysopa, and also habitat association, as shown in Chrysoperla, can evolve in a manner that is very similar to the evolution of host specificity in phytophagous insects; there is good evidence that both can be involved in speciation.

Adults of most chrysopid genera feed on honeydew and pollen; in these lacewings, the dorsal crop diverticulum has numerous tracheae and is filled with symbiotic yeast. These symbiotes provide essential nutrients that are deficient in the diet. Adults in a few genera are predacious. In some species, adults emit foul-smelling defensive odors when they are disturbed.

Some chrysopid species are multivoltine, others are univoltine; most enter diapause and undergo dormancy (hibernation, aestivation) during unfavorable (e.g., cold, hot, or dry) seasons. The diapausing stage (free-living larva, prepupa, or adult) varies among lacewings and is a characteristic of the genus. Some chrysopids that diapause as adults undergo seasonal color changes that appear to reflect the background color of their habitat during the unfavorable season. Although lacewings are not considered especially strong flyers, they can move considerable distances with the wind. In species that diapause as adults, there is a seasonal pattern to movement between habitats. Photoperiod often provides very important cues for timing lacewing dormancy and seasonal movement; temperature, moisture, and food can also be significant factors. The genetic basis for lacewing responses to seasonal cues has been demonstrated; some exhibit geographical variability and epistasis.

Chrysopine lacewings have two modes of hearing. The “ear” (tympanal organ) is at the base of the radial vein in each forewing. It is the smallest tympanal organ known, and it receives the ultrasonic signals of insectivorous bats. Ultrasonic signals at low rates (~1–50 pulses per second) cause the lacewing to cease flight and to fall. As the bat continues to approach, its signal increases in frequency; the high-frequency signal causes the lacewing to flip its wings open quickly and fly, thus aiding its escape. The second type of hearing, the perception of low-frequency, substrate-borne sounds that are emitted during courtship, is accomplished through scolopidial organs in the legs. Such sounds are an integral part of courtship in Chrysoperla species; variation in the production and perception of these sounds may have a role in speciation.

The endemic complex of green lacewings on the Hawaiian Islands, belonging to the genus Anonomaloctrysa, has evolved several unique characteristics and exhibits an extraordinary range of variation in morphology and behavior. For example, unlike any other known chrysopids, Anonomaloctrysa females lay sessile (unstalked) eggs, either singly or in batches. Larval body shapes range from fusiform with greatly reduced lateral tubercles and few, short setae, to flattened with well-developed lateral tubercles and numerous, long, robust setae. In continental lineages, such broad variation is found only among genera. In some species, adults or larvae are very bright and colorful; in others they are dull or resemble bird feces. Males and females may produce conspicuously loud clicking sounds during courtship and mating; how these sounds are produced and perceived is unknown.

Some species in the genus Chrysoperla are mass-reared for release in the biological control of agricultural and horticultural pests. Among those in North America are Chrysoperla carnea (s.l.) and Chrysoperla rufilabris. These species possess characteristics that are advantageous for mass-rearing. For example, adults do not require prey, but will reproduce when fed artificial diets; they can be stored for long periods without significant loss of reproductive potential; and larvae can develop when fed artificial or factitious prey. Larvae of Ceraeochrysa species, which are trash-carriers, share many of the above traits that subserve mass production. They have the added advantage of being camouflaged and thus protected from their own natural enemies, for example, ants. The role of lacewings in pest management, whether naturally occurring or augmentative, is far from fully exploited.

Hemerobiidae (Brown Lacewings)

Hemerobiidae constitutes a cosmopolitan clade that is relatively well known and easily recognized. It is the third largest neuropteran family, with ~550 species. Adults are generally small (forewing length 3–18 mm), brown, and inconspicuous. The ~27 extant genera of hemerobids fall into ten reasonably well-defined subfamilies. The Carobiinae and Psychobiellinae each consist of one genus that is restricted to the Australian region. Each of the Hemerobiinae, Symphorobinae, Notiobiellinae, and Microminae include three to five genera; all four of these subfamilies are cosmopolitan, but some of the small genera that they encompass have very restricted distributions. The Drepanacrinae and Drepanepteryginae each contain three genera with restricted distributions, and the Megalomiminae comprises one genus with broad distribution. The most recently described subfamily, Adelphohemerobiinae, consists of a single genus known only from South America.

Larval morphology may offer a rich suite of traits for phylogenetic analysis; however, the larvae of only nine genera (from 7 of the 10 subfamilies) have been described. There are three instars. In the first instar, body setation is sparse, and trumpet-shaped empodia are present between the tarsal claws. Second and third instars are similar
to each other except in size; they may have numerous short setae, and their empodia are short (Fig. 8E).

Mainly because the systematics of the family was neglected until recently, the life cycles of relatively few hemerobiid genera are known, and the groups that have been studied occur largely in the Northern Hemisphere. In general, hemerobiid eggs are sessile (unstalked) and laid singly or in clusters. Hatching is accomplished by means of an oviruptor.

Larvae prey upon a variety of small, soft-bodied arthropods and eggs. Little is known about the range of larval diet or its specificity, but some species have a strong association with a particular type of plant or habitat, and it is likely that some of these are also specific in their diets. Pupation occurs within thinly spun cocoons. Pupae have a peculiar set of hooks on the dorsum of the abdomen; their function is unknown. Most species seem to be predacious in the adult stage, but there are records of extensive honeydew feeding by adults. Life cycles range from univoltine to multivoltine, but for most taxa the wintering stages vary (prepupae within cocoons, free-living second instars). Eggs have minute scales, mites); adults may also feed on honeydew and perhaps pollen. Only a few species are associated with specific types of vegetation, and this habit may indicate prey specialization. Eggs are unstalked and laid near prey; there are three instars (Fig. 8F).

Adults and larvae prey on small, soft-bodied arthropods (aphids, scales, nites); adults may also feed on honeydew and perhaps pollen. Flattened cocoons with double walls are spun on foliage or tree trunks. Adults are usually active at dusk or at night. Life cycles and overwintering stages vary (prepupae within cocoons, free-living second instars) and have not been well studied.

Many species of coniopterygids are considered to be important natural biological control agents; unfortunately, their role has not been evaluated and their potential remains undeveloped.

**Coniopterygidae (Dustywings)**

Because of their small size and cryptic nature, coniopterygids are generally overlooked and thus considered rare. However, with ~450 species, the Coniopterygidae constitutes a relatively large family and is one of the best-known systematically. Although they clearly belong within the Neuroptera, coniopterygids differ in a number of ways from other neuropteran families. Previously, they were considered the sole family of a separate primitive suborder (superfamily), the Coniopterygoidea. However, a recent cladistic analysis provides some evidence that the Coniopterygidae and Sisyridae may form a derived sister group within the Hemerobiiformia.

The Coniopterygidae is generally a very homogeneous family characterized by very small adults (forewing length 2–5mm) with bodies covered by white waxy (“dusty”) secretions (Fig. 12). The secretions originate from hypodermal wax glands on the sternites and tergites of the abdomen and are spread over the body by the hindlegs. Other than in the coniopterygids, such glands are only found in the homopterans Aleurodina and Coccina. This similarity represents a remarkable example of convergent evolution especially because coniopterygids are frequently associated with these waxy homopterans.

Currently, the Coniopterygidae contains three well-defined, probably monophyletic subfamilies: Coniopteryginae, Aleuropteryginae, and Brucheiserinae. Both the Coniopteryginae and the Aleuropteryginae are large groups with cosmopolitan distributions. The Brucheiserinae differs from the other two subfamilies in having highly unusual reticulate wing venation. Brucheiserinae is known only from the neotropics and its larvae are not described. Some authors have considered it a separate family (Brucheiseridae), but this distinction is probably not justified. In this regard, discovery of the larvae may be very valuable.

The life histories of very few coniopterygid species are known. Both larvae and adults occur on trees and bushes (sometimes on low vegetation). Many species appear to be associated with specific types of vegetation, and this habit may indicate prey specialization. Eggs are unstalked and laid near prey; there are three instars (Fig. 8F).

Adults and larvae prey on small, soft-bodied arthropods (aphids, scales, nites); adults may also feed on honeydew and perhaps pollen. Flat cocoons with double walls are spun on foliage or tree trunks. Adults are usually active at dusk or at night. Life cycles and overwintering stages vary (prepupae within cocoons, free-living second instars) and have not been well studied.

Many species of coniopterygids are considered to be important natural biological control agents; unfortunately, their role has not been evaluated and their potential remains undeveloped.

**Dilaridae (Pleasing Lacewings)**

This small family of ~50 species has well-defined affinities with the Berothidae and Mantispidae. It contains two subfamilies: Dilarinae, which is confined to the Old World, and Nallachiinae, which occurs in the New World (with one species known from South Africa). It is one of the few neuropteran families absent from the Australian region.

Adults resemble small, delicate hemerobiids (forewing length 3–16mm in males and 5–22mm in females). But, they are differentiated by ocelli-like tubercles on the head of both sexes (functional

---

**FIGURE 11** Hawaiian hemerobiid adult in the genus *Micromus*. Note the sculptured wings and their color resemble the curved edges of dead fern leaves, where this species often rests. (Photograph by M. J. Tauber, Cornell University.)

**FIGURE 12** Adult of *Coniopteryx* from Switzerland (Coniopterygidae); note the powdery, white wings. (Photograph by P. Duelli; reproduced with permission, from Aspöck and Aspöck, 1999.)
natory conditions did not metamorphose successfully. Dilarid eggs are elongate and unstalked. Those of Nallachus are laid in association with dead trees. The larvae of Nallachus inhabit the galleries of insects in decaying logs or the area beneath the tightly adhering bark of erect, recently dead trees (Fig. S1). Larvae of Dilar have been found in the soil, but their larval diet is not known.

Development probably takes one year. Larvae may undergo supranumerary molts: that is, if undernourished, they may continue to molt as many as 12 times. However, those that did so under laboratory conditions did not metamorphose successfully.

**Mantispidae (Mantidflies)**

With ~400 species, Mantispidae is the largest family in the dilarid lineage (Dilaridae, Berothidae, Mantispidae). These moderate to large-sized lacewings (forewing length 5–30 mm) are recognized by raptorial forelegs that resemble those of mantids. Their simple, subequal wings are narrow and elongate, and they have a distinct pterostigma and chrysopid-like venation. Larvae are similar to those of the Berothidae in that they are hypermetamorphic; however, in the case of the mantispids the first instars are campodeiform and the second and third instars are grub-like (Fig. 8J). The mantispids differ from the Rhachiberothinae in their wing venation, terminalia, and larval characteristics, but they are of similar body-size and also have raptorial forelegs.

The family contains four, apparently monophyletic subfamilies: Symphrasinae, Drepanicinae, Calomantispinae, and Mantispinae. Symphrasinae encompasses a large, diverse assemblage of species that occur from South America through southern North America. Drepanicinae is a smaller subfamily that occurs in restricted areas within South America and mainland Australia. Calomantispinae, another small subfamily, also has a disjunct distribution: eastern Australia (including Tasmania), and southern North America. Finally, the large subfamily Mantispinae ranges between 50°N and 45°S throughout much of the world. The biology and immatures of Drepanicinae and Calomantispinae remain largely unknown, whereas those of several genera in Symphrasinae and Mantispinae have been studied.

Larvae in the subfamily Mantispinae usually inhabit the egg sacs of spiders where they feed upon the contents, although some may be subtrelanean predators or possibly generalist predators. Numerous (200–2000) stalked eggs are laid randomly (and sometimes in clusters) on leaves and other substrates.

The newly hatched campodeiform larvae find their hosts (spider eggs) via one of two methods. Either, they actively seek a previously constructed spider egg sac that they enter through direct penetration, or they climb onto a female spider and enter the egg sac during construction. Those that board spiders can feed on the hemolymph of their host, but they do not molt until they enter an egg sac. If the campodeiform larva attaches to a male spider, it may transfer to a female during copulation. After finding an egg sac, the larva feeds on the contents (predate) and undergoes hypermetamorphosis.

The mature larva spins a cocoon within the spider egg sac, and pupation occurs within the larval skin; thus, to emerge, the mature pupa cuts its way through its larval exoskeleton, the cocoon, and the egg sac. Adults are predacious and they are active during the day or night. Overwintering in some species occurs in the first instar, and there may be one to more generations per year.

Several species within the Symphrasinae have been reared from nests of aculeate Hymenoptera or in the laboratory on larvae or pupae of Lepidoptera, Coleoptera, and Diptera. First instars may find their hosts by attaching to an adult bee or wasp and moving into a cell when the egg is laid. Subsequently, they feed on a single host (parasitism) to which they adhere via a sticky, yellow secretion; they have the typical mantispid hypermetamorphosis.

Adult Climaciella can be highly polymorphic, with each of several morphs mimicking a different species of polistine wasp. The proportion of the different morphs may vary depending on the number and aggressiveness of the various wasp species at each locality.

The larval habits of the Drepanicinae are unknown; Calomantispine larvae may be generalist predators.

**Berothidae (Beaded Lacewings)**

The Berothidae is a small family of ~115 species in four more-or-less distinct subfamilies: Rhachiberothinae, Berothinae, Nosybinae, and Cyrenoberothinae. Adults typically are small to medium-sized (forewing length 6–15 mm) lacewings with brown wings and bodies. Frequently, the outer margin of the forewing is deeply incised (Fig. 13). Larvae are associated with termite nests. The family is cosmopolitan and occurs predominantly in warm temperate, tropical, and subtropical areas; the group is most speciose in Africa.

One subfamily of berothids, the Rhachiberothinae, differs considerably from the others. Its adults have raptorial forelegs that are very similar to those of mantispids. As a result, some authors consider them to be a separate family. However, because of the close similarity between the few known larvae in the two groups, we treat the Rhachiberothinae as a specialized subfamily of the Berothidae, while awaiting further study.

Eggs of three subfamilies are laid in clusters attached to one or several long, silken stalks; those of the fourth subfamily, Rhachiberothinae, are sessile. Little is known of the subsequent life history, except for the North American genus Lomamyia (Berothinae). Their eggs are laid on dead trees or logs that contain colonies of subtrelanean termites, with which their larvae (Fig. 8K and 8L) are associated. First instars are mobile and after entering the termite colony they feed and molt. The second instar does not feed, but hangs immobile from the roof of the termite tunnel. Third instars resume feeding on termites. They subdue their prey with an allomone that is emitted from the tip of the abdomen and/or a neurotoxin that is injected through the mouthparts. Pupation occurs within silken cocoons that are spun in the termite nest. Adults are primarily nocturnal. As many as three generations can occur per year; the prepupal stage overwinters.

**FIGURE 13** Adult of Podallea from Namibia (Berothidae); note the deeply scalloped wings. (Photograph by M. Stelzl; reproduced with permission, from Aspöck and Aspöck, 1999).
Classification has two meanings in English: the process by which things are grouped into classes by shared characters and the arrangement of those classes. Identification is the process of observing characters and thereby classifying things. Biological classifications are arrangements of organisms. The ability to classify is common to all animals, for to survive animals must group other organisms into at least three classes: those to be eaten, those to be avoided, and those to associate with, especially members of their own class. For scientists, classification is formalized into a nested or hierarchical set of hypotheses: hypotheses of characters, groups (taxa), and relationships among the groups. Individual specimens of organisms are observed and characteristics noted. So, for example, we may observe that some people are black, others yellow or white, and conclude as Linnaeus did that there are different groups of humans (Homo sapiens). This is a hypothesis that skin color is a useful character. Further testing of this character hypothesis has shown that skin color among humans does not define natural groups; hence we reject skin color as a character for humans as well as those groups this character defines. Color, however, is a very useful character for classifying many other groups. Then there is the hypothesis of a group. Groups of biological organisms are called taxa (taxon, singular) and these taxa are hierarchically arranged in our classifications. Taxa in a classification have rank, with the basic (basal, bottom) rank being designated as species. Some of the higher ranks are genus, tribe, family, order, class, phylum, and kingdom.

Nomenclature is a system of names along with the procedures for creating and maintaining that system. Classification, in its second definition, is the structure for nomenclature, being the model on which names are arranged. Names form the essential language of biology and are the means that we use to communicate about our science. To avoid a Tower of Babel, a common system of nomenclature is required, especially an effective, efficient, system that has a minimal cost.

**NAMES AND CLASSIFICATION**

Names are tags. Tags are words, short sequences of symbols (letters), used in place of something complex, which would require many more words to describe. Hence, tags save time and space. Instead of a long description, we use a short tag. A scientific name differs from a common name in that the scientific name is a unique tag. In nonscientific languages, such as English, there may be multiple tags (common names) for the same organism. For example, imagine the various words in English that are used to describe H. sapiens. In computer (database) jargon, data elements that are used to index information are termed keys, and keys that are unique are called primary keys. Scientific names are primary keys. The word "key" has another meaning in English, which is "something that unlocks something." Scientific names are those critical keys that unlock biosystematic information, which is all that we know about living organisms. To repeat: scientific names are tags that replace descriptions of objects.
or, more precisely, concepts based on objects (specimens). Scientific names are unique within a classification, there being only one valid scientific name for a particular concept, and each concept has only one valid scientific name.

Scientific names are more than just primary keys to information. They represent hypotheses. To most systematists, this is a trivial characteristic that is usually forgotten and thereby becomes a source of confusion later. To most users, this is an unknown characteristic that prevents them from obtaining the full value from scientific names. If a scientific name were only a unique key used for storing and retrieving information, it would be just like a social security number. *H. sapiens* is another unique key used to store and retrieve information about humans, but that key also places that information into a hierarchical classification. Hierarchical classifications allow for the storage at each node of the hierarchy of the information common to the subordinate nodes. Hence, redundant data, which would be spread throughout a nonhierarchical system, are eliminated. Biological classifications, however, do more than just hierarchically store information. If one accepts a single common (unique) history for life (phylogeny) and agrees that our biological classifications reflect this common history in their hierarchical arrangement, then biological classifications allow for prediction, namely that some information stored at a lower hierarchical node may belong to a higher node; that is, may be common to all members of the more inclusive group. Such predictions take the following form: if some members of a group share a characteristic that is unknown for other members of the same group, then that characteristic is likely to be common to all members of the group. So scientific names are tags, unique keys, hierarchical nodes, and phylogenetic hypotheses. Thus, systematists pack a lot of information into their names and users can get a lot from them.

Scientific names are hypotheses, not proven facts. Systematists may and frequently do disagree about hypotheses. Hypotheses, which in systematics range from what is a character to what is the classification that best reflects the history of life, are always prone to falsification, hence to change. Disagreements about classification can arise from differences in paradigm and/or information. Systematists use different approaches to construct classifications, such as cladistic vs. phenetic vs. phylogenetic methods. Given the same set of data that underlies a given hierarchy, cladists will derive classifications different from those derived by pheneticists (Fig. 1). Even among cladists, there can be differences about the rank (genus, family, order) and thereby the hierarchical groups used. These are disagreements based on paradigm. There can be disagreement about the hypotheses that underlie the information used to construct the classifications, such as what are the characters. And disagreement can arise among systematists because individuals use different information. While disagreements will affect the ability to predict, they need not affect the ability to retrieve information.

The desirable attribute that must be preserved to ensure complete access to information across multiple classifications is uniqueness. Our scientific nomenclature must guarantee that any scientific name that is used in any classification is unique among all classifications. This can be assured by having two primary keys. Unfortunately, having two keys increases the overhead of our information systems. So most systematists and all users want to avoid this problem by mandating that there be only one classification. Although in theory there is only one correct classification, as there was only one history of life, in reality there have been multiple classifications in the past, there may be multiple classifications in use today, and there will be multiple classifications in the future. That is the price of scientific progress, of the increase in our knowledge of the world. If information is to be retrieved across time—that is, if we want to extract information stored under obsolete classifications, and if we want to avoid dictating “the correct” classification—then we need a nomenclatural system that supports two unique keys.

The two keys for our language of biodiversity are the valid name and the original name. The valid name is the correct name for a concept (taxon) within a classification; the original name is the valid name in the classification in which it was proposed. Valid names may be different among classifications, but the original name is invariant across all classifications (Table I). Valid names are the best names to use because they provide the full value of scientific names. These are the names that provide a basis for prediction. The original name is useful only for information retrieval across multiple classifications. Although valid and original names may be and frequently are the same, users must know the differences between them. Specifically, they need to know that a valid name is a powerful inference tool, that a valid name provides for prediction about unknown attributes of the organism that bears the name. But they must understand that there may be multiple valid names in the literature and/or in use and that

![Diagram](attachment://diagram.png)
valid names represent hypotheses that may change as our knowledge is tested and improved. So most importantly, if there are multiple valid names in use, then there are conflicting scientific hypotheses being advocated, and users must select the name that best serves their purpose. If users do not want to decide, do not want to use classifications to organize and synthesize their information, then they may use the original name to index their information, being assured that it will always be a unique key.

There are other problems today with our classifications: synonymy, having two names for the same concept, and homonymy, having the same name for different concepts. These problems are, however, largely the result of ignorance. If we knew all names and their types and could agree on what are species, then by applying the rules of nomenclature we could immediately eliminate all synonymy and homonymy problems. Homonymy is eliminated by the rule of uniqueness. Synonymy is addressed by the rules of typification, which tie a physical instance of a concept to a name, and is resolved by logie of circumscription and the convention of priority (or usage). The name of a concept is the name affixed to one and only one of the types that falls within its circumscription (Fig. 1). The name used is determined by which name is the oldest (priority) or most widely used (usage). The specific rules for resolving homonymy and synonymy, as well as for the proper formation and documentation of names are our codes of nomenclature. These rules, however, do not address the problem of multiple classifications, nor can they establish order under conditions of ignorance of the universe of applicable names and their typification.

There is one final problem: the species problem. This is the problem of what is the basic unit of information and/or data. There is also the question of what species are and whether species are real or hypotheses. Species may be a category (rank) in classifications or a unit of information. The best current review on these questions is by Wheeler and Meier, but for nomenclature the species (or more precisely the species group, which includes the subspecies category) is considered to be a basic unit of information. The problem is that the species is not a data element. The species is not an indivisible unit, but consists of information, that is, data derived from specimens that have been identified as belonging to that species. Mistakes can be made during this identification, which is after all another hypothesis. Information is ultimately not derived from species, but from specimens. Biological information management really begins with specimen data management. The problems of specimen-based data management are not intractable but are readily addressed by the use of unique identifiers, such as bar codes, another form of unique keys.

The species problem is also one of circumscription, the definition of the limits of a taxon. A group with the same name and type may be more or less inclusive depending on the characters used to define its limits. Zoologists differ from botanists in not considering circumscription to be a problem, since minimally all identically named taxa have at least some characteristics in common. The problem of how much is held in common, therefore, is best resolved by enumeration of the included taxa or specimens. The history of circumscription can be tracked by use of an additional key that uniquely identifies the person who defined the limits and the date of that action. Sufficient for our purposes is to know that specimen-based data will always be summarized into species-based information units and that all species-based information should be specimen based.

**PARADIGMS AND CLASSIFICATIONS**

The information that is embedded in nomenclature comes from the classification used. As noted, classifications consist of hierarchically nested groups of taxa, with the basic unit being the taxa ranked as species. Paradigms are theories about scientific knowledge and its organization. The first classifications developed by Linnaeus and Fabricius were largely based on Aristotelian essentialism/typology. Things were grouped together because they shared the essences of the group, which is the type. Later, when evolution was articulated as a paradigm, classifications were based on phylogeny, which is the genealogical hypothesis of relationship. More recently, when computers began to appear, classifications were proposed on the basis of statistical measures of overall or phenetic similarity. Finally, different ways of deciphering phylogeny were developed, and so, different ways of translating phylogenetic information into a hierarchical classification were proposed (phylogenetic vs. cladistic methods). Over the past half-century, much has been written about the relative merits of phenetics, evolutionary systematics, and cladistics, but the inescapable conclusion for predictive and, therefore, maximally informative classifications, is that the cladistic paradigm is mandatory. Schuh provides a good summary of the arguments for cladistic classifications.

Regardless of the paradigm followed, all approaches leave unsolved the problem of how to translate the result of taxonomic analysis, be it a tree or a branching diagram of overall similarities, into a hierarchical classification. There are only two approaches to the translation of an analysis into a classification: subordination or sequencing. For subordination, each clade/branch becomes a recognized (named) taxon and a rank indicator provides a key to the relative level of subordination. Subordination works best when the phylogeny/branching diagram is balanced, that is, when each branching point divides the remaining terminal taxa into equal-sized groups. For example (Fig. 2, Table II), eight species could be clustered into four genera and two subfamilies, whereas a fully pectinate analysis would yield seven genera clustered into five named ranks (subfamily, infrafamily, supertribe, tribe, subtribe). For sequencing, only the terminal clades/branches are recognized, but their order is preserved and suitably indicated to encode their sequential level of subordination. This method is highly efficient for analyses that result in pectinate trees. The pectinate example could be reduced to seven sequenced genera. Sequencing does not work when the analysis is balanced. Given that most analyses are neither fully balanced nor fully pectinate, a mixture of subordination and sequencing should be used as long as the classification properly identifies which methodology was used for each portion. Wiley provides a full set of conventions to deal with these issues as well as others that involve the placement of fossil groups (plesion) or groups of uncertain or changeable position (sedis mutabilis) or unknown relationships (incertae sedis).

**Nomenclature and Classification, Principles of**

709
Figure 2 Balanced (top) and pectinate cladistic (bottom) hypotheses. See Table II for the different classifications that result from these hypotheses.

Beyond the translation of a taxonomical analysis into a hierarchical classification, another challenge remains, that is, what groups to formally name and what ranks to assign to those named groups. Obviously, when a group is fully resolved taxonomically, there could be as many named groups as there are terminal taxa. No school of taxonomy insists on naming all of them, but other than that there is no method nor any consensus among taxonomists on what taxa to recognize only a few. The merit of splitting is that the more taxa named, the more hierarchical information is embedded into those names and classification itself. Unfortunately that also leads to a loss of utility inasmuch as less information is summarized in each taxon.

Consider birds, the best-known group of organisms. Some 9700 species are clustered into 204 families and 2004 genera. Their scientific nomenclature is largely meaningless to many users, such as bird-watchers. For bird-watchers, common names, which more closely follow the original Linnaean classification, such as ducks (Anas) or hawks (Falco) or hummingbirds (Trochilus), are more meaningful groups than the oversplit genera. On the other hand, mosquitoes, some 3500 species, are clustered into only 34 genera. The important disease vectors, such as Anopheles for malaria and Aedes for yellow fever and dengue, remain large groups where the scientific name and common name are the same and are useful to doctors, public health workers, and other entomologists. The problem of the appropriate rank for groups recognized is similar. Naturally, splitters must have a greater series of rank indicators to express their fully named hierarchies. So, although there are relatively few species of birds, they are clustered into a large number of families (204), whereas flies (order Diptera) comprise 16 times as many species clustered into fewer families (142)!

The ranking issue also brings with it the question of equivalency. Obviously a family of birds is not an equivalent unit of biodiversity or of anything else in comparison to a family of flies. Rank equivalence is an important issue because many biologists want to make comparisons across different groups of organisms. Biological comparison should never be made on the basis of biological categories above the rank of species. For example, studies that base conclusions on the circumstance that one treatment or niche has more families, than another are totally meaningless because the units being compared are not equivalent. Biological comparison should be made only on the basis of cladistically defined sister-group relationships, since sister groups are of equal age.

The entomologist Willi Hennig proposed in 1966 an objective method for assigning ranks that also allowed for biological comparisons: Rank should reflect the hypothesized age of origin of the taxon. His suggestion has been rejected by all on the ground that the approach would cause a major upheaval in the traditional ranks of groups. For example, humans, placed in a separate kingdom by some (Psychozoa by Huxley in 1937), would be clustered among the apes and lemurs as nothing more than a species group. For entomology, some of the larger groups, like Coleoptera, Diptera, and Lepidoptera, which go back to Aristotle, would change in rank if not content. So after more than 2000 years of using those concepts, no one wants to split up the groups or change their rank.

These issues of classifications are largely ignored by working taxonomists, most of whom focus on their specialty and do not concern themselves with global classifications. Entomologists generally do not care how birds are classified, nor do beetle workers even worry about how flies are classified. Entomologists also tend to take a pragmatic, utilitarian approach, such that conservative ranks and grouping are used among mosquitoes and other economically important insects. In summary, a few general guidelines should be followed:

1. Only monophyletic taxa should be recognized and named.
2. Subordination or sequencing should be used as is most appropriate given the analysis and always should be annotated.
3. "Empty" taxa should never be named (i.e., if a family contains only a single genus, there is no a need to name a subfamily or tribe simply because these ranks are used elsewhere in the classification).
4. The fewer taxa named, the more useful the classification generally will be to non-specialists.
5. Traditional groups and ranks should be preserved where possible.
CODES OF NOMENCLATURE

Because names are critical for communication and information retrieval, nomenclature needs to be universal, precise, and accurate. Universality requires that the same methodology be used by all and that methodology ensure stable nomenclature over time. Precision requires that only one result be derived from an individual application of the rules of nomenclature. Accuracy requires that names be consistently and precisely tied to the hypotheses they denote. The International Commission on Zoological Nomenclature (ICZN) ensures the implementation of these basic functions in our scientific names and classification. This is achieved through a series of rules organized into chapters and articles.

Stability of nomenclature should not be confused with stability of taxonomic hypotheses (taxa) and classifications. As knowledge improves and more characters are discovered and analyzed, resulting in improved understanding of relationships among organisms, taxa, and classifications will change. So, as more is known about the history of life, old Aristotelian groups like reptiles will be replaced by better defined ones, and the name Reptilia will drop from our classifications. But in other well-characterized groups, such as spiders (order Araneae) or flies (order Diptera), which have proven to be natural, the names shall remain unchanged in our classification.

The current ICZN is the product of a long evolution that began with the system of binominal nomenclature introduced by Carolus Linnaeus, a Swedish professor of natural history. This system was the direct result of an earlier government biodiversity project. The Swedish crown had some far-flung possessions and wanted to know what use could be made of them. Linnaeus was sent to investigate, to survey what today is called biodiversity, and to write a report characterizing his findings with recommendations on how to use them. At the time, there was only a binary system of nomenclature: one word for the genus, with the species being described by a series of adjectives. Given the diversity Linnaeus found, he did not want to waste time repeating long strings of adjectives that were required to characterize the biodiversity. So, because the base characterizations were in his flora of Sweden, he used a combination of the genus name and single word (an epithet) for each species to form a unique key to those descriptions (Stearn gives more details).

The system was an immediate success. Linnaeus codified the system, built and maintained a universal information database for all names (his Systema Naturae, 10th edition in 1758), and trained a cadre of students to carry on his work. The students dispersed and converted others. But since there could be only one master, Linnaeus, they divided nature up. There was to be no more Systema Naturae. For entomology, the student in charge was Johann Christian Fabricius. Fabricius defined his principles in his Philosophia entomologica and produced a series of Systema for insects, the last comprehensive one being published in 1792–1794.

For the next 50 or so years, there was a significant increase in the number of animals discovered, described, and named, but little concern for nomenclature, which became muddled. This led a group of British zoologists, in 1843, to propose a formal set of rules, now known as the Strickland code, from which the modern ICZN evolved. After their effort, there was another half-century of new codes being proposed for various groups of animals (birds, fossils, insects) or nationalities (English, French, German). This proliferation led to zoologists joining forces and working toward an international code for all animals, resulting in the establishment of the ICZN in 1895 and Règles Internationales de la Nomenclature Zoologique in 1905. Although a few entomologists (e.g., Banks and Caudell in 1912) continued to work on a specialized code for insect names, these development efforts were quickly abandoned.

For the next half-century, the Règles and the commission operated well, but clearly improvements were needed. So after the World War II, the task of revision began. After a series of international meetings, the American entomologist J. C. Bradley, then president of the commission, wrote out a draft that in 1962 became the second edition. The next edition, in 1985, and the current one, in 1999, were largely the work of Curtis W. Sabrosky, an American entomologist; David Ride, an Australian mammalogist; and Richard Melville, a British paleontologist.

Nomenclature and Classification, Principles of

TABLE II
Classification: Sequencing and Subordination
The challenge in writing codes of nomenclature is making a set of rules that demand the best practices of taxonomists today, but also preserve the names created by past workers. Hence, to accommodate the work of the past, a code makes general provisions followed by a series of exceptions qualified by dates. Also, in zoology, there are two options for preserving history. A provision can be made in the code to solve a problem, or an appeal can be made to the commission to set aside the code to preserve an old name. Changing the code affects all occurrences of a problem, but a ruling of the commission applies only to a particular occurrence. In the past the commission frequently took many years to rule on cases. Hence, for Sabrosky and others, changing provisions of the code became the preferred method of addressing problems of old names. Hence, the current ICZN has many clauses that exist only to make old names available and to preserve their customary usage. Unfortunately, in adding to the ICZN provisions of these kinds, Sabrosky and others frequently created unforeseen problems. So the ICZN must be used carefully, since for almost every positive statement there is usually an exception. Other linguistic constructions may also be confusing, such as the frequent use of the phrase “as such.” For example, this phrase, used in Article 1.3.2, requires subsequent workers to decipher the intent of the original author. If the original author knowingly was describing an aberrant specimen, then the scientific name does not enter into nomenclature, but if the author thought the specimen was typical of the taxon being described, then the name must be considered to be available for use in nomenclature. Finally, the ICZN uses a number of specialized terms or special definitions for words; these are all covered in its glossary.

INTERNATIONAL CODE OF ZOOLOGICAL NOMENCLATURE

The current 4th edition of the ICZN consists of a preamble, a series of 18 chapters comprising 90 articles, recommendations and examples, and a glossary. The book also contains a preface, an introduction, and three appendices (the first two are general recommendations and the last is the Constitution of the ICZN). The text is in both English and French, and there is a single combined index. This book, bounded in green, is the “official” edition published by the commission, but other official versions have been approved and published in different languages.

The preamble sets the objectives and basic principles of the code: “to promote stability and universality” of names and to ensure that the name of each taxon is unique. The preamble also declares that taxonomy is independent of nomenclature. The articles are the definitive rules, with examples of how they are applied in specific cases as well as recommendations of appropriate practices. The glossary defines each term used so that the rules can be interpreted consistently. The following is a summary of the code by major topics (in parentheses after the topic are the articles covered).

Scope (Arts. 1–3)

The scope of zoological nomenclature is restricted to names for animals published starting in 1758, the date of the 10th edition of Linnaeus’ Systema Naturae. Here, the ICZN uses the verb “deemed” to declare for nomenclature that Systema Naturae was published on 1 January and before Clerck’s Aranei Sueci (spiders of Sweden), neither of which is true, since Clerck’s work was actually published in 1757? Exclusions are also listed, such as hypothetical concepts. That simply means that if the Loch Ness monster is not real, then its name Nessiteras rhombopteryx Scott, is not a name covered by the ICZN.

Publication (Arts. 7–9), Dates (Arts. 21–22), and Authorship (Arts. 50–51)

Although zoological nomenclature is a language for communication, the names that are regulated are those “published.” Since taxonomy is based on some 250 years of work, the definition of publication used by the ICZN is based on printed works. For names and nomenclatural acts to be within the coverage of the ICZN, they must have been first published in a printed work in numerous copies available to the public and for the permanent scientific record. This definition excludes some printed works, such as daily newspapers, which are not published for the permanent and scientific record. The ICZN rules exclude the evolving digital world, such as the Internet. This assures that all users read the same material in determining what are the appropriate names. The ICZN does accept new digital media such as CD-ROM or DVD disks that are “stamped out,” not printed. The ICZN provides rules to determine who is the author of these works and their dates of publication.

Names (Arts. 4–6) and Their Formation [Arts. 11 (11.2–11.3, 11.7–11.9), 25–49]

Beyond falling within the scope of zoological nomenclature and having been published, names must be properly formed. They must be written with the Latin alphabet, and they must agree with various other requirements, many of which reflect the origin of the system at a time when all scholarly works were written in Latin. The ICZN groups scientific names into three kinds: family-group names, the names of taxa above the genus and species; genus-group names, the names for groups of species that form the first part of the binomen; and species-group names, the specific (epithet) names. The ICZN prescribes that names of higher taxa, such as superfamilies (-oidea), families (-idae), subfamilies (-inae), tribes (-ini), and subtribes (-ina), have specific suffixes; that generic and subgeneric names have gender and be nouns or be treated as such; and that specific names (epithets) be either nouns (and invariant) or adjectives (and whose ending agrees with the gender of the generic name with which it is combined).

Availability (Arts. 10, 12–20)

Given that all the foregoing conditions are fulfilled, names and nomenclatural acts must meet additional requirements if they are to be made available for consideration under the ICZN and if they are to be held to be valid. The distinction between available and valid is critical. A valid name is the correct name to be used for a taxon, that is, a hypothesis of a group; an available name is any name that meets the requirements of the ICZN.

The additional requirements that names must follow to be available are as follows: (1) they must be formed as part of the system of binominal nomenclature, and (2) they must represent taxa that are considered to be valid. How taxa are defined is further regulated in a series of articles that are applied according to time. Before 1930 the standards were simple, such as attaching a previously unpublished name to an illustration, but current requirements are much more rigorous. For example, one must explicitly declare that a new name is being proposed, fully document the hypothesis (a description that “purports” to differentiate the taxon from all others), and designate the type for the name (which for a species is usually a dead specimen); if extant, the specimen must be deposited in a named, bona fide collection, or plans for such deposition must be furnished (see Arts. 13.1.1, 16.1, and 16.4).
Nomenclature and Classification, Principles of

Validity (Arts. 23–24)

A key problem for nomenclature is the existence of two or more names for the same taxon, for only one name can be considered to be correct or valid. This reflects the more general problem in science of who is to be given the credit for new ideas when multiple people claim to have arrived at them first. The general principle involved is that of priority—credit should go to the first person who published the idea. This principle was set forth by Henry Oldenburg, the first secretary of the Royal Society and editor of its Philosophical Transactions (1664–1677). Unfortunately, sometimes priority fails because the first to publish may have been forgotten, and someone else has become recognized as the first. In scientific nomenclature, this means that one name may become so familiar to many people that to change it to a name that is less widely known would cause instability. Hence, the ICZN provides a saving clause to allow for a widely used and familiar name to be preserved as the valid name when an older, obscure name is rediscovered. So, the ICZN provides a statement of the principle of priority (Art. 23.1), how it is to be applied in various situations, and, finally, when the principle should not be used (reversal of precedence, Art. 23.9).

Homonymy (Arts. 52–60)

Another key problem of nomenclature occurs when two or more names that are the same apply to different taxa. This is known as homonymy. Because some names consisting of different Latin letters may mean the same thing, the ICZN defines "same": for example, the epithet pairs microdon and mikrodon, and litoralis and littoralis are considered to be the same (Art. 58). Then the ICZN dictates how homonymy is to be resolved: the senior name is to be retained, and the junior name is to be replaced; but there are exceptions as explained in Articles 52–60.

Typification (Arts. 61–76)

Since names are only tags from scientific hypotheses, the question of whether two or more names are synonyms involves both nomenclature and taxonomy. Taxonomy in this regard can be defined as the circumscription of character space (Fig. 3), that is, the definition of taxa. Nomenclature is then the name, the designation of types for the name, and the rules for selecting among multiple types (see earlier remarks under Validity). Thus, a nominal taxon is only a name and a type; a taxon, the hypothesis, includes at least one nominal taxon. For species-group names, the type is a specimen (holotype, neotype, or lectotype) or a group of specimens (syntypes), which is or are the ultimate source of character information. For genus-group names, the type is a species name (nominal taxon), and for family-group names the type is a genus-group name. The determination of the type/genus of a family-group name is self-evident because that genus is basis for the family-group name itself (the type of the family Muscidae is the genus Musca). For both genus-group and species-group names, the types are designated either by the original author of the name or by subsequent workers.

An author may declare that a particular species/specimen is the type (original designation/holotype), may include only one species/specimen in the taxon (monotypy/holotypy) or may for genus-group names include a species-group name that is the same as the genus-group name (absolute or Linnaean tautonymy). If the type is not clearly fixed in the original publication, the ICZN provides rules for determining what species/specimens may be designated the type by subsequent workers.

For genus-group names, all species included in a newly defined genus are eligible to be designated as the type species. But this applies only to genus-group names proposed before 1931, as is noted earlier, after 1930 type designation became a requirement of availability. If no species were originally included, then those first subsequently included are to be considered. To subsequently designate a type species, a worker merely, but unambiguously, declares one of these originally included species as the type.

For species-group names, when no type is designated in the original publication, all specimens upon which the author based the name (including specimens not seen by the author but referred to by bibliographic citation) are eligible to be designated lectotype and are called syntypes until such a lectotype is designated.

Collectively all specimens that are either holо-, lectо-, neo-, or syntypes are termed primary types. Other specimens studied by the author may be termed paratypes (or one may be an allotype if of a sex different from the holotype), but these secondary types have no nomenclatural significance. When all primary types are no longer extant (lost or destroyed), a subsequent worker may designate any specimen as the neotype to objectively define the nominal species-group taxon. Naturally, there are recommendations and restrictions about which specimen may make a more appropriate neotype. Provisions are also made for types that have been misidentified; that is, the characters used by an author to define a taxon do not agree with those of the nominal type. When this happens, workers are free to select as type either one that agrees with the characters or the named type.

Exceptions (Arts. 78, 80–83) and Registration (Art. 79)

The stated objectives of the ICZN are to promote stability and universality in the names of animals, and thus all its provisions must be subservient to these goals. Hence, the ICZN provides means by which any provision of the ICZN (except those that deal with its authority and exception handling) can be set aside in a particular situation. These articles outline how one appeals to the commission and how the commission arrives at its opinion, which is then published in its Bulletin of Zoological Nomenclature. These plenary
powers and specific powers are restricted to specific cases, usually involving only a few names or works. The ICZN has provided a procedure to rule on a whole set of names at once and has created a List of Available Names in Zoology. This specific power allows international groups of zoologists to propose a set of names that may be approved by the commission, thereby fixing all the relevant details about those names (their spelling, authorship, place and date of publication, and typification) and giving those names precedence over other names. Names not on the list are thereafter excluded from zoological nomenclature.

Authority (Arts. 77, 84–90)

The last section of the ICZN includes a series of rules explaining the derivation and perpetuation of its authority, as well as the various regulations governing the particular edition of the ICZN. These state that the ICZN is prepared by the ICZN with the participation of the zoological community under the authority of a single organization (originally the International Congresses of Zoology, now the International Union of Biological Sciences). For the future, authority can be delegated to other international organizations as specified. The effective date of the fourth edition is given as January 1, 2000, and all previous editions no longer have any force.

OTHER CODES

Currently there are five different codes of nomenclature in use for organisms—one each for plants, cultivated plants, bacteria, viruses, and animals. All these codes address the same problem, the need for universal, stable, and precise sets of names for organisms, and all are similar in their methodology. However, differences are significant and can cause difficulties for those developing databases that cover all life. Hence, in the early 1990s, an effort was undertaken to develop a single code of nomenclature for all life. Meetings were held and a draft BioCode was published, but nothing further has happened.

All the codes in use today are based on and have their origin in the binomial system established by Linnaeus. Although the Linnaean system has evolved from its topological roots into one adapted to the Darwinian evolutionary model, some believe that the system cannot fully express human knowledge about the cladistic relationships among organisms. A PhyloCode has been proposed to address these perceived failures. Unfortunately, the PhyloCode adds more uncertainty, since names for clades can be based on three different methods for defining groups, and clade names have no rank, which means that virtually all information content is lost (as discussed by Benton and Forey).

INTERNATIONAL COMMISSION ON ZOOLOGICAL NOMENCLATURE

Zoologists realized early on that no code of nomenclature could be perfect, always able to resolve all situations in a manner that promotes stability and universality in scientific names. Hence, zoologists established an international group of specialists with the authority not only to develop and maintain the ICZN, but to make rulings on specific names and situations. What the commission is empowered to do has been outlined in this article and is covered in Articles 78–81. How the commission operates is set in Articles 77 and 83 and in its constitution, which is published as Appendix 3 of the ICZN. To appeal to the commission, a worker prepares a proposal and submits it to the commission. The proposal is then published in the Bulletin of Zoological Nomenclature for public comment. After 6 months, the commission may vote on the proposal, and the ruling will later be published in the Bulletin. Each proposal is treated separately on its own merits. The commission does not set precedents or follow case law.

CONCLUSIONS

No modern science places as much emphasis on priority as taxonomy and nomenclature. This emphasis requires specialists to be familiar with at least a century of published work and sometimes 300 years’ worth. Some may question the value of such a long view, inasmuch as most sciences look back only a decade or so. Beyond the moral and ethical considerations, however, much can be gained by understanding the past. Recognition of taxa is an innate ability of humans. Ernst Mayr once noted that the primitive natives of New Guinea knew and had names for 137 of the 138 local species of birds that took western scientists years to formally describe. So, previous workers who failed to generate cladistic classifications and were not aware of the proper names for their taxa may well have recognized and characterized natural groups. So, one tries to understand how one’s predecessors, who looked at the same organisms, decided how to organize their observations into taxa. Thus, all who want to truly master nomenclature and classification are well advised to examine carefully what their predecessors did, appreciating what Newton once wrote: “If I have seen further, it is by standing upon the shoulders of Giants.”

Further Reading

Regarding nutritional requirements, insects share much in common in their physiology and ecology. Nutrition refers to the ingestion and processing of substances that intersect an animal's physiology and ecology. In the broadest sense, nutrition is the use of molecular genetics to establish new ways of thinking about the complexity of nutrition, and through the laboratory on artificial foods, thereby avoiding the often-costly effort necessary to maintain natural foods. Among the first successes was E. Bogdanow’s 1908 report on rearing of a dipteran Calliphora vomitoria on a diet containing meat extract, starch, and peptone. Similar accounts followed, describing the rearing of many insect species representing a variety of taxa. Numerous scientists are associated with this early work, including S. Beck, R. Craig, G. Fraenkel, W. Trager, and B. Uvarov and others. Subsequent research attempted to refine diets by using more purified natural products, or even pure nutritional chemicals. The effort was greatly aided by new information gleaned from research on the basic nutritional requirements of insects. A major advance was the discovery by E. Hobson in 1935 that insects require dietary sterol. This clearly distinguished the nutrition of insects from that of most mammals and other higher taxa, whose nutritional requirements were far better known. The discovery quickly led to advances in the study of insect dietetics and nutrition.

**ARTIFICIAL SYNTHETIC DIETS**

Despite the diversity of insect dietary habits, insect nutritionists have been remarkably successful at developing artificial diets for rearing insects. Published compilations of insect diets representing the collective effort of over one thousand scientific contributors indicate that several hundred species can be reared partially, or through their entire life cycles, in the absence of their natural foods. Literature is available describing various applications of this nutritional technology. The catalog of a well-known commercial concern lists for sale diets for rearing over 50 species of insects, and artificial diets have been employed for mass culture of several species. A United States Department of Agriculture laboratory in Phoenix, AZ, for example, is currently rearing on a completely artificial diet, 6–7 million pink bollworm moths, Pectinophora gossypiella, daily, for use in an autotrophic pest management control program in California.

**QUALITATIVE NUTRITIONAL REQUIREMENTS**

The nutritional requirements of insects were at first inferred from knowledge of the chemical compositions of natural foodstuffs. Insects were categorized as carnivorous, omnivorous, or phytophagous, with the appropriate inferences regarding the nutritional content of the animals, plants, and other foods eaten. Studies of food utilization, and the analysis and comparison of foodstuff eaten and excreted or unabsorbed, allowed further assessment of the relative importance of various nutrients for insects with different feeding habits. A more detailed and complete understanding of insect nutritional requirements finally emerged following the successful development of artificial diets, particularly chemically defined diets. The essentiality of many nutrients was established by dietary deletion, the sequential elimination of individual chemicals, potentially nutritious, from a diet. These advancements involved many scientists now recognized for their contributions to the foundation of insect nutrition—J. S. Barlow, R. H. Dadd, S. Friedman, H. T. Gordon, H. L. House, J. G. Rodriguez, T. Ito, E. S. Vanderzant, G. P. Waldbauer, and others.

A nutrient is deemed *essential* if, when deleted from the diet, further growth, development, and/or reproduction are prevented. Almost all insects have a common set of essential nutritional requirements. Nutrients demonstrated to be necessary for optimizing growth, development, and/or reproduction are *required* nutrients. The value of specific nutrients, however, often depends on total dietary content. Dietary carbohydrate, for example, is often unnecessary, but may be required or even become essential, for providing energy.
N in the absence of dietary fat, or protein in excess of the amount required for normal growth. The following summarizes the essential qualitative requirements of most insects.

### Nitrogen

Insects consume and utilize a wide variety of proteins to satisfy their nutritional requirements for amino acids. Of the commonly occurring amino acids that comprise most proteins, 10 are not synthesized by insects, or by most animals, and are essential nutrients. These include arginine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine/tyrosine, threonine, tryptophan, and valine. Beyond the bulk requirement for protein synthesis, these essential amino acids serve additional physiological functions of particular note in insects, and other invertebrates. Arginine, for example, is a precursor for the principal invertebrate muscle phosphagen, phosphogarginine. Tyrosine is important for production of phenolic and quinone metabolites, critical components for cross-linking of proteins during sclerotization.

The other 10 commonly occurring proteinaceous amino acids are generally non-essential, but may nevertheless be required to some degree for normal growth and development. Some amino acids, however, may be uniquely essential for some species. Several mosquitoes and one tachinid species, for example, may be unable to synthesize asparagine which is an essential dietary amino acid. An essential requirement for proline by several taxonomically disparate insect species may be related to a limited activity of the urea cycle. For unknown reasons, glutamic acid or aspartic acid, normally non-essential, have been reported as essential for a few species.

Few insects develop on diets containing only the 10 essential amino acids. Moreover, many insects do poorly on diets containing amino acids as the sole source of nitrogen, and require protein or a mixture of protein and amino acid for normal growth and development.

Insects generally synthesize their own nucleosides, nucleotides, and nucleic acids, although several species, particularly various dipteran species, have been shown to benefit by inclusion of nucleic acid or some constituents of nucleic acids. In a few cases, nucleic acid is considered essential for completion of development.

### Vitamins

Vitamins, particularly water-soluble B vitamins, including biotin (Vitamin H), folic acid (B11), niacin, pantothene acid, pyridoxine (B6), riboflavin (B2), and thiamine (B1), or close chemical relatives of these, are essential nutrients for all insects. They serve principally as precursors for the coenzymes of intermediary metabolism. Regarding the fat-soluble vitamins, only tocopherol (E) and retinol (A) have proven beneficial for reproduction and vision, respectively, by some insects. Tocopherol also plays an important role as a lipid antioxidant.

### Carbohydrate

Carbohydrate nutrients, although often required as an energy source, are rarely essential. An exception may be the case of some adult lepidopterans that feed solely on plant nectars. Indeed, some of these insects are thought to be capable of digesting sucrose alone. The same may hold true for some adult dipteran and hymenopteran species. In addition to their role as nutrients, sugars, particularly sucrose, are powerful phagostimulants, without which some insects feed poorly or not at all.

### Sterols

Insects have an essential requirement for a dietary sterol. Cholesterol appears to be widely acceptable, but a number of other plant sterols, particularly β-sitosterol are equally acceptable. Among a few exceptions, is the interesting example of Drosophila melanogaster, the senita cactus fly, that requires Δ7 dietary sterols, metabolic derivatives of schottenol, a Δ7 sterol found in its natural food, the senita cactus. In addition to the bulk requirement for sterol utilization in membrane formation, sterol is also important for the production of ecdysone and other molting hormones.

### Fatty Acids

Fatty acids are considered non-essential for most insects, but several mosquitoes and some lepidopterans require a polyunsaturated fatty acid. This requirement is associated with one of only a few known nutritional diseases or syndromes—the “crumpled wings” syndrome. Absence of a polyunsaturated fatty acid results in adult insects that fail to fully expand their wings following eclosion, and are thus unable to fly. The chemical nature of this requirement is poorly understood. In the case of mosquitoes, arachidonic acid or some closely related fatty acid with an ω-6 double bond is essential. In those Lepidoptera requiring a polyunsaturated fatty acid, however, some species utilize ω-6 fatty acids, whereas others utilize ω-3 fatty acids such as α-linolenic acid. Moreover, in those Lepidoptera requiring an ω-6 fatty acid, α-linolenic is generally preferred, whereas arachidonic acid is unsuitable. Nothing is known of the physiological basis for this requirement, but in the mosquitoes it may be linked to the synthesis of prostaglandins, local regulators that target a wide variety of cellular functions in vertebrate animals.

### Inorganics

A complex of mineral ions is essential for insects. The balance of minerals, however, is often dramatically different from the well-known salt requirements established for mammals. Many insects, for example, require much greater proportions of potassium, magnesium, and phosphate, relative to sodium, calcium, and chloride.

### Ascorbic Acid and Other Water-Soluble Growth Factors

L-ascorbic acid, vitamin C in vertebrate animals, is an essential growth factor for many phytophagous insects. In its absence, these insects generally fail to grow and/or develop. The pattern of this requirement among insects is thus similar to that of the higher animals where species that have adapted to a diet of fruit and/or vegetables have apparently lost the ability to synthesize ascorbic acid. In contrast to the vitamin C requirement of vertebrates, ascorbic acid is required by insects in relatively large amounts, although this may in part reflect the necessity for a high antioxidant activity in synthetic artificial diets employed for testing. Moreover, unlike vertebrates requiring L-ascorbic acid, some insects utilize dehydroascorbate as effectively as L-ascorbate, and may use the D geometric forms of closely related lactones, although these are generally not as effective. Although there is little understood about the role of ascorbic acid in insects, beyond its potential antioxidant action, it may play the same role as in vertebrates, that is, as a factor necessary for enzyme activities involving hydroxylation. Deficiency in insects is often associated with abnormalities of molting, possibly due to the absence of the effects of ascorbic acid on diphenoxylatedes.

The lipogenic growth factors, choline and inositol, principal components of phospholipids, are required by many insects. Choline may be essential nutrient for most insects.

A unique and essential requirement for carnitine is known for several tenebrionid beetles, where this usually non-essential nutrient is called vitamin B₇. Normally derived from choline, carnitine plays an important role in fatty acid transport.

Essential and non-essential nutrients are required in specific amounts, but as implied above, optimal levels of individual nutrients...
often depend on the presence and concentrations of other nutrients. Early studies with artificial diets purported to formulate optimal levels of nutrients, based on the relative concentrations found in natural foodstuffs. Diets employing these concentrations of nutrients often produced adequate results, but subsequent studies have demonstrated that the quantitative aspects of insect nutrition were far more complex than that approach suggested. Moreover, ecological, behavioral, and physiological factors are also important for optimal nutrition.

**Quantitative Nutrition**

If an insect is to survive, grow, and reproduce, it must ingest several dozen different types of nutrient molecules. These molecules come packaged in varying amounts and ratios within foods, along with non-nutritive (and sometimes toxic) compounds. Foods in turn are distributed through time and space, and their finding, ingestion, and processing engender metabolic and ecological costs. Moreover, the nutritional needs of insects change with age, stage of development, reproductive status, etc. Matching the multidimensional and changing nutritional demands of the insect against the complex and changing composition of the nutritional environment has posed one of the greatest challenges to evolution—and to scientists who study insect nutrition. The problem is particularly difficult for herbivorous insects, where the nutritional composition of host plants may be highly variable and there is the added complexity of secondary plant metabolites serving as antifeedants and toxins. There is a growing realization, however, that predators too may face considerable variation in food quality, and may therefore have to regulate their intake and use of multiple nutrients rather than relying on more general food properties.

A powerful way of defining and exploring nutritional regulation that has arisen from work on insects has been to represent the animal, its intake and growth requirements, and the foods in its environment using multienvironment plots. This “geometric framework” has enabled the identification of the key elements in complex nutritional systems, and the quantification of the interactions among them. These include interactions among the multiple constituents of the food, as well as between behavioral and physiological regulatory mechanisms. The resulting descriptions provide a powerful means to study the mechanisms, ecology, and evolution of nutritional systems.

**Quantifying Intake Requirements**

Estimating the intake requirements (intake target) is a primary aim of any nutritional study. One way to do this is to allow the insect to demonstrate whether it is able to regulate its nutrient intake, and if so in which nutrient dimensions. A well-documented study system is the locust, which has been shown to regulate its intake of both protein and carbohydrate under several challenges:

(a) **Pairs of complementary foods.** When locusts were provided with one of four complementary food pairings (28:14 or 14:7, % protein:% digestible carbohydrate vs. either 14:28 or 7:14), they adjusted the amount and ratio of the two foods eaten to maintain a constant point of protein and carbohydrate intake (Fig. 1, upper panel).

(b) **Food dilution.** When locusts were given one of five foods containing a near-optimal ratio of protein to digestible carbohydrate (1:1), but diluted up to fivefold with indigestible cellulose (35:35, 28:28, 21:21, 14:14, or 7:7, % protein:% digestible carbohydrate), they adjusted their consumption across all dilutions to maintain a constant point of nutrient intake (Fig. 1, middle panel).

(c) **Food frequencies.** When two complementary foods (31:11 and 7:35) were provided in relative abundances of 1:3, 2:2, or 3:1 dishes of one vs. the other food type, locusts precisely selected a point of protein to carbohydrate intake by adjusting their distribution of consumption between dishes (Fig. 1, lower panel).

These remarkable feats of homeostasis were found to extend to regulation of salt vs. macronutrient intake. Moreover, other studies indicate that such capabilities are by no means restricted to locusts.

**Changes in Intake Requirements with Time**

The intake requirements of insects are not static. They change with recent nutritional experience and level of activity. For instance, locusts and caterpillars select a protein-rich food following a short experience (only one meal in the case of the locust) of a protein-deplete food, and show a similar preference for carbohydrate-rich food after a 4h period of carbohydrate deprivation. Nutrient requirements also vary with stage of development, reproduction, and diapause. Over a longer time scale, nutritional requirements evolve to track changing nutritional environments and life histories.

**Mechanisms Regulating Intake**

Regulating nutrient intake requires two sources of information, the first being the composition of the food and the second the nutritional state of the animal. The responsiveness of an animal to a food of given composition should reflect, through feedbacks, the animal’s nutritional state. Insects are able to taste certain key nutrients, notably sugars, amino acids, salts, and water. Studies on locusts, caterpillars, and blow flies have shown that the responsiveness of taste receptors to sugars and amino acids varies with nutritional state, as represented by concentrations of these nutrients in the hemolymph. Such nutrient-specific feedbacks enable insects to make sophisticated behavioral decisions about what foods to eat to regulate nutrient intake. In addition, learning of various sorts, including aversion, learned specific appetites, and induced neophobic responses, also plays an important role in regulating food selection in insects. An impressive example is the ability of locusts to learn to associate the odor of a food with its protein content and to be attracted by odors previously paired with high-protein food, but only when in a state of protein deficit.

**Nutrient Balancing on Suboptimal Foods**

If an insect is restricted to suboptimal foods and is unable to reach its intake target, it must balance undereating some nutrients against overeating others, reaching some “point of compromise.” Such a situation exposes whether and how the mechanisms regulating intake of different nutrient groups interact. A simple means of exploring the interactions between regulatory systems for different nutrients is to provide insects with one of an array of foods of varying composition and to measure intake. Collectively, the resulting points of nutrient intake across the array of foods form a pattern that describes the relationship between the mechanisms regulating intake of the nutrients concerned.

Various such relationships have been described to date in insects. The simplest outcome is where the insect abandons regulation of one nutrient when forced to balance it against regulation of another. For instance, locusts regulated macronutrient (protein and carbohydrate) intake and let salt intake vary passively when fed single foods containing suboptimal salt levels, even though they regulated both salt and the macronutrients when allowed to switch between complementary foods. In other cases, one nutrient does not overwhelm the other. When locusts were fed foods varying in protein and carbohydrate content they balanced over- and undereating the two nutrients, with the precise balancing rule depending on the species of locust. The grass-feeding specialist, *Locusta migratoria*, was less able to overeat unbalanced foods to gain more of the limiting nutrient
FIGURE 1 Three experiments indicating regulation of intake to a point (intake target) in a carbohydrate–protein plane. The plots are of the form used in the geometric framework. Foods are shown as lines (rails) radiating out from the origin. An insect feeding from a single food is constrained to move along that food rail in intake space, while two foods provide the opportunity to move anywhere in between by food mixing. In the upper panel locusts were provided with one of four food choices (14:28 or 7:14, % protein:% carbohydrate vs. 28:14 or 14:7) and altered relative amounts eaten from the two foods, thus reaching the same place in nutrient space. Open symbols indicate where insects would have arrived were they to have eaten indiscriminately between the two foods provided. The middle panel shows locusts that were given one of five foods containing a 1:1 ratio of protein to digestible carbohydrate, but diluted to various degrees with indigestible cellulose. Those on food 7:7 ingested five times more food than those on 35:35, thus achieving the same intake of both protein and digestible carbohydrate. Open symbols show points of intake were insects not to have compensated for dilution but eaten the same amount of food on each treatment. Locusts in the lower panel were given four food dishes, containing either 7:35, % protein:% carbohydrate (food C), or 31:11 (food P). The two food types were provided at different frequencies (all four dishes contained C, all four contained P, or two contained C and two P). Locusts adjusted the amounts eaten from each dish and regulated nutrient intake. Open symbols indicate points of intake were locusts to have distributed feeding equally among dishes and not shown frequency-dependent food selection.

FIGURE 2 Arrays of nutrient intake shown by locusts when fed single foods, and hence forced to balance their intake of two nutrient groups. The two panels show how the grass-specialist *Locusta migratoria* and the host-plant generalist *Schistocerca gregaria* have different balancing rules for protein and carbohydrate. *L. migratoria* minimized the distance from the intake target in nutrient space when unable to reach its intake target (the CD rule), while in comparison *S. gregaria* ate more of the nutritionally unbalanced foods (the ED rule). It appears that the generalist species is better able to capitalize on excess ingested nutrients than is the specialist.

**Regulation of Growth and Metabolism**

Whereas an insect may be constrained from reaching its intake requirements by available foods, it may still be able to regulate post-ingestive processing and thus achieve its growth target (Fig. 3). Regulation of growth and body composition involves differentially using ingested nutrients: ridding nutrients in excess and conserving those in deficit. Locusts are extremely effective at regulating growth, excreting excess ingested nitrogen, and respiring excess ingested
carbohydrate or converting it to lipid. Deamination of excess ingested protein, principally by oxidation or transamination to the corresponding keto acid, may serve to augment limiting carbohydrate for energetic purposes.

Studies on *Drosophila* are beginning to uncover the molecular and cellular mechanisms involved in metabolic homeostasis and coming years promise a rapid expansion in knowledge about the roles of different tissues and signaling and sensing systems.

**NUTRIENT–ALLELOCHEMICAL INTERACTION**

The foods of many animals contain, in addition to primary nutrients, harmful or unpalatable non-nutritive materials. This is especially the case for plants, which contain an abundance of defensive secondary metabolites (often termed allelochemicals). In some cases, insects make use of such compounds either as cues for host-plant recognition or as resources in their own right for defense or communication. In the main, however, allelochemicals are an impediment to nutrient regulation. A key point is that the effectiveness of allelochemicals as anti-nutritive compounds depends on the nutritional context in which they occur in the food. For example, locusts are not affected adversely by the presence of tannic acid in their food, even up to 10% dry weight, if the protein and carbohydrate ratio and concentration are near optimal. When foods contain less than an optimal protein to carbohydrate ratio, tannic acid serves as a powerful feeding deterrent, and thus causes high mortality and extended development. However, at higher than optimal protein-to-carbohydrate ratios tannic acid does not reduce intake but instead results in high mortality by disrupting protein utilization. Dietary nutrient ratio has also been shown to moderate the toxic effects of nicotine on growth of tobacco hornworm caterpillars, *Manduca sexta*.

**MICROBIAL ASSOCIATIONS**

Symbionts, principally actinomycete fungi and bacteria, play a critical role in insect nutrition, enabling many species to develop normally on foods of limited nutritional value. Well-known examples of such foods include wood, blood, phloem, and plant litter. Many insects would quickly perish in the absence of these symbiotic relationships. Symbionts often provide nutrients directly as a result of synthetic capabilities that their insect hosts lack, and/or allow, through the production of gut enzymes, insects to digest otherwise indigestible foodstuff. Alternately, the symbiont itself may serve as food. Many symbiotic relationships are casual, involving ectosymbionts, usually comprising a rich gut microflora. Endosymbiosis is also common, and many insects have developed highly specialized anatomical and behavioral features for optimizing the benefits of the relationship and for efficiently transmitting their symbionts between generations.

Among the most significant endosymbioses are those involving mycetocytes and bacteriocytes, host cells specialized for housing symbiotic microorganisms—fungi or bacteria. Often these polyploid cells are associated with the midgut epithelium, although in the case of fungal-infected cells, aggregates called mycetomes may sometimes be found in the hemocoel. The genomes of the symbiont and the host cell are closely coordinated, forming a functional unit known as the symbiocosm. Such an endosymbiont is found in the rice weevil,
Sitophilus oryzae, where it is referred to as the SOPE or S. oryzae principal endosymbiont. This bacterium (family Enterobacteriaceae), whose expression is partly regulated by the host, occurs in the cytoplasm of the bacteriocyte \((2 \times 10^9 \text{ bacteria/host cell})\) and is known to be critically important in the insect's biology. It is, for example, the source of several vitamins, including riboflavin, pantothenic acid, and biotin. Moreover, the presence of the symbiont alters the balance of amino acid metabolism and mitochondrial phosphorylation, thereby affecting flight ability and performance.

The impact of symbionts on the quantitative nutrition of insects was recently made apparent by an analysis of the optimal dietary protein:carbohydrate ratio for 117 insect species. Insects housing symbionts displayed very steep intake target rails (Fig. 4), strongly suggesting that symbionts add considerably to the nitrogen nutrition of such species and, moreover, that this may generally be the case.

**CONCLUSION**

A thorough knowledge of insect nutrition is essential for understanding the biology of insects. The study of insect nutrition has recently undergone a metamorphosis, in that information gleaned from earlier investigations that focused principally on basic nutritional requirements and rearing technology is now being applied for understanding the feeding strategies, nutritional ecology, and evolution of insects. Nutritional physiology and biochemistry are also advancing, with the molecular arsenal available for *Drosophila* offering many new opportunities. The neurological bases for food selection and the role of biogenic amines in regulating food choice are beginning to be understood. The chemical composition of the hemolymph is now recognized as a dynamic indicator of nutritional status, affecting food selection and nutrient intake. The metabolic responses of insects to altered nutritional status and the effects of fat body metabolism on hemolymph composition are also being investigated. Future studies employing multidisciplinary approaches will continue to unravel the mysteries of insect nutrition and its consequences and significance to insect biology.

Odonata

(Dragonflies, Damselflies)

K.J. Tennessen

Florida State Collection of Arthropods, Gainesville, FL

Odonata (dragonflies) are paleopterous, exopterygote aquatic insects, probably more closely related to the Ephemeroptera (mayflies) than any other living insect group. Dragonfly adults are predaceous, relatively long-lived insects. Their large compound eyes, strong chewing mouthparts, long legs, and unparalleled flight capabilities are ideal adaptations for catching and consuming insect prey. Although adult dragonflies have mastered the air, the immature stage (called nymph or larva) is aquatic and usually much longer lived. Adaptation to an underwater existence has resulted in striking differences in form among nymphs, whereas adults are much more uniform in shape.

Dragonflies are quite harmless insects; they do not sting and will try to bite humans only when held captive. However, they are hosts of trematodes (flukes in the family Lecithodendriidae) in Southeast Asia, and when eaten raw, they can be a source of infection in humans (by ingestion of the metacercariae). On the whole, dragonflies are considered beneficial insects for several reasons. In both nymph and adult stages, they feed on many insects that are pests of humans and domestic animals, such as mosquitoes (Culicidae), deer flies (Tabanidae), black flies (Simulidae), and other Diptera. They are important components of aquatic food webs and are used as indicators of ecological health of streams and lakes; in some areas, nymphs are used as fish bait or as food. They make good subjects for behavioral and ecological studies, and poets and visual artists are often inspired by their beauty and behavior. Because some species are quite large and many are beautifully colored (Fig. 1), dragonflies have become fairly popular with the public. The relatively large size and distinctive color patterns allow the identification of many species of Odonata in the field, especially through binoculars. The recent appearance of several field guides such as Dunkle’s will facilitate natural history and behavioral studies also. As dragonflies become more popular, they may join butteflies as “ambassadors” for insect conservation and appreciation.

Dragonflies are a warm-water-adapted group that probably originated in a tropical environment, as evidenced by lower present-day species diversity in cooler climates (i.e. with increasing latitude and increasing altitude). At least 75% of the world fauna is tropically distributed, although a few genera (Aeshna, Somatochlora, and Leucorrhinia) have diversified in cooler climates and their centers of distribution are located at higher latitudes and altitudes. Most high-latitude species in these genera are centered in the warmer parts of their geographic ranges, but a few species (e.g. Somatochlora) are distributed mainly north of 60°.
The appearance of aquatic nymphs. The earliest fossil evidence of an aquatic nymph existence is from the Mesozoic, and it has been suggested that they were semi-aquatic before that period. However, the apparent sister group of the Odonata, the Ephemeroptera, show evidence of nymphs with gills in the early Permian at least 270 million years ago; no fossil mayfly nymphs have been regarded as terrestrial.

**SYSTEMATICS**

Although systematics of Odonata is relatively advanced, classification at the suborder and family level is still controversial. Until recently, three extant suborders were accepted, the Anisoptera, Zygoptera, and Anisozygoptera, with the latter group being represented by only two extant species of the Asian Epiophlebiidae. However, recent analyses indicate that “Anisozygoptera” is not a monophyletic group and that all taxa previously placed in that group are extinct. Therefore, the two living Epiophlebiidae are considered Anisoptera.

Classification at the family level also has been unstable. At present, 33 families are generally accepted (Table I), although there is some disagreement with this arrangement, especially within the Zygoptera. Molecularly derived data will undoubtedly result in further understanding of taxonomic relationships and changes in classification. Worldwide, over 5600 species of Odonata have been described. The two suborders (Anisoptera and Zygoptera) have approximately equal numbers of known species. The rate of species description has remained fairly constant throughout recent decades (on an average nearly 350 new species per decade in the 20th century), an indication that the order is far from being completely known.

Nymphs are much less well-known than adults, especially in the tropics. However, nymphs of nearly all the 427 North American species and 120 European species have been discovered, and much knowledge exists on their habitat requirements and life histories. Nymphs of approximately 30% of the more than 1200 South American species have been described.

**CHARACTERIZATION AND MORPHOLOGY**

**Characterization of the Order**

The order Odonata is characterized by having a prognathous head with chewing mouthparts, large compound eyes, three ocelli, small bristle-like antennae, a small prothorax, the meso- and metathoracic segments fused into a large pterothorax, relatively long legs with three-segmented tarsi, two pairs of elongate wings, elongate abdomen, accessory male genitalia including the intromittent organ (not homologous with the penis of other insects) on the venter of the second abdominal segment, and one-segmented cerci. The odonate pterothorax is unusual in several features: (1) the bases of the legs are crowded forward, an arrangement conducive not to walking but to grasping; (2) the sternal sclerites make up most of the lateral and dorsal walls, with the mesepisterna meeting dorsally to form a mid-dorsal carina; and (3) the wing bases are positioned posteriorly, and the tergal sclerites are extremely reduced. All these thoracic modifications facilitate strong flight and the pursuit and handling of prey. The huge flight muscles are connected directly to the bases of the wings. Therefore, the front and hind pairs can be moved independently. The wing beat rate is relatively slow compared to neopterous insects (20–40 beats s \(^{-1}\) vs. nearly 1000 beats s \(^{-1}\)), but dragonflies can fly almost as fast and as agilely as any other insect. Although most Zygoptera are relatively slow fliers, they can navigate precisely amongst stems and tangles of vegetation. The nymphs are unique among Insecta in possessing an elongate, hinged labium that

is folded under the head when not in use; it may be as long as one third of the nymph body when extended to capture prey.

**External Morphology**

The suborders differ in two major characters. In Zygoptera (Fig. 2), the head is wider than the thorax and the hind wings are similar to the fore wings in basal width and the orientation of the quadrangles. In Anisoptera (Fig. 3), the head is not wider than the thorax in dorsal view and the hind wings are wider at the base than are the fore wings; also, the triangle of the fore wing lies perpendicular to the long axis of the wing, whereas it usually lies parallel to the long axis in the hind wing. Nymphs of the two suborders differ in that Zygoptera have three elongate, platelike or saclike anal gills and two comparatively short cerci (Fig. 4A and 4B), whereas Anisoptera have five pointed anal appendages (Fig. 4C and 4D) and an internal rectal gill chamber. Although the term “dragonfly” typically is used for the entire order, some authors restrict this term to the Anisoptera and use “damselfly” for the more slender Zygoptera.

**FIGURE 2** Zygoptera adult.

The wings of Odonata are richly veined to support the wing membrane. Wing venation is extremely important in systematics, especially at the family level. The beautiful colors of the body are produced by pigments under the cuticle and by diffraction of light by the cuticle.
Females are often less strikingly colored than males of the same species, particularly in the large families Libellulidae and Coenagrionidae. Coloring may also be produced by pruinescence, a white or bluish white exudate of the hypodermis, which forms with sexual maturation, especially in males. Nymphs are usually darkly colored, probably an adaptation to the colors of their microhabitat. In contrast to adults, body shape is highly variable in nymphs, ranging from slender cylinders to nearly flat circles, and undoubtedly reflects specific habits of foraging and escaping predation. Antennae of the nymphs are more developed than in the adults. The most-distinguishing characteristic of nymphs is the prey-capturing labium, which is highly variable in its morphology and ranges from flat to cup- or spoon-shaped and from very elongate to short and wide. The palpal lobes and prementum are armed with a highly variable number of raptorial setae, though these may be absent.

**BIOLOGY**

**Life Cycle**

Odonata are hemimetabolous. The nymphs have external wing sheaths, and although there is no pupal stage, the nymph in its final stage differs greatly in form from the adult. Several developing adult structures, such as the labium, often can be seen at this stage through the nymphal integument. Of the three life stages (egg, nymph, adult), the nymphs show the greatest diversity in functional morphology.

**EGG STAGE**

Eggs are laid in or above permanent or temporary water bodies. The Zygoptera and a few Anisoptera families (Aeshnidae, Petaluridae) lay their eggs in plant tissue (endophytic oviposition); most Anisoptera families lay their eggs in open water (exophytic oviposition), although some species attach their eggs to plant tissue. Eggs are spindle shaped in endophytic species and usually round to ellipsoidal in exophytic species; they range in size from about 0.23 to 0.48 mm to 0.60 to 1.40 mm. Eggs are fertilized as they pass through the female’s vagina during oviposition, and embryogenesis begins immediately after the eggs are laid. Fertilized eggs change from creamy white or light gray to a light or reddish brown or dark gray color within the first 24 h. However, eggs of some tropical species are brightly colored (e.g., blue, green, pink) throughout the egg stage. Embryos that undergo direct development hatch within 5 – 60 days, whereas those undergoing delayed development (diapause) hatch between 80 and 200 days after oviposition depending on temperature.

The hatching process begins several hours before actual eclosion. Peristaltic movements of the esophagus result in swallowing of amniotic fluid, which causes water to enter the egg through the micropyles. In Zygoptera, increasing pressure within the egg causes the chorion to rupture, usually along curved lines of weakness. Continual swallowing and abdominal distention move the embryo forward, pushing the head forward into a chamber formed by the vitelline membrane. The embryo then swallows water, bursting the vitelline membrane, and the first instar slips most of the way out of the chorion, but typically the tip of its abdomen remains inside the egg. In Anisoptera, a sclerotized frontal crest, called an “egg burster,” is used to produce a longitudinal slit in the chorion, through which the nymph exits the egg.

**NYMPH STAGE**

The first instar, known also as the prolarva, is extremely brief in duration. It does not feed, and the legs are seldom functional. It may last for a few seconds to a few hours, depending on whether the egg was deposited in or out of water. In most species, the prolarva molts to the second instar while the tip of the abdomen is still within the egg. In species that hatch above the water line, the prolarva drops out of the egg and reaches the water primarily...
by jumping. Second instars retain some yolk in their midgut to provide nutrition for a day or so, allowing them to become adept at their predatory habits. They are usually fairly pale, becoming darker in succeeding instars, usually matching their microhabitat.

The number of instars is highly variable within the order, ranging from 9 to 17. Most species have 11–13 instars, but even siblings treated identically can undergo a different number of molts. Instar classification is especially difficult with field-collected nymphs, except that the first three and last three instars usually can be determined.

Duration of each instar is also highly variable and is dependent on species, temperature, and food availability. The final instar is the longest in duration, lasting as little as five days in rapidly developing species to a year or more in others. Growth occurs immediately after each molt for about an hour, while the integument is still pliable. Growth ratios (proportional increases in linear dimension from one instar to the next) for Odonata range from 1.2 to 1.3 and are usually very close to the average for Hemimetabola (1.27). Certain body structures change with successive molts; for example, the number of antennal segments and the number of palpal and premental setae increase, dorsal protuberances on the head of early instars disappear, the compound eyes become larger, color patterns develop, and rudiments of the sexual gonapophyses appear. Wing pads usually appear during the middle instars, and grow more rapidly than any other body part.

Most species of Odonata have one or two generations per year, but many are semivoltine. A higher percentage of species are multivoltine in the tropics than in temperate latitudes; many temperate-centered Anisoptera take four to six years to complete one generation. Odonate life cycles can be classified as either regulated or unregulated. In the tropics, life cycles are regulated by alternating wet and dry seasons, whereas in temperate zones they are regulated by alternating warm and cold seasons. In regulated types of life cycles, the dry season is usually passed as prereproductive adults or as eggs, whereas the cold season is passed as nymphs or as diapausing eggs. Species that occupy ephemeral habitats undergo rapid nymphal development, but they may or may not be multivoltine, depending on other environmental conditions (combinations of photoperiod and temperature). In continuously available habitats, life cycles are unregulated.

Although a few species of Odonata have terrestrial nymphs (e.g., *Megalestes* in Hawaii), the vast majority require fresh water for functions such as respiration and feeding and to prevent desiccation. Likewise, a few species occupy brackish water habitats (the libellulid *Erythrodiplax berenice* can tolerate truly saline conditions and occupy coastal marshes but not the open ocean). Shortly after hatching and throughout nymphal life, dragonflies must capture living prey and escape predation. In some ecosystems, they are at or near the top of the aquatic food web. Prey includes many kinds of Diptera, but probably all other kinds of aquatic insects are consumed (e.g., mayflies, hemipterans, caddisflies) as well as many other invertebrates (protozoans, oligochaetes, crustaceans, molluscs). Some species prey on small vertebrates such as larval fish and amphibians. Prey are detected usually by their movement, either tactually or visually. Motionless prey, such as snails, may be detected visually by recognition of their shape. Tactile detection is more important in earlier instars, vision becoming more keen after the first few molts. Nymphs either stalk or ambush their prey. The prehensile, protractile labium (Fig. 4C), unique to the Odonata, strikes within milliseconds to capture prey. The labium grasps the prey and brings it to the mandibles where it is chewed or engulfed whole. Because odonates are generalist predators, the potential for greatly affecting a particular prey population is low. Predators of dragonfly nymphs include fish, frogs, a few reptiles and birds, other odonates, aquatic beetles, and hemipterans. Escape mechanisms include reduction of movement, even fleeing death and seeking cover. When a predator grasps a zygopteran by a gill or leg, the appendage may be autotomized and later regenerated. Anisoptera are also capable of leg autotomy; when grasped by the head or thorax, may make stabbing movements with the abdomen, using the sharp tips of the anal appendages to deter a predator.

In general, habitats range from streams of all sizes to seeps, bogs, ponds, lakes, swamps, and marshes. Some families, such as the Calopterygidae and Cordulegastridae, are restricted to flowing waters. Within the broad habitat categories, various species occupy different microhabitats. For example, elongate, cylindrical nymphs, such as aeshnids and coenagrionids, usually cling to stems and sticks, whereas more flattened species, such as gomphids and libellulids, dwell near or in the bottom. A number of specialists occupy phytophylums, which includes leaf axils (such as provided by bromeliads), rotten holes in tree trunks, bamboo internodes, and depressions at the bases of large trees, mostly in tropical areas. There is great diversity in nymphal form and behavior that allows dragonflies to occupy different types of habitats. Four categories of nymphs (claspers, hiders, sprawlers, and burrowers) are based on how the microhabitat is occupied, although many species could be put in more than one of these categories and nymphs may move from one type of microhabitat to another, depending on age and season. Categorization is based mainly on leg shape and how the legs are used to situate the nymph in its resting position.

Claspers, which cling to rocks, stems, or logs, have stout curved legs and cylindrical abdomens. Hiders are less elongate and conceal themselves among dead leaves or other debris by using strong legs; they usually have many stout setae to accumulate mud particles for better concealment. Sprawlers usually are flattened dorsoventrally and lie flat at the water–substrate interface. Burrowers, which may be semicylindrical or flattened, dig into the substrate to hide; the tip of the abdomen is often elongated to protrude above the substrate for respiration. Some burrowers propel themselves through the water by forcing water out of the anus, a form of jet propulsion (e.g., *Progomphus* can move several inches horizontally with one pump). A very few burrowing nymphs make an actual burrow (e.g., some Petaluridae). The function of dorsal protuberances and lateral spines on the abdomen, common especially in Anisoptera, is not clear, although it is likely they serve multiple functions such as aiding in concealment and defense against attackers. Experimental evidence indicates that nymphs grow longer abdominal spines in the presence of fish predators than nymphs raised in the absence of such predators,
suggesting that habitat shifts may be responsible for some of the differences observed within and between closely related taxa.

**EMERGENCE** Late in the final instar, when the nymph is completing development but with a week or more before time to metamorphose to the adult stage, the wing pads begin to thicken. The final instar usually does not leave the water until the day it is to metamorphose. At this time, the pharate adult is encased in the exuviae of the final instar. The main requirement for the dragonfly at this time is to find proper support structure, as it must cling tightly in order for the metamorphosis to proceed successfully. The emergence support can include any physical object ranging from the horizontal, terrestrial substrate adjacent to the water body to upright (vertical or inclined) objects such as rocks, plants, or synthetic structures. Shortly after leaving the water and securing a support grip, the dragonfly splits the integument along the middorsal line of the thorax and begins to push the adult thorax through the narrow opening. A slit in the integument of the head then appears, and the head and thorax push out.Shortly afterward, the legs, wings and anterior portion of the abdomen appear. The dragonfly then remains motionless with legs folded for 10–20 min, hanging downward if oriented vertically, or protruding upright if oriented horizontally. When this apparent rest period is over, the legs are extended to grasp the exuviae and the rest of the abdomen is quickly withdrawn. Usually the cloudy wings then expand, followed by lengthening of the abdomen, each process taking about 15 min. As the wings become clear, drops of water are emitted from the anus and the abdomen becomes more slender, slowly taking on final adult shape. The wings are suddenly spread out horizontally, and begin to vibrate. The full emergence process lasts from about 30 min to 2 h, ending with the maiden flight.

Some species emerge at night, apparently to escape predation, although many emerge at dawn or in full daylight. Some species have relatively synchronized emergence, all individuals within a population emerging within a day to about 2 weeks of each other. Other species are unsynchronized, emerging throughout the warmer seasons. Periodic exuviae collections can reveal such trends in emergence curves and population size. In nearly all species studied, the ratio of males to females is close to 1:1, although usually a slightly higher percentage of males occurs in Zygoptera, contrasted by a slightly higher percentage of females in Anisoptera.

**Adult Behavior**

The two main phases of adult life are the prereproductive (or maturation) period and the reproductive period. The prereproductive period lasts from the completion of emergence to the onset of sexual maturity. A brief postreproductive period, after reproductive capacity has passed, is sometimes observable.

**PREREPRODUCTIVE PERIOD** Upon reaching safety following the maiden flight, dragonflies remain in a teneral condition for about a day, during which time colors begin to develop and the integument begins to harden. The prereproductive phase then lasts from 2 days to several months, depending on species and environmental conditions; females usually take slightly longer to mature than males. During the prereproductive period, the gonads mature, the thoracic musculature becomes fully developed for agile flight (necessary for attaining a mate), weight increases, and mature colors are attained (for sex and maturity recognition in some species).

**REPRODUCTIVE PERIOD** Males and females of nearly all species mate with more than one individual, although monogamy has been reported in the coenagrionid genus *Ischnura*.

**Male and Female Encounters** Vision is the main sense used by Odonata for finding mates. The sexes usually meet at or near the aquatic oviposition site. Males that occupy a fixed territory can be categorized either as “flyers,” patrolling continuously along the proper habitat, or as “perchers,” making short defensive flights from a convenient perch. Territories are maintained by flying at or even clashing with intruders, and pursuit often results in both individuals leaving the habitat temporarily. Resident males usually return quickly to their territory. Mating usually occurs when a female arrives at the water, although males will attempt to acquire females several hundred meters from an oviposition site.

**Recognition of Conspecifics** Males recognize females mainly by color, color pattern, body shape, and flight style. Males of most species directly pursue and attempt to grasp any female that comes within sight, and if successful in achieving tandem, will attempt immediately to initiate copulation. In such species, males sometimes take heterospecific females into tandem.

Courtship has been described in a few families (Calopterygidae, Chlorocyphidae, Euphaeidae, Hemiphlebiidae, Platycnemididae, Libellulidae). In some species within these families, some males (but not all) present color and/or posture displays to induce a female to copulate. For example, in *Perithemis tenera* (a small North American libellulid with sexual wing-color dimorphism), males establish territories around oviposition sites that consist of some sort of vegetation protruding from the water surface. On detecting a female near his site, a male will fly toward her and follow, moving from side to side. He then turns and flies to the oviposition site. The female may or may not follow him, depending on the suitability of the site. If acceptable, she will follow, whereupon the male hovers over the site, fluttering his wings. The female slows her wing beat frequency and may even perch on the site. At this signal, the male initiates tandem linkage and copulation follows. When females are unreceptive to a male’s approach, they perform distinctive refusal behaviors. Female Anisoptera usually fly very rapidly or erratically to escape, although some simply hide from males. Female Zygoptera usually perform refusal by remaining perched and spreading their wings, sometimes also raising the abdomen or curving down the posterior portion of the abdomen. Males respond to such displays often by leaving, although some still attempt to achieve tandem.

**Tandem Linkage and Sperm Transfer** The postures adopted by Odonata in male–female tandem linkage and in copulation are unique. Tandem linkage, a necessary precursor of copulation, is initiated by the male. Males land on and seize females usually in flight (Fig. 5A), although they may grasp perched females also. The male, after landing on the female's pterothorax, brings his abdomen up and forward so that he can grasp the female's head or thorax with his anal appendages; he then lets go with his legs and straightens his body, thus having achieved tandem linkage (Fig. 5B). In most Anisoptera, the male appendages fit over the dorsum and rear of the female head, whereas in Zygoptera they fit over the dorsum of the female pterothorax. In the anisopteran family Aeshnidae, the male cerci fit tightly on the rear of the female head but also touch the anterior part of the pterothorax; in some Zygoptera, the male cerci touch the anterior portion of the pterothorax. Shortly after achieving tandem, the male transfers sperm from the gonopore on abdominal segment 9 to the penis on segment 2 (Fig. 5C); this act is called intramale sperm translocation. Males sometimes translocate sperm before acquiring a female. The tandem pair either copulates in flight (most Anisoptera) or flies to a perch to copulate (Zygoptera and several Anisoptera families). The female swings her abdomen forward from underneath so that her...
Males of many Coenagrionidae project vertically in the air with legs and wings folded, their only support provided by the grip of their anal appendages on the female thorax. In many Libellulidae, male and female fly in tandem low over the oviposition site, the male lowering his abdomen to cause the end of the female’s abdomen to dip into the water and release eggs.

**Noncontact Guarding** When males do not maintain females in tandem, they guard females by flying or perching nearby and warding off any intruding males. Males display toward and chase intruding males; male-to-male body and wing clashes may ensue. Some males guard multiple females. When male density is high, intensity of guarding ovipositing females probably increases in most species, but it has been reported to decrease in at least one species. In many Zygoptera, the male takes the female in tandem to the oviposition site, then releases her, and either does or does not guard her. In some Trameinae, a subfamily of Libellulidae, the male releases the female as they fly in tandem over the oviposition site; she drops down to the water surface and releases a few eggs, then she flies back upward and the male takes her back into tandem. These latter two cases illustrate combinations of contact and noncontact guarding.

**FORAGING** Odonata feed on living prey throughout their adult life. When foraging, dragonflies can be categorized as “perchers” or “fliers.” Perchers spend much of their time stationary, making short flights from perches to capture prey and then perching to consume it. In contrast, fliers are on the wing for a large part of their feeding activity, capturing their prey in the air and swallowing small prey while in flight; they do however perch to consume larger prey. The “flier” mode requires much more energy, but fliers are more opportunistic feeders, able to forage later in the day. Perchers typically capture most of their prey during midday. This dichotomy of foraging styles results because fliers generate more body heat than perchers and can therefore remain active at lower air temperatures.

The major stimulus for detecting prey is movement. Odonata have very large eyes with many ommatidia, a specialization for detection of movement. However, a few species take stationary prey, apparently recognizing the prey by its shape. Prey such as small flying insects may be captured directly with the mouthparts, but the legs are also used for subduing certain types of prey. Odonata are typically generalists with few exceptions. Diptera, especially mosquitoes and midges, are a major component of the adult diet. One analysis found that Chironomidae constituted a significantly higher proportion of the gut contents than did Culicidae, probably reflecting differences in the flying and perching habits of midges and mosquitoes. Some species take mainly large prey, such as Lepidoptera and Odonata. For example, the large North American gomphid *Hagenius brevitarsus* often has been observed feeding on other Anisoptera and has been dubbed the “Dragonhunter.” Members of the Neotropical family Pseudostigmatidae are specialist feeders. They glean small spiders in the rain forest by vertically searching trees, hovering near webs found on leaf tips, then flying directly up to the webs and snatching the spiders from their perchers.

**THERMOREGULATION** Although insects are basically ectothermic, large species are able to generate body heat or adopt body positions to absorb sunlight and are able to maintain this heat gain via certain behavioral mechanisms. Odonata possess both ecto- and endothermic thermoregulatory capabilities. The two basic behavioral styles, fliers and perchers, use different strategies to prolong activity under less than optimal ambient temperatures. Under cool conditions, fliers warm the thorax by wing-whirring (endothermy),

---

**FIGURE 5** Mating sequence of Odonata (male with dark markings, female pale): (A) male grasping female, (B) tandem linkage, (C) intramale sperm translocation, and (D) copulatory wheel.

Genital aperture engages the center of segment 2 of the male; the pair is now in the copulation wheel (Fig. 5D). Sperm are then transferred from the male’s intromittent organ to the female’s sperm-storage organ. Copulation is usually extremely brief in flight (3–20 s) but can last from a few minutes to over an hour in perched pairs.

The male intromittent organ of Odonata is designed not only to inject sperm into the female, but also to remove or displace sperm of previous males. Jonathan Waage’s discovery of this dual function led to evolutionary understanding of the whole suite of reproductive phenomena, from sexual selection to sperm competition and mate-guarding. Sperm displacement may be achieved by removal, repositioning, or dilution. The structure and shape of the penis are vital to the mechanism employed: peneis with backwardly directed barbs or hooks remove sperm from the bursa copulatrix, whereas those that are rounded push sperm. Because most eggs are fertilized with sperm from the most-recent insemination as they pass the female’s fertilization pore during oviposition, the last male to copulate with a female is most likely to leave progeny. This phenomenon, termed sperm precedence, explains why males guard females after mating with them. By such postcopulatory association, a male protects his genetic investment by preventing other males from overtaking the female, and by inducing the female to deposit (and therefore fertilize with his sperm) most of the eggs she is carrying.

**Oviposition** When copulation is terminated, pairs may break tandem linkage or remain together. Oviposition usually takes place shortly after copulation regardless of whether the tandem linkage is maintained, although females do lay eggs at times when males are not at oviposition sites. Ovipositing late in the day is a fairly common way by which females avoid interference from males. Males of many species guard females with which they mate, either by maintaining tandem contact with or by remaining near them, or both. Attempts to guard females are not always successful, as intruding males sometimes grasp and copulate with guarded females. Typically, guarded females oviposit more rapidly than those unguarded; their fitness thereby is enhanced.

**Contact Guarding** Males of many Zygoptera remain in tandem with their mated female while she oviposits, even when she submerges.
whereas perchers expose as much of the surface area as possible to solar radiation. In some species of perchers, hairs on the thorax serve as insulators, or the wings may be deflected downward to insulate the thorax. Such species are among the first to appear in the spring at higher latitudes. Under very warm or hot conditions, perchers remain stationary longer and set their body posture to absorb less solar radiation. A common posture is the obelisk position, in which the abdomen is raised to expose the minimum surface area to the sun and the wings are lowered to reflect sunlight away from the thorax. Fliers generally become inactive during midday and hang up in the shade. However, some species of Libellulidae glide, and some species of Aeshnidae are able to continue flying by shunting warm blood from the thorax to the abdomen, where excess heat is dissipated. By prolonging activity at the breeding site, dragonflies increase their chances of obtaining mates, feeding, and escaping predation.

**Dispersal**

Most flight involves small-scale, intrahabitat movements for immediate needs (feeding, finding mates, and escaping predators) that directly affect individual survival and reproductive success. Such flights usually result in dispersal distances up to a few hundred meters. Large-scale flight resulting in interhabitat displacement is regarded as migratory flight. Corbet defined migration as “spatial displacement that typically entails part or all of a population leaving the habitat where emergence took place and moving to a new habitat in which reproduction ensues.” These dispersal movements also have consequences for survival and reproductive success.

In examples of migration so far elucidated for tropical species, migration is a means of overcoming drought in the area where the species developed. For example, in ephemeral lentic habitats in Africa, the aeshnid *Hemianax ephippiger* develops rapidly (within 60–90 days) and upon emergence flies with rain-developing systems several hundred kilometers to areas which will receive the rainfall, as far north as Europe. There they feed, mate, and lay eggs in newly filled water bodies. Temperate species migrate to circumvent cold temperatures. For example, the wide-ranging aeshnid *Anax junius* emerges early in the year in southern North America, and arrives in the northern United States and southern Canada during warm periods as early as March and April. These immigrants mate and lay eggs in shallow lentic habitats; their progeny complete development in late summer or fall. The second generation then flies south; large numbers of “green darners” have been observed flying overhead as late as mid-November. Migratory flights may be made up of several species, usually from the families Aeshnidae and Libellulidae. Very few Zygoptera are known to migrate, and all recorded so far are in the subfamily Ischnurinae (Coenagrionidae).

**ODONATA SURVIVAL IN A CHANGING WORLD**

Habitat creation, loss, and alteration are the major causes of odonate population changes. Some odonate species have increased their geographic ranges and population numbers in response to man-made changes in habitat. For example, in the United States many pond-dwelling Libellulidae that were historically centered in the eastern part of the country have moved far west of the Mississippi River with the advent of irrigation. Furthermore, exotic species can immigrate when gravid females ride tropical storms or can be introduced as eggs and nymphs with the aquarium trade, their ranges thereby increasing dramatically. Alternately, many riverine and wetland species have undoubtedly declined because of habitat degradation and drainage changes. For example, some riverine Gomphidae are extremely rare, but could be protected by conserving the remaining habitat (e.g., in the eastern United States, *Ophiogomphus edmondii* is known from three localities, and *Gomphus sandarius* is known from seven localities). Only one species in the United States has federal protection status as a threatened and endangered species, Hine’s emerald (*Somatochlora hinei*). Many species in this genus are locally distributed, inhabiting lakes and bogs in different stages of succession, and their populations depend greatly on the availability of the proper microhabitat.

Awareness of threats to dragonfly diversity and populations of sensitive species exists in most countries, especially in Europe and Japan, where protection efforts are designed to heal or prevent damaged ecosystems. In tropical areas, however, where diversity is highest and incompletely known, habitat destruction continues at alarming rates. There has been some effort toward habitat conservation for all organisms, as national parks and preserves have been established in many tropical countries. For example, in Thailand, almost all remaining forest areas are protected by parks, wildlife sanctuaries, and a ban on logging; this effort amounts to nearly 15% of the total land area. Such efforts will help protect dragonflies. In other countries, the situation is not so promising, and even preserves afford no insurance against habitat alteration. Odonata have existed for many millions of years, undoubtedly surviving small and massive extinction episodes; however, the comparative magnitude of present-day environmental change is unknown.

Orientation

Ring T. Cardé
University of California, Riverside

Orientation refers to the way in which organisms direct their course of movement—not to their body or positional orientation per se, although, if an organism is to aim its course, it must align its body’s long axis with its intended track. Although orientation maneuvers thus involve an organism’s orientation of body position, this article is concerned mainly with movements in location that range in scale from millimeters to thousands of kilometers. A minute parasitoid wasp may walk to a resource, such as a prospective host, only millimeters away. On the other hand, movements of insects also can cover considerable distances, such as the long-distance migration of several thousands of kilometers that is undertaken in autumn by monarch butterflies (Danaus plexippus) flying from northeastern North America to their overwintering site in central Mexico. The mechanisms that insects and other organisms use to accomplish such feats are enormously variable. Moment-to-moment steering typically relies on simultaneous inputs from multiple sensory modalities, such as chemical cues, light, sound, and wind. Most organisms use some stored information about very recent encounters with these cues and the organism’s past position. In many parasitic and social Hymenoptera, learned information, including spatial maps and landmarks, play a crucial role in these insects “knowing” either where they have been or their destination.

CLASSIFICATION OF ORIENTATION MANEUVERS

The modern system of categorizing orientation mechanisms by their forms of locomotion and their presumed sensory inputs dates to Fraenkel and Gunn’s The Orientation of Animals, first published in 1940. These authors’ classification of maneuvers relies on two distinctive patterns of movement. The first kind of maneuver is termed a kinesis (pl. kineses); it is defined as an undirected response in which the body’s long axis exhibits no consistent relationship to the direction of the stimulus and the direction of locomotion is random. If a gradient of stimulus intensity regulates either the frequency of turns or the amount of turning per unit of time, the reaction is termed a klinokinesis. If the gradient of stimulus intensity regulates either speed or the frequency of locomotion, then the reaction is termed an orthokinesis. Both kinds of kinesis require at a minimum one sensory detector to monitor stimulus intensity, although multiple detector systems (such as paired antennae, each with many receptors) are the norm. Randomly directed movement would seem to be an ineffective means for moving toward or away from a stimulus. Klinokinetie maneuvers can facilitate movement either toward or away from a stimulus gradient as illustrated in Fig. 1 where simply turning more frequently in bright light eventually results in motion by the organism away from the bright light.

FIGURE 1 Track that could be expected from a hypothetical animal that always changes its direction by 90° to the right at a rate that is dependent on light intensity. The animal starts at point O. Turns occur more frequently when the animal is in bright light. Because of this tendency, the path cd is longer than ab. Although this is a simplistic representation of a klinokinetic reaction (in reality, turns will vary in angle and may be random to the right or left), it nonetheless demonstrates how klinokinesis can result in an animal orienting along a shallow stimulus gradient. [Modified from Fraenkel, F., and Gunn, L. L. (1940).]

The second kind of maneuver is called a taxis (pl. taxes); it is defined as a directed reaction in which the organism’s body axis aligned with the stimulus and movement is more or less directed toward or away from the stimulus. In klinotaxis, the organism has available two strategies for sampling the intensity of the stimulus. In transverse klinotaxis, the sampling occurs by moving the entire body or a part of it from side-to-side along the path. Alternatively, in longitudinal klinotaxis, the organism samples intensity successively along its path. Both forms of klinotaxis require only a single detector capable of measuring stimulus intensity, although multiple receptors are typical. A classic transverse klinotactic reaction is the movement of blow-fly larvae (Lucilia) away from light (Fig. 2). A close examination of the movement of larvae along their path reveals that although their tracks are nearly straight, their heads move from side to side. A similar pattern is seen in ants following a pheromone trail (Fig. 3).

Tropotaxis, in contrast, relies on a paired detector system (such as the antennae); by balancing the stimulus intensity on the two sides of the organism, the heading can be aligned with a relatively steep stimulus gradient. Honey bee workers (Apis), for example, can center their body’s long axis between balanced inputs of odor to each antenna. Telotaxis is a “direct” form of orientation in which the stimulus intensity is processed by a receptor system that has an array of directionally sensitive receptors, so that setting of a course toward a stimulus involves the relatively simple navigational task of holding a certain part of the receptor array in alignment with the stimulus. Sometimes termed “goal orientation,” telotaxis is known only for orientation along a beam of light.

In klino-, tropo-, and telotactic reactions, the organism’s long body axis is aligned with the direction of the stimulus, such as a beam of light or a fairly steep gradient of odor. In menotaxis, orientation of the long body axis is at a fixed angle to the stimulus, and course setting is maintained by stimulation of the sensory apparatus in a manner similar to telotaxis. Menotaxis is commonly called “compass orientation,” and some still unresolved form of it is used by monarch butterflies to head toward their wintering grounds, and by honey bees in their dance language. A menotactic reaction also seems to be responsible for the attraction to lights seen in many moths and
other nocturnal insects. The assumption is that moths normally fly a straightened-out path by using celestial cues as a menotactic guide. When they encounter an artificial point source of light, they attempt to maintain a relatively constant angle with respect to the fixed point of light as in menotaxis, but in doing so they inevitably spiral toward the light source. Such a spiral path is indeed seen in the approach of some nocturnal insects to a light.

**CLASSIFICATION OF SENSORY INPUTS**

In describing how organisms orient, it is common to create terms that combine the kinds of environmental cue used in orientation with the form of taxis or kinesis. Common prefixes used include anemo (wind), chemo (odor or taste), mechano (pressure), phono (sound), photo (light), rheo (water flow), and scoto (darkness). The Lucilia maggot moving away from light can be said, for example, to be navigating by a transverse photoklinokinesis. It is obvious that the seeming precision of this classification scheme makes for an unwieldy terminology. This deficiency was noted in 1984 by Bell and Cardé, who highlighted the need for “more practical, functionally related terms” that are not “teleological, poorly defined, nonprobabilistic and difficult to spell.” A related problem is that these terms tend to define the reactions so precisely that they can dictate the boundaries of experimental investigations, such that these may either neglect the integration of mechanisms or fail to consider mechanisms that do not fall within these constructs.

**ALTERNATIVE CLASSIFICATIONS**

“Attraction” and “aggregation” are often used to categorize orientation, but these terms describe end points of orientation and tell us little about the preceding maneuvers. Attraction and aggregation nonetheless remain widely used to describe the consequences of taxes and kineses. Pheromones, for example, are often labeled as attraction pheromones or aggregation pheromones. In another approach to classifying orientation mechanisms, Jander emphasized the distinction between the two broad categories of information used in orientation: information that is based on immediate sensory processing (for extrinsic or “exokinetic” orientation) and information that is stored centrally (for intrinsic or “endokinetic” orientation). Information that is stored may be subdivided into memory and that which is genetically determined. Jander also stressed
the importance of ecology in studying orientation, and so his other categories included positional orientation (either staying in place or exhibiting locomotion), object orientation (movements with respect to the spatial position of either resources or sources of stress), topographic or home-range orientation (learned spatial orientation), and geographic orientation (migration over considerable distances).

Bell disavowed the time-tested system of taxes and kineses in his 1991 synthesis of foraging behavior. In analyzing the vast literature on foraging movements, Bell advocated describing the kinds of locomotory paths that were observed, the kinds of information available to mediate the motor output, and the presumed guidance system. Bell eschewed terming any of these maneuvers “taxi” or “kinetics.” Despite such attempts to devise a new terminology, however, the system of taxes and kineses is likely to remain prevalent for some time because no clear alternative has emerged.

ODOR-INDUCED OPTOMOTOR ANEMOTAXIS

Among the best-studied orientation systems are those that enable organisms to locate upwind resources by flying along a plume of odor to the odor’s source. Examples of such maneuvers include male moths flying over distances of hundreds and perhaps thousands of meters to a pheromone-releasing female, tsetse flies and mosquitoes flying over tens and perhaps hundreds of meters to a prospective vertebrate host, and parasitoid wasps flying over several meters to their intended host. All these reactions are mediated by odors that are released by the resource and form an odor plume as they are carried downwind. It is crucial to note that maneuvers cannot be governed by orienting to a gradient of odor. A gradient that would be sufficiently steep for such directional information exists only within a meter or less of the odor’s source. Instead, insects and other organisms orient by advancing upwind when they encounter an above-threshold concentration of the odor linked to the resource.

The nonintuitive mechanism permitting in-flight anemotaxis is the optomotor response. An organism immersed in air or water cannot discern the direction of the flow of these fluids by mechanosensory input, although it can use mechanosensory information to gauge its airspeed or water speed (i.e., its movement relative to the fluid flow). Instead, it detects its displacement relative to its ground position by literally seeing how the flow alters its path. For example, if an organism’s long body axis is aligned directly with the fluid flow and the organism is making progress along the plume, then the image flows directly below or above the organism flows from front to rear. If the organism is moving at an angle to the fluid flow, then the image flows obliquely across the eyes (Fig. 4).

Optomotor anemotaxis was first demonstrated experimentally in 1939 by John Kennedy, with the yellow fever mosquito, Aedes aegypti. Kennedy’s ingenious wind tunnel used a movable pattern, projected onto the tunnel’s floor, to manipulate the visual feedback a flying mosquito would experience. He was able to show that the upwind flight of females induced by carbon dioxide (the activating ingredient in human breath) was governed by the optomotor reaction. When the projected floor pattern was moved in the same direction as the airflow, mosquitoes decreased their airspeed, apparently deceiving by visual feedback from below that their airspeed had increased; conversely, when the image flow was reversed to the opposite direction, mosquitoes immediately increased their airspeed. Mosquitoes regulate their airspeed to maintain a relatively constant rate of longitudinal image flow. These simple manipulations verified that the mosquitoes’ perception of movement relative to their visual surroundings dictates their airspeed, rather than some form of mechanosensory feedback.

FIGURE 4 The relationship between a flying insect’s body heading and the track taken when flying at an angle to the wind. The vectors depict the wind direction and velocity and the fly’s direction and velocity along the track. The image flow the fly sees directly below has both longitudinal and transverse components, and therefore flows obliquely across the fly’s eyes. When the fly heads directly upwind, the image flow is entirely longitudinal, i.e., front to rear.

The task an insect faces in finding an upwind source of odor, however, is much more complicated than simply flying upwind when an appropriate odor is encountered. Because turbulent forces cause the plume to meander and undulate, the direction of the plume’s long axis is not always aligned with the upwind direction. Thus, an insect proceeding upwind often exits the plume. Thus many insects “lose” the plume and then “cast”; that is, they stop moving upwind and instead move back and forth lateral to the direction of wind flow. If they recontact the plume during such to-and-fro maneuvers, upwind flight may resume. A further difficulty is that turbulent forces fragment the plume’s internal structure. Plumes therefore have patchy distributions of odor, so that even within the plume’s overall boundaries, insects encounter filaments of odor interspersed with gaps of clean air. Filaments can be encountered many times a second; for moths, whenever the encounters with filaments of odor are frequent, say above 10 Hz, flight can be aimed rapidly upwind, but when the encounter rate falls below 5 Hz, the flight can exhibit a much more substantial crosswind component (Fig. 5).

Odor-induced, optomotor anemotaxis as used by flying insects exemplifies several points common to orientation mechanisms. Several kinds of input (here visual, mechanosensory, olfactory) and self-steering all contribute to course setting and motor output. It is the integration of information that allows organisms to set their course.

Several related situations illustrate the variations on this theme. A flying insect also can orient along a plume of odor for moderate distances by flying a course that is set upon takeoff. After detecting the odor, the insect gauges upwind direction by mechanoreceptors. Several kinds of input (here visual, mechanosensory, olfactory) and self-steering all contribute to course setting and motor output. It is the integration of information that allows organisms to set their course.
“know where to go.” Discovering how these maneuvers work—what information is extracted, how it is processed, and the nature of guidance systems—remains an active area of inquiry.

Orthoptera

Grasshoppers, Locusts, Katydids, Crickets)

Sigfrid Ingrisch
Museum Koenig Bonn

D.C.F. Rentz
California Academy of Sciences

Orthoptera is considered here in a restricted sense, excluding cockroaches, mantids, and stick insects, which are covered elsewhere. The Orthoptera include terrestrial insects commonly known as short-horned grasshoppers, katydids, bush crickets, crickets, and locusts. The adult size range is from a few millimeters to some of the largest living insects, with bodies over 11.5 cm in length and wingspans more than 22 cm. Orthopterans occur all over the world, except in the coldest areas. They are best developed in the tropics. In terms of numbers, they are among the most common insects and are an important component of the fauna in most parts of the world. The order is readily identified by the characteristic hind legs developed for jumping. Tropical nights and warm summer days in temperate climate are often dominated by the songs of many species in several families. Locusts are among the world’s most important economic insects, and many species cause devastation in many parts of the world. Orthopterans are mentioned in biblical writings and in the earliest of Chinese literature. In recent times they have been important elements in the development of several fields of biology. Biological lifestyles in the Orthoptera include phytophilous (leaf

CONCLUSION

Taxes and kineses remain the principal organizing system for understanding and investigating how insects and other organisms

FIGURE 5 Top view of flight tracks of males of the moth Cadra cautella flying toward a source of a sex pheromone. The moth is traveling from left to right. The dots represent the moth’s position every 1/30th of a second. The blue line shows the time-averaged centerline of the plume. Track “A” shows the path of a moth after intercepting a single puff of pheromone. [Redrawn from Mafra-Neto and Cardé (1994), Nature 369, 142–144.] About 200 ms after intercepting the puff, the male surges upwind briefly. Track “B” shows a male flying along a narrow ribbon plume of pheromone, sporadically encountering pheromone. Track “C” shows a male flying along a wide turbulent plume of pheromone, encountering many filaments of pheromone per second. Orthoptera

living), geophilous (living on and in the ground), cavernicolous (living in caves), and myrmecophilous (living with ants). Species can be diurnal and nocturnal. Almost 24,000 species are known, but it is estimated that this figure may double when a thorough census is made of uncollected regions of the globe.

CLASSIFICATION

Several disparate classifications of orthopteroid insects are used simultaneously, depending on preference. There has been an overall escalation of rank of categories in recent years at and above the tribal level. One of the extremes of these views was expressed by Dirsh, who created 10 orders from what was traditionally considered one. Kevan provides a synthesis of the classifications to 1982. The advent of cladistics and molecular phylogeny has spawned additional changes to orthopteroid classification. The Orthoptera usually are divided into two suborders: the Ensifera (long-horned Orthoptera) and the Caelifera (short-horned Orthoptera) (Table I). The ensiferans are considered to be the more ancient group, with fossils dating from the Carboniferous, whereas caeliferans are known only from as far back as the Upper Permian (Fig. 1A).

Orthoptera

FEATURES OF THE ORDER

General Comments

Orthoptera have been popular subjects for the behaviorists. Much has been done of an interdisciplinary nature relating to natural and sexual selection, signaling behavior, acoustic and vibrational communication, and displays.

Many orthopterans have excellent sight and hearing and are wary and difficult to approach. Others appear sluggish and rely on a number of cryptic strategies and distasteful properties for protection. For example, if seized, most species will kick out with their spiny hind legs and regurgitate acid contents of the crop. Because orthopterans are fed upon by a vast number of vertebrates and many other arthropods, such behavior is not entirely successful. If a grasshopper, cricket, or katydid is seized by the hind leg, the leg will generally be lost at a point between the femur and trochanter. A number of unrelated species will squirt or discharge repugnatorial secretions from intersegmental glands.

The majority of orthopteran species are phytophagous, feeding on the foliage of higher plants. A number of them feed on roots and others on fungi. Many species are predaceous, while others are omnivorous. Relatively few species have been studied for the purpose of discerning their feeding activities, but some are very highly specialized, feeding only on seeds, pollen, or nectar of certain plant types. The fore and middle legs are used by some predators to form a “clap-trap” to catch unwary insects.

Orthopterans are renowned examples of forms of crypsis. They span the range resembling leaves, twigs, bark, stones, or flowers. These appearances are meant to deceive vertebrate predators. To achieve this, various parts of the body are modified, and these combine with camouflaging colors and patterns, accompanied by the appropriate behavior. Mimicry of other insects abounds in the orthopteroids. Mimicry in the nymphal stages is often based on very different models from the adults. In a few examples, males mimic a different model from females. The distasteful properties involved with aposematic coloration are exhibited in many orthopterans in a wide range of families and genera. The normally associated behavioral traits of sluggish behavior, conspicuous situations, and gregariousness are also seen. Flash or frightening colors are exhibited in a number of species. It is short and “pronged,” and it penetrates the substrate of species. It is short and “pronged,” and it penetrates the substrate of species. It is short and “pronged,” and it penetrates the substrate of species.

Reproduction

Sperm are transferred mostly in spermatophores. In the Ensifera, the spermatophore is transferred at copulation, and the vesicle usually remains attached externally to the vulva; it is eaten by the female and serves an important nutrient function in the development of the fertilized embryos. In the Acridoidea, several small spermatophores may be inserted into the female tract, or the tubular part of the single spermatophore may penetrate the spermathecal duct while the vesicle remains in the phallus. Some other grasshoppers (the Australian endemic Morabinae of the Emmastacidae) produce no spermatophore, and their sperm is delivered directly to the bursa copulatrix, not the spermathecal duct.

Orthoptera eggs are most often laid in soil, but many other media are also used. Many Ensifera insert them singly or in small numbers, into stems, leaves, or roots, or cement them to stems, twigs, or bark. One Australian species coats the exposed egg laid on a twig with soil particles, apparently to protect the egg from the elements and possibly from parasites. Acridoidea lay their eggs in oothecae or pods, in groups of 4 to over 200, in pithy stems, in soft portions of dead timber, at the bases of grass tufts, or in animal dung; a number of species cement eggs to water plants below the surface. Burrowing forms deposit eggs in special chambers, lay them in the sides of chambers, or place the eggs around roots.

The ovipositor is often highly modified. In the Ensifera, mostly a needlelike spear is inserted into the substrate, usually the soil, wood, leaf sheaths of grasses, or other plant material. Many species lay specialized hardened eggs that are glued to twigs or leaves. Many select a thick leaf, and with alternating penetrations of a highly modified, laterally compressed ovipositor, insert a disklike egg into the leaf’s edge. In Caelifera, the ovipositor is relatively similar among the wide range of species. It is short and “pronged,” and it penetrates the substrate by opening, closing, and extending the abdomen. In the Acridoidea, the abdomen is frequently stretched to twice its normal length during oviposition.

Development

In tropical species, the eggs can hatch in 3–4 weeks. In temperate species, the eggs enter a period of diapause and hatch later. In some species, only a portion of the eggs hatch the following year, with the remainder hatching over a period of years. This serves as a “safety valve,” ensuring that the species survives in periods of unfavorable weather. Eggs of some common European Tettigoniidae survive up to nine winters until all eggs laid the same summer are hatched.

A hatching is enclosed in the embryonic cuticle and is called a pronymph or verniform larva. At hatching, the eggshell is fractured by pulsations of an extrusable structure known as the cervical ampulla, which is part of the dorsal membrane of the neck. This work is assisted by the cutting action of a ridge or row of teeth positioned at the front of the head. The ampulla is also involved in the emergence of the pronymph from the egg repository in the soil or plant tissue and in the intermediate molt by which the embryonic cuticle is cast when the insect is freed.

Nymphs differ from adults outwardly mainly in the reduced development of wings and reproductive organs, the less developed pronotum, and a reduced number of antennal segments. Nymphs undergo several molts. Their number can vary between species, between males and females, and under different environmental conditions. Between 4 and 14 molts have been reported so far; the highest numbers were observed in overwintering crickets, the lowest in male gomphocerid grasshoppers. The intermediate stages of the developmental process are called instars. Moulting occurs between instars and usually takes place at night under the protection of darkness or in early morning, when the relative humidity is favorable for such processes. The wing
Orthoptera

buds and terminal reproductive structures increase with each molt. Antennal segments are added at molting. To tell apart adults of short-winged grasshoppers from nymphs can be done by the wings; grasshoppers have two pairs of wings: the first pair is the tegmina and the second pair the wings. In immature grasshoppers, the wings are lateral, with the costal margin positioned ventral, as in the adult, but in the penultimate instar, they rotate and assume a reversed, dorsal position in which the costal margin is dorsal and the morphological ventral surface is external, with the hind wing overlapping the tegmen.

REVIEW OF TAXA

Suborder Ensifera

Crickets and katydids (bush crickets, long-horned grasshoppers, and relatives) comprise the suborder Ensifera. Ensiferans share important characters with members of the other suborder, the caeliferans, such as the biting–chewing mouthparts, the modified pronotum, “leaping” hind legs, the similarities in wing venation and shape, and the sound-producing capacities (stridulation) of males. Several phylogenies have been proposed. They result in similar higher taxa but differ with regard to the relations between those taxa. A key question is if the complex elytral stridulatory apparatus, which occurs in the Grylloidea, Hagloidea, and Tettigonioida but is absent in the other groups, and the corresponding auditory system evolved only once or at least two times independently. While phylogenies including behavioral characters favor the view of independent evolution of the stridulatory apparatus in Grylloidea and Tettigonioida (Guymer, 2001; Desutter-Grandcolas, 2003), recent molecular phylogeny supports a more traditional view of a single development of the stridulatory apparatus in Ensifera with several losses of it in some groups (Jost and Shaw, 2006). In Grylloidea, loss of stridulation is a common event that even occurred within genera.

More than 12,000 species are known in about 2000 genera with six superfamilies: Hagloidea, Stenopelmatoida (Gryllacridoidea), Bhaphidophoroidea, Schizodactyloidea, Tettigonioida, and Grylloidea. The classification we follow is illustrated in Fig. 1A.

HAGLOIDEA

It contains one family, the Haglidae (Prophantomopsidae of some authors), which are known as the ambidextrous crickets or hump-winged crickets. The single living family is divided into two subfamilies. One subfamily, the Prophantomopsinae, consists of three genera, each with a single species, Prophantomopsis from northern India and Tarragoilus and Abolominus from Sichuan, China; the Chinese species were discovered as late as 2001. The wings resemble a mixture of a tettigoniid and a gryllacridid. Two genera have the first and second tarsal segments partly fused; a character intermediate between Tettigonioida that have four tarsal segments and Grylloidea that have three. The second subfamily, the Cyrtophyllitinae, is represented by two living genera. All species are ground dwelling and live in coniferous forests, where they ascend tree boles after dark to broadcast their loud stridulations.

STENOPELMATOIDA (GRYLLACRIDIOIDEA, IN PART)

The Stenopelmatoida has been known as raspy crickets, leaf-rolling crickets, wood crickets, Jerusalem and sand crickets, king crickets, cave and camel crickets, and other names, it forms a distinctive, conspicuous group with many species quite large and presenting a ferocious appearance. Most, if not all, are nocturnal, with all needing to seek shelter during daylight because of the threat of destecation due to the thin integument. When the Grylloptera is recognized as a distinct order, this taxon with the Tettigoniidea constitutes the suborder Tettigonioida. Because of their nocturnal and subterranean habits, most species are light colored, with brown or grays dominating the color scheme. Cave-dwelling species are often pale or white; green forms are very rare.

These species occupy most habitats, including the driest deserts and the wettest rain forests. The majority of species seem to be concentrated in the Old World, especially in the Southern Hemisphere. A few are considered to be minor crop pests, many attract public attention because of their size, and several are considered to be endangered by reason of habitat deprivation or loss due to introduced organisms like rats. The group comprises about 1000 species, but there are many undescribed species known from many parts of the world, especially Australia.

Gryllacrididae Gryllacridids are known by a variety of names. They are best known as raspy or leaf-rolling crickets, but some are called king crickets or tree crickets. Most instars and adults spin threadlike “silk” from the mouthparts and use this material in reinforcing burrows and tying leaves and detritus together to form shelters. The integument of the body is soft and pliable (Fig. 1B), and the legs are adorned with many spines, some on the hind legs being modified for digging. They range in size from about 5 to 75 mm in body length. This family is best represented in the Old World. Ninety genera with nearly 700 species are known.

Of the few species of gryllacridids that have been studied, all have been found to have peculiar life histories. The majority of these studies come from Australia, where the insects comprise a notable portion of the orthopteran fauna at a given locality. Species may construct burrows or tie leaves and detritus together, forming individual enclosures in which they reside during the day. Others live in hollow branches or twigs, and yet others assume a commensal lifestyle with termites.

Raspy crickets feed on a wide range of material. Some are specific seed eaters, others predaceous, and others specialize on flowers or fruits. This last-mentioned activity can be of economic concern when ripe fruit is chewed and when cut flowers or orchids are damaged by feeding activities. At times when gryllacridids inadvertently enter houses, curtains and draperies may be ruined by their chewing and clipping as bits of material are tied together with silk to make shelters.

Raspy crickets produce sounds in more than one way. All species possess a femoralabdominal stridulatory mechanism featuring a hind femur that is rough on the inside, with a pattern or shagreening of dorsal surface. This roughened area is rubbed against a pattern of pegs or modified hairs on the side of one or more abdominal tergites. These stridulatory mechanisms seem to show species-specific patterns and have been used to distinguish species. Vibrational sounds are produced, often by both sexes, during courtship activities. Depending on the species, sounds are generated by rhythmic drumming of the abdomen on the substrate or by “stomping” of the hind feet against the substrate. Some species use combinations of drumming, stomping, and rasping during courtship. The fast-paced drumming is quite audible to the human ear for a short distance. Surprisingly, none of these insects possess any obvious organs that would enable them to hear the sounds they produce. Perhaps, they detect the vibrations through sensory hairs on the pads of the tarsi.

Cooloolididae The odd genus Cooloola with four species from Australia and a variety of peculiar genera from western North America have been placed in this category.

Anostostomatidae (Stenopelmatidae, in Part of Authors) The Anostostomatidae with 41 genera and over 200 species is a relatively recently proposed taxon accommodating a large range of genera.
formerly included in the Stenopelmatidae that live mainly in the tropical areas of the earth. Included here are the giant king crickets of Australia, New Zealand, and Southern Africa.

This family includes the Parktown prawn, Libanasisus vittatus, which lives in the Johannesburg area, where it is very well known. Females measure in excess of 6 cm, and most people fear them. They enter houses and beds of sleeping residents at night, and their scuttling and kicking is a common cause of concern. Their vile-smelling feces, ejected when disturbed, contribute to the unpleasantness.

Myths have arisen regarding this species: some people feel it is an alien invader or the result of a freak mutation. The notoriety of this cricket has been a useful vehicle for educating the public about the biodiversity crisis. One of the most interesting features of this cricket is the tuskslike mandibles of males. In this respect, they are similar to those of the New Zealand weta. The mandibles of *L. vittatus* serve in digging burrows as well as in battles with other males.

The New Zealand tree weta of the Deinacridinae are often large (8 cm or more in length), secretive, and aggressive species. The biology of *Hemideina* spp. is very well known. Some live in tree holes in galleries initially made by beetles or moth larvae. Others live in natural crevices and cavities. They prefer living trees to dead wood. These insects are herbivorous, feeding on leaves, flowers, and fruit. They may scavenge recently killed invertebrates. They remain arboreal except for a short period when females descend to the ground to oviposit. Some species have a unique-size polymorphism related to social behavior. There is allometric growth of the head and jaws, much as the Australian king crickets. Certain males have extra instars to gain the larger head and mandibles. There is a dominance hierarchy, with the largest megacephalic males commanding the most desirable resources, which include galleries and mature females. Smaller males spend more time defending their galleries. These males live in galleries with smaller apertures and have been advantageous in dealing with alien predators such as rats. Tree wetas are smooth and shiny, with contrasting bands on the abdomen.

Other New Zealand wetas live on the ground. Several species raise their hind legs vertical to the substrate when alarmed. With a female weighing 50 g and measuring 7.5 cm in body length, this is one of the more formidable insects in defense.

All members of the Anostostomatidae are vulnerable to alien predators. The large size of the adults of many species may be effective in battles with rats, for example, but other stages from eggs to moderate-sized nymphs are extremely vulnerable. As a result, several species are threatened with extinction.

**Stenopelmatidae** Four subfamilies are currently included in this family, but their relationship is not fully resolved. Well known are the Stenopelmatinae, comprising the Jerusalem crickets. The largest genus, *Stenopelma*, occurs in North and Central America. These insects are often found locally as “potato bugs” because they have been dug up in garden or potato fields. The derivation of the common name of the group, Jerusalem crickets, is shrouded in mystery. These insects have behavior patterns similar to those described for several anostostomatids.

There may be 100 species of the genus *Stenopelma*, but only 28 have been described. They are all very similar in overall appearance and differ only in their sexual drumming activities. Sympatric species have different drumming patterns. Both sexes and nymphs can produce rhythmic sounds by drumming their abdomens against the sides of their burrows or on the surface of the ground. Some of the sounds are audible from a distance of 20 m. Surprisingly, the nymphs produce species-specific drumming patterns in their later instars. The production of these sounds may serve to keep the species together and may be effective in areas where there are sympatric species.
