Preface

The purpose of the second edition of the *CRC Handbook of Mechanical Engineering* is to continue providing practicing engineers in industry, government, and academia with up-to-date information on the most important topics of modern mechanical engineering. The book covers traditional topics such as thermodynamics, solid and fluid mechanics, heat and mass transfer, materials, controls, energy conversion, manufacturing and design, robotics, environmental engineering, economics and project management, patent law, and transportation. These topics were covered in the first edition, but they have been updated, new references have been added, and efforts have been made to provide information on computer technology related to the topics at the end of each chapter.

But in the 10 years since the first edition of this handbook was published, changes have taken place in engineering and technology and additional topics that were not treated in the first edition have come to the fore. To bring the new edition up-to-date, chapters on topics such as nanotechnology, MEMS, electronic packaging, global climate change, electric and hybrid vehicles, and bioengineering have been added. Moreover, the editorial supervision for the second edition has been broadened by the addition of Yogi Goswami as co-editor.

In a work of the size of the second edition of this handbook, it is unavoidable that certain errors or omissions may have occurred. Therefore, the editors appreciate the readers calling any of these shortcomings to their attention and every effort will be made to correct them. We also welcome continuous feedback from readers about topics that may have been omitted and should be considered for inclusion in future editions of this work.

The editors would like to thank all the contributors, as well as the CRC staff, especially Helena Redshaw, Jessica Vakili, Cindy Carelli, and Susan Fox, for their assistance in the preparation of this handbook.

Editors

Dr. Frank Kreith is Professor Emeritus of Engineering at the University of Colorado, Boulder. From 1998 to 2001 he served as the American Society of Mechanical Engineers [ASME] International Legislative Fellow for Energy and Environment at the National Conference of State Legislatures (NCSL) where he provided assistance on energy, transportation, and environmental protection to legislators in all 50 state governments. Prior to joining NCSL in 1988, Dr. Kreith was the Chief of Thermal Research at the Solar Energy Research Institute (SERI), currently the National Renewable Energy Laboratory. During his tenure at SERI, he participated in the Presidential Domestic Energy Review, served as an advisor to the Governor of Colorado, and was the editor of the *ASME Journal of Solar Energy Engineering*. In 1993, he received the first General Achievement Award from SERI.

From 1951 to 1977, Dr. Kreith taught at the University of California, Lehigh University, and the University of Colorado. He is the author of over 100 peer-reviewed articles and the author of textbooks on heat transfer, solar energy, and transportation. He is the recipient of the Charles Greeley Abbot Award from ASES and the Max Jakob Award from ASME-AIChE. In 1992, he received the Ralph Coats Roe Medal from ASME for providing technical information to legislators about energy conservation and environmental protection, and in 1997 the Washington Award for “unselfish and preeminent service in advancing human progress.” In 1998, Dr. Kreith was awarded the ASME medal for research, publications, and public service.

Dr. Kreith has served as a consultant and advisor all over the world. His assignments include consultancies to Vice Presidents Rockefeller and Gore, the U.S. Department of Energy, NATO, the U.S. Agency for International Development, and the United Nations. He is a registered professional engineer, a Life Fellow of ASME and a Fellow ASES and the American Association for the Advancement of Science [AAAS].

D. Yogi Goswami, Ph.D., P.E., is a professor of mechanical and aerospace engineering and Director of the Solar Energy and Energy Conversion Laboratory at the University of Florida, Gainesville. Dr. Goswami is internationally known for his research in fundamental and applied areas of renewable energy. He has published as an author or editor 7 books, 12 book chapters, 4 conference proceedings, and more than 100 refereed technical papers. He also holds 5 U.S. patents and 1 worldwide patent. In 2001 he received the University of Florida’s award of Research Foundation Professor.

Dr. Goswami is the Editor-in-Chief of *Advances in Solar Energy: An Annual Review of the Developments in Solar Energy,* published by the American Solar Energy Society (ASES). He is also the Editor-in-Chief of the *Solar Energy* journal, published by the International Solar Energy Society (ISES) and a past associate editor of the ASME *Journal of Solar Engineering*. Dr. Goswami has chaired a number of task forces to advise the U.S. Congress and the federal administration on energy policy. He has also made oral presentations on behalf of ISES to the United Nations charrette on world sustainable energy.

Dr. Goswami is a recognized leader in professional scientific and technical societies. He is the President of ISES and a member of the Board of Governors of the ASME International. He has also served as Senior Vice President of ASME-International (2000–2003), President of the International Association for Solar Energy Education (IASEE, 2000–2002), and a member of the Board of Directors of ISES (2000–2002). He has also served as a Vice President for Energy Resources Board of ASME-International (1989–1993), Vice President of IASEE (1998–2000), and a member of the Board of Directors of ASES (1996–2000).

Dr. Goswami is a recipient of the John Yellott Award for Solar Energy from ASME and the Charles Greely Abbott award of the ASES, and more than 20 other awards from engineering and scientific societies. He is a registered professional engineer and a fellow of ASME International and ASES.

1.1 Introduction

Bela I. Sandor

Engineers use the concepts and methods of mechanics of solids in designing and evaluating tools, machines, and structures ranging from wrenches to cars to spacecraft. The required educational background for these includes courses in statics, dynamics, mechanics of materials, and related subjects. For example, knowledge of dynamics of rigid bodies is needed in generalizing the spectrum of service loads on a car, which is essential

---

Professor Sandor wishes to acknowledge the contributions made by Richard C. Duveneck, Ian K. Glasgow, David A. Jahnke, Maan H. Jawad, and Christopher J. Watson.

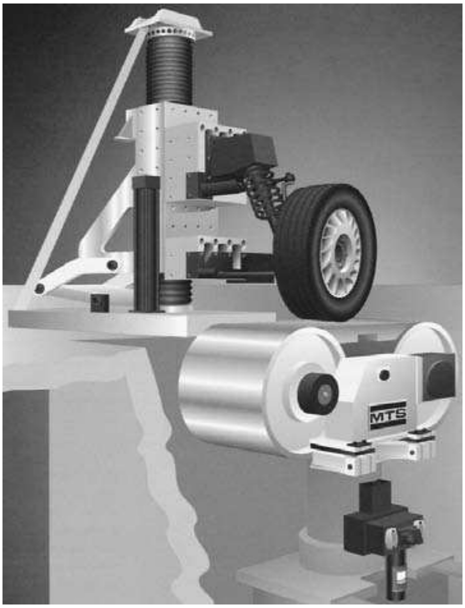

FIGURE 1.1.1 (See Color Figure 1.) Artist's concept of a moving stainless steel roadway to drive the suspension system through a spinning, articulated wheel, simulating three-dimensional motions and forces. (MTS Systems Corp., Minneapolis, MN. With permission.) Notes: Flat-Trac® Roadway Simulator, R&D100 Award-winning system in 1993.

in defining the vehicle's deformations and long-term durability. In regard to structural integrity and durability, the designer should think not only about preventing the catastrophic failures of products, but also of customer satisfaction. For example, a car with gradually loosening bolts (which is difficult to prevent in a corrosive and thermal and mechanical cyclic loading environment) is a poor product because of safety, vibration, and noise problems. Sophisticated methods are available to assure a product's performance and reliability, as exemplified in Figure 1.1.1. A similar but even more realistic test setup is shown in Color Figure 1.[1]

It is common experience among engineers that they need to review some old knowledge or learn something new because what they needed at the moment is not at their fingertips. This chapter may help in such a situation. Within the constraints of a single book on mechanical engineering, it provides overviews of topics with modern perspectives; illustrations of typical applications; modeling to solve problems quantitatively with realistic simplifications; equations and procedures; useful hints and reminders of common errors; trends of relevant material and mechanical system behaviors; and references to additional information.

This chapter is like an emergency toolbox. It includes a coherent assortment of basic tools, such as vector expressions useful for calculating bending stresses caused by a three-dimensional force system on a shaft, and sophisticated methods, such as life prediction of components using fracture mechanics and modern measurement techniques. In many cases much more information should be considered than is covered in this chapter.

1.2 Statics

Bela I. Sandor and Ryan J. Roloff

Vectors. Equilibrium of Particles. Free-Body Diagrams

Two kinds of quantities are used in engineering mechanics. A scalar quantity has only magnitude (mass, time, temperature, etc.). A vector quantity has magnitude and direction (force, velocity, etc.). Vectors are

---

[1] Color figures follow page **1**-104.

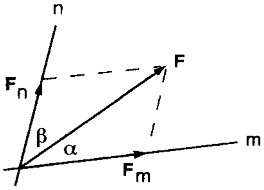

FIGURE 1.2.1 Components $\mathbf{F}_m$ and $\mathbf{F}_n$ of the vector **F**.

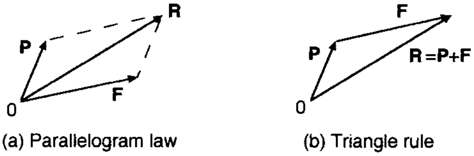

(a) Parallelogram law (b) Triangle rule

FIGURE 1.2.2 Addition of concurrent vectors **F** and **P**.

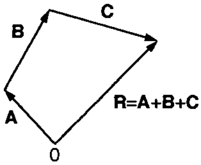

FIGURE 1.2.3 Addition of concurrent vectors **A**, **B**, and **C**.

represented here by arrows and bold-face symbols and are used in analysis according to universally applicable rules that facilitate calculations in a variety of problems. The vector methods are indispensable in three-dimensional mechanics analyses; however, in simple cases, equivalent scalar calculations are sufficient.

Vector Components and Resultants. Parallelogram Law

A given vector **F** may be replaced by two or three other vectors that have the same net effect and representation. This is illustrated for the chosen directions *m* and *n* for the components of **F** in two dimensions (Figure 1.2.1). Conversely, two concurrent vectors **F** and **P** of the same units may be combined to get a resultant **R** (Figure 1.2.2).

Any set of components of a vector **F** must satisfy the *parallelogram law*. According to Figure 1.2.1, the laws of sines and cosines may be useful:

$$\frac{F_n}{\sin\alpha} = \frac{F_m}{\sin\beta} = \frac{F}{\sin\left[180° - (\alpha+\beta)\right]}$$
$$F^2 = F_n^2 + F_m^2 - 2F_nF_m\cos\left[180° - (\alpha+\beta)\right] \tag{1.2.1}$$

Any number of concurrent vectors may be summed, mathematically or graphically, and in any order, using the preceding concepts (see Figure 1.2.3).

Unit Vectors

Mathematical manipulations of vectors are greatly facilitated by the use of unit vectors. A unit vector **n** has a magnitude of unity and a defined direction. The most useful of these are the unit coordinate vectors **i**, **j**, and **k** as shown in Figure 1.2.4. The three-dimensional components and associated quantities of a vector **F** are shown in Figure 1.2.5. The unit vector **n** is collinear with **F**.

The vector **F** is written in terms of its scalar components and the unit coordinate vectors,

$$\mathbf{F} = F_x\mathbf{i} + F_y\mathbf{j} + F_z\mathbf{k} = F\mathbf{n} \tag{1.2.2}$$

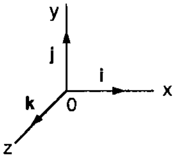

FIGURE 1.2.4 Unit vectors in Cartesian coordinates (the same **i**, **j**, and **k** set applies in a parallel **x′y′z′** system of axes).

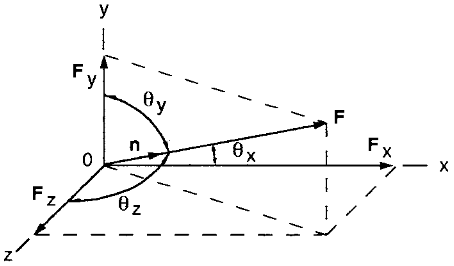

FIGURE 1.2.5 Three-dimensional components of a vector **F**.

where

$$F_x = F\cos\theta_x \quad F_y = F\cos\theta_y \quad F_z = F\cos\theta_z$$

$$F = \sqrt{F_x^2 + F_y^2 + F_z^2}$$

$$n_x = \cos\theta_x \quad n_y = \cos\theta_y \quad n_z = \cos\theta_z$$

$$n_x^2 + n_y^2 + n_z^2 = 1$$

$$\frac{n_x}{F_x} = \frac{n_y}{F_y} = \frac{n_z}{F_z} = \frac{1}{F}$$

The unit vector notation is convenient for the summation of concurrent vectors in terms of scalar or vector components:

Scalar components of the resultant **R**:

$$R_x = \sum F_x \qquad R_y = \sum F_y \qquad R_z = \sum F_z \tag{1.2.3}$$

Vector components:

$$\mathbf{R}_x = \sum \mathbf{F}_x = \sum F_x\mathbf{i} \qquad \mathbf{R}_y = \sum \mathbf{F}_y = \sum F_y\mathbf{j} \qquad \mathbf{R}_z = \sum \mathbf{F}_z = \sum F_z\mathbf{k} \tag{1.2.4}$$

Vector Determination from Scalar Information

A force, for example, may be given in terms of its magnitude *F*, its sense of direction, and its line of action. Such a force can be expressed in vector form using the coordinates of any two points on its line of action. The vector sought is

$$\mathbf{F} = F_x\mathbf{i} + F_y\mathbf{j} + F_z\mathbf{k} = F\mathbf{n}$$

The method is to find **n** on the line of points $A(x_1, y_1, z_1)$ and $B(x_2, y_2, z_2)$:

$$\mathbf{n} = \frac{\text{vector A to B}}{\text{distance A to B}} = \frac{d_x\mathbf{i} + d_y\mathbf{j} + d_z\mathbf{k}}{\sqrt{d_x^2 + d_y^2 + d_z^2}}$$

where $d_x = x_2 - x_1$, $d_y = y_2 - y_1$, $d_z = z_2 - z_1$.

Scalar Product of Two Vectors. Angles and Projections of Vectors

The scalar product, or dot product, of two concurrent vectors **A** and **B** is defined by

$$\mathbf{A} \cdot \mathbf{B} = AB\cos\phi \tag{1.2.5}$$

where **A** and **B** are the magnitudes of the vectors and ϕ is the angle between them. Some useful expressions are

$$\mathbf{A} \cdot \mathbf{B} = \mathbf{B} \cdot \mathbf{A} = A_xB_x + A_yB_y + A_zB_z$$

$$\phi = \arccos\frac{A_xB_x + A_yB_y + A_zB_z}{AB}$$

The projection F' of a vector **F** on an arbitrary line of interest is determined by placing a unit vector **n** on that line of interest, so that

$$F' = \mathbf{F} \cdot \mathbf{n} = F_xn_x + F_yn_y + F_zn_z$$

Equilibrium of a Particle

A particle is in **equilibrium** when the resultant of all forces acting on it is zero. In such cases, the algebraic summation of rectangular scalar components of forces is valid and convenient:

$$\sum F_x = 0 \qquad \sum F_y = 0 \qquad \sum F_z = 0 \tag{1.2.6}$$

Free-Body Diagrams

Unknown forces may be determined readily if a body is in equilibrium and can be modeled as a particle. The method involves **free-body diagrams**, which are simple representations of the actual bodies. The appropriate model is imagined to be isolated from all other bodies, with the significant effects of other bodies shown as force vectors on the free-body diagram.

Example 1

A mast has three guy wires. The initial tension in each wire is planned to be 200 lb. Determine whether this is feasible to hold the mast vertical (Figure 1.2.6).

Solution. The three tensions of known magnitude (200 lb) must be written as vectors.

$$\mathbf{R} = \mathbf{T}_{AB} + \mathbf{T}_{AC} + \mathbf{T}_{AD}$$

$$\mathbf{T}_{AB} = (\text{tension } AB)(\text{unit vector } A \text{ to } B) = 200\text{ lb }\mathbf{n}_{AB} = 200\text{ lb }\frac{\left(d_x\mathbf{i} + d_y\mathbf{j} + d_z\mathbf{k}\right)}{d}$$

$$= \frac{200\text{ lb}}{\sqrt{5^2 + 10^2 + 4^2}}(-5\mathbf{i} - 10\mathbf{j} + 4\mathbf{k})\frac{\text{ft}}{\text{ft}} = -84.2\text{ lb }\mathbf{i} - 168.4\text{ lb }\mathbf{j} + 67.4\text{ lb }\mathbf{k}$$

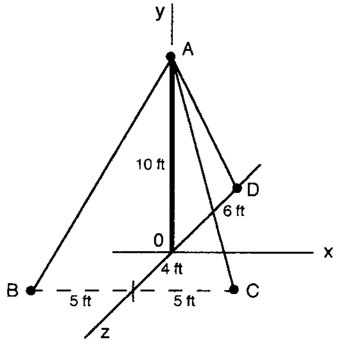

FIGURE 1.2.6 A mast with guy wires.

$$\mathbf{T}_{AC} = \frac{200\text{ lb}}{11.87\text{ ft}}(5\mathbf{i} - 10\mathbf{j} + 4\mathbf{k})\text{ ft} = 84.2\text{ lb }\mathbf{i} + 168.4\text{ lb }\mathbf{j} + 67.4\text{ lb }\mathbf{k}$$

$$\mathbf{T}_{AD} = \frac{200\text{ lb}}{11.66\text{ ft}}(0\mathbf{i} - 10\mathbf{j} + 6\mathbf{k})\text{ ft} = -171.5\text{ lb }\mathbf{j} - 102.9\text{ lb }\mathbf{k}$$

The resultant of the three tensions is

$$\mathbf{R} = \sum F_x\mathbf{i} + \sum F_y\mathbf{j} + \sum F_z\mathbf{k} = (-84.2 + 84.2 + 0)\text{ lb }\mathbf{i} + (-168.4 - 168.4 - 171.5)\text{ lb }\mathbf{j}$$

$$+ (67.4 + 67.4 - 102.9)\text{ lb }\mathbf{k} = 0\text{ lb }\mathbf{i} - 508\text{ lb }\mathbf{j} + 31.9\text{ lb }\mathbf{k}$$

There is a horizontal resultant of 31.9 lb at *A*, so the mast would not remain vertical.

Forces on Rigid Bodies

All solid materials deform when forces are applied to them, but often it is reasonable to model components and structures as rigid bodies, at least in the early part of the analysis. The forces on a rigid body are generally not concurrent at the center of mass of the body, which cannot be modeled as a particle if the force system tends to cause body rotation.

Moment of a Force

The turning effect of a force on a body is called the moment of the force, or torque. The moment M_A of a force **F** about a point *A* is defined as a scalar quantity

$$M_A = Fd \tag{1.2.7}$$

where *d* (the moment arm or lever arm) is the nearest distance from *A* to the line of action of **F**. This nearest distance may be difficult to determine in a three-dimensional scalar analysis; a vector method is needed in that case.

Equivalent Forces

Sometimes the equivalence of two forces must be established for simplifying the solution of a problem. The necessary and sufficient conditions for the equivalence of forces **F** and **F′** are that they have the same magnitude, direction, line of action, and moment on a given rigid body in static equilibrium. Thus,

$$\mathbf{F} = \mathbf{F}' \quad \text{and} \quad M_A = M'_A$$

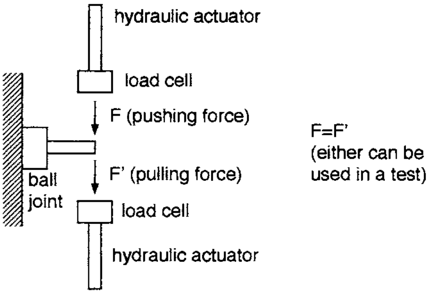

FIGURE 1.2.7 Schematic of testing a ball joint of a car.

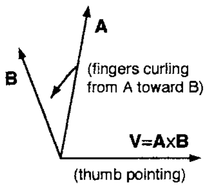

FIGURE 1.2.8 Right-hand rule for vector products.

For example, the ball joint *A* in Figure 1.2.7 experiences the same moment whether the vertical force is pushing or pulling downward on the yoke pin.

Vector Product of Two Vectors

A powerful method of vector mechanics is available for solving complex problems such as the moment of a force in three dimensions. The vector product (or cross product) of two concurrent vectors **A** and **B** is defined as the vector $\mathbf{V} = \mathbf{A} \times \mathbf{B}$ with the following properties:

1. **V** is perpendicular to the plane of vectors **A** and **B**.
2. The sense of **V** is given by the right-hand rule (Figure 1.2.8).
3. The magnitude of **V** is $\mathbf{V} = \mathbf{AB} \sin q$, where q is the angle between **A** and **B**.
4. $\mathbf{A} \times \mathbf{B} \sum \mathbf{B} \times \mathbf{A}$, but $\mathbf{A} \times \mathbf{B} = -(\mathbf{B} \times \mathbf{A})$.
5. For three vectors, $\mathbf{A} \times (\mathbf{B} + \mathbf{C}) = \mathbf{A} \times \mathbf{B} + \mathbf{A} \times \mathbf{C}$.

The vector product is calculated using a determinant,

$$\mathbf{V} = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ A_x & A_y & A_z \\ B_x & B_y & B_z \end{vmatrix} = A_y B_z \mathbf{i} + A_z B_x \mathbf{j} + A_x B_y \mathbf{k} - A_y B_x \mathbf{k} - A_x B_z \mathbf{j} - A_z B_y \mathbf{i} \tag{1.2.8}$$

Moment of a Force about a Point

The vector product is very useful in determining the moment of a force **F** about an arbitrary point *O*. The vector definition of moment is

$$\mathbf{M}_O = \mathbf{r} \times \mathbf{F} \tag{1.2.9}$$

where **r** is the position vector from point *O* to any point on the line of action of **F**. A double arrow is often used to denote a moment vector in graphics.

The moment $\mathbf{M}_O$ may have three scalar components, M_x, M_y, M_z, which represent the turning effect of the force **F** about the corresponding coordinate axes. In other words, a single force has only one moment about a given point, but this moment may have up to three components with respect to a coordinate system,

$$\mathbf{M}_O = M_x\mathbf{i} + M_y\mathbf{j} + M_z\mathbf{k}$$

Triple Products of Three Vectors

Two kinds of products of three vectors are used in engineering mechanics. The *mixed triple product* (or scalar product) is used in calculating moments. It is the dot product of vector **A** with the vector product of vectors **B** and **C**,

$$\mathbf{A}\cdot(\mathbf{B}\times\mathbf{C}) = \begin{vmatrix} A_x & A_y & A_z \\ B_x & B_y & B_z \\ C_x & C_y & C_z \end{vmatrix} = A_x\left(B_yC_z - B_zC_y\right) + A_y\left(B_zC_x - B_xC_z\right) + A_z\left(B_xC_y - B_yC_x\right) \quad (1.2.10)$$

The *vector triple product* $(\mathbf{A}\times\mathbf{B})\times\mathbf{C} = \mathbf{V}\times\mathbf{C}$ is easily calculated (for use in dynamics), but note that

$$(\mathbf{A}\times\mathbf{B})\times\mathbf{C} \neq \mathbf{A}\times(\mathbf{B}\times\mathbf{C})$$

Moment of a Force about a Line

It is common that a body rotates about an axis. In that case, the moment M_ℓ, of a force F about the axis, say line, ℓ, is usefully expressed as

$$\mathbf{M}_\ell = \mathbf{n}\cdot\mathbf{M}_O = \mathbf{n}\cdot(\mathbf{r}\times\mathbf{F}) = \begin{vmatrix} n_x & n_y & n_z \\ r_x & r_y & r_z \\ F_x & F_y & F_z \end{vmatrix} \quad (1.2.11)$$

where **n** is a unit vector along the line, ℓ, and **r** is a position vector from point O on ℓ, to a point on the line of action of **F**. Note that M_ℓ is the projection of $\mathbf{M}_O$ on line, ℓ.

Special Cases

- The moment about a line ℓ is zero when the line of action of **F** intersects ℓ (the moment arm is zero).
- The moment about a line ℓ is zero when the line of action of **F** is parallel to ℓ (the projection of $\mathbf{M}_O$ on ℓ is zero).

Moment of a Couple

A pair of forces equal in magnitude, parallel in lines of action, and opposite in direction is called a *couple*. The magnitude of the moment of a couple is

$$M = Fd$$

where d is the distance between the lines of action of the forces of magnitude F.

The moment of a couple is a free vector **M** that can be applied anywhere to a rigid body with the same turning effect, as long as the direction and magnitude of **M** are the same. In other words, a couple vector can be moved to any other location on a given rigid body if it remains parallel to its original position (equivalent couples). Sometimes a curled arrow in the plane of the two forces is used to denote a couple, instead of the couple vector **M**, which is perpendicular to the plane of the two forces.

Force-Couple Transformations

Sometimes it is advantageous to transform a force to a force system acting at another point, or vice versa. This method is illustrated in Figure 1.2.9.

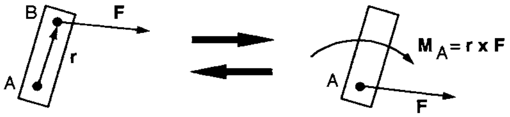

FIGURE 1.2.9 Force-couple transformations.

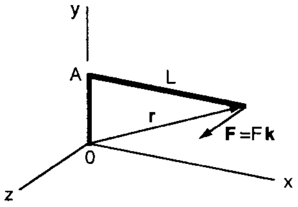

FIGURE 1.2.10 Model of a torque wrench.

1. A force **F** acting at B on a rigid body can be replaced by the same force **F** acting at A and a moment $\mathbf{M}_A = \mathbf{r} \times \mathbf{F}$ about A.
2. A force **F** and moment $\mathbf{M}_A$ acting at A can be replaced by a force **F** acting at B for the same total effect on the rigid body.

Simplification of Force Systems

Any force system on a rigid body can be reduced to an equivalent system of a resultant force **R** and a resultant moment $\mathbf{M}_R$. The **equivalent force-couple system** is formally stated as

$$\mathbf{R} = \sum_{i=1}^{n} \mathbf{F}_i \quad \text{and} \quad \mathbf{M}_R = \sum_{i=1}^{n} \mathbf{M}_i = \sum_{i=1}^{n} \left(\mathbf{r}_i \times \mathbf{F}_i\right) \tag{1.2.12}$$

where $\mathbf{M}_R$ depends on the chosen reference point.

Common Cases

- The resultant force is zero, but there is a resultant moment: $\mathbf{R} = 0$, $\mathbf{M}_R \neq 0$.
- Concurrent forces (all forces act at one point): $\mathbf{R} \neq 0$, $\mathbf{M}_R = 0$.
- Coplanar forces: $\mathbf{R} \neq 0$, $\mathbf{M}_R \neq 0$. $\mathbf{M}_R$ is perpendicular to the plane of the forces.
- Parallel forces: $\mathbf{R} \neq 0$, $\mathbf{M}_R \neq 0$. $\mathbf{M}_R$ is perpendicular to **R**.

Example 2

The torque wrench in Figure 1.2.10 has an arm of constant length L but a variable socket length $d = OA$ because of interchangeable tool sizes. Determine how the moment applied at point O depends on the length d for a constant force **F** from the hand.

Solution. Using $\mathbf{M}_O = \mathbf{r} \times \mathbf{F}$ with $\mathbf{r} = L\mathbf{i} + d\mathbf{j}$ and $\mathbf{F} = F\mathbf{k}$ in Figure 1.2.10,

$$\mathbf{M}_O = (L\mathbf{i} + d\mathbf{j}) \times F\mathbf{k} = Fd\mathbf{i} - FL\mathbf{j}$$

Judgment of the Result

According to a visual analysis, the wrench should turn clockwise, so the **–j** component of the moment is justified. Looking at the wrench from the positive x direction, point A has a tendency to rotate counterclockwise. Thus, the **i** component is correct using the right-hand rule.

Equilibrium of Rigid Bodies

The concept of equilibrium is used for determining unknown forces and moments of forces that act on or within a rigid body or system of rigid bodies. The equations of equilibrium are the most useful equations in the area of statics, and they are also important in dynamics and mechanics of materials. The drawing of appropriate free-body diagrams is essential for the application of these equations.

Conditions of Equilibrium

A rigid body is in static equilibrium when the equivalent force-couple system of the external forces acting on it is zero. In vector notation, this condition is expressed as

$$\begin{aligned} \sum \mathbf{F} &= 0 \\ \sum \mathbf{M}_O &= \sum (\mathbf{r} \times \mathbf{F}) = 0 \end{aligned} \tag{1.2.13}$$

where O is an arbitrary point of reference.

In practice it is often most convenient to write Equation (1.2.13) in terms of rectangular scalar components,

$$\begin{aligned} \sum F_x &= 0 \qquad \sum M_x = 0 \\ \sum F_y &= 0 \qquad \sum M_y = 0 \\ \sum F_z &= 0 \qquad \sum M_z = 0 \end{aligned}$$

Maximum Number of Independent Equations for One Body

1. One-dimensional problem: $\sum F = 0$
2. Two-dimensional problem:

$$\begin{aligned} &\sum F_x = 0 \qquad \sum F_y = 0 \qquad \sum M_A = 0 \\ \text{or} \quad &\sum F_x = 0 \qquad \sum M_A = 0 \qquad \sum M_B = 0 \qquad (x \text{ axis not} \perp \text{AB}) \\ \text{or} \quad &\sum M_A = 0 \qquad \sum M_B = 0 \qquad \sum M_C = 0 \qquad (AB \text{ not } \parallel \text{BC}) \end{aligned}$$

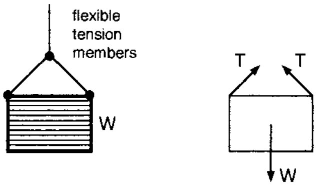
3. Three-dimensional problem:

$$\begin{aligned} &\sum F_x = 0 \qquad \sum F_y = 0 \qquad \sum F_z = 0 \\ &\sum M_x = 0 \qquad \sum M_y = 0 \qquad \sum M_z = 0 \end{aligned}$$

where xyz are orthogonal coordinate axes, and A, B, C are particular points of reference.

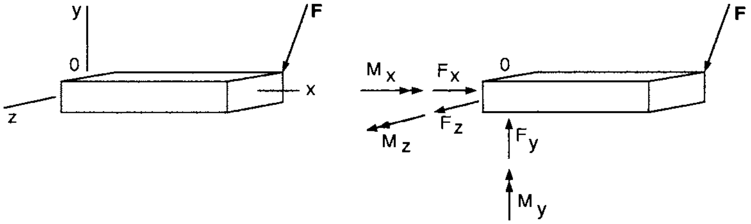
Calculation of Unknown Forces and Moments

In solving for unknown forces and moments, always draw the free-body diagram first. Unknown external forces and moments must be shown at the appropriate places of action on the diagram. The directions of unknowns may be assumed arbitrarily, but should be done consistently for systems of rigid bodies. A



(a) sketch of setup (b) free-body diagram

FIGURE 1.2.11 Example of two-dimensional modeling.



(a) cantilever beam with unsymmetric loading (b) free-body diagram

FIGURE 1.2.12 Example of three-dimensional modeling.

negative answer indicates that the initial assumption of the direction was opposite to the actual direction. Modeling for problem solving is illustrated in Figure 1.2.11 and Figure 1.2.12.

Notes on Three-Dimensional Forces and Supports

Each case should be analyzed carefully. Sometimes a particular force or moment is possible in a device, but it must be neglected for most practical purposes. For example, a very short sleeve bearing cannot support significant moments. A roller bearing may be designed to carry much larger loads perpendicular to the shaft than along the shaft.

Related Free-Body Diagrams

When two or more bodies are in contact, separate free-body diagrams may be drawn for each body. The mutual forces and moments between the bodies are related according to Newton's third law (action and reaction). The directions of unknown forces and moments may be arbitrarily assumed in one diagram, but these initial choices affect the directions of unknowns in all other related diagrams. The numbers of unknowns and of usable equilibrium equations increase with the number of related free-body diagrams.

Schematic Example in Two Dimensions (Figure 1.2.13)

Given: F_1, F_2, F_3, M
Unknowns: P_1, P_2, P_3, and forces and moments at joint A (rigid connection)

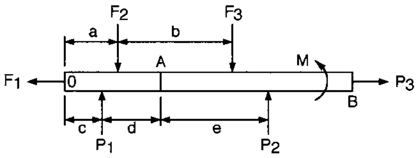


FIGURE 1.2.13 Free-body diagram.

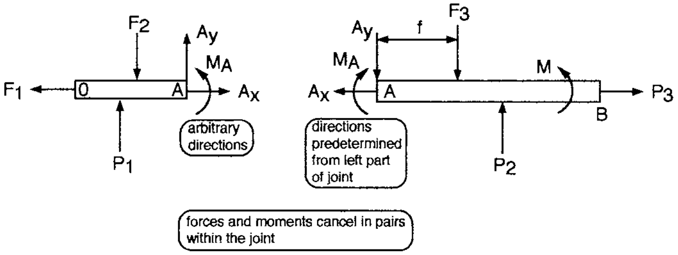

FIGURE 1.2.14 Related free-body diagrams.

Equilibrium Equations

$$\sum F_x = -F_1 + P_3 = 0$$

$$\sum F_y = P_1 + P_2 - F_2 - F_3 = 0$$

$$\sum M_O = P_1 c + P_2(c + d + e) + M - F_2 a - F_3(a + b) = 0$$

Three unknowns (P_1, P_2, P_3) are in three equations.

Related Free-Body Diagrams (Figure 1.2.14)

Dimensions a, b, c, d, and e of Figure 1.2.13 are also valid here.

New Set of Equilibrium Equations

Left part: (OA)

$$\sum F_x = -F_1 + A_x = 0$$

$$\sum F_y = P_1 + A_y - F_2 = 0$$

$$\sum M_O = P_1 c + A_y(c + d) + M_A - F_2 a = 0$$

Right side: (AB)

$$\sum F_x = -A_x + P_3 = 0$$

$$\sum F_y = P_2 - A_y - F_3 = 0$$

$$\sum M_A = -M_A + P_2 e + M - F_3 f = 0$$

Six unknowns (P_1, P_2, P_3, A_x, A_y, M_A) are in six equations. Note that, in the first diagram (Figure 1.2.13), the couple M may be moved anywhere from O to B. M is not shown in the second diagram (O to A) because it is shown in the third diagram (in which it may be moved anywhere from A to B).

Example 3

The arm of a factory robot is modeled as three bars (Figure 1.2.15) with coordinates A: (0.6, –0.3, 0.4) m; B: (1, –0.2, 0) m; and C: (0.9, 0.1, –0.25) m. The weight of the arm is represented by $\mathbf{W}_A = -60$ N$\mathbf{j}$ at A, and $\mathbf{W}_B = -40$ N$\mathbf{j}$ at B. A moment $\mathbf{M}_C = (100\mathbf{i} - 20\mathbf{j} + 50\mathbf{k})$ N · m is applied to the arm at C. Determine the force and moment reactions at O, assuming that all joints are temporarily fixed.

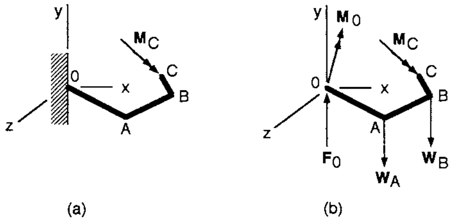

FIGURE 1.2.15 Model of a factory robot.

Solution. The free-body diagram showing the unknown force and moment reactions at O, is drawn in Figure 1.2.15b. From Equation (1.2.13),

$$\sum \mathbf{F} = 0$$

$$\mathbf{F}_O + \mathbf{W}_A + \mathbf{W}_B = 0$$

$$\mathbf{F}_O - 60\ \text{N}\,\mathbf{j} - 40\ \text{N}\,\mathbf{j} = 0$$

$$\mathbf{F}_O = 100\ \text{N}\,\mathbf{j}$$

$$\sum M_O = 0$$

$$\mathbf{M}_O + \mathbf{M}_C + \left(\mathbf{r}_{OA} \times \mathbf{W}_A\right) + \left(\mathbf{r}_{OB} \times \mathbf{W}_B\right) = 0$$

$$\mathbf{M}_O + \left(100\mathbf{i} - 20\mathbf{j} + 50\mathbf{k}\right)\ \text{N}\cdot\text{m} + \left(0.6\mathbf{i} - 0.3\mathbf{j} + 0.4\mathbf{k}\right)\ \text{m} \times \left(-60\ \text{N}\,\mathbf{j}\right) + \left(\mathbf{i} - 0.2\mathbf{j}\right)\ \text{m} \times \left(-40\ \text{N}\,\mathbf{j}\right) = 0$$

$$\mathbf{M}_O + 100\ \text{N}\cdot\text{m}\,\mathbf{i} - 20\ \text{N}\cdot\text{m}\,\mathbf{j} + 50\ \text{N}\cdot\text{m}\,\mathbf{k} - 36\ \text{N}\cdot\text{m}\,\mathbf{k} + 24\ \text{N}\cdot\text{m}\,\mathbf{i} - 40\ \text{N}\cdot\text{m}\,\mathbf{k} = 0$$

$$\mathbf{M}_O = \left(-124\mathbf{i} + 20\mathbf{j} + 26\mathbf{k}\right)\ \text{N}\cdot\text{m}$$

Example 4

A load of 7 kN may be placed anywhere within *A* and *B* in the trailer of negligible weight. Determine the reactions at the wheels at *D*, *E*, and *F*, and the force on the hitch *H* mounted on the car, for the extreme positions *A* and *B* of the load. The mass of the car is 1500 kg, and its weight is acting at *C* (see Figure 1.2.16).

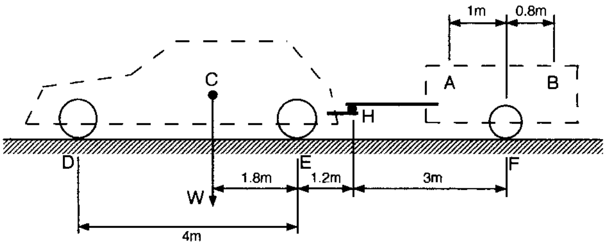

FIGURE 1.2.16 Analysis of a car with trailer.

Solution. The scalar method is best here. Put the load at position A first.

For the trailer alone, with y as the vertical axis:
$\Sigma M_F = 7(1) - H_y(3) = 0,\ H_y = 2.33$ kN
On the car:
$H_y = 2.33$ kN $\downarrow$ Ans.
$\Sigma F_y = 2.33 - 7 + F_y = 0,\ F_y = 4.67$ kN $\uparrow$ Ans.
For the car alone:
$\Sigma M_E = -2.33(1.2) - D_y(4) + 14.72(1.8) = 0$
$D_y = 5.93$ kN $\uparrow$ Ans.
$\Sigma F_y = 5.93 + E_y - 14.72 - 2.33 = 0$
$E_y = 11.12$ kN $\uparrow$ Ans.

Put the load at position B next.

For the trailer alone:
$\Sigma M_F = 0.8(7) - H_y(3) = 0,\ H_y = -1.87$ kN
On the car:
$H_y = 1.87$ kN $\downarrow$ Ans.
$\Sigma F_y = -1.87 - 7 + E_y = 0$
$E_y = 8.87$ kN $\uparrow$ Ans.
For the car alone:
$\Sigma M_E = -(1.87)(1.2) - D_y(4) + 14.72(1.8) = 0$
$D_y = 7.19$ kN $\uparrow$Ans.
$\Sigma F_y = 7.19 + E_y - 14.72 - (-1.87) = 0$
$E_y = 5.66$ kN $\uparrow$ Ans.

Forces and Moments in Beams

Beams are common structural members whose main function is to resist bending. The geometric changes and safety aspects of beams are analyzed by first assuming that they are rigid. The preceding subsections enable one to determine (1) the external (supporting) reactions acting on a statically determinate beam; and (2) the internal forces and moments at any cross section in a beam.

Classification of Supports

Common supports and external reactions for two-dimensional loading of beams are shown in Figure 1.2.17.

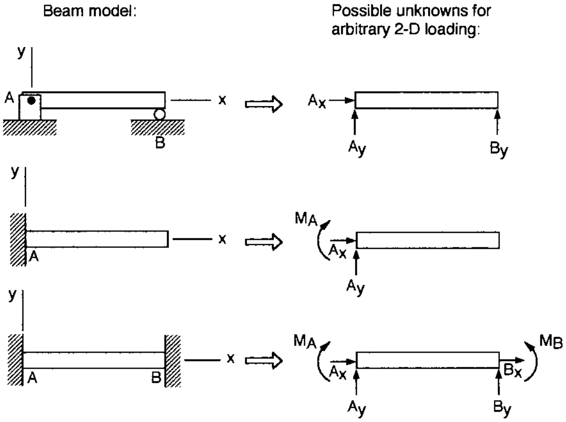

FIGURE 1.2.17 Common beam supports.

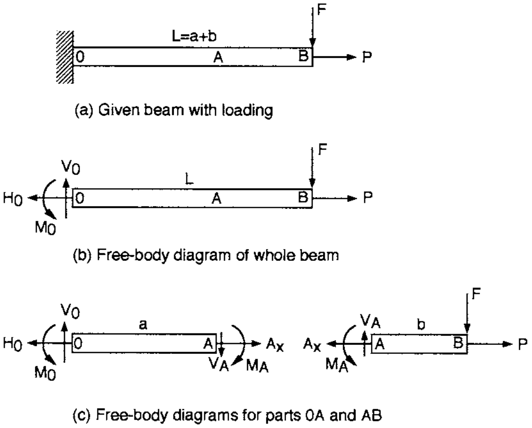

FIGURE 1.2.18 Internal forces and moments in a cantilever beam.

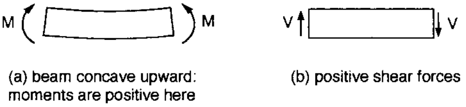

FIGURE 1.2.19 Preferred sign conventions.

Internal Forces and Moments

The internal force and moment reactions in a beam caused by external loading must be determined for evaluating the strength of the beam. If there is no torsion of the beam, three kinds of internal reactions are possible: a horizontal normal force H on a cross section; vertical (transverse) shear force V; and bending moment M. These reactions are calculated from the equilibrium equations applied to the left or right part of the beam from the cross section considered. The process involves free-body diagrams of the beam and a consistently applied system of signs. The modeling is illustrated for a cantilever beam in Figure 1.2.18.

Sign conventions. Consistent sign conventions should be used in any given problem. These can be arbitrarily set up, but the following is slightly advantageous. It makes the signs of the answers to the equilibrium equations correct for the directions of the shear force and bending moment.

A moment that makes a beam concave upward is taken as positive. Thus, a clockwise moment is positive on the left side of a section, and a counterclockwise moment is positive on the right side. A shear force that acts upward on the left side of a section, or downward on the right side, is positive (Figure 1.2.19).

Shear Force and Bending Moment Diagrams

The critical locations in a beam are determined from shear force and bending moment diagrams for the whole length of the beam. The construction of these diagrams is facilitated by following the steps, which are illustrated for a cantilever beam in Figure 1.2.20.

1. Draw the free-body diagram of the whole beam and determine all reactions at the supports.
2. Draw the coordinate axes for the shear force (V) and bending moment (M) diagrams directly below the free-body diagram.
3. Immediately plot those values of V and M that can be determined by inspection (especially when they are zero), observing the sign conventions.
4. Calculate and plot as many additional values of V and M as are necessary for drawing reasonably accurate curves through the plotted points, or do it all by computer.

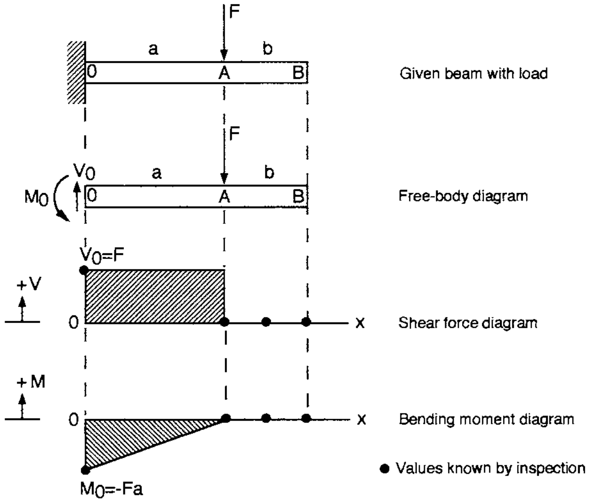

FIGURE 1.2.20 Construction of shear force and bending moment diagrams.

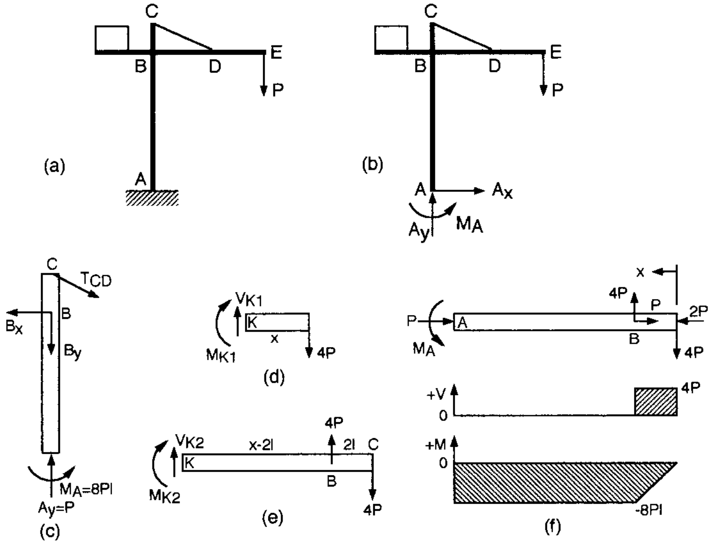

FIGURE 1.2.21 Shear force and bending moment diagrams of a component in a structure.

Example 5

A construction crane is modeled as a rigid bar AC that supports the boom by a pin at B and wire CD. The dimensions are AB = 10ℓ, BC = 2ℓ, BD = DE = 4ℓ. Draw the shear force and bending moment diagrams for bar AC (Figure 1.2.21).

Solution. From the free-body diagram of the entire crane,

$$\sum F_x = 0 \qquad \sum F_y = 0 \qquad \sum M_A = 0$$

$$A_x = 0 \qquad -P + A_y = 0 \qquad -P(8\ell) + M_A = 0$$

$$A_y = P \qquad M_A = 8P\ell$$

Now separate bar AC and determine the forces at B and C.

$$\sum F_x = 0$$

$$-B_x + T_{CD_x} = 0$$

$$\text{(a)}\quad B_x = \frac{2}{\sqrt{5}} T_{CD}$$

$$\sum F_y = 0$$

$$P - B_y - T_{CD_y} = 0$$

$$\text{(b)}\quad B_y = P - \frac{1}{\sqrt{5}} T_{CD}$$

$$\sum M_A = 0$$

$$-\frac{2}{\sqrt{5}} T_{CD}(12\ell) + B_x(10\ell) + M_A = 0$$

$$-\frac{24\ell}{\sqrt{5}} T_{CD} + \frac{20\ell}{\sqrt{5}} T_{CD} = -8P\ell$$

$$\text{(c)}\quad T_{CD} = \frac{8\sqrt{5}}{4} P = 2\sqrt{5}P$$

From (a) and (c), $B_x = 4P$ and $T_{CD_x} = 4P$. From (b) and (c), $B_y = P - 2P = -P$ and $= T_{CD_y} = 2P$.

Draw the free-body diagram of bar *AC* horizontally, with the shear force and bending moment diagram axes below it. Measure *x* from end *C* for convenience and analyze sections $0 \le x \le 2\ell$ and $2\ell \le x \le 12\ell$ (Figure 1.2.21b to 1.2.21f).

1. $0 \le x \le 2\ell$

$$\sum F_y = 0 \qquad\qquad \sum M_K = 0$$

$$-4P + V_{K_1} = 0 \qquad\qquad M_{K_1} + 4P(x) = 0$$

$$V_{K_1} = 4P \qquad\qquad M_{K_1} = -4Px$$

2. $2\ell \le x \le 12\ell$

$$\sum F_y = 0 \qquad\qquad \sum M_K = 0$$

$$4P - 4P + V_{K_2} = 0 \qquad\qquad M_{K_2} - 4P(x - 2\ell) + 4P(x) = 0$$

$$V_{K_2} = 0 \qquad\qquad M_{K_2} = -8P\ell$$

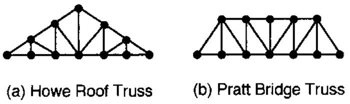
At point *B*, $x = 2\ell$, $M_{K_1} = -4P(2\ell) = -8P\ell = M_{K_2} = MA$. The results for section *AB*, $2\ell \le x \le 12\ell$, show that the combined effect of the forces at *B* and *C* is to produce a couple of magnitude $8P\ell$ on the beam. Thus, the shear force is zero and the moment is constant in this section. These results are plotted on the axes below the free-body diagram of bar *A-B-C*.

Simple Structures and Machines

Equilibrium equations are used to determine forces and moments acting on statically determinate simple structures and machines. A simple structure is composed solely of two-force members. A machine is composed of multiforce members. The method of joints and the method of sections are commonly used in such analysis.

Trusses

Trusses consist of straight, slender members whose ends are connected at joints. Two-dimensional *plane trusses* carry loads acting in their planes and are often connected to form three-dimensional *space trusses*. Two typical trusses are shown in Figure 1.2.22.



(a) Howe Roof Truss

(b) Pratt Bridge Truss

FIGURE 1.2.22 Schematic examples of trusses.

To simplify the analysis of trusses, assume frictionless pin connections at the joints. Thus, all members are two-force members with forces (and no moments) acting at the joints. Members may be assumed weightless or may have their weights evenly divided to the joints.

Method of Joints

Equilibrium equations based on the entire truss and its joints allow for determination of all internal forces and external reactions at the joints using the following procedure.

1. Determine the support reactions of the truss. This is done using force and moment equilibrium equations and a free-body diagram of the entire truss.
2. Select any arbitrary joint where only one or two unknown forces act. Draw the free-body diagram of the joint assuming unknown forces are tensions (arrows directed away from the joint).
3. Draw free-body diagrams for the other joints to be analyzed, using Newton's third law consistently with respect to the first diagram.
4. Write the equations of equilibrium, $\Sigma F_x = 0$ and $\Sigma F_y = 0$, for the forces acting at the joints and solve them. To simplify calculations, attempt to progress from joint to joint in such a way that each equation contains only one unknown. Positive answers indicate that the assumed directions of unknown forces were correct, and vice versa.

Example 6

Use the method of joints to determine the forces acting at A, B, C, H, and I of the truss in Figure 1.2.23a. The angles are $\alpha = 56.3°$; $\beta = 38.7°$; $\phi = 39.8°$; and $\theta = 36.9°$.

Solution. First the reactions at the supports are determined and are shown in Figure 1.2.23b. A joint at which only two unknown forces act is the best starting point for the solution. Choosing joint A, the solution is progressively developed, always seeking the next joint with only two unknowns. In each

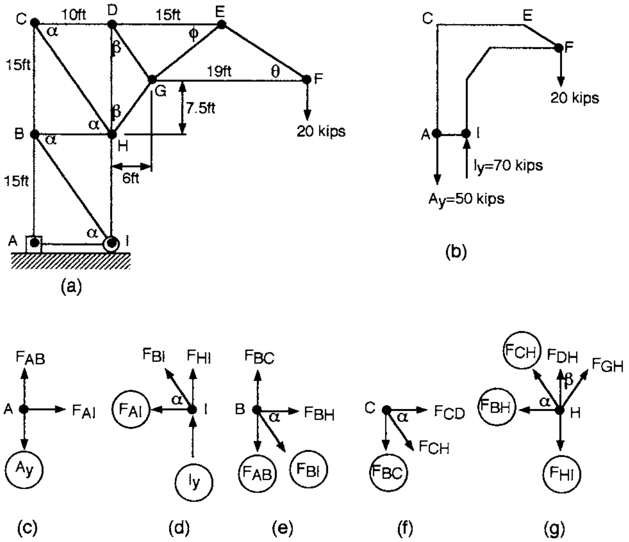


FIGURE 1.2.23 Method of joints in analyzing a truss.

diagram, circles indicate the quantities known from the preceding analysis. Sample calculations show the approach and some of the results.

Joint A:

$$\sum F_x = 0 \qquad \sum F_y = 0$$

$$F_{AI} = 0 \qquad F_{AB} - A_y = 0$$

$$F_{AB} - 50 \text{ kips} = 0$$

$$F_{AB} = 50 \text{ kips (tension)}$$

Joint H:

$$\sum F_x = 0 \qquad \sum F_y = 0$$

$$F_{GH} \sin\beta - F_{CH} \cos\alpha - F_{BH} = 0 \qquad F_{CH} \sin\alpha + F_{DH} + F_{GH} \cos\beta - F_{HI} = 0$$

$$F_{GH}(0.625) + (60.1 \text{ kips})(0.555) - 0 = 0 \qquad -(60.1 \text{ kips})(0.832) + F_{DH} - (53.4 \text{ kips})(0.780) + 70 \text{ kips} = 0$$

$$F_{GH} = -53.4 \text{ kips (compression)} \qquad F_{DH} = 21.7 \text{ kips (tension)}$$

Method of Sections

The method of sections is useful when only a few forces in truss members need to be determined regardless of the size and complexity of the entire truss structure. This method employs any section of the truss as a free body in equilibrium. The chosen section may have any number of joints and members in it, but the number of unknown forces should not exceed three in most cases. Only three equations of equilibrium can be written for each section of a plane truss. The following procedure is recommended:

1. Determine the support reactions if the section used in the analysis includes the joints supported.
2. Section the truss by making an imaginary cut through the members of interest, preferably through only three members in which the forces are unknowns (assume tensions). The cut need not be a straight line. The sectioning is illustrated by lines *l-l*, *m-m*, and *n-n* in Figure 1.2.24.
3. Write equations of equilibrium. Choose a convenient point of reference for moments to simplify calculations such as the point of intersection of the lines of action for two or more of the unknown forces. If two unknown forces are parallel, sum the forces perpendicular to their lines of action.
4. Solve the equations. If necessary, use more than one cut in the vicinity of interest to allow writing more equilibrium equations. Positive answers indicate assumed directions of unknown forces were correct, and vice versa.

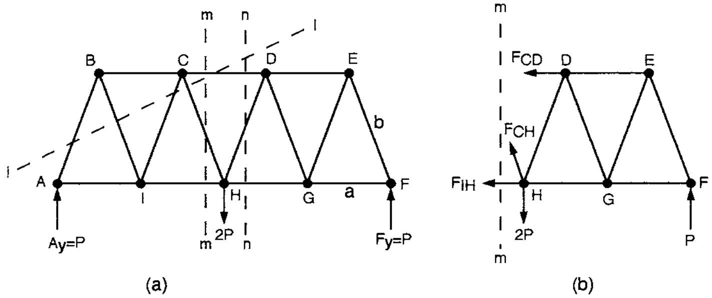

FIGURE 1.2.24 Method of sections in analyzing a truss.

Space Trusses

A space truss can be analyzed with the method of joints or with the method of sections. For each joint, there are three scalar equilibrium equations, $\Sigma F_x = 0$, $\Sigma F_y = 0$, and $\Sigma F_z = 0$. The analysis must begin at a joint at least one force is known and no more than three forces are unknown. The solution must progress to other joints in a similar fashion. Six scalar equilibrium equations are available when the method of sections is used: $\Sigma F_x = 0$; $\Sigma F_y = 0$; $\Sigma F_z = 0$; $\Sigma M_x = 0$; $\Sigma M_y = 0$; and $\Sigma M_z = 0$.

Frames and Machines

Multiforce members (with three or more forces acting on each member) are common in structures. In these cases the forces are not directed along the members, so they are a little more complex to analyze than the two-force members in simple trusses. Multiforce members are used in two kinds of structures. Frames are usually stationary and fully constrained. *Machines* have moving parts, so the forces acting on a member depend on the location and orientation of the member.

The analysis of multiforce members is based on the consistent use of related free-body diagrams. The solution is often facilitated by representing forces by their rectangular components. Scalar equilibrium equations are the most convenient for two-dimensional problems, and vector notation is advantageous in three-dimensional situations.

Often, an applied force acts at a pin joining two or more members, or a support or connection may exist at a joint between two or more members. In these cases, a choice should be made of a single member at the joint on which to assume the external force to be acting. This decision should be stated in the analysis. The following comprehensive procedure is recommended.

Three independent equations of equilibrium are available for each member or combination of members in two-dimensional loading; for example, $\Sigma F_x = 0$, $\Sigma F_y = 0$, $\Sigma M_A = 0$, where A is an arbitrary point of reference.

1. Determine the support reactions if necessary.
2. Determine all two-force members.
3. Draw the free-body diagram of the first member on which the unknown forces act, assuming that the unknown forces are tensions.
4. Draw the free-body diagrams of the other members or groups of members using Newton's third law (action and reaction) consistently with respect to the first diagram. Proceed until the number of equilibrium equations available is no longer exceeded by the total number of unknowns.
5. Write the equilibrium equations for the members or combinations of members and solve them. Positive answers indicate that the assumed directions for unknown forces were correct, and vice versa.

Distributed Forces

The most common distributed forces acting on a body are parallel force systems, such as the force of gravity. These can be represented by one or more concentrated forces to facilitate the required analysis. Several basic cases of distributed forces are presented here. The important topic of stress analysis is covered in mechanics of materials.

Center of Gravity

The center of gravity of a body is the point where the equivalent resultant force caused by gravity is acting. Its coordinates are defined for an arbitrary set of axes as

$$\bar{x} = \frac{\int x\, dW}{W} \qquad \bar{y} = \frac{\int y\, dW}{W} \qquad \bar{z} = \frac{\int z\, dW}{W} \tag{1.2.14}$$

where x, y, z are the coordinates of an element of weight dW, and W is the total weight of the body. In the general case, $dW = \gamma\, dV$, and $W = \int \gamma\, dV$, where γ = specific weight of the material and dV = elemental volume.

Centroids

If γ is a constant, the center of gravity coincides with the centroid, which is a geometrical property of a body. Centroids of lines L, areas A, and volumes V are defined analogously to the coordinates of the center of gravity,

$$\text{Lines:}\quad \bar{x} = \frac{\int x\, dL}{W} \qquad \bar{y} = \frac{\int y\, dL}{L} \qquad \bar{z} = \frac{\int z\, dL}{L} \tag{1.2.15}$$

$$\text{Areas:}\quad \bar{x} = \frac{\int x\, dA}{A} \qquad \bar{y} = \frac{\int y\, dA}{A} \qquad \bar{z} = \frac{\int z\, dA}{A} \tag{1.2.16}$$

$$\text{Volumes:}\quad \bar{x} = \frac{\int x\, dV}{V} \qquad \bar{y} = \frac{\int y\, dV}{V} \qquad \bar{z} = \frac{\int z\, dV}{V} \tag{1.2.17}$$

For example, an area A consists of discrete parts A_1, A_2, A_3, where the centroids x_1, x_2, x_3 of the three parts are located by inspection. The x coordinate of the centroid of the whole area A is $\bar{x}$ obtained from $A\bar{x} = A_1x_1 + A_2x_2 + A_3x_3$.

Surfaces of revolution. The surface areas and volumes of bodies of revolution can be calculated using the concepts of centroids by the theorems of Pappus.

Distributed Loads on Beams

The distributed load on a member may be its own weight and/or some other loading such as from ice or wind. The external and internal reactions to the loading may be determined using the condition of equilibrium.

External reactions. Replace the whole distributed load with a concentrated force equal in magnitude to the area under the load distribution curve and applied at the centroid of that area parallel to the original force system.

Internal reactions. For a beam under a distributed load $w(x)$, where x is distance along the beam, the shear force V and bending moment M are related according to Figure 1.2.25 as

$$w(x) = -\frac{dV}{dx} \qquad V = \frac{dM}{dx} \tag{1.2.18}$$

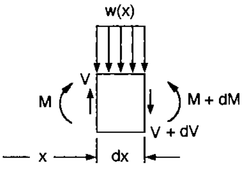

FIGURE 1.2.25 Internal reactions in a beam under distributed loading.

Other useful expressions for any two cross sections A and B of a beam are

$$V_A - V_B = \int_{x_A}^{x_B} w(x)\,dx = \text{area under } w(x)$$

$$M_B - M_A = \int_{x_A}^{x_B} V\,dx = \text{area under shear force diagram} \tag{1.2.19}$$

Example 7

See Figure 1.2.26.

Distributed Loads on Flexible Cables

The basic assumptions of simple analyses of cables are that there is no resistance to bending and that the internal force at any point is tangent to the cable at that point. The loading is denoted by $w(x)$, a continuous but possibly variable load, in terms of force per unit length. The differential equation of a cable is

$$\frac{d^2y}{dx^2} = \frac{w(x)}{T_o} \tag{1.2.20}$$

where T_o = constant = horizontal component of the tension T in the cable.

Two special cases are common:

- *Parabolic cables.* The cable supports a load w that is uniformly distributed horizontally. The shape of the cable is a parabola given by

$$y = \frac{wx^2}{2T_o} \quad (x = 0 \text{ at lowest point}) \tag{1.2.21}$$

  In a symmetric cable, the tension is $T = \sqrt{T_o^2 + w^2x^2}$.
- *Catenary cables.* When the load w is uniformly distributed along the cable, the cable's shape is given by

$$y = \frac{T_o}{w}\left(\cosh\frac{wx}{T_o} - 1\right) \tag{1.2.22}$$

  The tension in the cable is $T = T_o + wy$.

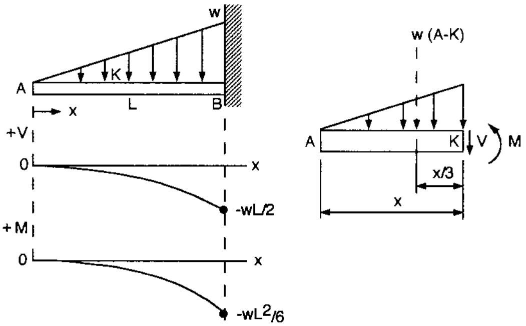

FIGURE 1.2.26 Shear force and bending moment diagrams for a cantilever beam.

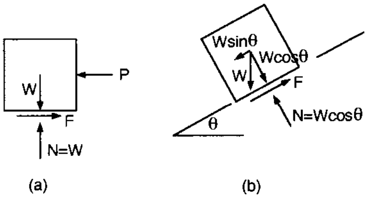

FIGURE 1.2.27 Models showing friction forces.

Friction

A friction force F (or $\mathcal{F}$, in typical other notation) acts between contacting bodies when they slide relative to one another, or when sliding tends to occur. This force is tangential to each body at the point of contact, and its magnitude depends on the normal force N pressing the bodies together and on the material and condition of the contacting surfaces. The material and surface properties are lumped together and represented by the coefficient of friction μ. The friction force opposes the force that tends to cause motion, as illustrated for two simple cases in Figure 1.2.27.

The friction forces F may vary from zero to a maximum value,

$$F_{\max} = \mu N \quad \left(0 \le F \le F_{\max}\right) \tag{1.2.23}$$

depending on the applied force that tends to cause relative motion of the bodies. The coefficient of kinetic friction μ_k (during sliding) is lower than the coefficient of static friction m or μ_s; μ_k depends on the speed of sliding and is not easily quantified.

Angle of Repose

The critical angle θ_c at which motion is impending is the angle of repose, where the friction force is at its maximum for a given block on an incline.

$$\tan\theta_c = \frac{F}{N} = \mu_s \tag{1.2.24}$$

Thus, θ_c is measured to obtain μ_s. Note that, even in the case of static, dry friction, μ_s depends on temperature; humidity; dust and other contaminants; oxide films; surface finish; and chemical reactions. The contact area and the normal force affect μ_s only when significant deformations of one or both bodies occur.

Classifications and Procedures for Solving Friction Problems

The directions of unknown friction forces are often, but not always, determined by inspection. The magnitude of the friction force is obtained from $F_{\max} = \mu_s N$ when it is known that motion is impending. Note that F may be less than $F_{\max}$. The major steps in solving problems of dry friction are organized in three categories as follows:

A. Given: bodies, forces, or coefficients of friction are known. Impending motion is not assured: $F \neq \mu_s N$.
   Procedure: to determine if equilibrium is possible:
   1. Construct the free-body diagram.
   2. Assume that the system is in equilibrium.
   3. Determine the friction and normal forces necessary for equilibrium.
   4. Results: (a) $F < \mu_s N$; the body is at rest; (b) $F > \mu_s N$; motion is occurring, so static equilibrium is not possible. Because there is motion, $F = \mu_k N$. Complete solution requires principles of dynamics.

B. Given: bodies, forces, or coefficients of friction are given. Impending motion is specified. $F = \mu_s N$ is valid.
   Procedure: to determine the unknowns:
   1. Construct the free-body diagram.
   2. Write $F = \mu_s N$ for all surfaces where motion is impending.
   3. Determine μ_s or the required forces from the equation of equilibrium.

C. Given: bodies, forces, and coefficients of friction are known. Impending motion is specified, but the exact motion is not given. The possible motions may be sliding, tipping, or rolling, or relative motion if two or more bodies are involved. Alternatively, the forces or coefficients of friction may need to be determined to produce a particular motion from several possible motions.
   Procedure: to determine the exact motion that may occur, or unknown quantities required:
   1. Construct the free-body diagram.
   2. Assume that motion is impending in one of the two or more possible ways. Repeat this for each possible motion and write the equation of equilibrium.
   3. Compare the results for the possible motions and select the likely event. Determine the required unknowns for any preferred motion.

Wedges and Screws

A wedge may be used to raise or lower a body. Thus, two directions of motion must be considered in each situation, with the friction forces always opposing the impending or actual motion. The self-locking aspect of a wedge may be of interest. The analysis is straightforward, using interrelated free-body diagrams and equilibrium equations.

Screw threads are special applications of the concept of wedges. Square threads are the easiest to model and analyze. The magnitude M of the moment of a couple required to move a square-threaded screw against an axial load P is

$$M = Pr\tan(\alpha + \phi) \tag{1.2.25}$$

where

r = radius of the screw
$\alpha = \tan^{-1}(L/2\pi r) = \tan^{-1}(np/2\pi r)$
L = lead = advancement per revolution
n = multiplicity of threads
p = pitch = distance between similar points on adjacent threads
$\phi = \tan^{-1}\mu$

The relative values of α and ϕ control whether a screw is self-locking; $\phi > \alpha$ is required for a screw to support an axial load without unwinding.

Disk Friction

Flat surfaces in relative rotary motion generate a friction moment M opposing the motion. For a hollow member with radii R_o and R_i, under an axial force P,

$$M = \frac{2}{3}\mu P \frac{R_o^3 - R_i^3}{R_o^2 - R_i^2} \tag{1.2.26}$$

The friction moment tends to decrease (down to about 75% of its original value) as the surfaces wear. Use the appropriate μ_s or μ_k value.

Axle Friction

The friction moment M of a rotating axle in a journal bearing (sliding bearing) is approximated (if μ is low) as

$$M = Pr\mu \tag{1.2.27}$$

where

P = transverse load on the axle
r = radius of the axle

Use the appropriate μ_s or μ_k value.

Rolling Resistance

Rolling wheels and balls have relatively low resistance to motion compared to sliding. This resistance is caused by internal friction of the materials in contact, and it may be difficult to predict or measure.

A coefficient of rolling resistance a is defined with units of length,

$$a \cong \frac{Fr}{P} \tag{1.2.28}$$

where

r = radius of a wheel rolling on a flat surface
F = minimum horizontal force to maintain constant speed of rolling
P = load on wheel

Values of a range upward from a low of about 0.005 mm for hardened steel elements.

Belt Friction

The tensions T_1 and T_2 of a belt, rope, or wire on a pulley or drum are related as

$$T_2 = T_1 e^{\mu\beta} \qquad \left(T_2 > T_1\right) \tag{1.2.29}$$

where β = total angle of belt contact, radians ($\beta = 2\pi n$ for a member wrapped around a drum n times). Use μ_s for impending slipping and μ_k for slipping.

For a V belt of belt angle 2ϕ,

$$T_2 = T_1 e^{\mu\beta/\sin\phi}$$

Work and Potential Energy

Work is a scalar quantity. It is the product of a force and the corresponding displacement. Potential energy is the capacity of a system to do work on another system. These concepts are advantageous in the analysis of equilibrium of complex systems, in dynamics, and in mechanics of materials.

Work of a Force

The work U of a constant force **F** is

$$U = Fs \tag{1.2.30}$$

where s = displacement of a body in the direction of the vector **F**.

For a displacement along an arbitrary path from point 1 to 2, with $d\mathbf{r}$ tangent to the path,

$$U = \int_1^2 \mathbf{F} \cdot d\mathbf{r} = \int_1^2 \left(F_x\, dx + F_y\, dy + F_z\, dz\right)$$

In theory, there is no work when:

- A force is acting on a fixed, rigid body ($dr = 0$, $dU = 0$).
- A force acts perpendicular to the displacement ($\mathbf{F} \cdot d\mathbf{r} = 0$).

Work of a Couple

A couple of magnitude M does work

$$U = M\theta \tag{1.2.31}$$

where θ = angular displacement (radians) in the same plane in which the couple is acting.

In a rotation from angular position α to β,

$$U = \int_{\alpha}^{\beta} \mathbf{M} \cdot d\theta = \int_{\alpha}^{\beta} \left(M_x \; d\theta_x + M_y \; d\theta_y + M_z \; d\theta_z \right)$$

Virtual Work

The concept of virtual work (through imaginary, infinitesimal displacements within the constraints of a system) is useful to analyze the equilibrium of complex systems. The virtual work of a force **F** or moment **M** is expressed as

$$\delta U = \mathbf{F} \cdot \delta \mathbf{r}$$

$$\delta U = \mathbf{M} \cdot \delta \theta$$

There is equilibrium if

$$\delta U = \sum_{i=1}^{m} \mathbf{F}_i \cdot \delta \mathbf{r}_i + \sum_{j=1}^{n} \mathbf{M}_i \cdot \delta \theta_j = 0 \tag{1.2.32}$$

where the subscripts refer to individual forces or couples and the corresponding displacements, ignoring frictional effects.

Mechanical Efficiency of Real Systems

Real mechanical systems operate with frictional losses, so

$$\underset{\text{(output work)}}{\text{input work} = \text{useful work}} + \text{work of friction}$$

The mechanical efficiency η of a machine is

$$\eta = \frac{\text{output work}}{\text{input work}} = \frac{\text{useful work}}{\text{total work required}}$$

$$0 < \eta < 1$$

Gravitational Work and Potential Energy

The potential of a body of weight W to do work because of its relative height h with respect to an arbitrary level is defined as its potential energy. If h is the vertical (y) distance between level 1 and a lower level 2, the work of weight W in descending is

$$U_{12} = \int_{1}^{2} W \, dy = Wh = \text{potential energy of the body at level 1 with respect to level 2}$$

The work of weight W in rising from level 2 to level 1 is

$$U_{21} = \int_2^1 -W\,dy = -Wh = \text{potential energy of the body at level 2 with respect to level 1}$$

Elastic Potential Energy

The potential energy of elastic members is another common form of potential energy in engineering mechanics. For a linearly deforming helical spring, the axial force F and displacement x are related by the spring constant k,

$$F = kx \qquad (\text{similarly, } M = k\theta \text{ for a torsion spring})$$

The work U of a force F on an initially undeformed spring is

$$U = \frac{1}{2}kx^2 \tag{1.2.33}$$

In the general case, deforming the spring from position x_1 to x_2,

$$U = \frac{1}{2}k\left(x_2^2 - x_1^2\right)$$

Notation for Potential Energy

The change in the potential energy V of a system is

$$U = -\Delta V$$

Note that negative work is done by a system while its own potential energy is increased by the action of an external force or moment. The external agent does positive work at the same time because it acts in the same direction as the resulting displacement.

Potential Energy at Equilibrium

For equilibrium of a system,

$$\frac{dV}{dq} = 0$$

where q = an independent coordinate along which displacement is possible.

For a system with n degrees of freedom,

$$\frac{\partial V}{\partial q_i} = 0, \qquad i = 1, 2, \ldots, n$$

Equilibrium is stable if $(d^2V/dq^2) > 0$.
Equilibrium is unstable if $(d^2V/dq^2) < 0$.
Equilibrium is neutral only if all derivatives of V are zero.

In cases of complex configurations, evaluate derivatives of higher order as well.

Moments of Inertia

The topics of inertia are related to the methods of first moments. They are traditionally presented in statics in preparation for application in dynamics or mechanics of materials.

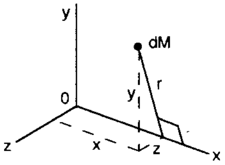

FIGURE 1.2.28 Mass element dM in xyz coordinates.

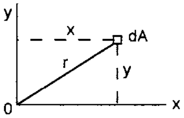

FIGURE 1.2.29 Area A in the xy plane.

Moments of Inertia of a Mass

The moment of inertia dI_x of an elemental mass dM about the x axis (Figure 1.2.28) is defined as

$$dI_x = r^2\ dM = \left(y^2 + z^2\right) dM$$

where r is the nearest distance from dM to the x axis. The moments of inertia of a body about the three coordinate axes are

$$\begin{aligned} I_x &= \int r^2\ dM = \int \left(y^2 + z^2\right) dM \\ I_y &= \int \left(x^2 + z^2\right) dM \\ I_z &= \int \left(x^2 + y^2\right) dM \end{aligned} \qquad (1.2.34)$$

Radius of Gyration. The radius of gyration r_g is defined by $r_g = \sqrt{I_x / M}$, and similarly for any other axis. It is based on the concept of the body of mass M being replaced by a point mass M (same mass) at a distance r_g from a given axis. A thin strip or shell with all mass essentially at a constant distance r_g from the axis of reference is equivalent to a point mass for some analyses.

Moment of Inertia of an Area

The moment of inertia of an elemental area dA about the x axis (Figure 1.2.29) is defined as

$$dI_x = y^2\ dA$$

where y is the nearest distance from dA to the x axis. The moments of inertia (second moments) of the area A about the x and y axes (because A is in the xy plane) are

$$I_x = \int y^2\ dA \qquad I_y = \int x^2\ dA \qquad (1.2.35)$$

The radius of gyration of an area is defined the same way as it is for a mass: $r_g = \sqrt{I_x / A}$, etc.

Polar Moment of Inertia of an Area

The polar moment of inertia is defined with respect to an axis perpendicular to the area considered. In Figure 1.2.29, this may be the z axis. The polar moment of inertia in this case is

$$J_O = \int r^2\ dA = \int \left(x^2 + y^2\right) dA = I_x + I_y \qquad (1.2.36)$$

Parallel-Axis Transformations of Moments of Inertia

It is often convenient first to calculate the moment of inertia about a centroidal axis and then transform this with respect to a parallel axis. The formulas for the transformations are

$$\begin{aligned} I &= I_C + Md^2 && \text{for a mass } M \\ I &= I_C + Ad^2 && \text{for an area } A \\ J_O &= J_C + Ad^2 && \text{for an area } A \end{aligned} \tag{1.2.37}$$

where

I or J_O = moment of inertia of M or A about any line,

I_C or J_C = moment of inertia of M or A about a line through the mass center or centroid and parallel to ℓ

d = nearest distance between the parallel lines

Note that one of the two axes in each equation must be a centroidal axis.

Products of Inertia

The products of inertia for areas and masses and the corresponding parallel-axis formulas are defined in similar patterns. Using notations in accordance with the preceding formulas, products of inertia are

$$\begin{aligned} I_{xy} &= \int xy\,dA \quad \text{for area,} && \text{or} \quad \int xy\,dM \quad \text{for mass} \\ I_{yz} &= \int yz\,dA && \text{or} \quad \int yz\,dM \\ I_{xz} &= \int xz\,dA && \text{or} \quad \int xz\,dM \end{aligned} \tag{1.2.38}$$

Parallel-axis formulas are

$$\begin{aligned} I_{xy} &= I_{x'y'} + A\,d_x d_y \quad \text{for area,} && \text{or} \quad I_{x'y'} + M\,d_x d_y \quad \text{for mass} \\ I_{yz} &= I_{y'z'} + A\,d_y d_z && \text{or} \quad I_{y'z'} + M\,d_y d_z \\ I_{xz} &= I_{x'z'} + A\,d_x d_z && \text{or} \quad I_{x'z'} + M\,d_x d_z \end{aligned} \tag{1.2.39}$$

Note that the moment of inertia is always positive. The product of inertia may be positive, negative, or zero; it is zero if *x* or *y* (or both) is an axis of symmetry of the area. Transformations of known moments and product of inertia to axes that are inclined to the original set of axes are possible but not covered here. These transformations are useful for determining the principal (maximum and minimum) moments of inertia and the principal axes when the area or body has no symmetry. The principal moments of inertia for objects of simple shape are available in many texts.

1.3 Dynamics

Stephen M. Birn and Bela I. Sandor

The two major categories in dynamics are kinematics and kinetics. **Kinematics** involves the time- and geometry-dependent motion of a particle, rigid body, deformable body, or a fluid without considering the forces that cause the motion. It relates position, velocity, acceleration, and time. **Kinetics** combines the concepts of kinematics and the forces that cause the motion.

Kinematics of Particles

Scalar Method

The scalar method of particle kinematics is adequate for one-dimensional analysis. A particle is a body whose dimensions can be neglected (in some analyses, very large bodies are considered particles). The equations described here are easily adapted and applied to two and three dimensions.

Average and Instantaneous Velocity

The average velocity of a particle is the change in distance divided by the change in time. The instantaneous velocity is the particle's velocity at a particular instant.

$$v_{ave} = \frac{\Delta x}{\Delta t} \qquad v_{inst} = \lim_{\Delta t \to 0} \frac{\Delta x}{\Delta t} = \frac{dx}{dt} = \dot{x} \tag{1.3.1}$$

Average and Instantaneous Acceleration

The average acceleration is the change in velocity divided by the change in time. The instantaneous acceleration is the particle's acceleration at a particular instant.

$$a_{ave} = \frac{\Delta v}{\Delta t} \qquad a_{inst} = \lim_{\Delta t \to 0} \frac{\Delta v}{\Delta t} = \frac{dv}{dt} = \dot{v} = \ddot{x} \tag{1.3.2}$$

Displacement, velocity, acceleration, and time are related to one another. For example, if velocity is given as a function of time, the displacement and acceleration can be determined through integration and differentiation, respectively. The following example illustrates this concept.

Example 8

A particle moves with a velocity $v(t) = 3t^2 - 8t$. Determine $x(t)$ and $a(t)$, if $x(0) = 5$.

Solution.

1. Determine $x(t)$ by integration.

$$v = \frac{dx}{dt}$$

$$v\,dt = dx$$

$$\int 3t^2 - 8t\,dt = \int dx$$

$$t^3 - 4t^2 + C = x$$

$$\text{from } x(0) = 5 \qquad C = 5$$

$$x(t) = t^3 - 4t^2 + 5$$

2. Determine $a(t)$ by differentiation.

$$a = \frac{dv}{dt} = \frac{d}{dt}\left(3t^2 - 8t\right)$$

$$a(t) = 6t - 8$$

Four key points can be seen from these graphs (Figure 1.3.1).

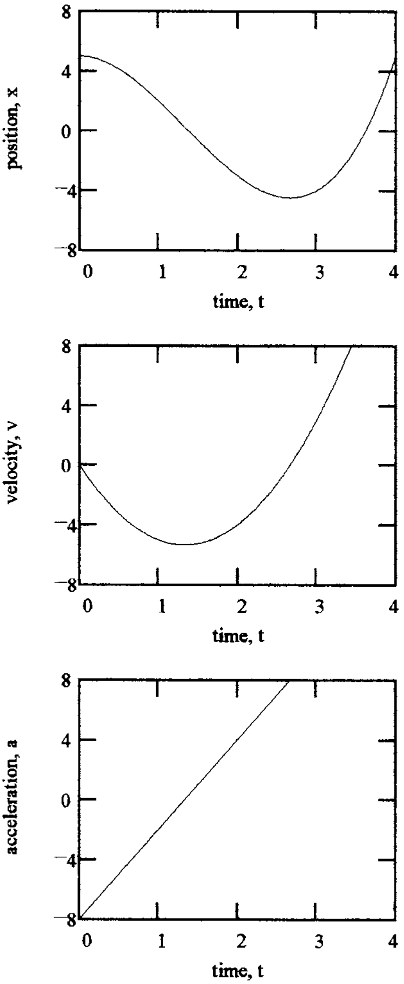

FIGURE 1.3.1 Plots of a particle's kinematics.

1. $v = 0$ at the local maximum or minimum of the x-t curve.
2. $a = 0$ at the local maximum or minimum of the v-t curve.
3. The area under the v-t curve in a specific time interval is equal to the net displacement change in that interval.
4. The area under the a-t curve in a specific time interval is equal to the net velocity change in that interval.

Useful Expressions Based on Acceleration

Equations for nonconstant acceleration are

$$a = \frac{dv}{dt} \Rightarrow \int_{v_0}^{v} dv = \int_{0}^{t} a\,dt \tag{1.3.3}$$

$$v\,dv = a\,dx \Rightarrow \int_{v_0}^{v} v\,dv = \int_{x_0}^{x} a\,dx \tag{1.3.4}$$

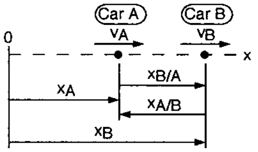

FIGURE 1.3.2 Relative motion of two particles along a straight line.

Equations for constant acceleration (projectile motion; free fall) are

$$v = at + v_0$$
$$v^2 = 2a\left(x - x_0\right) + v_0^2 \tag{1.3.5}$$
$$x = \frac{1}{2}at^2 + v_0 t + x_0$$

These equations are only to be used when the acceleration is known to be a constant. Other expressions are available, depending on how a variable acceleration is given as a function of time, velocity, or displacement.

Scalar Relative Motion Equations

The concept of relative motion can be used to determine the displacement, velocity, and acceleration between two particles that travel along the same line. Equation (1.3.6) provides the mathematical basis for this method. These equations can also be used when analyzing two points on the same body that are not attached rigidly to each other (Figure 1.3.2).

$$x_{B/A} = x_B - x_A$$
$$v_{B/A} = v_B - v_A \tag{1.3.6}$$
$$a_{B/A} = a_B - a_A$$

The notation B/A represents the displacement, velocity, or acceleration of particle B as seen from particle A. Relative motion can be used to analyze many different degrees-of-freedom systems. A degree of freedom of a mechanical system is the number of independent coordinate systems needed to define the position of a particle.

Vector Method

The vector method facilitates the analysis of two- and three-dimensional problems. In general, curvilinear motion occurs and is analyzed using a convenient coordinate system.

Vector Notation in Rectangular (Cartesian) Coordinates

Figure 1.3.3 illustrates the vector method. The mathematical method is based on determining **v** and **a** as functions of the position vector **r**. Note that the time derivatives of unit vectors are zero when the *xyz* coordinate system is fixed. The scalar components $(\dot{x}, \dot{y}, \ddot{x}, \ldots)$ can be determined from the appropriate scalar equations previously presented that only include the quantities relevant to the coordinate direction considered.

$$\mathbf{r} = x\mathbf{i} + y\mathbf{j} + z\mathbf{k}$$
$$\mathbf{v} = \frac{d\mathbf{r}}{dt} = \frac{dx}{dt}\mathbf{i} + \frac{dy}{dt}\mathbf{j} + \frac{dz}{dt}\mathbf{k} = \dot{x}\mathbf{i} + \dot{y}\mathbf{j} + \dot{z}\mathbf{k} \tag{1.3.7}$$
$$\mathbf{a} = \frac{d\mathbf{v}}{dt} = \frac{d^2x}{dt^2}\mathbf{i} + \frac{d^2y}{dt^2}\mathbf{j} + \frac{d^2z}{dt^2}\mathbf{k} = \ddot{x}\mathbf{i} + \ddot{y}\mathbf{j} + \ddot{z}\mathbf{k}$$

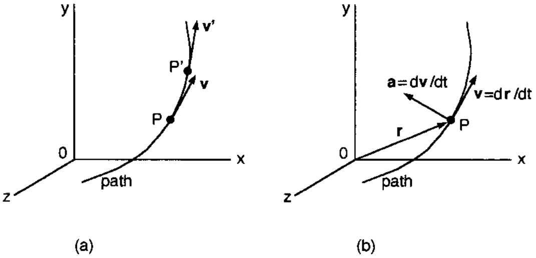

FIGURE 1.3.3 Vector method for a particle.

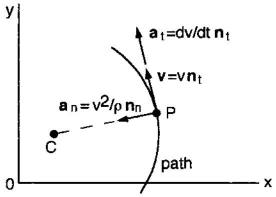

FIGURE 1.3.4 Tangential and normal components. *C* is the center of curvature.

A few key points should be remembered when considering curvilinear motion. First, the instantaneous velocity vector is *always* tangent to the path of the particle. Second, the speed of the particle is the magnitude of the velocity vector. Third, the acceleration vector is not tangent to the path of the particle and not collinear with **v** in curvilinear motion.

Tangential and Normal Components

Tangential and normal components are useful in analyzing velocity and acceleration. Figure 1.3.4 illustrates the method and Equation (1.3.8) comprises the governing equations for it.

$$\begin{gathered} \mathbf{v} = v\mathbf{n}_t \\ \mathbf{a} = a_t\mathbf{n}_t + a_n\mathbf{n}_n \\ a_t = \frac{dv}{dt} \qquad a_n = \frac{v^2}{\rho} \\ \rho = \frac{\left[1+\left(dy/dx\right)^2\right]^{3/2}}{d^2y/dx^2} \\ \rho = r = \text{constant for a circular path} \end{gathered} \tag{1.3.8}$$

The *osculating plane* contains the unit vectors $\mathbf{n}_t$ and $\mathbf{n}_n$, thus defining a plane. When using normal and tangential components, it is common to forget to include the component of normal acceleration, especially if the particle travels at a constant speed along a curved path. For a particle that moves in circular motion,

$$\begin{gathered} v = r\dot{\theta} = r\omega \\ a_t = \frac{dv}{dt} = r\ddot{\theta} = r\alpha \\ a_n = \frac{v^2}{r} = r\dot{\theta}^2 = r\omega^2 \end{gathered} \tag{1.3.9}$$

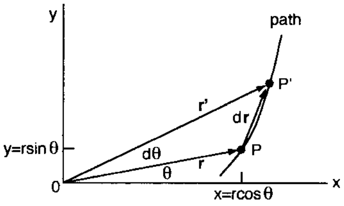

FIGURE 1.3.5 Motion of a particle in polar coordinates.

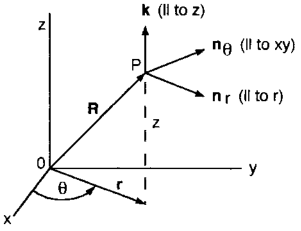

FIGURE 1.3.6 Motion of a particle in cylindrical coordinates.

Motion of a Particle in Polar Coordinates

Sometimes it may be best to analyze particle motion by using polar coordinates as follows (Figure 1.3.5):

$$\mathbf{v} = \dot{r}\mathbf{n}_r + r\dot{\theta}\mathbf{n}_\theta \qquad \text{(always tangent to the path)}$$

$$\frac{d\theta}{dt} = \dot{\theta} = \omega, \ \ \text{rad/s} \tag{1.3.10}$$

$$\mathbf{a} = \left(\ddot{r} - r\dot{\theta}^2\right)\mathbf{n}_r + \left(r\ddot{\theta} + 2\dot{r}\dot{\theta}\right)\mathbf{n}_\theta$$

For a particle that moves in circular motion the equations simplify to

$$\frac{d\dot{\theta}}{dt} = \ddot{\theta} = \dot{\omega} = \alpha, \ \ \text{rad/s}^2$$

$$\mathbf{v} = r\dot{\theta}\mathbf{n}_\theta \tag{1.3.11}$$

$$\mathbf{a} = -r\dot{\theta}^2\mathbf{n}_r + r\ddot{\theta}\mathbf{n}_\theta$$

Motion of a Particle in Cylindrical Coordinates

Cylindrical coordinates provide a means of describing three-dimensional motion as illustrated in Figure 1.3.6.

$$\begin{gathered}\mathbf{v} = \dot{r}\mathbf{n}_r + r\dot{\theta}\mathbf{n}_\theta + \dot{z}\mathbf{k} \\ \mathbf{a} = \left(\ddot{r} - r\dot{\theta}^2\right)\mathbf{n}_r + \left(r\ddot{\theta} + 2\dot{r}\dot{\theta}\right)\mathbf{n}_\theta + \ddot{z}\mathbf{k}\end{gathered} \tag{1.3.12}$$

Motion of a Particle in Spherical Coordinates

Spherical coordinates are useful in a few special cases but are difficult to apply to practical problems. The governing equations for them are available in many texts.

Relative Motion of Particles in Two and Three Dimensions

Figure 1.3.7 shows relative motion in two and three dimensions. This can be used in analyzing the translation of coordinate axes. Note that the unit vectors of the coordinate systems are the same. Subscripts are arbitrary but must be used consistently because $\mathbf{r}_{B/A} = -\mathbf{r}_{A/B}$, etc.

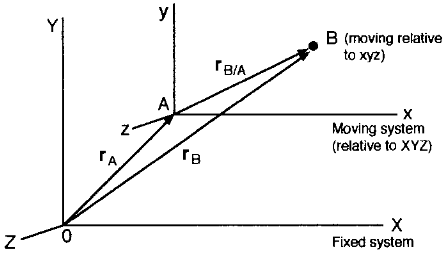

FIGURE 1.3.7 Relative motion using translating coordinates.

$$\begin{aligned} \mathbf{r}_B &= \mathbf{r}_A + \mathbf{r}_{B/A} \\ \mathbf{v}_B &= \mathbf{v}_A + \mathbf{v}_{B/A} \\ \mathbf{a}_B &= \mathbf{a}_A + \mathbf{a}_{B/A} \end{aligned} \tag{1.3.13}$$

Kinetics of Particles

Kinetics combines the methods of kinematics and the forces that cause the motion. Several useful methods of analysis are based on Newton's second law.

Newton's Second Law

The magnitude of the acceleration of a particle is directly proportional to the magnitude of the resultant force acting on it and inversely proportional to its mass. The direction of the acceleration is the same as the direction of the resultant force.

$$\mathbf{F} = m\mathbf{a} \tag{1.3.14}$$

where m is the particle's mass. Three key points should be remembered when applying this equation.

1. **F** is the resultant force.
2. **a** is the acceleration of a single particle (use $\mathbf{a}_C$ for the center of mass for a system of particles).
3. The motion is in a nonaccelerating reference frame.

Equations of Motion

The **equations of motion** for vector and scalar notations in rectangular coordinates are

$$\begin{gathered} \sum \mathbf{F} = m\mathbf{a} \\ \sum F_x = ma_x \qquad \sum F_y = ma_y \qquad \sum F_z = ma_z \end{gathered} \tag{1.3.15}$$

The equations of motion for tangential and normal components are

$$\begin{gathered} \sum F_n = ma_n = m\frac{v^2}{\rho} \\ \sum F_t = ma_t = m\dot{v} = mv\frac{dv}{ds} \end{gathered} \tag{1.3.16}$$

The equations of motion in a polar coordinate system (radial and transverse components) are

$$\begin{aligned} \sum F_r &= ma_r = m\left(\ddot{r} - r\dot{\theta}^2\right) \\ \sum F_\theta &= ma_\theta = m\left(r\ddot{\theta} - 2\dot{r}\dot{\theta}\right) \end{aligned} \tag{1.3.17}$$

Procedure for Solving Problems

1. Draw a free-body diagram of the particle showing all forces. (The free-body diagram will look unbalanced because the particle is not in static equilibrium.)
2. Choose a convenient nonaccelerating reference frame.
3. Apply the appropriate equations of motion for the reference frame chosen to calculate the forces or accelerations applied to the particle.
4. Use kinematics equations to determine velocities and/or displacements if needed.

Work and Energy Methods

Newton's second law is not always the most convenient method for solving a problem. Work and energy methods are useful in problems involving changes in displacement and velocity, if it is not necessary to calculate accelerations.

Work of a Force

The total work of a force **F** in displacing a particle *P* from position 1 to position 2 along any path is

$$U_{12} = \int_1^2 \mathbf{F} \cdot d\mathbf{r} = \int_1^2 \left(F_x\ dx + F_y\ dy + F_z\ dz\right) \tag{1.3.18}$$

Potential and Kinetic Energies

- Gravitational potential energy: $U_{12} = \int_1^2 W\ dy = Wh = V_g$, where W = weight and h = vertical elevation difference
- Elastic potential energy: $U = \int_{x_1}^{x_2} kx\ dx = \frac{1}{2}k(x_2^2 - x_1^2) = V_e$, where k = spring constant
- Kinetic energy of a particle: $T = 1/2mv^2$, where m = mass and v = magnitude of velocity.

Kinetic energy can be related to work by the *principle of work* and *energy*,

$$U_{12} = T_2 - T_1 \tag{1.3.19}$$

where

U_{12} is the work of a force on the particle moving it from position 1 to position 2.
T_1 is the kinetic energy of the particle at position 1 (initial kinetic energy).
T_2 is the kinetic energy of the particle at position 2 (final kinetic energy).

Power

Power is defined as work done in a given time.

$$\text{power} = \frac{dU}{dt} = \frac{\mathbf{F} \cdot d\mathbf{r}}{dt} = \mathbf{F} \cdot \mathbf{v} \tag{1.3.20}$$

where **v** is velocity.

Important units and conversions of power are

$$1\ \mathrm{W} = 1\ \mathrm{J/s} = 1\ \mathrm{N}\cdot\mathrm{m/s}$$

$$1\ \mathrm{hp} = 550\ \mathrm{ft}\cdot\mathrm{lb/s} = 33{,}000\ \mathrm{ft}\cdot\mathrm{lb/min} = 746\ \mathrm{W}$$

$$1\ \mathrm{ft}\cdot\mathrm{lb/s} = 1.356\ \mathrm{J/s} = 1.356\ \mathrm{W}$$

Advantages and Disadvantages of the Energy Method

Using the energy method in engineering problems offers four advantages:

1. Accelerations do not need to be determined.
2. Modifications of problems are easy to make in the analysis.
3. Scalar quantities are summed, even if the path of motion is complex.
4. Forces that do not do work are ignored.

The main disadvantage of the energy method is that quantities of work or energy cannot be used to determine accelerations or forces that do no work. In these instances, Newton's second law must be used.

Conservative Systems and Potential Functions

Sometimes it is useful to assume a conservative system where friction does not oppose the motion of the particle. The work in a conservative system is independent of the path of the particle, and potential energy is defined as

$$\underbrace{U_{12}}_{\substack{\text{work of } \mathbf{F}\\ \text{from 1 to 2}}} = \underbrace{-\Delta V}_{\substack{\text{difference of potential}\\ \text{energies at 1 and 2}}}$$

A special case is one in which the particle moves in a closed path. One trip around the path is called a cycle.

$$U = \oint dU = \oint \mathbf{F}\cdot d\mathbf{r} = \oint \left(F_x\ dx + F_y\ dy + F_z\ dz\right) = 0 \qquad (1.3.21)$$

In advanced analysis, differential changes in the potential energy function (V) are calculated by the use of partial derivatives,

$$\mathbf{F} = F_x\mathbf{i} + F_y\mathbf{j} + F_z\mathbf{k} = -\left(\frac{\partial V}{\partial x}\mathbf{i} + \frac{\partial V}{\partial y}\mathbf{j} + \frac{\partial V}{\partial z}\mathbf{k}\right)$$

Conservation of Mechanical Energy

Conservation of mechanical energy is assumed if kinetic energy (T) and potential energy (V) change back and forth in a conservative system (the dissipation of energy is considered negligible). Equation (1.3.22) formalizes such a situation, in which position 1 is the initial state and position 2 is the final state. The reference (datum) should be chosen to reduce the number of terms in the equation.

$$T_1 + V_1 = T_2 + V_2 \qquad (1.3.22)$$

Linear and Angular Momentum Methods

The concept of linear momentum is useful in engineering when the accelerations of particles are not known but the velocities are. The linear momentum is derived from Newton's second law,

$$\mathbf{G} = m\mathbf{v} \qquad (1.3.23)$$

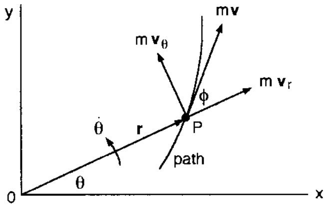

FIGURE 1.3.8 Definition of angular momentum for a particle.

The time rate of change of linear momentum is equal to force. When $m\mathbf{v}$ is constant, the conservation of momentum equation results,

$$\sum \mathbf{F} = \dot{\mathbf{G}} = \frac{d}{dt}(m\mathbf{v})$$

$$\sum \mathbf{F} = 0 \qquad m\mathbf{v} = \text{constant} \qquad (\text{conservation of momentum}) \tag{1.3.24}$$

The method of angular momentum is based on the momentum of a particle about a fixed point, using the vector product in the general case (Figure 1.3.8).

$$\mathbf{H}_O = \mathbf{r} \times m\mathbf{v} \tag{1.3.25}$$

The angular momentum equation can be solved using a scalar method if the motion of the particle remains in a plane,

$$\mathbf{H}_O = mrv\sin\phi = mrv_\theta = mr^2\dot\theta$$

If the particle does not remain in a plane, then the general space motion equations apply. They are derived from the cross product $\mathbf{r} \times m\mathbf{v}$,

$$\begin{gathered} \mathbf{H}_O = H_x\mathbf{i} + H_y\mathbf{j} + H_z\mathbf{k} \\ H_x = m(yv_z - zv_y) \\ H_y = m(zv_x - xv_z) \\ H_z = m(xv_y - yv_x) \end{gathered} \tag{1.3.25a}$$

Time Rate of Change of Angular Momentum

In general, a force acting on a particle changes its angular momentum: *the time rate of change of angular momentum of a particle is equal to the sum of the moments of the forces acting on the particle.*

Vectors: $$\dot{\mathbf{H}}_O = \frac{d}{dt}(\mathbf{r} \times m\mathbf{v}) = \mathbf{r} \times \sum \mathbf{F} = \sum \mathbf{H}_O \tag{1.3.26}$$

Scalars: $$\sum M_x = \dot H_x \qquad \sum M_y = \dot H_y \qquad \sum M_z = \dot H_z$$

$$\sum \mathbf{M}_O = 0 \qquad \mathbf{H}_O = \mathbf{r} \times m\mathbf{v} = \text{constant}$$

$$(\text{conservation of angular momentum}) \tag{1.3.27}$$

A special case is when the sum of the moments about point O is zero. This is the conservation of angular momentum. In this case (motion under a central force), if the distance r increases, the velocity must decrease, and vice versa.

Impulse and Momentum

Impulse and momentum are important in considering the motion of particles in impact. The linear impulse and momentum equation is

$$\underbrace{\int_{t_1}^{t_2} \mathbf{F}\, dt}_{\text{impulse}} = \underbrace{m\mathbf{v}_2}_{\substack{\text{final}\\\text{momentum}}} - \underbrace{m\mathbf{v}_1}_{\substack{\text{initial}\\\text{momentum}}} \tag{1.3.28}$$

Conservation of Total Momentum of Particles

Conservation of total momentum occurs when *the initial momentum of n particles is equal to the final momentum of those same n particles*,

$$\underbrace{\sum_i^n \left(m_i \mathbf{v}_i\right)_1}_{\substack{\text{total initial}\\\text{momentum at time } t_1}} = \underbrace{\sum_i^n \left(m_i \mathbf{v}_i\right)_2}_{\substack{\text{total final}\\\text{momentum at time } t_2}} \tag{1.3.29}$$

When considering the response of two deformable bodies to direct central impact, the coefficient of restitution is used. This coefficient e relates the initial velocities of the particles to the final velocities,

$$e = \frac{v_{Bf} - v_{Af}}{v_A - v_B} = \frac{|\text{relative velocity of separation}|}{|\text{relative velocity of approach}|} \tag{1.3.30}$$

For real materials, $0 < e < 1$. If both bodies are *perfectly elastic*, $e = 1$, and if either body is *perfectly plastic*, $e = 0$.

Kinetics of Systems of Particles

There are three distinct types of systems of particles: discrete particles; continuous particles in fluids; and continuous particles in rigid or deformable bodies. This subsection considers methods for discrete particles that have relevance to the mechanics of solids. Methods involving particles in rigid bodies will be discussed in later sections.

Newton's Second Law Applied to a System of Particles

Newton's second law can be extended to systems of particles,

$$\sum_{i=1}^n \mathbf{F}_i = \sum_{i=1}^n m_i \mathbf{a}_i \tag{1.3.31}$$

Motion of the Center of Mass

The center of mass of a system of particles moves under the action of internal and external forces as if the total mass of the system and all the external forces were at the center of mass. Equation (1.3.32) defines the position, velocity, and acceleration of the center of mass of a system of particles.

$$m\mathbf{r}_C = \sum_{i=1}^n m_i \mathbf{r}_i \qquad m\mathbf{v}_C = \sum_{i=1}^n m_i \mathbf{v}_i \qquad m\mathbf{a}_C = \sum_{i=1}^n m_i \mathbf{a}_i \qquad \sum \mathbf{F} = m\mathbf{a}_C \tag{1.3.32}$$

Work and Energy Methods for a System of Particles

Gravitational Potential Energy. The gravitational potential energy of a system of particles is the sum of the potential energies of the individual particles of the system:

$$V_g = g\sum_{i=1}^{n} m_i y_i = \sum_{i=1}^{n} W_i y_i = mgy_C = Wy_C \tag{1.3.33}$$

where

g = acceleration of gravity
y_C = vertical position of center of mass with respect to a reference level

Kinetic energy. The kinetic energy of a system of particles is the sum of the kinetic energies of the individual particles of the system with respect to a fixed reference frame,

$$T = \frac{1}{2}\sum_{i=1}^{n} m_i v_i^2 \tag{1.3.34}$$

A translating reference frame located at the mass center C of a system of particles can be used advantageously, with

$$T = \underbrace{\frac{1}{2}mv_C^2}_{\substack{\text{motion of total}\\ \text{mass imagined to}\\ \text{be concentrated at C}}} + \underbrace{\frac{1}{2}\sum_{i=1}^{n} m_i v_i'^2}_{\substack{\text{motion of all}\\ \text{particles relative to } C}} \qquad (v' \text{ are with respect to a translating frame}) \tag{1.3.35}$$

Work and Energy

The work and energy equation for a system of particles is similar to the equation stated for a single particle:

$$\begin{gathered}\sum_{i=1}^{n} U_i' = \sum_{i=1}^{n} V_i + \sum_{i=1}^{n} T_i \\ U' = \Delta V + \Delta T\end{gathered} \tag{1.3.36}$$

Momentum Methods for a System of Particles

Moments of Forces on a System of Particles. The moments of external forces on a system of particles about a point O are given by

$$\sum_{i=1}^{n}\left(\mathbf{r}_i \times \mathbf{F}_i\right) = \sum_{i=1}^{n} \mathbf{M}_{i_O} + \sum_{i=1}^{n}\left(\mathbf{r}_i \times m_i \mathbf{a}_i\right) \tag{1.3.37}$$

Linear and Angular Momenta of a System of Particles. The resultant of the external forces on a system of particles equals the time rate of change of linear momentum of that system:

$$\mathbf{G} = \sum_{i=1}^{n} m_i \mathbf{v}_i \qquad \sum \mathbf{F} = \dot{\mathbf{G}} \tag{1.3.38}$$

The angular momentum equation for a system of particles about a fixed point O is

$$\mathbf{H}_O = \sum_{i=1}^{n} \left(\mathbf{r}_i \times m_i \mathbf{a}_i\right)$$

$$\sum \mathbf{M}_O = \dot{\mathbf{H}}_O = \sum_{i=1}^{n} \left(\mathbf{r}_i \times m_i \mathbf{a}_i\right) \tag{1.3.39}$$

This last equation means that *the resultant of the moments of the external forces on a system of particles equals the time rate of change of angular momentum of that system.*

Angular Momentum about the Center of Mass

The preceding equations work well for stationary reference frames, but sometimes a special approach may be useful, noting that *the angular momentum of a system of particles about its center of mass C is the same whether it is observed from a fixed frame at point O or from the centroidal frame, which may be translating but not rotating*. In this case

$$\mathbf{H}_O = \mathbf{H}_C + \mathbf{r}_C \times m\mathbf{v}_C$$

$$\sum \mathbf{M}_O = \dot{\mathbf{H}}_C + \mathbf{r}_C \times m\mathbf{a}_C \tag{1.3.40}$$

Conservation of Momentum

The conservation of momentum equations for a system of particles is analogous to that for a single particle.

$$\left.\begin{aligned} \mathbf{G} &= \text{constant} \\ \mathbf{H}_O &= \text{constant} \\ \mathbf{H}_C &= \text{constant} \end{aligned}\right\} \quad \text{not the same constants in general}$$

Impulse and Momentum of a System of Particles

The linear impulse momentum for a system of particles is

$$\sum_{i=1}^{n} \int_{t_1}^{t_2} \mathbf{F}_i \, dt = \mathbf{G}_2 - \mathbf{G}_1 = m\mathbf{v}_{C_2} - m\mathbf{v}_{C_1} \tag{1.3.41}$$

The angular impulse momentum for a system of particles is

$$\sum_{i=1}^{n} \int_{t_1}^{t_2} \mathbf{M}_{i_O} \, dt = \mathbf{H}_{O_2} - \mathbf{H}_{O_1} \tag{1.3.42}$$

Kinematics of Rigid Bodies

Rigid body kinematics is used when the methods of particle kinematics are inadequate to solve a problem. A rigid body is defined as one in which the particles are rigidly connected. This assumption allows for some similarities to particle kinematics. The two kinds of rigid body motion are translation and rotation. These motions may occur separately or in combination.

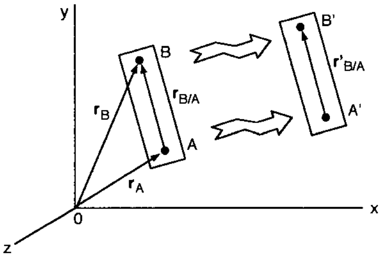

FIGURE 1.3.9 Translational motion of a rigid body.

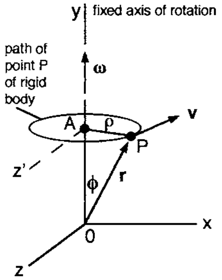

FIGURE 1.3.10 Rigid body rotating about a fixed axis.

Translation

Figure 1.3.9 models the translational motion of a rigid body.

$$\begin{aligned} \mathbf{r}_B &= \mathbf{r}_A + \mathbf{r}_{B/A} \qquad \left(\mathbf{r}_{B/A} = \text{constant}\right) \\ \mathbf{v}_B &= \dot{\mathbf{r}}_B = \dot{\mathbf{r}}_A = \mathbf{v}_A \\ \mathbf{a}_B &= \dot{\mathbf{v}}_B = \dot{\mathbf{v}}_A = \mathbf{a}_A \end{aligned} \tag{1.3.43}$$

These equations represent an important fact: *when a rigid body is in translation, the motion of a single point completely specifies the motion of the whole body.*

Rotation about a Fixed Axis

Figure 1.3.10 models a point P in a rigid body rotating about a fixed axis with an angular velocity ω. The velocity **v** of point P is determined assuming that the magnitude of **r** is constant,

$$\mathbf{v} = \omega \times \mathbf{r} \tag{1.3.44}$$

The acceleration **a** of point P is determined conveniently by using normal and tangential components,

$$\begin{aligned} \mathbf{a}_P &= \underbrace{\alpha \times r}_{\mathbf{a}_t} + \underbrace{\omega \times \left(\omega \times \mathbf{r}\right)}_{\mathbf{a}_n} \\ a_t &= \rho\alpha \qquad a_n = \rho\omega^2 \end{aligned} \tag{1.3.45}$$

Note that *the angular acceleration a and angular velocity w are valid for any line perpendicular to the axis of rotation of the rigid body at a given instant.*

Kinematics Equations for Rigid Bodies Rotating in a Plane

For rotational motion with or without a fixed axis, if displacement is measured by an angle θ,

Angular speed: $$\omega = \frac{d\theta}{dt}$$

Angular acceleration: $$\alpha = \frac{d\omega}{dt} = \omega \frac{d\omega}{d\theta}$$

For a constant angular speed ω,

Angular displacement: $$\theta = \theta_o + \omega t \qquad (\theta = \theta_o \text{ at } t = 0)$$

For a constant angular acceleration α,

$$\omega = \omega_o + \alpha t \qquad (\omega = \omega_o \text{ at } t = 0)$$

$$\theta = \theta_o + \omega_o t + \frac{1}{2}\alpha t^2$$

$$\omega^2 = \omega_o^2 + 2\alpha(\theta - \theta_o)$$

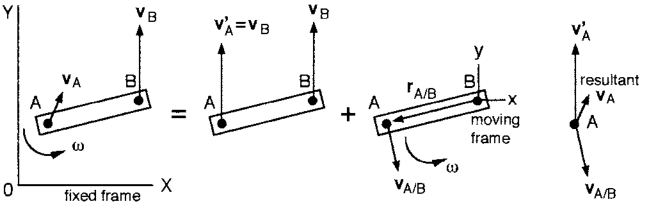
Velocities in General Plane Motion

General plane motion of a rigid body is defined by simultaneous translation and rotation in a plane. Figure 1.3.11 illustrates how the velocity of a point *A* can be determined using Equation (1.3.46), which is based on relative motion of particles.

$$\mathbf{v}_A = \underbrace{\mathbf{v}_B}_{\text{translation}} + \underbrace{\omega \times \mathbf{r}_{A/B}}_{\text{rotation}} \tag{1.3.46}$$

Five important points should be remembered when solving general plane motion problems, including those of interconnected rigid bodies.

1. The angular velocity of a rigid body in plane motion is independent of the reference point.
2. The common point of two or more pin-jointed members must have the same absolute velocity even though the individual members may have different angular velocities.



(a) General plane motion
(b) Translation only
(c) Rotation only
(d) Result for point A

FIGURE 1.3.11 Analysis of velocities in general plane motion.

3. The points of contact in members that are in temporary contact may or may not have the same absolute velocity. If sliding occurs between the members, the points in contact have different absolute velocities. The absolute velocities of the contacting particles are always the same if no sliding takes place.
4. If the angular velocity of a member is not known, but some points of the member move along defined paths (i.e., the end points of a piston rod), these paths define the directions of the velocity vectors and are useful in the solution.
5. The geometric center of a wheel rolling on a flat surface moves in rectilinear motion. If no slipping occurs at the point of contact, the linear distance that the center point travels is equal to the portion of the rim circumference that has rolled along the flat surface.

Instantaneous Center of Rotation

The method of *instantaneous center of rotation* is a geometric method of determining the angular velocity when two velocity vectors are known for a given rigid body. Figure 1.3.12 illustrates the method. This procedure can also be used to determine velocities parallel to one of the given velocities, by similar triangles. Velocities $\mathbf{v}_A$ and $\mathbf{v}_B$ are given; thus the body is rotating about point I at that instant. Point I has zero velocity at that instant, but generally has an acceleration. This method does not work for the determination of angular accelerations.

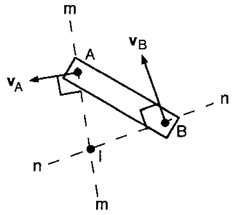


FIGURE 1.3.12 Schematic for instantaneous center of rotation.

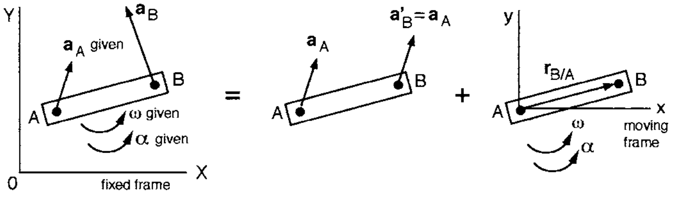
Acceleration in General Plane Motion

Figure 1.3.13 illustrates a method of determining accelerations of points of a rigid body. This is similar to (but more difficult than) the procedure of determining velocities.

$$\mathbf{a}_B = \mathbf{a}_A + \alpha \times \mathbf{r}_{B/A} + \omega \times \left(\omega \times \mathbf{r}_{B/A}\right)$$

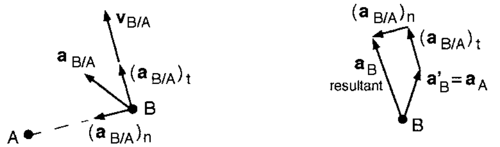
$$\mathbf{a}_B = \underbrace{\mathbf{a}_A}_{\text{translation}} + \underbrace{\left(\mathbf{a}_{B/A}\right)_t + \left(\mathbf{a}_{B/A}\right)_n}_{\text{rotation}} \tag{1.3.47}$$



(a) General plane motion

(b) Translation only

(c) Rotation only



(d) Velocity and acceleration of point B from rotation only

(e) Total acceleration of point B

FIGURE 1.3.13 Accelerations in general plane motion.

Six key points should be considered when solving this kind of a problem.

1. The angular velocity and acceleration of a rigid body in plane motion are independent of the reference point.
2. The common points of pin-jointed members must have the same absolute acceleration even though the individual members may have different angular velocities and angular accelerations.
3. The points of contact in members that are in temporary contact may or may not have the same absolute acceleration. Even when no sliding between the members occurs, only the tangential accelerations of the points in contact are the same; the normal accelerations are frequently different in magnitude and direction.
4. The instantaneous center of zero velocity in general has an acceleration and should *not* be used as a reference point for accelerations unless its acceleration is known and included in the analysis.
5. If the angular acceleration of a member is not known, but some points of the member move along defined paths, the geometric constraints of motion define the directions of normal and tangential acceleration vectors and are useful in the solution.
6. The geometric center of a wheel rolling on a flat surface moves in rectilinear motion. If no slipping occurs at the point of contact, the linear acceleration of the center point is parallel to the flat surface and equal to *ra* for a wheel of radius *r* and angular acceleration α.

General Motion of a Rigid Body

Figure 1.3.14 illustrates the complex general motion (three-dimensional) of a rigid body. It is important to note that here the angular velocity and angular acceleration vectors are not necessarily in the same direction as they are in general plane motion. Equation (1.3.48) gives the velocity and acceleration of a point on the rigid body. These equations are the same as those presented for plane motion.

$$\begin{aligned} \mathbf{v}_B &= \mathbf{v}_A + \omega \times \mathbf{r}_{B/A} \\ \mathbf{a}_B &= \mathbf{a}_A + \alpha \times \mathbf{r}_{B/A} + \omega \times \left(\omega \times \mathbf{r}_{B/A}\right) \\ \mathbf{a}_B &= \mathbf{a}_A + \left(\mathbf{a}_{B/A}\right)_t + \left(\mathbf{a}_{B/A}\right)_n \end{aligned} \tag{1.3.48}$$

The most difficult part of solving a general motion problem is determining the angular acceleration vector. There are three cases for the determination of the angular acceleration:

1. The direction of ω is constant. This is plane motion and $\alpha = \dot{\omega}$ can be used in scalar solutions of problems.
2. The magnitude of ω is constant but its direction changes. An example of this is a wheel that travels at a constant speed on a curved path.
3. The magnitude and direction of ω change. This is *space motion* because all or some points of the rigid body have three-dimensional paths. An example of this is a wheel that accelerates on a curved path.

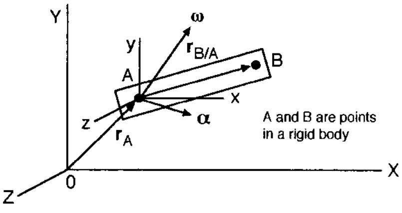


FIGURE 1.3.14 General motion of a rigid body.

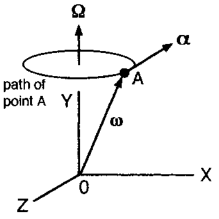

FIGURE 1.3.15 Rigid body fixed at point *O*.

A useful expression can be obtained from the second item and Figure 1.3.15. The rigid body is fixed at point *O* and ω has a constant magnitude. Let ω rotate about the **Y** axis with angular velocity **Ω**. The angular acceleration is determined from Equation (1.3.49).

$$\alpha = \frac{d\omega}{dt} = \Omega \times \omega \tag{1.3.49}$$

For *space motion*, it is essential to combine the results of the first two items, which provide components of α for the change in magnitude and the change in direction. The following example illustrates the procedure.

Example 9

The rotor shaft of an alternator in a car is in the horizontal plane. It rotates at a constant angular speed of 1500 rpm while the car travels at v = 60 ft/sec on a horizontal road of 400 ft radius (Figure 1.3.16). Determine the angular acceleration of the rotor shaft if v increases at the rate of 8 ft/sec^2.

Solution. There are two components of α. One is the change in the direction of the rotor shaft's ω_x, and the other is the change in magnitude from the acceleration of the car.

- Component from the change in direction. Determine ω_c of the car. Use Equation (1.3.49):

$$v = r\omega_c$$

$$\omega_c = 0.15 \text{ rad/sec } \mathbf{k}$$

$$\alpha = \omega_c \times \omega = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ 0 & 0 & 0.15 \\ 157.1 & 0 & 0 \end{vmatrix} = 23.6\mathbf{j} \text{ rad/sec}^2$$

- Component from the acceleration of the car. Use Equation (1.3.9):

$$\alpha_C r = a_t$$

$$\alpha_C = 0.02\mathbf{k}\,\text{rad/sec}^2$$

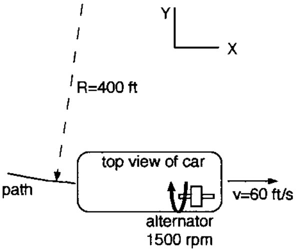

FIGURE 1.3.16 Schematic of shaft's motion.

The angular acceleration of the rotor shaft is

$$\alpha = (23.6\mathbf{j} + 0.02\mathbf{k})\text{rad/sec}^2$$

This problem could also be solved using the method in the next section.

Time Derivative of a Vector Using a Rotating Frame

The basis of determining time derivatives of a vector using a rotating frame is illustrated in Figure 1.3.17.

$$(\mathbf{Q})_{XYZ} = \left(\dot{\mathbf{Q}}\right)_{xyz} + \Omega \times \mathbf{Q}$$

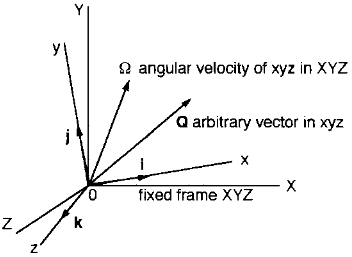

FIGURE 1.3.17 Time derivative of a vector using a rotating reference frame.

Analysis of Velocities and Accelerations Using Rotating and Translating Frames

With the concept of general motion understood, an advantageous method of determining velocities and accelerations is available by the method of rotating reference frames. This method can be used in two cases:

1. For a common origin of *XYZ* and *xyz*, with **r** a position vector to a point *P*,

$$\mathbf{v}_P = \mathbf{v}_{xyz} + \Omega \times \mathbf{r}$$
$$\mathbf{a}_P = \mathbf{a}_{xyz} + \dot{\Omega} \times \mathbf{r} + \Omega \times (\Omega \times \mathbf{r}) + 2\Omega \times \mathbf{v}_{xyz} \tag{1.3.50}$$

2. For the origin *A* of *xyz* translating with respect *XYZ*:

$$\mathbf{v}_P = \mathbf{v}_A + \left(\dot{\mathbf{r}}_{P/A}\right)_{xyz} + \Omega \times \mathbf{r}_{P/A}$$
$$\mathbf{a}_P = \mathbf{a}_A + \mathbf{a}_{xyz} + \dot{\Omega} \times \mathbf{r}_{P/A} + \Omega \times \left(\Omega \times \mathbf{r}_{P/A}\right) + 2\Omega \times \mathbf{v}_{xyz} \tag{1.3.51}$$

where Ω is the angular velocity of the *xyz* frame with respect to *XYZ*. $2\Omega \times \mathbf{v}_{xyz}$ is the Coriolis acceleration.

Kinetics of Rigid Bodies in Plane Motion

Equation of Translational Motion

The fundamental equation for rigid body translation is based on Newton's second law. In Equation (1.3.52), **a** is the acceleration of the center of mass of the rigid body, no matter where the resultant force acts on the body. *The sum of the external forces is equal to the mass of the rigid body times the acceleration of the mass center of the rigid body*, independent of any rotation of the body.

$$\sum \mathbf{F} = m\mathbf{a}_C \tag{1.3.52}$$

Equation of Rotational Motion

Equation (1.3.53) states that *the sum of the external moments on the rigid body is equal to the moment of inertia about an axis times the angular acceleration of the body about that axis*. The angular acceleration α is for the rigid body rotating about an axis. This equation is independent of rigid body translation.

$$\sum \mathbf{M}_C = I_C \alpha \qquad (1.3.53)$$

where $\Sigma \mathbf{M}_C = \dot{\mathbf{H}}_C$, $\mathbf{H}_C = I_C \omega$. An application is illustrated in Color Figure 2.

Applications of Equations of Motion

It is important to use the equations of motion properly. For plane motion, three scalar equations are used to define the motion in a plane:

$$\sum F_x = ma_{C_x} \qquad \sum F_y = ma_{C_y} \qquad \sum M_C = I_C \alpha \qquad (1.3.54)$$

If a rigid body undergoes only translation,

$$\sum F_x = ma_{C_x} \qquad \sum F_y = ma_{C_y} \qquad \sum M_C = 0 \qquad (1.3.55)$$

If the rigid body undergoes pure rotation about the center of mass,

$$\sum F_x = 0 \qquad \sum F_y = 0 \qquad \sum M_C = I_C \alpha \qquad (1.3.56)$$

Rigid body motions are categorized according to the constraints of the motion:

1. *Unconstrained Motion*: Equation (1.3.54) is directly applied, with all three equations independent of one another.
2. *Constrained Motion*: the equations in Equation (1.3.54) are not independent of one another. Generally, a kinematics analysis must be made to determine how the motion is constrained in the plane. Consider two special cases:
   a. Point constraint: the body has a fixed axis.
   b. Line constraint: the body moves along a fixed line or plane.

When considering systems of rigid bodies, it is important to remember that, at most, only three equations of motion are available from each free-body diagram for plane motion to solve for three unknowns. The motion of interconnected bodies must be analyzed using related free-body diagrams.

Rotation about a Fixed Axis not through the Center of Mass

The methods presented previously are essential in analyzing rigid bodies that rotate about a fixed axis, which is common in machines (shafts, wheels, gears, linkages). The mass of the rotating body may be nonuniformly distributed as modeled in Figure 1.3.18. Note that r_C is the nearest distance between the fixed axis O and the mass center C. The figure also defines the normal and tangential coordinate system used in Equation (1.3.57), which comprises the scalar equations of motion using normal and tangential components. The sum of the forces must include all reaction forces on the rigid body at the axis of rotation.

$$\sum F_n = mr_C \omega^2 \qquad \sum F_t = mr_C \alpha \qquad \sum M_O = I_O \alpha \qquad (1.3.57)$$

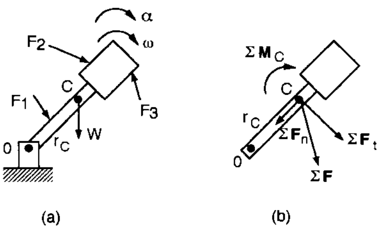

FIGURE 1.3.18 Rotation of a rigid body about a fixed axis.

General Plane Motion

A body that is translating and rotating is in general plane motion. The scalar equations of motion are given by Equation (1.3.54). If an arbitrary axis A is used to find the resultant moment,

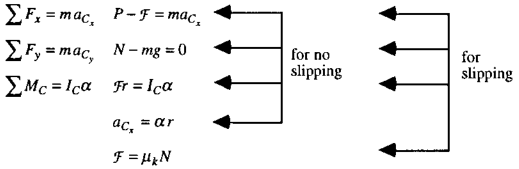
$$\sum \mathbf{M}_A = I_A \alpha + \mathbf{r} \times m\mathbf{a}_C \tag{1.3.58}$$

where C is the center of mass. It is a common error to forget to include the cross-product term in the analysis.

General plane motion has two special cases: *rolling* and *sliding*. Figure 1.3.19 shows pure rolling of a wheel without slipping with the center of mass C at the geometric center of the wheel. This is called pure rolling of a balanced wheel. From this figure the scalar equation of motion results,

$$a_{C_x} = r\alpha \qquad \sum \mathbf{M}_A = I_A \alpha \tag{1.3.59}$$

For balanced wheels that slide or do not slide, the following schematic is helpful:



$\sum F_x = ma_{C_x}$ $\quad P - \mathcal{F} = ma_{C_x}$

$\sum F_y = ma_{C_y}$ $\quad N - mg = 0$

$\sum M_C = I_C \alpha$ $\quad \mathcal{F}r = I_C \alpha$

$a_{C_x} = \alpha r$

$\mathcal{F} = \mu_k N$

If slipping is not certain, assume that no slipping has occurred and check whether $\mathcal{F} \le \mu_s N$. If $\mathcal{F} > \mu_s N$ (not possible; there is sliding), start the solution over using $\mathcal{F} = \mu_k N$ but not using $a_{C_x} = r\alpha$, which is not valid here.

For the problem involving unbalanced wheels (the mass center and geometric center do not coincide), Equation (1.3.60) results:

$$\begin{gathered} a_{C_x} \neq r\alpha \qquad a_G = r\alpha \\ \mathbf{a}_C = \mathbf{a}_G + \mathbf{a}_{C/G} = \mathbf{a}_G + \left(\mathbf{a}_{C/G}\right)_n + \left(\mathbf{a}_{C/G}\right)_t \end{gathered} \tag{1.3.60}$$

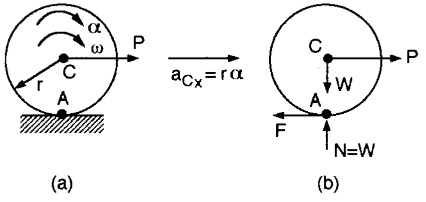


FIGURE 1.3.19 Pure rolling of a wheel.

Energy and Momentum Methods for Rigid Bodies in Plane Motion

Newton's second law in determining kinetics relationships is not always the most efficient, although it always works. When particles are considered, energy and momentum methods are often useful to analyze rigid bodies in plane motion.

Work of a Force on a Rigid Body

The work of a force acting on a rigid body moving from position 1 to 2 is

$$U_{12} = \int_1^2 \mathbf{F} \cdot d\mathbf{r} = \int_1^2 \mathbf{F} \cdot \mathbf{v}\, dt \tag{1.3.61}$$

Work of a Moment

The work of a moment has a similar form, for angular positions θ,

$$U_{12} = \int_{\theta_1}^{\theta_2} \mathbf{M} \cdot d\theta \tag{1.3.62}$$

In the common case in which the moment vector **M** is perpendicular to the plane of motion, $\mathbf{M} \cdot d\theta = M\, d\theta$.

It is important to note those forces that do no work:

- Forces that act at fixed points on the body do not do work. For example, the reaction at a fixed, frictionless pin does no work on the body that rotates about that pin.
- A force that is always perpendicular to the direction of the motion does no work.
- The weight of a body does no work when the body's center of gravity moves in a horizontal plane.
- The friction force $\mathscr{F}$ at a point of contact on a body that rolls without slipping does no work because the point of contact is the instantaneous center of zero velocity.

Kinetic Energy of a Rigid Body

The kinetic energy of a particle only consists of the energy associated with its translational motion. The kinetic energy of a rigid body also includes a term for the rotational energy of the body,

$$T = T_{trans} + T_{rot} = \frac{1}{2} m v_C^2 + \frac{1}{2} I_C \omega^2 \tag{1.3.63}$$

where C is the center of mass of the rigid body.

The kinetic energy of a rigid body rotating about an arbitrary axis at point O is

$$T = \frac{1}{2} I_O \omega^2$$

Principle of Work and Energy

The principle of work and energy for a rigid body is the same as that used for particles with the addition of the rotational energy terms.

$$T_2 = T_1 + U_{12} \tag{1.3.64}$$

where

T_1 = initial kinetic energy of the body
T_2 = final kinetic energy of the body
U_{12} = work of all external forces and moments acting on the body moving from position 1 to 2

This method is advantageous when displacements and velocities are the desired quantities.

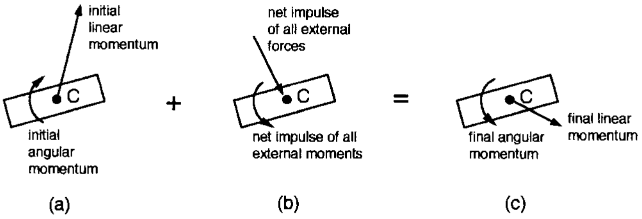

FIGURE 1.3.20 Impulse and momentum for rigid bodies.

Conservation of Energy

The conservation of energy in a conservative rigid body system is

$$T_1 + V_1 = T_2 + V_2 \tag{1.3.65}$$

where

T = kinetic energy
V = total potential energy (gravitational and elastic)

Power

The net power supplied to or required of the system is

$$\text{power} = \dot{T}_{trans} + \dot{T}_{rot} + \dot{V}_g + \dot{V}_e \tag{1.3.66}$$

This can be calculated by taking time derivatives of the kinetic and potential energy terms. Each term is considered positive when it represents the power supplied to the system and negative when power is taken from the system.

Impulse and Momentum of a Rigid Body

Impulse and momentum methods are particularly useful when time and velocities are of interest. Figure 1.3.20 shows how rigid bodies are to be considered for this kind of analysis. Notice that rotational motion of the rigid body must be included in the modeling.

The impulse of the external forces in the given interval is

$$\int_{t_1}^{t_2} \sum \mathbf{F}\, dt = m_{C_2}\left(\mathbf{v}_{C_2} - \mathbf{v}_{C_1}\right) \tag{1.3.67}$$

where

t is time
C is the center of mass
$\Sigma\mathbf{F}$ includes all external forces

The impulse of the external moments in the given interval is

$$\int_{t_1}^{t_2} \sum \mathbf{M}_C\, dt = \mathbf{H}_{C_2} - \mathbf{H}_{C_1} \tag{1.3.68}$$

For plane motion, if $\Sigma\mathbf{M}$ is parallel to w, the scalar expressions are

$$\int_{t_1}^{t_2} \sum M_C \, dt = I_C(\omega_2 - \omega_1)$$

$$\int_{t_1}^{t_2} \sum M_O \, dt = I_O(\omega_2 - \omega_1) \quad \text{for rotation about a fixed point } O \tag{1.3.69}$$

Impulse and Momentum of a System of Rigid Bodies

A system of rigid bodies can be analyzed using one of the two following procedures, illustrated in Figure 1.3.21:

1. Apply the principle of impulse and momentum to each rigid member separately. The mutual forces acting between members must be included in the formulation of the solution.
2. Apply the principle of impulse and momentum to the entire system of bodies, ignoring the mutual forces between members.

Conservation of Momentum

The principle of conservation of linear and angular momentum of particles can be extended to rigid bodies that have no external forces or moments acting on them. The conservation of linear momentum means that the center of mass *C* moves at a constant speed in a constant direction,

$$\sum \mathbf{F} = 0 \Rightarrow \Delta \mathbf{G} = 0$$

$$\mathbf{v}_{C_1} = \mathbf{v}_{C_2} \tag{1.3.70}$$

Likewise, for conservation of angular momentum of rigid bodies,

$$\sum \mathbf{M} = 0 \Rightarrow \Delta \mathbf{H}_C = 0$$

$$I_C \omega_1 = I_C \omega_2 \tag{1.3.71}$$

For a system of rigid bodies, use the same fixed reference point *O* for all parts of the system. Thus, for plane motion,

$$\Delta \mathbf{H}_O = 0 \qquad I_O \omega_1 = I_O \omega_2 \tag{1.3.72}$$

Two important points should be remembered when these equations are used. First, $\Delta \mathbf{H}_C = 0$ does not imply that $\Delta \mathbf{H}_O = 0$, or vice versa. Second, conservation of momentum does not require the simultaneous conservation of angular and linear momenta (for example, there may be an angular impulse while linear momentum is conserved).

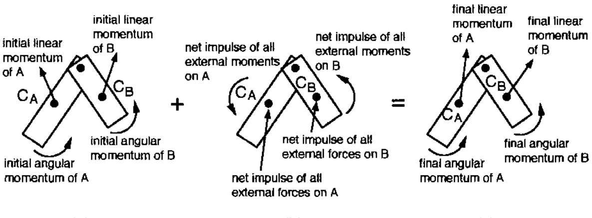

FIGURE 1.3.21 System of rigid bodies.

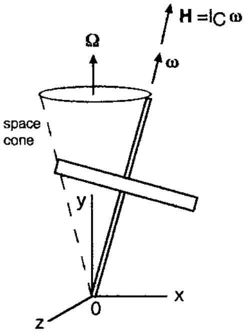

FIGURE 1.3.22 Motion of an inclined, spinning top.

Kinetics of Rigid Bodies in Three Dimensions

The concepts of plane rigid body motion can be extended to the more complicated problems in three dimensions, such as those of gyroscopes and jet engines. This section briefly covers some fundamental topics. Many additional topics and useful methods are included in the technical literature.

Angular Momentum in Three Dimensions

For analyzing three-dimensional angular momentum, three special definitions are used. These can be visualized by considering a spinning top (Figure 1.3.22):

- *Precession* — rotation of the angular velocity vector about the y axis
- *Space Cone* — locus of the absolute positions of the instantaneous axis of rotation
- *Body Cone* — locus of the positions of the instantaneous axis relative to the body; the body cone appears to roll on the space cone (not shown here)

Equation (1.3.73) provides the scalar components of the total angular momentum.

$$\begin{aligned} H_x &= I_x\omega_x - I_{xy}\omega_y - I_{xz}\omega_z \\ H_y &= -I_{xy}\omega_x + I_y\omega_y - I_{yz}\omega_z \\ H_z &= -I_{zx}\omega_x - I_{zy}\omega_y + I_z\omega_z \end{aligned} \tag{1.3.73}$$

Impulse and Momentum of a Rigid Body in Three-Dimensional Motion

The extension of the planar motion equations of impulse and momentum to three dimensions is straightforward:

$$\text{System momenta} = \begin{cases} \text{linear momentum of mass center } (\mathbf{G}) \\ \text{angular momentum about mass center } (\mathbf{H}_C) \end{cases} \tag{1.3.74}$$

where **G** and **H** have different units. The principle of impulse and momentum is applied for the period of time t_1 to t_2,

$$\begin{aligned} \mathbf{G}_2 &= \mathbf{G}_1 + (\text{external linear impulses})\Big|_1^2 \\ \mathbf{H}_{C_2} &= \mathbf{H}_{C_1} + (\text{external angular impulses})\Big|_1^2 \end{aligned} \tag{1.3.75}$$

Kinetic Energy of a Rigid Body in Three-Dimensional Motion

The total kinetic energy of a rigid body in three dimensions is

$$T = \underbrace{\frac{1}{2}mv_C^2}_{\substack{\text{translation}\\ \text{of mass center}}} + \underbrace{\frac{1}{2}\omega \cdot \mathbf{H}_C}_{\substack{\text{rotation about}\\ \text{mass center}}} \tag{1.3.76}$$

For a rigid body that has a fixed point *O*,

$$T = \frac{1}{2}\omega \cdot \mathbf{H}_O \tag{1.3.77}$$

Equations of Motion in Three Dimensions

The equations of motion for a rigid body in three dimensions are extensions of the equations previously stated:

$$\begin{gathered} \sum \mathbf{F} = m\mathbf{a}_C \\ \sum \mathbf{M}_C = \dot{\mathbf{H}}_C = \left(\dot{\mathbf{H}}_C\right)_{xyz} + \Omega \times \mathbf{H}_C \end{gathered} \tag{1.3.78}$$

where

$\mathbf{a}_C$ = acceleration of mass center
$\mathbf{H}_C$ = angular momentum of the body about its mass center
xyz = frame fixed in the body with origin at the mass center
Ω = angular velocity of the *xyz* frame with respect to a fixed *XYZ* frame

Note that an arbitrary fixed point *O* may be used for reference if done consistently.

Euler's Equations of Motion

Euler's equations of motion results from the simplification of allowing the *xyz* axes to coincide with the principal axes of inertia of the body.

$$\begin{aligned} \sum M_x &= I_x\dot{\omega}_x - \left(I_y - I_z\right)\omega_y\omega_z \\ \sum M_y &= I_y\dot{\omega}_y - \left(I_z - I_x\right)\omega_z\omega_x \\ \sum M_z &= I_z\dot{\omega}_z - \left(I_x - I_y\right)\omega_x\omega_y \end{aligned} \tag{1.3.79}$$

where all quantities must be evaluated with respect to the appropriate principal axes.

Solution of Problems in Three-Dimensional Motion

In order to solve a three-dimensional problem, it is necessary to apply the six independent scalar equations:

$$\sum F_x = ma_{C_x} \qquad \sum F_y = ma_{C_y} \qquad \sum F_z = ma_{C_z}$$

$$\sum M_x = \dot{H}_x + \omega_y H_z - \omega_z H_y$$
$$\sum M_y = \dot{H}_y + \omega_z H_x - \omega_x H_z \tag{1.3.80}$$
$$\sum M_z = \dot{H}_z + \omega_x H_y - \omega_y H_x$$

These equations are valid in general. Some common cases are briefly stated:

- *Unconstrained motion.* The six governing equations should be used with *xyz* axes attached at the center of mass of the body.
- *Motion of a body about a fixed point.* The governing equations are valid for a body rotating about a noncentroidal fixed point *O*. The reference axes *xyz* must pass through the fixed point to allow using a set of moment equations that do not involve the unknown reactions at *O*.
- *Motion of a body about a fixed axis.* This is the generalized form of plane motion of an arbitrary rigid body. The analysis of unbalanced wheels and shafts and corresponding bearing reactions falls in this category.

1.4 Vibrations

Bela I. Sandor and Stephen M. Birn

Vibrations in machines and structures should be analyzed and controlled if they have undesirable effects such as noise, unpleasant motions, or fatigue damage with potentially catastrophic consequences. Conversely, vibrations are sometimes employed to useful purposes, such as for compacting materials.

Undamped Free and Forced Vibrations

The simplest vibrating system has motion of one degree of freedom (DOF) described by the coordinate x in Figure 1.4.1. (An analogous approach is used for torsional vibrations, with similar results.) Assuming that the spring has no mass and that no damping occurs in the system, the equation of motion for **free vibration** (motion under internal forces only; $F = 0$) is

$$m\ddot{x} + kx = 0 \qquad \text{or} \qquad \ddot{x} + \omega^2 x = 0 \tag{1.4.1}$$

where $\omega = \sqrt{k/m}$ = natural circular frequency in radians per second.

The displacement x as a function of time t is

$$x = C_1 \sin \omega t + C_2 \cos \omega t \tag{1.4.2}$$

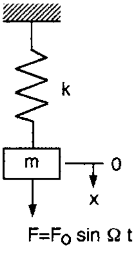

FIGURE 1.4.1 Model of a simple vibrating system.

where C_1 and C_2 are constants depending on the initial conditions of the motion. Alternatively,

$$x = A\sin(\omega t + \phi)$$

where $C_1 = A\cos\phi$, $C_2 = A\sin\phi$, and ϕ is the phase angle, another constant. A complete cycle of the motion occurs in time τ, the *period of simple harmonic motion*,

$$\tau = \frac{2\pi}{\omega} = 2\pi\sqrt{\frac{m}{k}}\ (\text{seconds per cycle})$$

The *frequency* in units of cycles per second (cps) or hertz (Hz) is $f = 1/\tau$.

The simplest case of **forced vibration** is modeled in Figure 1.4.1, with the force F included. Using typical simplifying assumptions as done previously, the equation of motion for a harmonic force of forcing frequency Ω, is

$$m\ddot{x} + kx = F_o\sin\Omega t \tag{1.4.3}$$

The vibrations of a mass m may also be induced by the displacement $d = d_o\sin\Omega t$ of a foundation or another mass M to which m is attached by a spring k. Using the same reference point and axis for x and d, the equation of motion for m is

$$\begin{gathered} m\ddot{x} + k(x - d_o\sin\Omega t) = 0 \\ m\ddot{x} + kx = kd_o\sin\Omega t \end{gathered} \tag{1.4.4}$$

where d_o is the amplitude of vibration of the moving support M, and Ω is its frequency of motion.

The general solution of the forced vibration in the *steady state* (after the initial transient behavior) is

$$\begin{aligned} x &= A\sin\Omega t \\ A &= \frac{F_o}{k - m\Omega^2} = \frac{F_o/k}{1-(\Omega/\omega)^2} \end{aligned} \tag{1.4.5}$$

where Ω is the forcing frequency and w is the natural circular frequency of the system of m and k.

Resonance. The amplitude of the oscillations in forced vibrations depends on the frequency ratio Ω/ω. Without damping or physical constraints, the amplitude would become infinite at $\Omega = \omega$, the condition of **resonance**. Dangerously large amplitudes may occur at resonance and at other frequency ratios near the resonant frequency. A *magnification factor* is defined as

$$MF = \frac{F}{F_o/k} = \frac{A}{d_o} = \frac{1}{1-(\Omega/\omega)^2} \tag{1.4.6}$$

Several special cases of this are noted:

1. Static loading: $\Omega = 0$, or $\Omega \ll \omega$; $MF \simeq 1$.
2. Resonance: $\Omega = \omega$; $MF = 8$.
3. High-frequency excitation: $\Omega \gg \omega$; $MF.\ 0$.
4. Phase relationships: the vibration is in phase for $\Omega < \omega$, and it is 180° *out of phase* for $\Omega > \omega$.

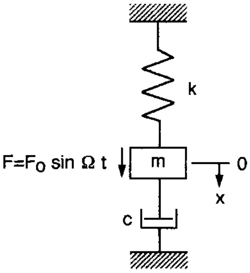

FIGURE 1.4.2 Model of a damped vibrating system.

Damped Free and Forced Vibrations

A vibrating system of one degree of freedom and damping is modeled in Figure 1.4.2. The equation of motion for *damped free vibrations* ($F = 0$) is

$$m\ddot{x} + c\dot{x} + kx = 0 \tag{1.4.7}$$

The displacement x as a function of time t is

$$x = e^{\lambda t} \tag{1.4.8}$$

$$\lambda_{1,2} = \frac{-c}{2m} \pm \sqrt{\left(\frac{c}{2m}\right)^2 - \frac{k}{m}}$$

The value of the coefficient of viscous damping c that makes the radical zero is the *critical damping coefficient* $c_c = 2m\sqrt{k/m} = 2m\omega$. Three special cases of damped free vibrations are noted:

1. Overdamped system: $c > c_c$; the motion is *nonvibratory* or *aperiodic*
2. Critically damped system: $c = c_c$; this motion is also nonvibratory; x decreases at the fastest rate possible without oscillation of the mass
3. Underdamped system: $c < c_c$; the roots $\lambda_{1,2}$ are complex numbers; the displacement is

$$x = Ae^{-(c/2m)t} \sin\left(\omega_d t + \phi\right)$$

where A and ϕ are constants depending on the initial conditions, and the *damped natural frequency* is

$$\omega_d = \omega\sqrt{1 - \left(\frac{c}{c_c}\right)^2}$$

The ratio c/c_c is the *damping factor* ζ. The damping in a system is determined by measuring the rate of decay of free oscillations. This is expressed by the *logarithmic decrement* δ, involving any two successive amplitudes x_i and x_{i+1},

$$\delta = \ln\frac{x_i}{x_{i+1}} = \frac{2\pi\zeta}{\sqrt{1-\zeta^2}} \simeq 2\pi\zeta$$

The simplifying approximation for δ is valid for up to about 20% damping ($\zeta \simeq 0.2$).

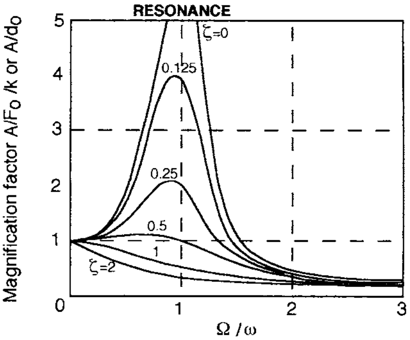

FIGURE 1.4.3 Magnification factor in damped forced vibration.

The *period of the damped vibration* is $\tau_d = 2\pi/\omega_d$. It is a constant, but always larger than the period of the same system without damping. In many real systems the damping is relatively small ($\zeta < 0.2$), where $\tau_d \simeq \tau$ and $\omega_d \simeq \omega$ can be used.

The equation of motion for *damped forced vibrations* (Figure 1.4.2; $F \neq 0$) is

$$m\ddot{x} + c\dot{x} + kx = F_o \sin \Omega t \tag{1.4.9}$$

The solution for steady-state vibration of the system is

$$x = A\sin(\Omega t - \phi) \tag{1.4.10}$$

where the amplitude and phase angle are from

$$A = \frac{F_o}{\sqrt{(c\Omega)^2 + (k - m\Omega^2)^2}}$$

$$\tan\phi = \frac{c\Omega}{k - m\Omega^2}$$

The *magnification factor* for the amplitude of the oscillations is

$$MF = \frac{A}{F_o/k} = \frac{A}{d_o} = \frac{1}{\sqrt{[2\zeta(\Omega/\omega)]^2 + [1 - (\Omega/\omega)^2]^2}} \tag{1.4.11}$$

This quantity is sketched as a function of the frequency ratio Ω/ω for several damping factors in Figure 1.4.3. Note that the amplitude of vibration is reduced at all values of Ω/ω if the coefficient of damping c is increased in a particular system.

Vibration Control

Vibration Isolation

It is often desirable to reduce the forces transmitted, or the noise and motions inside or in the neighborhood of vibrating machines and structures. This can be done to some extent within the constraints of space and additional weight and cost by the use of isolators, such as rubber engine mounts and wheel suspension systems in cars. Many kinds of isolating materials and systems are available commercially.

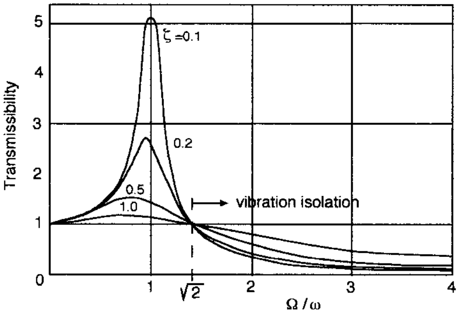

FIGURE 1.4.4 Transmissibility patterns of a vibration isolator.

The effectiveness of vibration isolation is expressed by the *transmissibility TR*, the ratio of the force transmitted F_T to the disturbing force F_o. A simple isolation system is modeled as a spring and a dashpot in parallel, for which the transmissibility is given by Equation (1.4.12) and sketched in Figure 1.4.4.

$$TR = \frac{F_T}{F_o} = \frac{\sqrt{1 + 4\zeta^2(\Omega/\omega)^2}}{\sqrt{\left[1 - (\Omega/\omega)^2\right]^2 + 4\zeta^2(\Omega/\omega)^2}} \tag{1.4.12}$$

When damping is negligible,

$$TR \simeq \frac{1}{(\Omega/\omega)^2 - 1}$$

Note from the figure that

- Vibration isolation occurs at $\Omega/\omega > \sqrt{2}$.
- Isolation efficiency increases with decreasing stiffness of the isolation mounts.
- Damping reduces isolation efficiency. However, some damping is normally required if resonance may occur in a system even for short periods.
- The response curves are essentially independent of damping when Ω/ω is large ($\gtrsim 3$) and damping is low ($\zeta \lesssim 0.2$). Here $TR \simeq 1/[(\Omega/\omega)^2 - 1]$.
- For a system with more than one excitation frequency, the lowest excitation frequency is of primary importance.

The efficiency of an isolating system is defined by the reduction R in transmissibility,

$$R = 1 - TR$$

If a certain reduction R in transmissibility is desired, the appropriate stiffness k of an isolation system is obtained from $\omega = \sqrt{k/m}$ and

$$\frac{\Omega}{\omega} = \sqrt{\frac{2 - R}{1 - R}}$$

A small magnitude of stiffness k makes the reduction R in transmissibility large. It is difficult to achieve isolation for very low excitation frequencies because of the required large static deflections. To obtain highly efficient isolation at low excitation frequencies, a large supporting mass M may be utilized, with the value of

$$\omega = \sqrt{k/(m + M)}$$

Vibration Absorption

In some cases, a vibratory force is purposely generated in a system by a secondary spring-mass system to oppose a primary disturbing force and thereby reduce or eliminate the undesirable net effect. An interesting example of this is the "tuned-mass damper" in a few skyscrapers, designed to counter the oscillatory motions caused by wind. The secondary spring-mass system has disadvantages of its own, such as extra weight, complexity, and effectiveness limited to a single frequency.

Balancing of Rotating Components

The conditions of static or dynamic unbalance of rotating bodies have long been recognized. These can be analyzed by the methods of elementary mechanics; simple tests can be performed in many cases and adequate corrections can be made routinely to achieve balance, such as for the wheels of automotive vehicles. Three categories of increasing complexity are distinguished.

1. *Static unbalance.* The distributed or lumped masses causing unbalance are in a single axial plane and all on the same side of the axis of rotation (Figure 1.4.5). Thin disks are also in this category. Static unbalance is detected in a static test because the center of gravity of the body is not on the axis, and correction is made by adding or removing mass at a convenient radial distance from the axis.
2. *Static balance with dynamic unbalance.* This may be the case when the masses causing unbalance are in a single axial plane but on opposite sides of the axis of rotation (Figure 1.4.6a). Static balance is achieved if the center of gravity of the body is on the axis, but dynamic unbalance results from the couple of the unbalance forces ($m\omega^2 r$) during rotation, causing a shaking of the axle.
3. *Static and dynamic unbalance.* This is the general case of unbalance, which can be visualized by not allowing m_1 and m_2 and the axis of rotation to lie in the same plane (Figure 1.4.6b).

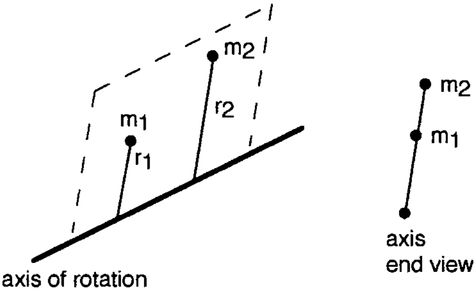

FIGURE 1.4.5 Schematic of static unbalance.

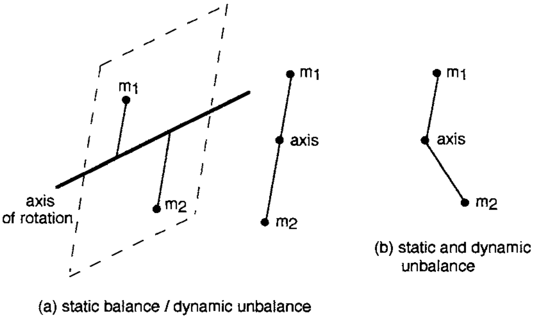

(a) static balance / dynamic unbalance

(b) static and dynamic unbalance

FIGURE 1.4.6 Schematic of two cases of dynamic unbalance.

The magnitude and angular position of a body's unbalance can be determined using a dynamic balancing machine. Here the shaking forces are measured by electronically sensing the small oscillations of the bearings that can be correlated with the position of the body.

Critical Speed of Rotating Shafts

A rotating shaft may become dangerously unstable and whirl with large lateral amplitudes of displacement at a critical speed of rotation. The critical speed, in revolutions per second, corresponds with the natural frequency of lateral vibration of the system. Thus, it can be analytically predicted fairly well and can be safely measured in a real but nonrotating machine with high precision. If unavoidable, as at startup, the critical speed should be passed over rapidly. Other ways of minimizing the problems of whirling shafts include the proper balancing of rotors and the replacing of bent shafts and worn bearings.

Random Vibrations. Shock Excitation

Many structures are subjected to nonharmonic excitations and respond with transient vibrations rather than steady-state motions. Random vibration is often caused by *shock* excitation, which implies that the loading occurs suddenly, in a short time with respect to the natural period of vibration of the system. Such a loading, typically caused by impact conditions, may be highly irregular in terms of amplitude, waveform, and repetition (Figure 1.4.7), but normally it is possible to extract practically uniform critical events from the loading history for purposes of future design and life prediction.

For most practical purposes, this plot represents aperiodic motion, in which the important quantities are the maximum and average large amplitudes and the projected total repetitions (in this case, at the rate of about 1000 per day) over the design life of the structure. The small-amplitude transient vibrations associated with the large events are likely to be negligible here in terms of dynamic behavior as well as fatigue damage, although the relatively large number of small oscillations may cause concern in some cases.

Random vibrations are difficult to deal with analytically. Numerical methods involving computers are advantageous to obtain response (or shock) spectrums of a system, assuming key parameters and simple models of nonharmonic excitations such as impulsive forces and force step functions. Because the

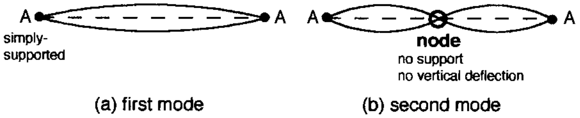

FIGURE 1.4.8 Simply supported beam in two modes of vibration.

maximum transient response is relatively insensitive to damping, an undamped system is useful in modeling response spectrums. Experimental techniques are needed to verify the analytical predictions, especially when the behavior of a multiple-degree-of-freedom system is determined from the response spectrum of a single-degree-of-freedom system.

Multiple-Degree-of-Freedom Systems. Modal Analysis

The analysis of a system with more than one degree of freedom requires an independent coordinate for each degree of freedom to describe the configurations. Thus, an n-degree-of-freedom system has n natural frequencies and n normal *modes* of vibration. Complex systems can be classified as (1) discrete and lumped-parameter systems with finite numbers of degrees of freedom; or (2) continuous elastic bodies of distributed mass with infinite number of degrees of freedom (in theory). A common example of the latter is a vibrating beam, with the first two modes of vibration shown in Figure 1.4.8. Each *nodal point* is a point of zero deflection. Usually the *fundamental natural frequency* (the lowest) is the most important, and only the lowest few frequencies are considered in practice.

A system's harmonic vibrations are its *principal modes*. The system can vibrate nonharmonically in many ways. Periodic motion of complex wave form can be analyzed as a combination of principal-mode vibrations.

The classical method of mathematical solution and the experimental techniques become increasingly cumbersome and sometimes inaccurate for a system of more than a few degrees of freedom. The recent emergence of sophisticated numerical (finite element; Figure 1.4.9) and experimental (electro-optics) techniques has resulted in significant progress in this area. The synergistic aspects of several new methods are especially remarkable. For example, damage caused by vibrations can significantly affect a system's own modal behavior and, consequently, the rate of damage evolution. Such nonlinear changes of a system can now be investigated and eventually predicted by the hybrid applications of computerized numerical methods; fatigue and fracture mechanics (Section 1.6); and high-speed, noncontacting, full-field vibration and stress imaging (Section 1.4, "Vibration-Measuring Instruments," and Section 1.5, "Experimental Stress Analysis and Mechanical Testing"). These enhance the already powerful modern methods of *modal analysis* for accurately describing the response of multiple-degree-of-freedom systems.

Vibration-Measuring Instruments

Many kinds of instruments can be used for the experimental investigation of vibrating systems. They range from simple, inexpensive devices to sophisticated electro-optics with lasers or infrared detectors, with the list still expanding in many areas.

The basic quantities of interest regarding a vibrating system are the displacement, velocity, acceleration, and frequency. A typical sensor (or pickup or transducer) for determining these is the piezoelectric accelerometer, which is attached to the vibrating machine or structure to be analyzed. The complete setup normally includes amplifiers, frequency analyzer, oscilloscope, and recorders. An instrumented impact hammer may be used to provide well-defined impulse excitation to determine the natural frequencies of structures. The frequency analyzer can display the accelerometer output in the time or the frequency domain. Other kinds of devices used for vibration sensing include seismic spring-mass systems, electrical-resistance strain gages, and electromagnetic transducers.

Care must be exercised in matching a transducer to the task at hand because reliable data can be obtained only if the transducer has a "flat-response" frequency region for the measurements of interest.

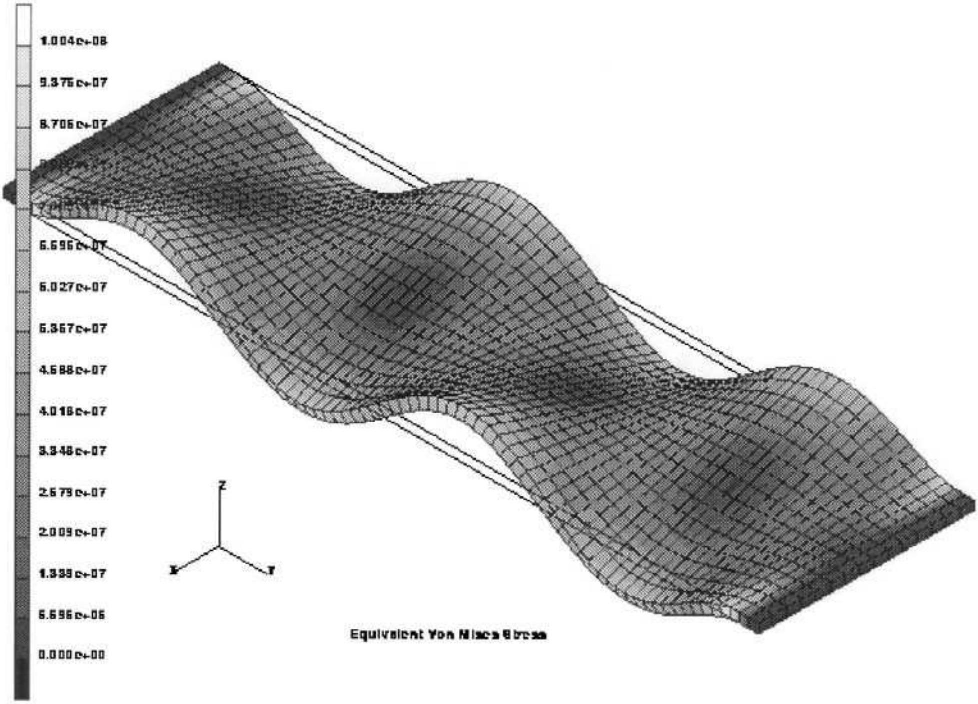

FIGURE 1.4.9 Modal analysis of a vibrating plate. (Photo courtesy David T. Corr, University of Wisconsin–Madison.)

For example, electromagnetic vibrometers (or seismometers) are low-frequency transducers that have low natural frequency compared to the frequency of the motion to be measured. At the other extreme, piezoelectric accelerometers are designed to have higher natural frequency than the frequency to be measured.

It is also important to use transducers of negligible mass compared to the mass of the vibrating system being measured. Very small, light-weight accelerometers are available to satisfy this condition in many cases. In some situations, however, only noncontacting means of motion measurement provide satisfactory results. Optical techniques are prominent in this area, offering several advantages besides the noncontacting measurement capability. They can be full-field techniques, which means that data may be obtained rapidly from many points on a body using one instrument. They have excellent resolution and precision, and some of them are easy to use. Three kinds of optical instruments are distinguished here for vibratory system analysis, depending on the primary quantity measured:

1. *Displacement measurement*. Holography and speckle pattern imaging have excellent resolution, but they are adversely affected by unstable measuring conditions. They are most useful in laboratory applications.
2. *Velocity measurement*. Laser Doppler systems provide time-resolved, accelerometer-like measurements. They are relatively unaffected by measuring conditions, and are simple and rugged enough to use in the laboratory or in the field. Several important capabilities of such a vibration pattern imaging system are worth mentioning (Color Figure 3 through Color Figure 7):
   - Noncontacting; the structure's response is not affected by the instrumentation; applicable in some hazardous environments (hot structures, etc.), and short or long range (over 200 m) on natural surfaces
   - Single-point or full-field data acquisition at high resolution from areas of 0.5 × 0.5 mm to 8 × 8 m; up to 500 individual points can be programmed
   - Wide frequency range; 0 to 100 kHz (for example, Figure 1.4.10)

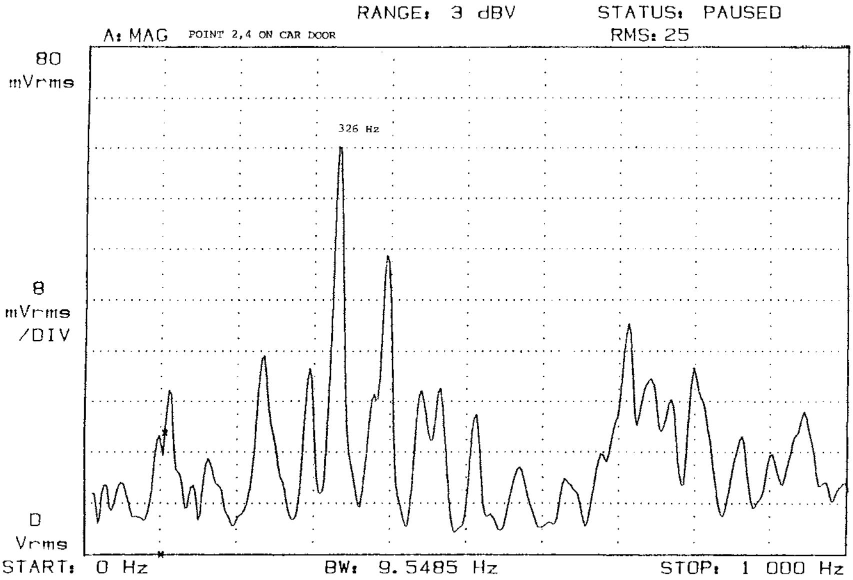

FIGURE 1.4.10 Laser-based, noncontacting vibration analysis of a point on a car door. (Data courtesy of Ometron Inc., Sterling, VA.)

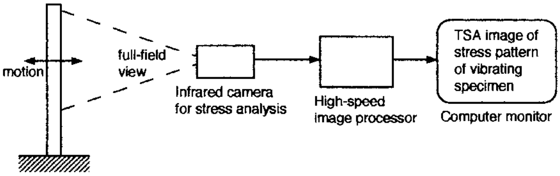

FIGURE 1.4.11 Schematic of modal analysis of a jet engine turbine blade by thermal imaging of the stress field caused by complex vibration. For sample data, see Color Figure 8.

- Sensitivity to a wide range of vibration velocities; 0.005 to 1000 mm/sec
- Large depth of focus; ±3 m at 10-m working distance
- Node spacing down to a few millimeters can be resolved
- Resolution of small displacements, down to the wavelength of the laser source (typically, ≈1 Å)
- Safe, class II laser system; <1 mW output
- Conventional signal processing is used to give multipoint modal parameters in familiar format for analytical comparisons

3. *Dynamic stress measurement.* Differential thermography via dynamic thermoelasticity (Figure 1.4.11) has recently become a powerful technique for measuring the modal response of vibrating structures and, uniquely, for directly assessing the structural integrity and durability aspects of the situation. This approach uses high-speed infrared electro-optics and has predictive capability because it can be quantitatively combined with modern fatigue and fracture mechanics methods. For example, it can effectively relate vibration modes to complex fracture modes and damage evolution rates of a real component even under arbitrary and unknown loading with unknown boundary conditions. See Section 1.5, "Experimental Stress Analysis and Mechanical Testing," for more on the dynamic thermoelasticity technique.

1.5 Mechanics of Materials

Bela I. Sandor, Stephen M. Birn, and Michael L. Brown

Mechanics of materials, also called strength of materials, provides quantitative methods to determine stresses (the intensity of forces) and strains (the severity of deformations), or overall deformations or load-carrying abilities of components and structures. The stress-strain behavior of materials under a wide range of service conditions must be considered in many designs. It is also crucial to base the analysis on correct modeling of component geometries and external loads. This can be difficult in the case of multiaxial loading, and even more so if time- or temperature-dependent material behaviors must be considered.

Proper modeling involves free-body diagrams and equations of equilibrium. However, it is important to remember that *the equilibrium equations of statics are valid only for forces or for moments of forces*, and not for stresses.

Stress

The intensity of a force is called stress and is defined as the force acting on an infinitesimal area. A normal stress σ is defined as

$$\sigma = \lim_{dA \to 0} \frac{dF}{dA} \tag{1.5.1}$$

where dF is a differential normal force acting on a differential area dA. It is often useful to calculate the average normal stress $\sigma = P/A$, where P is the resultant force on an area A. A shear stress τ caused by a shearing force V is defined likewise:

$$\tau = \lim_{dA \to 0} \frac{dV}{dA} \tag{1.5.2}$$

An average shear stress is obtained from V/A.

It is helpful to consider the general cases of stresses using rectangular elements in two and three dimensions, while ignoring the deformations caused by the stresses.

Plane Stress

In some relatively simple cases, all stress vectors lie in the same plane. This is represented by a two-dimensional element in Figure 1.5.1, where σ_x and/or σ_y may be tensile (pulling on the element as shown) or compressive (pushing on the element; not shown). Normal stresses are easy to visualize and set up correctly.

Shear stresses need to be discussed here in a little detail. The notation means that τ_{xy}, for example, is a shear stress acting in the y direction on a face perpendicular to the x axis. It follows that τ_{yx} is acting in the x direction on a face perpendicular to the y axis. The four shear stress vectors are pointed as they are because of the requirement that the element be in equilibrium: the net forces and moments of forces

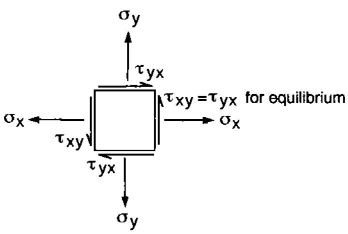

FIGURE 1.5.1 Generalized plane stress.

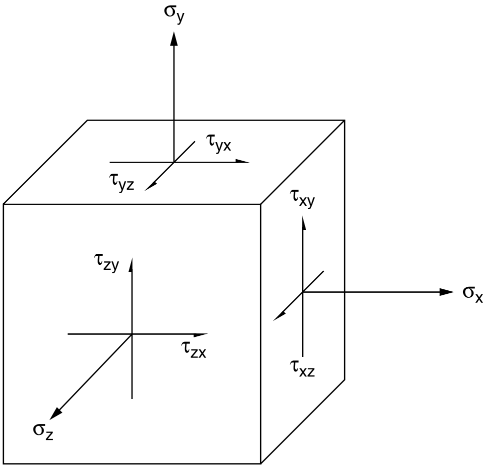

FIGURE 1.5.2 Three-dimensional general state of stress.

on it must be zero. Thus, reversing the direction of all four τs in Figure 1.5.1 is possible, but reversing less than four is not realistic.

Three-Dimensional State of Stress

The concept of plane stress can be generalized for a three-dimensional element as shown in Figure 1.5.2, working with the three primary faces of the cube and not showing stresses on the hidden faces, for clarity.

Again, the normal stresses are easy to set up, while the shear stresses may require considerable attention. The complex cases of stresses result from multiaxial loading, such as combined axial, bending, and torsional loading. Note that, even in complex situations, simplifications are possible. For example, if the right face in Figure 1.5.2 is a free surface, $\sigma_x = \tau_{xz} = \tau_{xy} = 0$. This leaves a plane stress state with σ_y, σ_z, and τ_{yz}, at most.

Stress Transformation

A free-body element with known stresses on it allows the calculation of stresses in directions other than the given *xyz* coordinates. This is useful when potentially critical welded or glued joints, or fibers of a composite, are along other axes. The stress transformations are simplest in the case of plane stress and can be done in several ways. In any case, at a given point in a material, only one state of stress is present at a particular instant. At the same time, the components of the stresses depend on the orientation of the chosen coordinate system.

The stress transformation equations depend on the chosen coordinate system and the sign convention adopted. A common arrangement is shown in Figure 1.5.3, where (a) is the known set of stresses and (b) is the unknown set, denoted by primes.

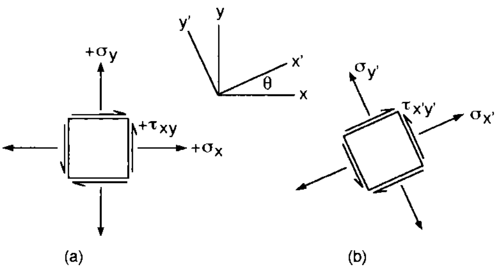

FIGURE 1.5.3 Elements for stress transformation.

In the present sign convention, an outward normal stress is positive and an upward shear stress on the right-hand face of the element is positive. The transformation equations are

$$\begin{aligned} \sigma_{x'} &= \frac{\sigma_x + \sigma_y}{2} + \frac{\sigma_x - \sigma_y}{2}\cos 2\theta + \tau_{xy}\sin 2\theta \\ \sigma_{y'} &= \frac{\sigma_x + \sigma_y}{2} - \frac{\sigma_x - \sigma_y}{2}\cos 2\theta - \tau_{xy}\sin 2\theta \\ \tau_{x'y'} &= -\frac{\sigma_x - \sigma_y}{2}\sin 2\theta + \tau_{xy}\cos 2\theta \end{aligned} \tag{1.5.3}$$

A negative result means that the actual direction of the stress is opposite to the assumed direction.

Principal Stresses

It is often important to determine the maximum and minimum values of the stress at a point and the orientations of the planes of these stresses. For plane stress, the maximum and minimum normal stresses, called **principal stresses**, are obtained from

$$\sigma_{1,2} = \frac{\sigma_x + \sigma_y}{2} \pm \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \tag{1.5.4}$$

No shear stress is acting on the principal planes on which the principal stresses are acting. However, shear stresses are on other planes. The maximum shear stress is calculated from

$$\tau_{\max} = \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \tag{1.5.5}$$

This stress acts on planes oriented 45° from the planes of principal stress. There is a normal stress on these planes of $\tau_{\max}$, the average of σ_x and σ_y:

$$\sigma_{ave} = \frac{\sigma_x + \sigma_y}{2} \tag{1.5.6}$$

Mohr's Circle for Plane Stress

The equations for plane stress transformation have a graphical solution, called Mohr's circle, which is convenient to use in engineering practice, including "back-of-the-envelope" calculations. Mohr's circle is plotted on an $\sigma - \tau$ coordinate system as in Figure 1.5.4, with the center C of the circle always on the σ axis at $\sigma_{\text{ave}} = (\sigma_x + \sigma_y)/2$ and its radius $R = \sqrt{[(\sigma_x - \sigma_y)/2]^2 + \tau_{xy}^2}$. The positive τ axis is downward for convenience in order to make θ on the element and the corresponding 2θ on the circle agree in sense (both counterclockwise here). The following aspects of Mohr's circle should be noted:

- The center C of the circle is always on the σ axis, but it may move left and right in a dynamic loading situation. This should be considered in failure prevention.
- The radius R of the circle is $\tau_{\max}$, and it may change, even pulsate, in dynamic loading. This is also relevant in failure prevention.
- Working back and forth between the rectangular element and the circle should be done carefully and consistently. An angle θ on the element should be represented by 2θ in the corresponding circle. If τ is positive downward for the circle, the sense of rotation is identical in the element and the circle.

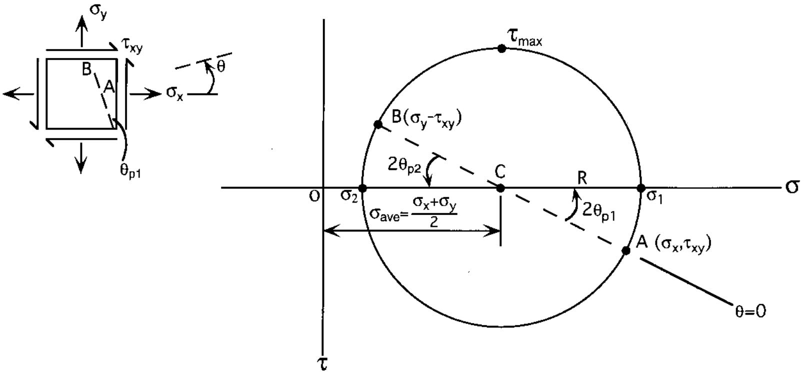

FIGURE 1.5.4 Mohr's circle.

- The principal stresses σ_1 and σ_2 are on the σ axis ($\tau = 0$).
- The planes on which σ_1 and σ_2 act are oriented at $2\theta_p$ from the planes of σ_x and σ_y (respectively) in the circle and at θ_p in the element.
- The stresses on an arbitrary plane can be determined by their σ and τ coordinates from the circle. These coordinates give magnitudes and signs of the stresses. The physical meaning of $+\tau$ vs. $-\tau$ regarding material response is normally not as distinct as $+\sigma$ vs. $-\sigma$ (tension vs. compression).
- To plot the circle, use the calculated center *C* coordinate and the radius *R* or directly plot the stress coordinates for two mutually perpendicular planes and draw the circle through the two points (*A* and *B* in Figure 1.5.4), which must be diametrically opposite on the circle.

Special Cases of Mohr's Circles for Plane Stress

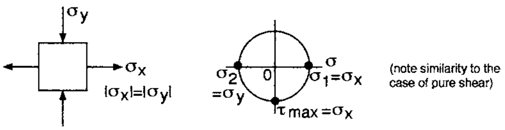

FIGURE 1.5.9 Biaxial tension-compression: $|\sigma_x| = |\sigma_y|$ (similar to the case of pure shear).

Absolute Maximum Shear Stress

In the case of a general three-dimensional state of stress, the transformations to arbitrary planes are complex and beyond the scope of this book. It is useful to note, however, that in general three principal stresses exist at any point in a material. (Plane stress is a special case with one of these stresses being zero.) If the three principal stresses are known, it is easy to determine the absolute maximum shear stress, which is valuable in assessing a material's performance in service. The idea is to view the element as three separate two-dimensional elements, each time from a different principal direction, and plot the Mohr's circles for them in the same diagram. This is illustrated schematically in Figure 1.5.10 for an element with three tensile principal stresses of maximum, minimum, and intermediate values.

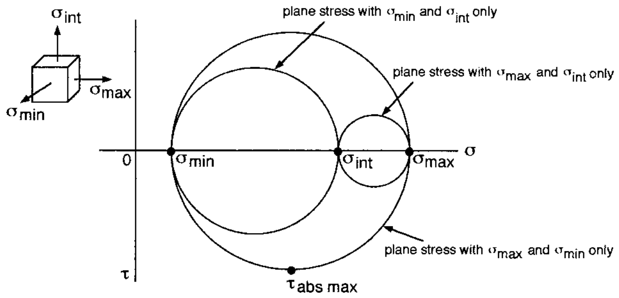

FIGURE 1.5.10 Principal stresses of three-dimensional element.

The Mohr's circles are interrelated because the three views of the element have common principal stresses associated with them. The absolute maximum shear stress is

$$\tau_{\text{abs max}} = \frac{\sigma_{\max} - \sigma_{\min}}{2} \tag{1.5.7}$$

Note that in calculating the absolute maximum shear stress for a state of plane stress, the actual third principal stress of $\sigma_3 = 0$ may be significant, if that is the minimum stress, and should be used in Equation (1.5.7) instead of a larger intermediate stress. For example, assume $\sigma_x = 200$ ksi and $\sigma_y = 100$ ksi in a case of plane stress. Using these as $\sigma_{\max}$ and $\sigma_{\min}$, $\tau_{\max} = (200 - 100)/2 = 50$ ksi. However, the fact that $\sigma_z = 0$ is important here. Thus, correctly, $\tau_{\text{abs max}} = (200 - 0)/2 = 100$ ksi. There is an important lesson here: apparently negligible quantities cannot always be ignored in mechanics of materials.

Strain

Solid materials deform when forces are acting on them. Large deformations are possible in some materials. Extremely small deformations are difficult to measure, but they still may be significant in critical geometry change or gradual damage evolution. Deformations are normally nonuniform even in apparently uniform components of machines and structures. The severity of deformation is called strain, which is separately defined for volumetric change and angular distortion of a body.

Normal Strain

The elongation or shortening of a line segment of unit length is called normal strain or axial strain. To define this quantitatively, consider a uniform bar of length L_o, and call this original length the gage length.

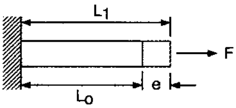

FIGURE 1.5.11 Model for calculating axial or normal strain.

Assume the bar elongates by an amount *e* to a new length L_1 under the action of a force *F* (Figure 1.5.11) or by thermal expansion. The normal strain ε is defined, with the gage length approaching zero in the limit, as

$$\varepsilon = \frac{e}{L_o} \tag{1.5.8}$$

The strain calculated this way is called engineering strain, which is useful and fairly accurate for small deformations. Elongation is considered positive.

Normal strain is a dimensionless quantity, but it is customary to label it in a way that indicates strain, such as in./in.; m/m; %; μ in./in.; or με (microstrain), depending on the system of units and the numerical representation.

True Strain

A difficulty of proper definition arises if the deformation *e* is not infinitesimal because, in a sense, the gage length is increasing. The correct definition in such a case is based on the instantaneous length *L* and infinitesimal changes *dL* in that length. Thus, the total true strain in a member axially deforming from length L_o to a final length L_f by an amount *e* is

$$\varepsilon = \int_{L_o}^{L_f} \frac{dL}{L} = \ell n \frac{L_f}{L_o} = \ell n(1+e) \tag{1.5.9}$$

True strain is practically identical to engineering strain up to a few percent of engineering strain. The approximate final length L_f of an axially deformed, short line segment of original length L_o is sometimes expressed as

$$L_f \approx (1+\varepsilon)L_o \tag{1.5.10}$$

Shear Strain

Angular distortions are called shear strains. More precisely, shear strain γ is the change in angle of two originally perpendicular ($\theta = \pi/2$) line segments. For consistency, assume that a decreasing angle represents positive shear strain, and an increasing angle is from negative shear strain. The angle γ is measured in radians. A useful way to show shear strain is given in Figure 1.5.12.

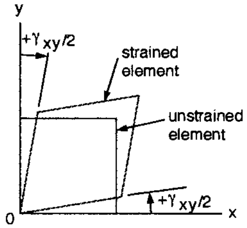

FIGURE 1.5.12 Shear strain in two dimensions.

Strain Transformation

The method of transforming strain at a point is similar to that for stress. In general, normal strain has three components: ε_x, ε_y, and ε_z, and shear strain has three: γ_{xy}, γ_{xz}, and γ_{yz}. Transformations of plane strain components are the simplest.

For a consistent approach, assume that strain transformation is desired from an *xy* coordinate system to an *x′y′* set of axes, where the latter is rotated counterclockwise (+θ) from the *xy* system. The transformation equations for plane strain are

$$\varepsilon_{x'} = \frac{\varepsilon_x + \varepsilon_y}{2} + \frac{\varepsilon_x - \varepsilon_y}{2}\cos 2\theta + \frac{\gamma_{xy}}{2}\sin 2\theta$$

$$\varepsilon_{y'} = \frac{\varepsilon_x + \varepsilon_y}{2} - \frac{\varepsilon_x - \varepsilon_y}{2}\cos 2\theta - \frac{\gamma_{xy}}{2}\sin 2\theta \tag{1.5.11}$$

$$\frac{\gamma_{x'y'}}{2} = -\frac{\varepsilon_x - \varepsilon_y}{2}\sin 2\theta + \frac{\gamma_{xy}}{2}\cos 2\theta$$

Note the similarity between the strain and stress transformation equations, as well as the differences.

Principal Strains

For isotropic materials only, principal strains (with no shear strain) occur along the principal axes for stress. In plane strain the principal strains ε_1 and ε_2 are expressed as

$$\varepsilon_{1,2} = \frac{\varepsilon_x + \varepsilon_y}{2} +/- \sqrt{\left(\frac{\varepsilon_x - \varepsilon_y}{2}\right)^2 - \left(\frac{\gamma_{xy}}{2}\right)^2} \tag{1.5.12}$$

The angular position θ_p of the principal axes (measured positive counterclockwise) with respect to the given *xy* system is determined from

$$\tan 2\theta_p = \frac{\gamma_{xy}}{\varepsilon_x - \varepsilon_y} \tag{1.5.13}$$

As in the case of stress, the maximum in-plane shear strain is

$$\frac{\gamma_{x'y'\max}}{2} = \sqrt{\left(\frac{\varepsilon_x - \varepsilon_y}{2}\right)^2 + \left(\frac{\gamma_{xy}}{2}\right)^2} \tag{1.5.14}$$

which occurs along axes at 45° from the principal axes, determined from

$$\tan 2\theta = -\frac{\varepsilon_x - \varepsilon_y}{\gamma_{xy}} \tag{1.5.15}$$

The corresponding average normal strain is

$$\varepsilon_{ave} = \frac{\varepsilon_x + \varepsilon_y}{2} \tag{1.5.16}$$

Mohr's Circle for Plane Strain

As in the case of stress, there is a graphical overview by Mohr's circle of the directional dependence of the normal and shear strain components at a point in a material. This circle has a center *C* at $\varepsilon_{\text{ave}} = (\varepsilon_x + \varepsilon_y)/2$, which is always on the *e* axis, but is shifting left and right in a dynamic loading situation. The radius *R* of the circle is

$$R = \sqrt{\left(\frac{\varepsilon_x - \varepsilon_y}{2}\right)^2 + \left(\frac{\gamma_{xy}}{2}\right)^2} \tag{1.5.17}$$

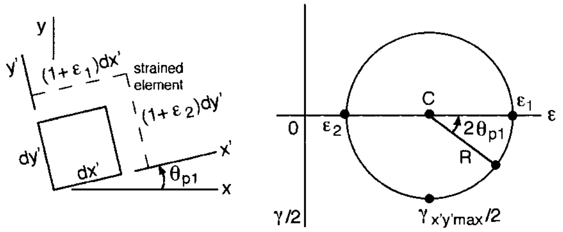

FIGURE 1.5.13 Mohr's circle for plane strain.

Note the proper labeling (ε vs. $\gamma/2$) and preferred orientation of the strain axes as shown in Figure 1.5.13. This sets up a favorable uniformity of angular displacement between the element ($+\theta$ counterclockwise) and the circle ($+2\theta$ counterclockwise).

Mechanical Behaviors and Properties of Materials

The stress–strain response of a material depends on its chemical composition, microstructure, geometry, magnitude and rate of change of stress or strain applied, and environmental factors. Numerous quantitative mechanical properties are used in engineering. Some of the basic properties and their common variations are described here because they are essential in mechanics of materials analyses.

Stress–Strain Diagrams

Uniaxial tension or compression stress–strain plots have several distinctive shapes, depending on the material, test conditions, and quantities plotted. The chosen representative schematic diagram here is a true stress vs. true strain curve for a ductile, nonferrous metal tested in tension (Figure 1.5.14). The important mechanical properties listed in Table 1.5.1 are obtained from such a test or a similar one in pure shear (not all are shown in Figure 1.5.14).

Another useful mechanical property (not measured from the $\sigma - \varepsilon$ plot) is hardness. This is a flow property, with some qualitative correlations to the other properties.

It is important to appreciate that the mechanical properties of a material depend on its chemical composition and its history of thermal treatment and plastic deformations (cold work; cyclic plasticity). For example, consider the wide ranges of monotonic and cyclic stress–strain curves for 1045 steel (a given chemical composition), at room temperature, as functions of its hardness resulting from thermal treatment (Figure 1.5.15). See Section 1.6, "Fatigue," for more on cycle-dependent material behaviors.

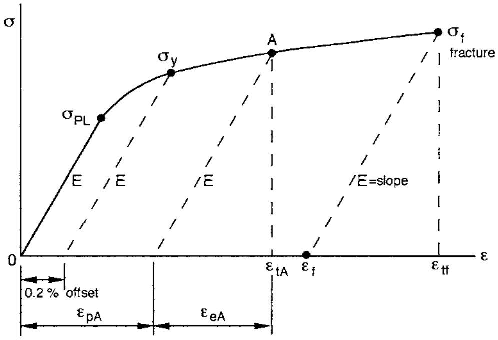

FIGURE 1.5.14 True stress vs. true strain for a ductile, nonferrous metal.

TABLE 1.5.1 Basic Mechanical Properties

Symbol	Definition	Remarks
E	Modulus of elasticity; Young's modulus; $E = \sigma/\varepsilon_e$	Hooke's law; T and ε_p effects small
G	Shear modulus of elasticity $G = \dfrac{\tau}{\gamma_e} = E/2(1+v)$	T and ε_p effects small
v	Poisson's ratio; $v = \dfrac{\varepsilon_{lateral}}{\varepsilon_{longit.}}$	T and ε_p effects small
σ_{PL}	Proportional limit; at onset of noticeable yielding (or at onset of nonlinear elastic behavior)	Flow property; inaccurate; T and ε_p effects large
σ_y	0.2% offset yield strength (but yielding can occur at $\sigma < \sigma_y$ if $\sigma_{PL} < \sigma_y$)	Flow property; accurate; T and ε_p effects large
σ_f	True fracture strength; $\sigma_f = \dfrac{P_f}{A_f}$	Fracture property; T and ε_p effects medium
ε_f	True fracture ductility; $\varepsilon_f = \ln\dfrac{A_O}{A_f} = \ln\dfrac{100}{100 - \%\text{RA}}$	Max. ε_p; fracture property; T and ε_p effects medium
% RA	Percent reduction of area; $\%\text{RA} = \dfrac{A_O - A_f}{A_O} \times 100$	Fracture property; T and ε_p effects medium
n	Strain hardening exponent; $\sigma = K\varepsilon_p^n$	Flow property; T and ε_p effects small to large
Toughness	Area under σ vs. ε_p curve	True toughness or intrinsic toughness; T and ε_p effects large
σ_u	Ultimate strength; $\dfrac{P_{\max}}{A_O}$	Fracture property; T and ε_p effects medium
M_r	Modulus of resilience; $M_r = \dfrac{\sigma_{PL}^2}{2E}$	Area under original elastic portion of $\sigma - \varepsilon$ curve

Notes: T is temperature; ε_p refers to prior plastic strain, especially cyclic plastic strain (fatigue). These are qualitative indicators here; exceptions are possible.

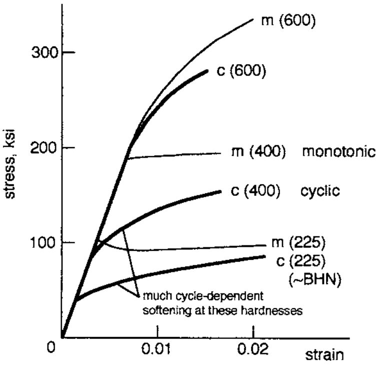

FIGURE 1.5.15 Influence of hardness and deformation history on the stress-strain response of SAE 1045 steel.

Generalized Stress–Strain Expressions. Hooke's Law

An important special case of stress–strain responses is when the material acts entirely elastically ($\varepsilon_p = 0$, $\varepsilon_t = \varepsilon_e$). In this case, for uniaxial loading, the basic **Hooke's law**, $\sigma = E\varepsilon$, can be used, and similarly for unidirectional shear, $\tau = G\gamma$. For multiaxial loading (Color Figure 9), the generalized Hooke's law is applicable,

$$\varepsilon_x = \frac{1}{E}\left[\sigma_x - v\left(\sigma_y + \sigma_z\right)\right]$$

$$\varepsilon_y = \frac{1}{E}\left[\sigma_y - v\left(\sigma_x + \sigma_z\right)\right] \tag{1.5.18}$$

$$\varepsilon_z = \frac{1}{E}\left[\sigma_z - v\left(\sigma_x + \sigma_y\right)\right]$$

Other useful expressions for ideally elastic behavior are as follows. Relating the axial and shear moduli,

$$G = \frac{E}{2(1+v)} \tag{1.5.19}$$

The change in volume per unit volume is the volumetric strain or dilatation,

$$e = \frac{1-2v}{E}\left(\sigma_x + \sigma_y + \sigma_z\right) \tag{1.5.20}$$

The bulk modulus k is the ratio of a uniform stress (hydrostatic) to the dilatation,

$$k = \frac{\sigma}{e} = \frac{E}{3(1-2v)} \tag{1.5.21}$$

For most metals, $v \approx 1/3$ and $k \approx E$.

Uniaxial Elastic Deformations

The total elastic deformation δ of axially loaded bars, columns, and wires is calculated with the aid of basic expressions. Using $\sigma = E\varepsilon$ and $\sigma = P(x)/A(x)$, where $P(x)$ and $A(x)$ are, respectively, the internal force and cross-sectional area of a bar at a distance x from one end,

$$\delta = \int_0^L \frac{P(x)}{A(x)E}\,dx \tag{1.5.22}$$

where L is the total length considered.

In most cases, $A(x)$ is a constant; $P(x)$ may also be a constant, except where several different axial forces are applied and, occasionally, for vertical bars and columns, where the member's own weight may cause $P(x)$ to vary significantly along the length. If $A(x)$, $P(x)$, and E are constants,

$$\delta = \frac{PL}{AE} \tag{1.5.23}$$

Thermally Induced Deformations

Thermal expansion or contraction is a linearly dependent, recoverable deformation as purely elastic deformations are. For a homogeneous and isotropic material, the thermally induced deformation from the original length L is calculated from

$$\delta_T = \alpha\Delta TL \tag{1.5.24}$$

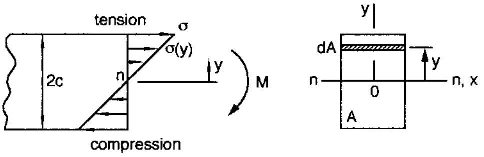

FIGURE 1.5.16 Internal normal stresses in a beam caused by bending.

where α is the linear coefficient of thermal expansion (strain per degree of temperature, a material property), and ΔT is the change in temperature. The thermal strain can be prevented or reduced by constraining a member. In that case, the stresses and strains can be calculated using the methods pertaining to statically indeterminate members.

Stresses in Beams

To calculate stresses in beams, one must first model the beam correctly in terms of its supports and loading (such as simply supported, with distributed loading); determine the appropriate unknown external reactions; and establish the corresponding shear and moment diagrams using a consistent sign convention. Normal and shear stresses may need to be calculated, but typically the normal stresses are the most significant.

Flexure Formula

The normal stresses at a particular cross section in a beam are caused by the bending moment that acts at that cross section, and are distributed by magnitude and sign (both tension and compression) so that the beam is in equilibrium. The basic concept for calculating the stresses is that a neutral axis *n-n* of $\varepsilon = \sigma = 0$ is in the beam, and that the longitudinal normal strain varies linearly with distance y from the neutral axis.

If the beam is behaving entirely elastically, the stress distribution is also linear, as in Figure 1.5.16. In this case, the stress at a distance y from the neutral axis is calculated from $M = \int \sigma(y) y \, dA$ and results in

$$\sigma(y) = \frac{My}{I} \tag{1.5.25}$$

where I = moment of inertia of the cross-sectional area about the neutral axis.

The maximum stress, with the appropriate sign, is

$$\sigma = \frac{Mc}{I} \tag{1.5.26}$$

Several special cases of bending require additional consideration and analysis as outlined next.

Inelastic Bending

A beam may plastically deform under an increasing moment, yielding first in its outer layers and ultimately throughout its depth. Such a beam is analyzed by assuming that the normal strains are still linearly varying from zero at the neutral axis to maximum values at the outer layers. Thus, the stress distributions depend on the stress–strain curve of the material. With the stress distribution established, the neutral axis can be determined from $\int \sigma(y) \, dA = 0$, and the resultant moment from $M = \int y \sigma(y) \, dA$. A fully plastic beam of rectangular cross section and flat-top yielding supports 50% more bending moment than its maximum elastic moment.

Neutral Axis of Semisymmetric Area

If the cross-sectional area is semisymmetric, such as a T-shape, and the loading is in a centroidal plane of symmetry, the neutral axis for elastic deformations is at the centroid *C* of the area as shown in Figure 1.5.17, and Equation (1.5.25) can be used. Note that the magnitudes of the maximum tensile and compressive stresses are not the same in this case.

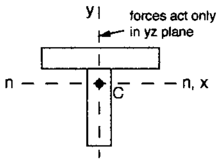

FIGURE 1.5.17 Neutral axis of a semisymmetric area.

Unsymmetric Bending

In the general case, the cross-sectional area has an arbitrary shape and the loading is arbitrarily applied. The problem of an arbitrary area is handled by choosing the centroidal *xy* coordinate system so that the axes are principal axes of inertia for the area. The principal axes can be determined by using inertia transformation equations or Mohr's circle of inertia. Having an axis of symmetry is a simple special case because the principal axes are the axis of symmetry and the axis perpendicular to it.

The **flexure formula** can be applied directly if the principal axes of inertia are known, and the bending moment is applied about one of these centroidal principal axes. A more complex case is if the moment is not about a principal axis as shown in Figure 1.5.18.

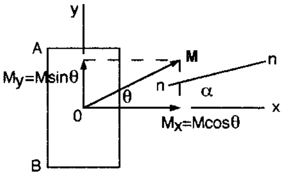

FIGURE 1.5.18 Schematic of arbitrary bending moment.

Different texts may present different formulas for calculating the bending stresses in such situations, depending on the choice of a coordinate system and the sign convention adopted. It is better not to rely on a cookbook formula, but to break down the problem into simple, easily visualized parts, and then reason out an algebraic superposition of the stress components. To illustrate this approach schematically, consider the stresses at points *A* and *B* in Figure 1.5.18. Instead of working directly with the applied moment **M**, resolve **M** into its components M_x and M_y. M_x causes a tensile stress $\sigma_{z_{A_1}}$ at *A* and a compressive stress $-\sigma_{z_{B_1}}$ at *B*. M_y causes tensile stresses at *A* and *B*, $\sigma_{z_{A_2}}$ and $\sigma_{z_{B_2}}$. The magnitudes of these stress components are readily calculated from the flexure formula with the appropriate dimensions and inertias for each. The resultant stresses are

$$\sigma_A = \sigma_{z_{A_1}} + \sigma_{z_{A_2}}$$

$$\sigma_B = -\sigma_{z_{B_1}} + \sigma_{z_{B_2}}$$

The neutral axis at angle α in the general case is not coincident with the direction of **M** (Figure 1.5.18). In the present case, α is defined by

$$\tan\alpha = \frac{I_x}{I_y}\tan\theta \tag{1.5.27}$$

Composite Beams

Nonhomogeneous beams are often designed to take advantage of the properties of two different materials. The approach for analyzing these is to imagine a transformation of the beam's cross section to an equivalent cross section of a different shape but of a single material, so that the flexure formula is usable. This is illustrated for a beam *A* with reinforcing plates *B*, as in Figure 1.5.19.

The transformation factor *n* is obtained from

$$n = \frac{E_B}{E_A} \tag{1.5.28}$$

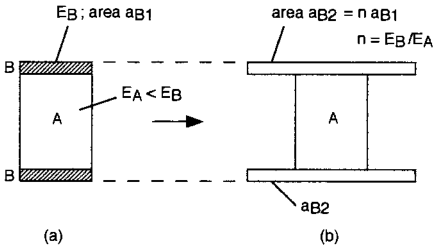

FIGURE 1.5.19 Equivalent area method for a symmetric composite beam.

Note that, in a composite beam, the strains vary linearly with distance from the neutral axis; however, the stresses do not because of the different elastic moduli of the components. The actual stress σ in the transformed area is determined by first calculating the "pretend" stress σ' for the uniform transformed area and then multiplying it by n:

$$\sigma = n\sigma' \tag{1.5.29}$$

Nonsymmetric composite beams (such as having only one reinforcing plate B in Figure 1.5.19) are analyzed similarly, but first require the location of the neutral axis.

Reinforced concrete beams are important special cases of composite beams. Their stress analysis is influenced by the fact that concrete is much weaker in tension than in compression. Empirical approaches are particularly useful in this area.

Curved Beams

The stress analysis of curved beams requires some additional considerations. For example, the flexure formula is about 7% in error (the calculated stresses are too low) when the beam's radius of curvature is five times its depth (hooks, chain links). The curved-beam formula provides realistic values in such cases.

Shear Stresses in Beams

Transverse loads on beams are common, and they cause transverse and complementary longitudinal shear stresses in the beams. Schematically, the transverse shear stresses are distributed on a rectangular cross section as shown in Figure 1.5.20. The shear stress is zero at free surfaces by definition.

The internal shear stress is calculated according to Figure 1.5.20 from

$$\tau = \frac{VQ}{It} \tag{1.5.30}$$

where

τ = shear stress value at any point on the line $\ell - \ell$ at a distance y' from the neutral axis
V = total shear force on cross-sectional area A
$Q = \bar{y}'A'$; A' = area above line $\ell - \ell$; $\bar{y}'$ = distance from neutral axis to centroid of A'
I = moment of inertia of entire area A about neutral axis
t = width of cross section where τ is to be determined

This shear formula gives $\tau_{max} = 1.5\ V/A$ if t is constant for the whole section (rectangle). Note that the magnitude of the shear stress distribution changes sharply when an abrupt change occurs in width t, such as in an I-beam (Figure 1.5.21).

Shear Flow

In the analysis of built-up members, such as welded, bolted, nailed, or glued box beams and channels, a useful quantity is the shear flow q measured in force per unit length along the beam:

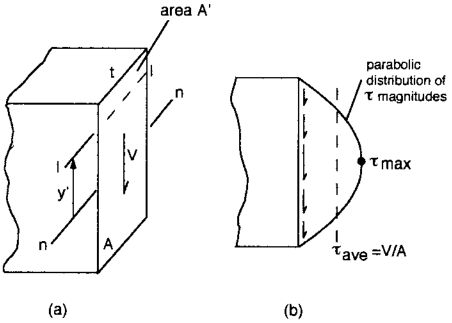

FIGURE 1.5.20 Transverse shear stress distribution.

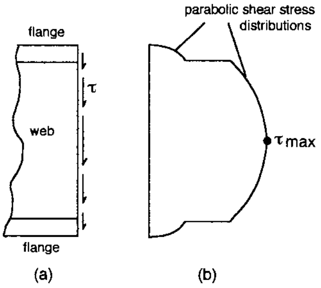

FIGURE 1.5.21 Shear stress distribution for I-beam.

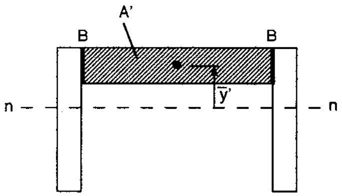

FIGURE 1.5.22 Critical joint regions of a built-up beam.

$$q = \frac{VQ}{I} \tag{1.5.31}$$

where all quantities are defined as for Equation (1.5.30).

Care must be taken to use the appropriate value for Q. For example, consider a channel section of three flat pieces glued together as in Figure 1.5.22. There are two critical joint regions B here, and the area A' is between them. The shear flow is carried by the two joints together, so the actual force per unit length on one joint is $q/2$ here.

Shear Flow in Thin-Walled Beams

The shear-flow distribution over the cross section of a thin-walled member is governed by equilibrium requirements. Schematic examples of this are given in Figure 1.5.23. Note the special case of unsymmetrical loading in part (c), which causes bending and twisting of the beam. The twisting is prevented if the vertical force V is applied at the shear center C, defined by the quantity e:

$$e = \frac{dH}{V} \tag{1.5.32}$$

where d is the centroidal distance between the two horizontal flanges and H is the shear force in the flanges (q_{ave} times width of flange).

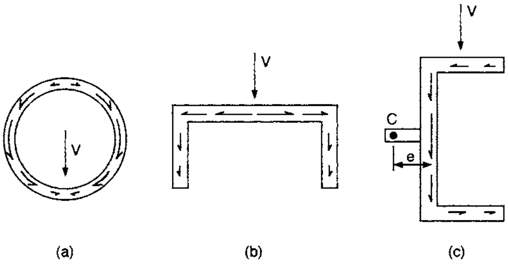

FIGURE 1.5.23 Shear flow distributions.

Deflections of Beams

Small deflections of beams can be determined relatively easily. The first step is to assess a beam's loading and support conditions and sketch an exaggerated elastic deflection curve as in Figure 1.5.24. The boundary conditions at the supports are useful in the solution for the whole beam. Here, at the fixed end *A*, no vertical displacement and no rotation occur, while at the roller support *B*, no vertical displacement is present, but rotation of the continuous beam occurs. The boundary and continuity conditions can be determined by inspection in simple cases.

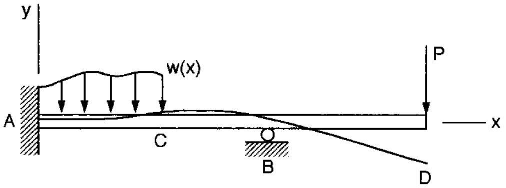

FIGURE 1.5.24 Exaggerated elastic curve of a beam in bending.

Moment vs. Curvature

For a homogeneous and elastic beam,

$$\frac{1}{\rho} = \frac{M}{EI} \tag{1.5.33}$$

where ρ = radius of curvature at a specific point on the elastic curve and 1/ρ is the curvature. The product *EI* is called the flexural rigidity; it is often a constant along the whole beam.

Integration Method for Slope and Displacement

For small displacements, $1/\rho = d^2y/dx^2$. In the general case, a distributed external loading *w*(*x*) should be included in the modeling of the problem. A set of expressions is available to solve for the deflections in rectangular coordinates:

$$-w(x) = \frac{dV}{dx} = EI\frac{d^4y}{dx^4}$$

$$V(x) = \frac{dM}{dx} = EI\frac{d^3y}{dx^3} \tag{1.5.34}$$

$$M(x) = EI\frac{d^2y}{dx^2}$$

TABLE 1.5.2

Beam	Slope: $\lvert dy/dx \rvert$	Max. deflection
	$PL^2 / 16EI$ at $x=0, L$	$PL^3 / 48EI$ at $x=L/2$
	$wL^3 / 24EI$ at $x=0, L$	$5wL^4 / 384EI$ at $x=L/2$
	$PL^2 / 2EI$ at $x=L$	$PL^3 / 3EI$ at $x=L$
	$wL^3 / 6EI$ at $x=L$	$wL^4 / 8EI$ at $x=L$
	0 at $x=0, L/2, L$	$PL^3 / 192EI$ at $x=L/2$
	0 at $x=0, L/2, L$	$wL^4 / 384EI$ at $x=L/2$

The deflection y of the elastic curve is obtained by successive integrations, using appropriate constants of integration to satisfy the boundary and continuity conditions. In general, several functions must be written for the moment $M(x)$ — one for each distinct region of the beam — between loading discontinuities. For example, these regions in Figure 1.5.24 are AC, CB, and BD. Considerable care is required to set up a solution with a consistent sign convention and selection of coordinates for simple and efficient forms of $M(x)$.

In practice, even relatively complex problems of beam deflections are solved using the principle of superposition and handbook values of slopes and deflections for subsets of basic loadings and supports. The literature contains a large variety of such subsets, a sampling of which is given in Table 1.5.2.

Deflection Caused by Shear

The transverse shear acting on a beam causes a displacement that tends to be significant compared to bending deflections only in very short beams. The shear deflection over a length L is approximated by

$$y = \frac{\tau_{ave} L}{G} \tag{1.5.35}$$

Torsion

The simplest torsion members have circular cross sections. The main assumptions in their analysis are that cross-sectional circles remain plane circles during twisting of a shaft and that radial lines on any

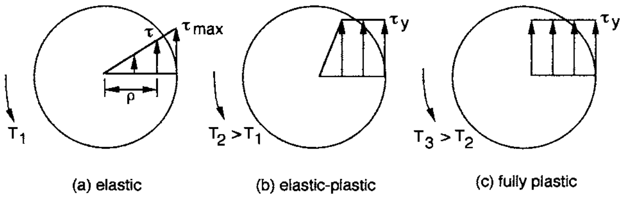

FIGURE 1.5.25 Shear stress distributions in a shaft.

cross section remain straight and rotate through the same angle. The length and diameter of the shaft are unchanged in small angular displacements. It is useful in the analysis that shear strain γ varies linearly along any radial line, from zero at the centerline of a solid or tubular shaft to a maximum at the outer surface:

$$\gamma = \frac{\rho}{r}\gamma_{\max} \tag{1.5.36}$$

where

ρ = radial distance to any element in the shaft
r = radius of the shaft.

Using $\tau = G\gamma$ for an elastically deforming material (Figure 1.5.25),

$$\tau = \frac{\rho}{r}\tau_{\max} \tag{1.5.37}$$

The torsion formula relating shear stress to the applied torque T is from $T = 2\pi \int \tau\rho^2\, d\rho$:

$$\tau_{\max} = \frac{Tr}{J} \quad \text{or} \quad \tau = \frac{T\rho}{J} \tag{1.5.38}$$

where J = the polar moment of inertia of the cross-sectional area; for a solid circle, $J = \pi r^4/2$; for a tube, $J = (\pi/2)(r_0^4 - r_i^4)$.

Power Transmission

The power P transmitted by a shaft under torque T and rotating at angular velocity w is

$$P = T\omega \tag{1.5.39}$$

where $\omega = 2\pi f$ and f = frequency of rotation or number of revolutions per second.

Angle of Twist

For a homogeneous shaft of constant area and G over a length L, under a torque T, the angular displacement of one end relative to the other is

$$\phi = \frac{TL}{JG} \tag{1.5.40}$$

For a shaft consisting of segments with various material and/or geometric properties, under several different torques in each, the net angular displacement is calculated from the vector sum of the individual twists:

$$\phi = \sum \frac{T_i L_i}{J_i G_i} \tag{1.5.41}$$

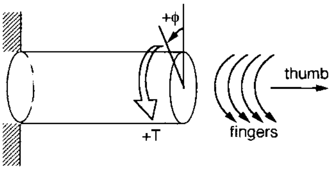

FIGURE 1.5.26 Right-hand rule for positive torque and angle.

The right-hand rule is used for a sign convention for torques and angles: T and ϕ are positive, with the thumb pointing outward from a shaft and the fingers curling in the direction of torque and/or rotation, as in Figure 1.5.26. Note that regardless of the number of torques applied to a shaft at various places along its length, only one torque is at a given cross section, and this torque is a constant in that segment of the shaft (until another external torque is encountered, requiring a different free-body diagram).

Inelastic Torsion

A shaft may plastically deform under an increasing torque, yielding first in its outer layers and ultimately throughout the cross section. Such a shaft is analyzed by assuming that the shear strains are still linearly varying from zero at the centerline to a maximum at the outer layers. Thus, the shear stress distribution depends on the shear stress–strain curve of the material. For example, an elastic, elastic–plastic, and fully plastic solid circular shaft is modeled in Figure 1.5.25, assuming flat-top yielding at τ_y. The torque T in any case is obtained by integrating the shear stresses over the whole area:

$$T = 2\pi \int_A \tau \rho^2 \, d\rho \tag{1.5.42}$$

The fully plastic torque in this case is 33% greater than the maximum elastic torque.

Noncircular Shafts

The analysis of solid noncircular members such as rectangles and triangles is beyond the scope of this book. The reason for the difficulty is that plane sections do not remain plane, but warp. It can be noted here, however, that a circular shaft utilizes material the most efficiently because it has a smaller maximum shear stress and a smaller angle of twist than a noncircular shaft of the same weight per unit length under the same torque.

Noncircular tubes with thin walls can be analyzed using the concept of shear flow that must be continuous and constant on the closed path of the cross-sectional area. The shear stress under a torque T is essentially constant over a uniformly thin wall (from inside to outside) and is given by

$$\tau = \frac{T}{2tA_m} \tag{1.5.43}$$

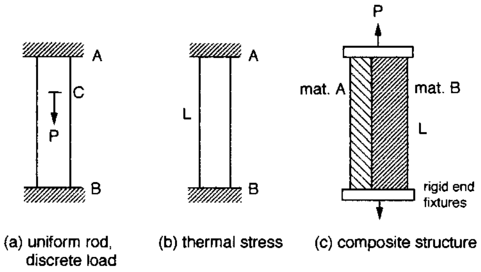
where t = thickness of the tube and A_m = mean area within the centerline of the wall thickness.

The angle of twist for an elastically deforming thin-walled tube of length L and constant thickness t is

$$\phi = \frac{TL}{4A_m^2 Gt} \oint ds \tag{1.5.44}$$

where the line integral represents the total length of the wall's centerline boundary in the cross section (for a circular tube, this becomes ≈$2\pi r$). For a tube with variable thickness t, the integrand becomes

$$\oint ds/t.$$



(a) uniform rod, discrete load (b) thermal stress (c) composite structure

FIGURE 1.5.27 Statically indeterminate axially loaded members.

Statically Indeterminate Members

Members that have more supports or constraints than the minimum required for static equilibrium are called statically indeterminate. They can be analyzed if a sufficient number of additional relationships are available. These are fundamentally similar to one another in terms of compatibility for displacements and are described separately for special cases.

Statically Indeterminate Axially Loaded Members

Several subsets of these are common; three are shown schematically in Figure 1.5.27.

1. From a free-body diagram of part (a), assuming upward forces F_A and F_B at ends A and B, respectively, the force equilibrium equation is

$$F_A + F_B - P = 0$$

The displacement compatibility condition is that both ends are fixed, so

$$\delta_{A/B} = 0$$

Then

$$\frac{F_A L_{AC}}{AE} - \frac{F_B L_{BC}}{AE} = 0, \quad F_A = P\frac{L_{BC}}{L_{AB}}, \quad F_B = P\frac{L_{AC}}{L_{AB}}$$

Alternatively, first assume that $F_B = 0$ and calculate the total downward displacement (tensile) of the free end B. Then calculate the required force F_B to compressively deform the rod upward so that after the superposition there is no net displacement of end B. The results are the same as previously for elastically deforming members.

2. Constrained thermal expansion or contraction of part (b) is handled as before, using the expression for thermally induced deformation:

$$\delta_T = \alpha\, \Delta T L \tag{1.5.45}$$

where α = linear coefficient of thermal expansion and ΔT = change in temperature.

3. The force equilibrium equation of part (c) is

$$P - F_A - F_B = 0$$

Here the two different component materials are deforming together by the same amount, so

$$\delta_A = \delta_B$$

$$\frac{F_A L}{A_A E_A} = \frac{F_B L}{A_B E_B}$$

providing two equations with two unknowns, F_A and F_B. Note that rigid supports are not necessarily realistic to assume in all cases.

Statically Indeterminate Beams

For axially loaded members, the redundant reactions of beams are determined from the given conditions of geometry (the displacement compatibility conditions). Various approaches can be used to solve problems of statically indeterminate beams, using the methods of integration, moment-areas, or superposition. Handbook formulas for the slopes and deflections of beams are especially useful; the boundary conditions must be well defined in any case. The method of superposition is illustrated in Figure 1.5.28.

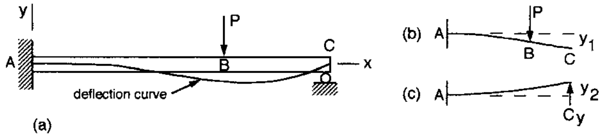


FIGURE 1.5.28 A statically indeterminate beam.

Choosing the reaction at C as the redundant support reaction (otherwise, the moment at A could be taken as redundant) and first removing the unknown reaction C_y, the statically determinate and stable primary beam is obtained in Figure 1.5.28b. Here the slope and deflection at A are zero. The slopes at B and C are the same because segment BC is straight. Next, the external load P is removed, and a cantilever beam fixed at A and with load C_y is considered in Figure 1.5.28c. From the original boundary conditions at C, $-y_1 + y_2 = 0$, and the problem can be solved easily using any appropriate method.

Statically Indeterminate Torsion Members

Torsion members with redundant supports are analyzed essentially the same way as other kinds of statically indeterminate members. The unknown torques, for example, are determined by setting up a solution to satisfy the requirements of equilibrium ($\Sigma T = 0$); angular displacement compatibility; and torque-displacement (angle = TL/JG) relationships. Again, the boundary conditions must be reasonably well defined.

Buckling

The elastic buckling of relatively long and slender members under axial compressive loading could result in sudden and catastrophic large displacements. The critical buckling load is the smallest for a given ideal column when it is pin supported at both ends; the critical load is larger than this for other kinds of supports. An ideal column is made of homogeneous material, is perfectly straight prior to loading, and is loaded only axially through the centroid of its cross-sectional area.

Critical Load. Euler's Equation

The buckling equation (Euler's equation) for a pin-supported column gives the critical or maximum axial load P_{cr} as

$$P_{cr} = \frac{\pi^2 EI}{L^2} \tag{1.5.46}$$

where

E = modulus of elasticity
I = smallest moment of inertia of the cross-sectional area
L = unsupported length of the pinned column

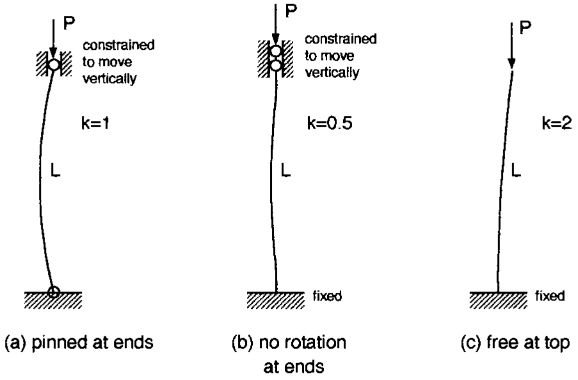

FIGURE 1.5.29 Common end conditions of slender columns.

A useful form of this equation gives the critical average stress prior to any yielding, for arbitrary end conditions,

$$\sigma_{cr} = \frac{\pi^2 E}{\left(k\,L/r\right)^2} \tag{1.5.47}$$

where

$r = \sqrt{I/A}$ = radius of gyration of cross-sectional area A
L/r = slenderness ratio
k = effective-length factor; constant, dependent on the end constraints
kL/r = effective-slenderness ratio

The slenderness ratio indicates, for a given material, the tendency for elastic buckling or failure by yielding (where the Euler formula is not applicable). For example, buckling is expected in mild steel if L/r is approximately 90 or larger, and in an aluminum alloy if $L/r > 60$. Yielding would occur first at smaller values of L/r. Ratios of 200 or higher indicate very slender members that cannot support large compressive loads. Several common end conditions of slender columns are shown schematically in Figure 1.5.29.

Secant Formula

Real columns are not perfectly straight and homogeneous and are likely to be loaded eccentrically. Such columns first bend and deflect laterally, rather than buckle suddenly. The maximum elastic compressive stress in this case is caused by the axial and bending loads and is calculated for small deflections from the secant formula,

$$\sigma_{\max} = \frac{P}{A}\left[1 + \frac{ec}{r^2}\sec\left(\frac{L}{2r}\sqrt{\frac{P}{EA}}\right)\right] \tag{1.5.48}$$

where e is the eccentricity of the load P (distance from the neutral axis of area A) and c is measured from the neutral axis to the outer layer of the column where $\sigma_{\max}$ occurs.

The load and stress are nonlinearly related; if several loads are on a column, the loads should be properly combined first before using the secant formula, rather than linearly superposing several individually determined stresses. Similarly, factors of safety should be applied to the resultant load.

Inelastic Buckling

For columns that may yield before buckling elastically, the generalized Euler equation, also called the Engesser equation, is appropriate. This involves substituting the tangent modulus E_T (tangent to the stress–strain curve) for the elastic modulus E in the Euler equation:

$$\sigma_{cr} = \frac{\pi^2 E_T}{(kL/r)^2} \tag{1.5.49}$$

Note that E_T must be valid for the stress σ_{cr}, but E_T is dependent on stress when the deformations are not entirely elastic. Thermal or plastic-strain events may even alter the stress–strain curve of the material, thereby further changing E_T. Thus, Equation (1.5.49) should be used with caution in a trial-and-error procedure.

Impact Loading

A mass impacting another object causes deformations that depend on the relative velocity between them. The simplest model for such an event is a mass falling on a spring. The maximum dynamic deformation d of a linearly responding spring is related to the static deformation d_{st} (the deformation caused by a weight W applied slowly) by a factor that depends on h, the height of free fall from a static position.

$$d = d_{st}\left(1 + \sqrt{1 + \frac{2h}{d_{st}}}\right) \tag{1.5.50}$$

The dynamic and static stresses are related in a similar way:

$$\sigma = \sigma_{st}\left(1 + \sqrt{1 + \frac{2h}{d_{st}}}\right) \tag{1.5.51}$$

The quantity in parentheses is called the impact factor and shows the magnification of deflection or stress in impacts involving free fall. Note that the real impact factor is somewhat smaller than what is indicated here because some energy is always dissipated by friction during the fall and deceleration of the body. This includes internal friction during plastic flow at the points of contact between the bodies. Other small errors may result from neglecting the mass and possible inelasticity of the spring.

A special value of the impact factor is worth remembering. When the load is applied suddenly without a prior free fall, $h = 0$, and

$$d = 2d_{st} \quad \text{and} \quad \sigma = 2\sigma_{st}$$

This means that the minimum impact factor is about two; it is likely to be larger than two, causing perhaps a "bottoming out" of the spring, or permanent damage somewhere in the structure or the payload supported by the spring.

Combined Stresses

Combinations of different kinds of loads on a member are common. The resultant states of stress at various points of interest can be determined by superposition if the material does not yield. The three-dimensional visualization and correct modeling of such a problem are typically the most difficult parts of the solution, followed by routine calculations of the stress components and resultants. No new methods of analysis are needed here.

The approach is to sketch an infinitesimal cube at each critical point in the member and determine the individual stresses (magnitudes and signs) acting on that element, generally caused by axial, shear, bending, torsion, and internal pressure loading. This is illustrated for a case of medium complexity in Figure 1.5.30.

Consider a solid circular rod of radius R, fixed at $z = 0$ (in the xy plane), and loaded by two forces at point B of a rigid arm. Set up the stress analysis at point A $(-R, 0, 0)$, assuming that no stress concentration is present at the wall fixture of the rod (Figure 1.5.30a).

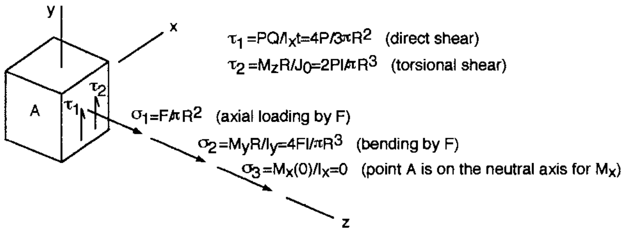
(b) equivalent loading at 0 (caused by forces F and P)



(c) superposition of stresses at point A

FIGURE 1.5.30 Illustration of stress analysis for combined axial, shear, bending, and torsion loading.

First, the equivalent loading at the origin 0 is determined (Figure 1.5.30b). This can be done most accurately in vector form. The individual stresses at point *A* are set up in the subdiagram (c). Check that each stress (even in symbolic form) has the proper units of force per area. The net normal force in this case is $\sigma_1 + \sigma_2$, and the net shear stress is $\tau_1 + \tau_2$.

The state of stress is different at other points in the member. Note that some of the stresses at a point could have different signs, reducing the resultant stress at that location. Such is the case at a point *C* diametrically opposite to point *A* in the present example (R, 0, 0), where the axial load **F** and $\mathbf{M}_y$ generate normal stresses of opposite signs. This shows the importance of proper modeling and setting up a problem of combined loads before finding the numerical solution.

Pressure Vessels

Pressure vessels, which are an important special category of combined stresses, are made in different shapes and sizes (Figure 1.5.31 and Color Figure 10) and are used in diverse applications. The applications range from air receivers in gasoline stations to nuclear reactors in submarines to heat exchangers in refineries. The required thicknesses for some commonly encountered pressure vessel components depend on the geometry as follows.

Cylindrical Shells

The force per unit length in the hoop (tangential) direction, N_t, required to contain a given pressure p in a cylindrical shell is obtained by taking a free-body diagram (Figure 1.5.32a) of the cross section. Assuming the thickness t to be much smaller than the radius R and summing forces in the vertical direction gives

$$2N_tL = 2RLp$$

or

$$N_t = pR \tag{1.5.52}$$

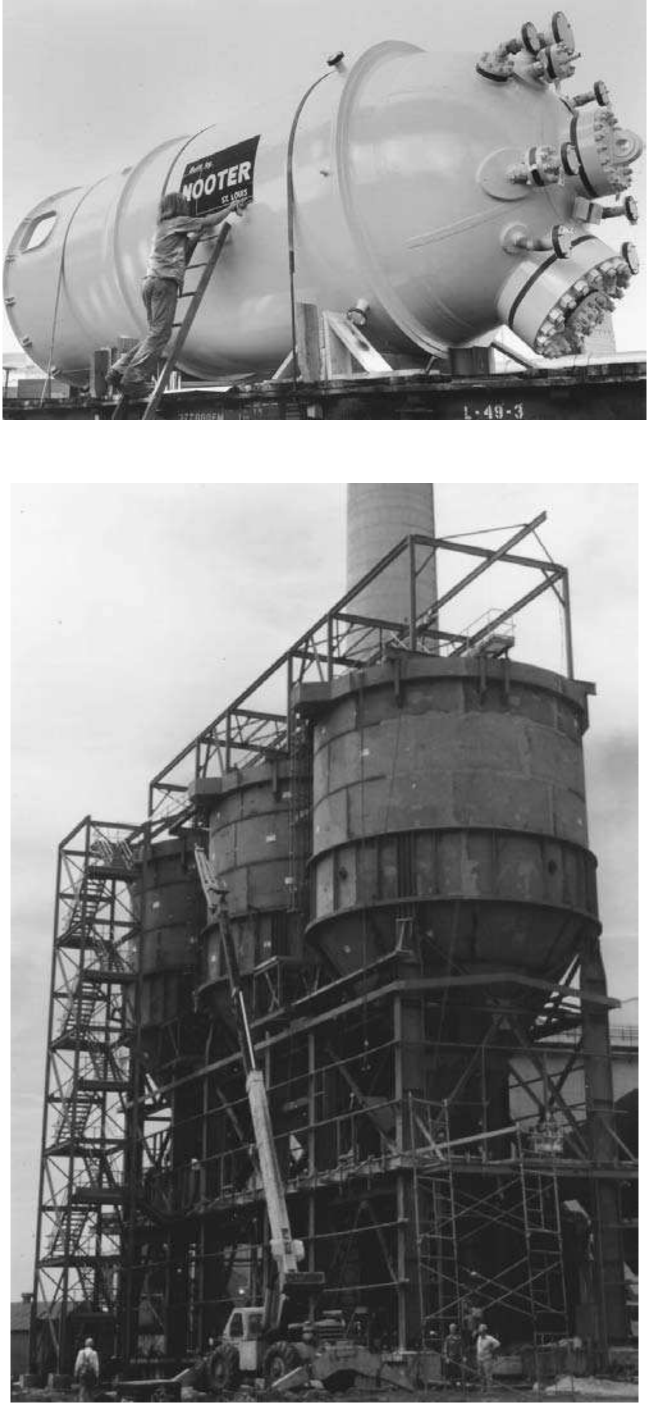


FIGURE 1.5.31 Various pressure vessels. (Photos courtesy Nooter Corp., St. Louis, MO.)

The corresponding hoop stress is $\sigma_t = pR/t$.

The longitudinal force per unit length, N_x, in the cylinder due to pressure is obtained by summing forces in the axial direction (Figure 1.5.32b),

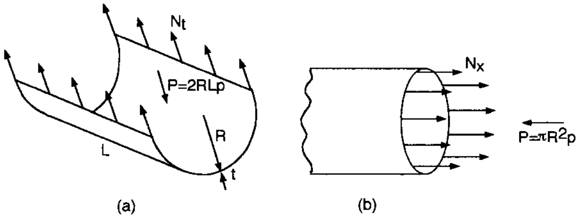

FIGURE 1.5.32 Analysis of cylindrical pressure vessels.

$$2\pi R N_x = \pi R^2 p$$

or

$$N_x = pR/2 \tag{1.5.53}$$

The corresponding axial stress is $\sigma_x = pR/2t$. It is seen that the magnitude of N_t (and σ_t) is twice that of N_x (and σ_x). If S is the allowable stress and t is the required minimum thickness,

$$t = pR/S \tag{1.5.54}$$

Spherical Shells

A free-body diagram of the spherical cross section is shown in Figure 1.5.33. Summation of forces gives

$$t = pR/2S \tag{1.5.55}$$

Example 10

Determine the required thickness of the shell and heads of the air receiver shown in Figure 1.5.34 if p = 100 psi and S = 15,000 psi.

Solution. From Equation (1.5.54), the required thickness for the cylindrical shell is

$$t = 100 \times 18/15{,}000 = 0.12 \text{ in.}$$

The required head thickness from Equation 1.5.55 is

$$t = 100 \times 18/2 \times 15{,}000 = 0.06 \text{ in.}$$

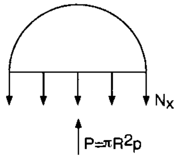

FIGURE 1.5.33 Analysis of spherical pressure vessels.

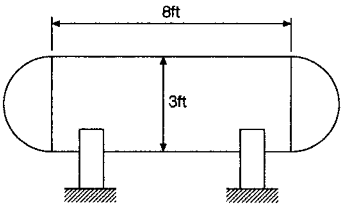

FIGURE 1.5.34 Sketch of a pressure vessel.

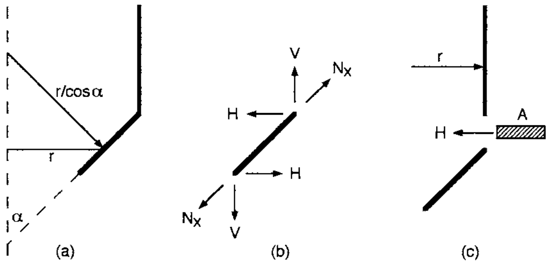

FIGURE 1.5.35 Analysis of conical shells.

Conical Shells

The governing equations for the longitudinal and circumferential forces in a conical shell (Figure 1.5.35a) due to internal pressure are similar to Equation (1.5.52) and Equation (1.5.53) for cylindrical shells, with the radius taken normal to the surface. Thus,

$$N_t = pr/\cos\alpha \tag{1.5.56}$$

$$N_x = pr/2\cos\alpha \tag{1.5.57}$$

where α is half the apex angle of the cone.

The junction between a conical and cylindrical shell, Figure 1.5.35b, is subjected to an additional force, *H*, in the horizontal direction due to internal pressure. The magnitude of this additional force per unit length can be obtained by taking a free-body diagram as shown in Figure 1.5.35b:

$$H = N_x \sin\alpha \tag{1.5.58}$$

A ring is usually provided at the cone-to-cylinder junction to carry the horizontal force *H*. The required area *A* of the ring is obtained from Figure 1.5.35c as

$$H2r = 2AS$$

or

$$A = Hr/S = \left(N_x \sin\alpha\right)r/S = \left(pr^2 \sin\alpha\right)/(2S\cos\alpha) \tag{1.5.59}$$

The stress in the ring is compressive at the large end of the cone and tensile at the small end due to internal pressure. This stress may reverse in direction due to other loading conditions such as weight of contents and end loads on the cone due to wind and earthquake loads.

Example 11

Determine the required thickness of the two cylindrical shells and cone shown in Figure 1.5.36a due to an internal pressure of 200 psi. Calculate the area of the rings required at the junctions. Assume the allowable stress to be 20 ksi in tension and 10 ksi in compression.

Solution. From Equation (1.5.54), the thickness of the large cylinder is

$$t = 200 \times 60/20{,}000 = 0.60 \text{ in.}$$

The thickness of the small cylinder is

$$t = 200 \times 30/20{,}000 = 0.30 \text{ in.}$$

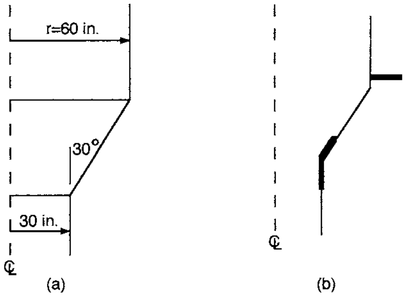

FIGURE 1.5.36 Cylindrical shells with cone connection.

The thickness of the cone is obtained from Equation (1.5.56) as

$$t = 200 \times 60/(20{,}000 \times \cos 30°) = 0.69 \text{ in.}$$

The required area of the ring at the large end of the cone is obtained from Equation (1.5.59) using the allowable compressive stress of 10 ksi:

$$A = 200 \times 60^2 \times \sin 30°/(2 \times 10{,}000 \times \cos 30°) = 20.78 \text{ in.}^2$$

The required area of the ring at the small end of the cone is obtained from Equation (1.5.59) using the allowable tensile stress of 20 ksi:

$$A = 200 \times 30^2 \times \sin 30°/(2 \times 20{,}000 \times \cos 30°) = 2.60 \text{ in.}^2$$

The rings at the junction are incorporated in a number of ways such as those shown in Figure 1.5.36b.

Nozzle Reinforcement

Reinforcements around openings in pressure vessels are needed to minimize the local stress in the area of the opening. The calculation for the needed reinforcement around an opening is based on the concept that pressure in a given area of a vessel is contained by the material in the vessel wall surrounding the pressure. Thus, in Figure 1.5.37, if one takes an infinitesimal length dL along the cylinder, the force caused by the pressure within this length is given by the quantity $pR\ dL$. The force in the corresponding vessel wall is given by $St\ dL$. Equating these two quantities results in the expression $t = pR/S$ that is given earlier as Equation (1.5.54). Similarly for the nozzle in Figure 1.5.37, $T = pr/S$. The intersection of the nozzle with the cylinder results in an opening where the pressure in area $ABCD$ is not contained by any material. Accordingly, an additional area must be supplied in the vicinity of the opening to prevent overstress of the vessel. The required area A is determined from Figure 1.5.37 as

$$A = pRr/S$$

Substituting Equation (1.5.54) into this expression gives

$$A = tr \tag{1.5.60}$$

This equation indicates that the needed additional area is equal to the removed area of the vessel wall.

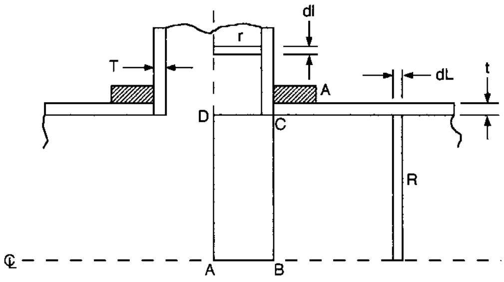

FIGURE 1.5.37 Nozzle reinforcement.

Creep–Fatigue of Boilers and Pressure Vessels

See Figure 1.6.27 in Section 1.6, "Fatigue."

Composite Materials for Pressure Vessels

Some pressure vessels can be made of fibrous composite materials with high strength-to-weight ratios. The advantages of using such a material are remarkable in the case of a tubular vessel, where the hoop stress is twice the longitudinal stress, if the fiber quantities and orientations are optimally designed to resist the applied load caused by internal pressure. Simplistically (because a basic element of a composite is strong along the fibers and weak perpendicular to the fibers), this requires twice as many fibers oriented circumferentially as axially. In practice, fibers are commonly laid at ± (a winding angle) at which the hoop and axial stress components are equal, to efficiently create an optimized configuration.

Example 12

Determine the minimum weight of the tube portion of a thin-walled cylindrical pressure vessel of $r = 8$ in. (20 mm), $\ell = 10$ ft (3.05 m), $p = 8$ ksi (55 MPa); $t = ?$ Assume using a typical graphite/epoxy composite of 60% fibers by volume with allowable tensile stress $\sigma_y = 300$ ksi (207 MPa) at 0.058 lb/in.^{3} (1600 kg/m^3). For comparison, consider a steel of $\sigma_y = 200$ ksi (138 MPa) at 0.285 lb/in.^{3} (7890 kg/m^3).

Solution.

Composite: $\sigma_y = pr/t$, $t = 0.213$ in. (5.41 mm) for circumferential plies and $\sigma_y = pr/2t$, $t = 0.107$ in. (2.72 mm) for axial plies

Total minimum wall thickness: 0.32 in. (8.13 mm)

Total material in tube: 112 lb (50.8 kg)

Steel: $\sigma_y = pr/t$, $t = 0.32$ in. (8.13 mm)

Total material in tube: 550 lb (249 kg) = 4.9 (composite material)

Note that additional considerations exist in practice, such as cost and potential problems in making adequate connections to the tube.

Thick-Walled Cylinders and Interference Fits

The previous section provided design considerations and analysis of thin-walled pressure vessels. However, some applications require thick-walled pressure vessel analysis, as is the case when $r/t > 10$, for example, when small diameter tubes are used to transport high pressure fluids. This section covers thick-walled pressure vessel analysis and a special case for interference fits.

Referring to Figure 1.5.38, the hoop and radial stress components (dependent on pressure and geometry) are shown without derivation in Equation (1.5.61a) and Equation (1.5.61b).

$$_{Hoop} = \overbrace{\frac{p_i R_i^2}{R_o^2 \quad R_i^2} \; 1 + \frac{R_o^2}{r^2}}^{\text{Internal Pressure Component}} \quad \overbrace{\frac{p_o R_o^2}{R_o^2 \quad R_i^2} \; 1 + \frac{R_i^2}{r^2}}^{\text{External Pressure Component}} \tag{1.5.61a}$$

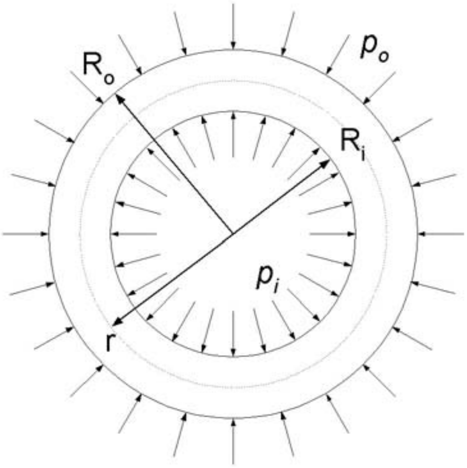

FIGURE 1.5.38 Thick-walled cylinder analysis nomenclature.

$$\sigma_{Radial} = \frac{p_i R_i^2}{R_o^2 - R_i^2}\left(1 - \frac{R_o^2}{r^2}\right) - \frac{p_o R_o^2}{R_o^2 - R_i^2}\left(1 - \frac{R_i^2}{r^2}\right) \tag{1.5.61b}$$

These equations can be simplified by setting the internal or external pressure to zero. As R_i approaches R_o, with $t = R_o - R_i$ the thin-wall pressure vessel equation, $\sigma_{Hoop} = pR/t$ (where $\sigma_{Hoop} = \sigma_t$ as stated in the pressure vessel section), is apparent.

A thick-walled cylinder with end caps exerts an axial force on the caps, thus applying a longitudinal stress component on the cylinder as given by

$$\sigma_z = \frac{p_i R_i^2 - p_o R_o^2}{R_o^2 - R_i^2} \tag{1.5.62}$$

The interference fit analysis is a special case that can be used for nesting pressure vessels (for example, to increase a pressure vessel's capacity) and for use as an assembly method (for example, to join an electric motor core to its output shaft). The interference fit equations are based on Equation (1.5.61a), Equation (1.5.61b), and Figure 1.5.39. An interface pressure p is generated by expanding the outer cylinder's inside diameter over the larger inner cylinder's outside diameter by a radial interference δ.

The first step in formulating the interference fit analysis is determining the hoop stress equations in the assembled inner and outer cylinders. These hoop stresses are calculated by recognizing that Figure 1.5.38 and Equation (1.5.61a) and Equation (1.5.61b) can be reduced by using p, the interface pressure, as the internal pressure on the outer cylinder and the external pressure on the inner cylinder (the internal and external pressures on the assembly are equal to zero).

$$\sigma_{Hoop_{Inner}} = -p\frac{b^2 + a^2}{b^2 - a^2} \tag{1.5.63a}$$

$$\sigma_{Hoop_{Outer}} = p\frac{c^2 + b^2}{c^2 - b^2} \tag{1.5.63b}$$

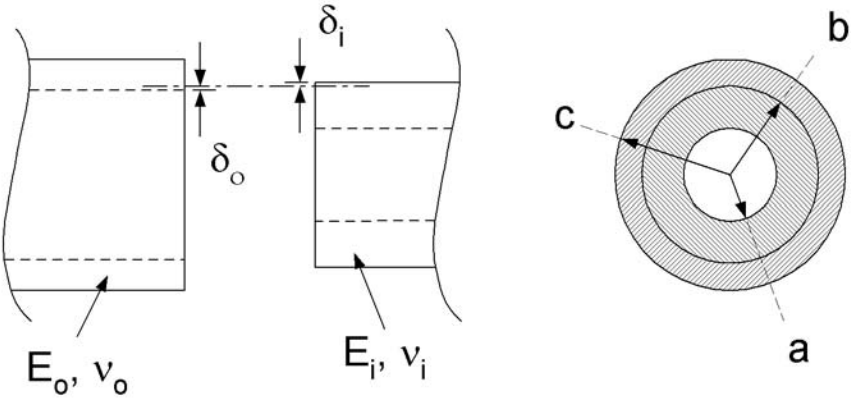

FIGURE 1.5.39 Interference fit schematic and analysis notations.

To solve Equation (1.5.63a) and Equation (1.5.63b), the interface pressure p must be determined. Referring to Figure 1.5.38 and using the strain relationships that result from the change in the interface diameters (from the change in circumference), the interferences are expressed as functions of radius,

$$\delta_o = \frac{pb}{E_o}\left(\frac{c^2+b^2}{c^2-b^2}+\nu_0^2\right) \tag{1.5.64a}$$

$$\delta_i = \frac{-pb}{E_i}\left(\frac{b^2+a^2}{b^2-a^2}-\nu_i^2\right) \tag{1.5.64b}$$

Recognizing that $\delta = \delta_o - \delta_i$, the interference fit equation is stated as

$$\delta = \frac{pb}{E_o}\left(\frac{c^2+b^2}{c^2-b^2}+\nu_0^2\right) - \frac{pb}{E_i}\left(\frac{b^2+a^2}{b^2-a^2}-\nu_i^2\right) \tag{1.5.65}$$

Given the geometry and material properties, the interface pressure p is calculated from Equation (1.5.65). This equation is useable for an assembly of two different materials, as is the case of a steel pin pressed into an aluminum housing. However, further simplification of Equation (1.5.65) is possible if both cylinders are of the same material; with $E_i = E_o$ and $\nu_i = \nu_o$,

$$p = \frac{E\delta}{b}\left(\frac{\left(c^2-b^2\right)\left(b^2-a^2\right)}{2b^2\left(c^2-a^2\right)}\right) \tag{1.5.66}$$

With the interface pressure p obtained, the hoop stresses at the interface can be found using Equation (1.5.63a) and Equation (1.5.63b). At this point, the design engineer should verify that the outer cylinder does not yield at this stress. Yielding of the outer cylinder leads to a reduced interference fit that may be detrimental to the assembly. If the stress at the interface is deemed too high, the assembly geometries should be iterated and the problem solved again. This process is to be repeated until the margins of safety are acceptable in the design.

The stress distributions across the thickness in the hoop and radial directions on the inner and outer cylinders are solved using Equation (1.5.61a) and Equation (1.5.61b), by recognizing the outer cylinder external pressure $p_o = 0$ and $p_i = p$, and the inner cylinder internal pressure $p_o = p$ and $p_i = 0$. The interference

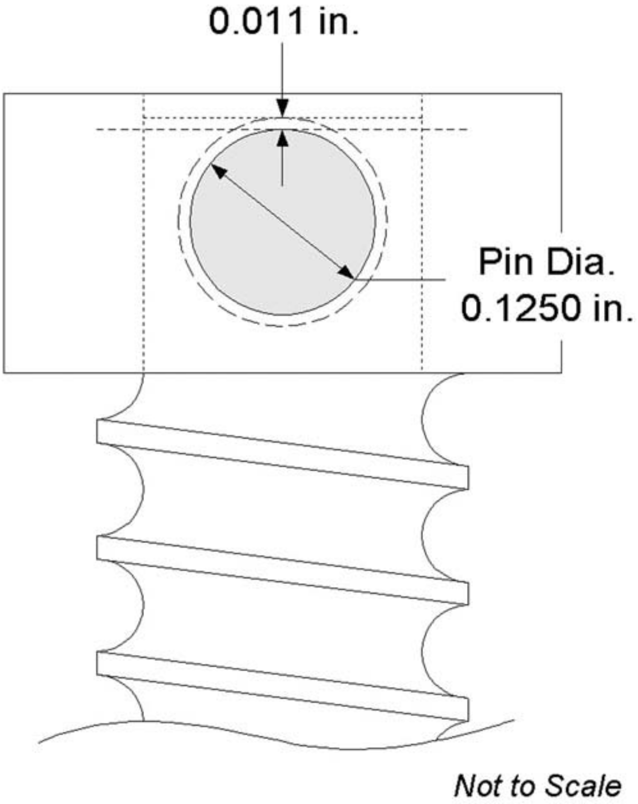

FIGURE 1.5.40 End-stop assembly.

fit equations presented previously are valid under the assumption that the inner and outer cylinders are of the same length. In the case of a hub fit over a shaft, a stress concentration should be employed.

It is worthwhile to note that a person must be able to assemble such a fit. This is usually accomplished by heating the outer cylinder and cooling the inner cylinder to develop a suitable clearance for assembly. It is important to understand the limits to which the cylinders can be heated and cooled with the available equipment and, possibly more importantly, without altering their material properties. Neglecting the practicality of the interference fit process often leads to unnecessary assembly problems.

Example 13

A mechanical stop is attached to a linear ballscrew assembly by pinning the stop to the screw as shown in Figure 1.5.40. The screw is recessed below the top surface of the end-stop. The minimum wall section between the pin outer edge and the top surface of the screw is 0.011 in. (the result of a complex and partially flawed design process that will not be discussed here). The pin of diameter 0.1250 in. is to be inserted into a reamed hole of 0.1240 in. Calculate the hoop stress in the "outer cylinder" for the screw.

Solution. Using Equation (1.5.65), $a = 0$ in., $b = 0.1250/2$ in., and $c = (0.1240 + 2 \times 0.011)/2$ in. The maximum interference fit is 0.0010 in. by completion of the tolerance analysis. Assuming both parts are steel ($E = 30 \times 10^6$ psi), the interface pressure is

$$p = \frac{\left(30\times10^6\right)\left(0.0005\right)}{\left(0.0625\right)}\left(\frac{\left(0.0730^2 - 0.0625^2\right)\left(0.0625^2 - 0^2\right)}{2\left(0.0625^2\right)\left(0.0730^2 - 0\right)}\right) = 32{,}000 \text{ psi (interface pressure)}$$

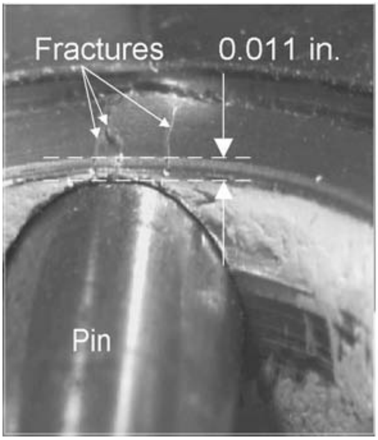

FIGURE 1.5.41 Assembled ballscrew end-stop with fractures. (Photo courtesy Moog Inc., Torrance, CA.)

With the interface pressure (also σ_{Radial} at b) solved, the hoop stress in the outer cylinder is calculated by using Equation (1.5.63b):

$$\sigma_{Hoop_{Outer}} = 32{,}000\frac{0.0730^2 + 0.0625^2}{0.0730^2 - 0.0625^2} = 207{,}700 \text{ psi}$$

The engineer should recognize that the hoop stress calculated here is above the yield strength and ultimate strength of most steels. The photograph of the assembly in Figure 1.5.41 shows the fractured thin-walled section.

This example illustrates that the engineer must check even seemingly benign loadings and geometries with respect to relevant material properties to assure structural integrity.

Experimental Stress Analysis and Mechanical Testing

Experimental stress analysis is based mostly on the measurement of strains, which may be transformed into stresses. A variety of techniques is available to measure strains. A few of these are described here.

Properties of Strain-Measuring Systems

Strain-measuring systems are based on a variety of sensors, including mechanical, optical, and electrical devices. Each has some special advantages but can usually be adapted for other needs as well. No one system is entirely satisfactory for all practical requirements, so it is necessary to optimize the gage system to each problem according to a set of desirable characteristics. Some of the common characteristics used to evaluate the system's adequacy for a typical application are

- The calibration constant for the gage should be stable; it should not vary with time, temperature, or other environmental factors.
- The gage should be able to measure strains with an accuracy of ±1 $\mu\varepsilon$ over a strain range of ±10%.
- The gage size, i.e., the gage length l_0 and width w_0, should be small so that strain at a point is approximated with small error.
- The response of the gage, largely controlled by its inertia, should be sufficient to permit recording of dynamic strains with frequency components exceeding 100 kHz.
- The gage system should permit on-location or remote readout.
- Both the gage and the associated auxiliary equipment should be inexpensive.
- The gage system should be easy to install and operate.
- The gage should exhibit a linear response to strain over a wide range.

Three of these basic characteristics deserve further mention here: the gage length l_0; gage sensitivity; and range of the strain gage. The gage length is often the most important because in nonlinear strain fields the error will depend on the gage length.

Sensitivity is the smallest value of strain that can be read on the scale associated with the strain gage and should not be mistaken for accuracy or precision. The sensitivity chosen should not be higher than necessary because it needlessly increases the complexity of the measuring method and introduces new problems.

The range of the strain gage refers to the maximum value of strain that can be recorded. Because the range and sensitivity of the gage are interrelated, it is often necessary to compromise between the two for optimal performance of both. Various compromises have resulted in two main kinds of strain gages: extensometers and electrical strain gages. Although electrical strain gage systems are numerous, only electrical-resistance strain gages will be considered here.

Extensometers

Various extensometers involving mechanical, electrical, magnetic, or optical devices are used in material test systems. A typical extensometer (Figure 1.5.42) is used in the conventional tensile test in which the stress-strain diagram is recorded. This kind of extensometer is attached to the specimen by knife edges and spring clips. Electrical-resistance strain gages are attached to the cross-flexural member and provide the strain output. The main advantage of extensometers is that they can be reused and recalibrated after each test. The disadvantages are that they are much larger and more expensive than electrical-resistance strain gages.

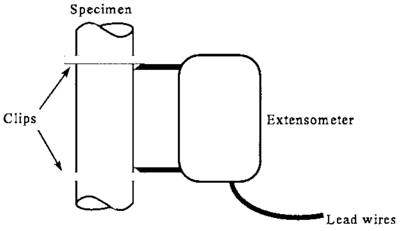

FIGURE 1.5.42 Extensometer attached to a tensile specimen.

Electrical-Resistance Strain Gages

The electrical-resistance strain gage fulfills most of the requirements of an optimum system and is widely used for experimental stress analysis. This gage consists of a metal-foil grid bonded to a polymer backing (Figure 1.5.43). A Wheatstone bridge is often used to enhance its ability to measure changes in resistance. As a specimen is deformed, the strain is transmitted to the grid, which has a current applied to it. The change in resistance of the grid is converted to a voltage signal output of the Wheatstone bridge. The basic equation used with this system is

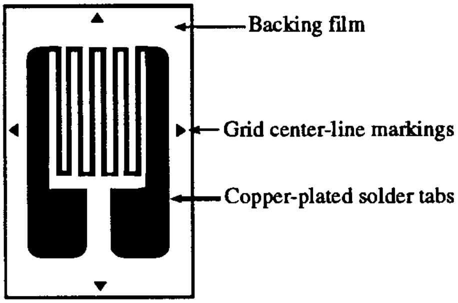

FIGURE 1.5.43 Model of metal-foil strain gages.

$$\frac{\Delta R}{R} = S_A \varepsilon \tag{1.5.67}$$

where R is the resistance of the gage; ε is the applied strain; and S_A is the sensitivity, or gage factor, of the metallic alloy used in the conductor. The most commonly used alloy is a copper–nickel alloy called Advance, for which the sensitivity is 2.1.

Electrical-Resistance Strain Gage Mounting Methods

For precision strain measurements, the correct adhesive and proper mounting procedures must be employed. The adhesive serves a vital function in the strain-measuring system: it must transmit the strain from the specimen to the sensing element without distortion. Bonding a strain gage to a specimen is one of the most critical steps in the entire process of measuring strain with an electric-resistance strain gage. When mounting a strain gage, it is important to prepare the surface of the component where the gage is to be located carefully. This includes sanding, degreasing, etching, cleaning, and, finally, neutralizing the surface where the gage is to be mounted. Next, the surface is marked to allow accurate orientation of the strain gage. The gage is then put in place and held with tape while the adhesive is allowed to dry.

Several of the adhesive systems commonly used for this are epoxy cements, cyanoacrylate cement, polyester adhesives, and ceramic adhesives. Once the adhesive has been placed, the drying process becomes vitally important because it can cause residual stresses in the grid work of the gage, which could influence the output. After allowing the adhesive to dry, the cure must be tested to ensure complete drying. Failure to do so will affect the stability of the gage and the accuracy of the output. The cure state of the adhesive can be tested by various resistance tests. Also, the bonded surface is inspected to determine if any voids are present between the gage and the specimen due to bubbling of the adhesive.

After the bonding process is complete, the lead wires are attached from the soldering tabs of the gage to an anchor terminal, which is also bonded to the test specimen. This anchoring terminal is used to protect the fragile metal-foil gages. Finally, wires are soldered from this anchor terminal to the instrumentation used to monitor the resistance changes.

Gage Sensitivities and Gage Factor

The electrical-resistance strain gage has a sensitivity to axial and transverse strain. The magnitude of the transverse strain transmitted to the grid depends on a number of factors, including the thickness and elastic modulus of the adhesive; the carrier material; the grid material; and the width-to-thickness ratio of the axial segments of the grid. Sometimes it is necessary to calculate the true value of strain that includes all contributions from

$$\varepsilon_a = \frac{(\Delta R/R)}{S_g}\frac{1-\nu_0 K_t}{1+K_t(\varepsilon_t/\varepsilon_a)} \qquad (1.5.68)$$

where

ε_a = the normal strain along the axial direction of the gage
ε_t = the normal strain along the transverse direction of the gage
ν_0 = 0.285 is Poisson's ratio for the calibration beam
K_t = the transverse-sensitivity factor of the gage

The strain gage sensitivity factor, S_g, is a calibration constant provided by the manufacturer. By using Equation (1.5.67) and Equation (1.5.68), the percent error involved in neglecting the transverse sensitivity can be calculated. These errors can be significant for large values of K_t and $\varepsilon_t/\varepsilon_a$, so it may be necessary to correct for the transverse sensitivity of the gage (Figure 1.5.44).

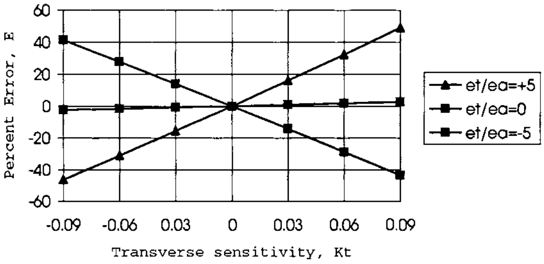

FIGURE 1.5.44 Error as a function of transverse-sensitivity factor with the biaxial strain ratio as a parameter.

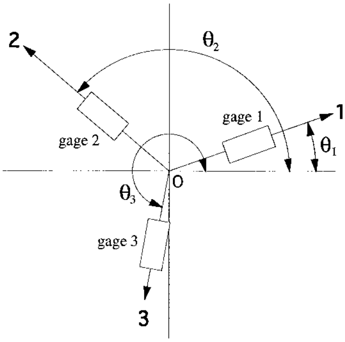

FIGURE 1.5.45 Three gage elements placed at arbitrary angles relative to the *x* and *y* axes.

Strain Analysis Methods

Electrical-resistance strain gages are normally employed on the free surface of a specimen to establish the stress at a particular point on this surface. In general, it is necessary to measure three strains at a point to define the stress or the strain field completely. For this general case in which nothing is known about the stress field or its directions before experimental analysis, three-element rosettes are required to establish the stress field. This is accomplished by using the three-element gage with orientations at arbitrary angles, as shown in Figure 1.5.45. Using this setup, the strains ε_x, ε_y, and γ_{xy} can be determined. These values can be used to determine the principal strains and principal directions:

$$\begin{aligned} \varepsilon_1 &= \frac{1}{2}\left(\varepsilon_{xx} + \varepsilon_{yy}\right) + \frac{1}{2}\sqrt{\left(\varepsilon_{xx} - \varepsilon_{yy}\right)^2 + \gamma_{xy}^2} \\ \varepsilon_2 &= \frac{1}{2}\left(\varepsilon_{xx} + \varepsilon_{yy}\right) - \frac{1}{2}\sqrt{\left(\varepsilon_{xx} - \varepsilon_{yy}\right)^2 + \gamma_{xy}^2} \\ \tan 2\phi &= \frac{\gamma_{xy}}{\varepsilon_{xx} - \varepsilon_{yy}} \end{aligned} \tag{1.5.69}$$

where ϕ is the angle between the principal axis (σ_1) and the *x* axis. The principal stresses can be computed using the principal strains:

$$\begin{aligned} \sigma_1 &= \frac{E}{1 - v^2}\left(\varepsilon_1 + v\varepsilon_2\right) \\ \sigma_2 &= \frac{E}{1 - v^2}\left(\varepsilon_2 + v\varepsilon_1\right) \end{aligned} \tag{1.5.70}$$

These expressions give the complete state of stress because the principal directions are known from Equation (1.5.69).

Optical Methods of Strain Analysis

Moiré Method of Strain Analysis. The moiré technique depends on an optical phenomenon of fringes caused by relative displacement of two sets of arrays of lines. The arrays used to produce the fringes may be a series of straight parallel lines; a series of radial lines emanating from a point; a series of concentric circles; or a pattern of dots. The straight parallel line “grids” are used most often for strain analysis work and consist of equal width lines with opaque spacing of the same width between them. These straight parallel lines are spaced in a “grating” scheme of typically 50 to 1000 lines per inch for moiré work.

In the cross-grid system of two perpendicular line arrays, the grid placed on the specimen is referred to as the model grid. The second grid is referred to as the reference grid and is overlaid on top of the model grid. Often a thin layer of oil or some other low-friction substance is placed between the model grid and the reference grid to keep them in contact while attempting to minimize the transmission of strains from the model to the reference grid.

To obtain a moiré fringe pattern, the grids are first aligned on the unloaded model so that no pattern is present. The model is loaded and light is transmitted through the two grids. Strain displacement is observed in the model grid while the reference grid remains unchanged. A moiré fringe pattern is formed each time the model grating undergoes a deformation in the primary direction equal to the pitch p of the reference grating. For a unit gage length, $\Delta L = np$, where ΔL is the change in length per unit length, p is the pitch of the reference grating, and n is the number of fringes in the unit gage length. In order to calculate ε_x, ε_y, and γ_{xy}, two sets of gratings must be applied in perpendicular directions. Then displacements u and v (displacements in the x and y directions, respectively) can be established and the Cartesian strain components can be calculated from slopes of the displacement surfaces: $\varepsilon_{xx} = \partial u/\partial x$, $\varepsilon_{yy} = \partial v/\partial y$, and $\gamma_{xy} = \partial v/\partial x + \partial u/\partial y$. The displacement gradients in the z direction, $\partial w/\partial x$ and $\partial w/\partial y$, have been neglected here because they are not considered in moiré analysis of in-plane deformation fields.

Photoelasticity. The method of photoelasticity is based on the physical behavior of transparent, noncrystalline, optically isotropic materials that exhibit optically anisotropic characteristics, referred to as temporary double refraction, while they are stressed. To observe and analyze these fringe patterns, a device called a polariscope is used. Two kinds of polariscope are common: the plane polariscope and the circular polariscope.

The plane polariscope (Figure 1.5.46) consists of a light source, two polarizing elements, and the model. The axes of the two polarizing elements are oriented at a 90° angle from each other. If the specimen is not stressed, no light passes through the analyzer and a dark field is observed. If the model is stressed, two sets of fringes — isoclinics and isochromatics — will be obtained. Black isoclinic fringe patterns are the loci of points where the principal-stress directions coincide with the axis of the polarizer. These fringe patterns are used to determine the principal stress directions at all points of a photoelastic model. When

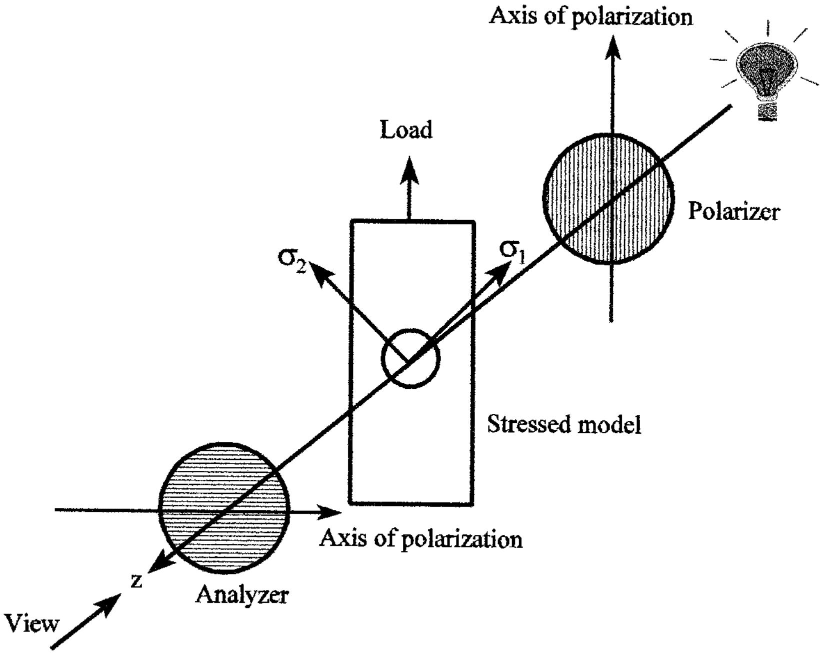

FIGURE 1.5.46 Schematic of a stressed photoelastic model in a plane polariscope.

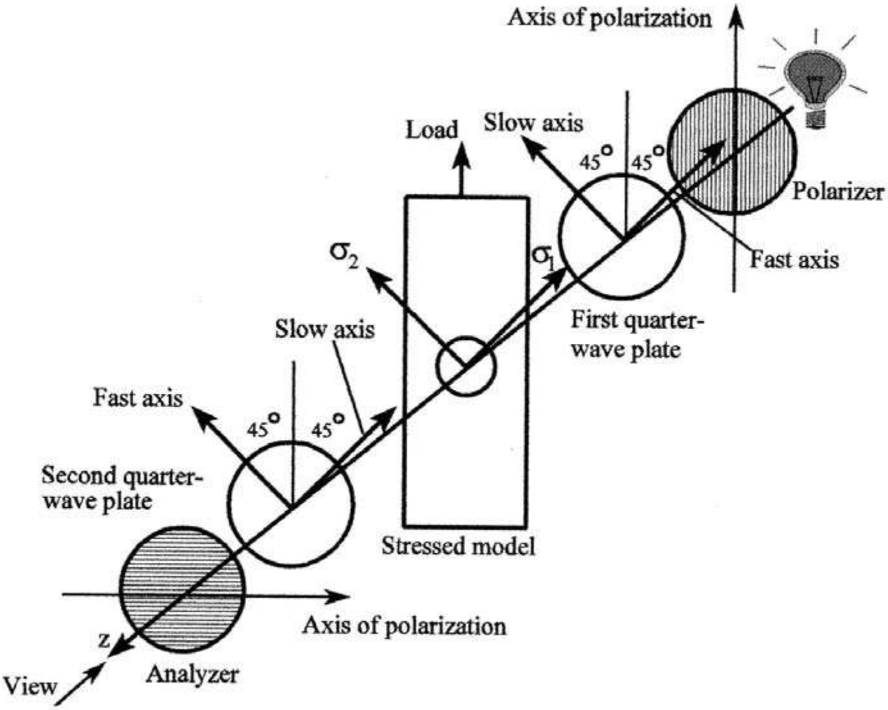

FIGURE 1.5.47 Schematic of a stressed photoelastic model in a circular polariscope.

the principal stress difference is zero ($n = 0$) or sufficient to produce an integral number of wavelengths of retardation ($n = 1, 2, 3, \ldots$), the intensity of light emerging from the analyzer is zero. This condition for extinction gives a second fringe pattern, called isochromatics, where the fringes are the loci of points exhibiting the same order of extinction ($n = 0, 1, 2, 3, \ldots$):

$$n = N = \frac{h}{f_\sigma}\left(\sigma_1 - \sigma_2\right) \tag{1.5.71}$$

where N is the isochromatic fringe order. The order of extinction n depends on the principal stress difference ($\sigma_1 - \sigma_2$), the thickness h of the model, and the material fringe value f_σ. When monochromatic light is used, the isochromatic fringes appear as dark bands. When white light is used, the isochromatic fringes appear as a series of colored bands. Black fringes appear in this case only where the principal stress difference is zero.

A circular polariscope is a plane polariscope with two additional polarizing plates, called quarter-wave plates, added between the model and the original polarizing plates (Figure 1.5.47). The two quarter-wave plates are made of a permanently doubly refracting material. The circular polariscope is used to eliminate the isoclinic fringes while maintaining the isochromatic fringes. To accomplish this, monochromatic light must be used because the quarter-wave plates are designed for a specific wavelength of light. For the dark-field arrangement shown, no light is passed through the polariscope when the model is unstressed. A light-field arrangement is achieved by rotating the analyzer 90°. The advantage of using light- and dark-field analysis is that twice as much data are obtained for the whole-field determination of $\sigma_1 - \sigma_2$. If a dark-field arrangement is used, n and N still coincide, as in Equation (1.5.71). If a light-field arrangement is used, they are not coincident. In this case, Equation (1.5.71) becomes

$$N = \frac{1}{2} + n = \frac{h}{f_\sigma}\left(\sigma_1 - \sigma_2\right) \qquad n = 0,\ 1,\ 2,\ 3,\ \ldots \tag{1.5.72}$$

By determining the isoclinic fringes and the isochromatic fringes, the principal-stress directions and the principal-stress difference can be obtained. In order to obtain the individual principal stresses, a stress separation technique would need to be employed.

The advantages of the photoelastic method are that it allows a full-field stress analysis and it makes it possible to determine the magnitude and direction of the principal stresses. The disadvantages are that it requires a plastic model of the actual component and it takes a considerable effort to separate the principal stresses.

Major advances have been made in this area recently, and a variety of special-purpose equipment is available to solve difficult engineering problems efficiently. Readers are encouraged to visit Internet sites such as www.stressphotonics.com for more information.

Thermoelastic Stress Analysis. Modern thermoelastic stress analysis (TSA) employs advanced differential thermography (or AC thermography) methods based on dynamic thermoelasticity and focal-plane-array infrared equipment capable of rapidly measuring small temperature changes (down to 0.001°C) caused by destructive or nondestructive alternating stresses. Stress resolutions comparable to those of strain gages can be achieved in a large variety of materials. The digitally stored data can be processed in near-real time to determine the gradient stress fields and related important quantities (such as combined-mode stress intensity factors) in complex components and structures, with no upper limit in temperature. The efficient, user-friendly methods can be applied in the laboratory, field, vehicles, and structures such as bicycles, automobiles, aircraft, surgical implants, welded bridges, and microelectronics. Optimum design, rapid prototyping, failure analysis, life prediction, and rationally accelerated testing can be facilitated with the new TSA methods (Color Figure 8 and Color Figure 11 through Color Figure 14).

Major advances have been made in this area recently, and a variety of special-purpose equipment is available to solve difficult engineering problems efficiently. Readers are encouraged to visit Internet sites, such as www.stressphotonics.com, for more information.

Brittle Coatings. If a coating is applied to a specimen that is thin in comparison with the thickness of the specimen, then the strains developed at the surface of the specimen are transmitted without significant change to the coating. This is the basis of the brittle coating method of stress analysis. The two kinds of coatings available are resin-based and ceramic-based coatings. The ceramic-based coatings are seldom used due to the high application temperatures (950 to 1100°F) required. The coatings are sprayed on the component until a layer approximately 0.003 to 0.010 in. thick has accumulated. It is also necessary to spray calibration bars with the coating at the same time in order to obtain the threshold strain at which the coating will crack. These calibration bars are tested in a cantilever apparatus and the threshold strain is calculated using the flexure formula and Hooke's law. Once the threshold strain is known and the actual specimen has been tested, the principal stress perpendicular to the crack can be determined by using Hooke's law. The procedure is to load the component, apply the coating, and then quickly release the loading in steps to observe any cracks.

The main advantages of this method are that magnitude and direction of the principal strains can be quickly obtained and that the coating is applied directly to the component. This also allows a quick analysis of where the maximum stress regions are located so that a better method can be used to obtain more accurate results. The main disadvantage is that the coatings are very sensitive to ambient temperature and might not have sufficiently uniform thickness.

Mechanical Testing

Standards. Many engineering societies have adopted mechanical testing standards; the most widely accepted are the standards published by the American Society for Testing and Materials. Standards for many engineering materials and mechanical tests (tension, compression, fatigue, plane strain fracture toughness, etc.) are available in the *Annual Book of ASTM Standards*.

Open-Loop Testing Machines. In an open-loop mechanical testing system, no feedback is offered to the control mechanism that would allow for continuous adjustment of the controlled parameter. Instead, the chosen parameter is "controlled" by the preset factory adjustments of the control mechanism. It is not possible for such a machine continually to adjust its operation to achieve a chosen (constant or not constant) displacement rate or loading rate. A human operator can be added to the control loop in some systems in an attempt to maintain some parameter, such as a loading rate, at a constant level. This is a poor means of obtaining improved equipment response and is prone to error.

Closed-Loop Testing Machines. In a closed-loop, most commonly electrohydraulic, testing system, a servo controller is used to control the chosen parameter continuously. When the difference between the desired value programmed in and the actual value measured is small, the servo controller adjusts the flow of hydraulic fluid to the actuator to reduce the difference (the error). This correction occurs at a rate much faster than any human operator could achieve. A standard system makes 10,000 adjustments per second automatically.

A typical closed-loop system (Color Figure 9, Color Figure 11, and Color Figure 15) allows the operator to control load, strain, or displacement as a function of time and can be adjusted to control other parameters as well. This makes it possible to perform many different kinds of tests, such as tension, compression, torsion, creep, stress relaxation, fatigue, and fracture.

Impact Testing. The most common impact testing machines utilize a pendulum hammer or a dropped weight. In the pendulum system, a hammer is released from a known height and strikes a small notched specimen, causing it to fracture. The hammer proceeds to some final height. The difference between the initial and final heights of the hammer is directly proportional to the energy absorbed by the specimen. For the Charpy test, the specimen is mounted horizontally with the ends supported so that the pendulum will strike the specimen in midspan, opposite the notch. In the Izod test, the specimen bottom is mounted in a vertical cantilever support so that the pendulum will strike the specimen at a specific distance above the notch, near the unsupported top end. A large variety of drop-weight tests is also available to investigate the behaviors of materials and packages during impact.

Hardness Testing. The major hardness tests are the Brinell, Rockwell, Vickers, and Shore scleroscope tests. The Brinell hardness test uses a hardened steel ball indenter that is pushed into the material under a specified force. The diameter of the indentation left in the surface of the material is measured and a Brinell hardness number is calculated from this diameter. The Rockwell hardness test differs from the Brinell test in that it uses a 120° diamond cone with a spherical tip for hard metals and a 1/16-in. steel ball for soft metals. The Rockwell tester gives a direct readout of the hardness number. The Rockwell scale consists of a number of different letter designators (B, C, etc.) based on the depth of penetration into the test material.

The Vickers hardness test uses a small pyramidal diamond indenter and a specified load. The diagonal length of the indentation is measured and used to obtain the Vickers hardness number. The Shore scleroscope uses a weight that is dropped on the specimen to determine the hardness. This hardness number is determined from the rebound height of the weight.

1.6 Structural Integrity and Durability

Bela I. Sandor

The engineer is often concerned about the long-term behavior and durability of machines and structures. Designs based only on statics, dynamics, and basic mechanics of materials are typically able to satisfy only minimal performance and reliability requirements. For realistic service conditions, numerous degradations may need to be considered. A simple and common approach is to use safety factors based on experience and judgment. The degradations could become severe and require sophisticated analyses if unfavorable interactions occur. For example, fatigue with corrosion or high temperatures is difficult to predict accurately, and much more so when corrosion is occurring at a high temperature.

There are many kinds of degradations and interactions between them, and a large (and still growing) technical literature is available in most of these areas. The present coverage cannot possibly do justice to the magnitude of the most serious problems and the available resources to deal with them. Instead, the material here highlights some common problems and provides fundamental concepts to prepare for more serious efforts. The reader is encouraged to study the technical literature (including that by technical societies such as ASM, ASME, ASNT, ASTM, SAE), attend specialized short courses, and seek consulting advice (ASM, ASTM, Teltech) as necessary.

Finite Element Analysis. Stress Concentrations

The most common problem in creating a machine or structure with good strength-to-weight ratio is to identify its critical locations and the corresponding maximum stresses or strains and to adjust the design optimally. This is difficult if a member's geometry, including the geometry and time dependence of the loading, is complex. The modern analytical tool for addressing such problems is finite element analysis (FEA) or finite element modeling (FEM).

Finite Element Analysis

The finite element (FE) method was developed by engineers using physical insight. In all applications, the analyst seeks to calculate a *field quantity*: in stress analysis, it is the displacement field or the stress field; in thermal analysis, it is the temperature field or the heat flux; and so on. Results of the greatest interest are usually peak values of the field quantity or its gradients. The FE method is a way of getting a *numerical* solution to a *specific* problem. An FEA does not produce a formula as a solution, nor does it solve a class of problems. Also, the solution is approximate unless the problem is so simple that a convenient exact formula is already available. Furthermore, it is important to validate the numerical solution instead of trusting it blindly.

The power of the FE method is its versatility. The structure analyzed may have arbitrary shape, arbitrary supports, and arbitrary loads. Such generality does not exist in classical analytical methods. For example, temperature-induced stresses are usually difficult to analyze with classical methods, even when the structure geometry and the temperature field are simple. The FE method treats thermal stresses as readily as stresses induced by mechanical load, and the temperature distribution can be calculated by FE. However, it is easy to make mistakes in describing a problem to the computer program. Therefore, *it is essential that the user have a good understanding of the problem and the modeling* so that errors in computed results can be detected by judgment.

Stress Concentrations

Geometric discontinuities cause localized stress increases above the average or far-field stress. A stress raiser's effect can be determined quantitatively in several ways, but not always readily. The simplest method, if applicable, is to use a known theoretical **stress concentration factor**, K_t, to calculate the peak stress from the nominal, or average, value:

$$\sigma_{\max} = K_t \sigma_{ave} \tag{1.6.1}$$

This is illustrated in Figure 1.6.1. The area under the true stress distribution always equals the area under the nominal stress level,

$$\int_A \sigma_{true}\, dA = \int_A \sigma_{ave}\, dA = \sigma_{ave} A \tag{1.6.2}$$

The factor K_t depends mainly on the geometry of the notch, not on the material, except when the material deforms severely under load. K_t values are normally obtained from plots such as in Figure 1.6.2 and are strictly valid only for ideally elastic, stiff members. K_t values can also be determined by FEA or by several experimental techniques. There are no K_t values readily available for sharp notches and cracks, but one can always assume that such discontinuities produce the highest stress concentrations, sometimes factors of tens. This is the reason why brittle, high-strength materials are extremely sensitive even to

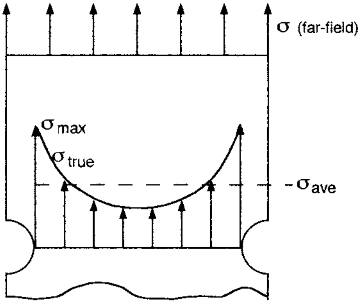

FIGURE 1.6.1 Stress distribution (simplistic) in a notched member under uniaxial load.

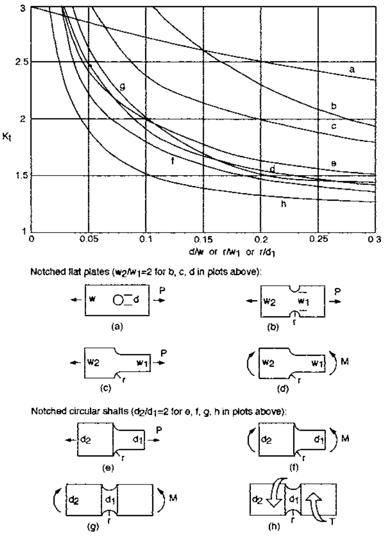

FIGURE 1.6.2 Samples of elastic stress concentration factors. (Condensed from Figure 10.1, Figure 10.2 and Figure 10.2, Dowling N.E., *Mechanical Behavior of Materials*, Prentice Hall, Englewood Cliffs, NJ, 1993. With permission.)

minor scratches. In fatigue, for example, invisible toolmarks may lead to premature, unexpected failures in strong steels.

Many other factors may seem similar to K_t, but they should be carefully distinguished. The first is the true stress concentration factor K_σ, defined as

$$K_\sigma = \frac{\sigma_{\max}}{\sigma_{ave}} \tag{1.6.3}$$

which means that $K_\sigma = K_t$ (by Equation 1.6.1) for ideally elastic materials. K_σ is most useful in the case of ductile materials that yield at the notch tip and lower the stress level from that indicated by K_t. Similarly, a true strain concentration factor, K_ε, is defined as

$$K_\varepsilon = \frac{\varepsilon_{\max}}{\varepsilon_{\text{ave}}} \tag{1.6.4}$$

where $\varepsilon_{\text{ave}} = \sigma_{\text{ave}}/E$.

Furthermore, a large number of **stress intensity factors** are used in fracture mechanics, and these (such as K, K_c, K_I, etc.) are easily confused with K_t and K_σ, but their definitions and uses are different as seen in the next section.

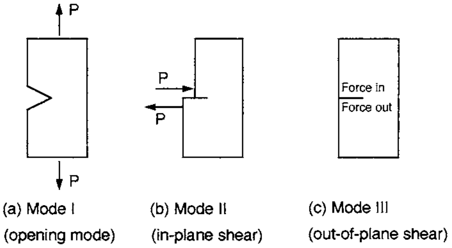

FIGURE 1.6.3 Modes of deformation.

Fracture Mechanics

Notches and other geometric discontinuities are common in solid materials, and they tend to facilitate the formation of cracks, which are in turn more severe stress raisers. Sharp cracks and their further growth are seldom simple to analyze and predict because the actual stresses and strains at a crack tip are not known with the required accuracy. In fact, this is the reason that classical failure theories (maximum normal stress, or Rankine, theory; maximum shear stress, or Tresca, theory; distortion energy, or von Mises or octahedral shear stress, theory), elegantly simple as they are, are not sufficiently useful in dealing with notched members. A powerful modern methodology in this area is fracture mechanics, which was originated by A. A. Griffith[2] in 1920 and has grown in depth and breadth enormously in recent decades. The space here is not adequate to list all of the significant references in this still expanding area. The purpose here is to raise the engineer's awareness to a quantitative, practically useful approach in dealing with stress concentrations as they affect structural integrity and durability.

Brittle and Ductile Behaviors. Embrittlements

Brittleness and ductility are often the first aspects of fracture considerations, but they often require some qualifications. Simplistically, a material that fractures in a tension test with 0% reduction of area (RA) is perfectly brittle (and very susceptible to fracture at stress raisers), while one with 100% RA is perfectly ductile (and quite tolerant of discontinuities). Between these extremes fall most engineering materials, with the added complication that embrittlement is often made possible by several mechanisms or environmental conditions. For example, temperature, microstructure, chemical environment, internal gases, and certain geometries are common factors in embrittlement. A few of these will be discussed later.

Linear-Elastic Fracture Mechanics (LEFM)

A major special case of fracture mechanics is when little or no plastic deformation occurs at the critical locations of notches and cracks. It is important that even intrinsically ductile materials may satisfy this condition in common circumstances.

Modes of Deformation. Three basic modes of deformation (or crack surface displacement) of cracked members are defined as illustrated schematically in Figure 1.6.3. Each of these modes is very common, but Mode I is the easiest to deal with analytically and experimentally, so most data available are for Mode I.

Stress Intensity Factors. The stresses on an infinitesimal element near a crack tip under Mode I loading are obtained from the theory of linear elasticity. Referring to Figure 1.6.4,

---

[2] The Griffith criterion of fracture states that a crack may propagate when the decrease in elastic strain energy is at least equal to the energy required to create the new crack surfaces. The available elastic strain energy must also be adequate to convert into other forms of energy associated with the fracture process (heat from plastic deformation, kinetic energy, etc.). The critical nominal stress for fracture according to the Griffith theory is proportional to $1/\sqrt{\text{crack length}}$. This is significant since crack length, even inside a member, is easier to measure nondestructively than stresses at a crack tip. Modern, practical methods of fracture analysis are sophisticated engineering tools on a common physical and mathematical basis with the Griffith theory.

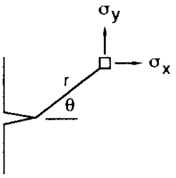

FIGURE 1.6.4 Coordinates for fracture analysis.

$$
\begin{aligned}
\sigma_x &= \frac{K_I}{\sqrt{2\pi r}} f_1(\theta) + \ldots \\
\sigma_y &= \frac{K_I}{\sqrt{2\pi r}} f_2(\theta) + \ldots \\
\tau_{xy} &= \frac{K_I}{\sqrt{2\pi r}} f_3(\theta) + \ldots \\
\tau_{xz} &= \tau_{zx} = 0
\end{aligned}
\tag{1.6.5}
$$

There are two special cases of σ_z:

1. $\sigma_z = 0$ for plane stress (thin members)
2. $\sigma_z = \nu(\sigma_x + \sigma_y)$ for plane strain, with $\varepsilon_z = 0$ (thick members)

The factor K in these and similar expressions characterizes the intensity or magnitude of the stress field near the crack tip. It is thus called the stress intensity factor, which represents a very useful concept different from that of the well-known stress concentration factor. K_I is a measure of the severity of a crack, and most conveniently it is expressed as

$$K_I = \sigma\sqrt{\pi a}\, f(\text{geometry}) \tag{1.6.6}$$

where a is the crack length and f is a function of the geometry of the member and of the loading (typically, $f \cong 1 \pm 0.25$). Sometimes f includes many terms, but all stress intensity factors have the same essential features and units of stress $\sqrt{\text{length}}$. In any case, expressions of K for many common situations are available in the literature, and numerical methods are presented for calculating special K values. Differential thermography via dynamic thermoelasticity is a powerful, efficient modern method for the measurement of actual stress intensity factors under a variety of complex conditions (Section 1.6, "Experimental Stress Analysis and Mechanical Testing"; Figure 1.6.12; Color Figure 8; Color Figure 11 through Color Figure 14).

Fracture Toughness of Notched Members

The stress intensity factor, simply K for now, is analogous to a stress-strain curve, as in Figure 1.6.5. K increases almost linearly from 0 at $\sigma = 0$, to a value K_c at a critical (fracture) event. K_c is called the *fracture*

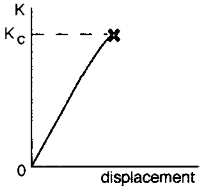

FIGURE 1.6.5 K_c = fracture toughness of a particular member.

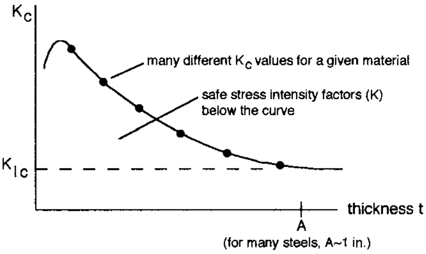

FIGURE 1.6.6 K_{Ic} = plane strain fracture toughness of material.

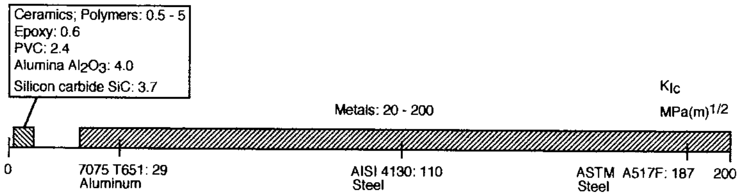

FIGURE 1.6.7 Plane strain fracture toughness ranges (approximate).

toughness of a particular member tested. It depends on the material, but it is not a reliable material property because it depends on the size of the member too much. This is illustrated in Figure 1.6.6 for plates of the same material but different thicknesses.

At very small thickness, K_c tends to drop. More significantly, K_c approaches a lower limiting value at large thickness (>A). This worst-case value of K_c is called K_{Ic}, the *plane strain fracture toughness* in Mode I. It may be considered a pseudomaterial property because it is independent of geometry at least over a range of thicknesses. It is important to remember that the thickness effect can be rather severe. An intrinsically ductile metal may fracture in an apparently brittle fashion if it is thick enough and has a notch.

Fracture Toughness Data. Certain criteria about crack sharpness and specimen dimensions must be satisfied in order to obtain reliable basic K_{Ic} data (see *ASTM Standards*). These data for many engineering materials are available in the technical literature. A schematic overview of various materials' K_{Ic} values is given in Figure 1.6.7. Note that particular expected values are not necessarily attained in practice. Poor material production or manufacturing shortcomings and errors could result in severely lowered toughness. On the other hand, special treatments or combinations of different but favorably matched materials (as in composites) could substantially raise the toughness.

Besides the thickness effect, there are a number of major influences on a given material's toughness, and they may occur in favorable or unfavorable combinations. Several of these are described here schematically, showing general trends. Note that some of the actual behavior patterns are not necessarily as simple or well defined as indicated.

Yield Strength. High yield strength results in a low fracture toughness (Figure 1.6.8); therefore, it should be chosen carefully, understanding the consequences.

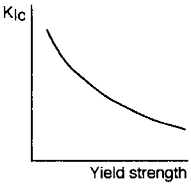

FIGURE 1.6.8 Yield strength effect on toughness.

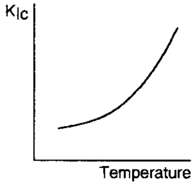

FIGURE 1.6.9 Temperature effect on toughness.

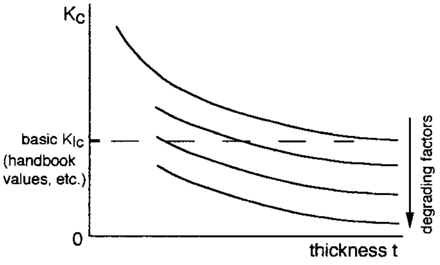

FIGURE 1.6.10 Trends of toughness degradations.

Temperature. Two kinds of temperature effect on toughness should be mentioned here. They may appear, at least for part of the data, as in Figure 1.6.9, with high temperature causing increased toughness. One temperature effect is by the increased ductility at higher temperature. This tends to lower the yield strength (except in low-carbon steels that strain-age at moderately elevated temperatures, about 100 to 500°C); increase the plastic zone at the notch tip; and effectively blunt the stress concentration. Another effect — the distinct temperature-transition behavior in low-carbon steels (BCC metals, in general; easily shown in Charpy tests) — is caused by microstructural changes in the metal and is relatively complex in mechanism.

Loading Rate. The higher the rate of loading, the lower the fracture toughness is in most cases. Note that toughness results obtained in notch-impact or explosion tests are most relevant to applications in which the rate of loading is high.

Microstructural Aspects. In some cases, apparently negligible variations in chemical composition or manufacturing processes may have a large effect on a material's fracture toughness. For example, carbon, sulfur, and hydrogen contents may be significant in several embrittling mechanisms. Also, the common mechanical processing of cold or hot working (rolling, extruding, forging) influences the grain structure (grain size and texture) and the corresponding toughness. Neutron radiation also tends to cause microscopic defects, increasing the yield strength and consequently lowering the ductility and toughness of the material.

Overview of Toughness Degradations. A multitude of mechanisms and situations must be considered singly and in realistic combinations, as illustrated schematically in Figure 1.6.10 (review Figure 1.6.6 for relevant toughness definitions).

Degrading Factors
Some chemical compositions
Sharper notch
Greater thickness
Faster loading
Lower temperature
Higher yield strength
Hostile chemical environment
Liquid metal embrittlement
Tensile residual stress
Neutron irradiation
Microstructural features
Moisture
Gases in solid solution
Surface hardening

Note that the toughness can drop essentially to zero in some cases.

Crack Propagation

Crack growth may be classified as stable (subcritical) or unstable (critical). Often stable cracks become unstable in time, although the opposite behavior, cracks decelerating and even stopping, is sometimes possible. Unstable cracks under load control are extremely dangerous because they propagate at speeds nearly 40% of the speed of sound in that particular solid. For example, in steels, this means a crack growth speed of about 1 mi/sec. Thus, warnings and even electronically activated, automated countermeasures during unstable propagation are useless. The only reasonable course is to provide, by design and proper manufacture, preventive measures such as ductile regions in a structure where cracks become stable and slow to grow, thus allowing for inspection and repair.

Each of the three kinds of stable crack growth is important in its own right; interactions among the three are possible. Under steady loads, environmentally assisted crack growth (also called stress corrosion cracking) and creep crack growth are commonly found. Under cyclic loading, fatigue crack growth is likely to occur. In each case the **rate of crack growth** tends to accelerate in time or with progressive cycles of load if the loads are maintained while the cracks reduce the load-bearing cross-sectional area. This common situation, caused by increasing true stresses, is illustrated schematically in Figure 1.6.11, where a_0 is an initial flaw's size, da/dN and da/dt are the fatigue and creep crack growth rates, respectively, and a_c is the critical crack size. The rate of stable crack growth is controlled by the stress intensity factor. This will be discussed later.

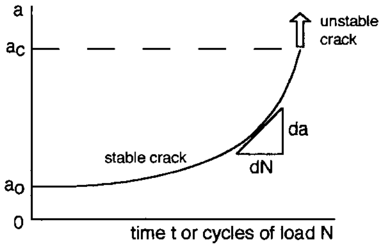

FIGURE 1.6.11 Crack growth rates under constant load.

Design and Failure Analysis Using Stress Intensity Concepts

The concept of stress intensity of cracked members is highly useful and practical. Three major possibilities are outlined here with respect to the essential framework of

$$K \propto \text{stress} \sqrt{\text{crack length}} \tag{1.6.7}$$

Here K may be an operating stress intensity factor or a K_{Ic} value, a material property (the units are the same). In design, the idea is to fix one or two quantities by some initial constraints of the case, then work with the results according to Equation (1.6.7).

- Operating stress and material (K_{Ic}) are predetermined. This forces one to measure crack length and set the maximum allowable size of cracks.
- Operating stress and detectable crack size are predetermined. This forces one to choose an appropriate material with the required K_{Ic} value.
- The material (K_{Ic} value) and the detectable crack size are predetermined. This forces one to limit the operating stress accordingly.

Similar thinking can be used in failure analysis and corresponding design iteration. For example, the critical crack size at the end of the stable propagation (and start of the unstable, high-speed growth) can

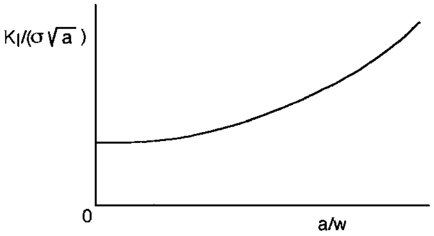

FIGURE 1.6.12 Practical fracture mechanics with NDE: nearly instantaneous measurement of crack size *and* the actual stress intensity factor via advanced thermoelastic stress analysis. The member's loading (including boundary conditions) need not be known to obtain reliable data using this method.

often be determined by looking at the broken parts. The material property, K_{Ic}, can also be estimated from the parts at hand, and thus the stress that caused the failure can be calculated. Whether the stress was within normal bounds or was an overload from misuse of the equipment can be determined. These are powerful, quantitative methods useful in improving designs and manufacturing.

Special Methods

The many other important and useful methods in fracture mechanics cannot even be listed here. For example, several methods in the area of elastic–plastic fracture mechanics are available. Within this area, mainly applicable to thin members of ductile materials, the J-integral approach alone has been covered in a large number of books and journal articles.

Nondestructive Evaluation

Because all of fracture mechanics is based on knowing the crack size and its location and orientation, nondestructive evaluation (NDE) is a major part of quantitative, predictive work in this area. Many techniques of NDE are available, and some are still rapidly evolving. Two major categories of NDE methods are defined here:

1. *Geometry-based methods.* At best, the size, shape, location, and orientation of a flaw are measured. Considerable additional effort is needed to estimate the effect of the flaw on structural integrity and durability. Common methods involve acoustic, magnetic, microwave, optical (including thermal), or x-ray instruments.
2. *Stress-based methods.* A flaw's effect on the stress–strain field is directly measured, which is often much more important than just finding that flaw (a flaw of a given geometry may be benign or malignant, depending on the stress field of the neighborhood). Only a few optical methods are readily available for stress-based NDE; the most effective one for laboratory and field applications is thermoelastic stress analysis by infrared means (Figure 1.6.12; Color Figure 8; Color Figure 11 through Color Figure 14; Section 1.5, "Experimental Stress Analysis and Mechanical Testing").

Creep and Stress Relaxation

Creep and stress relaxation are related time- and temperature-dependent phenomena, with creep occurring under load control and stress relaxation under deformation control. In both cases the material's temperature is a governing factor regarding what happens. Specifically, for most metals, the creep and relaxation regimes are defined as high homologous (relative, dimensionless) temperatures, normally those above half the melting point in absolute temperature for each metal. Thus, solder at room temperature creeps significantly under load, while steel and aluminum do not. However, some creep and relaxation may occur even at low homologous temperatures, and they are not always negligible. For polymers, the creep regime is above the glass transition temperature. This is typically not far from room temperature.

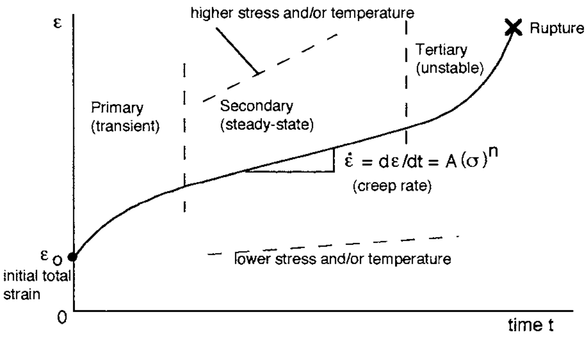

FIGURE 1.6.13 Creep under constant load. $d\varepsilon/dt = A(\sigma)^n$. A and n are material parameters.

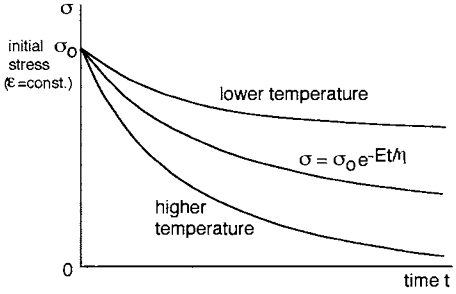

FIGURE 1.6.14 Stress relaxation under constant deformation. $\sigma = \sigma_0 e^{-Et/\eta}$. E and η are material parameters.

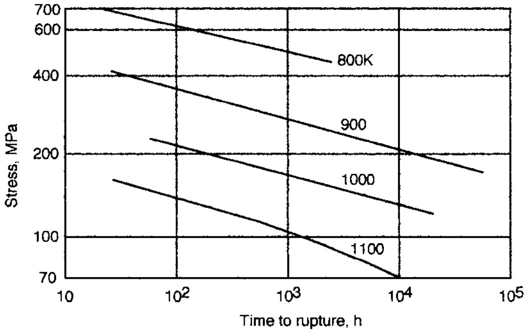

FIGURE 1.6.15 Approximate stress vs. rupture lives of S-590 alloy as functions of temperature. (After Figure 15.8, Dowling, N.E., *Mechanical Behavior of Materials.* Prentice Hall, Englewood Cliffs, NJ, 1993. With permission.)

Figure 1.6.13 and Figure 1.6.14 show trends of creep and stress relaxation in the large-scale phenomenon region. Stress vs. rupture life curves for creep may be nearly linear when plotted on log–log coordinates (Figure 1.6.15).

Mechanical Models of Viscoelastic Behaviors

Creep and stress relaxation appear to be combinations of behaviors of viscous liquids and elastic solids. The so-called viscoelastic phenomena are commonly modeled by simple mechanical components, springs and dashpots, as in Figure 1.6.16. The Maxwell model and related others are based on such elements.

The Maxwell model for creep under constant stress σ_0 is

$$\varepsilon = \varepsilon_1 + \varepsilon_2 = \frac{\sigma}{E} + \int_0^t \sigma_0 \, dt = \frac{\sigma_0}{E} + \frac{\sigma_0 t}{\eta} \tag{1.6.8}$$

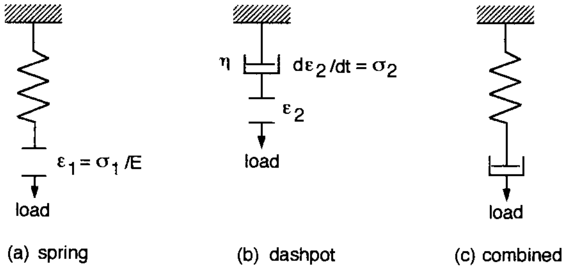

FIGURE 1.6.16 Viscoelastic elements.

For relaxation, ε = constant and σ varies, so

$$\frac{d\varepsilon}{dt} = 0 = \frac{1}{E}\frac{d\sigma}{dt} + \frac{\sigma}{\eta} \tag{1.6.9}$$

$$\int_{\sigma_0}^{\sigma} \frac{d\sigma}{\sigma} = -\frac{E}{\eta}\int_0^t dt, \quad \sigma = \sigma_0 e^{-Et/\eta}$$

Time–Temperature Parameters. Life Estimation

It is often necessary to extrapolate from laboratory creep test data, which are limited in time (from days to years), to real service lives, which tend to be from years to several decades. Time–temperature parameters are useful for this purpose. Three common parameters are outlined here. Note that no such parameter is entirely reliable in all cases; they are best if used consistently in direct comparisons of materials.

Sherby–Dorn Parameter (P_{SD})

$$P_{SD} = \log\theta_r = \log t_r - 0.217Q\left(\frac{1}{T}\right) \tag{1.6.10}$$

where, for steady-state creep,

θ_r = temperature-compensated time to rupture
t_r = rupture time, hours
Q = activation energy = constant
T = temperature, K

Stress-life data at high T and low t_r are needed to plot P_{SD} vs. stress, in order to predict a longer t_r at a lower T.

Larson–Miller Parameter (P_{LM})

This approach is analogous to the Sherby–Dorn approach, but is based on different assumptions and equations.

$$P_{LM} = 0.217Q = T\left(\log t_r + C\right) \tag{1.6.11}$$

where $C = -\log\theta_r \cong 20$ for steels. For using temperature in degrees Fahrenheit (as in most of the data):

$$P_{LM}\big|_{^\circ F} = 1.8 P_{LM}\big|_{K} \tag{1.6.12}$$

Manson–Haferd Parameter (P_{MH})

$$P_{MH} = \frac{T - T_a}{\log t_r - \log t_a} \tag{1.6.13}$$

where T_a and t_a are temperature and time constants representing a point of convergence for a family of data points. As shown previously, for different temperature scales:

$$P_{MH}\big|_{°F} = 1.8 P_{MH}\big|_{K} \tag{1.6.14}$$

Overview. The greater the extrapolation using any parameter, the greater the likelihood of error is. A factor of 10 or less extrapolation in life is often reasonable. At very large extrapolations, damage mechanisms may be different from those of the tests and unpredictable service loading and environmental conditions as well.

Fatigue

Fatigue is a process of damage evolving in a material due to repeated loads, also called cyclic loads. This is a common degradation that affects virtually all solid materials, and thus it is often the main (or a contributing) factor in the failure of vehicles, machinery, structures, appliances, toys, electronic devices, and surgical implants. Many apparently well-designed and -fabricated items that fail inexplicably have problems rooted in the fatigue area.

Nearly two centuries of fatigue studies and engineering efforts have resulted in a huge, and still expanding, technical literature. This brief review can cover only a few major topics, some old but valuable items of wisdom, and practical modern methods. Three important approaches are presented: the stress-based (useful for long lives), strain-based (useful for short lives), and fracture mechanics methods.

Definitions

Constant-amplitude, stress- or strain-controlled cycling is common in testing and some service situations. Figure 1.6.17 shows the stress (σ) quantities in such cycling. Similar notations are used for strains. In completely reversed stress, $\sigma_m = 0$ and $R = -1$. Zero-to-tension (a special case of pulsating tension) has $\sigma_{\min} = 0$ and $R = 0$.

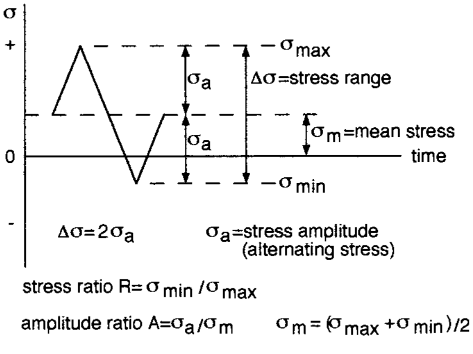

FIGURE 1.6.17 Notation for constant-amplitude stress cycling.

Material Properties in Cyclic Loading

The mechanical properties of some materials are gradually changed by cyclic plastic strains. The changes that occur are largest early in the fatigue life and become negligible beyond about 20 to 50% of the life. The most important material properties that could change significantly this way are the flow properties (yield strength, proportional limit, strain hardening exponent), while the modulus of elasticity is little affected. For metals, three initial conditions can be defined using the strain hardening exponent n as a key parameter. The concept of a cyclic stress–strain curve, as opposed to that in monotonic (static) loading, is also used to distinguish possible material behaviors in fatigue, as follows.

- **Stable**: $0.15 < n < 0.2$ (approx.)
  The monotonic and cyclic stress–strain curves are the same for most practical purposes (though seldom coincident).
  Examples: 7075-T6 Al; 4142 steel (550 BHN)
- **Cycle-dependent softening**: $n < 0.15$ (approx.) (means initially hard, cold-worked material)
  The cyclic stress-strain curve falls significantly below the monotonic curve, which means a gradually decreasing deformation resistance as cyclic loading progresses. The cyclic yield strength may be less than half the tensile yield strength in some cases.
  Examples: 4340 steel (350 BHN); 4142 steel (400 BHN)
- **Cycle-dependent hardening**: $n > 0.2$ (approx.) (means initially soft, annealed material)
  The cyclic stress–strain curve is significantly above the monotonic curve, which means a gradually increasing deformation resistance as cyclic loading progresses.
  Examples: 2024-T4 Al; 4142 steel (670 BHN)

Note that the hardest steels tend to harden further in cyclic loading. Thus, a given steel (such as 4142) may be stable, softening, or hardening, depending on its initial hardness.

In the technical literature, primes are normally used to denote cyclic material properties. For example, σ'_y is the yield strength obtained from a cyclic stress–strain curve.

Stress vs. Life (S-N) Curves

The most common and historical fatigue life plots present data of stress amplitude (simplistically, S or S_a) on a linear scale vs. cycles to failure (N or N_f) on a logarithmic scale as in Figure 1.6.18. Many steels (plain carbon or low alloy) appear to have a distinct fatigue limit. For other metals that do not have such a limit (aluminum, for example), an arbitrary fatigue limit is defined as a stress amplitude corresponding to a specified life, typically 10^7 or 10^8 cycles.

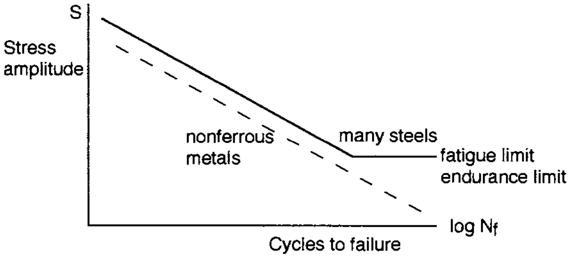

FIGURE 1.6.18 Schematic of S–N curves.

Trends in S-N Curves

There are many influences on the shape and position of a material's fatigue life curve as briefly discussed below.

Ultimate Strength. It is widely believed that, at least for steels, the fatigue limit σ_e is about one half of the ultimate strength σ_u. In fact, this is a gross oversimplification; actual values are lower or higher than that in many cases.

Mean Stress, Residual Stress. Several main points are worth remembering: residual stresses (also called self-stresses) are common, and they are to be treated as mean stresses (by sign and magnitude) in fatigue; a tensile mean stress lowers the life while a compressive one increases it. Simplistically, a tensile mean stress lowers the allowable cyclic stress amplitude, according to Figure 1.6.19 where

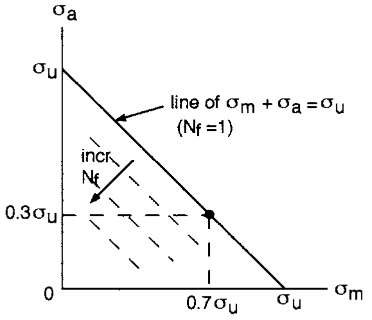

FIGURE 1.6.19 Schematic of tensile mean stress effect.

$$\sigma_m + \sigma_a \le \sigma_u \quad \text{or} \quad \sigma_y \qquad \text{(if yielding is to be prevented)}$$

For example, if $\sigma_m = 0.7\sigma_u$, then the maximum alternating stress for one cycle is $0.3\sigma_u$. This kind of graphical relationship is called a Goodman diagram. Several special expressions are used for dealing with the detrimental effects of tensile mean stresses. For example, the modified Goodman equation is

$$\frac{\sigma_a}{\sigma_e} + \frac{\sigma_m}{\sigma_u} = 1 \tag{1.6.15}$$

where σ_e is the fatigue limit for fully reversed loading.

Sometimes curved lines represent real behavior better than the linear theory shown in Figure 1.6.19. In that case, the Gerber parabola may be appropriate, in the form of

$$\frac{\sigma_a}{\sigma_e} + \left(\frac{\sigma_m}{\sigma_u}\right)^2 = 1 \qquad \text{for} \quad \sigma_m \ge 0 \tag{1.6.16}$$

Another approach worth mentioning is the mechanistically elegant and sensible Morrow expression, which will be presented later.

Note that tensile mean stresses are generally detrimental and that many approaches have been proposed to deal with them, although no single method is capable of good predictions in all cases. In practice, it is best to use a particular method that has a good track record for the material and situation at hand. Constant-life diagrams are useful, elaborate derivatives of the Goodman approach, if they include a broad data base (Figure 1.6.20).

Notch Effects. Stress raisers can be extremely detrimental in fatigue, except when they help create localized compressive residual stresses in ductile metals, delaying crack formation and growth. These are discussed in connection with the strain-based approach.

Microstructure. Large grain size (annealed metals) lowers the fatigue strength, and small grain size (by cold working) increases it, especially at long lives, under load control.

Surface Effects. The condition of a material's surface may influence the fatigue behavior in many ways, typically in combinations.

Toolmarks are common detrimental features, especially because they often are aligned perpendicular to the principal tensile stress in axial or bending loading. An example is a shaft cut in a lathe. Note that in the case of high-strength, hard materials even invisible scratches from grinding and buffing may be stress raisers. Machining also tends to create tensile or compressive residual stresses in surface layers.

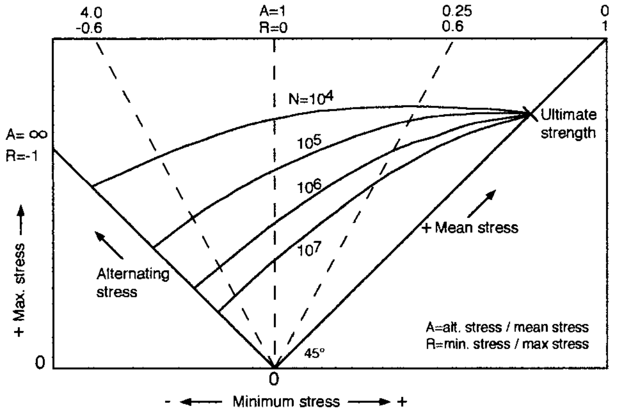

FIGURE 1.6.20 Constant-life diagram.

Surface treatments such as carburizing or nitriding of steels affect the fatigue life by changes in chemical composition, microstructure, hardness, or residual stress. Shot peening, surface rolling, or burnishing is done to introduce compressive residual stresses, which delay cracking in long-life service. Plating (chromium, nickel) tends to create layers of poor fatigue resistance and harmful tensile residual stresses. Shot peening after plating is a beneficial step.

Environment. Hostile chemical environments can severely reduce most materials' fatigue resistance. Common causes of problems are salt water, salt in the air, salt on the road, moisture, and even pollutants in the air. For example, sulfur in the air results in aggressive sulfuric acid on machines and structures.

Statistical Scatter. Statistical scatter is always in a material's fatigue life at any given stress level, especially at long lives. The scatter band may cover several orders of magnitude in life at a single stress level. Because of the scatter, there is no unique fatigue life curve for any material — the curve depends not only on physical factors such as environment, but also on the number of tests done. It is not sufficient to do a handful of tests and draw a curve somewhere through the data points. As a simple rule, to have a high level of confidence (>99%) in a fatigue life curve, at least six identical tests are needed to obtain a mean value at each of several levels of stresses in the general life range of interest. A curve through these mean values is fairly representative of the average life curve (50% probability of failure), but still may not be adequate to deal with scatter. Note that the minimum number of test specimens according to the ASTM Standard E 739 is 6 to 12 for preliminary, exploratory work or for research and development and component testing, and 12 to 24 for design allowables or reliability assessment.

Ideally, additional analysis is done, using Gaussian (normal) statistical distribution or some other model, such as the Weibull distribution. The latter is particularly informative in determining the probability of fatigue failure. The practical problem is that engineers may require very low probabilities of failure (less than 1%), but neither the necessary mathematical methods nor the data bases are available for that. A family of fatigue life curves for various probabilities of failure and other relevant considerations for one material are shown schematically in Figure 1.6.21 through Figure 1.6.23.

Variable Amplitude Loading

Many machines, vehicles, and structures experience random or blockwise changing loading. They can be simplistically modeled for life prediction using the Palmgren–Miner rule, illustrated in Figure 1.6.24. There are two major assumptions for this rule for completely reversed loading:

1. Every cycle at a given level of stress amplitude causes the same amount of damage, whether the cycle is early or late in the life.
2. The percentage of damage caused by a cycle of load at any level of stress is equivalent to the same percentage of damage at any other level of stress.

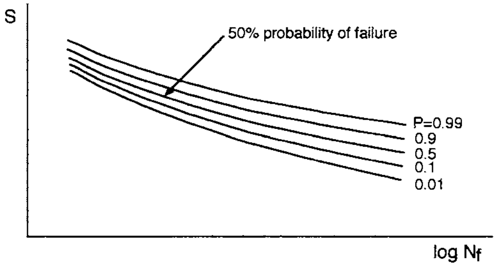

FIGURE 1.6.21 Schematic S–N curves with various probabilities of failure.

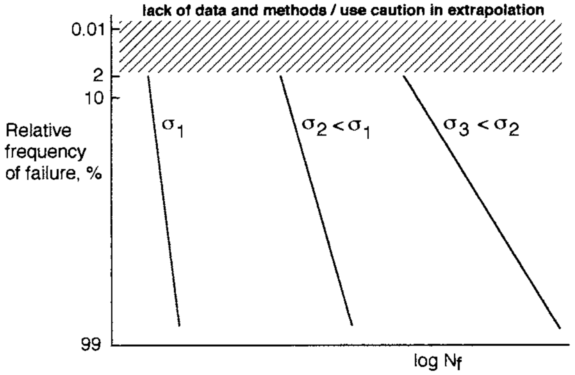

FIGURE 1.6.22 Probability aspects of fatigue depending on stress level.

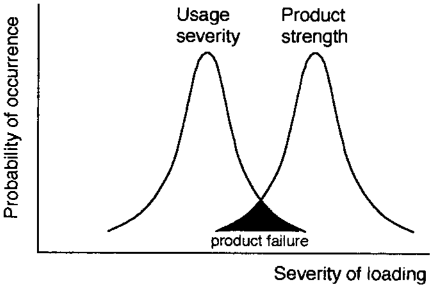

FIGURE 1.6.23 Probability aspects of fatigue depending on applied stress and product strength.

Thus, because 100% of the life N_{fi} is exhausted at failure at any single stress amplitude σ_i, in multilevel loading the life fractions sum to unity, as mathematically formulated here and illustrated in Figure 1.6.24:

$$\frac{N_1}{N_{f1}} + \frac{N_2}{N_{f2}} + \ldots = \sum \frac{N_i}{N_{fi}} = 1 \tag{1.6.17}$$

where N_i is the actual number of cycles at σ_i and N_{fi} is the life at σ_i.

In practice, summations of about 0.8 to 1.2 can be accepted, saying that the Palmgren–Miner rule is valid in that case. Gross deviations from summations of one are common, especially when the mean stress is not zero. Modified versions of the basic rule for such cases should be used with caution.

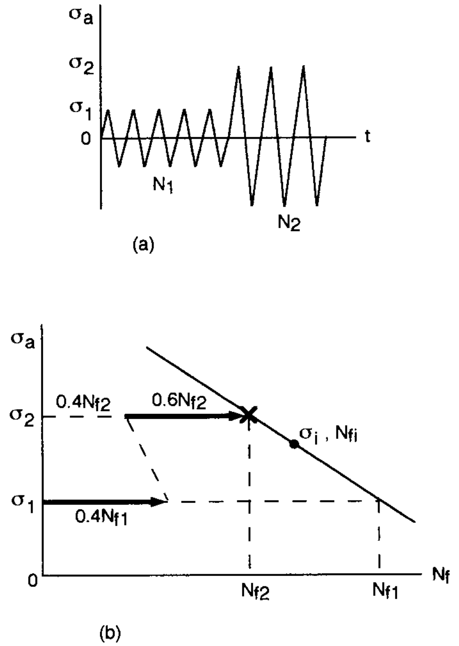

FIGURE 1.6.24 Schematic for Palmgren–Miner rule.

Cycle Counting. Highly irregular loading requires the use of special cycle counting methods, such as level crossing, range counting, or rainflow cycle counting. The latter is the best modern method, lending itself to efficient field data acquisition and computer work (ASTM Standard E1049; *SAE Fatigue Design Handbook*).

Multiaxial Fatigue

Complex states of stress are common in engineering components, and in fatigue analysis they may cause serious difficulties. Although many methods are available, none of them is adequate for all cases. The simplest situations that might be handled reasonably well involve fully reversed loading by in-phase or 180° out-of-phase proportional stresses at the same frequency. Multiaxial fatigue testing is difficult and expensive, so it is often desired to use uniaxial test data for predicting the multiaxial behavior. A typical approach for this is based on computing an effective stress amplitude *se* from the amplitudes of the principal stresses σ_{1a}, σ_{2a}, σ_{3a}. With the concept of the octahedral shear yield criterion,

$$\sigma_e = \frac{1}{\sqrt{2}}\sqrt{\left(\sigma_{1a}-\sigma_{2a}\right)^2+\left(\sigma_{2a}-\sigma_{3a}\right)^2+\left(\sigma_{3a}-\sigma_{1a}\right)^2} \tag{1.6.18}$$

where in-phase stresses are positive and 180° out-of-phase stresses are negative.

The life is estimated by entering σ_e on the appropriate S-N curve. Note that mean stresses, localized or general yielding, creep, and random frequencies of loading further complicate the problem and require more sophisticated methods than outlined here.

Strain vs. Life (ε-N) Curves

A strain-based approach is necessary in fatigue when measurable inelastic strains occur. In general, total strain consists of elastic, plastic, and creep strains, with the latter two in the category of inelastic strains:

$$\varepsilon_t = \varepsilon_e + \varepsilon_p + \varepsilon_c \tag{1.6.19}$$

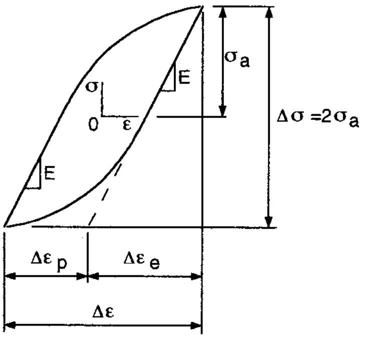

FIGURE 1.6.25 Hysteresis loop.

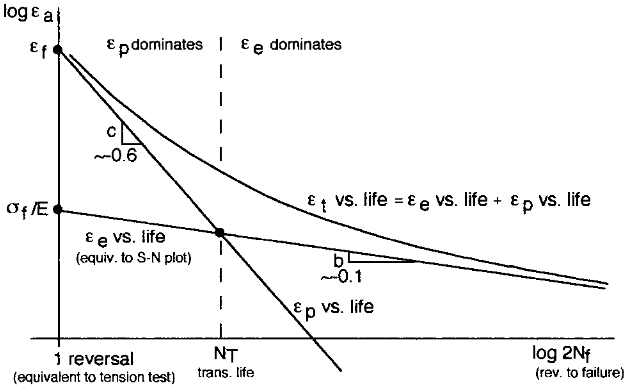

FIGURE 1.6.26 Schematic of strain vs. life curves.

When ε_p or/and ε_c are dominant, the life is relatively short and the situation is called low-cycle fatigue (LCF), as opposed to high-cycle fatigue (HCF), where ε_e is dominant. The mechanics of LCF can be understood by first considering hysteresis loops of elastic and plastic strains as defined in Figure 1.6.25.

Simplistically, HCF means a thin loop (a straight line at very long life) and LCF means a fat loop. Strain-life plots are especially useful in the LCF regime where material properties (ε_f, σ_f) obtained in monotonic tension tests are directly useful in fatigue life prediction as shown in Figure 1.6.26. Most commonly, the total strain amplitude ε_a is plotted vs. the life $2N_f$, with a corresponding equation (called Coffin–Manson equation) for fully reversed loading:

$$\varepsilon_a = \frac{\sigma_f}{E}\left(2N_f\right)^b + \varepsilon_f\left(2N_f\right)^c \tag{1.6.20}$$

It is remarkable that all metals are similar to one another in their values of the exponents b (≈ –0.1) and c (≈ –0.6), differing only in fracture strength σ_f and fracture ductility ε_f. These allow a simplistic fatigue life prediction if at least σ_f and ε_f are known.

If there is a mean stress, its effect is equivalent to an altered fracture strength. Using the Morrow approach in a simplified version,

$$\varepsilon_a = \frac{\sigma_f}{E}\left(1-\frac{\sigma_m}{\sigma_f}\right)\left(2N_f\right)^b + \varepsilon_f\left(2N_f\right)^c \tag{1.6.21}$$

where σ_m is positive for tensile and negative for compressive mean stress.

Notch Effects

The localized plastic strains of notched members complicate fatigue analysis considerably. It should be noted, first of all, that the theoretical stress concentration factor K_t is not entirely relevant to such members because yielding lowers the actual peak stresses from those predicted. This leads to the definitions of the true stress and strain concentration factors:

$$K_\sigma = \frac{\text{peak stress}}{\text{ave. stress}} \qquad K_\varepsilon = \frac{\text{peak strain}}{\text{ave. strain}} \tag{1.6.22}$$

According to Neuber's rule:

$$K_t = \sqrt{K_\sigma K_\varepsilon} \tag{1.6.23}$$

which is useful for notch analysis in fatigue. This expression is strictly true for ideally elastic behavior and is qualitatively evident for elastic–plastic deformations.

Residual Stresses at Notches. An extremely important, and somewhat surprising, phenomenon can occur in notched members if they yield locally under variable-amplitude loading. If a large load (called an overload) causes yielding at a notch and is followed only by smaller loads, a residual stress of the opposite sign to the overload's sign is generated at the root of the notch. Thus, a tensile overload (such as at one side of a shaft in a straightening operation) creates a compressive residual stress, and vice versa. These stresses may remain in the member for a long time or be relaxed by other plastic strain events or by annealing. Of course, such stresses are effective mean stresses and can alter the life greatly.

Creep–Fatigue Interactions

Inelastic strains (plastic and creep strains) are the basic causes of time- and cycle-dependent damage processes. When both kinds of strains occur during the life of a particular component, complex damage interactions may arise. The simplest and most elegant approach in such a case is to sum both of the different damages linearly (as in the Palmgren–Miner summation for pure fatigue), assuming that they are equivalent to one another. In other words, assume that X percentage of creep life exhausted is equivalent to the same X percentage of fatigue life exhausted. Thus, a linear expression involving time and cycle fractions can be stated:

$$\underset{\text{pure creep}}{\sum \frac{t_i}{t_{ri}}} + \underset{\text{pure fatigue}}{\sum \frac{n_j}{N_{fj}}} = \underset{\text{at failure}}{1} \tag{1.6.24}$$

where

t_i = actual time spent at stress level i in creep
t_{ri} = total time to rupture at stress level i
n_j = actual number of cycles at stress level j
N_{fj} = cycles to failure at stress level j

This idealized linear expression is plotted as a dashed line in Figure 1.6.27; in contrast, a more realistic ASME code and possible severe degradations are also plotted.

Many other methods (such as damage rate equations; strain-range partitioning) can be used to deal with creep–fatigue problems, but none of them is adequate for all situations. The difficulty is mainly because of the need to account for important, complex details of the loading cycle (frequency, hold times, temperature, and deformation wave shape).

Fracture Mechanics Method in Fatigue

Cyclic loading can cause crack growth with or without the presence of a hostile chemical environment. The rate of crack growth depends on the stress intensity factor $K \propto \sigma\sqrt{a}$. Investigations of this dependence

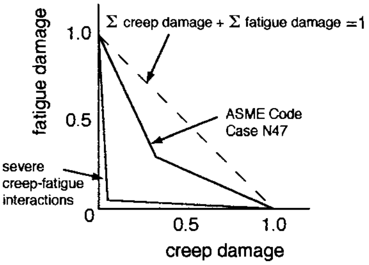

FIGURE 1.6.27 Schematic of creep–fatigue interactions. The bilinear damage rule is recommended in the ASME Boiler and Pressure Vessel Code, Section III, Code Case N47.

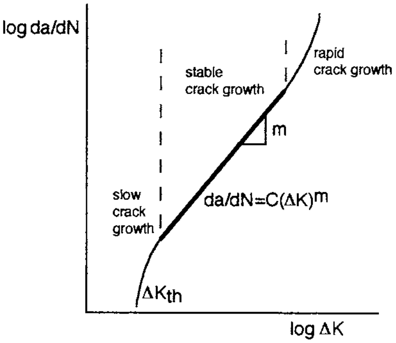

FIGURE 1.6.28 Schematic of fatigue crack propagation data.

have led to the development of powerful techniques in design and failure analysis. The fatigue crack growth behavior is quantified by the Paris equation:

$$\frac{da}{dN} = C(\Delta K)^m \tag{1.6.25}$$

where

da/dN = crack growth rate
C, m = material constants
$\Delta K = K_{\max} - K_{\min}$ = stress intensity factor range
$K_{\max} \propto \sigma_{\max}$
$K_{\min} \propto \sigma_{\min}$

Typical data for a wide range of crack growth rates have patterns as in Figure 1.6.28, where ΔK_{th} is a threshold value akin to a fatigue limit. The linear part of the curve is useful for life prediction and failure analysis.

Abridged Example of a Modern Fatigue Analysis

Many of the concepts mentioned earlier are applied in Sandia National Laboratories' "User's Manual for FAROW: Fatigue and Reliability of Wind Turbine Components," SAND94-2460, November 1994. FAROW is a computer program for the probabilistic analysis of large wind turbines, using structural reliability techniques to calculate the mean time to failure; probability of failure before a target lifetime; relative importance of each of the random inputs; and sensitivity of the reliability to all input parameters. The method is useful whether extensive data are available or not (showing how much can be gained by reducing the uncertainty in each input). It helps one understand the fatigue reliability of a component and indicates how to improve the reliability. The sample figures (Figure 1.6.29 through Figure 1.6.32) illustrate some of the key data and results for the machines and materials considered.

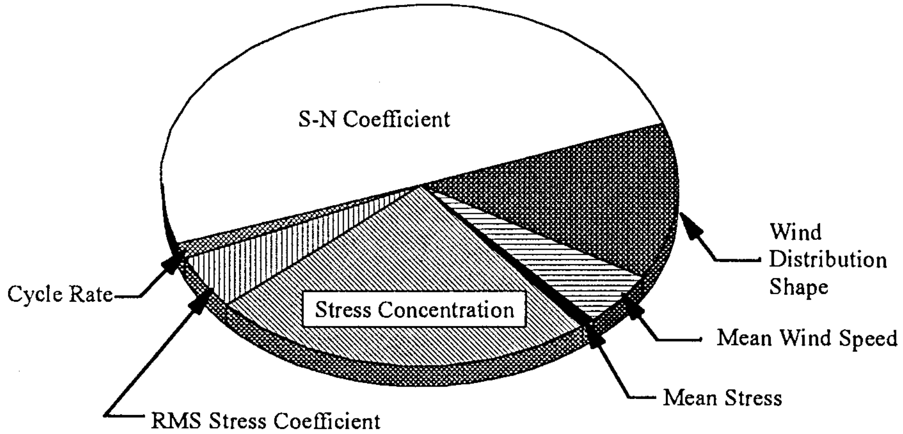

FIGURE 1.6.29 Relative importance factors as fractions of the total influence on the probability of failure. (Courtesy Sandia National Laboratories, Albuquerque, NM.)

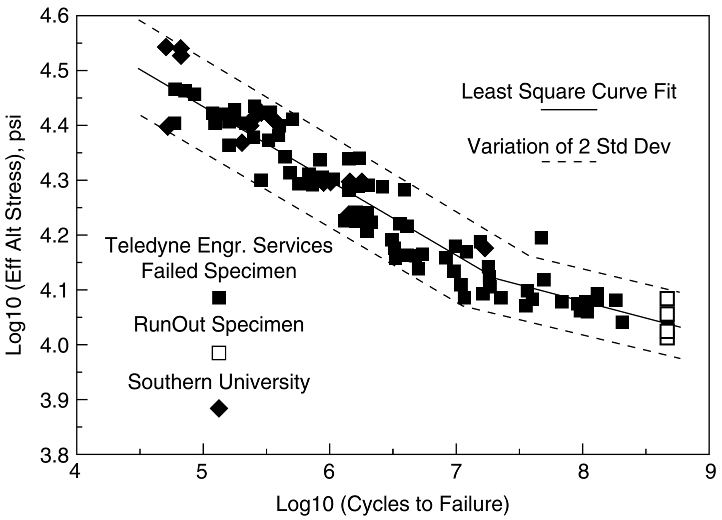

FIGURE 1.6.30 Fatigue life data for 6063 Al. (Courtesy Sandia National Laboratories, Albuquerque, NM.)

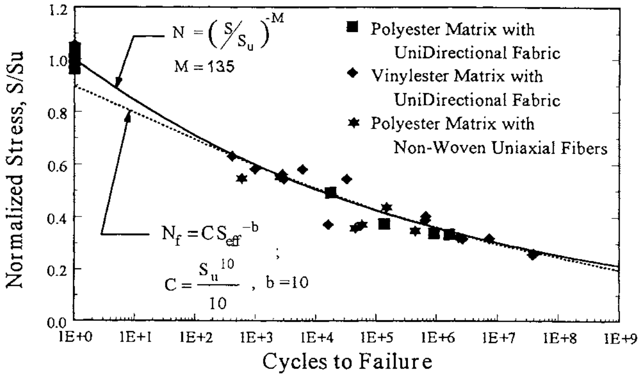

FIGURE 1.6.31 Fatigue life data for uniaxial fiberglass composite. (Courtesy Sandia National Laboratories, Albuquerque, NM.)

FIGURE 1.6.32 Example FAROW results for probability of premature failure as a function of target lifetime. (Courtesy Sandia National Laboratories, Albuquerque, NM.)

Note especially a large discrepancy between mean lifetime and probability of failure in a few years. A mean lifetime of 600 years was calculated for a critical component, using the median values for all the random variables considered and using the constant values for all the other input parameters. However, the probability of the component failing in less than 5 years is estimated at 7.6% (Figure 1.6.32). This shows the uncertainty — even in sophisticated fatigue life calculations — because of reasonable uncertainty in the inputs and the sensitivity of fatigue life to parameter variation.

1.7 Comprehensive Example of Using Mechanics of Solids Methods

Bela I. Sandor

A concise overview of an engineering project is presented to illustrate the relevance and coordinated application of several concepts and methods in this chapter. The sketchy outline is limited in breadth and depth, emphasizes modern methods, and is not aiming for completeness in any particular area.

The Project

Analyze the currently used A-shaped arm of the suspension system of a small, special-purpose ground vehicle. The goal is to redesign the component to save weight and, more importantly, reduce the cost of manufacturing while assuring the product's reliability over its expected service life.

Concepts and Methods

Statics

Vectors
Free-body diagrams. Equilibrium
Two-force member: shock absorber
Frame components
Beams. Bending moments
Moments of inertia
Center of mass

Dynamics

Velocity, acceleration
Rigid-body dynamics
General plane motion
Relative motion

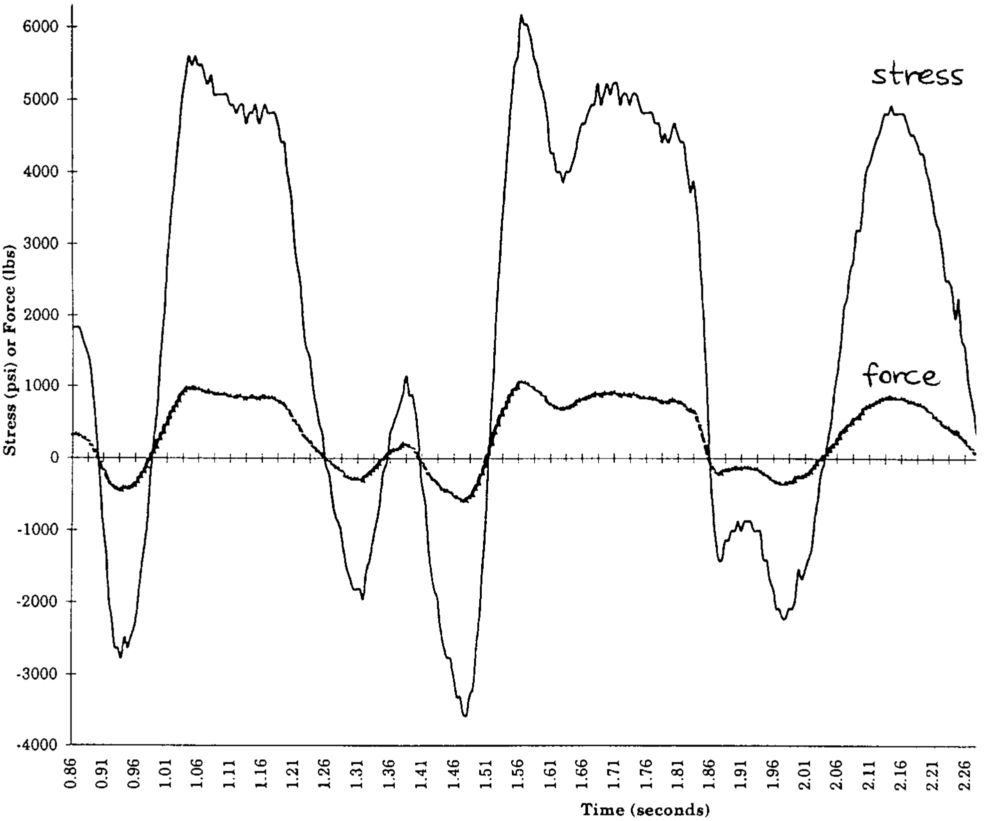

FIGURE 1.7.2 Axial stress and force vs. time in shock absorber shaft.

Defining Terms

Statics

Equilibrium: A concept used to determine unknown forces and moments. A rigid body is in equilibrium when the equivalent force-couple system of the external forces acting on it is zero. The general conditions of equilibrium are expressed in vector form ($\Sigma\mathbf{F} = 0$; $\Sigma\mathbf{M}_O = \Sigma[\mathbf{r} \times \mathbf{F}] = 0$) or scalar form ($\Sigma F_x = 0$; $\Sigma F_y = 0$; $\Sigma F_z = 0$; $\Sigma M_x = 0$; $\Sigma M_y = 0$; $\Sigma M_z = 0$).

Equivalent force-couple system: Any system of forces and moments acting on a rigid body can be reduced to a resultant force and a resultant moment. Transformations of a force-couple system involving chosen points of reference are easy to make. These are useful for determining unknown forces and moments and the critical locations in structural members.

Free-body diagram: A method of modeling and simplifying a problem for the efficient use of the equilibrium equations to determine unknown forces and moments. A body or group of bodies is imagined to be isolated from all other bodies, and all significant external forces and moments (known or unknown) are shown to act on the free-body model.

Dynamics

Equations of motion: Expressions of the acceleration of a body related to the forces acting on the body. The basic equation of motion for a particle of mass m is $\Sigma\mathbf{F} = m\mathbf{a}$. Many other equations of motion may be stated, depending on the dimensions of the body and its motion (such as two- or three-dimensional motion) and the coordinate system chosen.

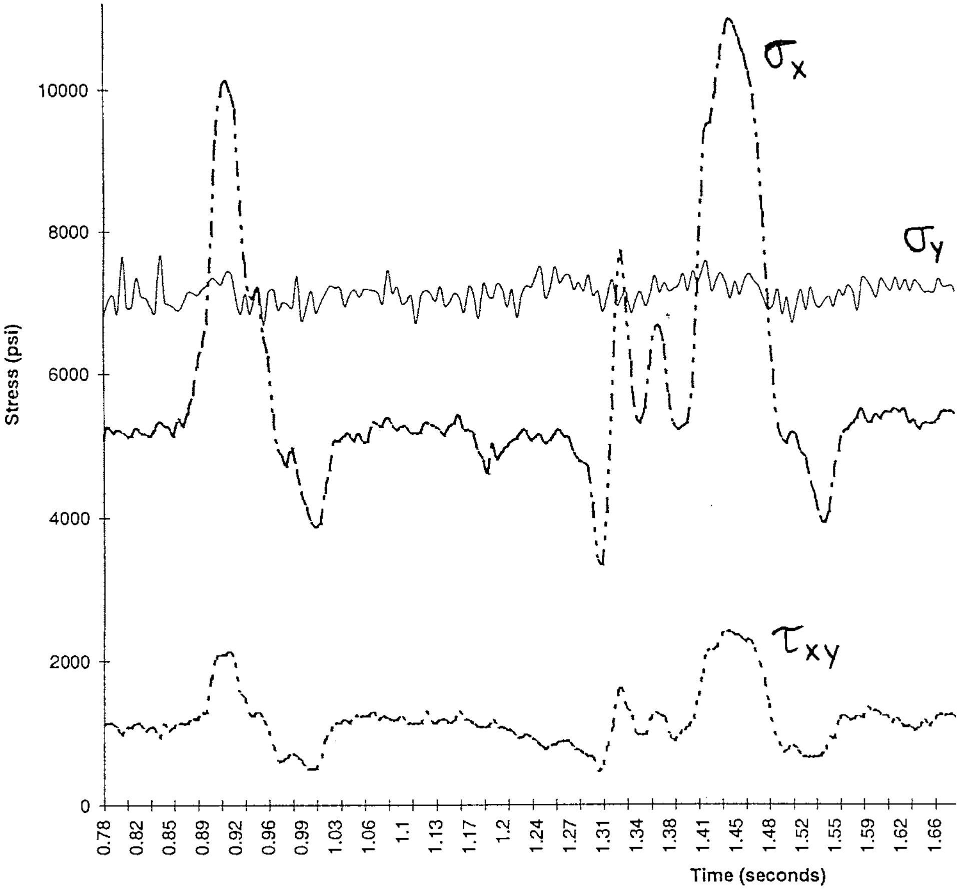

FIGURE 1.7.3 Stresses σ_x, σ_y, and τ_{xy} measured at one point of the A-arm by strain gages as the vehicle travels over bumps.

Kinematics: The analysis of motion based on geometry and time-dependent aspects. Forces may or may not be associated with the motion, but the analysis does not involve considerations of forces. The parameters of interest in kinematics are position, displacement, velocity, acceleration, and time.

Kinetics: The analysis of motion based on kinematics and the effects of forces on masses.

Vibrations

Forced vibration: Involves an exciting force applied periodically during the motion. A forced vibration may also be described in terms of the displacement of a foundation or primary mass that supports the vibrating system.

Free vibration: Occurs when only two kinds of forces are acting on a mass: (1) the elastic restoring force within the system; and (2) the force of gravity or other constant forces that cause no displacement from the equilibrium configuration of the system.

Resonance: A critical aspect of forced vibrations that occurs when the forcing frequency equals the system's natural frequency. In this condition, the amplitude of the displacements becomes infinite in theory or dangerously large in practice when the damping is small. Near-resonance conditions may also be undesirable.

Mechanics of Materials

Flexure formula: Used to calculate the bending stresses in beams. Must be applied with modifications if there are inelastic deformations or unsymmetric bending, or for composite beams and curved beams.

Hooke's law: Applicable for calculating uniaxial or multiaxial stress–strain responses when the material acts entirely elastically. Involves the modulus of elasticity E and Poisson's ratio ν.

Principal stresses: The maximum and minimum normal stresses at a point on an infinitesimal element. An important related quantity is the absolute maximum shear stress. These quantities can be determined (given an arbitrary state of applied stress) from stress transformation equations or from their graphical solution, Mohr's circle. Principal strains are determined in a similar way.

Stress–strain diagram: Shows the stress–strain response and many important mechanical properties for a material. These properties depend greatly on the material's chemical composition and several other factors of fabrication and service conditions. Monotonic (tension or compression) and cyclic loading conditions may result in grossly different mechanical behaviors, even for a given material.

Structural Integrity and Durability

Rate of crack growth: A measure of damage evolution and remaining life of a member. In fatigue, the crack propagation rate da/dN depends on the stress intensity factor range DK and material properties. This relationship is the basis of the powerful, well-established damage-tolerant design method.

Stress concentration factor: The localized stress-raising effect of a geometric discontinuity. Many potentially confusing forms of quantifying this effect exist. The most prominent factors are distinguished concisely:

- Theoretical stress concentration factor, $K_t = \sigma_{\max}/\sigma_{\text{ave}}$
  - Depends on geometry of notch, not on material
  - Has no engineering units
- True stress concentration factor, $K_\sigma = \sigma_{\max}/\sigma_{\text{ave}}$
  - Depends on geometry of notch and material; $K_\sigma = K_t$ for perfectly elastic material, $K_\sigma < K_t$ for ductile material
  - Has no engineering units
- True strain concentration factor, $K_\varepsilon = \varepsilon_{\max}/\varepsilon_{\text{ave}}$, $\varepsilon_{\text{ave}} = \sigma_{\text{ave}}/E$
  - Depends on geometry of notch and material; $K_\varepsilon = K_t$ for perfectly elastic material, $K_\varepsilon > K_t$ for ductile material
  - Has no engineering units

Stress intensity factor : A measure of the severity of a crack or the intensity of the stress field near the crack tip. Many potentially confusing forms of this factor exist; they have identical engineering units of stress $\sqrt{\text{length}}$, but a variety of definitions and applications. A few are listed concisely:

- Opening-mode stress intensity factor, K_I
  - Depends on geometry of a crack and applied stress, not on material
  - Units of stress $\sqrt{\text{length}}$
- Plane strain fracture toughness, K_{IC}
  - Depends on material but not on geometry above a certain thickness, and not on applied stress
  - Units of stress $\sqrt{\text{length}}$
- Stress intensity factor range, $\Delta K = K_{\max} - K_{\min}$
  - Depends on geometry of a crack and applied cyclic stress, not on material
  - Units of stress $\sqrt{\text{length}}$

Further Information

Many technical societies are active in various areas of mechanics of solids, and they are excellent, steady sources of long-accepted and new information, some of which is available within hours. They also organize committee work, conferences, symposia, short courses, and workshops; establish codes and standards; and publish books, papers, journals, and proceedings covering the latest developments in numerous specialties. A short list of societies is given here; note that they tend to have international breadth, regardless of the name. It is wise to belong to several relevant societies and at least scan their announcements.

ASM International (formerly American Society for Metals) (800-336-5152)
ASME — American Society for Mechanical Engineers (800-843-2763)
ASNT — American Society for Nondestructive Testing (800-222-2768)
ASTM — American Society for Testing and Materials (215-299-5585)
SAE — Society of Automotive Engineers (412-776-4841)
SEM — Society for Experimental Mechanics (203-790-6373)
SES — Standards Engineering Society (513-223-2410)

As a hint of the scope and magnitude of what is available from the large technical societies, here are selected offerings of ASTM:

- ASTM staff access/tel: 215-299-5585; fax: 215-977-9679; e-mail: infoctr@local.astm.org
- *ASTM Standardization News*, a monthly magazine, regularly presents information on "the development of voluntary full consensus standards for materials, products, systems and services and the promotion of related knowledge… the research, testing and new activities of the ASTM standards-writing committees… the legal, governmental and international events impacting on the standards development process" (quotes from the masthead).
- Over 50 volumes of ASTM Standards

  Samples of standards:
    - Friction, wear, and abrasion (B611 on wear resistance of carbides; G77 on ranking of materials in sliding wear)
    - Fracture mechanics (E399 on fracture toughness testing of metals)
    - Fatigue (E466 on axial fatigue tests of metals; D671 on flexural fatigue of plastics)
- Training courses for ASTM Standards (215-299-5480)
- ASTM International Directory of Testing Laboratories
- ASTM Directory of Scientific & Technical Consultants & Expert Witnesses
- ASTM Special Technical Publications (STP) are books of peer-reviewed papers on recent research and developments

  Samples of STPs:
    - STP 1198 — *Nondestructive Testing of Pavements and Backcalculation of Moduli*, 2nd Vol.; 1995
    - STP 1231 — *Automation in Fatigue and Fracture: Testing and Analysis*; 1995.

Engineering Thermodynamics

Michael J. Moran
The Ohio State University

Although various aspects of what is now known as thermodynamics have been of interest since antiquity, formal study began only in the early 19th century through consideration of the motive power of *heat*: the capacity of hot bodies to produce *work*. Today the scope is larger, dealing generally with *energy and entropy*, and with relationships among the *properties* of matter. Moreover, in the past 25 years engineering thermodynamics has undergone a revolution, both in terms of the presentation of fundamentals and in the manner that it is applied. In particular, the second law of thermodynamics has emerged as an effective tool for engineering analysis and design.

0-8493-0866-6/05/$0.00+$1.50

2.1 Fundamentals

Classical thermodynamics is concerned primarily with the macrostructure of matter. It addresses the gross characteristics of large aggregations of molecules and not the behavior of individual molecules. The microstructure of matter is studied in kinetic theory and statistical mechanics (including quantum thermodynamics). In this chapter, the classical approach to thermodynamics is featured.

Basic Concepts and Definitions

Thermodynamics is both a branch of physics and an engineering science. The scientist is normally interested in gaining a fundamental understanding of the physical and chemical behavior of fixed, quiescent quantities of matter and uses the principles of thermodynamics to relate the *properties* of matter. Engineers are generally interested in studying *systems* and how they interact with their *surroundings.* To facilitate this, engineers have extended the subject of thermodynamics to the study of systems through which matter flows.

System

In a thermodynamic analysis, the *system is* the subject of the investigation. Normally the system is a specified quantity of matter and/or a region that can be separated from everything else by a well-defined surface. The defining surface is known as the *control surface* or *system boundary.* The control surface may be movable or fixed. Everything external to the system is the *surroundings.* A system of fixed mass is referred to as a *control mass* or as a *closed system.* When there is flow of mass through the control surface, the system is called a *control volume,* or *open, system.* An *isolated* system is a closed system that does not interact in any way with its surroundings.

State, Property

The condition of a system at any instant of time is called its *state.* The state at a given instant of time is described by the properties of the system. A *property is any* quantity whose numerical value depends on the state but not the history of the system. The value of a property is determined in principle by some type of physical operation or test.

Extensive properties depend on the size or extent of the system. Volume, mass, energy, and entropy are examples of extensive properties. An extensive property is additive in the sense that its value for the whole system equals the sum of the values for its parts. *Intensive* properties are independent of the size or extent of the system. Pressure and temperature are examples of intensive properties.

A mole is a quantity of substance having a mass numerically equal to its molecular weight. Designating the molecular weight by $\mathcal{M}$ and the number of moles by n, the mass m of the substance is $m = n\mathcal{M}$. One kilogram mole, designated kmol, of oxygen is 32.0 kg and one pound mole (lbmol) is 32.0 lb. When an extensive property is reported on a unit mass or a unit mole basis, it is called a *specific* property. An overbar is used to distinguish an extensive property written on a per-mole basis from its value expressed per unit mass. For example, the volume per mole is $\bar{v}$, whereas the volume per unit mass is v, and the two specific volumes are related by $\bar{v} = \mathcal{M}v$.

Process, Cycle

Two states are identical if, and only if, the properties of the two states are identical. When any property of a system changes in value there is a change in state, and the system is said to undergo a *process.* When a system in a given initial state goes through a sequence of processes and finally returns to its initial state, it is said to have undergone a *cycle.*

Phase and Pure Substance

The term *phase* refers to a quantity of matter that is homogeneous throughout in both chemical composition and physical structure. Homogeneity in physical structure means that the matter is all *solid,* or all *liquid*, or all *vapor* (or equivalently all *gas). A* system can contain one or more phases. For example, a system of liquid water and water vapor (steam) contains *two* phases. A *pure substance* is one that is uniform and invariable in chemical composition. *A* pure substance can exist in more than one phase, but its chemical composition must be the same in each phase. For example, if liquid water and water vapor form a system with two phases, the system can be regarded as a pure substance because each phase has the same composition. The nature of phases that coexist in equilibrium is addressed by the *phase rule* (Section 2.3, Multicomponent Systems).

Equilibrium

Equilibrium means a condition of balance. In thermodynamics the concept includes not only a balance of forces, but also a balance of other influences. Each kind of influence refers to a particular aspect of thermodynamic (complete) equilibrium. *Thermal* equilibrium refers to an equality of temperature, *mechanical* equilibrium to an equality of pressure, and *phase* equilibrium to an equality of chemical potentials (Section 2.3, Multicomponent Systems). *Chemical* equilibrium is also established in terms of chemical potentials (Section 2.4, Reaction Equilibrium). For complete equilibrium the several types of equilibrium must exist individually.

To determine if a system is in thermodynamic equilibrium, one may think of testing it as follows: isolate the system from its surroundings and watch for changes in its observable properties. If there are no changes, it may be concluded that the system was in equilibrium at the moment it was isolated. The system can be said to be at an *equilibrium state.* When a system is *isolated,* it cannot interact with its surroundings; however, its state can change as a consequence of spontaneous events occurring internally as its intensive properties, such as temperature and pressure, tend toward uniform values. When all such changes cease, the system is in equilibrium. At equilibrium. temperature and pressure are uniform throughout. If gravity is significant, a pressure variation with height can exist, as in a vertical column of liquid.

Temperature

A scale of temperature independent of the *thermometric substance* is called a *thermodynamic* temperature scale. The Kelvin scale, a thermodynamic scale, can be elicited from the second law of thermodynamics (Section 2.1, The Second Law of Thermodynamics, Entropy). The definition of temperature following from the second law is valid over all temperature ranges and provides an essential connection between the several *empirical* measures of temperature. In particular, temperatures evaluated using a *constant-volume gas thermometer* are identical to those of the Kelvin scale over the range of temperatures where gas thermometry can be used.

The empirical *gas scale* is based on the experimental observations that (1) at a given temperature level all gases exhibit the same value of the product $p\bar{v}$ (p is pressure and $\bar{v}$ the specific volume on a molar basis) if the pressure is low enough, and (2) the value of the product $p\bar{v}$ increases with the temperature level. On this basis the gas temperature scale is defined by

$$T = \frac{1}{\bar{R}} \lim_{p \to 0} \left(p\bar{v} \right)$$

where T is temperature and $\bar{R}$ is the *universal gas constant.* The absolute temperature at the *triple point of water* (Section 2.3, *P-v-T* Relations) is fixed by international agreement to be 273.16 K on the *Kelvin* temperature scale. $\bar{R}$ is then evaluated experimentally as $\bar{R} = 8.314$ kJ/kmol · K (1545 ft · lbf/lbmol · °R).

The *Celsius termperature scale* (also called the centigrade scale) uses the degree Celsius (°C), which has the same magnitude as the kelvin. Thus, temperature *differences* are identical on both scales. However, the zero point on the Celsius scale is shifted to 273.15 K, as shown by the following relationship between the Celsius temperature and the Kelvin temperature:

$$T(°\mathrm{C}) = T(\mathrm{K}) - 273.15 \tag{2.1}$$

On the Celsius scale, the triple point of water is 0.01°C and 0 K corresponds to –273.15°C.

Two other temperature scales are commonly used in engineering in the U.S. By definition, the *Rankine scale,* the unit of which is the degree rankine (°R), is proportional to the Kelvin temperature according to

$$T(°\mathrm{R}) = 1.8T(\mathrm{K}) \tag{2.2}$$

The Rankine scale is also an absolute thermodynamic scale with an absolute zero that coincides with the absolute zero of the Kelvin scale. In thermodynamic relationships, temperature is always in terms of the Kelvin or Rankine scale unless specifically stated otherwise.

A degree of the same size as that on the Rankine scale is used in the *Fahrenheit scale,* but the zero point is shifted according to the relation

$$T(°\mathrm{F}) = T(°\mathrm{R}) - 459.67 \tag{2.3}$$

Substituting Equation 2.1 and Equation 2.2 into Equation 2.3 gives

$$T(°\mathrm{F}) = 1.8T(°\mathrm{C}) + 32 \tag{2.4}$$

This equation shows that the Fahrenheit temperature of the *ice point* (0°C) is 32°F and of the *steam point* (100°C) is 212°F. The 100 Celsius or Kelvin degrees between the ice point and steam point corresponds to 180 Fahrenheit or Rankine degrees.

To provide a standard for temperature measurement taking into account both theoretical and practical considerations, the International Temperature Scale of 1990 (ITS-90) is defined in such a way that the temperature measured on it conforms with the thermodynamic temperature, the unit of which is the kelvin, to within the limits of accuracy of measurement obtainable in 1990. Further discussion of ITS-90 is provided by Preston-Thomas (1990).

The First Law of Thermodynamics, Energy

Energy is a fundamental concept of thermodynamics and one of the most significant aspects of engineering analysis. Energy can be *stored* within systems in various macroscopic forms: kinetic energy, gravitational potential energy, and internal energy. Energy can also be *transformed* from one form to another and *transferred* between systems. For closed systems, energy can be transferred by *work* and *heat transfer.* The total amount of energy is *conserved* in all transformations and transfers.

Work

In thermodynamics, the term *work* denotes a means for transferring energy. Work is an effect of one system on another that is identified and measured as follows: work is done by a system on its surroundings if the *sole effect* on everything external to the system *could have been* the raising of a weight. The test of whether a work interaction has taken place is not that the elevation of a weight is actually changed, nor that a force actually acted through a distance, but that the sole effect *could be* the change in elevation of a mass. The magnitude of the work is measured by the number of standard weights that could have been raised. Since the raising of a weight is in effect a force acting through a distance, the work concept of mechanics is preserved. This definition includes work effects such as is associated with rotating shafts, displacement of the boundary, and the flow of electricity.

Work done *by* a system is considered positive: $W > 0$. Work done *on* a system is considered negative: $W < 0$. The time rate of doing work, or *power,* is symbolized by $\dot{W}$ and adheres to the same sign convention.

Energy

A closed system undergoing a process that involves only work interactions with its surroundings experiences an *adiabatic* process. On the basis of experimental evidence, it can be postulated that *when a closed system is altered adiabatically, the amount of work is fixed by the end states of the system and is* *independent of the details of the process.* This postulate, which is one way the *first law of thermodynamics* can be stated, can be made regardless of the type of work interaction involved, the type of process, or the nature of the system.

As the work in an adiabatic process of a closed system is fixed by the end states, an extensive property called *energy* can be defined for the system such that its change between two states is the work in an adiabatic process that has these as the end states. In engineering thermodynamics the change in the energy of a system is considered to be made up of three macroscopic contributions: the change in *kinetic energy, KE,* associated with the motion of the system *as a whole* relative to an external coordinate frame, the change in gravitational *potential energy, PE,* associated with the position of the system *as a whole* in the Earth's gravitational field, and the change in *internal energy, U,* which accounts for all other energy associated with the system. Like kinetic energy and gravitational potential energy, internal energy is an extensive property.

In summary, the change in energy between two states of a closed system in terms of the work W_{ad} of an adiabatic process between these states is

$$\left(KE_2 - KE_1\right) + \left(PE_2 - PE_1\right) + \left(U_2 - U_1\right) = -W_{ad} \tag{2.5}$$

where 1 and 2 denote the initial and final states, respectively, and the minus sign before the work term is in accordance with the previously stated sign convention for work. Since any arbitrary value can be assigned to the energy of a system at a given state 1, no particular significance can be attached to the value of the energy at state 1 or at *any* other state. Only *changes* in the energy of a system have significance.

The specific energy (energy per unit mass) is the sum of the specific internal energy, u, the specific kinetic energy, $\mathrm{v}^2/2$, and the specific gravitational potential energy, gz, such that

$$\text{specific energy} = u + \frac{\mathrm{v}^2}{2} + \mathrm{gz} \tag{2.6}$$

where the velocity v and the elevation z are each relative to specified datums (often the Earth's surface) and g is the acceleration of gravity.

A property related to internal energy u, pressure p, and specific volume v is *enthalpy*, defined by

$$h = u + pv \tag{2.7a}$$

or on an extensive basis

$$H = U + pV \tag{2.7b}$$

Heat

Closed systems can also interact with their surroundings in a way that cannot be categorized as work, as, for example, a gas (or liquid) contained in a closed vessel undergoing a process while in contact with a flame. This type of interaction is called a *heat interaction,* and the process is referred to as *nonadiabatic.*

A fundamental aspect of the energy concept is that energy is conserved. Thus, since a closed system experiences precisely the same energy change during a nonadiabatic process as during an adiabatic process between the same end states, it can be concluded that the *net* energy transfer to the system in each of these processes must be the same. It follows that heat interactions also involve energy transfer. Denoting the amount of energy transferred *to* a closed system in heat interactions by Q, these considerations can be summarized by the *closed system energy balance:*

$$\left(U_2 - U_1\right) + \left(KE_2 - KE_1\right) + \left(PE_2 - PE_1\right) = Q - W \tag{2.8}$$

The closed system energy balance expresses the conservation of energy principle for closed systems of all kinds.

The quantity denoted by Q in Equation 2.8 accounts for the amount of energy transferred to a closed system during a process by means other than work. On the basis of experiments it is known that such an energy transfer is induced only as a result of a temperature difference between the system and its surroundings and occurs only in the direction of decreasing temperature. This means of energy transfer is called an *energy transfer by heat.* The following sign convention applies:

$Q > 0$: heat transfer *to* the system

$Q < 0$: heat transfer *from* the system

The time rate of heat transfer, denoted by $\dot{Q}$, adheres to the same sign convention.

Methods based on experiment are available for evaluating energy transfer by heat. These methods recognize two basic transfer mechanisms: *conduction* and *thermal radiation.* In addition, theoretical and empirical relationships are available for evaluating energy transfer involving *combined* modes such as *convection.* Further discussion of heat transfer fundamentals is provided in Chapter 4.

The quantities symbolized by W and Q account for *transfers* of energy. The terms *work* and *heat* denote different *means* whereby energy is transferred and not *what* is transferred. Work and heat are not properties, and it is improper to speak of work or heat "contained" in a system. However, to achieve economy of expression in subsequent discussions, W and Q are often referred to simply as work and heat transfer, respectively. This less formal approach is commonly used in engineering practice.

Power Cycles

Since energy is a property, over each cycle there is no net change in energy. Thus, Equation 2.8 reads for *any* cycle

$$Q_{cycle} = W_{cycle}$$

That is, for *any* cycle the net amount of energy received through heat interactions is equal to the net energy transferred out in work interactions. A *power cycle,* or *heat* engine, is one for which a net amount of energy is transferred out by work: $W_{cycle} > 0$. This equals the net amount of energy transferred in by heat.

Power cycles are characterized both by addition of energy by heat transfer, Q_A, and inevitable rejections of energy by heat transfer, Q_R:

$$Q_{cycle} = Q_A - Q_R$$

Combining the last two equations,

$$W_{cycle} = Q_A - Q_R$$

The *thermal efficiency* of a heat engine is defined as the ratio of the net work developed to the total energy added by heat transfer:

$$\eta = \frac{W_{cycle}}{Q_A} = 1 - \frac{Q_R}{Q_A} \tag{2.9}$$

The thermal efficiency is strictly less than 100%. That is, some portion of the energy Q_A supplied is invariably rejected $Q_R \neq 0$.

The Second Law of Thermodynamics, Entropy

Many statements of the second law of thermodynamics have been proposed. Each of these can be called a statement of the second law *or* a corollary of the second law since, if one is invalid, all are invalid. In every instance where a consequence of the second law has been tested directly or indirectly by experiment it has been verified. Accordingly, the basis of the second law, like every other physical law, is experimental evidence.

Kelvin-Planck Statement

The Kelvin-Planck statement of the second law of thermodynamics refers to a *thermal reservoir.* A thermal reservoir is a system that remains at a constant temperature even though energy is added or removed by heat transfer. A reservoir is an idealization, of course, but such a system can be approximated in a number of ways — by the Earth's atmosphere, large bodies of water (lakes, oceans), and so on. Extensive properties of thermal reservoirs, such as internal energy, can change in interactions with other systems even though the reservoir temperature remains constant, however.

The Kelvin-Planck statement of the second law can be given as follows: *It is impossible for any system to operate in a thermodynamic cycle and deliver a net amount of energy by work to its surroundings while receiving energy by heat transfer from a single thermal reservoir.* In other words, a *perpetual-motion machine of the second kind* is impossible. Expressed analytically, the Kelvin-Planck statement is

$$W_{cycle} \leq 0 \qquad \text{(single reservoir)}$$

where the words *single reservoir* emphasize that the system communicates thermally only with a single reservoir as it executes the cycle. The "less than" sign applies when *internal irreversibilities* are present as the system of interest undergoes a cycle and the "equal to" sign applies only when no irreversibilities are present.

Irreversibilities

A process is said to be *reversible* if it is possible for its effects to be eradicated in the sense that there is some way by which *both* the system and its surroundings can be *exactly restored* to their respective initial states. A process is *irreversible* if there is no way to undo it. That is, there is no means by which the system and its surroundings can be exactly restored to their respective initial states. A system that has undergone an irreversible process is not necessarily precluded from being restored to its initial state. However, were the system restored to its initial state, it would not also be possible to return the surroundings to their initial state.

There are many effects whose presence during a process renders it irreversible. These include, but are not limited to, the following: heat transfer through a finite temperature difference; unrestrained expansion of a gas or liquid to a lower pressure; spontaneous chemical reaction; mixing of matter at different compositions or states; friction (sliding friction as well as friction in the flow of fluids); electric current flow through a resistance; magnetization or polarization with hysteresis; and inelastic deformation. The term *irreversibility* is used to identify effects such as these.

Irreversibilities can be divided into two classes, *internal* and *external.* Internal irreversibilities are those that occur within the system, while external irreversibilities are those that occur within the surroundings, normally the immediate surroundings. As this division depends on the location of the boundary there is some arbitrariness in the classification (by locating the boundary to take in the immediate surroundings, all irreversibilities are internal). Nonetheless, valuable insights can result when this distinction between irreversibilities is made. When internal irreversibilities are absent during a process, the process is said to be *internally reversible.* At every intermediate state of an internally reversible process of a closed system, all intensive properties are uniform throughout each phase present: the temperature, pressure, specific volume, and other intensive properties do not vary with position. The discussions to follow compare the actual and internally reversible process concepts for two cases of special interest.

For a gas as the system, the work of expansion arises from the force exerted by the system to move the boundary against the resistance offered by the surroundings:

$$W = \int_1^2 F dx = \int_1^2 pA dx$$

where the force is the product of the moving area and the pressure exerted by the system there. Noting that *Adx* is the change in total volume of the system,

$$W = \int_1^2 p dV$$

This expression for work applies to both actual and internally reversible expansion processes. However, for an internally reversible process *p* is not only the pressure at the moving boundary but also the pressure of the entire system. Furthermore, for an internally reversible process the volume equals *mv*, where the specific volume *v* has a single value throughout the system at a given instant. Accordingly, the work of an internally reversible expansion (or compression) process is

$$W = m\int_1^2 p dv \tag{2.10}$$

When such a process of a closed system is represented by a continuous curve on a plot of pressure vs. specific volume, the area *under* the curve is the magnitude of the work per unit of system mass (area a-b-c′-d′ of Figure 2.3, for example).

Although improved thermodynamic performance can accompany the reduction of irreversibilities, steps in this direction are normally constrained by a number of practical factors often related to costs. For example, consider two bodies able to communicate thermally. With a *finite* temperature difference between them, a spontaneous heat transfer would take place and, as noted previously, this would be a source of irreversibility. The importance of the heat transfer irreversibility diminishes as the temperature difference narrows; and as the temperature difference between the bodies vanishes, the heat transfer approaches *ideality.* From the study of heat transfer it is known, however, that the transfer of a finite amount of energy by heat between bodies whose temperatures differ only slightly requires a considerable amount of time, a large heat transfer surface area, or both. To approach *ideality,* therefore, a heat transfer would require an exceptionally long time and/or an exceptionally large area, each of which has cost implications constraining what can be achieved practically.

Carnot Corollaries

The two corollaries of the second law known as *Carnot* corollaries state: (1) the thermal efficiency of an irreversible power cycle is always less than the thermal efficiency of a reversible power cycle when each operates between the same two thermal reservoirs; (2) all reversible power cycles operating between the same two thermal reservoirs have the same thermal efficiency. A cycle is considered *reversible* when there are no irreversibilities within the system as it undergoes the cycle, and heat transfers between the system and reservoirs occur ideally (that is, with a vanishingly small temperature difference).

Kelvin Temperature Scale

Carnot corollary 2 suggests that the thermal efficiency of a reversible power cycle operating between two thermal reservoirs depends only on the temperatures of the reservoirs and not on the nature of the substance making up the system executing the cycle or the series of processes. With Equation 2.9 it can be concluded that the ratio of the heat transfers is also related only to the temperatures, and is independent of the substance and processes:

$$\left(\frac{Q_C}{Q_H}\right)_{\substack{rev\\cycle}} = \psi\left(T_C, T_H\right)$$

where Q_H *is* the energy transferred to the system by heat transfer from a *hot* reservoir at temperature T_H, and Q_C is the energy rejected from the system to a *cold* reservoir at temperature T_C. The words *rev cycle* emphasize that this expression applies only to systems undergoing reversible cycles while operating between the two reservoirs. Alternative temperature scales correspond to alternative specifications for the function ψ in this relation.

The *Kelvin temperature scale is* based on $\psi(T_C, T_H) = T_C/T_H$. Then

$$\left(\frac{Q_C}{Q_H}\right)_{\substack{rev\\cycle}} = \frac{T_C}{T_H} \tag{2.11}$$

This equation defines only a ratio of temperatures. The specification of the Kelvin scale is completed by assigning a numerical value to one standard reference state. The state selected is the same used to define the *gas scale:* at the triple point of water the temperature is specified to be 273.16 K. If a reversible cycle is operated between a reservoir at the reference-state temperature and another reservoir at an unknown temperature T, then the latter temperature is related to the value at the reference state by

$$T = 273.16\left(\frac{Q}{Q'}\right)_{\substack{rev\\cycle}}$$

where Q is the energy received by heat transfer from the reservoir at temperature T, and Q' is the energy rejected to the reservoir at the reference temperature. Accordingly, a temperature scale is defined that is valid over all ranges of temperature and that is independent of the thermometric substance.

Carnot Efficiency

For the special case of a reversible power cycle operating between thermal reservoirs at temperatures T_H and T_C on the Kelvin scale, combination of Equation 2.9 and Equation 2.11 results in

$$\eta_{\max} = 1 - \frac{T_C}{T_H} \tag{2.12}$$

called the *Carnot efficiency.* This is the efficiency of *all* reversible power cycles operating between thermal reservoirs at T_H and T_C. Moreover, it is the *maximum theoretical* efficiency that any power cycle, real or ideal, could have while operating between the same two reservoirs. As temperatures on the Rankine scale differ from Kelvin temperatures only by the factor 1.8, the above equation may be applied with either scale of temperature.

The Clausius Inequality

The Clausius inequality provides the basis for introducing two ideas instrumental for quantitative evaluations of processes of systems from a second law perspective: *entropy* and *entropy generation.* The Clausius inequality states that

$$\oint\left(\frac{\delta Q}{T}\right)_b \le 0 \tag{2.13a}$$

where δQ represents the heat transfer at a part of the system boundary during a portion of the cycle, and T is the absolute temperature at that part of the boundary. The symbol δ is used to distinguish the differentials of *nonproperties,* such as heat and work, from the differentials of properties, written with the symbol *d*. The subscript *b* indicates that the integrand is evaluated at the boundary of the system executing the cycle. The symbol $\oint$ indicates that the integral is to be performed over all parts of the boundary and over the entire cycle. The Clausius inequality can be demonstrated using the Kelvin-Planck statement of the second law, and the significance of the inequality is the same: the equality applies when there are no internal irreversibilities as the system executes the cycle, and the inequality applies when internal irreversibilities are present.

The Clausius inequality can be expressed alternatively as

$$\oint \left(\frac{\delta Q}{T} \right)_b = -S_{gen} \tag{2.13b}$$

where S_{gen} can be viewed as representing the *strength* of the inequality. The value of S_{gen} is positive when internal irreversibilities are present, zero when no internal irreversibilities are present, and can never be negative. Accordingly, S_{gen} is a measure of the irreversibilities present within the system executing the cycle. In the next section, S_{gen} is identified as the *entropy* generated (or *produced*) by internal irreversibilities during the cycle.

Entropy and Entropy Generation

Entropy

Consider two cycles executed by a closed system. One cycle consists of an internally reversible process A from state 1 to state 2, followed by an internally reversible process C from state 2 to state 1. The other cycle consists of an internally reversible process B from state 1 to state 2, followed by the same process C from state 2 to state 1 as in the first cycle. For these cycles, Equation 2.13b takes the form

$$\left(\int_1^2 \frac{\delta Q}{T} \right)_A + \left(\int_2^1 \frac{\delta Q}{T} \right)_C = -S_{gen} = 0$$

$$\left(\int_1^2 \frac{\delta Q}{T} \right)_B + \left(\int_2^1 \frac{\delta Q}{T} \right)_C = -S_{gen} = 0$$

where S_{gen} has been set to zero since the cycles are composed of internally reversible processes. Subtracting these equations leaves

$$\left(\int_1^2 \frac{\delta Q}{T} \right)_A = \left(\int_1^2 \frac{\delta Q}{T} \right)_B$$

Since A and B are arbitrary, it follows that the integral of $\delta Q/T$ has the same value for *any* internally reversible process between the two states: the value of the integral depends on the end states only. It can be concluded, therefore, that the integral defines the change in some property of the system. Selecting the symbol *S* to denote this property, its change is given by

$$S_2 - S_1 = \left(\int_1^2 \frac{\delta Q}{T} \right)_{\substack{int \\ rev}} \tag{2.14a}$$

where the subscript *int rev* indicates that the integration is carried out for any internally reversible process linking the two states. This extensive property is called *entropy.*

Since entropy is a property, the change in entropy of a system in going from one state to another is the same for *all* processes, both internally reversible and irreversible, between these two states. In other words, once the change in entropy between two states has been evaluated, this is the magnitude of the entropy change for *any* process of the system between these end states.

The definition of entropy change expressed on a differential basis is

$$dS = \left(\frac{\delta Q}{T}\right)_{\substack{int \\ rev}} \tag{2.14b}$$

Equation 2.14b indicates that when a closed system undergoing an internally reversible process *receives* energy by heat transfer, the system experiences an *increase* in entropy. Conversely, when energy is *removed* from the system by heat transfer, the entropy of the system *decreases.* This can be interpreted to mean that an entropy transfer is *associated* with (or accompanies) heat transfer. The direction of the entropy transfer is the same as that of the heat transfer. In an *adiabatic* internally reversible process of a closed system the entropy would remain constant. A constant entropy process is called an *isentropic* process.

On rearrangement, Equation 2.14b becomes

$$(\delta Q)_{\substack{int \\ rev}} = TdS$$

Then, for an internally reversible process of a closed system between state 1 and state 2,

$$Q_{\substack{int \\ rev}} = m\int_1^2 Tds \tag{2.15}$$

When such a process is represented by a continuous curve on a plot of temperature vs. specific entropy, the area *under* the curve is the magnitude of the heat transfer per unit of system mass.

Entropy Balance

For a cycle consisting of an actual process from state 1 to state 2, during which internal irreversibilities are present, followed by an internally reversible process from state 2 to state 1, Equation 2.13b takes the form

$$\int_1^2 \left(\frac{\delta Q}{T}\right)_b + \int_2^1 \left(\frac{\delta Q}{T}\right)_{\substack{int \\ rev}} = -S_{gen}$$

where the first integral is for the actual process and the second integral is for the internally reversible process. Since no irreversibilities are associated with the internally reversible process, the term S_{gen} accounting for the effect of irreversibilities during the cycle can be identified with the actual process only.

Applying the definition of entropy change, the second integral of the foregoing equation can be expressed as

$$S_1 - S_2 = \int_2^1 \left(\frac{\delta Q}{T}\right)_{\substack{int \\ rev}}$$

Introducing this and rearranging the equation, the *closed system entropy balance* results:

$$\underbrace{S_2 - S_1}_{\substack{\text{entropy} \\ \text{change}}} = \underbrace{\int_1^2 \left(\frac{\delta Q}{T}\right)_b}_{\substack{\text{entropy} \\ \text{transfer}}} + \underbrace{S_{gen}}_{\substack{\text{entropy} \\ \text{generation}}} \tag{2.16}$$

When the end states are fixed, the entropy change on the left side of Equation 2.16 can be evaluated independently of the details of the process from state 1 to state 2. However, the two terms on the right side depend explicitly on the nature of the process and cannot be determined solely from knowledge of the end states. The first term on the right side is associated with heat transfer to or from the system during the process. This term can be interpreted as the *entropy transfer associated with (or accompanying) heat transfer.* The direction of entropy transfer is the same as the direction of the heat transfer, and the same sign convention applies as for heat transfer: a positive value means that entropy is transferred into the system, and a negative value means that entropy is transferred out.

The entropy change of a system is not accounted for solely by entropy transfer, but is also due to the second term on the right side of Equation 2.16 denoted by S_{gen}. The term S_{gen} is positive when internal irreversibilities are present during the process and vanishes when internal irreversibilities are absent. This can be described by saying that entropy is *generated* (or produced) within the system by the action of irreversibilities. The second law of thermodynamics can be interpreted as specifying that entropy is generated by irreversibilities and conserved only in the limit as irreversibilities are reduced to zero. Since S_{gen} measures the effect of irreversibilities present within a system during a process, its value depends on the nature of the process and not solely on the end states. Entropy generation is *not* a property.

When applying the entropy balance, the objective is often to evaluate the entropy generation term. However, the value of the entropy generation for a given process of a system usually does not have much significance by itself. The significance is normally determined through comparison. For example, the entropy generation within a given component might be compared to the entropy generation values of the other components included in an overall system formed by these components. By comparing entropy generation values, the components where appreciable irreversibilities occur can be identified and rank ordered. This allows attention to be focused on the components that contribute most heavily to inefficient operation of the overall system.

To evaluate the entropy transfer term of the entropy balance requires information regarding both the heat transfer and the temperature on the boundary where the heat transfer occurs. The entropy transfer term is not always subject to direct evaluation, however, because the required information is either unknown or undefined, such as when the system passes through states sufficiently far from equilibrium. In practical applications, it is often convenient, therefore, to enlarge the system to include enough of the immediate surroundings that the temperature on the boundary of the *enlarged system* corresponds to the ambient temperature, T_{amb}. The entropy transfer term is then simply Q/T_{amb}. However, as the irreversibilities present would not be just those for the system of interest but those for the enlarged system, the entropy generation term would account for the effects of internal irreversibilities within the system *and* external irreversibilities present within that portion of the surroundings included within the enlarged system.

A form of the entropy balance convenient for particular analyses is the *rate form:*

$$\frac{dS}{dt} = \sum_j \frac{\dot{Q}_j}{T_j} + \dot{S}_{gen} \tag{2.17}$$

where *dS/dt* is the time rate of change of entropy of the system. The term $\dot{Q}_j / T_j$ represents the time rate of entropy transfer through the portion of the boundary whose instantaneous temperature is T_j. The term $\dot{S}_{gen}$ accounts for the time rate of entropy generation due to irreversibilities within the system.

For a system *isolated* from its surroundings, the entropy balance is

$$\left(S_2 - S_1\right)_{isol} = S_{gen} \tag{2.18}$$

where S_{gen} is the total amount of entropy generated within the isolated system. Since entropy is generated in all actual processes, the only processes of an isolated system that actually can occur are those for which the entropy of the isolated system increases. This is known as the *increase of entropy principle.*

2.2 Control Volume Applications

Since most applications of engineering thermodynamics are conducted on a control volume basis, the control volume formulations of the mass, energy, and entropy balances presented in this section are especially important. These are given here in the form of *overall* balances. Equations of change for mass, energy, and entropy in the form of differential equations are also available in the literature (see, e.g., Bird et al., 1960).

Conservation of Mass

When applied to a control volume, the principle of mass conservation states: *The time rate of accumulation of mass within the control volume equals the difference between the total rates of mass flow in and out across the boundary.* An important case for engineering practice is one for which inward and outward flows occur, each through one or more ports. For this case the conservation of mass principle takes the form

$$\frac{dm_{cv}}{dt} = \sum_i \dot{m}_i - \sum_e \dot{m}_e \tag{2.19}$$

The left side of this equation represents the time rate of change of mass contained within the control volume, $\dot{m}_i$ denotes the mass flow rate at an inlet, and $\dot{m}_e$ is the mass flow rate at an outlet.

The *volumetric flow rate* through a portion of the control surface with area dA is the product of the velocity component normal to the area, $\mathrm{v_n}$, times the area: $\mathrm{v_n}\, dA$. The *mass* flow rate through dA is $\rho(\mathrm{v_n}\, dA)$. The mass rate of flow through a port of area A is then found by integration over the area

$$\dot{m} = \int_A \rho \mathrm{v_n}\, dA$$

For *one-dimensional* flow the intensive properties are uniform with position over area A, and the last equation becomes

$$\dot{m} = \rho \mathrm{v} A = \frac{\mathrm{v}A}{v} \tag{2.20}$$

where v denotes the specific volume and the subscript n has been dropped from velocity for simplicity.

Control Volume Energy Balance

When applied to a control volume, the principle of energy conservation states: *The time rate of accumulation of energy within the control volume equals the difference between the total incoming rate of energy transfer and the total outgoing rate of energy transfer.* Energy can enter and exit a control volume by work and heat transfer. Energy also enters and exits with flowing streams of matter. Accordingly, for a control volume with one-dimensional flow at a single inlet and a single outlet,

$$\frac{d(U + KE + PE)_{cv}}{dt} = \dot{Q}_{cv} - \dot{W} + \dot{m}\underline{\left(u_i + \frac{\mathrm{v}_i^2}{2} + \mathrm{g}z_i\right)} - \dot{m}\underline{\left(u_e + \frac{\mathrm{v}_e^2}{2} + \mathrm{g}z_e\right)} \tag{2.21}$$

where the underlined terms account for the specific energy of the incoming and outgoing streams. The terms $\dot{Q}_{cv}$ and $\dot{W}$ account, respectively, for the net rates of energy transfer by heat and work over the boundary (control surface) of the control volume.

Because work is always done on or by a control volume where matter flows across the boundary, the quantity $\dot{W}$ of Equation 2.21 can be expressed in terms of two contributions: one is the work associated with the force of the fluid pressure as mass is introduced at the inlet and removed at the exit. The other, denoted as $\dot{W}_{cv}$, includes *all other* work effects, such as those associated with rotating shafts, displacement of the boundary, and electrical effects. The work rate concept of mechanics allows the first of these contributions to be evaluated in terms of the product of the pressure force, *pA*, and velocity at the point of application of the force. To summarize, the work term $\dot{W}$ of Equation 2.21 can be expressed (with Equation 2.20) as

$$\begin{aligned} \dot{W} &= \dot{W}_{cv} + (p_e A_e)\mathrm{v}_e - (p_i A_i)\mathrm{v}_i \\ &= \dot{W}_{cv} + \dot{m}_e(p_e v_e) - \dot{m}_i(p_i v_i) \end{aligned} \tag{2.22}$$

The terms $\dot{m}_i$ (pv_i) and $\dot{m}_e$ $(p_e v_e)$ account for the work associated with the pressure at the inlet and outlet, respectively, and are commonly referred to as *flow work.*

Substituting Equation 2.22 into Equation 2.21, and introducing the specific enthalpy *h*, the following form of the control volume energy rate balance results:

$$\frac{d(U + KE + PE)_{cv}}{dt} = \dot{Q}_{cv} - \dot{W}_{cv} + \dot{m}_i\left(h_i + \frac{\mathrm{v}_i^2}{2} + \mathrm{g}z_i\right) - \dot{m}_e\left(h_e + \frac{\mathrm{v}_e^2}{2} + \mathrm{g}z_e\right) \tag{2.23}$$

To allow for applications where there may be several locations on the boundary through which mass enters or exits, the following expression is appropriate:

$$\frac{d(U + KE + PE)_{cv}}{dt} = \dot{Q}_{cv} - \dot{W}_{cv} + \sum_i \dot{m}_i\left(h_i + \frac{\mathrm{v}_i^2}{2} + \mathrm{g}z_i\right) - \sum_e \dot{m}_e\left(h_e + \frac{\mathrm{v}_e^2}{2} + \mathrm{g}z_e\right) \tag{2.24}$$

Equation 2.24 is an *accounting* rate balance for the energy of the control volume. It states that the time rate of accumulation of energy within the control volume equals the difference between the total rates of energy transfer in and out across the boundary. The mechanisms of energy transfer are heat and work, as for closed systems, and the energy accompanying the entering and exiting mass.

Control Volume Entropy Balance

Like mass and energy, entropy is an extensive property. And like mass and energy, entropy can be transferred into or out of a control volume by streams of matter. As this is the principal difference between the closed system and control volume forms, the control volume entropy rate balance is obtained by modifying Equation 2.17 to account for these entropy transfers. The result is

$$\underbrace{\frac{dS_{cv}}{dt}}_{\substack{\text{rate of}\\\text{entropy}\\\text{change}}} = \underbrace{\sum_j \frac{\dot{Q}_j}{T_j} + \sum_i \dot{m}_i s_i - \sum_e \dot{m}_e s_e}_{\substack{\text{rate of}\\\text{entropy}\\\text{transfer}}} + \underbrace{\dot{S}_{gen}}_{\substack{\text{rate of}\\\text{entropy}\\\text{generation}}} \tag{2.25}$$

where dS_{cv}/dt represents the time rate of change of entropy within the control volume. The terms $\dot{m}_i s_i$ and $\dot{m}_e s_e$ account, respectively, for rates of entropy *transfer* into and out of the control volume associated with mass flow. One-dimensional flow is assumed at locations where mass enters and exits. $\dot{Q}_j$ represents the time rate of heat transfer at the location on the boundary where the instantaneous temperature is T_j; and $\dot{Q}_j / T_j$ accounts for the associated rate of entropy *transfer.* $\dot{S}_{gen}$ denotes the time rate of entropy *generation* due to irreversibilities *within* the control volume. When a control volume comprises a number of components, $\dot{S}_{gen}$ is the sum of the rates of entropy generation of the components.

Control Volumes at Steady State

Engineering systems are often idealized as being at *steady state,* meaning that all properties are unchanging in time. For a control volume at steady state, the identity of the matter within the control volume change continuously, but the total amount of mass remains constant. At steady state, Equation 2.19 reduces to

$$\sum_i \dot{m}_i = \sum_e \dot{m}_e \tag{2.26a}$$

The energy rate balance of Equation 2.24 becomes, at steady state,

$$0 = \dot{Q}_{cv} - \dot{W}_{cv} + \sum_i \dot{m}_i \left(h_i + \frac{\mathrm{v}_i^2}{2} + \mathrm{g}\mathrm{z}_i \right) - \sum_e \dot{m}_e \left(h_e + \frac{\mathrm{v}_e^2}{2} + \mathrm{g}\mathrm{z}_e \right) \tag{2.26b}$$

At steady state, the entropy rate balance of Equation 2.25 reads

$$0 = \sum_j \frac{\dot{Q}_j}{T_j} + \sum_i \dot{m}_i s_i - \sum_e \dot{m}_e s_e + \dot{S}_{gen} \tag{2.26c}$$

Mass and energy are conserved quantities, but entropy is not generally conserved. Equation 2.26a indicates that the total rate of mass flow into the control volume equals the total rate of mass flow out of the control volume. Similarly, Equation 2.26b states that the total rate of energy transfer into the control volume equals the total rate of energy transfer out of the control volume. However, Equation 2.26c shows that the rate at which entropy is transferred out *exceeds* the rate at which entropy enters, the difference being the rate of entropy generation within the control volume owing to irreversibilities.

Applications frequently involve control volumes having a single inlet and a single outlet, as, for example, the control volume of Figure 2.1 where heat transfer (if any) occurs at T_b: the temperature, or a suitable average temperature, on the boundary where heat transfer occurs. For this case the mass rate balance, Equation 2.26a, reduces to $\dot{m}_i = \dot{m}_e$. Denoting the common mass flow rate by $\dot{m}$, Equation 2.26b and Equation 2.26c read, respectively,

$$0 = \dot{Q}_{cv} - \dot{W}_{cv} + \dot{m} \left[\left(h_i - h_e \right) + \left(\frac{\mathrm{v}_i^2 - \mathrm{v}_e^2}{2} \right) + \mathrm{g} \left(\mathrm{z}_i - \mathrm{z}_e \right) \right] \tag{2.27a}$$

$$0 = \frac{\dot{Q}_{cv}}{T_b} + \dot{m} \left(s_i - s_e \right) + \dot{S}_{gen} \tag{2.28a}$$

When Equation 2.27a and Equation 2.28a are applied to particular cases of interest, additional simplifications are usually made. The heat transfer term $\dot{Q}_{cv}$ is dropped when it is insignificant relative to other energy transfers across the boundary. This may be the result of one or more of the following: (1) the outer surface of the control volume is insulated; (2) the outer surface area is too small for there to be effective heat transfer; (3) the temperature difference between the control volume and its surroundings is small enough that the heat transfer can be ignored; (4) the gas or liquid passes through the control volume so quickly that there is not enough time for significant heat transfer to occur. The work term

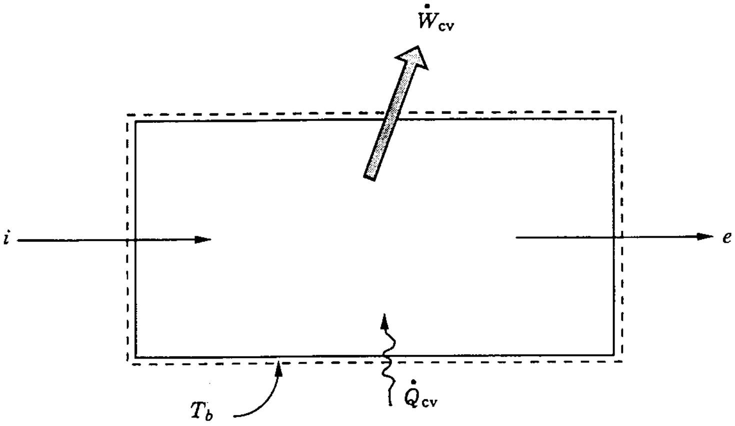

FIGURE 2.1 One-inlet, one-outlet control volume at steady state.

$\dot{W}_{cv}$ drops out of the energy rate balance when there are no rotating shafts, displacements of the boundary, electrical effects, or other work mechanisms associated with the control volume being considered. The changes in kinetic and potential energy of Equation 2.27a are frequently negligible relative to other terms in the equation.

The special forms of Equation 2.27a and Equation 2.28a listed in Table 2.1 are obtained as follows: when there is no heat transfer, Equation 2.28a gives

$$s_e - s_i = \frac{\dot{S}_{gen}}{\dot{m}} \geq 0 \tag{2.28b}$$

(no heat transfer)

Accordingly, when irreversibilities are present within the control volume, the specific entropy increases as mass flows from inlet to outlet. In the ideal case in which no internal irreversibilities are present, mass passes through the control volume with no change in its entropy — that is, *isentropically.*

For no heat transfer, Equation 2.27a gives

$$\dot{W}_{cv} = \dot{m}\left[\left(h_i - h_e\right) + \left(\frac{\mathrm{v}_i^2 - \mathrm{v}_e^2}{2}\right) + \mathrm{g}\left(\mathrm{z}_i - \mathrm{z}_e\right)\right] \tag{2.27b}$$

A special form that is applicable, at least approximately, to *compressors*, *pumps*, and *turbines* results from dropping the kinetic and potential energy terms of Equation 2.27b, leaving

$$\dot{W}_{cv} = \dot{m}\left(h_i - h_e\right) \tag{2.27c}$$

(*compressors*, *pumps*, and *turbines*)

In *throttling devices* a significant reduction in pressure is achieved simply by introducing a restriction into a line through which a gas or liquid flows. For such devices $\dot{W}_{cv} = 0$ and Equation 2.27c reduces further to read

TABLE 2.1 Energy and Entropy Balances for One-Inlet, One-Outlet Control Volumes at Steady State and No Heat Transfer

---

Energy balance

$$\dot{W}_{cv} = \dot{m}\left[\left(h_i - h_e\right) + \left(\frac{\mathrm{v}_i^2 - \mathrm{v}_e^2}{2}\right) + g\left(z_i - z_e\right)\right] \qquad (2.27b)$$

Compressors, pumps, and turbines[a]

$$\dot{W}_{cv} = \dot{m}\left(h_i - h_e\right) \qquad (2.27c)$$

Throttling

$$h_e \cong h_i \qquad (2.27d)$$

Nozzles, diffusers[b]

$$\mathrm{v}_e = \sqrt{\mathrm{v}_i^2 + 2\left(h_i - h_e\right)} \qquad (2.27f)$$

Entropy balance

$$s_e - s_i = \frac{\dot{S}_{gen}}{\dot{m}} \geq 0 \qquad (2.28b)$$

---

[a] For an ideal gas with constant c_p, Equation 1′ of Table 2.7 allows Equation 2.27c to be written as

$$\dot{W}_{cv} = \dot{m}c_p\left(T_i - T_e\right) \qquad (2.27c')$$

The power developed in an *isentropic process* is obtained with Equation 5′ of Table 2.7 as

$$\dot{W}_{cv} = \dot{m}c_p T_i\left[1 - \left(p_e/p_i\right)^{(k-1)/k}\right] \quad (s = c) \qquad (2.27c'')$$

where $c_p = kR/(k - 1)$.

[b] For an ideal gas with constant c_p, Equation 1′ of Table 2.7 allows Equation 2.27f to be written as

$$\mathrm{v}_e = \sqrt{\mathrm{v}_i^2 + 2c_p\left(T_i - T_e\right)} \qquad (2.27f')$$

The exit velocity for an *isentropic process* is obtained with Equation 5′ of Table 2.7 as

$$\mathrm{v}_e = \sqrt{\mathrm{v}_i^2 + 2c_p T_i\left[1 - \left(p_e/p_i\right)^{(k-1)/k}\right]} \quad (s = c) \qquad (2.27f'')$$

where $c_p = kR/(k - 1)$.

$$h_e \cong h_i \quad (\textit{throttling process}) \qquad (2.27d)$$

That is, upstream and downstream of the throttling device, the specific enthalpies are equal.

A *nozzle* is a flow passage of varying cross-sectional area in which the velocity of a gas or liquid increases in the direction of flow. In a *diffuser,* the gas or liquid decelerates in the direction of flow. For such devices, $\dot{W}_{cv} = 0$. The heat transfer and potential energy change are also generally negligible. Then Equation 2.27b reduces to

$$0 = h_i - h_e + \frac{\mathrm{v}_i^2 - \mathrm{v}_e^2}{2} \qquad (2.27e)$$

Solving for the outlet velocity

$$\mathrm{v}_e = \sqrt{\mathrm{v}_i^2 + 2(h_i - h_e)} \tag{2.27f}$$
$$(\textit{nozzle, diffuser})$$

Further discussion of the flow-through nozzles and diffusers is provided in Chapter 3.

The mass, energy, and entropy rate balances, Equations 2.26, can be applied to control volumes with multiple inlets and/or outlets, as, for example, cases involving heat-recovery steam generators, feedwater heaters, and counterflow and crossflow heat exchangers. Transient (or unsteady) analyses can be conducted with Equation 2.19, Equation 2.24, and Equation 2.25. Illustrations of all such applications are provided by Moran and Shapiro (1995).

Example 1

A turbine receives steam at 7 MPa, 440°C and exhausts at 0.2 MPa for subsequent process heating duty. If heat transfer and kinetic/potential energy effects are negligible, determine the steam mass flow rate, in kg/hr, for a turbine power output of 30 MW when (a) the steam quality at the turbine outlet is 95%, (b) the turbine expansion is internally reversible.

Solution. With the indicated idealizations, Equation 2.27c is appropriate. Solving, $\dot{m} = \dot{W}_{cv}/(h_i - h_e)$. Steam table data (Table A.5) at the inlet condition are h_i = 3261.7 kJ/kg, s_i = 6.6022 kJ/kg · K.

(a) At 0.2 MPa and $x = 0.95$, h_e = 2596.5 kJ/kg. Then

$$\dot{m} = \frac{30\ \text{MW}}{(3261.7 - 2596.5)\ \text{kJ/kg}}\left(\frac{10^3\ \text{kJ/sec}}{1\ \text{MW}}\right)\left(\frac{3600\ \text{sec}}{1\ \text{hr}}\right)$$
$$= 162{,}357\ \text{kg/hr}$$

(b) For an internally reversible expansion, Equation 2.28b reduces to give $s_e = s_i$. For this case, h_e = 2499.6 kJ/kg ($x = 0.906$), and $\dot{m}$ = 141,714 kg/hr.

Example 2

Air at 500°F, 150 lbf/in.^{2}, and 10 ft/sec expands adiabatically through a nozzle and exits at 60°F, 15 lbf/in.^{2}. For a mass flow rate of 5 lb/sec determine the exit area, in in.^{2}. Repeat for an isentropic expansion to 15 lbf/in.^{2}. Model the air as an ideal gas (Section 2.3, Ideal Gas Model) with specific heat c_p = 0.24 Btu/lb · °R ($k = 1.4$).

Solution. The nozle exit area can be evaluated using Equation 2.20, together with the ideal gas equation, v = RT/p:

$$A_e = \frac{\dot{m}v_e}{\mathrm{V}_e} = \frac{\dot{m}(RT_e/p_e)}{\mathrm{V}_e}$$

The exit velocity required by this expression is obtained using Equation 2.27f′ of Table 2.1,

$$\mathrm{v}_e = \sqrt{\mathrm{v}_i^2 + 2c_p(T_i - T_e)}$$
$$= \sqrt{\left(\frac{10\ \text{ft}}{s}\right)^2 + 2\left(0.24\frac{\text{Btu}}{\text{lb}\cdot\text{R}}\right)\left(\frac{778.17\ \text{ft}\cdot\text{lbf}}{1\ \text{Btu}}\right)(440°\text{R})\left(\frac{32.174\ \text{lb}\cdot\text{ft/sec}^2}{1\ \text{lbf}}\right)}$$
$$= 2299.5\ \text{ft sec}$$

Finally, with $R = \bar{R}/\mathcal{M}$ = 53.33 ft · lbf/lb · °R,

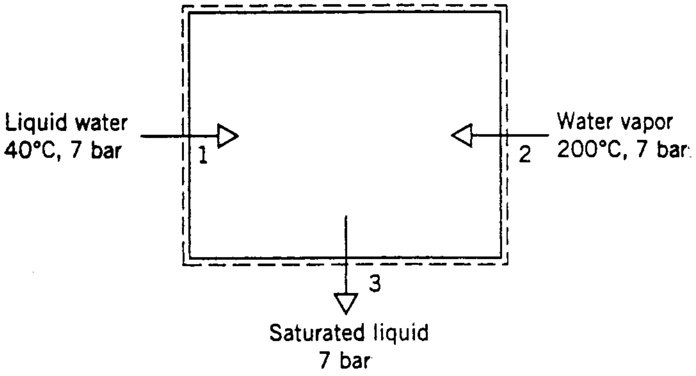

FIGURE 2.2 Open feedwater heater.

$$A_e = \frac{\left(5\frac{\text{lb}}{\text{sec}}\right)\left(53.3\frac{\text{ft}\cdot\text{lbf}}{\text{lb}\cdot{}^\circ\text{R}}\right)(520^\circ\text{R})}{\left(2299.5\frac{\text{ft}}{\text{sec}}\right)\left(15\frac{\text{lbf}}{\text{in.}^2}\right)} = 4.02 \text{ in.}^2$$

Using Equation 2.27f″ in Table 2.1 for the isentropic expansion,

$$\text{v}_e = \sqrt{(10)^2 + 2(0.24)(778.17)(960)(32.174)\left[1 - \left(\frac{15}{150}\right)^{0.4/1.4}\right]}$$

$$= 2358.3 \text{ ft/sec}$$

Then $A_e = 3.92$ in.^{2}.

Example 3

Figure 2.2 provides steady-state operating data for an open feedwater heater. Ignoring heat transfer and kinetic/potential energy effects, determine the ratio of mass flow rates, $\dot{m}_1/\dot{m}_2$.

Solution. For this case Equation 2.26a and Equation 2.26b reduce to read, respectively,

$$\dot{m}_1 + \dot{m}_2 = \dot{m}_3$$

$$0 = \dot{m}_1 h_1 + \dot{m}_2 h_2 - \dot{m}_3 h_3$$

Combining and solving for the ratio $\dot{m}_1/\dot{m}_2$,

$$\frac{\dot{m}_1}{\dot{m}_2} = \frac{h_2 - h_3}{h_3 - h_1}$$

Inserting steam table data, in kJ/kg, from Table A.5,

$$\frac{\dot{m}_1}{\dot{m}_2} = \frac{2844.8 - 697.2}{697.2 - 167.6} = 4.06$$

Internally Reversible Heat Transfer and Work

For one-inlet, one-outlet control volumes at steady state, the following expressions give the heat transfer rate and power in the absence of internal irreversibilities:

$$\left(\frac{\dot{Q}_{cv}}{\dot{m}}\right)_{\substack{int\\rev}} = \int_1^2 Tds \tag{2.29}$$

$$\left(\frac{\dot{W}_{cv}}{\dot{m}}\right)_{\substack{int\\rev}} = -\int_1^2 vdp + \frac{V_1^2 - V_2^2}{2} + g(z_1 - z_2) \tag{2.30a}$$

(see, e.g., Moran and Shapiro, 1995).

If there is no significant change in kinetic or potential energy from inlet to outlet, Equation 2.30a reads

$$\left(\frac{\dot{W}_{cv}}{\dot{m}}\right)_{\substack{int\\rev}} = -\int_1^2 vdp \qquad (\Delta ke = \Delta pe = 0) \tag{2.30b}$$

The specific volume remains approximately constant in many applications with liquids. Then Equation 30b becomes

$$\left(\frac{\dot{W}_{cv}}{\dot{m}}\right)_{\substack{int\\rev}} = -v(p_2 - p_1) \qquad (v = \text{constant}) \tag{2.30c}$$

When the states visited by a unit of mass flowing without irreversibilities from inlet to outlet are described by a continuous curve on a plot of temperature vs. specific entropy, Equation 2.29 implies that the area under the curve is the magnitude of the heat transfer per unit of mass flowing. When such an ideal process is described by a curve on a plot of pressure vs. specific volume, as shown in Figure 2.3, the magnitude of the integral $\int vdp$ of Equation 2.30a and Equation 2.30b is represented by the area a-b-c-d *behind* the curve. The area a-b-c′-d′ *under* the curve is identified with the magnitude of the integral $\int pdv$ of Equation 2.10.

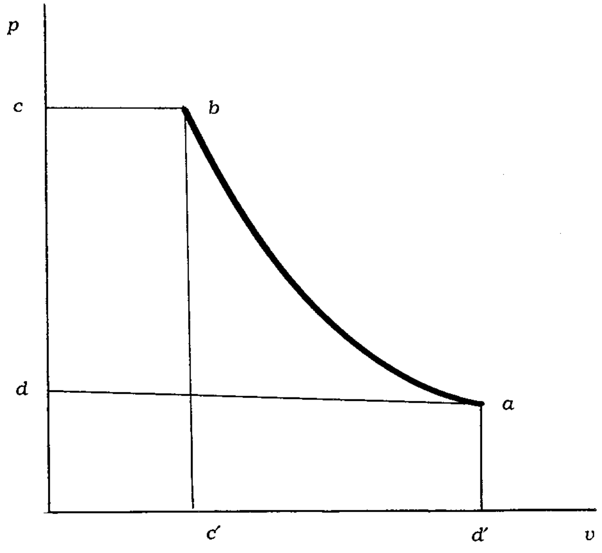

FIGURE 2.3 Internally reversible process on *p–v* coordinates.

2.3 Property Relations and Data

Pressure, temperature, volume, and mass can be found experimentally. The relationships between the specific heats c_v and c_p and temperature at relatively low pressure are also accessible experimentally, as are certain other property data. Specific internal energy, enthalpy, and entropy are among those properties that are not so readily obtained in the laboratory. Values for such properties are calculated using experimental data of properties that are more amenable to measurement, together with appropriate property relations derived using the principles of thermodynamics. In this section property relations and data sources are considered for *simple compressible systems*, which include a wide range of industrially important substances.

Property data are provided in the publications of the *National Institute of Standards and Technology* (formerly the U.S. Bureau of Standards), of professional groups such as the *American Society of Mechanical Engineering (ASME),* the *American Society of Heating. Refrigerating, and Air Conditioning Engineers (ASHRAE)*, and the *American Chemical Society,* and of corporate entities such as *Dupont* and *Dow Chemical.* Handbooks and property reference volumes such as included in the list of references for this chapter are readily accessed sources of data. Property data are also retrievable from various commercial online data bases. Computer software is increasingly available for this purpose as well.

Basic Relations for Pure Substances

An energy balance in differential form for a closed system undergoing an internally reversible process in the absence of overall system motion and the effect of gravity reads

$$dU = (\delta Q)_{\substack{int\\rev}} - (\delta W)_{\substack{int\\rev}}$$

From Equation 2.14b, $(\delta Q)_{\substack{int\\rev}} = TdS$. When consideration is limited to *simple compressible systems:* systems for which the only significant work in an internally reversible process is associated with volume change, $(\delta W)_{\substack{int\\rev}} = pdV$, the following equation is obtained:

$$dU = TdS - pdV \tag{2.31a}$$

Introducing enthalpy, $H = U + pV$, the Helmholtz function, $\Psi = U - TS$, and the Gibbs function, $G = H - TS$, three additional expressions are obtained:

$$dH = TdS + Vdp \tag{2.31b}$$

$$d\Psi = -pdV - SdT \tag{2.31c}$$

$$dG = Vdp - SdT \tag{2.31d}$$

Equations 2.31 can be expressed on a per-unit-mass basis as

$$du = Tds - pdv \tag{2.32a}$$

$$dh = Tds + vdp \tag{2.32b}$$

$$d\psi = -pdv - sdT \tag{2.32c}$$

$$dg = vdp - sdT \tag{2.32d}$$

Similar expressions can be written on a per-mole basis.

TABLE 2.2 Relations from Exact Differentials

Function	*Differential*	*Coefficients*	*Maxwell*
General:			
$z = z(x, y)$	$dz = M(x,y)dx + N(x,y)dy$	$\left(\frac{\partial z}{\partial x}\right)_y = M$	$\left(\frac{\partial M}{\partial y}\right)_x = \left(\frac{\partial N}{\partial x}\right)_y$
		$\left(\frac{\partial z}{\partial y}\right)_x = N$	
Internal energy:			
$u(s, v)$	$du = Tds - pdv$	$\left(\frac{\partial u}{\partial s}\right)_v = T$	$\left(\frac{\partial T}{\partial v}\right)_s = -\left(\frac{\partial p}{\partial s}\right)_v$
		$\left(\frac{\partial u}{\partial v}\right)_s = -p$	
Enthalpy:			
$h(s, p)$	$dh = Tds + vdp$	$\left(\frac{\partial h}{\partial s}\right)_p = T$	$\left(\frac{\partial T}{\partial p}\right)_s = \left(\frac{\partial v}{\partial s}\right)_p$
		$\left(\frac{\partial h}{\partial p}\right)_s = v$	
Helmholtz function:			
$\psi(v, T)$	$d\psi = -pdv - sdT$	$\left(\frac{\partial \psi}{\partial v}\right)_T = -p$	$\left(\frac{\partial p}{\partial T}\right)_v = \left(\frac{\partial s}{\partial v}\right)_T$
		$\left(\frac{\partial \psi}{\partial T}\right)_v = -s$	
Gibbs function:			
$g(T, p)$	$dg = vdp - sdT$	$\left(\frac{\partial g}{\partial p}\right)_T = v$	$\left(\frac{\partial v}{\partial T}\right)_p = -\left(\frac{\partial s}{\partial p}\right)_T$
		$\left(\frac{\partial g}{\partial T}\right)_p = -s$	

Maxwell Relations

Since only properties are involved, each of the four differential expressions given by Equations 2.32 is an *exact* differential exhibiting the general form $dz = M(x, y)dx + N(x, y)dy$, where the second mixed partial derivatives are equal: $(\partial M/\partial y) = (\partial N/\partial x)$. Underlying these exact differentials are, respectively, functions of the form $u(s, v)$, $h(s, p)$, $\psi(v, T)$, and $g(T, p)$. From such considerations the *Maxwell relations* given in Table 2.2 can be established.

Example 4

Derive the Maxwell relation following from Equation 2.32a.

Solution. The differential of the function $u = u(s, v)$ is

$$du = \left(\frac{\partial u}{\partial s}\right)_v ds + \left(\frac{\partial u}{\partial v}\right)_s dv$$

By comparison with Equation 2.32a,

$$T = \left(\frac{\partial u}{\partial s}\right)_v, \quad -p = \left(\frac{\partial u}{\partial v}\right)_s$$

In Equation 2.32a, T plays the role of M and $-p$ plays the role of N, so the equality of second mixed partial derivatives gives the Maxwell relation,

$$\left(\frac{\partial T}{\partial v}\right)_s = -\left(\frac{\partial p}{\partial s}\right)_v$$

Since each of the properties T, p, v, and s appears on the right side of two of the eight coefficients of Table 2.2, four additional property relations can be obtained by equating such expressions:

$$\left(\frac{\partial u}{\partial s}\right)_v = \left(\frac{\partial h}{\partial s}\right)_p, \quad \left(\frac{\partial u}{\partial v}\right)_s = \left(\frac{\partial \psi}{\partial v}\right)_T$$

$$\left(\frac{\partial h}{\partial p}\right)_s = \left(\frac{\partial g}{\partial p}\right)_T, \quad \left(\frac{\partial \psi}{\partial T}\right)_v = \left(\frac{\partial g}{\partial T}\right)_p$$

These four relations are identified in Table 2.2 by brackets. As any three of Equations 2.32 can be obtained from the fourth simply by manipulation, the 16 property relations of Table 2.2 also can be regarded as following from this single differential expression. Several additional first-derivative property relations can be derived; see, e.g., Zemansky, 1972.

Specific Heats and Other Properties

Engineering thermodynamics uses a wide assortment of thermodynamic properties and relations among these properties. Table 2.3 lists several commonly encountered properties.

Among the entries of Table 2.3 are the specific heats c_v and c_p. These intensive properties are often required for thermodynamic analysis, and are defined as partial derivations of the functions $u(T, v)$ and $h(T, p)$, respectively,

$$c_v = \left(\frac{\partial u}{\partial T}\right)_v \tag{2.33}$$

$$c_p = \left(\frac{\partial h}{\partial T}\right)_p \tag{2.34}$$

Since u and h can be expressed either on a unit mass basis or a per-mole basis, values of the specific heats can be similarly expressed. Table 2.4 summarizes relations involving c_v and c_p. The property k, the specific heat ratio, is

$$k = \frac{c_p}{c_v} \tag{2.35}$$

Values for c_v and c_p can be obtained via statistical mechanics using *spectroscopic* measurements. They can also be determined macroscopically through exacting property measurements. Specific heat data for

TABLE 2.3 Symbols and Definitions for Selected Properties

Property	Symbol	Definition	Property	Symbol	Definition
Pressure	p		Specific heat, constant volume	c_v	$(\partial u/\partial T)_v$
Temperature	T		Specific heat, constant pressure	c_p	$(\partial h/\partial T)_p$
Specific volume	v		Volume expansivity	β	$\frac{1}{v}(\partial v/\partial T)_p$
Specific internal energy	u		Isothermal compressivity	κ	$-\frac{1}{v}(\partial v/\partial p)_T$
Specific entropy	s		Isentropic compressibility	α	$-\frac{1}{v}(\partial v/\partial p)_s$
Specific enthalpy	h	$u + pv$	Isothermal bulk modulus	B	$-v(\partial p/\partial v)_T$
Specific Helmholtz function	ψ	$u - Ts$	Isentropic bulk modulus	B_s	$-v(\partial p/\partial v)_s$
Specific Gibbs function	g	$h - Ts$	Joule-Thomson coefficient	μ_J	$(\partial T/\partial p)_h$
Compressibility factor	Z	pv/RT	Joule coefficient	η	$(\partial T/\partial v)_u$
Specific heat ratio	k	c_p/c_v	Velocity of sound	c	$\sqrt{-v^2(\partial p/\partial v)_s}$

common gases, liquids, and solids are provided by the handbooks and property reference volumes listed among the Chapter 2 references. Specific heats are also considered in Section 2.3 as a part of the discussions of the *incompressible model* and the *ideal gas model.* Figure 2.4 shows how c_p for water vapor varies as a function of temperature and pressure. Other gases exhibit similar behavior. The figure also gives the variation of c_p with temperature in the limit as pressure tends to zero (the ideal gas limit). In this limit c_p increases with increasing temperature, which is a characteristic exhibited by other gases as well.

The following two equations are often convenient for establishing relations among properties:

$$\left(\frac{\partial x}{\partial y}\right)_z\left(\frac{\partial y}{\partial x}\right)_z = 1 \tag{2.36a}$$

$$\left(\frac{\partial y}{\partial z}\right)_x\left(\frac{\partial z}{\partial x}\right)_y\left(\frac{\partial x}{\partial y}\right)_z = -1 \tag{2.36b}$$

Their use is illustrated in Example 5.

Example 5

Obtain Equation 2 and Equation 11 of Table 2.4 from Equation 1.

Solution. Identifying x, y, z with s, T, and v, respectively, Equation 2.36b reads

$$\left(\frac{\partial T}{\partial v}\right)_s\left(\frac{\partial v}{\partial s}\right)_T\left(\frac{\partial s}{\partial T}\right)_v = -1$$

Applying Equation 2.36a to each of $(\partial T/\partial v)_s$ and $(\partial v/\partial s)_T$,

$$\left(\frac{\partial s}{\partial T}\right)_v = -\frac{1}{(\partial T/\partial v)_s(\partial v/\partial s)_T} = -\left(\frac{\partial v}{\partial T}\right)_s\left(\frac{\partial s}{\partial v}\right)_T$$

TABLE 2.4 Specific Heat Relations[a]

$c_v = \left(\frac{\partial u}{\partial T}\right)_v = T\left(\frac{\partial s}{\partial T}\right)_v$	(1)
$= -T\left(\frac{\partial p}{\partial T}\right)_v \left(\frac{\partial v}{\partial T}\right)_s$	(2)
$c_p = \left(\frac{\partial h}{\partial T}\right)_p = T\left(\frac{\partial s}{\partial T}\right)_p$	(3)
$= T\left(\frac{\partial v}{\partial T}\right)_p \left(\frac{\partial p}{\partial T}\right)_s$	(4)
$c_p - c_v = T\left(\frac{\partial p}{\partial T}\right)_v \left(\frac{\partial v}{\partial T}\right)_p$	(5)
$= -T\left(\frac{\partial v}{\partial T}\right)_p^2 \left(\frac{\partial p}{\partial v}\right)_T$	(6)
$= \frac{Tv\beta^2}{\kappa}$	(7)
$c_p = \frac{1}{\mu_J}\left[T\left(\frac{\partial v}{\partial T}\right)_p - v\right]$	(8)
$c_v = -\frac{1}{\eta}\left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right]$	(9)
$k = \frac{c_p}{c_v} = \left(\frac{\partial v}{\partial p}\right)_T \left(\frac{\partial p}{\partial v}\right)_s$	10)
$\left(\frac{\partial c_v}{\partial v}\right)_T = T\left(\frac{\partial^2 p}{\partial T^2}\right)_v$	(11)
$\left(\frac{\partial c_p}{\partial p}\right)_T = -T\left(\frac{\partial^2 v}{\partial T^2}\right)_p$	(12)

[a] See, for example, Moran, M.J. and Shapiro, H.N. 1995. *Fundamentals of Engineering Thermodynamics*, 3rd ed. Wiley, New York, chap. 11.

Introducing the Maxwell relation from Table 2.2 corresponding to $\psi(T, v)$,

$$\left(\frac{\partial s}{\partial T}\right)_v = -\left(\frac{\partial v}{\partial T}\right)_s \left(\frac{\partial p}{\partial T}\right)_v$$

With this, Equation 2 of Table 2.4 is obtained from Equation 1, which in turn is obtained in Example 6. Equation 11 of Table 2.4 can be obtained by differentiating Equation 1 with repect to specific volume at fixed temperature, and again using the Maxwell relation corresponding to ψ.

P-v-T Relations

Considerable pressure, specific volume, and temperature data have been accumulated for industrially important gases and liquids. These data can be represented in the form $p = f(v, T)$, called an *equation of state*. Equations of state can be expressed in tabular, graphical, and analytical forms.

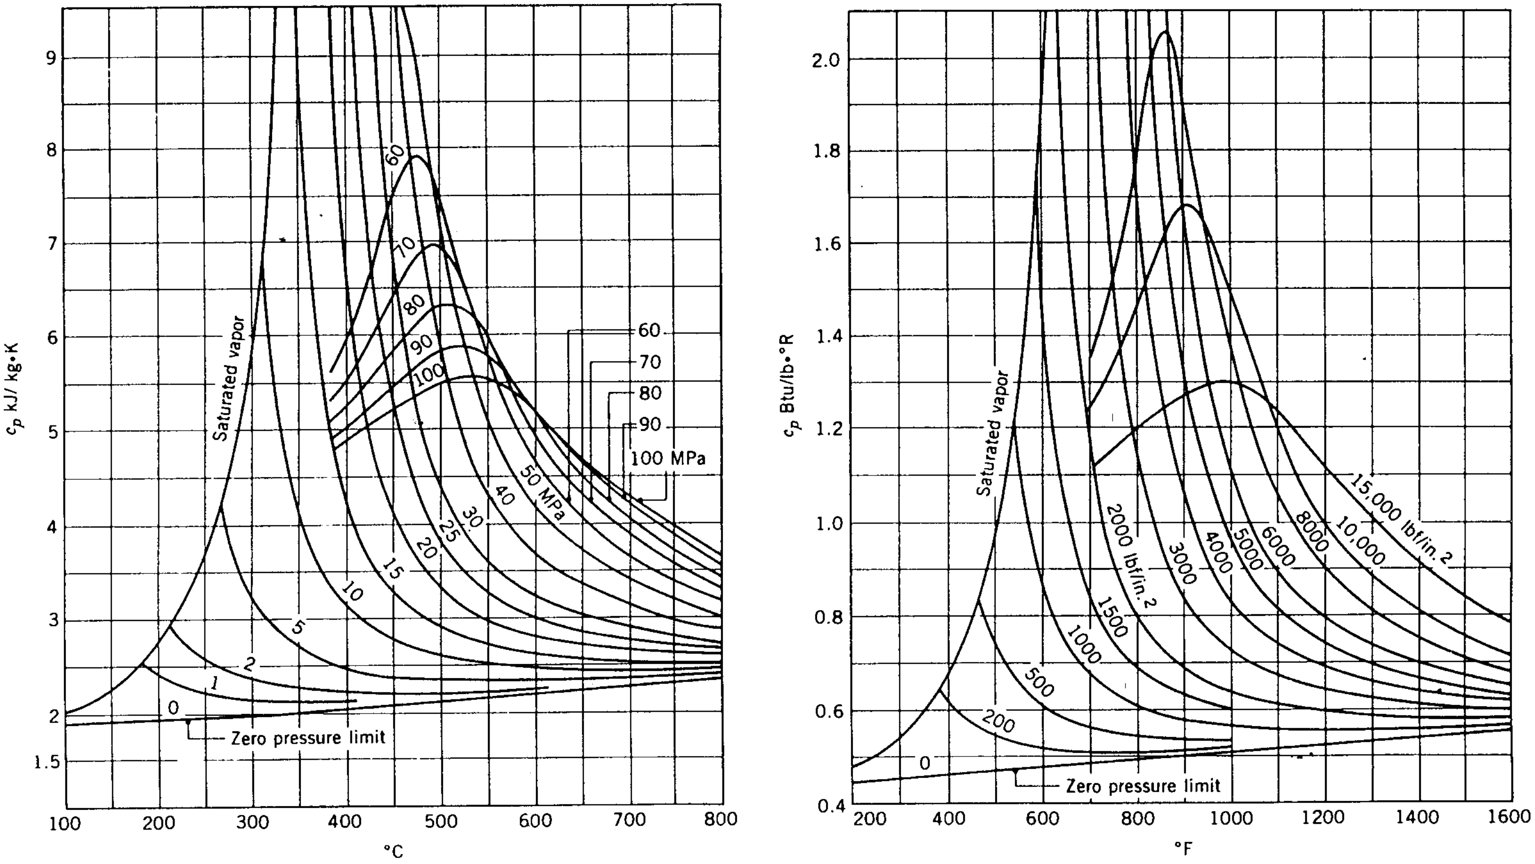

FIGURE 2.4 c_p of water vapor as a function of temperature and pressure. (Adapted from Keenan, J.H., Keyes, F.G., Hill, P.G., and Moore, J.G. 1969 and 1978. *Steam Tables — S.I. Units* (*English Units*). John Wiley & Sons, New York.)

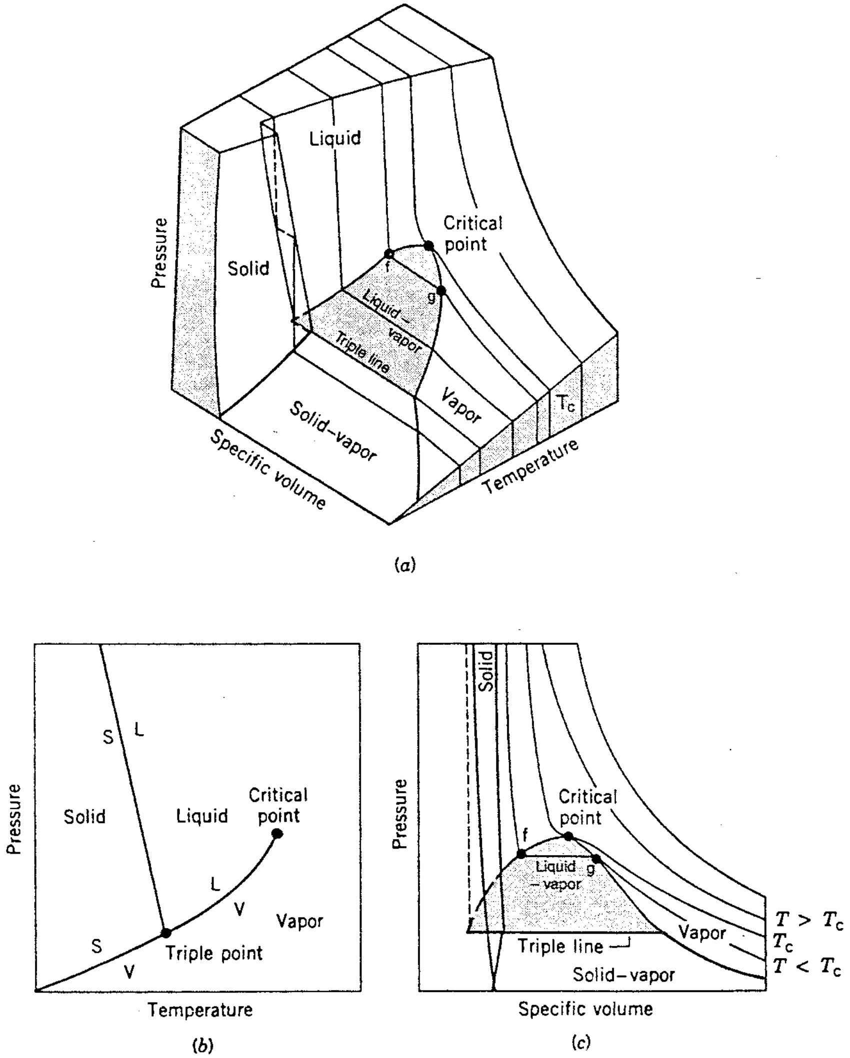

FIGURE 2.5 Pressure-specific volume-temperature surface and projections for water (not to scale).

P-v-T Surface

The graph of a function $p = f(v, T)$ is a surface in three-dimensional space. Figure 2.5 shows the *p-v-T* relationship for water. Figure 2.5b shows the projection of the surface onto the pressure-temperature plane, called the *phase diagram.* The projection onto the *p–v* plane is shown in Figure 2.5c.

Figure 2.5 has three regions labeled solid, liquid, and vapor where the substance exists only in a single phase. Between the single phase regions lie *two-phase* regions, where two phases coexist in equilibrium. The lines separating the single-phase regions from the two-phase regions are *saturation lines.* Any state represented by a point on a saturation line is a *saturation state.* The line separating the liquid phase and the two-phase liquid-vapor region is the saturated liquid line. The state denoted by f is a saturated liquid state. The saturated vapor line separates the vapor region and the two-phase liquid-vapor region. The state denoted by g is a saturated vapor state. The saturated liquid line and the saturated vapor line meet at the *critical point.* At the critical point, the pressure is the *critical pressure* p_c, and the temperature is the *critical temperature* T_c. Three phases can coexist in equilibrium along the line labeled *triple line.* The triple line projects onto a point on the phase diagram. The triple point of water is used in defining the Kelvin temperature scale (Section 2.1, Basic Concepts and Definitions; The Second Law of Thermodynamics, Entropy).

When a phase change occurs during constant pressure heating or cooling, the temperature remains constant as long as both phases are present. Accordingly, in the two-phase liquid-vapor region, a line of constant pressure is also a line of constant temperature. For a specified pressure, the corresponding temperature is called the *saturation temperature.* For a specified temperature, the corresponding pressure is called the *saturation pressure.* The region to the right of the saturated vapor line is known as the *superheated vapor region* because the vapor exists at a temperature greater than the saturation temperature for its pressure. The region to the left of the saturated liquid line is known as the *compressed liquid region* because the liquid is at a pressure higher than the saturation pressure for its temperature.

When a mixture of liquid and vapor coexists in equilibrium, the liquid phase is a saturated liquid and the vapor phase is a saturated vapor. The total volume of any such mixture is $V = V_f + V_g$; or, alternatively, $mv = m_f v_f + m_g v_g$, where m and v denote mass and specific volume, respectively. Dividing by the total mass of the mixture m and letting the *mass fraction* of the vapor in the mixture, m_g/m, be symbolized by x, called the *quality*, the apparent specific volume v of the mixture is

$$\begin{aligned} v &= (1-x)v_{\mathrm{f}} + xv_{\mathrm{g}} \\ &= v_{\mathrm{f}} + xv_{\mathrm{fg}} \end{aligned} \tag{2.37a}$$

where $v_{\mathrm{fg}} = v_{\mathrm{g}} - v_{\mathrm{f}}$. Expressions similar in form can be written for internal energy, enthalpy, and entropy:

$$\begin{aligned} u &= (1-x)u_{\mathrm{f}} + xu_{\mathrm{g}} \\ &= u_{\mathrm{f}} + xu_{\mathrm{fg}} \end{aligned} \tag{2.37b}$$

$$\begin{aligned} h &= (1-x)h_{\mathrm{f}} + xh_{\mathrm{g}} \\ &= h_{\mathrm{f}} + xh_{\mathrm{fg}} \end{aligned} \tag{2.37c}$$

$$\begin{aligned} s &= (1-x)s_{\mathrm{f}} + xs_{\mathrm{g}} \\ &= s_{\mathrm{f}} + xs_{\mathrm{fg}} \end{aligned} \tag{2.37d}$$

For the case of water, Figure 2.6 illustrates the phase change from solid to liquid (melting): *a-b-c*; from solid to vapor (sublimation): *a′-b′-c′*; and from liquid to vapor (vaporization): *a″-b″-c″*. During any such phase change the temperature and pressure remain constant and thus are not independent properties. The *Clapeyron equation* allows the change in enthalpy during a phase change at fixed temperature to be evaluated from *p-v-T* data pertaining to the phase change. For vaporization, the Clapeyron equation reads

$$\left(\frac{dp}{dT}\right)_{sat} = \frac{h_{\mathrm{g}} - h_{\mathrm{f}}}{T\left(v_{\mathrm{g}} - v_{\mathrm{f}}\right)} \tag{2.38}$$

where $(dp/dT)_{sat}$ is the slope of the saturation pressure-temperature curve at the point determined by the temperature held constant during the phase change. Expressions similar in form to Equation 2.38 can be written for sublimation and melting.

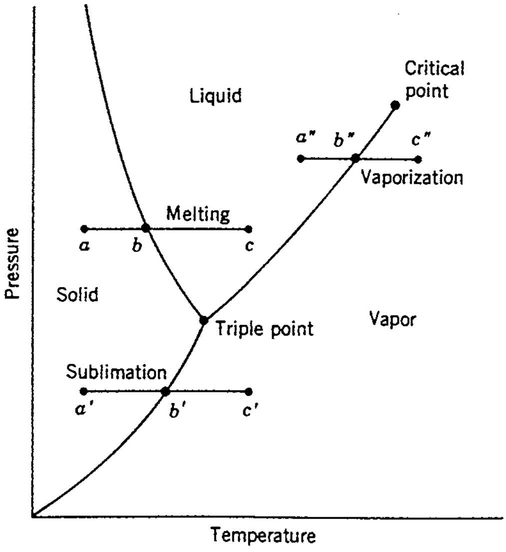

FIGURE 2.6 Phase diagram for water (not to scale).

The Clapeyron equation shows that the slope of a saturation line on a phase diagram depends on the signs of the specific volume and enthalpy changes accompanying the phase change. In most cases, when a phase change takes place with an increase in specific enthalpy, the specific volume also increases, and $(dp/dT)_{sat}$ is positive. However, in the case of the melting of ice and a few other substances, the specific volume decreases on melting. The slope of the saturated solid-liquid curve for these few substances is negative, as illustrated for water in Figure 2.6.

Graphical Representations

The intensive states of a pure, simple compressible system can be represented graphically with any two independent intensive properties as the coordinates, excluding properties associated with motion and gravity. While any such pair may be used, there are several selections that are conventionally employed. These include the p-T and p-v diagrams of Figure 2.5, the T-s diagram of Figure 2.7, the h-s (Mollier) diagram of Figure 2.8, and the p-h diagram of Figure 2.9. The compressibility charts considered next use the compressibility factor as one of the coordinates.

Compressibility Charts

The p-v-T relation for a wide range of common gases is illustrated by the generalized compressibility chart of Figure 2.10. In this chart, the compressibility factor, Z, is plotted vs. the *reduced* pressure, p_R, *reduced* temperature, T_R, and *pseudoreduced* specific volume, v_R', where

$$Z = \frac{p\bar{v}}{\bar{R}T} \tag{2.39}$$

and

$$p_R = \frac{p}{p_c}, \quad T_R = \frac{T}{T_c}, \quad v_R' = \frac{\bar{v}}{\left(\bar{R}T_c/p_c\right)} \tag{2.40}$$

In these expressions, $\bar{R}$ is the universal gas constant and p_c and T_c denote the critical pressure and temperature, respectively. Values of p_c and T_c are given for several substances in Table A.9. The reduced

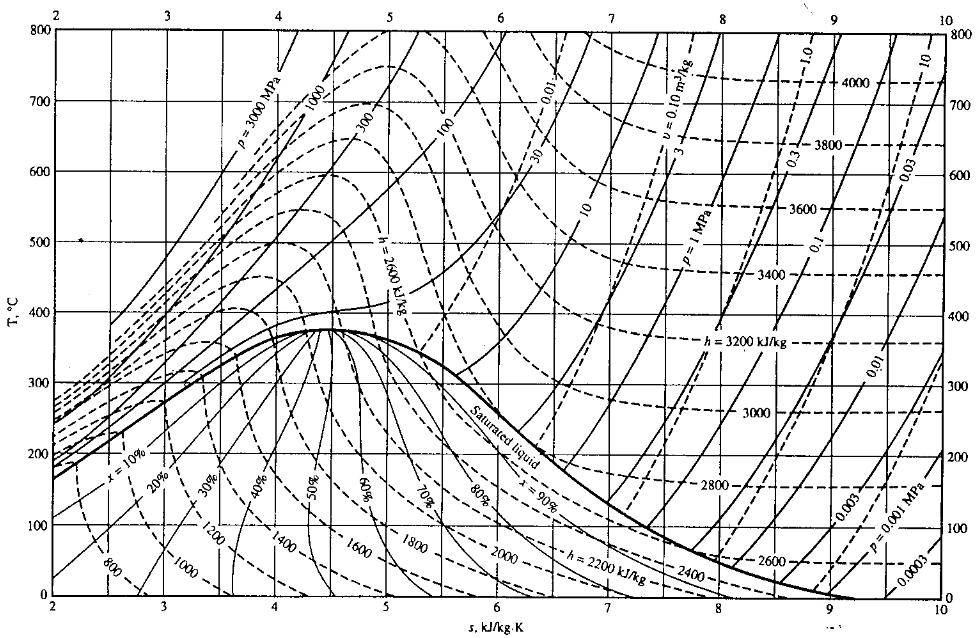

FIGURE 2.7 Temperature-entropy diagram for water. (*Source:* Jones, J.B. and Dugan, R.E. 1996. *Engineering Thermodynamics*, Prentice-Hall, Englewood Cliffs, NJ, based on data and formulations from Haar, L., Gallagher, J.S., and Kell, G.S. 1984. *NBS/NRC Steam Tables.* Hemisphere, Washington, D.C.)

isotherms of Figure 2.10 represent the best curves fitted to the data of several gases. For the 30 gases used in developing the chart, the deviation of observed values from those of the chart is at most on the order of 5% and for most ranges is much less.[1]

Figure 2.10 gives a common value of about 0.27 for the compressibility factor at the critical point. As the critical compressibility factor for different substances actually varies from 0.23 to 0.33, the chart is inaccurate in the vicinity of the critical point. This source of inaccuracy can be removed by restricting the correlation to substances having essentially the same Z_c values. which is equivalent to including the critical compressibility factor as an independent variable: $Z = f\,(T_R, p_R, Z_c)$. To achieve greater accuracy variables other than Z_c have been proposed as a third parameter — for example, the *acentric factor* (see, e.g., Reid and Sherwood, 1966).

Generalized compressibility data are also available in tabular form (see, e.g., Reid and Sherwood, 1966) and in equation form (see, e.g., Reynolds, 1979). The use of generalized data in any form (graphical, tabular, or equation) allows p, v, and T for gases to be evaluated simply and with reasonable accuracy. When accuracy is an essential consideration, generalized compressibility data should not be used as a substitute for p-v-T data for a given substance as provided by computer software, a table, or an equation of state.

Equations of State

Considering the isotherms of Figure 2.10, it is plausible that the variation of the compressibility factor might be expressed as an equation, at least for certain intervals of p and T. Two expressions can be written that enjoy a theoretical basis. One gives the compressibility factor as an infinite series expansion in pressure,

---

[1] To determine Z for hydrogen, helium, and neon above a T_R of 5, the reduced temperature and pressure should be calculated using $T_R = T/(T_c + 8)$ and $P_R = p/(p_c + 8)$, where temperatures are in K and pressures are in atm.

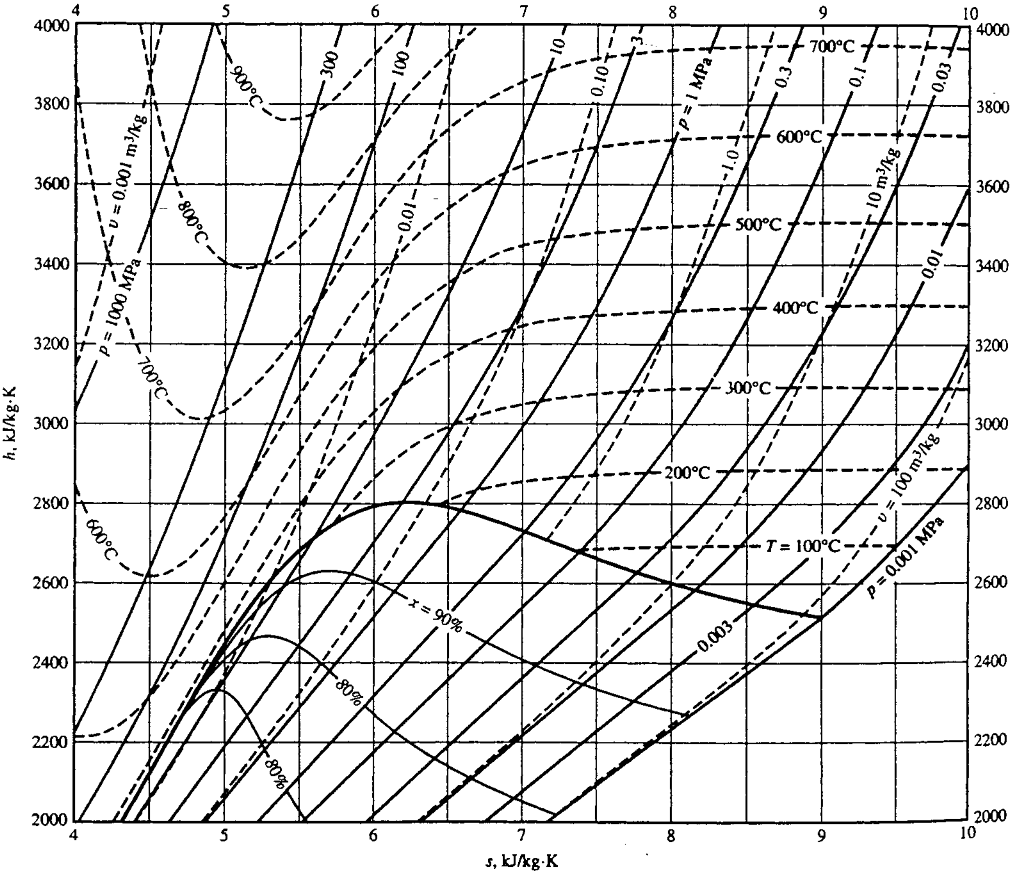

FIGURE 2.8 Enthalpy-entropy (Mollier) diagram for water. (*Source:* Jones, J.B. and Dugan, R.E. 1996. *Engineering Thermodynamics*. Prentice-Hall, Englewood Cliffs, NJ, based on data and formulations from Haar, L., Gallagher, J.S., and Kell, G.S. 1984. *NBS/NRC Steam Tables*. Hemisphere, Washington, D.C.)

$$Z = 1 + \hat{B}(T)p + \hat{C}(T)p^2 + \hat{D}(T)p^3 + \dots$$

and the other is a series in $1/\bar{v}$,

$$Z = 1 + \frac{B(T)}{\bar{v}} + \frac{C(T)}{\bar{v}^2} + \frac{D(T)}{\bar{v}^3} + \dots$$

These expressions are known as *virial expansions*, and the coefficients $\hat{B}$, $\hat{C}$ $\hat{D}$, … and B, C, D … are called *virial coefficients*. In principle, the virial coefficients can be calculated using expressions from statistical mechanics derived from consideration of the force fields around the molecules. Thus far only the first few coefficients have been calculated and only for gases consisting of relatively simple molecules. The coefficients also can be found, in principle, by fitting p-v-T data in particular realms of interest. Only the first few coefficients can be found accurately this way, however, and the result is a *truncated* equation valid only at certain states.

Over 100 equations of state have been developed in an attempt to portray accurately the p-v-T behavior of substances and yet avoid the complexities inherent in a full virial series. In general, these equations exhibit little in the way of fundamental physical significance and are mainly empirical in character. Most

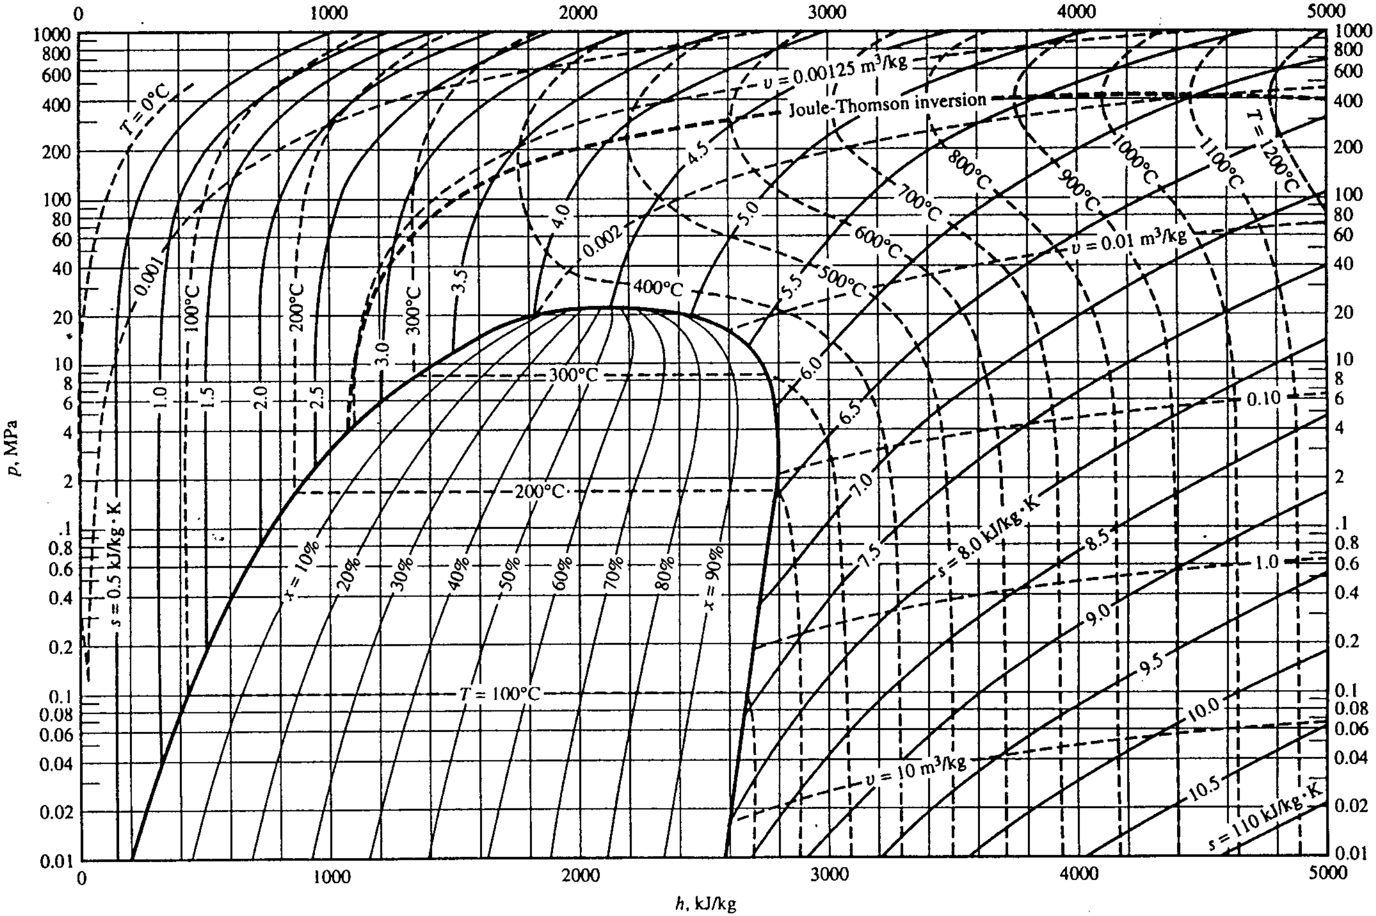

FIGURE 2.9 Pressure-enthalpy diagram for water. (*Source:* Jones, J.B. and Dugan, R.E. 1996. *Engineering Thermodynamics*. Prentice-Hall, Englewood Cliffs, NJ, based on data and formulations from Haar, L., Gallagher, J.S., and Kell, G.S. 1984. *NBS/NRC Steam Tables*. Hemisphere, Washington, D.C.)

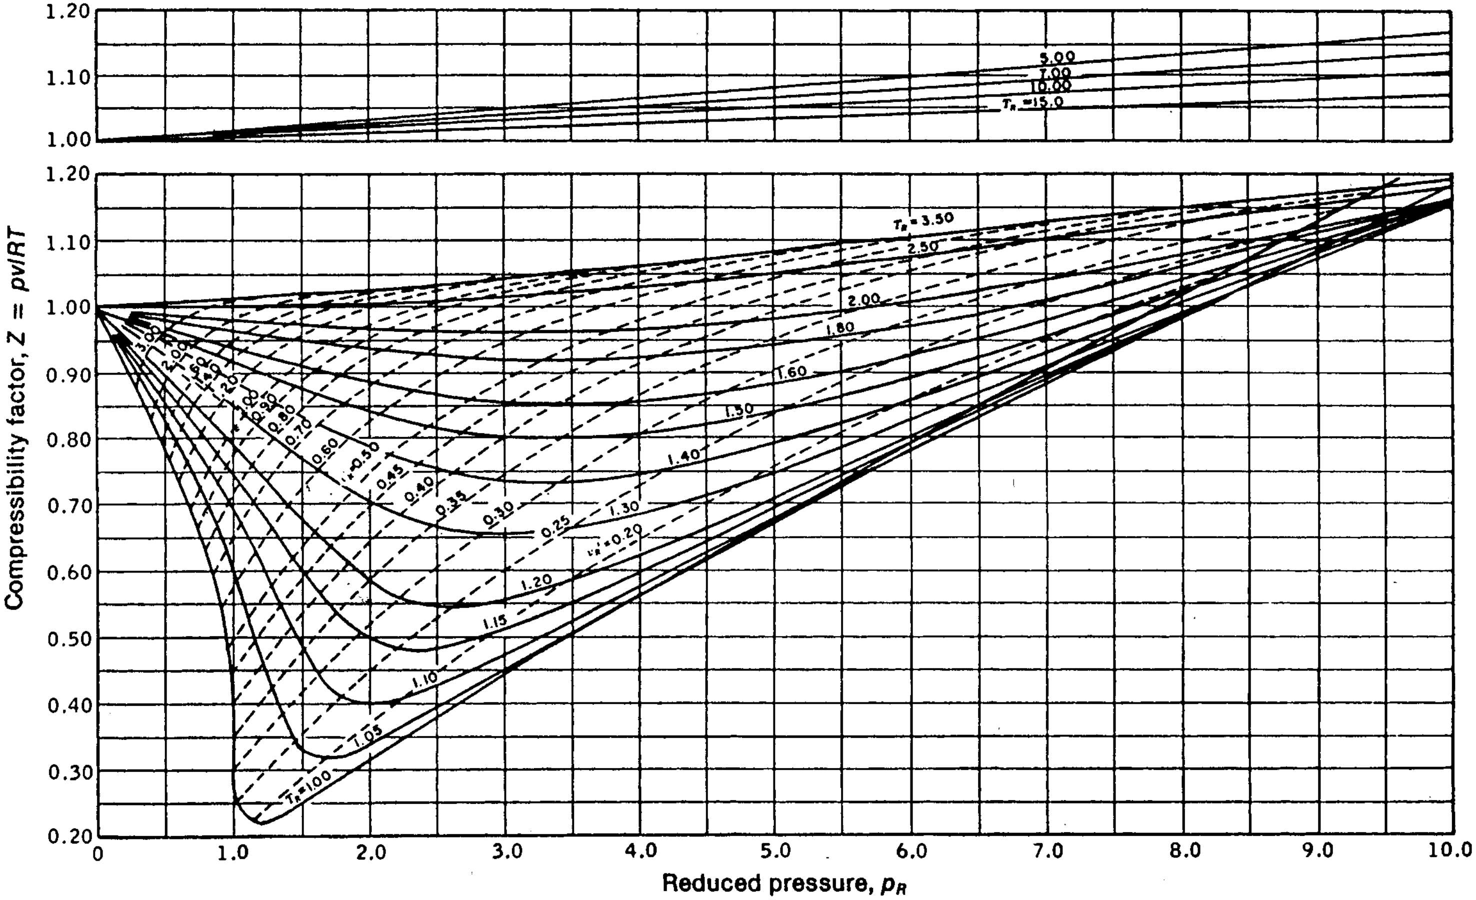

FIGURE 2.10 Generalized compressibility chart ($T_R = T/T_C$, $p_R = p/p_C$, $v_R' = \bar{v}p_C/RT_C$) for $p_R \leq 10$. (*Source:* Obert, E.F. 1960 *Concepts of Thermodynamics*. McGraw-Hill, New York.)

are developed for gases, but some describe the *p-v-T* behavior of the liquid phase, at least qualitatively. Every equation of state is restricted to particular states. The realm of applicability is often indicated by giving an interval of pressure, or density, where the equation can be expected to represent the *p-v-T* behavior faithfully. When it is not stated, the realm of applicability often may be approximated by expressing the equation in terms of the compressibility factor Z and the reduced properties, and superimposing the result on a generalized compressibility chart or comparing with compressibility data from the literature.

Equations of state can be classified by the number of adjustable constants they involve. The Redlich-Kwong equation is considered by many to be the best of the two-constant equations of state. It gives pressure as a function of temperature and specific volume and thus is *explicit* in pressure:

$$p = \frac{\bar{R}T}{\bar{v} - b} - \frac{a}{\bar{v}(\bar{v} + b)T^{1/2}} \tag{2.41}$$

This equation is primarily empirical in nature, with no rigorous justification in terms of molecular arguments. Values for the Redlich-Kwong constants for several substances are provided in Table A.9. Modified forms of the equation have been proposed with the aim of achieving better accuracy.

Although the two-constant Redlich-Kwong equation performs better than some equations of state having several adjustable constants, two-constant equations tend to be limited in accuracy as pressure (or density) increases. Increased accuracy normally requires a greater number of adjustable constants. For example, the Benedict-Webb-Rubin equation, which involves eight adjustable constants, has been successful in predicting the *p-v-T* behavior of *light hydrocarbons.* The Benedict-Webb-Rubin equation is also explicit in pressure,

$$p = \frac{\bar{R}T}{\bar{v}} + \left(B\bar{R}T - A - \frac{C}{T^2}\right)\frac{1}{\bar{v}^2} + \frac{\left(b\bar{R}T - a\right)}{\bar{v}^3} + \frac{a\alpha}{\bar{v}^6} + \frac{c}{\bar{v}^3T^2}\left(1 + \frac{\gamma}{\bar{v}^2}\right)\exp\left(-\frac{\gamma}{\bar{v}^2}\right) \tag{2.42}$$

Values of the Benedict-Webb-Rubin constants for various gases are provided in the literature (see, e.g., Cooper and Goldfrank, 1967). A modification of the Benedict-Webb-Rubin equation involving 12 constants is discussed by Lee and Kessler, 1975. Many multiconstant equations can be found in the engineering literature, and with the advent of high speed computers, equations having 50 or more constants have been developed for representing the *p-v-T* behavior of different substances.

Gas Mixtures

Since an unlimited variety of mixtures can be formed from a given set of pure components by varying the relative amounts present, the properties of mixtures are reported only in special cases such as air. Means are available for predicting the properties of mixtures, however. Most techniques for predicting mixture properties are empirical in character and are not derived from fundamental physical principles. The realm of validity of any particular technique can be established by comparing predicted property values with empirical data. In this section, methods for evaluating the *p-v-T* relations for pure components are adapted to obtain plausible estimates for gas mixtures. The case of ideal gas mixtures is discussed in Section 2.3, Ideal Gas Model. In Section 2.3, Multicomponent Systems, some general aspects of property evaluation for multicomponent systems are presented.

The total number of moles of mixture, n, *is* the sum of the number of moles of the components, n_i:

$$n = n_1 + n_2 + \ldots n_j = \sum_{i=1}^{j} n_i \tag{2.43}$$

The *relative* amounts of the components present can be described in terms of *mole fractions.* The mole fraction y_i of component i is $y_i = n_i/n$. The sum of the mole fractions of all components present is equal to unity. The apparent molecular weight $\mathcal{M}$ is the mole fraction average of the component molecular weights, such that

$$\mathcal{M} = \sum_{i=1}^{j} y_i \mathcal{M}_i \tag{2.44}$$

The *relative* amounts of the components present also can be described in terms of *mass fractions:* m_i/m, where m_i is the mass of component i and m is the total mass of mixture.

The p-v-T relation for a gas mixture can be estimated by applying an equation of state to the overall mixture. The constants appearing in the equation of state are *mixture values* determined with empirical combining rules developed for the equation. For example, mixture values of the constants a and b for use in the Redlich-Kwong equation are obtained using relations of the form

$$a = \left(\sum_{i=1}^{j} y_i a_i^{1/2} \right)^2, \quad b = \sum_{i=1}^{j} y_i b_i \tag{2.45}$$

where a_i and b_i are the values of the constants for component i. Combination rules for obtaining mixture values for the constants in other equations of state are also found in the literature.

Another approach is to regard the mixture as if it were a single pure component having critical properties calculated by one of several mixture rules. *Kay's rule is* perhaps the simplest of these, requiring only the determination of a mole fraction averaged critical temperature T_c and critical pressure p_c:

$$T_c = \sum_{i=1}^{j} y_i T_{c,i}, \quad p_c = \sum_{i=1}^{j} y_i p_{c,i} \tag{2.46}$$

where $T_{c,i}$ and $p_{c,i}$ are the critical temperature and critical pressure of component i, respectively. Using T_c and p_c, the mixture compressibility factor Z is obtained as for a single pure component. The unkown quantity from among the pressure p, volume V, temperature T, and total number of moles n of the gas mixture can then be obtained by solving $Z = pV/n\bar{R}T$.

Additional means for predicting the p-v-T relation of a mixture are provided by empirical mixture rules. Several are found in the engineering literature. According to the *additive pressure rule*, the pressure of a gas mixture is expressible as a sum of pressures exerted by the individual components:

$$p = p_1 + p_2 + p_3 \ldots \Big]_{T,V} \tag{2.47a}$$

where the pressures p_1, p_2, etc. are evaluated by considering the respective components to be at the volume V and temperature T of the mixture. The additive pressure rule can be expressed alternatively as

$$Z = \sum_{i=1}^{j} y_i Z_i \Bigg]_{T,V} \tag{2.47b}$$

where Z is the compressibility factor of the mixture and the compressibility factors Z_i are determined assuming that component i occupies the entire volume of the mixture at the temperature T.

The *additive volume rule* postulates that the volume V of a gas mixture is expressible as the sum of volumes occupied by the individual components:

$$V = V_1 + V_2 + V_3 \ldots \Big]_{p,T} \tag{2.48a}$$

where the volumes V_1, V_2, etc. are evaluated by considering the respective components to be at the pressure p and temperature T of the mixture. The additive volume rule can be expressed alternatively as

$$Z = \left.\sum_{i=1}^{j} y_i Z_i \right]_{p,T} \tag{2.48b}$$

where the compressibility factors Z_i are determined assuming that component i exists at the pressure p and temperature T of the mixture.

Evaluating Δh, Δu, and Δs

Using appropriate specific heat and p-v-T data, the changes in specific enthalpy, internal energy, and entropy can be determined between states of single-phase regions. Table 2.5 provides expressions for such property changes in terms of particular choices of the independent variables: temperature and pressure, and temperature and specific volume.

Taking Equation 1 of Table 2.5 as a representative case, the change in specific enthalpy between states 1 and 2 can be determined using the three steps shown in the accompanying property diagram. This requires knowledge of the variation of c_p with temperature at a fixed pressure p', and the variation of $[v - T(\partial v/\partial T)_p]$ with pressure at temperatures T_1 and T_2:

1-a: Since temperature is constant at T_1, the first integral of Equation 1 in Table 2.5 vanishes, and

$$h_a - h_1 = \int_{p_1}^{p'} \left[v - T\left(\partial v/\partial T\right)_p \right] dp$$

a-b: Since pressure is constant at p', the second integral of Equation 1 vanishes, and

$$h_b - h_a = \int_{T_1}^{T_2} c_p\left(T, p'\right) dT$$

b-2: Since temperature is constant at T_2, the first integral of Equation 1 vanishes, and

$$h_2 - h_b = \int_{p'}^{p_2} \left[v - T\left(\partial v/\partial T\right)_p \right] dp$$

Adding these expressions, the result is $h_2 - h_1$. The required integrals may be performed numerically or analytically. The analytical approach is expedited when an equation of state explicit in specific volume is known.

Similar considerations apply to Equation 2 to Equation 4 of Table 2.5. To evaluate $u_2 - u_1$ with Equation 3, for example, requires the variation of c_v with temperature at a fixed specific volume v', and the variation of $[T(\partial p/\partial T)_v - p]$ with specific volume at temperatures T_1 and T_2. An analytical approach to performing the integrals is expedited when an equation of state explicit in pressure is known.

As changes in specific enthalpy and internal energy are related through $h = u + pv$ by

$$h_2 - h_1 = \left(u_2 - u_1\right) + \left(p_2 v_2 - p_1 v_1\right) \tag{2.49}$$

only one of $h_2 - h_1$ and $u_2 - u_1$ need be found by integration. The other can be evaluated from Equation 2.49. The one found by integration depends on the information available: $h_2 - h_1$ would be found when an equation of state explicit in v and c_p as a function of temperature at some fixed pressure is known, $u_2 - u_1$ would be found when an equation of state explicit in p and c_v as a function of temperature at some specific volume is known.

TABLE 2.5 Δh, Δu, Δs Expressions

Independent properties:	temperature and pressure	temperature and specific volume
Preferred data:	$v(T, p)$, $c_p(T, p)$	$p(T, v)$, $c_v(T, v)$
Property diagram:		Property expressions:	$h(T, p)$: $dh = \underbrace{\left(\frac{\partial h}{\partial T}\right)_p}_{c_p} dT + \underbrace{\left(\frac{\partial h}{\partial p}\right)_T}_{\left[v - T\left(\frac{\partial v}{\partial T}\right)_p\right]} dp$ (1′) $\Delta h = \int c_p dT + \int \left[v - T\left(\frac{\partial v}{\partial T}\right)_p\right] dp$ (1) $s(T, p)$: $ds = \underbrace{\left(\frac{\partial s}{\partial T}\right)_p}_{\frac{c_p}{T}} dT + \underbrace{\left(\frac{\partial s}{\partial p}\right)_T}_{-\left(\frac{\partial v}{\partial T}\right)_p} dp$ (2′) $\Delta s = \int \frac{c_p}{T} dT - \int \left(\frac{\partial v}{\partial T}\right)_p dp$ (2)	$u(T, v)$: $du = \underbrace{\left(\frac{\partial u}{\partial T}\right)_v}_{c_v} dT + \underbrace{\left(\frac{\partial u}{\partial v}\right)_T}_{\left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right]} dv$ (3′) $\Delta u = \int c_v dT + \int \left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right] dv$ (3) $s(T, v)$: $ds = \underbrace{\left(\frac{\partial s}{\partial T}\right)_v}_{\frac{c_v}{T}} dT + \underbrace{\left(\frac{\partial s}{\partial v}\right)_T}_{\left(\frac{\partial p}{\partial T}\right)_v} dv$ (4′) $\Delta s = \int \frac{c_v}{T} dT + \int \left(\frac{\partial p}{\partial T}\right)_v dv$ (4)

Example 6

Obtain Equation 1 of Table 2.4 and Equation 3 and Equation 4 of Table 2.5.

Solution. With Equation 2.33 and the Maxwell relation corresponding to ψ(T, v) from Table 2.2, Equation 3′ and Equation 4′ of Table 2.5 become, respectively,

$$du = c_v dT + \left(\frac{\partial u}{\partial v}\right)_T dv$$

$$ds = \left(\frac{\partial s}{\partial T}\right)_v dT + \left(\frac{\partial p}{\partial T}\right)_v dv$$

Introducing these expressions for *du* and *ds* in Equation 2.32a, and collecting terms,

$$\left[T\left(\frac{\partial s}{\partial T}\right)_v - c_v\right]dT = \left[\left(\frac{\partial u}{\partial v}\right)_T + p - T\left(\frac{\partial p}{\partial T}\right)_v\right]dv$$

Since *T* and *v* are independent, the coefficients of *dT* and *dv* must vanish, giving, respectively,

$$\left(\frac{\partial s}{\partial T}\right)_v = \frac{c_v}{T}$$

$$\left(\frac{\partial u}{\partial v}\right)_T = T\left(\frac{\partial p}{\partial T}\right)_v - p$$

The first of these corresponds to Equation 1 of Table 2.4 and Equation 4 of Table 2.5. The second of the above expressions establishes Equation 3 of Table 2.5. With similar considerations, Equation 3 of Table 2.4 and Equation 1 and Equation 2 of Table 2.5 may be obtained.

Fundamental Thermodynamic Functions

A fundamental thermodynamic function is one that provides a complete description of the thermodynamic state. The functions $u(s, v)$, $h(s, p)$, $\psi(T, v)$, and $g(T, p)$ listed in Table 2.2 are fundamental thermodynamic functions.

In principle, all properties of interest can be determined from a fundamental thermodynamic function by differentiation and combination. Taking the function $\psi(T, v)$ as a representative case, the properties *v* and *T*, being the independent variables, are specified to fix the state. The pressure *p* and specific entropy *s* at this state can be determined by differentiation of $\psi(T, v)$, as shown in Table 2.2. By definition, $\psi = u - Ts$, so specific internal energy is obtained as

$$u = \psi + Ts$$

with *u*, *p*, and *v* known, the specific enthalpy can be found from the definition $h = u + pv$. Similarly, the specific Gibbs function is found from the definition $g = h - Ts$. The specific heat c_v can be determined by further differentiation $c_v = (\partial u/\partial T)_v$.

The development of a fundamental function requires the selection of a functional form in terms of the appropriate pair of independent properties and a set of adjustable coefficients that may number 50 or more. The functional form is specified on the basis of both theoretical and practical considerations. The coefficients of the fundamental function are determined by requiring that a set of selected property values and/or observed conditions be statisfied in a least-squares sense. This generally involves property data requiring the assumed functional form to be differentiated one or more times, for example *p-v-T* and specific heat data. When all coefficients have been evaluated, the function is tested for accuracy by using it to evaluate properties for which accepted values are known such as *velocity of sound* and *Joule-Thomson* data. Once a suitable fundamental function is established, extreme accuracy in and consistency among the thermodynamic properties are possible. The properties of water tabulated by Keenan et al. (1969) and by Haar et al. (1984) have been calculated from representations of the Helmholtz function.

Thermodynamic Data Retrieval

Tabular presentations of pressure, specific volume, and temperature are available for practically important gases and liquids. The tables normally include other properties useful for thermodynamic analyses, such as internal energy, enthalpy, and entropy. The various *steam tables* included in the references of this chapter provide examples. Computer software for retrieving the properties of a wide range of substances is also available, as, for example, the ASME Steam Tables (1993) and Bornakke and Sonntag (1996). Increasingly, textbooks come with computer disks providing thermodynamic property data for water, certain refrigerants, and several gases modeled as ideal gases — see, e.g., Moran and Shapiro (1996).

The sample *steam table* data presented in Table 2.6 are representative of data available for substances commonly encountered in mechanical engineering practice. Table A.5 and Figure 2.7 to Figure 2.9 provide *steam table* data for a greater range of states. The form of the tables and figures, and how they are used are assumed to be familiar. In particular, the use of *linear interpolation* with such tables is assumed known.

Specific internal energy, enthalpy, and entropy data are determined relative to arbitrary datums and such datums vary from substance to substance. Referring to Table 2.6a, the datum state for the specific internal energy and specific entropy of water is seen to correspond to saturated liquid water at 0.01°C (32.02°F), the triple point temperature. The value of each of these properties is set to zero at this state. If calculations are performed involving only differences in a particular specific property, the datum cancels. When there are changes in chemical composition during the process, special care should be exercised. The approach followed when composition changes due to chemical reaction is considered in Section 2.4.

Liquid water data (see Table 2.6d) suggests that at fixed temperature the variation of specific volume, internal energy, and entropy with pressure is slight. The variation of specific enthalpy with pressure at fixed temperature is somewhat greater because pressure is explicit in the definition of enthalpy. This behavior for v, u, s, and h is exhibited generally by liquid data and provides the basis for the following set of equations for estimating property data at liquid states from saturated liquid data:

$$v(T,p) \approx v_\mathrm{f}(T) \tag{2.50a}$$

$$u(T,p) \approx u_\mathrm{f}(T) \tag{2.50b}$$

$$h(T,p) \approx h_f(T) + \underline{v_\mathrm{f}\left[p - p_{sat}(T)\right]} \tag{2.50c}$$

$$s(T,p) \approx s_\mathrm{f}(T) \tag{2.50d}$$

As before, the subscript f denotes the saturated liquid state at the temperature T, and p_{sat} *is* the corresponding saturation pressure. The underlined term of Equation 2.50c is often negligible, giving $h(T, p) \approx h_\mathrm{f}(\mathrm{T})$, which is used in Example 3 to evaluate h_1.

In the absence of saturated liquid data, or as an alternative to such data, the *incompressible model* can be employed:

$$\text{Incompressible model: } \begin{cases} v = \text{constant} \\ u = u(T) \end{cases} \tag{2.51}$$

Source: Moran, M.J. and Shapiro, H.N. 1995. *Fundamentals of Engineering Thermodynamics*, 3rd ed. Wiley, New York, as extracted from Keenan, J. H., Keyes, F.G., Hill, P.G., and Moore, J.G. 1969. *Steam Tables*. Wiley, New York.

This model is also applicable to solids. Since internal energy varies only with temperature, the specific heat c_v is also a function of only temperature: $c_v(T) = du/dT$. Although specific volume is constant, enthalpy varies with both temperature and pressure, such that

$$h(T,p) = u(T) + pv \tag{2.52}$$

Differentiation of Equation 2.52 with respect to temperature at fixed pressure gives $c_p = c_v$. The common specific heat is often shown simply as c. Specific heat and density data for several liquids and solids are provided in Table B.2, Table C.1, and Table C.2. As the variation of c with temperature is slight, c is frequently taken as constant.

When the incompressible model is applied. Equation 2.49 takes the form

$$\begin{aligned} h_2 - h_1 &= \int_{T_1}^{T_2} c(T)dT + v(p_2 - p_1) \\ &= c_{ave}(T_2 - T_1) + v(p_2 - p_1) \end{aligned} \tag{2.53}$$

Also, as Equation 2.32a reduces to $du = Tds$, and $du = c(T)dT$, the change in specific entropy is

$$\begin{aligned} \Delta s &= \int_{T_1}^{T_2} \frac{c(T)}{T} dT \\ &= c_{ave} \ln \frac{T_2}{T_1} \end{aligned} \tag{2.54}$$

Ideal Gas Model

Inspection of the generalized compressibility chart, Figure 2.10, shows that when p_R is small, and for many states when T_R is large, the value of the compressibility factor Z is close to 1. In other words, for pressures that are low relative to p_c, and for many states with temperatures high relative to T_c, the compressibility factor approaches a value of 1. Within the indicated limits, it may be assumed with reasonable accuracy that $Z = 1$ — that is,

$$p\bar{v} = \bar{R}T \quad \text{or} \quad pv = RT \tag{2.55a}$$

where $R = \bar{R}/\mathcal{M}$ is the *specific* gas constant. Other forms of this expression in common use are

$$pV = n\bar{R}T, \qquad pV = mRT \tag{2.55b}$$

Referring to Equation 3′ of Table 2.5, it can be concluded that $(\partial u/\partial v)_T$ vanishes identically for a gas whose equation of state is *exactly* given by Equation 2.55, and thus the specific internal energy depends only on temperature. This conclusion is supported by experimental observations beginning with the work of Joule, who showed that the internal energy of air at low density depends primarily on temperature.

These considerations allow for an *ideal gas model* of each real gas: (1) the equation of state is given by Equation 2.55 and (2) the internal energy and enthalpy are functions of temperature alone. The real gas approaches the model in the limit of low reduced pressure. At other states the actual behavior may depart substantially from the predictions of the model. Accordingly, caution should be exercised when invoking the ideal gas model lest significant error is introduced.

Specific heat data for gases can be obtained by direct measurement. When extrapolated to zero pressure, ideal gas-specific heats result. Ideal gas-specific heats also can be calculated using molecular models of

TABLE 2.7 Ideal Gas Expressions for Δh, Δu, and Δs

Variable Specific Heats		Constant Specific Heats	
$h(T_2) - h(T_1) = \int_{T_1}^{T_2} c_p(T)dT$	(1)	$h(T_2) - h(T_1) = c_p(T_2 - T_1)$	(1′)
$s(T_2, p_2) - s(T_1, p_1) = \int_{T_1}^{T_2} \frac{c_p(T)}{T} dT - R\ln\frac{p_2}{p_1}$	(2)	$s(T_2, p_2) - s(T_1, p_1) = c_p \ln\frac{T_2}{T_1} - R\ln\frac{p_2}{p_1}$	(2′)
$u(T_2) - u(T_1) = \int_{T_1}^{T_2} c_v(T)dT$	(3)	$u(T_2) - u(T_1) = c_v(T_2 - T_1)$	(3′)
$s(T_2, v_2) - s(T_1, v_1) = \int_{T_1}^{T_2} \frac{c_v(T)}{T} dT + R\ln\frac{v_2}{v_1}$	(4)	$s(T_2, v_2) - s(T_1, v_1) = c_v \ln\frac{T_2}{T_1} + R\ln\frac{v_2}{v_1}$	(4′)
$s_2 = s_1$		$s_2 = s_1$	
$\frac{p_r(T_2)}{p_r(T_1)} = \frac{p_2}{p_1}$	(5)	$\frac{T_2}{T_1} = \left(\frac{p_2}{p_1}\right)^{(k-1)/k}$	(5′)
$\frac{v_r(T_2)}{v_r(T_1)} = \frac{v_2}{v_1}$	(6)	$\frac{T_2}{T_1} = \left(\frac{v_1}{v_2}\right)^{k-1}$	(6′)

matter together with data from spectroscopic measurements. Table A.9 provides ideal gas-specific heat data for a number of substances. The following ideal gas-specific heat relations are frequently useful:

$$c_p(T) = c_v(T) + R \tag{2.56a}$$

$$c_p = \frac{kR}{k-1}, \quad c_v = \frac{R}{k-1} \tag{2.56b}$$

where $k = c_p/c_v$.

With the ideal gas model, Equation 1 to Equation 4 of Table 2.5 give Equation 1 to Equation 4 of Table 2.7, respectively. Equation 2 of Table 2.7 can be expressed alternatively using $s°(T)$ defined by

$$s°(T) \equiv \int_0^T \frac{c_p(T)}{T} dT \tag{2.57}$$

as

$$s(T_2, p_2) - s(T_1, p_1) = s°(T_2) - s°(T_1) - R\ln\frac{p_2}{p_1} \tag{2.58}$$

Expressions similar in form to Equation 2.56 to Equation 2.68 can be written on a molar basis.

For processes of an ideal gas between states having the same specific entropy, $s_2 = s_1$, Equation 2.58 gives

$$\frac{p_2}{p_1} = \frac{\exp\left[s°(T_2)/R\right]}{\exp\left[s°(T_1)/R\right]}$$

or with $p_r = \exp[s°(T)/R]$

$$\frac{p_2}{p_1} = \frac{p_r(T_2)}{p_r(T_1)} \qquad (s_2 = s_1) \tag{2.59a}$$

A relation between the specific volume and temperatures for two states of an ideal gas having the same specific entropy can also be developed:

$$\frac{v_2}{v_1} = \frac{v_r(T_2)}{v_r(T_1)} \qquad (s_2 = s_1) \tag{2.59b}$$

Equations 2.59 are listed in Table 2.7 as Equation 5 and Equation 6, respectively.

Table A.8 provides a tabular display of h, u, $s°$, p_r, and v_r vs. temperature for air as an ideal gas. Tabulations of $\bar{h}$, $\bar{u}$, and $\bar{s}°$ for several other common gases are provided in Table A.2. Property retrieval software also provides such data; see, e.g., Moran and Shapiro (1996). The use of data from Table A.8 for the nozzle of Example 2 is illustrated in Example 7.

When the ideal gas-specific heats are assumed constant, Equation 1 to Equation 6 of Table 2.7 become Equation 1′ to Equation 6′, respectively. The specific heat c_p is taken as constant in Example 2.

Example 7

Using data from Table A.8, evaluate the exit velocity for the nozzle of Example 2 and compare with the exit velocity for an isentropic expansion to 15 lbf/in.^{2}.

Solution. The exit velocity is given by Equation 2.27f

$$\mathrm{v}_e = \sqrt{\mathrm{v}_i^2 + 2(h_i - h_e)}$$

At 960 and 520°R, Table A.8 gives, respectively, h_i = 231.06 Btu/lb and h_e = 124.27 Btu/lb. Then

$$\mathrm{v}_e = \sqrt{\left(\frac{10\ \text{ft}}{s}\right)^2 + 2(231.06 - 124.27)\left(\frac{\text{Btu}}{\text{lb}}\right)\left(\frac{778.17\ \text{ft}\cdot\text{lbf}}{1\ \text{Btu}}\right)\left(\frac{32.174\ \text{lb}\cdot\text{ft/sec}^2}{1\ \text{lbf}}\right)}$$
$$= 2312.5\ \text{ft sec}$$

Using Equation 2.59a and p_r data from Table A.8, the specific enthalpy at the exit for an isentropic expansion is found as follows:

$$p_r(T_e) = p_r(T_i)\frac{p_e}{p_i} = 10.61\left(\frac{15}{150}\right) = 1.061$$

Interpolating with p_r data, h_e = 119.54 Btu/lb. With this, the exit velocity is 2363.1 ft/sec. The actual exit velocity is about 2% less than the velocity for an isentropic expansion, the maximum theoretical value. In this particular application, there is good agreement in each case between velocities calculated using Table A.8 data and, as in Example 2, assuming c_p constant. Such agreement cannot be expected generally, however. See, for example, the Brayton cycle data of Table 2.15.

Polytropic Processes

An internally reversible process described by the expression pv^n = constant is called a *polytropic process* and n *is* the *polytropic exponent.* Although this expression can be applied with real gas data, it most generally appears in practice together with the use of the ideal gas model. Table 2.8 provides several expressions applicable to polytropic processes and the special forms they take when the ideal gas model is assumed. The expressions for $\int p dv$ and $\int v dp$ have application to work evaluations with Equation 2.10 and Equation 2.30, respectively. In some applications it may be appropriate to determine n by fitting pressure-specific volume data.

Example 8 illustrates both the polytropic process and the reduction in the compressor work achievable by cooling a gas as it is compressed.

TABLE 2.8 Polytropic Processes: pv^n = Constant[a]

General		Ideal Gas[b]	
$\frac{p_2}{p_1}=\left(\frac{v_1}{v_2}\right)^n$	(1)	$\frac{p_2}{p_1}=\left(\frac{v_1}{v_2}\right)^n=\left(\frac{T_2}{T_1}\right)^{n/(n-1)}$	(1′)

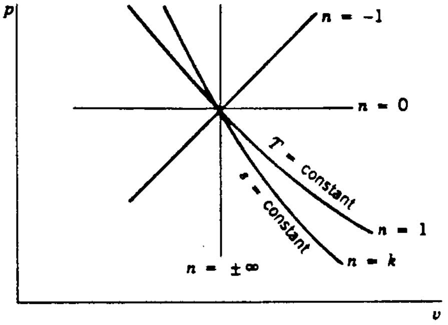
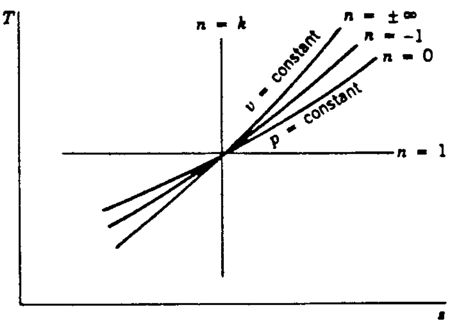
---

[a] For polytropic processes of closed systems where volume change is the only work mode, Equation 2, Equation 4, and Equation 2′, Equation 4′ are applicable with Equation 2.10 to evaluate the work. When each unit of mass passing through a one-inlet, one-exit control volume at steady state undergoes a polytropic process, Equation 3, Equation 5, and Equation 3′, Equation 5′ are applicable with Equation 2.30a and Equation 2.30b to evaluate the power. Also note that generally, $-\int_1^2 v\,dp = n\int_1^2 p\,dv$.

[b]





Example 8

A compressor operates at steady state with air entering at 1 bar, 20°C and exiting at 5 bar. (a) If the air undergoes a polytropic process with $n = 1.3$, determine the work and heat transfer, each in kJ/kg of air flowing. Repeat for (b) an isothermal compression and (c) an isentropic compression.

Solution. Using Equation 5′ of Table 2.8 together with Equation 2.30b,

$$\frac{\dot{W}_{cv}}{\dot{m}} = \frac{nRT_1}{n-1}\left[1 - \left(\frac{p_2}{p_1}\right)^{(n-1)/n}\right]$$

$$= \left(\frac{1.3}{0.3}\right)\left(\frac{8.314}{28.97}\frac{\text{kJ}}{\text{kg}\cdot\text{K}}\right)(293\ \text{K})\left[1-(5)^{0.3/1.3}\right]$$

$$= -163.9\ \frac{\text{kJ}}{\text{kg}}$$

(The area behind process 1-2 of Figure 2.11, area 1-2-a-b, represents the magnitude of the work required, per unit mass of air flowing.) Also, Equation 1′ of Table 2.8 gives T_2 = 425 K.

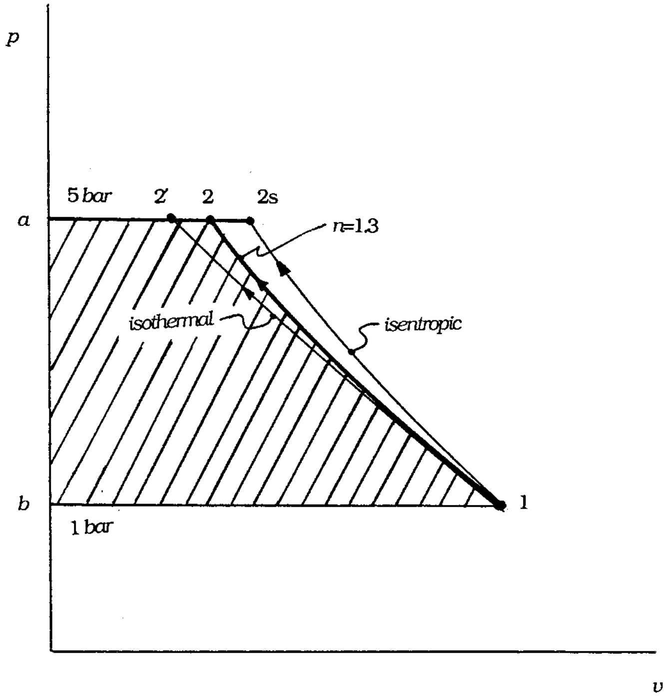


FIGURE 2.11 Internally reversible compression processes.

An energy rate balance at steady state and enthalpy data from Table A.8 gives

$$\frac{\dot{Q}_{cv}}{\dot{m}} = \frac{\dot{W}_{cv}}{\dot{m}} + h_2 - h_1$$

$$= -163.9 + (426.3 - 293.2) = -30.8\frac{\text{kJ}}{\text{kg}}$$

(b) Using Equation 3′ of Table 2.8 together with Equation 2.30b,

$$\frac{\dot{W}_{cv}}{\dot{m}} = -RT\ln\frac{p_2}{p_1}$$

$$= -\left(\frac{8.314}{28.97}\right)(293)\ln 5$$

$$= -135.3\frac{\text{kJ}}{\text{kg}}$$

Area 1-2′-*a*-*b* on Figure 2.11 represents the magnitude of the work required, per unit of mass of air flowing. An energy balance reduces to give $\dot{Q}_{cv}/\dot{m} = \dot{W}_{cv}/\dot{m} = -135.3$ kJ/kg. (c) For an isentropic compression, $\dot{Q}_{cv} = 0$ and an energy rate balance reduces to give $\dot{W}_{cv}/\dot{m} = -(h_{2s} - h_1)$, where 2*s* denotes the exit state. With Equation 2.59a and p_r data, $h_{2s} = 464.8$ kJ/kg ($T_{2s} = 463$K). Then $\dot{W}_{cv}/\dot{m} = -(464.8 - 293.2) = -171.6$ kJ/kg. Area 1-2s-*a*-*b* on Figure 2.11 represents the magnitude of the work required, per unit of mass of air flowing.

Ideal Gas Mixtures

When applied to an ideal gas mixture, the additive pressure rule (Section 2.3, *p*-*v*-*T* Relations) is known as the *Dalton model.* According to this model, each gas in the mixture acts as if it exists separately at the volume and temperature of the mixture. Applying the ideal gas equation of state to the mixture as a whole and to each component *i*, $pV = n\bar{R}T$, $p_iV = n_i\bar{R}T$, where p_i, the *partial pressure* of component *i*, is the pressure that component *i* would exert if n_i moles occupied the full volume *V* at the temperature *T*. Forming a ratio, the partial pressure of component *i* is

$$p_i = \frac{n_i}{n}p = y_i p \tag{2.60}$$

where y_i is the mole fraction of component *i*. The sum of the partial pressures equals the mixture pressure.

The internal energy, enthalpy, and entropy of the mixture can be determined as the sum of the respective properties of the component gases, provided that the contribution from each gas is evaluated at the condition at which the gas exists in the mixture. On a *molar* basis,

$$U = \sum_{i=1}^{j} n_i\bar{u}_i \quad \text{or} \quad \bar{u} = \sum_{i=1}^{j} y_i\bar{u}_i \tag{2.61a}$$

$$H = \sum_{i=1}^{j} n_i\bar{h}_i \quad \text{or} \quad \bar{h} = \sum_{i=1}^{j} y_i\bar{h}_i \tag{2.61b}$$

$$S = \sum_{i=1}^{j} n_i\bar{s}_i \quad \text{or} \quad \bar{s} = \sum_{i=1}^{j} y_i\bar{s}_i \tag{2.61c}$$

The specific heats $\bar{c}_v$ and $\bar{c}_p$ for an ideal gas mixture in terms of the corresponding specific heats of the components are expressed similarly:

$$\bar{c}_v = \sum_{i=1}^{j} y_i\bar{c}_{vi} \tag{2.61d}$$

$$\bar{c}_p = \sum_{i=1}^{j} y_i\bar{c}_{pi} \tag{2.61e}$$

When working on a *mass* basis, expressions similar in form to Equations 2.61 can be written using *mass* and *mass fractions* in place of *moles* and *mole fractions*, respectively, and using u, h, s, c_p, and c_v in place of $\bar{u}, \bar{h}, \bar{s}, \bar{c}_p$, and $\bar{c}_V$, respectively.

The internal energy and enthalpy of an ideal gas depend only on temperature, and thus the $\bar{u}_i$ and $\bar{h}_i$ terms appearing in Equations 2.61 are evaluated at the temperature of the mixture. Since entropy depends on *two* independent properties, the $\bar{s}_i$ terms are evaluated either at the temperature and the partial pressure p_i of component i, or at the temperature and volume of the mixture. In the former case

$$\begin{aligned} S &= \sum_{i=1}^{j} n_i \bar{s}_i(T, p_i) \\ &= \sum_{i=1}^{j} n_i \bar{s}_i(T, x_i p) \end{aligned} \tag{2.62}$$

Inserting the expressions for H and S given by Equation 2.61b and Equation 2.61c into the Gibbs function, $G = H - TS$,

$$\begin{aligned} G &= \sum_{i=1}^{j} n_i \bar{h}_i(T) - T \sum_{i=1}^{j} n_i \bar{s}_i(T, p_i) \\ &= \sum_{i=1}^{j} n_i \bar{g}_i(T, p_i) \end{aligned} \tag{2.63}$$

where the molar-specific Gibbs function of component i is $g_i(T, p_i) = h_i(T) - Ts_i(T, p_i)$. The Gibbs function of i can be expressed alternatively as

$$\begin{aligned} \bar{g}_i(T, p_i) &= \bar{g}_i(T, p') + \bar{R}T \ln(p_i/p') \\ &= \bar{g}_i(T, p') + \bar{R}T \ln(x_i p/p') \end{aligned} \tag{2.64}$$

were p' is some specified pressure. Equation 2.64 is obtained by integrating Equation 2.32d at fixed temperature T from pressure p' to p_i.

Moist Air

An ideal gas mixture of particular interest for many practical applications is *moist air.* Moist air refers to a mixture of dry air and water vapor in which the dry air is treated as if it were a pure component. Ideal gas mixture principles usually apply to moist air. In particular, the *Dalton model is* applicable, and so the mixture pressure p is the sum of the partial pressures p_a and p_v of the dry air and water vapor, respectively.

Saturated air is a mixture of dry air and saturated water vapor. For saturated air, the partial pressure of the water vapor equals $p_{sat}(T)$, which is the saturation pressure of water corresponding to the dry-bulb (mixture) temperature T. The makeup of moist air can be described in terms of the *humidity ratio* (*specific humidity*) and the *relative humidity.* The bulb of a *wet-bulb thermometer* is covered with a wick saturated with liquid water, and the *wet-bulb* temperature of an air-water vapor mixture is the temperature indicated by such a thermometer exposed to the mixture.

When a sample of moist air is cooled at constant pressure, the temperature at which the sample becomes saturated is called the *dew point temperature.* Cooling below the dew point temperature results in the condensation of some of the water vapor initially present. When cooled to a final equilibrium state at a temperature below the dew point temperature, the original sample would consist of a gas phase of dry air and saturated water vapor in equilibrium with a liquid water phase.

Psychrometric charts are plotted with various moist air parameters, including the dry-bulb and wet-bulb temperatures, the humidity ratio, and the relative humidity, usually for a specified value of the mixture pressure such as 1 atm. Further discussion of moist air and related psychrometric principles and applications is provided in Chapter 9.

Generalized Charts for Enthalpy, Entropy, and Fugacity

The changes in enthalpy and entropy between two states can be determined in principle by correcting the respective property change determined using the ideal gas model. The corrections can be obtained, at least approximately, by inspection of the generalized enthalpy correction and entropy correction charts, Figure 2.12 and Figure 2.13, respectively. Such data are also available in tabular form (see, e.g., Reid and Sherwood, 1966) and calculable using a generalized equation for the compressibility factor (Reynolds, 1979). Using the superscript * to identify ideal gas property values, the changes in specific enthalpy and specific entropy between states 1 and 2 are

$$\bar{h}_2 - \bar{h}_1 = \underline{\bar{h}_2^* - \bar{h}_1^*} - \underline{\bar{R}T_c\left[\left(\frac{\bar{h}^* - \bar{h}}{\bar{R}T_c}\right)_2 - \left(\frac{\bar{h}^* - \bar{h}}{\bar{R}T_c}\right)_1\right]} \tag{2.65a}$$

$$\bar{s}_2 - \bar{s}_1 = \underline{\bar{s}_2^* - \bar{s}_1^*} - \underline{\bar{R}\left[\left(\frac{\bar{s}^* - \bar{s}}{\bar{R}}\right)_2 - \left(\frac{\bar{s}^* - \bar{s}}{\bar{R}}\right)_1\right]} \tag{2.65b}$$

The first underlined term on the right side of each expression represents the respective property change assuming ideal gas behavior. The second underlined term is the correction that must be applied to the ideal gas value to obtain the actual value. The quantities $(\bar{h}^* - \bar{h})/\bar{R}T_c$ *and* $(\bar{s}^* - \bar{s})/\bar{R}$ at state 1 would be read from the respective correction chart or table or calculated, using the reduced temperature T_{R1} and reduced pressure p_{R1} corresponding to the temperature T_1 and pressure p_1 at state 1, respectively. Similarly, $(\bar{h}^* - \bar{h})/\bar{R}T_c$ *and* $(\bar{s}^* - \bar{s})/\bar{R}$ at state 2 would be obtained using T_{R2} and p_{R2}. Mixture values for T_c and p_c determined by applying Kay's rule or some other mixture rule also can be used to enter the generalized enthalpy correction and entropy correction charts.

Figure 2.14 gives the *fugacity* coefficient, *f/p*, as a function of reduced pressure and reduced temperature. The fugacity *f* plays a similar role in determining the specific Gibbs function for a real gas as pressure plays for the ideal gas. To develop this, consider the variation of the specific Gibbs function with pressure at fixed temperature (from Table 2.2)

$$\left.\frac{\partial g}{\partial p}\right)_T = v$$

For an ideal gas, integration at fixed temperature gives

$$g^* = RT\ln p + C(T)$$

where $C(T)$ is a function of integration. To evaluate g for a real gas, fugacity replaces pressure,

$$g = RT\ln f + C(T)$$

In terms of the fugacity coefficient the departure of the real gas value from the ideal gas value at fixed temperature is then

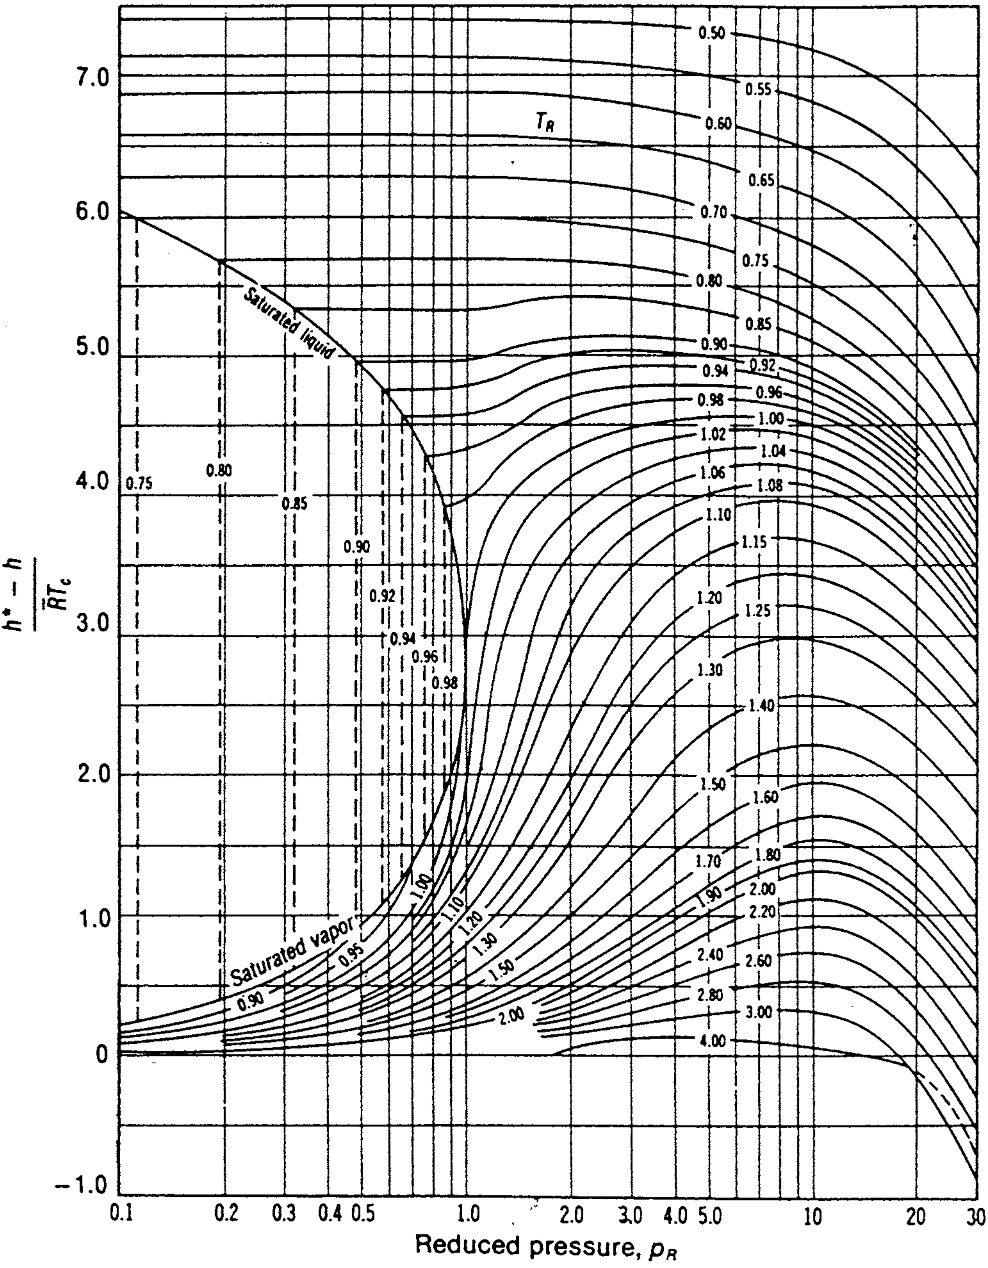

FIGURE 2.12 Generalized enthalpy correction chart. (*Source:* Adapted from Van Wylen, G. J. and Sonntag, R. E. 1986. *Fundamentals of Classical Thermodynamics*, 3rd ed., English/SI. Wiley, New York.)

$$g - g^* = RT \ln \frac{f}{p} \tag{2.66}$$

As pressure is reduced at fixed temperature, *f/p* tends to unity, and the specific Gibbs function is given by the ideal gas value.

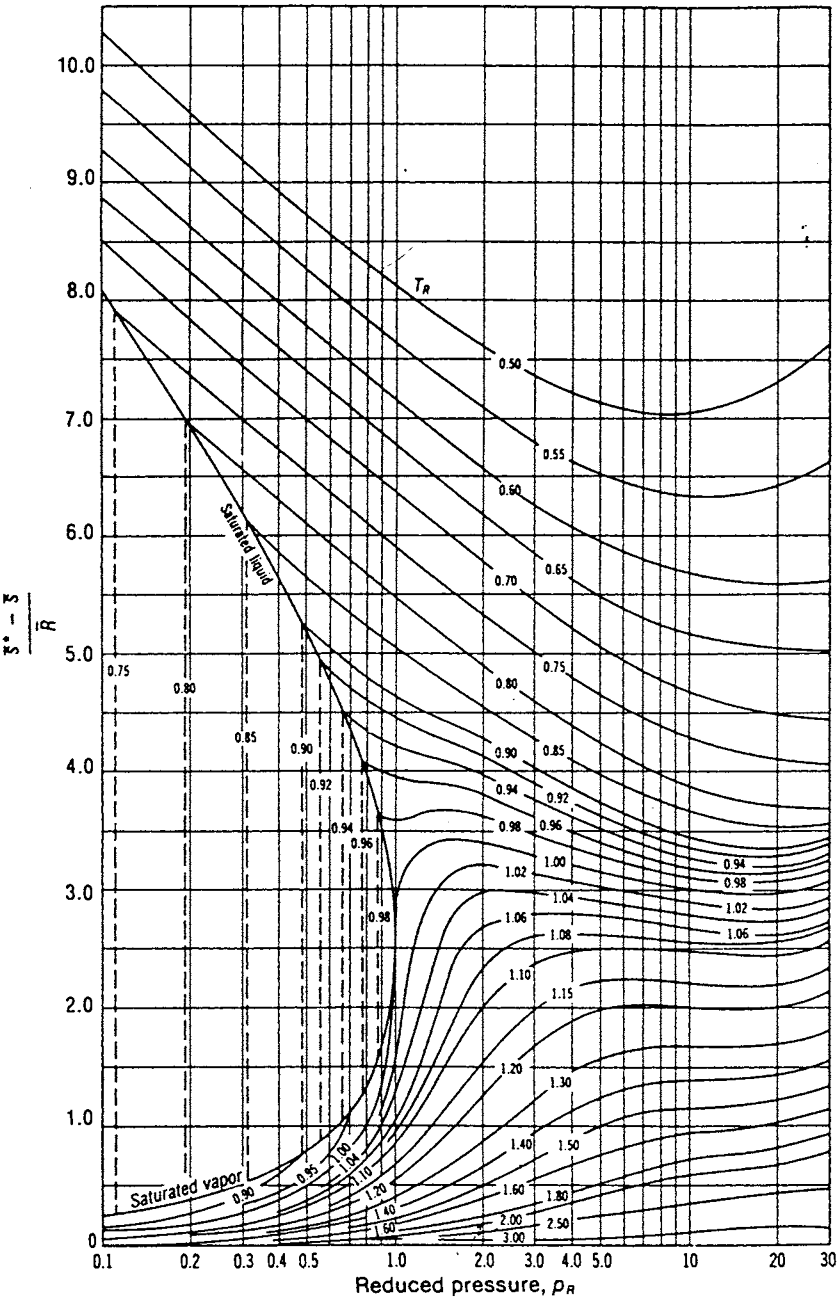

FIGURE 2.13 Generalized entropy correction chart. (*Source:* Adapted from Van Wylen, G. J. and Sonntag, R. E. 1986. *Fundamentals of Classical Thermodynamics*, 3rd ed., English/SI. Wiley, New York.)

Multicomponent Systems

In this section are presented some general aspects of the properties of multicomponent systems consisting of nonreacting mixtures. For a single phase *multicomponent* system consisting of *j* components, an extensive property *X* may be regarded as a function of temperature, pressure, and the number of moles

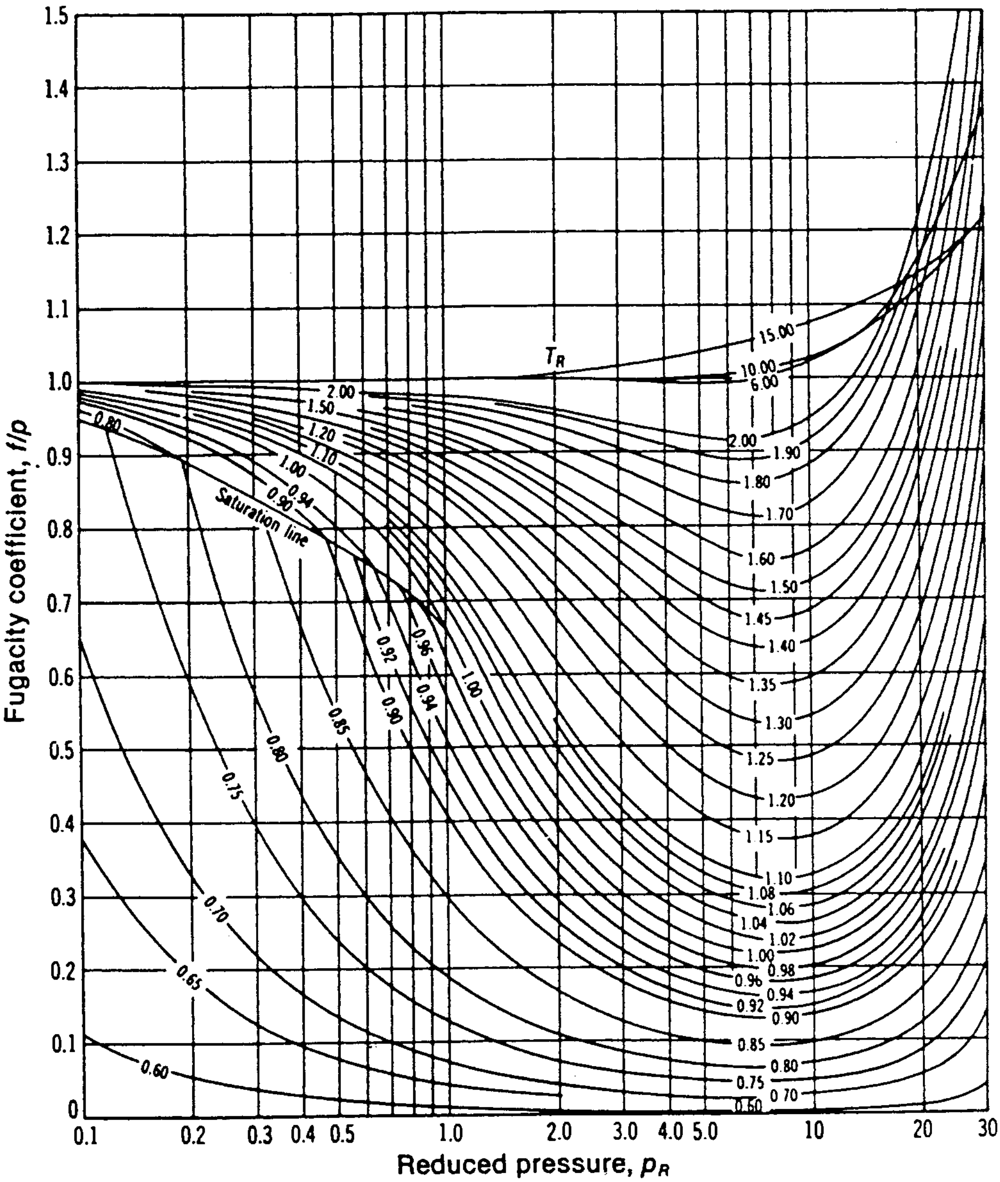

FIGURE 2.14 Generalized fugacity coefficient chart. (*Source:* Van Wylen, G. J. and Sonntag, R. E. 1986. *Fundamentals of Classical Thermodynamics*, 3rd ed., English/SI. Wiley, New York.)

of each component present in the mixture: $X = X(T, p, n_1, n_2, \ldots n_j)$. Since X is mathematically *homogeneous of degree one* in the n's, the function is expressible as

$$X = \sum_{i=1}^{j} n_i \overline{X}_i \tag{2.67}$$

where the *partial molar property* $\overline{X}_i$ is by definition

$$\overline{X}_i = \left.\frac{\partial X}{\partial n_i}\right)_{T,p,n_\ell} \tag{2.68}$$

and the subscript n_ℓ denotes that all n's except n_i are held fixed during differentiation. As $\overline{X}_i$ depends in general on temperature, pressure, and mixture composition: $\overline{X}_i\,(T, p, n_1, n_2, \ldots n_j)$, the partial molal property $\overline{X}_i$ is an intensive property of the mixture and not simply a property of the i*th* component.

Selecting the extensive property X to be volume, internal energy, enthalpy, entropy, and the Gibbs function, respectively, gives

$$\begin{aligned} V &= \sum_{i=1}^{j} n_i \overline{V}_i, \qquad & U &= \sum_{i=1}^{j} n_i \overline{U}_i \\ H &= \sum_{i=1}^{j} n_i \overline{H}_i, \qquad & S &= \sum_{i=1}^{j} n_i \overline{S}_i \\ G &= \sum_{i=1}^{j} n_i \overline{G}_i \end{aligned} \tag{2.69}$$

where $\overline{V}_i, \overline{U}_i, \overline{H}_i, \overline{S}_i$, and $\overline{G}_i$ denote the respective partial molal properties.

When pure components, each initially at the same temperature and pressure, are mixed, the changes in volume, internal energy, enthalpy, and entropy on mixing are given by

$$\Delta V_{\text{mixing}} = \sum_{i=1}^{j} n_i \left(\overline{V}_i - \bar{v}_i\right) \tag{2.70a}$$

$$\Delta U_{\text{mixing}} = \sum_{i=1}^{j} n_i \left(\overline{U}_i - \bar{u}_i\right) \tag{2.70b}$$

$$\Delta H_{\text{mixing}} = \sum_{i=1}^{j} n_i \left(\overline{H}_i - \bar{h}_i\right) \tag{2.70c}$$

$$\Delta S_{\text{mixing}} = \sum_{i=1}^{j} n_i \left(\overline{S}_i - \bar{s}_i\right) \tag{2.70d}$$

where $\bar{v}_i, \bar{u}_i, \bar{h}_i$, and $\bar{s}_i$ denote the molar-specific volume, internal energy, enthalpy, and entropy of pure component i.

Chemical Potential

The partial molal Gibbs function of the ith component of a multicomponent system is the *chemical potential*, μ_i,

$$\mu_i = \overline{G}_i = \left.\frac{\partial G}{\partial n_i}\right)_{T,p,n_\ell} \tag{2.71}$$

Like temperature and pressure, the chemical potential, μ_i is an *intensive* property.

When written in terms of chemical potentials, Equation 2.67 for the Gibbs function reads

$$G = \sum_{i=1}^{j} n_i \mu_i \tag{2.72}$$

For a *single component sysrem*, Equation 2.72 reduces to $G = n\mu$; that is, the chemical potential equals the molar Gibbs function. For an ideal gas mixture, comparison of Equation 2.63 and Equation 2.72 suggests $\mu_i = \bar{g}_i\ (T, p_i)$; that is, the chemical potential of component i in an ideal gas mixture equals its Gibbs function per mole of gas i evaluated at the mixture temperature and the partial pressure of the ith gas of the mixture.

The chemical potential is a measure of the *escaping tendency* of a substance in a multiphase system: a substance tends to move from the phase having the higher chemical potential for that substance to the phase having a lower chemical potential. A necessary condition for *phase equilibrium is* that the chemical potential of each component has the same value in every phase.

The *Gibbs phase rule* gives the number F of independent intensive properties that may be arbitrarily specified to fix the intensive state of a system at equilibrium consisting of N nonreacting components present in P phases: $F = 2 + N - P$. F is called the *degrees of freedom* (or the *variance*). For water as a single component, for example, $N = 1$ and $F = 3 - P$.

- For a single phase, $P = 1$ and $F = 2$: two intensive properties can be varied independently, say temperature *and* pressure, while maintaining a single phase.
- For two phases, $P = 2$ and $F = 1$: only one intensive property can be varied independently if two phases are maintained — for example, temperature *or* pressure.
- For three phases, $P = 3$ and $F = 0$: there are no degrees of freedom; each intensive property of each phase is fixed. For a system consisting of ice, liquid water, and water vapor at equilibrium, there is a unique temperature: 0.01°C (32.02°F) and a unique pressure: 0.6113 kPa (0.006 atm).

The phase rule does not address the relative amounts that may be present in the various phases.

With $G = H - TS$ and $H = U + pV$, Equation 2.72 can be expressed as

$$U = TS - pV + \sum_{i=1}^{j} n_i \mu_i \tag{2.73}$$

from which can be derived

$$dU = TdS - pdV + \sum_{i=1}^{j} \mu_i dn_i \tag{2.74}$$

When the mixture composition is constant, Equation 2.74 reduces to Equation 2.31a.

Ideal Solution

The *Lewis-Randall rule* states that the fugacity $\bar{f}_i$ of each component i in an *ideal solution* is the product of its mole fraction and the fugacity of the pure component, f_i, at the same temperature, pressure, and state of aggregation (gas, liquid, or solid) as the mixture:

$$\bar{f}_i = y_i f_i \qquad \text{(Lewis-Randall rule)} \tag{2.75}$$

The following characteristics are exhibited by an ideal solution: $\bar{V}_i = \bar{v}_i, \bar{U}_i = \bar{u}_i, \bar{H}_i = \bar{h}_i$. With these, Equation 2.70a, Equation 2.70b, and Equation 2.70c show that there is no change in volume, internal energy, or enthalpy on mixing pure components to form an ideal solution. The *adiabatic* mixing of different pure components would result in an increase in entropy, however, because such a process is irreversible.

The volume of an ideal solution is

$$V = \sum_{i=1}^{j} n_i \bar{v}_i = \sum_{i=1}^{j} V_i \qquad \text{(ideal solution)} \tag{2.76}$$

where V_i is the volume that pure component i would occupy when at the temperature and pressure of the mixture. Comparing Equation 2.48a and Equation 2.76, the *additive volume rule* is seen to be exact for ideal solutions. The internal energy and enthalpy of an ideal solution are

$$U = \sum_{i=1}^{j} n_i \bar{u}_i, \quad H = \sum_{i=1}^{j} n_i \bar{h}_i \qquad \text{(ideal solution)} \tag{2.77}$$

where $\bar{u}_i$ and $\bar{h}_i$ denote, respectively, the molar internal energy and enthalpy of pure component i at the temperature and pressure of the mixture. Many gaseous mixtures at low to moderate pressures are adequately modeled by the Lewis Randall rule. The ideal gas mixtures considered in Section 2.3, Ideal Gas Model, is an important special case. Some liquid solutions also can be modeled with the Lewis-Randall rule.

2.4 Combustion

The thermodynamic analysis of reactive systems is primarily an extension of principles presented in Sections 2.1 to 2.3. It is necessary, though, to modify the methods used to evaluate specific enthalpy and entropy.

Reaction Equations

In combustion reactions, rapid oxidation of combustible elements of the fuel results in energy release as combustion products are formed. The three major combustible chemical elements in most common fuels are carbon, hydrogen, and sulfur. Although sulfur is usually a relatively unimportant contributor to the energy released, it can be a significant cause of pollution and corrosion.

The emphasis in this section is on hydrocarbon fuels, which contain hydrogen, carbon, sulfur, and possibly other chemical substances. Hydrocarbon fuels may be liquids, gases, or solids such as coal. Liquid hydrocarbon fuels are commonly derived from crude oil through distillation and cracking processes. Examples are gasoline, diesel fuel, kerosene, and other types of fuel oils. The compositions of liquid fuels are commonly given in terms of mass fractions. For simplicity in combustion calculations, gasoline is often considered to be octane, C_8H_{18}, and diesel fuel is considered to be dodecane, $C_{12}H_{26}$. Gaseous hydrocarbon fuels are obtained from natural gas wells or are produced in certain chemical processes. Natural gas normally consists of several different hydrocarbons, with the major constituent being methane, CH_4. The compositions of gaseous fuels are commonly given in terms of mole fractions. Both gaseous and liquid hydrocarbon fuels can be synthesized from coal, oil shale, and tar sands. The composition of coal varies considerably with the location from which it is mined. For combustion calculations, the makeup of coal is usually expressed as an *ultimate analysis* giving the composition on a mass basis in terms of the relative amounts of chemical elements (carbon, sulfur, hydrogen, nitrogen, oxygen) and ash. Coal combustion is considered further in Chapter 8, Energy Conversion.

A fuel is said to have burned *completely* if all of the carbon present in the fuel is burned to carbon dioxide, all of the hydrogen is burned to water, and all of the sulfur is burned to sulfur dioxide. In practice, these conditions are usually not fulfilled and combustion is *incomplete.* The presence of carbon monoxide (CO) in the products indicates incomplete combustion. The products of combustion of *actual* combustion reactions and the relative amounts of the products can be determined with certainty only by experimental means. Among several devices for the experimental determination of the composition of products of combustion are the *Orsat analyzer*, *gas chromatograph*, *infrared analyzer*, and *flame ionization detector*. Data from these devices can be used to determine the makeup of the gaseous products of combustion. Analyses are frequently reported on a "dry" basis: mole fractions are determined for all gaseous products as if no water vapor were present. Some experimental procedures give an analysis including the water vapor, however.

Since water is formed when hydrocarbon fuels are burned, the mole fraction of water vapor in the gaseous products of combustion can be significant. If the gaseous products of combustion are cooled at constant mixture pressure, the *dew point temperature* (Section 2.3, Ideal Gas Model) is reached when water vapor begins to condense. Corrosion of duct work, mufflers, and other metal parts can occur when water vapor in the combustion products condenses.

Oxygen is required in every combustion reaction. Pure oxygen is used only in special applications such as cutting and welding. In most combustion applications, air provides the needed oxygen. Idealizations are often used in combustion calculations involving air: (1) all components of air other than oxygen (O_2) *are* lumped with nitrogen (N_2). On a molar basis air is then considered to be 21% oxygen and 79% nitrogen. With this idealization the molar ratio of the nitrogen to the oxygen in combustion air is 3.76; (2) the water vapor present in air may be considered in writing the combustion equation or ignored. In the latter case the combustion air is regarded as *dry*; (3) additional simplicity results by regarding the nitrogen present in the combustion air as inert. However, if high-enough temperatures are attained, nitrogen can form compounds, often termed NO_X, such as nitric oxide and nitrogen dioxide. Even trace amounts of oxides of nitrogen appearing in the exhaust of internal combustion engines can be a source of air pollution.

The minimum amount of air that supplies sufficient oxygen for the complete combustion of all the combustible chemical elements is the *theoretical*, or *stoichiometic*, amount of air. In practice, the amount of air actually supplied may be greater than or less than the theoretical amount, depending on the application. The amount of air is commonly expressed as the *percent of theoretical air* or the *percent excess* (or *percent deficiency*) of air. The *air-fuel ratio* and its reciprocal *the fuel-air ratio*, each of which can be expressed on a mass or molar basis, are other ways that fuel-air mixtures are described. Another is the *equivalence ratio:* the ratio of the actual fuel-air ratio to the fuel-air ratio for complete combustion with the theoretical amount of air. The reactants form a *lean* mixture when the equivalence ratio is less than unity and a *rich* mixture when the ratio is greater than unity.

Example 9

Methane, CH_4, is burned with dry air. The molar analysis of the products on a dry basis is CO_2, 9.7%; CO, 0.5%; O_2, 2.95%; and N_2, 86.85%. Determine (a) the air-fuel ratio on both a molar and a mass basis, (b) the percent of theoretical air, (c) the equivalence ratio, and (d) the dew point temperature of the products, in °F, if the pressure is 1 atm.

Solution.

(a) The solution is conveniently conducted on the basis of 100 lbmol of dry products. The chemical equation then reads

$$a\mathrm{CH_4} + b\left(\mathrm{O_2} + 3.76\mathrm{N_2}\right) \rightarrow 9.7\mathrm{CO_2} + 0.5\mathrm{CO} + 2.95\mathrm{O_2} + 86.85\mathrm{N_2} + c\mathrm{H_2O}$$

where N_2 is regarded as inert. Water is included in the products together with the assumed 100 lbmol of dry products. Balancing the carbon, hydrogen, and oxygen, the reaction equation is

$$10.2\mathrm{CH_4} + 23.1\left(\mathrm{O_2} + 3.76\mathrm{N_2}\right) \rightarrow 9.7\mathrm{CO_2} + 0.5\mathrm{CO} + 2.95\mathrm{O_2} + 86.85\mathrm{N_2} + 20.4\mathrm{H_2O}$$

The nitrogen also balances, as can be verified. This checks the accuracy of both the given product analysis and the calculations conducted to determine the unknown coefficients. Exact closure cannot be expected with measured data, however. On a molar basis, the air-fuel ratio is

$$\overline{\text{AF}} = \frac{23.1(4.76)}{10.2} = 10.78\frac{\text{lbmol(air)}}{\text{lbmol(fuel)}}$$

On a mass basis

$$\text{AF} = (10.78)\left(\frac{28.97}{16.04}\right) = 19.47\frac{\text{lb(air)}}{\text{lb(fuel)}}$$

(b) The balanced chemical equation for the complete combustion of methane with the *theoretical* amount of air is

$$CH_4 + 2(O_2 + 3.76N_2) \rightarrow CO_2 + 2H_2O + 7.52N_2$$

The theoretical air-fuel ratio on a molar basis is

$$\left(\overline{\text{AF}}\right)_{theo} = \frac{2(4.76)}{1} = 9.52\frac{\text{lbmol(air)}}{\text{lbmol(fuel)}}$$

The percent theoretical air is then

$$\begin{aligned}\%\text{ theoretical air} &= \frac{\left(\overline{\text{AF}}\right)}{\left(\overline{\text{AF}}\right)_{theo}} \\ &= \frac{10.78}{9.52} = 1.13(113\%)\end{aligned}$$

(c) Equivalence ratio = $(\overline{FA})/(\overline{FA})_{theo}$ = 9.52/10.78 = 0.88. The reactants form a lean mixture.

(d) To determine the dew point temperature requires the partial pressure p_v of the water vapor. The mole fraction of the water vapor is

$$y_v = \frac{20.4}{100 + 20.4} = 0.169$$

Since $p = 1$ atm, $p_v = 0.169$ atm = 2.48 lbf/in.^{2}. With $p_{sat} = 2.48$ lbf/in.^{2}, the corresponding saturation temperature from the steam tables is 134°F. This is the dew point temperature.

Property Data for Reactive Systems

Tables of thermodynamic properties such as the steam tables provide values for the specific enthalpy and entropy relative to some arbitrary datum state where the enthalpy (or alternatively the internal energy) and entropy are set to zero. When a chemical reaction occurs, however, reactants disappear and products are formed, and it is generally no longer possible to evaluate $\Delta\bar{h}$ and $\Delta\bar{s}$ so that these arbitrary datums cancel. Accordingly, special means are required to assign specific enthalpy and entropy for application to reacting systems.

Property data suited for the analysis of reactive systems are available from several sources. The encyclopedic *JANAF Thermochemical Tables* is commonly used. Data for a wide range of substances are retrievable from Knacke et al. (1991), which provides both tabular data and analytical expressions readily programmable for use with personal computers of the specific heat, enthalpy, entropy, and Gibbs function. Textbooks on engineering thermodynamics also provide selected data, as, for example, Moran and Shapiro (1995).

Enthalpy of Formation

An enthalpy datum for reacting systems can be established by assigning arbitrarily a value of zero to the enthalpy of the *stable elements* at a *standard reference state* where the temperature is $T_{ref} = 298.15$ K (25°C) and the pressure is p_{ref}, which may be 1 bar or 1 atm depending on the data source. The term stable simply means that the particular element is chemically stable. For example, at the standard state the stable forms of hydrogen, oxygen, and nitrogen are H_2, O_2, and N_2 and not the monatomic H, O, and N.

The molar enthalpy of a *compound* at the standard state equals its *enthalpy of formation*, symbolized here by $\bar{h}_f^\circ$. The enthalpy of formation is the energy released or absorbed when the compound is formed from its elements, the compound and elements all being at T_{ref} and p_{ref}. The enthalpy of formation may be determined by application of procedures from statistical thermodynamics using observed spectroscopic data. The enthalpy of formation also can be found in principle by measuring the heat transfer in a reaction in which the compound is formed from the elements. In this chapter, the superscript ° is used to denote p_{ref}. For the case of the enthalpy of formation, the reference temperature T_{ref} is also intended by this symbol. Table 2.9 gives the values of the enthalpy of formation of various substances at 298 K and 1 atm.

The molar enthalpy of a substance at a state other than the standard state is found by adding the molar enthalpy change $\Delta\bar{h}$ between the standard state and the state of interest to the molar enthalpy of formation:

$$\bar{h}(T,p) = \bar{h}_f^\circ + \left[\bar{h}(T,p) - \bar{h}\left(T_{ref}, p_{ref}\right)\right] = \bar{h}_f^\circ + \Delta\bar{h} \tag{2.78}$$

That is, the enthalpy of a substance is composed of $\bar{h}_f^\circ$, associated with the formation of the substance from its elements, and $\Delta\bar{h}$, associated with a change of state at constant composition. An arbitrarily chosen datum can be used to determine $\Delta\bar{h}$, since it is a *difference* at constant composition. Accordingly, $\Delta\bar{h}$ can be evaluated from sources such as the steam tables and the ideal gas tables.

The *enthalpy of combustion*, $\bar{h}_{RP}$, is the difference between the enthalpy of the products and the enthalpy of the reactants, each on a per-mole-of-fuel basis, when complete combustion occurs and both reactants and products are at the same temperature and pressure. For hydrocarbon fuels the enthalpy of combustion is negative in value since chemical internal energy is liberated in the reaction. The *heating value* of a fuel is a positive number equal to the magnitude of the enthalpy of combustion. Two heating values are recognized: the *higher* heating value and the *lower* heating value. The higher heating value is obtained when all the water formed by combustion is a liquid; the lower heating value is obtained when all the water formed by combustion is a vapor. The higher heating value exceeds the lower heating value by the energy that would be required to vaporize the liquid water formed at the specified temperature. Heating values are typically reported at a temperature of 25°C (77°F) and a pressure of 1 bar (or 1 atm). These values also depend on whether the fuel is a liquid or a gas. A sampling is provided on a unit-mass-of-fuel basis in Table 2.10.

In the absence of work $\dot{W}_{cv}$ and appreciable kinetic and potential energy effects, the energy liberated on combustion is transferred from a reactor at steady state in two ways: the energy accompanying the exiting combustion products and by heat transfer. The temperature that would be achieved by the products in the limit of adiabatic operation is the *adiabatic flame* or *adiabatic combustion* temperature.

For a specified fuel and specified temperature and pressure of the reactants, the *maximum* adiabatic flame temperature is realized for complete combustion with the theoretical amount of air. Example 10 provides an illustration. The measured value of the temperature of the combustion products may be several hundred degrees below the calculated maxunum adiabatic flame temperature, however, for several reasons including the following: (1) heat loss can be reduced but not eliminated; (2) once adequate oxygen has been provided to permit complete combustion, bringing in more air dilutes the combustion products, lowering the temperature; (3) incomplete combustion tends to reduce the temperature of the products, and combustion is seldom complete; (4) as result of the high temperatures achieved, some of the combustion products may dissociate. Endothermic dissociation reactions also lower the product temperature.

TABLE 2.9 Enthalpy of Formation, Gibbs Function of Formation, and Absolute Entropy of Various Substances at 298 K and 1 atm

$\bar{h}_f^\circ$ and $\bar{g}_f^\circ$ (kJ/kmol), $\bar{s}^\circ$ (kJ/kmol•K)

Substance	Formula	$\bar{h}_f^\circ$	$\bar{g}_f^\circ$	$\bar{s}^\circ$

Absolute Entropy

A common datum for assigning entropy values to substances involved in chemical reactions is realized through the *third law* of thermodynamics, which is based on experimental observations obtained primarily from studies of chemical reactions at low temperatures and specific heat measurements at temperatures approaching absolute zero. The third law states that the entropy of a pure crystalline substance is zero at the absolute zero of temperature, 0 K or 0°R. Substances not having a pure crystalline structure have a nonzero value of entropy at absolute zero.

The third law provides a datum relative to which the entropy of each substance participating in a reaction can be evaluated. The entropy relative to this datum is called the *absolute* entropy. The change in entropy of a substance between absolute zero and any given state can be determined from measurements of energy transfers and specific heat data or from procedures based on statistical thermodynamics and observed molecular data. Table 2.9, Table A.2 and Table A.8 provide absolute entropy data for various substances. In these tables, $p_{ref} = 1$ atm.

When the absolute entropy is known at pressure p_{ref} and temperature T, the absolute entropy at the same temperature and *any* pressure p can be found from

$$\bar{s}(T,p) = \bar{s}\left(T,p_{ref}\right) + \left[\bar{s}(T,p) - \bar{s}\left(T,p_{ref}\right)\right] \tag{2.79}$$

For an ideal gas, the second term on the right side of Equation 2.79 can be evaluated by using Equation 2.58, giving

$$\bar{s}(T,p) = \bar{s}^\circ(T) - \bar{R}\ln\frac{p}{p_{ref}} \qquad \text{(ideal gas)} \tag{2.80}$$

In this expression, $\bar{s}^\circ(T)$ denotes the absolute entropy at temperature T and pressure p_{ref}.

The entropy of the ith component of an *ideal gas mixture* is evaluated at the mixture temperature T and the *partial* pressure p_i: $\bar{s}_i(T, p_i)$. For the ith component, Equation 2.80 takes the form

$$\begin{aligned} \bar{s}_i\left(T,p_i\right) &= \bar{s}_i^\circ(T) - \bar{R}\ln\frac{p_i}{p_{ref}} \\ &= \bar{s}_i^\circ(T) - \bar{R}\ln\frac{y_i p}{p_{ref}} \qquad \text{(ideal gas)} \end{aligned} \tag{2.81}$$

where $\bar{s}_i^\circ(T)$ is the absolute entropy of component i at temperature T and p_{ref}.

Example 10

Liquid octane at 25°C, 1 atm enters a well insulated reactor and reacts with dry air entering at the same temperature and pressure. For steady-state operation and negligible effects of kinetic and potential energy, determine the temperature of the combustion products for complete combustion with the theoretical amount of air, and (b) the rates of entropy generation and exergy destruction, each per kmol of fuel.

Solution. For combustion of liquid octane with the theoretical amount of air, the chemical equation is

$$C_8H_{18}(l) + 12.5O_2 + 47N_2 \rightarrow 8CO_2 + 9H_2O(g) + 47N_2$$

(a) At steady state, the control volume energy rate balance reduces to read

$$0 = \cancel{\frac{\dot{Q}_{cv}}{\dot{n}_F}}^{\,0} - \cancel{\frac{\dot{W}_{cv}}{\dot{n}_F}}^{\,0} + \sum_R n_i\left(\bar{h}_f^\circ + \Delta\bar{h}\right)_i - \sum_P n_e\left(\bar{h}_f^\circ + \Delta\bar{h}\right)_e$$

where R denotes reactants, P denotes products, and the symbols for enthalpy have the same significance as in Equation 2.78. Since the reactants enter at 25°C, the corresponding $(\Delta\bar{h})_i$ terms vanish, and the energy rate equation becomes

$$\sum_P n_e\left(\Delta\bar{h}\right)_e = \sum_R n_i\bar{h}^\circ_{fi} - \sum_P n_e\bar{h}^\circ_{fe}$$

Introducing coefficients from the reaction equation, this takes the form

$$8\left(\Delta\bar{h}\right)_{CO_2} + 9\left(\Delta\bar{h}\right)_{H_2O(g)} + 47\left(\Delta\bar{h}\right)_{N_2} = \left[\left(\bar{h}^\circ_f\right)_{C_8H_{18}(l)} + 12.5\left(\bar{h}^\circ_f\right)_{O_2} + 47\left(\bar{h}^\circ_f\right)_{N_2}\right]$$

$$-\left[8\left(\bar{h}^\circ_f\right)_{CO_2} + 9\left(\bar{h}^\circ_f\right)_{H_2O(g)} + 47\left(\Delta\bar{h}^\circ_f\right)_{N_2}\right]$$

Using data from Table 2.9 to evaluate the right side,

$$8\left(\Delta\bar{h}\right)_{CO_2} + 9\left(\Delta\bar{h}\right)_{H_2O(g)} + 47\left(\Delta\bar{h}\right)_{N_2} = 5{,}074{,}630\ \text{kJ/kmol (fuel)}$$

Each $\Delta\bar{h}$ term on the left side of this equation depends on the temperature of the products, T_p, which can be solved for iteratively as $T_p = 2395$ K.

(b) The entropy rate balance on a per-mole-of-fuel basis takes the form

$$0 = \cancel{\sum_j \frac{\dot{Q}_j/T_j}{\dot{n}_F}}^{\,0} + \bar{s}_F + \left(12.5\bar{s}_{O_2} + 47\bar{s}_{N_2}\right) - \left(8\bar{s}_{CO_2} + 9\bar{s}_{H_2O(g)} + 47\bar{s}_{N_2}\right) + \frac{\dot{S}_{gen}}{\dot{n}_F}$$

or on rearrangement,

$$\frac{\dot{S}_{gen}}{\dot{n}_F} = \left(8\bar{s}_{CO_2} + 9\bar{s}_{H_2O(g)} + 47\bar{s}_{N_2}\right) - \bar{s}_F - \left(12.5\bar{s}_{O_2} + 47\bar{s}_{N_2}\right)$$

The absolute entropy of liquid octane from Table 2.9 is 360.79 kJ/mol · K. The oxygen and nitrogen in the combustion air enter the reactor as components of an ideal gas mixture at T_{ref}, p_{ref}. With Equation 2.81, where $p = p_{ref}$, and absolute entropy data from Table 2.9,

$$\begin{aligned}\bar{s}_{O_2} &= \bar{s}^\circ_{O_2}\left(T_{ref}\right) - \bar{R}\ln y_{O_2}\\ &= 205.03 - 8.314\ln 0.21 = 218.01\ \text{kJ/kmol}\cdot\text{K}\\ \bar{s}_{N_2} &= \bar{s}^\circ_{N_2}\left(T_{ref}\right) - \bar{R}\ln y_{N_2}\\ &= 191.5 - 8.314\ln 0.79 = 193.46\ \text{kJ/kmol}\cdot\text{K}\end{aligned}$$

The product gas exits as a gas mixture at 1 atm, 2395 K with the following composition: y_{CO_2} = 8/64 = 0.125, $y_{H_2O(g)}$ = 9/64 = 0.1406, y_{N_2} = 47/64 = 0.7344. With Equation 2.81, where $p = p_{ref}$, *an*d absolute entropy data at 2395 K from Table A.2,

$$\begin{aligned}\bar{s}_{CO_2} &= 320.173 - 8.314\ln 0.125 = 337.46\ \text{kJ/kmol}\cdot\text{K}\\ \bar{s}_{H_2O} &= 273.986 - 8.314\ln 0.1406 = 290.30\ \text{kJ/kmol}\cdot\text{K}\\ \bar{s}_{N_2} &= 258.503 - 8.314\ln 0.7344 = 261.07\ \text{kJ/kmol}\cdot\text{K}\end{aligned}$$

Inserting values, the rate of entropy generation is

$$\frac{\dot{S}_{gen}}{\dot{n}_F} = 8(337.46) + 9(290.30) + 47(261.07) - 360.79 - 12.5(218.01) - 47(193.46)$$

$$= 5404 \ \text{kJ/kmol} \cdot \text{K}$$

Using Equation 2.87 and assuming $T_0 = 298$ K, the rate of exergy destruction is $\dot{E}_D / \dot{n}_F = 1.61 \times 10^6$ kJ/kmol.

Gibbs Function of Formation

Paralleling the approach used for enthalpy, a value of zero is assigned to the Gibbs function of each stable element at the standard state. The *Gibbs function of formation* of a compound equals the change in the Gibbs function for the reaction in which the compound is formed from its elements. Table 2.9 provides Gibbs function of formation data of various substances at 298 K and 1 atm.

The Gibbs function at a state other than the standard state is found by adding to the Gibbs function of formation the change in the specific Gibbs function $\Delta\bar{g}$ between the standard state and the state of interest:

$$\bar{g}(T,p) = \bar{g}_f^\circ + \left[\bar{g}(T,p) - \bar{g}\left(T_{ref}, p_{ref}\right)\right] = \bar{g}_f^\circ + \Delta\bar{g} \tag{2.82a}$$

where

$$\Delta\bar{g} = \left[\bar{h}(T,p) - \bar{h}\left(T_{ref}, p_{ref}\right)\right] - \left[T\bar{s}(T,p) - T_{ref}\bar{s}\left(T_{ref}, p_{ref}\right)\right] \tag{2.82b}$$

The Gibbs function of component i in an ideal gas mixture is evaluated at the partial pressure of component i and the mixture temperature.

As an application, the maximum theoretical work that can be developed, per mole of fuel consumed, is evaluated for the control volume of Figure 2.15, where the fuel and oxygen each enter in separate streams and carbon dioxide and water each exit separately. All entering and exiting streams are at the same temperature T and pressure p. The reaction is complete:

$$C_aH_b + \left(a + \frac{b}{4}\right)\text{O}_2 \rightarrow a\text{CO}_2 + \frac{b}{2}\text{H}_2\text{O}$$

This control volume is similar to idealized devices such as a reversible fuel *cell* or a *van't Hoff equilibrium box.*

For steady-state operation, the energy rate balance reduces to give

$$\frac{\dot{W}_{cv}}{\dot{n}_F} = \frac{\dot{Q}_{cv}}{\dot{n}_F} + \bar{h}_F + \left(a + \frac{b}{4}\right)\bar{h}_{\text{O}_2} - a\bar{h}_{\text{CO}_2} - \frac{b}{2}\bar{h}_{\text{H}_2\text{O}}$$

where $\dot{n}_F$ denotes the molar flow rate of the fuel. Kinetic and potential energy effects are regarded as negligible. If heat transfer occurs only at the temperature T, an entropy balance for the control volume takes the form

$$0 = \frac{\dot{Q}_{cv}/\dot{n}_F}{T} + \bar{s}_F + \left(a + \frac{b}{4}\right)\bar{s}_{\text{O}_2} - a\bar{s}_{\text{CO}_2} - \frac{b}{2}\bar{s}_{\text{H}_2\text{O}} + \frac{\dot{S}_{gen}}{\dot{n}_F}$$

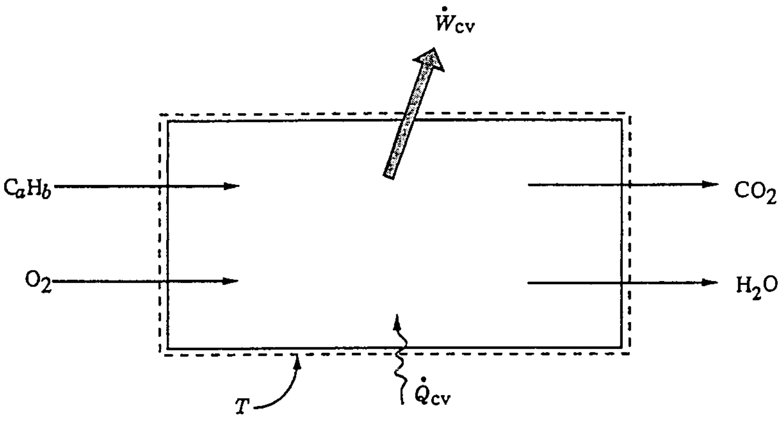

FIGURE 2.15 Device for evaluating maximum work.

Eliminating the heat transfer term from these expressions, an expression for the maximum theoretical value of the work developed per mole of fuel is obtained when the entropy generation term is set to zero:

$$\left(\frac{\dot{W}_{cv}}{\dot{n}_F}\right)_{\substack{int\\rev}} = \left[\bar{h}_F + \left(a+\frac{b}{4}\right)\bar{h}_{O_2} - a\bar{h}_{CO_2} - \frac{b}{2}\bar{h}_{H_2O}\right](T,p) - T\left[\bar{s}_F + \left(a+\frac{b}{4}\right)\bar{s}_{O_2} - a\bar{s}_{CO_2} - \frac{b}{2}\bar{s}_{H_2O}\right](T,p)$$

This can be written alternatively in terms of the enthalpy of combustion as

$$\left(\frac{\dot{W}_{cv}}{\dot{n}_F}\right)_{\substack{int\\rev}} = -\bar{h}_{RP}(T,p) - T\left[\bar{s}_F + \left(a+\frac{b}{4}\right)\bar{s}_{O_2} - a\bar{s}_{CO_2} - \frac{b}{2}\bar{s}_{H_2O}\right](T,p) \tag{2.83a}$$

or in terms of Gibbs functions as

$$\left(\frac{\dot{W}_{cv}}{\dot{n}_F}\right)_{\substack{int\\rev}} = \left[\bar{g}_F + \left(a+\frac{b}{4}\right)\bar{g}_{O_2} - a\bar{g}_{CO_2} - \frac{b}{2}\bar{g}_{H_2O}\right](T,p) \tag{2.83b}$$

Equation 2.83b is used in the solution to Example 11.

Example 11

Hydrogen (H_2) and oxygen (O_2), each at 25°C, 1 atm, enter a fuel cell operating at steady state, and liquid water exits at the same temperature and pressure. The hydrogen flow rate is 2×10^{-4} kmol/sec and the fuel cell operates isothermally at 25°C. Determine the maximum theoretical power the cell can develop, in kW.

Solution. The overall cell reaction is $H_2 + 1/2\ O_2 \rightarrow H_2O(\ell)$, and Equations 2.83 are applicable. Selecting Equation 2.83b, and using Gibbs function data from Table 2.9,

$$\left(\frac{\dot{W}_{cv}}{\dot{n}_F}\right)_{\substack{int\\rev}} = \left(\bar{g}_{H_2} + \frac{1}{2}\bar{g}_{O_2} - \bar{g}_{H_2O(\ell)}\right)(25°\text{C, 1 atm})$$

$$= 0 + \frac{1}{2}(0) - (-237{,}180) = 237{,}180 \text{ kJ/kmol}$$

Then

$$\left(\dot{W}_{cv}\right)_{\substack{int\\rev}} = \left(237{,}180\frac{\text{kJ}}{\text{kmol}}\right)\left(2\times10^{-4}\frac{\text{kmol}}{\text{s}}\right)\left(\frac{\text{kW}}{1\text{kJ/s}}\right) = 47.4\text{ kW}$$

Reaction Equilibrium

Let the objective be to determine the equilibrium composition of a system consisting of five gases A, B, C, D, and E, at a temperature T and pressure p, subject to a chemical reaction of the form

$$v_A A + v_B B \leftrightarrow v_C C + v_D D$$

where the v's are stoichiometric coefficients. Component E is assumed to be inert and thus does not appear in the reaction equation. The equation suggests that at equilibrium the tendency of A and B to form C and D is just balanced by the tendency of C and D to form A and B.

At equilibrium, the temperature and pressure would be uniform throughout the system. Additionally, the *equation of reaction equilibrium* must be satisfied:

$$v_A\mu_A + v_B\mu_B = v_C\mu_C + v_D\mu_D \tag{2.84a}$$

where the μ's are the chemical potentials (Section 2.3, Multicomponent Systems) of A, B, C, and D in the equilibrium mixture. In principle, the composition that would be present at equilibrium for a given temperature and pressure can be determined by solving this equation.

For ideal gas mixtures, the solution procedure is simplified by using the *equilibrium constant* $K(T)$ and the following equation:

$$\begin{aligned} K(T) &= \frac{y_C^{v_C} y_D^{v_D}}{y_A^{v_A} y_B^{v_B}}\left(\frac{p}{p_{ref}}\right)^{v_C+v_D-v_A-v_B} \\ &= \frac{n_C^{v_C} n_D^{v_D}}{n_A^{v_A} n_B^{v_B}}\left(\frac{p/p_{ref}}{n}\right)^{v_C+v_D-v_A-v_B} \end{aligned} \tag{2.84b}$$

where y_A, y_B, y_C, and y_D denote the mole fractions of A, B, C, and D in the equilibrium mixture and $n = n_A + n_B + n_C + n_D + n_E$, where the n's denote the molar amounts of the gases in the mixture. Tabulations of $K(T)$ for each of several reactions of the form Equation 2.84a are provided in Table 2.11. An application of Equation 2.84b is provided in Example 12.

Example 12

One kmol of CO reacts with the theoretical amount of dry air to form an equilibrium mixture of CO_2, CO, O_2, and N_2 at 2500 K, 1 atm. Determine the amount of CO in the equilibrium mixture, in kmol.

Solution. The reaction of CO with the theoretical amount of dry air to form CO_2, CO, O_2, and N_2 is

$$\text{CO} + \frac{1}{2}\text{O}_2 + 1.88\text{N}_2 \rightarrow z\text{CO} + \frac{z}{2}\text{O}_2 + (1-z)\text{CO}_2 + 1.88\text{N}_2$$

where z is the amount of CO, in kmol, present in the equilibrium mixture. The total number of moles n is

$$n = z + \frac{z}{2} + (1-z) + 1.88 = \frac{5.76 + z}{2}$$

TABLE 2.11 Logarithms to the Base 10 of the Equilibrium Constant K

	$\log_{10} K$

Source: Based on data from the JANAF Thermochemical Tables, NSRDS-NBS-37, 1971.

At equilibrium $CO_2 \leftrightarrow CO + 1/2\ O_2$; and Equation 2.84b takes the form

$$K = \frac{z(z/2)^{1/2}}{1-z}\left[\frac{p/p_{ref}}{(5.76+z)/2}\right]^{1/2}$$

where $p/p_{ref} = 1$. At 2500 K, Table 2.11 gives $K = 0.0363$. Solving iteratively, z = 0.175.

2.5 Exergy Analysis

The method of *exergy analysis* (*availability analysis*) presented in this section enables the location, cause, and true magnitude of energy resource waste and loss to be determined. Such information can be used in the design of new energy-efficient systems and for improving the performance of existing systems. Exergy analysis also provides insights that elude a purely first-law approach. For example, on the basis of first-law reasoning alone, the condenser of a power plant may be mistakenly identified as the component primarily responsible for the plant's seemingly low overall performance. An exergy analysis correctly reveals not only that the condenser loss is relatively unimportant (see the last two rows of the Rankine cycle values of Table 2.15), but also that the steam generator is the principal site of thermodynamic inefficiency owing to combustion and heat transfer irreversibilities within it.

When exergy concepts are combined with principles of engineering economy, the result is known as *thermoeconomics*. Thermoeconomics allows the real cost sources at the component level to be identified: capital investment costs, operating and maintenance costs, and the costs associated with the destruction and loss of exergy. Optimization of thermal systems can be achieved by a careful consideration of such cost sources. From this perspective thermoeconomics *is exergy-aided cost minimization.*

Discussions of exergy analysis and thermoeconomics are provided by Bejan et al. (1996), Moran (1989), and Moran and Shapiro (1995). In this section salient aspects are presented.

Defining Exergy

An opportunity for doing work exists whenever two systems at different states are placed in communication because, in principle, work can be developed as the two are allowed to come into equilibrium. When one of the two systems is a suitably idealized system called an *environment* and the other is some system of interest, *exergy* is the maximum theoretical useful work (shaft work or electrical work) obtainable as the systems interact to equilibrium, heat transfer occurring with the environment only. (Alternatively, exergy is the minimum theoretical useful work required to form a quantity of matter from substances present in the environment and to bring the matter to a specified state.) Exergy is a measure of the *departure* of the state of the system from that of the environment, and is therefore an attribute of the system and environment together. Once the environment is specified, however, a value can be assigned to exergy in terms of property values for the system only, so exergy can be regarded as an extensive property of the system.

Exergy can be destroyed and generally is not conserved. A limiting case is when exergy would be completely destroyed, as would occur if a system were to come into equilibrium with the environment *spontaneously* with no provision to obtain work. The capability to develop work that existed initially would be completely wasted in the spontaneous process. Moreover, since no work needs to be done to effect such a spontaneous change, the value of exergy can never be negative.

Environment

Models with various levels of specificity are employed for describing the environment used to evaluate exergy. Models of the environment typically refer to some portion of a system's surroundings, the intensive properties of each phase of which are uniform and do not change significantly as a result of any process under consideration. The environment is regarded as composed of common substances existing in abundance within the Earth's atmosphere, oceans, and crust. The substances are in their stable forms as they exist naturally, and there is no possibility of developing work from interactions — physical or chemical — between parts of the environment. Although the intensive properties of the environment are assumed to be unchanging, the extensive properties can change as a result of interactions with other systems. Kinetic and potential energies are evaluated relative to coordinates in the environment, all parts of which are considered to be at rest with respect to one another.

For computational ease, the temperature T_0 and pressure p_0 of the environment are often taken as standard-state values, such as 1 atm and 25°C (77°F). However, these properties may be specified differently depending on the application. T_0 and p_0 might be taken as the average ambient temperature and pressure, respectively, for the location at which the system under consideration operates. Or, if the system uses atmospheric air, T_0 might be specified as the average air temperature. If both air and water from the natural surroundings are used, T_0 would be specified as the lower of the average temperatures for air and water.

Dead States

When a system is in equilibrium with the environment, the state of the system is called the *dead state.* At the dead state, the conditions of mechanical, thermal, and chemical equilibrium between the system and the environment are satisfied: the pressure, temperature, and chemical potentials of the system equal those of the environment, respectively. In addition, the system has no motion or elevation relative to coordinates in the environment. Under these conditions, there is no possibility of a spontaneous change within the system or the environment, nor can there be an interaction between them. The value of exergy is zero.

Another type of equilibrium between the system and environment can be identified. This is a restricted form of equilibrium where only the conditions of mechanical and thermal equilibrium must be satisfied. This state of the system is called the *restricted dead state.* At the restricted dead state, the fixed quantity of matter under consideration is imagined to be sealed in an envelope impervious to mass flow, at zero velocity and elevation relative to coordinates in the environment, and at the temperature T_0 and pressure p_0.

Exergy Balances

Exergy can be transferred by three means: exergy transfer associated with work, exergy transfer associated with heat transfer, and exergy transfer associated with the matter entering and exiting a control volume. All such exergy transfers are evaluated relative to the environment used to define exergy. Exergy is also destroyed by irreversibilities within the system or control volume.

Exergy balances can be written in various forms, depending on whether a closed system or control volume is under consideration and whether steady-state or transient operation is of interest. Owing to its importance for a wide range of applications, an exergy rate balance for control volumes at steady state is presented next.

Control Volume Exergy Rate Balance

At steady state, the control volume exergy rate balance takes the form

$$0 = \underbrace{\sum_j \dot{E}_{q,j} - \dot{W}_{cv} + \sum_i \dot{E}_i - \sum_e \dot{E}_e}_{\substack{\text{rates of}\\ \text{exergy}\\ \text{transfer}}} - \underbrace{\dot{E}_D}_{\substack{\text{rate of}\\ \text{exergy}\\ \text{destruction}}} \tag{2.85a}$$

or

$$0 = \sum_j \left(1 - \frac{T_0}{T_j}\right)\dot{Q}_j - \dot{W}_{cv} + \sum_i \dot{m}_i e_i - \sum_e \dot{m}_e e_e - \dot{E}_D \tag{2.85b}$$

$\dot{W}_{cv}$ has the same significance as in Equation 2.22: the work rate excluding the flow work. $\dot{Q}_j$ is the time rate of heat transfer at the location on the boundary of the control volume where the instantaneous temperature is T_j. The associated rate of exergy transfer is

$$\dot{E}_{q,j} = \left(1 - \frac{T_0}{T_j}\right)\dot{Q}_j \tag{2.86}$$

As for other control volume rate balances, the subscripts *i* and *e* denote inlets and outlets, respectively. The exergy transfer rates at control volume inlets and outlets are denoted, respectively, as $\dot{E}_i = \dot{m}_i e_i$ and $\dot{E}_e = \dot{m}_e e_e$. Finally, $\dot{E}_D$ accounts for the time rate of exergy destruction due to irreversibilities within the control volume. The exergy destruction rate is related to the entropy generation rate by

$$\dot{E}_D = T_0 \dot{S}_{gen} \tag{2.87}$$

The specific exergy transfer terms e_i and e_e are expressible in terms of four components: physical exergy e^{PH}, kinetic exergy e^{KN}, potential exergy e^{PT}, and chemical exergy e^{CH}:

$$e = e^{PH} + e^{KN} + e^{PT} + e^{CH} \tag{2.88}$$

The first three components are evaluated as follows:

$$e^{PH} = \left(h - h_0\right) - T_0\left(s - s_0\right) \tag{2.89a}$$

$$e^{KN} = \frac{1}{2}\mathrm{v}^2 \tag{2.89b}$$

$$e^{PT} = gz \tag{2.89c}$$

In Equation 2.89a, h_0 and s_0 denote, respectively, the specific enthalpy and specific entropy at the restricted dead state. In Equation 2.89b and Equation 2.89c, v and z denote velocity and elevation relative to coordinates in the environment, respectively. The chemical exergy e^{CH} is considered next.

Chemical Exergy

To evaluate the chemical exergy, the exergy component associated with the departure of the chemical composition of a system from that of the environment, the substances comprising the system are referred to the properties of a suitably selected set of environmental substances. For this purpose, alternative models of the environment have been developed. For discussion, see, for example, Moran (1989) and Kotas (1995).

Exergy analysis is facilitated, however, by employing a *standard environment* and a corresponding table of *standard chemical exergies.* Standard chemical exergies are based on standard values of the environmental temperature T_0 and pressure p_0 — for example, 298.15 K (25°C) and 1 atm, respectively. A standard environment is also regarded as consisting of a set of reference substances with standard concentrations reflecting as closely as possible the chemical makeup of the natural environment. The reference substances generally fall into three groups: gaseous components of the atmosphere, solid substances from the lithosphere, and ionic and noninonic substances from the oceans. The chemical exergy data of Table 2.12 correspond to two alternative standard exergy reference environments, called here model I and model II, that have gained acceptance for engineering evaluations.

Although the use of standard chemical exergies greatly facilitates the application of exergy principles, the term *standard* is somewhat misleading since there is no one specification of the environment that suffices for all applications. Still, chemical exergies calculated relative to alternative specifications of the environment are generally in good agreement. For a broad range of engineering applications the simplicity and ease of use of standard chemical exergies generally outweigh any slight lack of accuracy that might result. In particular, the effect of slight variations in the values of T_0 and p_0 about the values used to determine the standard chemical exergies reported in Table 2.12 can be neglected.

The literature of exergy analysis provides several expressions allowing the chemical exergy to be evaluated in particular cases of interest. The molar chemical exergy of a gas mixture, for example, can be evaluated from

$$\bar{e}^{CH} = \sum_{i=1}^{j} y_i \bar{e}_i^{CH} + \bar{R}T_0 \sum_{i=1}^{j} y_i \ln y_i \tag{2.90}$$

where $\bar{e}_i^{CH}$ is the molar chemical exergy of the ith component.

TABLE 2.12 Standard Molar Chemical Exergy, e^{CH} (kJ/kmol), of Various Substances at 298 K and p_0

Substance	Formula	Model I[a]	Model II[b]
Nitrogen	$N_2(g)$	640	720
Oxygen	$O_2(g)$	3,950	3,970
Carbon dioxide	$CO_2(g)$	14,175	19,870
Water	$H_2O(g)$	8,635	9,500
	$H_2O(l)$	45	900
Carbon (graphite)	C(s)	404,590	410,260
Hydrogen	$H_2(g)$	235,250	236,100
Sulfur	S(s)	598,160	609,600
Carbon monoxide	CO(g)	269,410	275,100
Sulfur dioxide	$SO_2(g)$	301,940	313,400
Nitrogen monoxide	NO(g)	88,850	88,900
Nitrogen dioxide	$NO_2(g)$	55,565	55,600
Hydrogen sulfide	$H_2S(g)$	799,890	812,000
Ammonia	$NH_3(g)$	336,685	337,900
Methane	$CH_4(g)$	824,350	831,650
Ethane	$C_2H_6(g)$	1,482,035	1,495,840
Methanol	$CH_3OH(g)$	715,070	722,300
	$CH_3OH(l)$	710,745	718,000
Ethyl alcohol	$C_2H_5OH(g)$	1,348,330	1,363,900
	$C_2H_5OH(l)$	1,342,085	1,357,700

[a] Ahrendts, J. 1977. Die Exergie Chemisch Reaktionsfähiger Systeme, *VDI-Forschungsheft*. VDI-Verlag, Dusseldorf, 579. Also see Reference States, *Energy — The International Journal*, 5: 667–677, 1980. In Model I, p_0 = 1.019 atm. This model attempts to impose a criterion that the reference environment be in equilibrium. The reference substances are determined assuming restricted chemical equilibrium for nitric acid and nitrates and unrestricted thermodynamic equilibrium for all other chemical components of the atmosphere, the oceans, and a portion of the Earth's crust. The chemical composition of the gas phase of this model approximates the composition of the natural atmosphere.

[b] Szargut, J., Morris, D. R., and Steward, F. R. 1988. *Energy Analysis of Thermal, Chemical, and Metallurgical Processes*. Hemisphere, New York. In Model II, p_0 = 1.0 atm. In developing this model a reference substance is selected for each chemical element from among substances that contain the element being considered and that are abundantly present in the natural environment, even though the substances are not in completely mutual stable equilibrium. An underlying rationale for this approach is that substances found abundantly in nature have little economic value. On an overall basis, the chemical composition of the exergy reference environment of Model II is closer than Model I to the composition of the natural environment, but the equilibrium criterion is not always satisfied.

Example 13

Ignoring the kinetic and potential exergies, determine the exergy rate, in kJ/kg, associated with each of the following streams of matter:

(a) Saturated water vapor at 20 bar.
(b) Methane at 5 bar, 25°C.

Let T_0 = 298 K, p_0 = 1.013 bar (1 atm).

Solution. Equation 2.88 reduces to read

$$e = \left(h - h_0\right) - T_0\left(s - s_0\right) + e^{CH}$$

(a) From Table A.5, h = 2799.5 kJ/kg, s = 6.3409 kJ/kg · K. At T_0 = 298 K (25°C), water would be a liquid; thus with Equation 2.50c and Equation 2.50d, $h_0 \approx 104.9$ kJ/kg, $s_0 \approx 0.3674$ kJ/kg · K. Table 2.12 (model I) gives $e^{CH} = 45/18.02 = 2.5$ kJ/kg. Then

$$\begin{aligned} e &= (2799.5 - 104.9) - 298(6.3409 - 0.3674) + 2.5 \\ &= 914.5 + 2.5 = 917.0 \ \text{kJ/kg} \end{aligned}$$

Here the specific exergy is determined predominately by the physical component.

(b) Assuming the ideal gas model for methane, $h - h_0 = 0$. Also, Equation 2.58 reduces to give $s - s_0 = -R\ln p/p_0$. Then, Equation 2.88 reads

$$e = RT_0 \ln p/p_0 + e^{CH}$$

With $e^{CH} = 824{,}350/16.04 = 51{,}393.4$ kJ/kg from Table 2.12 (model I),

$$\begin{aligned} e &= \left(\frac{8.314}{16.04}\frac{\text{kJ}}{\text{kg} \cdot \text{K}}\right)(298 \text{ K})\ln\frac{5}{1.013} + 51{,}393.4\frac{\text{kJ}}{\text{kg}} \\ &= 246.6 + 51{,}393.4 \\ &= 51{,}640 \ \text{kJ/kg} \end{aligned}$$

Here the specific exergy is determined predominately by the chemical component.

The small difference between p_0 = 1.013 bar and the value of p_0 for model I has been ignored.

Exergetic Efficiency

The exergetic efficiency (second law efficiency, effectiveness, or rational efficiency) provides a true measure of the performance of a system from the thermodynamic viewpoint. To define the exergetic efficiency both a *product* and a *fuel* for the system being analyzed are identified. The product represents the desired result of the system (power, steam, some combination of power and steam, etc.). Accordingly, the definition of the product must be consistent with the purpose of purchasing and using the system. The fuel represents the resources expended to generate the product and is not necessarily restricted to being an actual fuel such as a natural gas, oil, or coal. Both the product and the fuel are expressed in terms of exergy.

For a control volume at steady state whose exergy rate balance reads

$$\dot{E}_F = \dot{E}_P + \dot{E}_D + \dot{E}_L$$

the exergetic efficiency is

$$\varepsilon = \frac{\dot{E}_P}{\dot{E}_F} = 1 - \frac{\dot{E}_D + \dot{E}_L}{\dot{E}_F} \tag{2.91}$$

where the rates at which the fuel is supplied and the product is generated are $\dot{E}_F$ and $\dot{E}_P$, respectively. $\dot{E}_D$ and $\dot{E}_L$ denote the rates of exergy destruction and exergy loss, respectively. Exergy is destroyed by irreversibilities within the control volume, and exergy is lost from the control volume via stray heat transfer, material streams vented to the surroundings, and so on. The exergetic efficiency shows the percentage of the fuel exergy provided to a control volume that is found in the product exergy. Moreover, the difference between 100% and the value of the exergetic efficiency, expressed as a percent, is the percentage of the fuel exergy wasted in this control volume as exergy destruction and exergy loss.

To apply Equation 2.91, decisions are required concerning what are considered as the fuel and the product. Table 2.13 provides illustrations for several common components. Similar considerations are used to write exergetic efficiencies for systems consisting of several such components, as, for example, a power plant.

Exergetic efficiencies can be used to assess the thermodynamic performance of a component, plant, or industry relative to the performance of *similar* components, plants, or industries. By this means the performance of a gas turbine, for instance, can be gauged relative to the typical present-day performance level of gas turbines. A comparison of exergetic efficiencies for *dissimilar* devices — gas turbines and heat exchangers, for example — is generally not significant, however.

The exergetic efficiency is generally more meaningful, objective, and useful than other efficiencies based on the first or second law of thermodynamics, including the thermal efficiency of a power plant, the isentropic efficiency of a compressor or turbine, and the effectiveness of a heat exchanger. The thermal efficiency of a cogeneration system, for instance, is misleading because it treats both work and heat transfer as having equal thermodynamic value. The isentropic turbine efficiency (Equation 2.95a) does not consider that the working fluid at the outlet of the turbine has a higher temperature (and consequently a higher exergy that may be used in the next component) in the actual process than in the isentropic process. The heat exchanger effectiveness fails, for example, to identify the exergy destruction associated with the pressure drops of the heat exchanger working fluids.

Example 14

Evaluate the exergetic efficiency of the turbine in part (a) of Example 1 for $T_0 = 298$ K.

Solution. The exergetic efficiency from Table 2.13 is

$$\varepsilon = \frac{\dot{W}}{\dot{E}_1 - \dot{E}_2} = \frac{\dot{W}}{\dot{m}\left(e_1 - e_2\right)}$$

Using Equation 2.88 and Equation 2.89a, and noting that the chemical exergy at 1 and 2 cancels,

$$\varepsilon = \frac{\dot{W}}{\dot{m}\left[\left(h_1 - h_2\right) - T_0\left(s_1 - s_2\right)\right]}$$

Since $\dot{W} = \dot{m}(h_1 - h_2)$,

$$\varepsilon = \frac{\dot{W}}{\dot{W} + \dot{m}T_0\left(s_2 - s_1\right)}$$

Finally, using data from Example 1 and $s_2 = 6.8473$ kJ/kg · K,

$$\varepsilon = \frac{30 \text{ MW}}{30 \text{ MW} + \left(\frac{162{,}357}{3600}\frac{\text{kg}}{\text{s}}\right)(298 \text{ K})(6.8473 - 6.6022)\left(\frac{\text{kJ}}{\text{kg} \cdot \text{K}}\right)\left(\frac{1 \text{ MW}}{10^3 \text{ kJ/sec}}\right)}$$

$$= \frac{30 \text{ MW}}{(30 + 3.29)\text{MW}} = 0.9(90\%)$$

TABLE 2.13 The Exergetic Efficiency for Selected Components at Steady State[a]

---

[a] For discussion, see Bejan et al. (1996).

[b] This definition assumes that the purpose of the heat exchanger is to heat the cold stream ($T_1 \geq T_0$). If the purpose of the heat exchanger is to provide cooling ($T_3 \geq T_0$), then the following relations should be used: $\dot{E}_P = \dot{E}_4 - \dot{E}_3$ and $\dot{E}_F = \dot{E}_1 - \dot{E}_2$.

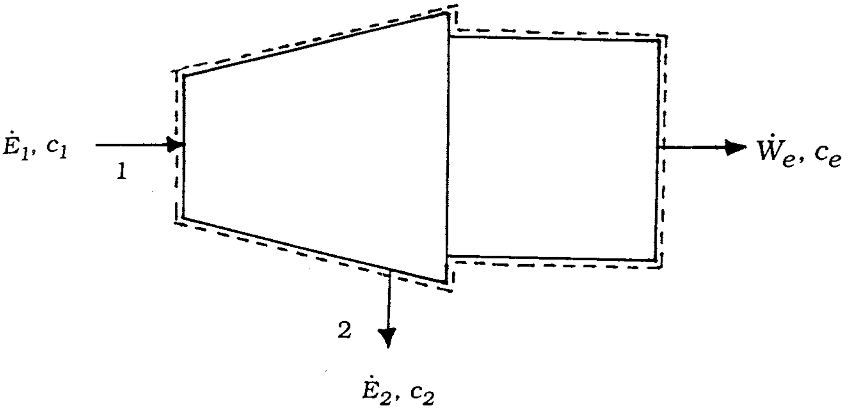

FIGURE 2.16 Steam turbine/electric generator used to discuss exergy costing.

Exergy Costing

Since exergy measures the true thermodynamic values of the work, heat, and other interactions between the system and its surroundings as well as the effect of irreversibilities within the system, exergy is a rational basis for assigning costs. This aspect of thermoeconomics is called *exergy costing.*

Referring to Figure 2.16 showing a steam turbine-electric generator at steady state, the total cost to produce the electricity and exiting steam equals the cost of the entering steam plus the cost of owning and operating the device. This is expressed by the *cost rate balance* for the turbine-generator:

$$\dot{C}_e + \dot{C}_2 = \dot{C}_1 + \dot{Z} \tag{2.92a}$$

where $\dot{C}_e$ is the cost rate associated with the electricity, $\dot{C}_1$ and $\dot{C}_2$ are the cost rates associated with the entering steam and exiting steam, respectively, and $\dot{Z}$ accounts for the cost rate associated with owning and operating the system, each *annualized* in \$ per year.

With exergy costing, the cost rates $\dot{C}_1$, $\dot{C}_2$, and $\dot{C}_e$ are evaluated in terms of the associated rate of exergy transfer and a *unit cost.* Equation 2.92a then appears as

$$c_e\dot{W}_e + c_2\dot{E}_2 = c_1\dot{E}_1 + \dot{Z} \tag{2.92b}$$

The coefficients c_1, c_2, and c_e in Equation 2.92b denote the *average* cost per unit of exergy for the associated exergy rate. The unit cost c_1 of the entering steam would be obtained from exergy costing applied to the components upstream of the turbine. Assigning the same unit cost to the exiting steam: $c_2 = c_1$ on the basis that the purpose of the turbine-generator is to generate electricity and thus all costs associated with owning and operating the system should be charged to the power, Equation 2.92b becomes

$$c_e\dot{W}_e = c_1\left(\dot{E}_1 - \dot{E}_2\right) + \dot{Z} \tag{2.92c}$$

The first term on the right side accounts for the cost of the net exergy used and the second term accounts for cost of the system itself. Introducing the exergetic efficiency from Table 2.13, the unit cost of the electricity is

$$c_e = \frac{c_1}{\varepsilon} + \frac{\dot{Z}}{\dot{W}_e} \tag{2.93}$$

This equation shows, for example, that the unit cost of electricity would increase if the exergetic efficiency were to decrease owing to a deterioration of the turbine with use.

Example 15

A turbine-generator with an exergetic efficiency of 90% develops 7×10^7 kW · hr of electricity annually. The annual cost of owning and operating the system is $\$2.5 \times 10^5$. If the average unit cost of the steam entering the system is \$0.0165 per kW · hr of exergy, evaluate the unit cost of the electricity.

Solution. Substituting values into Equation 2.93,

$$c_e = \frac{\$0.0165/\text{kW}\cdot\text{h}}{0.9} + \frac{\$2.5\times10^5/\text{year}}{7\times10^7\ \text{kW}\cdot\text{h/year}}$$

$$= 0.0183 + 0.0036 = \$0.0219/\text{kW}\cdot\text{h}$$

2.6 Vapor and Gas Power Cycles

Vapor and gas power systems develop electrical or mechanical power from energy sources of chemical, solar, or nuclear origin. In *vapor* power systems the *working fluid*, normally water, undergoes a phase change from liquid to vapor, and conversely. In *gas* power systems, the working fluid remains a gas throughout, although the composition normally varies owing to the introduction of a fuel and subsequent combustion. The present section introduces vapor and gas power systems. Further discussion is provided in Chapter 8. Refrigeration systems are considered in Chapter 9.

The processes taking place in power systems are sufficiently complicated that idealizations are typically employed to develop tractable thermodynamic models. The *air standard analysis* of gas power systems considered later in the present section is a noteworthy example. Depending on the degree of idealization, such models may provide only qualitative information about the performance of the corresponding real-world systems. Yet such information is frequently useful in gauging how changes in major operating parameters might affect actual performance. Elementary thermodynamic models can also provide simple settings to assess, at least approximately, the advantages and disadvantages of features proposed to improve thermodynamic performance.

Rankine and Brayton Cycles

In their simplest embodiments vapor power and gas turbine power plants are represented conventionally in terms of four components in series, forming, respectively, the Rankine cycle and the Brayton cycle shown schematically in Table 2.14. The thermodynamically ideal counterparts of these cycles are composed of four internally reversible processes in series: two isentropic processes alternated with two constant pressure processes. Table 2.14 provides property diagrams of the actual and corresponding ideal cycles. Each actual cycle is denoted 1-2-3-4-1; the ideal cycle is 1-2s-3-4s-1. For simplicity, pressure drops through the boiler, condenser, and heat exchangers are not shown. Invoking Equation 2.29 for the ideal cycles, the heat added per unit of mass flowing is represented by the area *under* the isobar from state 2s to state 3: area a-2s-3-b-a. The heat rejected is the area *under* the isobar from state 4s to state 1: area a-1-4s-b-a. Enclosed area 1-2s-3-4s-1 represents the net heat added per unit of mass flowing. For any power cycle, the net heat added equals the net work done.

Expressions for the principal energy transfers shown on the schematics of Table 2.14 are provided by Equation 1 to Equation 4 of the table. They are obtained by reducing Equation 2.27a with the assumptions of negligible heat loss and negligible changes in kinetic and potential energy from the inlet to the outlet of each component. All quantities are positive in the directions of the arrows on the figure. Using these expressions, the thermal efficiency is

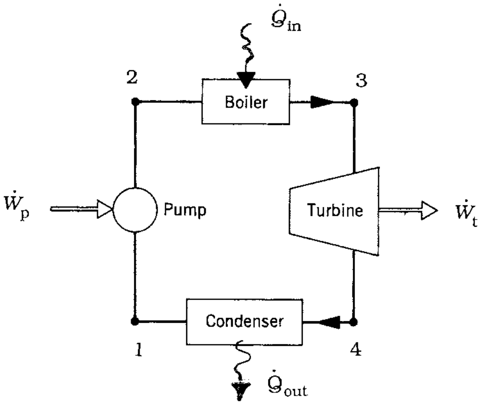
$$\eta = \frac{(h_3 - h_4) - (h_2 - h_1)}{h_3 - h_2} \tag{2.94}$$

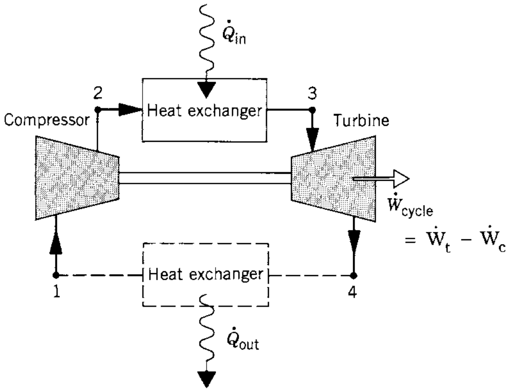
To obtain the thermal efficiency of the ideal cycle, h_{2s} replaces h_2 and h_{4s} replaces h_4 in Equation 2.94.

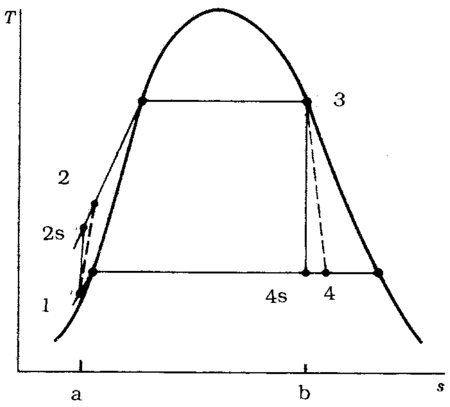
TABLE 2.14 Rankine and Brayton Cycles

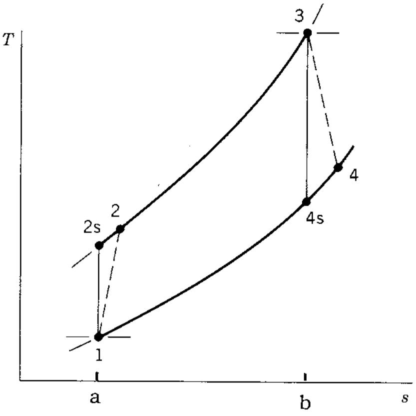
Rankine Cycle

Brayton Cycle









$$\left.\begin{matrix}\dot{W}_p\\ \dot{W}_c\end{matrix}\right\} = \dot{m}\left(h_2 - h_1\right) \qquad (>0) \tag{1}$$

$$\dot{Q}_{in} = \dot{m}\left(h_3 - h_2\right) \qquad (>0) \tag{2}$$

$$\dot{W}_t = \dot{m}\left(h_3 - h_4\right) \qquad (>0) \tag{3}$$

$$\dot{Q}_{out} = \dot{m}\left(h_1 - h_4\right) \qquad (>0) \tag{4}$$

Decisions concerning cycle operating conditions normally recognize that the thermal efficiency tends to increase as the average temperature of heat addition increases and/or the temperature of heat rejection decreases. In the Rankine cycle, a high average temperature of heat addition can be achieved by superheating the vapor prior to entering the turbine, and/or by operating at an elevated steam-generator pressure. In the Brayton cycle an increase in the compressor pressure ratio p_2/p_1 tends to increase the average temperature of heat addition. Owing to materials limitations at elevated temperatures and pressures, the state of the working fluid at the turbine inlet must observe practical limits, however. The turbine inlet temperature of the Brayton cycle, for example, is controlled by providing air far in excess of what is required for combustion. In a Rankine cycle using water as the working fluid, a low temperature of heat rejection is typically achieved by operating the condenser at a pressure below 1 atm. To reduce erosion and wear by liquid droplets on the blades of the Rankine cycle steam turbine, at least 90% quality should be maintained at the turbine exit: $x_4 > 0.9$.

The *back work ratio*, bwr, is the ratio of the work required by the pump or compressor to the work developed by the turbine:

$$bwr = \frac{h_2 - h_1}{h_3 - h_4} \tag{2.95}$$

As a relatively high specific volume vapor expands through the turbine of the Rankine cycle and a much lower specific volume liquid is pumped, the back work ratio is characteristically quite low in vapor power plants — in many cases on the order of 1 to 2%. In the Brayton cycle, however, both the turbine and compressor handle a relatively high specific volume gas, and the back ratio is much larger, typically 40% or more.

The effect of friction and other irreversibilities for flow-through turbines, compressors, and pumps is commonly accounted for by an appropriate *isentropic efficiency.* The isentropic turbine efficiency is

$$\eta_t = \frac{h_3 - h_4}{h_3 - h_{4s}} \tag{2.95a}$$

The isentropic compressor efficiency is

$$\eta_c = \frac{h_{2s} - h_1}{h_2 - h_1} \tag{2.95b}$$

In the isentropic pump efficiency, η_p, which takes the same form as Equation 2.95b, the numerator is frequently approximated via Equation 2.30c *as* $h_{2s} - h_1 \approx v_1 \Delta p$, where Δp is the pressure rise across the pump.

Simple gas turbine power plants differ from the Brayton cycle model in significant respects. In actual operation, excess air is continuously drawn into the compressor, where it is compressed to a higher pressure; then fuel is introduced and combustion occurs; finally the mixture of combustion products and air expands through the turbine and is subsequently discharged to the surroundings. Accordingly, the low-temperature heat exchanger shown by a dashed line in the Brayton cycle schematic of Table 2.14 is not an actual component, but included only to account formally for the cooling in the surroundings of the hot gas discharged from the turbine.

Another frequently employed idealization used with gas turbine power plants is that of an *air-standard analysis.* An air-standard analysis involves two major assumptions: (1) as shown by the Brayton cycle schematic of Table 2.14, the temperature rise that would be brought about by combustion is effected instead by a heat transfer from an external source; (2) the working fluid throughout the cycle is air, which behaves as an ideal gas. In a *cold* air-standard analysis the specific heat ratio k for air is taken as constant. Equation 1 to Equation 6 of Table 2.7 together with data from Table A.8 apply generally to air-standard analyses. Equation 1′ to Equation 6′ of Table 2.7 apply to cold air-standard analyses, as does the following expression for the turbine power obtained from Table 2.1 (Equation 27c″):

$$\dot{W}_t = \dot{m}\frac{kRT_3}{k-1}\left[1 - \left(p_4/p_3\right)^{(k-1)/k}\right] \tag{2.96}$$

(Equation 2.96 also corresponds to Equation 5′ of Table 2.8 when $n = k$.) An expression similar in form can be written for the power required by the compressor.

TABLE 2.15 Sample Calculations for the Rankine and Brayton Cycles of Table 2.14

Rankine Cycle

Given data: $p_1 = p_4 = 8$ kPa (saturated liquid at 1)
$T_3 = 480$°C (superheated vapor at 3)
$p_2 = p_3 = 8$ MPa
$\dot{W}_{net} = 100$ MW
Ideal cycle: $\eta_t = \eta_p = 100\%$
Actual cycle: $\eta_t = 85\%$, $\eta_p = 70\%$

Parameter	Ideal Cycle	Actual Cycle
x_4	0.794	0.873
h_2 (kJ/ kg)	181.9[a]	185.4
$\dot{m}$ (kg/h)	2.86×10^5	3.38×10^5
η (%)	39.7	33.6
$\dot{Q}_{out}$ (MW)	151.9	197.6
$\dot{E}_{q,out}$ (MW)[b]	8.2	10.7

[a] $h_{2s} \approx h_1 + v_1 \Delta p$

[b] Equation 2.86 with $T_0 = 298$ K, $T_j = T_{sat}$ (8 kPa) = 315 K

Brayton Cycle

Given data: $p_1 = p_4 = 1$ bar
$p_2 = p_3 = 10$ bar
$T_3 = 1400$ K
$\eta_t = \eta_c = 100\%$

Parameter	Air-Standard Analysis	Cold Air-Standard Analysis $k = 1.4$
T_2 (K)	574.1	579.2
T_4 (K)	787.7	725.1
$\dot{W}_{net}/\dot{m}$ (kJ/kg)	427.2	397.5
η (%)	45.7	48.2
bwr	0.396	0.414

For the simple Rankine and Brayton cycles of Table 2.14 the results of sample calculations are provided in Table 2.15. The Brayton cycle calculations are on an air-standard analysis basis.

Otto, Diesel, and Dual Cycles

Although most gas turbines are also internal combustion engines, the name is usually reserved to *reciprocating* internal combustion engines of the type commonly used in automobiles, trucks, and buses. Two principal types of reciprocating internal combustion engines are the *spark-ignition* engine and the *compression-ignition* engine. In a spark-ignition engine a mixture of fuel and air is ignited by a spark plug. In a compression ignition engine air is compressed to a high-enough pressure and temperature that combustion occurs spontaneously when fuel is injected.

In a *four-stroke* internal combustion engine, a piston executes four distinct strokes within a cylinder for every two revolutions of the crankshaft. Figure 2.17 gives *a* pressure-displacement diagram as it might

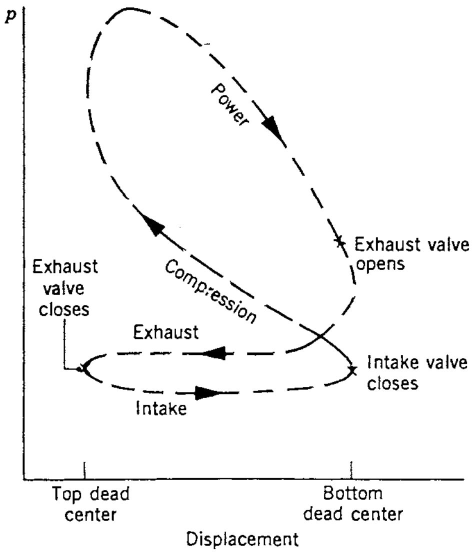


FIGURE 2.17 Pressure-displacement diagram for a reciprocating internal combustion engine.

be displayed electronically. With the intake valve open, the piston makes an *intake stroke* to draw a fresh charge into the cylinder. Next, with both valves closed, the piston undergoes a *compression stroke* raising the temperature and pressure of the charge. A combustion process is then initiated, resulting in a high-pressure, high-temperature gas mixture. A *power* stroke follows the compression stroke, during which the gas mixture expands and work is done on the piston. The piston then executes an *exhaust stroke* in which the burned gases are purged from the cylinder through the open exhaust valve. Smaller engines operate on *two-stroke* cycles. In two-stroke engines, the intake, compression, expansion, and exhaust operations are accomplished in one revolution of the crankshaft. Although internal combustion engines undergo *mechanical* cycles, the cylinder contents do not execute a *thermodynamic* cycle, since matter is introduced with one composition and is later discharged at a different composition.

A parameter used to describe the performance of reciprocating piston engines is the *mean effective pressure*, or mep. The mean effective pressure is the theoretical constant pressure that, if it acted on the piston during the power stroke, would produce the same *net* work as actually developed in one cycle. That is,

$$\text{mep} = \frac{\text{net work for one cycle}}{\text{displacement volume}} \tag{2.97}$$

where the displacement volume is the volume swept out by the piston as it moves from the top dead center to the bottom dead center. For two engines of equal displacement volume, the one with a higher mean effective pressure would produce the greater net work and, if the engines run at the same speed, greater power.

Detailed studies of the performance of reciprocating internal combustion engines may take into account many features, including the combustion process occurring within the cylinder and the effects of irreversibilities associated with friction and with pressure and temperature gradients. Heat transfer between the gases in the cylinder and the cylinder walls and the work required to charge the cylinder and exhaust the products of combustion also might be considered. Owing to these complexities, accurate modeling of reciprocating internal combustion engines normally involves computer simulation.

To conduct *elementary* thermodynamic analyses of internal combustion engines, considerable simplification is required. A procedure that allows engines to be studied *qualitatively* is to employ an *air-standard analysis* having the following elements: (1) a fixed amount of air modeled as an ideal gas is the system; (2) the combustion process is replaced by a heat transfer from an external source and generally represented in terms of elementary thermodynamic processes; (3) there are no exhaust and intake processes as in an actual engine: the cycle is completed by a constant-volume heat rejection process; (4) all processes are internally reversible.

The processes employed in air-standard analyses of internal combustion engines are selected to represent the events taking place within the engine simply and mimic the appearance of observed pressure-displacement diagrams. In addition to the constant volume heat rejection noted previously, the compression stroke and at least a portion of the power stroke are conventionally taken as isentropic. The heat addition is normally considered to occur at constant volume, at constant pressure, or at constant volume followed by a constant pressure process, yielding, respectively, the Otto, Diesel, and Dual cycles shown in Table 2.16.

Reducing the closed system energy balance, Equation 2.8, gives the following expressions for heat and work applicable in each case shown in Table 2.16:

$$\frac{W_{12}}{m} = u_1 - u_2 \qquad (< 0)$$

$$\frac{W_{34}}{m} = u_3 - u_4 \qquad (> 0)$$

$$\frac{Q_{41}}{m} = u_1 - u_4 \qquad (< 0)$$

Table 2.16 provides additional expressions for work, heat transfer, and thermal efficiency identified with each case individually. The thermal efficiency, evaluated from Equation 2.9, takes the form

$$\eta = 1 - \frac{\left|Q_{41}/m\right|}{Q_A/m}$$

Equation 1 to Equation 6 of Table 2.7 together with data from Table A.8, apply generally to air-standard analyses. In a *cold* air-standard analysis the specific heat ratio k for air is taken as constant. Equation 1′ to Equation 6′ of Table 2.7 apply to cold air-standard analyses, as does Equation 4′ of Table 2.8, with $n = k$ for the isentropic processes of these cycles.

Referring to Table 2.16, the ratio v_1/v_2 is the *compression ratio, r*. For the Diesel cycle, the ratio v_3/v_2 is the *cutoff ratio*, r_c. Figure 2.18 shows the variation of the thermal efficiency with compression ratio for an Otto cycle and Diesel cycles having cutoff ratios of 2 and 3. The curves are determined on a cold air-standard basis with $k = 1.4$ using the following expression:

$$\eta = 1 - \frac{1}{r^{k-1}}\left[\frac{r_c^k - 1}{k\left(r_c - 1\right)}\right] \qquad \text{(constant } k\text{)} \tag{2.98}$$

where the Otto cycle corresponds to $r_c = 1$.

As all processes are internally reversible, areas on the p-v and T-s diagrams of Table 2.16 can be interpreted, respectively, as work and heat transfer. Invoking Equation 2.10 and referring to the p-v diagrams, the areas under process 3-4 of the Otto cycle, process 2-3-4 of the Diesel cycle, and process x-3-4 of the Dual cycle represent the work done by the gas during the power stroke, per unit of mass. For each cycle, the area under the isentropic process 1-2 represents the work done on the gas during the compression stroke, per unit of mass. The enclosed area of each cycle represents the net work done per unit mass. With Equation 2.15 and referring to the T-s diagrams, the areas under process 2-3 of the Otto and Diesel cycles and under process 2-x-3 of the Dual cycle represent the heat added per unit of mass. For each cycle, the area under the process 4-1 represent the heat rejected per unit of mass. The enclosed area of each cycle represents the net heat added, which equals the net work done, each per unit of mass.

TABLE 2.16 Otto, Diesel, and Dual Cycles

(a) Otto Cycle	(b) Diesel Cycle	(c) Dual Cycle
				$\frac{W_{23}}{m} = 0$	$\frac{W_{23}}{m} = p_2\left(v_3 - v_2\right)$	$\frac{W_{2x}}{m} = 0, \quad \frac{Q_{2x}}{m} = u_x - u_2$
$\frac{Q_{23}}{m} = u_3 - u_2$	$\frac{Q_{23}}{m} = h_3 - h_2$	$\frac{W_{x3}}{m} = p_3\left(v_3 - v_2\right), \quad \frac{Q_{x3}}{m} = h_3 - h_x$
$\eta = 1 - \frac{u_4 - u_1}{u_3 - u_2}$	$\eta = 1 - \frac{u_4 - u_1}{h_3 - h_2}$	$\eta = 1 - \frac{u_4 - u_1}{\left(u_x - u_2\right) + \left(h_3 - h_x\right)}$

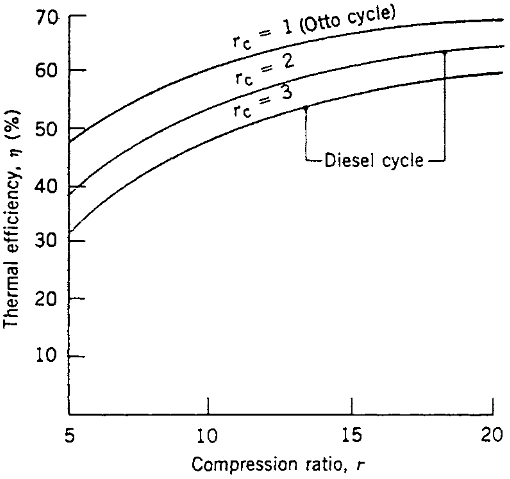

FIGURE 2.18 Thermal efficiency of the cold air-standard Otto and Diesel cycles, $k = 1.4$.

Carnot, Ericsson, and Stirling Cycles

Three thermodynamic cycles that exhibit the Carnot efficiency (Equation 2.12) are the Carnot, Ericsson, and Stirling cycles shown in Figure 2.19. Each case represents a reversible power cycle in which heat is added from an external source at a constant temperature T_H (process 2-3) and rejected to the surroundings at a constant temperature T_C (process 4-1). Carnot cycles can be configured both as vapor power cycles and as cycles executed by a gas in a piston-cylinder assembly (see, e.g., Moran and Shapiro, 1995). Carnot cycles also can be executed in systems where a capacitor is charged and discharged, a paramagnetic substance is magnetized and demagnetized, and in other ways. Regardless of the type of device and the working substance used, the Carnot cycle always has the same four internally reversible processes in series: two isentropic processes alternated with two isothermal processes.

The Ericsson and Stirling cycles also consist of four internally reversible processes in series: heating from state 1 to state 2 (at constant pressure in the Ericsson cycle and at constant volume in the Stirling cycle), isothermal heating from state 2 to state 3 at temperature T_H, cooling from state 3 to state 4 (at constant pressure in the Ericsson cycle and at constant volume in the Stirling cycle), and isothermal cooling from state 4 to state 1 at temperature T_C. An ideal regenerator allows the heat input required for process 1-2 to be obtained from the heat rejected in process 3-4. Accordingly, as in the Carnot cycle all the heat added externally occurs at T_H and all of the heat rejected to the surroundings occurs at T_C.

The Ericsson and Stirling cycles are principally of theoretical interest as examples of cycles that exhibit the same thermal efficiency as the Carnot cycle: Equation 2.12. However, a practical engine of the piston-cylinder type that operates on a closed regenerative cycle having features in common with the Stirling cycle has been under study in recent years. This engine, known as the *Stirling engine*, offers the opportunity for high efficiency together with reduced emissions from combustion products because the combustion takes place externally and not within the cylinder as in internal combustion engines. In the Stirling engine, energy is transferred to the working fluid from products of combustion, which are kept separate. It is an *external* combustion engine.

2.7 Guidelines for Improving Thermodynamic Effectiveness

Thermal design frequently aims at the most effective system from the cost viewpoint. Still, in the cost optimization process, particularly of complex energy systems, it is often expedient to begin by identifying a design that is nearly optimal thermodynamically; such a design can then be used as a point of departure for cost optimization. Presented in this section are guidelines for improving the use of fuels (natural gas,

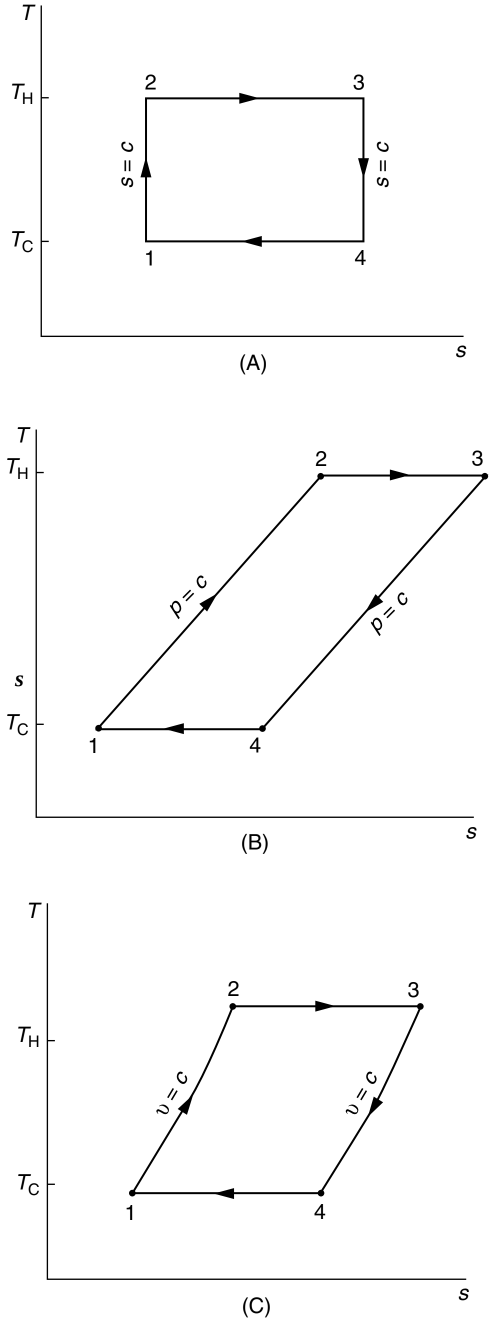

FIGURE 2.19 (A) Carnot, (B) Ericsson, and (C) Stirling cycles.

oil, and coal) by reducing sources of thermodynamic inefficiency in thermal systems. Further discussion is provided by Bejan et al. (1996).

To improve thermodynamic effectiveness it is necessary to deal directly with inefficiencies related to exergy destruction and exergy loss. The primary contributors to exergy destruction are chemical reaction, heat transfer, mixing, and friction, including unrestrained expansions of gases and liquids. To deal with them effectively, the principal sources of inefficiency not only should be understood qualitatively, but also determined quantitatively, at least approximately. Design changes to improve effectiveness must be done judiciously, however, for the cost associated with different sources of inefficiency can be different. For example, the unit cost of the electrical or mechanical power required to provide for the exergy destroyed owing to a pressure drop is generally higher than the unit cost of the fuel required for the exergy destruction caused by combustion or heat transfer.

Since chemical reaction is a significant source of thermodynamic inefficiency, it is generally good practice to minimize the use of combustion. In many applications the use of combustion equipment such as boilers is unavoidable, however. In these cases a significant reduction in the combustion irreversibility by conventional means simply cannot be expected, for the major part of the exergy destruction introduced by combustion is an inevitable consequence of incorporating such equipment. Still, the exergy destruction in practical combustion systems can be reduced by minimizing the use of excess air and by preheating the reactants. In most cases only a small part of the exergy destruction in a combustion chamber can be avoided by these means. Consequently, after considering such options for reducing the exergy destruction related to combustion, efforts to improve thermodynamic performance should focus on components of the overall system that are more amenable to betterment by cost-effective conventional measures. In other words, *some exergy destructions and energy losses can be avoided*, *others cannot. Efforts should be centered on those that can be avoided.*

Nonidealities associated with heat transfer also typically contribute heavily to inefficiency. Accordingly, unnecessary or cost-ineffective heat transfer must be avoided. Additional guidelines follow:

- The higher the temperature T at which a heat transfer occurs in cases where $T > T_0$, where T_0 denotes the temperature of the environment (Section 2.5), the more valuable the heat transfer and, consequently, the greater the need to avoid heat transfer to the ambient, to cooling water, or to a refrigerated stream. Heat transfer across T_0 should be avoided.
- The lower the temperature T at which a heat transfer occurs in cases where $T < T_0$, the more valuable the heat transfer and, consequently, the greater the need to avoid direct heat transfer with the ambient or a heated stream.
- Since exergy destruction associated with heat transfer between streams varies inversely with the temperature level, the lower the temperature level, the greater the need to minimize the stream-to-stream temperature difference.
- Avoid the use of intermediate heat transfer fluids when exchanging energy by heat transfer between two streams

Although irreversibilities related to friction, unrestrained expansion, and mixing are often secondary in importance to those of combustion and heat transfer, they should not be overlooked, and the following guidelines apply:

- Relatively more attention should be paid to the design of the lower temperature stages of turbines and compressors (the last stages of turbines and the first stages of compressors) than to the remaining stages of these devices.
- For turbines, compressors, and motors, consider the most thermodynamically efficient options.
- Minimize the use of throttling; check whether power recovery expanders are a cost-effective alternative for pressure reduction.
- Avoid processes using excessively large thermodynamic driving forces (differences in temperature, pressure, and chemical composition). In particular, minimize the mixing of streams differing significantly in temperature, pressure, or chemical composition.
- The greater the mass rate of flow, the greater the need to use the exergy of the stream effectively.
- The lower the temperature level, the greater the need to minimize friction.

Flowsheeting or *process simulation* software can assist efforts aimed at improving thermodynamic effectiveness by allowing engineers to readily model the behavior of an overall system, or system components, under specified conditions and do the required thermal analysis, sizing, costing, and optimization. Many of the more widely used flowsheeting programs: ASPEN PLUS, PROCESS, and CHEMCAD are of the *sequential-modular* type. SPEEDUP is a popular program of the *equation-solver* type. Since process simulation is a rapidly evolving field, vendors should be contacted for up-to-date information concerning the features of flowsheeting software, including optimization capabilities (if any). As background for further investigation of suitable software, see Biegler (1989) for a survey of the capabilities of 15 software products.

Fluid Mechanics

3.1 Fluid Statics

Stanley A. Berger

Equilibrium of a Fluid Element

If the sum of the external forces acting on a fluid element is zero, the fluid will be at rest or moving as a solid body — in either case, the fluid element is in *equilibrium*. This section considers fluids in such an equilibrium state. For fluids in equilibrium, the only internal stresses acting will be normal forces because the shear stresses depend on velocity gradients, and all such gradients, by the definition of equilibrium, are zero. If one then carries out a balance between the body forces, assumed proportional to volume or mass — such as gravity — and the normal surface stresses acting on an elementary prismatic fluid volume, the resulting equilibrium equations, after shrinking the volume to zero, show that the normal stresses at a point are the same in all directions; because they are known to be negative, this common value, called the pressure, is denoted by $-p$.

Hydrostatic Pressure

Carrying out an equilibrium of forces on an elementary volume element $dxdydz$, the forces being pressures acting on the faces of the element and gravity acting in the $-z$ direction, one obtains

$$\frac{\partial p}{\partial x} = \frac{\partial p}{\partial y} = 0, \text{ and } \frac{\partial p}{\partial z} = -\rho g \equiv -\gamma \tag{3.1.1}$$

where γ is the specific weight of the fluid. The first two of these imply that the pressure is the same in all directions at the same vertical height in a gravitational field. The third shows that the pressure increases with depth in a gravitational field, the variation depending on $\rho(z)$. For homogeneous fluids, for which ρ = const., this last equation can be integrated, yielding

$$p_2 - p_1 = -\rho g\left(z_2 - z_1\right) = -\rho g\left(h_2 - h_1\right) \tag{3.1.2}$$

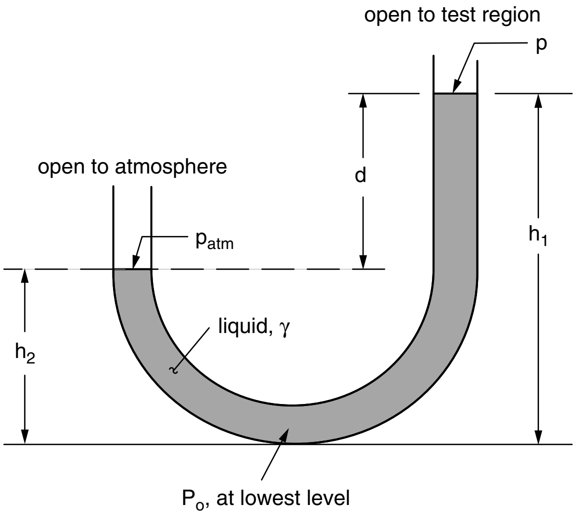

FIGURE 3.1.1 U-tube manometer.

or

$$p_2 + \rho g h_2 = p_1 + \rho g h_1 = \text{const.} \tag{3.1.3}$$

where h denotes the elevation. These are the equations for the *hydrostatic pressure variation*.

When applied to problems in which a liquid, such as the ocean, lies below the atmosphere, with constant pressure p_{atm}, h is usually measured from the ocean/atmosphere interface; p at any distance h below this interface differs from p_{atm} by an amount

$$p - p_{\text{atm}} = \rho g h \tag{3.1.4}$$

Pressures may be given as *absolute pressure*, which is pressure measured relative to absolute vacuum, or *gauge pressure*, pressure measured relative to atmospheric pressure.

Manometry

The hydrostatic pressure variation may be employed to measure pressure differences in terms of heights of liquid columns, Such devices are called *manometers* and are commonly used in wind tunnels and in a host of other applications and devices. Consider, for example, the U-tube manometer shown in Figure 3.1.1 filled with liquid of specific weight γ, the left leg open to the atmosphere and the right to the region whose pressure p is to be determined. In terms of the quantities shown in the figure:

$$\text{in left leg:} \qquad p_0 - \rho g h_2 = p_{\text{atm}} \tag{3.1.5a}$$

$$\text{in right leg:} \quad p_0 - \rho g h_1 = p \tag{3.1.5b}$$

The difference is

$$p - p_{\text{atm}} = -\rho g\left(h_1 - h_2\right) = -\rho g d = -\gamma d \tag{3.1.6}$$

and p is determined in terms of the height difference $d = h_1 - h_2$ between the levels of the fluid in the two legs of the manometer.

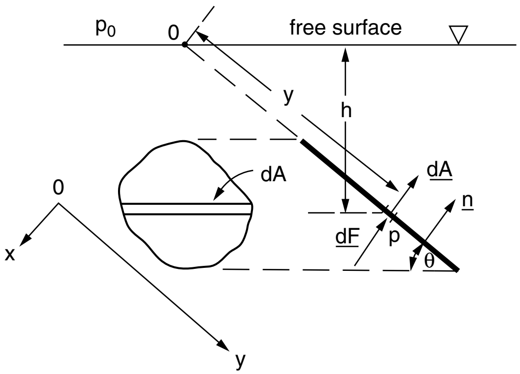

FIGURE 3.1.2 Hydrostatic force on a plane surface.

Hydrostatic Forces on Submerged Objects

Now consider the force acting on a submerged object due to the hydrostatic pressure. This is given by

$$\boldsymbol{F} = \iint p\, \boldsymbol{dA} = \iint p \cdot \boldsymbol{n}\, dA = \iint \rho g h\, \boldsymbol{dA} + p_0 \iint \boldsymbol{dA} \tag{3.1.7}$$

where h is the variable vertical depth of the element $\boldsymbol{dA}$; $\boldsymbol{n}$ is the local (outward) normal to this elemental area, and p_0 is the pressure at the surface. In turn, consider plane and nonplanar surfaces.

Forces on Plane Surfaces

Consider the planar surface A at an angle θ to a free surface shown in Figure 3.1.2. The force on one side of the planar surface, from Equation (3.1.7), is

$$\boldsymbol{F} = \rho g \boldsymbol{n} \iint_A h\, dA + p_0 A \boldsymbol{n} \tag{3.1.8}$$

but $h = y \sin\theta$, so

$$\iint_A h\, dA = \sin\theta \iint_A y\, dA = y_c A \sin\theta = h_c A \tag{3.1.9}$$

where the subscript c indicates the distance measured to the centroid of the area A. Thus, the total force (on one side) is

$$\boldsymbol{F} = \gamma h_c \boldsymbol{A} + p_0 \boldsymbol{A} \tag{3.1.10}$$

Thus, the magnitude of the force is independent of the angle θ and is equal to the pressure at the centroid, $\gamma h_c + p_0$, times the area. If gauge pressure is used, the term $p_0 A$ in Equation (3.1.10) is dropped.

Because p is not evenly distributed over A, but varies with depth, $\boldsymbol{F}$ does not act through the centroid. The point of action of $\boldsymbol{F}$, called the *center of pressure*, can be determined by considering moments in Figure 3.1.2. The moment of the hydrostatic force acting on the elementary area $\boldsymbol{dA}$ about the axis perpendicular to the page passing through the point 0 on the free surface is

$$y\, dF = y(\gamma\, y \sin\theta\, dA) = \gamma\, y^2 \sin\theta\, dA \tag{3.1.11}$$

so, if y_{cp} denotes the distance to the center of pressure,

$$y_{\mathrm{cp}} F = \gamma \sin\theta \iint y^2 \, dA = \gamma \sin\theta \, I_x \tag{3.1.12}$$

where I_x is the moment of inertia of the plane area with respect to the axis formed by the intersection of the plane containing the planar surface and the free surface (e.g., 0x). Dividing by $F = \gamma h_c A = \gamma y_c \sin\theta A$ gives

$$y_{\mathrm{cp}} = \frac{I_{\mathrm{x}}}{y_c A} \tag{3.1.13}$$

By using the parallel axis theorem $I_{\mathrm{x}} = I_{\mathrm{xc}} + A y_{\mathrm{c}}^2$, where I_{xc} is the moment of inertia with respect to an axis parallel to 0x passing through the centroid, Equation (3.1.13) becomes

$$y_{\mathrm{cp}} = y_{\mathrm{c}} + \frac{I_{\mathrm{xc}}}{y_{\mathrm{c}} A} \tag{3.1.14}$$

which shows that, in general, the center of pressure lies below the centroid.

Similarly, x_{cp} can be found by taking moments about the y axis, specifically

$$x_{\mathrm{cp}} F = \gamma \sin\theta \iint xy \, dA = \gamma \sin\theta \, I_{xy} \tag{3.1.15}$$

or

$$x_{\mathrm{cp}} = \frac{I_{\mathrm{xy}}}{y_{\mathrm{c}} A} \tag{3.1.16}$$

where I_{xy} is the product of inertia with respect to the x and y axes. Again, the parallel axis theorem, $I_{xy} = I_{xyc} + A x_c y_c$, where the subscript c denotes the value at the centroid, allows Equation (3.1.16) to be written

$$x_{\mathrm{cp}} = x_{\mathrm{c}} + \frac{I_{\mathrm{xyc}}}{y_{\mathrm{c}} A} \tag{3.1.17}$$

This completes the determination of the center of pressure (x_{cp}, y_{cp}). Note that if the submerged area is symmetrical with respect to an axis passing through the centroid and parallel to the x or y axis, $I_{xyc} = 0$ and $x_{\mathrm{cp}} = x_c$; also, as y_c increases, $y_{\mathrm{cp}} \to y_c$. Centroidal moments of inertia and centroidal coordinates for some common areas are shown in Figure 3.1.3.

Forces on Curved Surfaces

The most convenient approach to calculating the pressure force on a curved surface is by separating it into its horizontal and vertical components. A free-body diagram of the forces acting on the volume of fluid lying above a curved surface together with the conditions of static equilibrium of such a column shows that:

- The *horizontal* components of force on a curved submerged surface are equal to the forces exerted on the planar areas formed by the projections of the curved surface onto vertical planes normal to these components; the lines of action of these forces are calculated as described earlier for planar surfaces.
- The *vertical* component of force on a curved submerged surface is equal in magnitude to the weight of the entire column of fluid lying above the curved surface and acts through the center of mass of this volume of fluid.

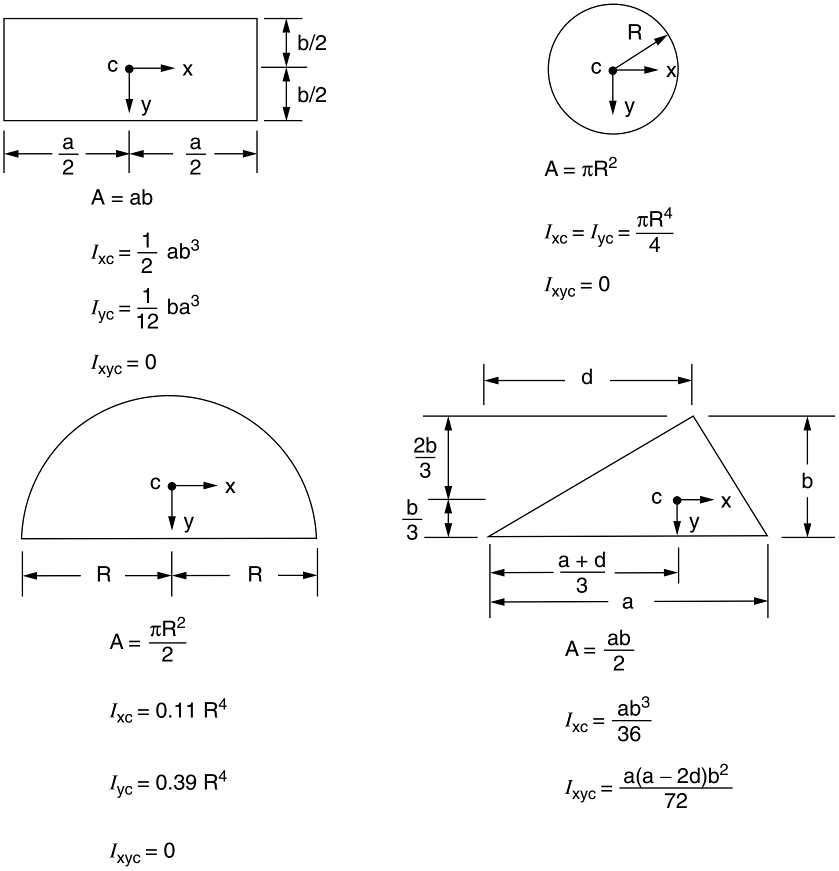

FIGURE 3.1.3 Centroidal moments of inertia and coordinates for some common areas.

These three components of force, two horizontal and one vertical, need not meet at a single point, so there is, in general, no single resultant force. They may, however, be combined into a single force at any arbitrary point of application together with a moment about that point.

Hydrostatic Forces in Layered Fluids

The preceding results employing the linear hydrostatic variation of pressure are valid only for homogeneous fluids. In heterogeneous fluids consisting of individual layers, each of constant density, the pressure varies linearly, with a different slope in each layer. The preceding analyses must be carried out by computing and summing the separate contributions to forces and moments.

Buoyancy

The principles used to compute hydrostatic forces may be used to determine the net pressure force acting on completely submerged or floating bodies. These laws of buoyancy, the *principles of Archimedes*, are:

- A completely submerged body experiences a vertical upward force equal to the weight of the displaced fluid.
- A floating or partially submerged body displaces its own weight in the fluid in which it floats (i.e., the vertical upward force is equal to the body weight).

The line of action of the buoyancy force in both these principles passes through the centroid of the displaced volume of fluid. This point, the *center of buoyancy,* need not correspond to the center of mass of the body (the body may be of nonuniform density). Previously, it has also been assumed that the displaced fluid has a constant γ. If this is not so, e.g., as in a layered fluid, the magnitude of the buoyant force is still equal to the weight of the displaced fluid, but its line of action passes through the center of gravity of the displaced volume, not the centroid. A body whose weight is exactly equal to that of the volume of fluid it displaces is said to be *neutrally buoyant* and will remain at rest at any point of immersion in a (homogeneous) fluid.

Pressure Variation in Rigid-Body Motion of a Fluid

In rigid-body motion of a fluid, all the particles translate and rotate as a whole; there is no relative motion between particles and thus no viscous stresses because these are proportional to velocity gradients. The equation of motion is then a balance among pressure, gravity, and the fluid acceleration, specifically:

$$\nabla p = \rho(\boldsymbol{g} - \boldsymbol{a}) \tag{3.1.18}$$

where $\boldsymbol{a}$ is the uniform acceleration of the body. Equation (3.1.18) shows that the lines of constant pressure, including a free surface if any, are perpendicular to the direction $\boldsymbol{g} - \boldsymbol{a}$. Two important applications of this are to fluids in uniform linear translation and rigid-body rotation. Although such problems are not, strictly speaking, fluid statics problems, their analysis and the resulting pressure variation are similar to those for static fluids.

Uniform Linear Acceleration

For a fluid partially filling a large container moving to the right with constant acceleration $\boldsymbol{a} = (a_x, a_y)$, the geometry of Figure 3.1.4 shows that the magnitude of the pressure gradient in the direction $\boldsymbol{n}$ normal to the accelerating free surface, in the direction $\boldsymbol{g} - \boldsymbol{a}$, is

$$\frac{dp}{dn} = \rho\left[a_x^2 + \left(g + a_y\right)^2\right]^{\frac{1}{2}} \tag{3.1.19}$$

and the angle to the horizontal of the free surface is

$$\theta = \tan^{-1}\left[\frac{a_x}{g + a_y}\right] \tag{3.1.20}$$

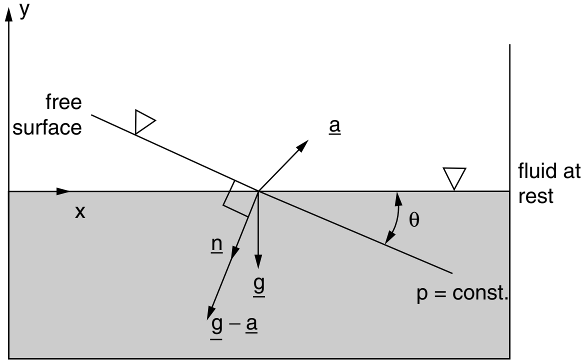

FIGURE 3.1.4 A fluid with a free surface in uniform linear acceleration.

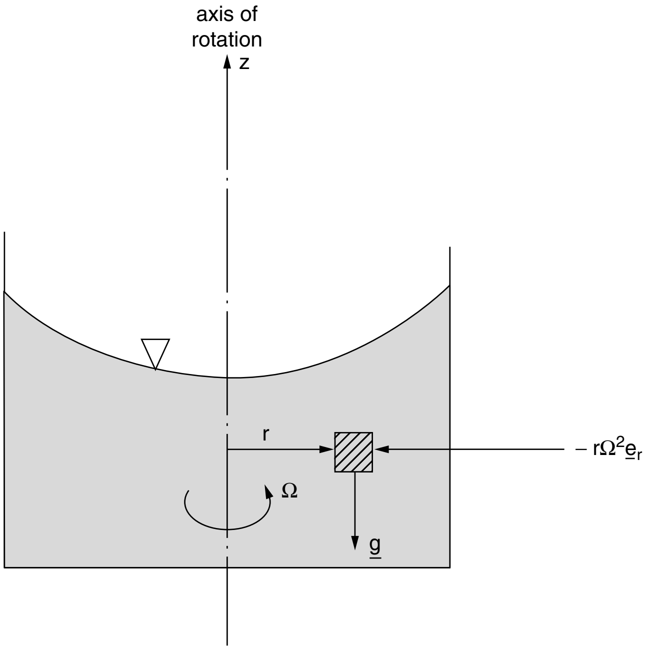

FIGURE 3.1.5 A fluid with a free surface in rigid-body rotation.

Rigid-Body Rotation

Consider a fluid-filled circular cylinder rotating uniformly with angular velocity $\boldsymbol{\Omega} = \Omega \boldsymbol{e}_z$ (Figure 3.1.5). The only acceleration is the centripetal acceleration $\boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \boldsymbol{r}) = -r\Omega^2 \boldsymbol{e}_r$, so Equation 3.1.18 becomes:

$$\nabla p = \frac{\partial p}{\partial r}\boldsymbol{e}_r + \frac{\partial p}{\partial z}\boldsymbol{e}_z = \rho(\boldsymbol{g} - \boldsymbol{a}) = \rho\left(r\Omega^2 \boldsymbol{e}_r - g\boldsymbol{e}_z\right) \tag{3.1.21}$$

or

$$\frac{\partial p}{\partial r} = \rho r \Omega^2, \qquad \frac{\partial p}{\partial z} = -\rho g = -\gamma \tag{3.1.22}$$

Integration of these equations leads to

$$p = p_0 - \gamma z + \frac{1}{2}\rho r^2 \Omega^2 \tag{3.1.23}$$

where p_0 is a reference pressure (at $r = z = 0$). Thus, at any fixed r, the pressure varies hydrostatically in the vertical direction, and the constant pressure surfaces, including the free surface, are paraboloids of revolution.

Further Information

The reader may find more detail and additional information on the topics in this section in any of the many excellent introductory texts on fluid mechanics, such as

White, F.M. 2003. *Fluid Mechanics*, 5th ed., McGraw–Hill, Boston.

Munson, B.R., Young, D.F., and Okiishi, T.H. 2003. *Fundamentals of Fluid Mechanics*, 4th ed., John Wiley & Sons, New York.

3.2 Equations of Motion and Potential Flow

Stanley A. Berger

Integral Relations for a Control Volume

Like most physical conservation laws, those governing motion of a fluid apply to (*moving*) material particles or systems of such particles. This so-called *Lagrangian viewpoint* is generally not as useful in practical fluid flows as an analysis using *fixed* (deformable) control volumes — the *Eulerian viewpoint*. The relationship between these two viewpoints can be deduced from the Reynolds transport theorem, from which one also most readily derives the governing integral and differential equations of motion.

Reynolds Transport Theorem

An *extensive* quantity *B*, which can be a scalar, vector, or tensor, is defined as any physical property of the fluid (e.g., momentum, energy) and *b* as the corresponding value per unit mass (the *intensive value*). The *Reynolds transport theorem* for a moving and arbitrarily deforming control volume *CV*, with boundary *CS* (see Figure 3.2.1), states that

$$\frac{d}{dt}\left(B_{\text{system}}\right)=\frac{d}{dt}\iiint_{\text{CV}}\rho b\,d\upsilon+\iint_{\text{CS}}\rho b\left(\boldsymbol{V}_r\cdot\boldsymbol{n}\right)dA \tag{3.2.1}$$

where B_{system} is the total quantity of *B* in the system (any mass of fixed identity); $\boldsymbol{n}$ is the outward normal to the CS, $\boldsymbol{V}_r = \boldsymbol{V}(\boldsymbol{r},t) - \boldsymbol{V}_{\text{CS}}(\mathbf{r},t)$, the velocity of the fluid particle, $\boldsymbol{V}(\boldsymbol{r},t)$, relative to that of the CS, $\boldsymbol{V}_{\text{CS}}(\mathbf{r},t)$; and *d/dt* on the left-hand side is the derivative following the fluid particles, i.e., the fluid mass comprising the system.

The theorem states that the time rate of change of the total *B* in the system is equal to the rate of change within the *CV* plus the net flux of *B* through the CS. To distinguish between the *d/dt* that appear on the two sides of Equation (3.2.1) but which have different interpretations, the derivative on the left-hand side, following the system, is denoted by *D/Dt* and is called the *material derivative*. This notation is used in what follows. For any function *f(x, y, z, t),*

$$\frac{Df}{Dt}=\frac{\partial f}{\partial t}+\boldsymbol{V}\cdot\nabla f$$

For a CV fixed with respect to the reference frame, Equation (3.2.1) reduces to

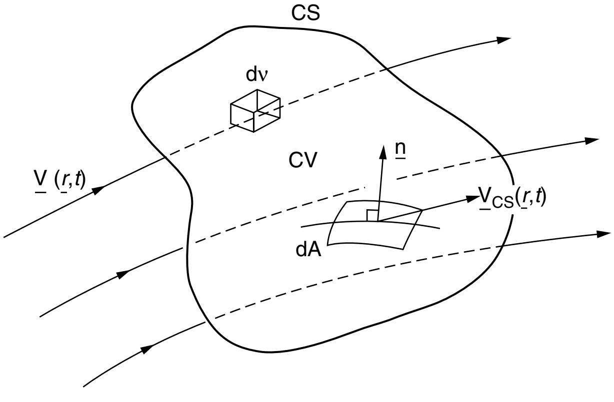

FIGURE 3.2.1 Control volume.

$$\frac{D}{Dt}\left(B_{\text{system}}\right)=\frac{d}{dt}\iiint\limits_{\substack{\text{CV}\\ \text{(fixed)}}}\rho b\,d\upsilon+\iint\limits_{\text{CS}}\rho \mathrm{b}\left(\boldsymbol{V}\cdot\boldsymbol{n}\right)dA \tag{3.2.2}$$

(In addition, for this case, the time derivative operator in the first term on the right-hand side may be moved inside the integral, in which case it is then to be interpreted as the partial derivative $\partial/\partial t$.)

Conservation of Mass

Applying Equation (3.2.2) for a fixed control volume, with B_{system} the total mass in the system, then, because conservation of mass requires that $DB_{\text{system}}/Dt = 0$, it follows, because $b = B_{\text{system}}/m = 1$, that

$$\iiint\limits_{\substack{\text{CV}\\ \text{(fixed)}}}\frac{\partial\rho}{\partial t}\,d\upsilon+\iint\limits_{\text{CS}}\rho\left(\boldsymbol{V}\cdot\boldsymbol{n}\right)dA=0 \tag{3.2.3}$$

This is the *integral form* of the *conservation of mass law* for a *fixed control volume*. For steady flow, Equation (3.2.3) reduces to

$$\iint\limits_{\text{CS}}\rho\left(\boldsymbol{V}\cdot\boldsymbol{n}\right)dA=0 \tag{3.2.4}$$

whether *compressible* or *incompressible*. For an incompressible flow, ρ = constant, so

$$\iint\limits_{\text{CS}}\left(\boldsymbol{V}\cdot\boldsymbol{n}\right)dA=0 \tag{3.2.5}$$

whether the flow is steady or unsteady.

Conservation of Momentum

The *conservation of (linear) momentum* states that

$$\boldsymbol{F}_{\text{total}}\equiv\sum\left(\text{external forces acting on the fluid system}\right)=\frac{D\boldsymbol{M}}{Dt}\equiv\frac{D}{Dt}\iiint\limits_{\text{system}}\rho\boldsymbol{V}\,d\upsilon \tag{3.2.6}$$

where $\boldsymbol{M}$ is the total system momentum. For an arbitrarily moving, deformable control volume, it then follows from Equation (3.2.1) with b set to $\boldsymbol{V}$, that

$$\boldsymbol{F}_{\text{total}}=\frac{d}{dt}\iiint\limits_{\text{CV}}\rho\boldsymbol{V}\,d\upsilon+\iint\limits_{\text{CS}}\rho\boldsymbol{V}\left(\boldsymbol{V}_r\cdot\boldsymbol{n}\right)dA \tag{3.2.7}$$

This expression is only valid in an *inertial coordinate frame*. For the equivalent expression in a *noninertial frame*, the relationship between the acceleration $\boldsymbol{a}_I$ in an inertial frame and that in a noninertial frame, $\boldsymbol{a}_R$, is used:

$$\boldsymbol{a}_I=\boldsymbol{a}_R+\frac{d^2\boldsymbol{R}}{dt^2}+2\boldsymbol{\Omega}\times\boldsymbol{V}+\boldsymbol{\Omega}\times\left(\boldsymbol{\Omega}\times\boldsymbol{r}\right)+\frac{d\boldsymbol{\Omega}}{dt}\times\boldsymbol{r} \tag{3.2.8}$$

where $\boldsymbol{R}$ is the position vector of the origin of the noninertial frame with respect to that of the inertial frame; $\boldsymbol{\Omega}$ is the angular velocity of the noninertial frame; and $\boldsymbol{r}$ and $\boldsymbol{V}$ the position and velocity vectors in the noninertial frame. The third term on the right-hand side of Equation (3.2.8) is the *Coriolis acceleration* and the fourth term is the *centrifugal acceleration*. In a noninertial frame, Equation (3.2.7) is

$$\begin{aligned}\boldsymbol{F}_{\text{total}} - \iiint_{\text{system}} \left[\frac{d^2\boldsymbol{R}}{dt^2} + 2\boldsymbol{\Omega}\times\boldsymbol{V} + \boldsymbol{\Omega}\times(\boldsymbol{\Omega}\times\boldsymbol{r}) + \frac{d\boldsymbol{\Omega}}{dt}\times\boldsymbol{r}\right]\rho\, d\upsilon &= \frac{D}{Dt}\iiint_{\text{system}} \rho\boldsymbol{V}\, d\upsilon \\ &= \frac{d}{dt}\iiint_{\text{CV}} \rho\boldsymbol{V}\, d\upsilon + \iint_{\text{CS}} \rho\boldsymbol{V}(\boldsymbol{V}_r\cdot\boldsymbol{n})\, dA\end{aligned} \tag{3.2.9}$$

where the frame acceleration terms of Equation (3.2.8) have been brought to the left-hand side because, to an observer in the noninertial frame, they act as “apparent” body forces.

For a *fixed control volume* in an *inertial frame for steady flow*, it follows from the preceding that

$$\boldsymbol{F}_{\text{total}} = \iint_{\text{CS}} \rho\boldsymbol{V}(\boldsymbol{V}\cdot\boldsymbol{n})\, dA \tag{3.2.10}$$

This expression is the basis of many control volume analyses for fluid flow problems.

The cross product of $\boldsymbol{r}$, the position vector with respect to a convenient origin, with the momentum Equation (3.2.6) written for an elementary particle of mass dm, noting that $(d\boldsymbol{r}/dt)\times\boldsymbol{V} = 0$, leads to the *integral moment of momentum equation*:

$$\sum \boldsymbol{M} - \boldsymbol{M}_I = \frac{D}{Dt}\iiint_{\text{system}} \rho(\boldsymbol{r}\times\boldsymbol{V})\, d\upsilon \tag{3.2.11}$$

where $\Sigma\boldsymbol{M}$ is the sum of the moments of all the external forces acting on the system about the origin of $\boldsymbol{r}$, and $\boldsymbol{M}_I$ is the moment of the apparent body forces (see Equation 3.2.9). The right-hand side can be written for a control volume using the appropriate form of the Reynolds transport theorem.

Conservation of Energy

The conservation of energy law follows from the first law of thermodynamics for a moving system

$$\dot{Q} - \dot{W} = \frac{D}{Dt}\iiint_{\text{system}} \rho e\, d\upsilon \tag{3.2.12}$$

where $\dot{Q}$ is the rate at which heat is added to the system; $\dot{W}$ the rate at which the system works on its surroundings; and e the total energy per unit mass, the specific energy.

For a particle of mass dm, the contributions to e are the internal energy u; the kinetic energy $V^2/2$; and the potential energy, which, in the case of gravity (the only body force to be considered here) is gz, where z is the vertical displacement opposite to the direction of gravity. (No energy transfer due to chemical reaction, as well as no magnetic or electric fields, is assumed.) For a fixed control volume, it follows from Equation (3.2.2) and Equation (3.2.12) (with $b = e = u + (V^2/2) + gz$) that

$$\dot{Q} - \dot{W} = \frac{d}{dt}\iiint_{\text{CV}} \rho\left[u + \frac{1}{2}V^2 + gz\right] d\upsilon + \iint_{\text{CS}} \rho\left[u + \frac{1}{2}V^2 + gz\right](\boldsymbol{V}\cdot\boldsymbol{n})\, dA \tag{3.2.13}$$

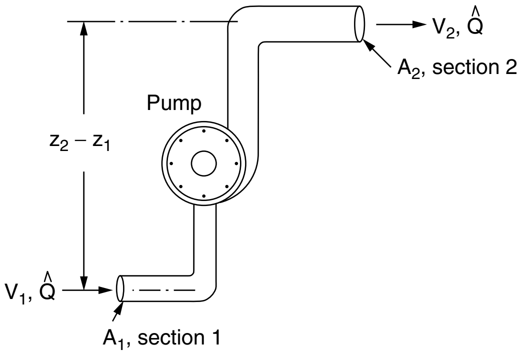

FIGURE 3.2.2 Pump producing pressure increase.

Problem

An incompressible fluid flows through a pump at a volumetric flow rate $\hat{Q}$. The (head) loss between sections 1 and 2 (see Figure 3.2.2) is equal to $\beta\rho V_1^2/2$ (V is the average velocity at the section). Calculate the power that must be delivered by the pump to the fluid to produce a given increase in pressure, $\Delta p = p_2 - p_1$.

Solution: The principal equation needed is the energy equation (Equation 3.2.13). The term $\dot{W}$, the rate at which the system does work on its surroundings, for such problems has the form:

$$\dot{W} = -\dot{W}_{\text{shaft}} + \iint_{\text{CS}} p\boldsymbol{V}\cdot\boldsymbol{n}\,dA \tag{P.3.2.1}$$

where $\dot{W}_{\text{shaft}}$ represents the work done on the fluid by a moving shaft, such as by turbines, propellers, fans, etc., and the second term on the right side represents the rate of working by the normal stress, the pressure, at the boundary. For steady flow in a control volume coincident with the physical system boundaries and bounded by sections 1 and 2, Equation (3.2.13) reduces to ($u \equiv 0$),

$$\dot{Q} + \dot{W}_{\text{shaft}} - \iint_{\text{CS}} p\boldsymbol{V}\cdot\boldsymbol{n}\,dA = \iint_{\text{CS}} \left[\frac{1}{2}\rho V^2 + \gamma z\right](\boldsymbol{V}\cdot\boldsymbol{n})\,dA \tag{P.3.2.2}$$

Using average quantities at sections 1 and 2, and the continuity equation (Equation 3.2.5), which reduces in this case to

$$V_1A_1 = V_2A_2 = \hat{Q}, \tag{P.3.2.3}$$

Equation (P.3.2.2) can be written as

$$\dot{Q} + \dot{W}_{\text{shaft}} - (p_2 - p_1)\hat{Q} = \left[\frac{1}{2}\rho\left(V_2^2 - V_1^2\right) + \gamma(z_2 - z_1)\right]\hat{Q} \tag{P.3.2.4}$$

$\dot{Q}$, the rate at which heat is added to the system, is here equal to $-\beta\rho V_1^2/2$, the head loss between sections 1 and 2. Equation (P.3.2.4) then can be rewritten

$$\dot{W}_{\text{shaft}} = \beta\rho\frac{V_1^2}{2} + (\Delta p)\hat{Q} + \frac{1}{2}\rho\left(V_2^2 - V_1^2\right)\hat{Q} + \gamma(z_2 - z_1)\hat{Q}$$

or, in terms of the given quantities,

$$\dot{W}_{\text{shaft}} = \frac{\beta\rho\hat{Q}^2}{A_1^2} + (\Delta p)\hat{Q} + \frac{1}{2}\rho\frac{\hat{Q}^3}{A_2^2}\left(1 - \frac{A_2^2}{A_1^2}\right) + \gamma(z_2 - z_1)\hat{Q} \tag{P.3.2.5}$$

Thus, for example, if the fluid is water ($\rho \approx 1000$ kg/m^3, $\gamma = 9.8$ kN/m^3), $\hat{Q} = 0.5$ m^3/sec, the heat loss is $0.2\rho V_1^2/2$, and $\Delta p = p_2 - p_1 = 2 \times 10^5$ N/m^2 = 200 kPa, $A_1 = 0.1$ m^2 = $A_2/2$, $(z_2 - z_1) = 2$ m, we find, using Equation (P.3.2.5),

$$\begin{aligned}\dot{W}_{\text{shaft}} &= \frac{0.2(1000)(0.5)^2}{(0.1)^2} + (2\times10^5)(0.5) + \frac{1}{2}(1000)\frac{(0.5)^3}{(0.2)^2}(1-4) + (9.8\times10^3)(2)(0.5)\\ &= 5{,}000 + 10{,}000 - 4{,}688 + 9{,}800 = 20{,}112\,\text{Nm/sec}\\ &= 20{,}112\ \text{W} = \frac{20{,}112}{745.7}\text{hp} = 27\,\text{hp}\end{aligned}$$

Differential Relations for Fluid Motion

In the previous section, the conservation laws were derived in integral form. These forms are useful in calculating, generally using a control volume analysis, gross features of a flow. Such analyses usually require some *a priori* knowledge or assumptions about the flow. In any case, an approach based on integral conservation laws cannot be used to determine the point-by-point variation of the dependent variables, such as velocity, pressure, temperature, etc. To do this requires the use of the differential forms of the conservation laws, which are presented next.

Mass Conservation — Continuity Equation

Applying Gauss's theorem (the divergence theorem) to Equation (3.2.3) yields

$$\underset{\substack{\text{CV}\\ \text{(fixed)}}}{\iiint}\left[\frac{\partial\rho}{\partial t} + \nabla\cdot(\rho\boldsymbol{V})\right]d\upsilon = 0 \tag{3.2.14}$$

which, because the control volume is arbitrary, immediately yields

$$\frac{\partial\rho}{\partial t} + \nabla\cdot(\rho\boldsymbol{V}) = 0 \tag{3.2.15}$$

This can also be written as

$$\frac{D\rho}{Dt} + \rho\nabla\cdot\boldsymbol{V} = 0 \tag{3.2.16}$$

using the fact that

$$\frac{D\rho}{Dt} = \frac{\partial\rho}{\partial t} + \boldsymbol{V}\cdot\nabla\rho \tag{3.2.17}$$

Special cases:

1. Steady flow $[(\partial/\partial t)\,() \equiv 0]$

$$\nabla\cdot(\rho\boldsymbol{V})=0 \tag{3.2.18}$$

2. Incompressible flow $(\mathrm{D}\rho/\mathrm{Dt} \equiv 0)$

$$\nabla\cdot\boldsymbol{V}=0 \tag{3.2.19}$$

Momentum Conservation

As a consequence of mass conservation for a system, the right-hand side of Equation (3.2.6) can be written as

$$\frac{D}{Dt}\underset{\text{system}}{\iiint}\rho\boldsymbol{V}\,d\upsilon \equiv \underset{\text{system}}{\iiint}\rho\frac{D\boldsymbol{V}}{Dt}\,d\upsilon \tag{3.2.20}$$

The total force acting on the system is the sum of the *body forces* $\boldsymbol{F}_b$ and *surface forces* $\boldsymbol{F}_s$. Body forces are often given as forces per unit mass (e.g., gravity) and thus can be written

$$\boldsymbol{F}_b = \underset{\text{system}}{\iiint}\rho\boldsymbol{f}\,d\upsilon \tag{3.2.21}$$

The surface forces are represented in terms of the second-order *stress tensor*[1] $\underline{\underline{\sigma}} = \{\sigma_{ij}\}$, where σ_{ij} is defined as the force per unit area in the i direction on a planar element whose normal lies in the j direction.[2] From elementary *angular momentum* considerations for an infinitesimal volume, it can be shown that σ_{ij} is a *symmetric tensor* and therefore has only six independent components. The total surface force exerted on the system by its surroundings is

$$\boldsymbol{F}_s = \underset{\substack{\text{system}\\\text{surface}}}{\iint}\underline{\underline{\sigma}}\cdot\boldsymbol{n}\,dA,\ \text{with } i-\text{component } \mathrm{F}_{s_i} = \iint\sigma_{ij}\boldsymbol{n}_j\,dA \tag{3.2.22}$$

The integral momentum conservation law, Equation (3.2.6), can then be written

$$\underset{\text{system}}{\iiint}\rho\frac{D\boldsymbol{V}}{Dt}d\upsilon = \underset{\text{system}}{\iiint}\rho\boldsymbol{f}\,d\upsilon + \underset{\substack{\text{system}\\\text{surface}}}{\iint}\underline{\underline{\sigma}}\cdot\boldsymbol{n}\,dA \tag{3.2.23}$$

The application of the divergence theorem to the last term in Equation (3.2.23) leads to

$$\underset{\text{system}}{\iiint}\rho\frac{D\boldsymbol{V}}{Dt}d\upsilon = \underset{\text{system}}{\iiint}\rho\boldsymbol{f}\,d\upsilon + \underset{\text{system}}{\iiint}\nabla\cdot\underline{\underline{\sigma}}\,d\upsilon \tag{3.2.24}$$

---

[1] It is assumed that the reader is familiar with elementary Cartesian tensor analysis and the associated subscript notation and conventions. The reader for whom this is not true should skip the details and concentrate on the final principal results and equations given at the ends of the next few subsections.

[2] This assignment of roles to the first and second subscripts of the stress tensor is a convention that is far from universal. Frequently, their roles are reversed: the first subscript denotes the direction of the normal to the planar element and the second denotes the direction of the force.

where $\nabla \cdot \underline{\underline{\sigma}} \equiv \{\partial\sigma_{ij}/\partial x_j\}$. Because Equation (3.2.24) holds for any material volume, it follows that

$$\rho \frac{D\boldsymbol{V}}{Dt} = \rho \boldsymbol{f} + \nabla \cdot \underline{\underline{\sigma}} \tag{3.2.25}$$

[With the preceding decomposition of $\boldsymbol{F}_{\text{total}}$, Equation (3.2.10) can be written

$$\iiint\limits_{\text{CV}} \rho \boldsymbol{f}\, d\upsilon + \iint\limits_{\text{CS}} \underline{\underline{\sigma}} \cdot \boldsymbol{n}\, dA = \iint\limits_{\text{CS}} \rho \boldsymbol{V}(\boldsymbol{V} \cdot \boldsymbol{n})\, dA \tag{3.2.26}$$

If ρ is uniform and $\boldsymbol{f}$ is a *conservative body force*, i.e., $\boldsymbol{f} = -\nabla\Psi$, where Ψ is the *body force potential*, then Equation (3.2.26), after application of the divergence theorem to the body force term, can be written

$$\iint\limits_{\text{CS}} \left(-\rho\Psi\boldsymbol{n} + \underline{\underline{\sigma}} \cdot \boldsymbol{n}\right) dA = \iint\limits_{\text{CS}} \rho \boldsymbol{V}(\boldsymbol{V} \cdot \boldsymbol{n})\, dA \tag{3.2.27}$$

This integral form of the momentum equation, involving integrals only over the surface of the control volume, is commonly used in control volume analyses, particularly when the body force term is absent.]

Analysis of Rate of Deformation

The principal aim of the following two subsections is to derive a relationship between the *stress* and the *rate of strain* to be used in the momentum equation (Equation 3.2.25). The reader less familiar with tensor notation may skip these sections, apart from noting some of the terms and quantities defined therein, and proceed directly to Equation (3.2.38) or Equation (3.2.39).

The relative motion of two neighboring points P and Q, separated by a distance η, can be written (**u** is the local velocity)

$$\boldsymbol{u}(Q) = \boldsymbol{u}(P) + (\nabla \boldsymbol{u})\boldsymbol{\eta}$$

or, equivalently, writing $\nabla \boldsymbol{u}$ as the sum of antisymmetric and symmetric tensors,

$$\boldsymbol{u}(Q) = \boldsymbol{u}(P) + \frac{1}{2}\left((\nabla \boldsymbol{u}) - (\nabla \boldsymbol{u})^*\right)\boldsymbol{\eta} + \frac{1}{2}\left((\nabla \boldsymbol{u}) + (\nabla \boldsymbol{u})^*\right)\boldsymbol{\eta} \tag{3.2.28}$$

where $\nabla \boldsymbol{u} = \{\partial u_i/\partial x_j\}$, and the superscript * denotes transpose, so $(\nabla \boldsymbol{u})^* = \{\partial u_j/\partial x_i\}$. The second term on the right-hand side can be rewritten in terms of the *vorticity*, $\nabla \times \boldsymbol{u}$, so Equation (3.2.28) becomes

$$\boldsymbol{u}(Q) = \boldsymbol{u}(P) + \frac{1}{2}(\nabla \times \boldsymbol{u}) \times \boldsymbol{\eta} + \frac{1}{2}\left((\nabla \boldsymbol{u}) + (\nabla \boldsymbol{u})^*\right)\boldsymbol{\eta} \tag{3.2.29}$$

which shows that the *local rate of deformation* consists of a *rigid-body translation*, a *rigid-body rotation* with *angular velocity* $\frac{1}{2}(\nabla \times \boldsymbol{u})$ and a *velocity or rate of deformation*. The coefficient of η in the last term in Equation (3.2.29) is defined as the *rate-of-strain tensor* and is denoted by $\underline{\underline{e}}$, in subscript form

$$e_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \tag{3.2.30}$$

From $\underline{\underline{e}}$, one can define a *rate-of-strain central quadric*, along the *principal axes* of which the deforming motion consists of a *rate of pure extension* or *contraction*.

Relationship between Forces and Rate of Deformation

Now the required relationship between the stress tensor and the rate of deformation is considered. Assuming that in a static fluid the stress reduces to a (negative) hydrostatic or thermodynamic pressure, equal in all directions, one can write

$$\underline{\underline{\sigma}} = -p\underline{\underline{\boldsymbol{I}}} + \underline{\underline{\tau}} \quad \text{or} \quad \sigma_{ij} = -p\delta_{ij} + \tau_{ij} \tag{3.2.31}$$

where $\underline{\underline{\tau}}$ is the viscous part of the total stress and is called the *deviatoric stress tensor*; $\underline{\underline{\boldsymbol{I}}}$ is the *identity tensor*, and δ_{ij} is the *Kronecker delta* ($\delta_{ij} = 0$ if $i \neq j$; $\delta_{ij} = 1$ if $i = j$). It is further assumed that (1) the fluid exhibits no preferred directions; (2) the stress is independent of any previous history of distortion; and (3) the stress depends only on the local thermodynamic state and the kinematic state of the immediate neighborhood. Specifically, $\underline{\underline{\tau}}$ is assumed to be linearly proportional to the first spatial derivatives of $\boldsymbol{u}$, the coefficient of proportionality depending only on the local thermodynamic state.

These assumptions, and the relations below that follow from them, are appropriate for a *Newtonian fluid*. Most common fluids, such as air and water under most conditions, are Newtonian, but many other fluids, including many that arise in industrial applications, exhibit so-called *non-Newtonian* properties. The study of such non-Newtonian fluids, such as viscoelastic fluids, is the subject of the field of *rheology*.

With the preceding Newtonian fluid assumptions and the *symmetry* of $\underline{\underline{\tau}}$, which follows from the symmetry of $\underline{\underline{\sigma}}$, one can show that the viscous part $\underline{\underline{\tau}}$ of the stress can be written as

$$\underline{\underline{\tau}} = \lambda(\nabla \cdot \boldsymbol{u})\underline{\underline{\boldsymbol{I}}} + 2\mu\underline{\underline{e}} \tag{3.2.32}$$

Thus, the total stress for a Newtonian fluid is

$$\underline{\underline{\sigma}} = -p\underline{\underline{\boldsymbol{I}}} + \lambda(\nabla \cdot \boldsymbol{u})\underline{\underline{\boldsymbol{I}}} + 2\mu\underline{\underline{e}} \tag{3.2.33}$$

or, in subscript notation

$$\sigma_{ij} = -p\delta_{ij} + \lambda\left(\frac{\partial u_k}{\partial x_k}\right)\delta_{ij} + \mu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \tag{3.2.34}$$

(The *Einstein summation convention* is assumed here: namely, that in any expression containing a repeated subscript, such as in the second term on the right-hand side above, that subscript is to be given all its possible values and the results then summed; note also that $\nabla \cdot \boldsymbol{u} = \partial u_k/\partial x_k = e_{kk}$.)

The coefficient λ is called the *second viscosity* and μ the *absolute viscosity* or, more commonly, the *dynamic viscosity*, or simply the "viscosity." For a Newtonian fluid, λ and μ depend only on local thermodynamic state, primarily on the temperature.

Note that, from Equation (3.2.34), whereas in a fluid at rest the pressure is an isotropic normal stress (equal to p in all directions), this is not the case for a moving fluid because, in general, $\sigma_{11} \neq \sigma_{22} \neq \sigma_{33}$. To have a quantity analogous to p for a moving fluid we define the pressure in a moving fluid as the negative mean normal stress, denoted, say, by $\bar{p}$, thusly:

$$\bar{p} = -\frac{1}{3}\sigma_{ii} \tag{3.2.35}$$

(σ_{ii} is the *trace* of $\underline{\underline{\sigma}}$ and an *invariant* of $\underline{\underline{\sigma}}$, independent of the orientation of the axes.) From Equation (3.2.34)

$$\bar{p} = -\frac{1}{3}\sigma_{ii} = p - \left(\lambda + \frac{2}{3}\mu\right)\nabla \cdot \boldsymbol{u} \tag{3.2.36}$$

For an incompressible fluid, $\nabla \cdot \boldsymbol{u} = 0$ and thus $\bar{p} \equiv p$. The quantity $(\lambda + \tfrac{2}{3}\mu)$ is called the *bulk viscosity.* If one assumes that the deviatoric stress tensor τ_{ij} makes no contribution to the mean normal stress, it follows that $\lambda + \tfrac{2}{3}\mu = 0$, so again $\bar{p} = p$. This condition, $\lambda = -\tfrac{2}{3}\mu$, is called the *Stokes assumption* or *hypothesis.* If neither the incompressibility nor the Stokes assumptions are made, the difference between $\bar{p}$ and p is usually negligibly small because generally $(\lambda + \tfrac{2}{3}\mu)\nabla \cdot \boldsymbol{u} << p$. If the Stokes hypothesis is made, as is often done, Equation (3.2.34) becomes

$$\sigma_{ij} = -p\delta_{ij} + 2\mu\left(e_{ij} - \frac{1}{3}e_{kk}\delta_{ij}\right) \tag{3.2.37}$$

The Navier–Stokes Equations

Substitution of Equation (3.2.33) into Equation (3.2.25), because $\nabla \cdot (\phi \underline{\underline{\boldsymbol{I}}}) = \nabla\phi$, for any scalar function ϕ, yields (replacing $\mathbf{u}$ in Equation (3.2.33) by $\boldsymbol{V}$)

$$\rho\frac{D\boldsymbol{V}}{Dt} = \rho\boldsymbol{f} - \nabla p + \nabla(\lambda\nabla \cdot \boldsymbol{V}) + \nabla \cdot \left(2\mu\underline{\underline{e}}\right) \tag{3.2.38}$$

These are the *Navier–Stokes equations* (although the name is as often given to the full set of governing conservation equations). With the Stokes assumption $(\lambda = -\tfrac{2}{3}\mu)$, Equation (3.2.38) becomes

$$\rho\frac{D\boldsymbol{V}}{Dt} = \rho\boldsymbol{f} - \nabla p + \nabla \cdot \left[2\mu\left(\underline{\underline{e}} - \frac{1}{3}e_{kk}\underline{\underline{\boldsymbol{I}}}\right)\right] \tag{3.2.39}$$

If the Eulerian frame is not an inertial frame, one can transform to an inertial frame using Equation (3.2.8) or the “apparent” body force formulation, Equation (3.2.9).

Energy Conservation — Mechanical and Thermal Energy Equations

The derivation of the differential form of the energy equation using Equation (3.2.12) begins by assuming that heat enters or leaves the material or control volume by heat conduction across the boundaries, the *heat flux per unit area* being $\boldsymbol{q}$, so

$$\dot{Q} = -\iint \boldsymbol{q} \cdot \boldsymbol{n}\, dA = -\iiint \nabla \cdot \boldsymbol{q}\, d\upsilon \tag{3.2.40}$$

The work-rate term $\dot{W}$ can be decomposed into the rate of work done against body forces

$$-\iiint \rho\boldsymbol{f} \cdot \boldsymbol{V}\, d\upsilon \tag{3.2.41}$$

and the rate of work done against surface stresses

$$-\iint_{\substack{\text{system}\\ \text{surface}}} \boldsymbol{V} \cdot \left(\underline{\underline{\sigma}}\boldsymbol{n}\right) dA \tag{3.2.42}$$

Substitution of these expressions for $\dot{Q}$ and $\dot{W}$ into Equation (3.2.12), use of the divergence theorem, and conservation of mass lead to

$$\rho\frac{D}{Dt}\left(u + \frac{1}{2}V^2\right) = -\nabla \cdot \boldsymbol{q} + \rho\boldsymbol{f} \cdot \boldsymbol{V} + \nabla \cdot \left(\boldsymbol{V}\underline{\underline{\sigma}}\right) \tag{3.2.43}$$

(The potential energy term no longer appears in *e*, the total specific energy, because it is accounted for by the body force rate-of-working term $\rho \boldsymbol{f} \cdot \boldsymbol{V}$.)

Equation (3.2.43), the total energy equation,[3] shows how the energy changes as a result of working by the body and surface forces, and heat transfer. It is useful to have an equation purely for the thermal energy. This is obtained by subtracting from Equation (3.2.43) the dot product of $\boldsymbol{V}$ with the momentum Equation (3.2.25), after expanding the last term in Equation (3.2.43); this results in

$$\rho \frac{Du}{Dt} = \frac{\partial V_i}{\partial x_j} \boldsymbol{\sigma}_{ij} - \nabla \cdot \boldsymbol{q} \tag{3.2.44}$$

With $\sigma_{ij} = -p\delta_{ij} + \tau_{ij}$, and the continuity equation, Equation (3.2.16), the first term on the right-hand side of Equation (3.2.44) may be written

$$\frac{\partial V_i}{\partial x_j} \sigma_{ij} = -\rho \frac{D(p/\rho)}{Dt} + \frac{Dp}{Dt} + \Phi \tag{3.2.45}$$

where Φ is the *rate of dissipation of mechanical energy per unit mass* due to *viscosity*, given by

$$\Phi \equiv \frac{\partial V_i}{\partial x_j} \tau_{ij} = 2\mu \left(e_{ij} e_{ij} - \frac{1}{3} e_{kk}^2 \right) = 2\mu \left(e_{ij} - \frac{1}{3} e_{kk} \delta_{ij} \right)^2 \tag{3.2.46}$$

With the introduction of Equation (3.2.45), Equation (3.2.44) becomes

$$\rho \frac{De}{Dt} = -p \nabla \cdot \boldsymbol{V} + \Phi - \nabla \cdot \boldsymbol{q} \tag{3.2.47}$$

or

$$\rho \frac{Dh}{Dt} = \frac{Dp}{Dt} + \Phi - \nabla \cdot \boldsymbol{q} \tag{3.2.48}$$

where $h = e + (p/\rho)$ is the *specific enthalpy*. Unlike the other terms on the right-hand side of Equation (3.2.47), which can be negative or positive, Φ is always non-negative and represents the increase in internal energy (or enthalpy) owing to irreversible degradation of mechanical energy.

Finally, from elementary thermodynamic considerations

$$\frac{Dh}{Dt} = T \frac{DS}{Dt} + \frac{1}{\rho} \frac{Dp}{Dt}$$

where *S* is the *entropy*, so Equation (3.2.48) can be written

$$\rho T \frac{DS}{Dt} = \Phi - \nabla \cdot \boldsymbol{q} \tag{3.2.49}$$

---

[3] There may be energy production, source, terms not included in this energy equation, which, depending on circumstances, should be included. The irreversible degradation of mechanical energy into heat by viscosity is accounted for (see Equation 3.2.48), but other contributions — chemical, electromagnetic, nuclear, etc. — may be important and their roles in the energy balance equation should then be taken into account. (See Bird et al., 2002.)

If the heat conduction is assumed to obey the *Fourier heat conduction law*, so that $\boldsymbol{q} = -k\nabla T$, where k is the *thermal conductivity*, then in the preceding equations

$$-\nabla \cdot \boldsymbol{q} = \nabla \cdot \left(k \nabla T\right) = k \nabla^2 T \tag{3.2.50}$$

the last of these equalities holding only if k = constant.

If the thermodynamic quantities vary little, the coefficients of the constitutive relations for $\underline{\underline{\sigma}}$ and $\boldsymbol{q}$ may be taken to be constant and the preceding equations simplified accordingly.

Incompressible Flow

If the flow is incompressible, then the mass conservation, or continuity, equation simplifies to

$$\nabla \cdot \boldsymbol{V} = 0 \tag{3.2.51}$$

and the momentum Equation (3.2.38) simplifies to

$$\rho \frac{D\boldsymbol{V}}{Dt} = \rho \boldsymbol{f} - \nabla p + \mu \nabla^2 \boldsymbol{V} \tag{3.2.52}$$

where ∇^2 is the Laplacian operator. Then the small temperature changes, compatible with the incompressibility assumption, are determined for a perfect gas with constant k and specific heats by the energy equation, rewritten for the temperature, in the form

$$\rho c_v \frac{DT}{Dt} = k \nabla^2 T + \Phi \tag{3.2.53}$$

where c_v is the *specific heat.*

Boundary Conditions

The appropriate boundary conditions to be applied at the boundary of a fluid in contact with another medium depend on the nature of this other medium — solid, liquid, or gas. A few of the more important cases are discussed here:

- *At a solid–fluid interface*: $\boldsymbol{V}$ and T are continuous. Contained in this boundary condition is the "no-slip" condition: namely, that the tangential velocity of the fluid in contact with the boundary of the solid is equal to that of the boundary. For an *inviscid* fluid, the no-slip condition does not apply, and only the normal component of velocity is continuous. If the wall is *permeable*, the tangential velocity is continuous and the normal velocity is arbitrary; the temperature boundary condition for this case depends on the nature of the injection or suction at the wall.
- *At a liquid–liquid interface*: The velocity components are continuous across the interface, as are the normal and tangential stress components.
- *At a liquid–gas interface*: For such cases the appropriate boundary conditions depend on what can be assumed about the gas in contact with the liquid. In the classical liquid-free surface problem, the tangential stresses in the gas, often atmospheric air, are generally negligible and the boundary conditions imposed are that (1) the normal velocity in the liquid at the interface is equal to the normal velocity of the interface; and (2) the pressure in the liquid at the interface is equal to that in the gas or, if *surface tension* is important, exceeds the atmospheric pressure by an amount equal to

$$\nabla p = p_{\text{liquid}} - p_{\text{atm}} = \sigma \left(\frac{1}{R_1} + \frac{1}{R_2} \right) \tag{3.2.54}$$

where R_1 and R_2 are the radii of curvature of the intercepts of the interface by two orthogonal planes containing the normal to the interface, and σ is the *surface tension*. (If the gas is a vapor that undergoes non-negligible interaction and exchanges with the liquid in contact with it, the boundary conditions can be more complex.) If surface tension is important in the liquid–liquid interfacial case, then Equation (3.2.54) is used with the left-hand side replaced by the difference in the normal stress instead of p alone.

For interfaces in general, the boundary conditions are derived from continuity conditions for each "transportable" quantity — namely, continuity of the appropriate intensity across the interface and continuity of the normal component of the flux vector. Fluid momentum and heat are two such transportable quantities; the associated intensities are velocity and temperature, and the associated flux vectors are stress and heat flux. Such general considerations are relative to more complex flow situations in which material passes through the interface (the discussion of the preceding three cases assumed this did not occur), such as when absorption; adsorption; evaporation; change of phase; or chemical reaction occur at the interface. (In the case of a rarefied gas in contact with a solid surface the boundary conditions must allow for velocity slip and temperature jump along the contact surface.) For situations in which heat and/or mass transfer are involved, see the section on heat and mass transfer. For consideration of a wide spectrum of important physical situations, see the updated transport classic by Bird, Stewart, and Lightfoot (2002).

Vorticity in Incompressible Flow

With μ and ρ constants, and $\boldsymbol{f} = -\boldsymbol{g} = -g\boldsymbol{k}$, the momentum equation, Equation (3.2.52), reduces to

$$\rho\frac{D\boldsymbol{V}}{Dt} = -\nabla p - \rho g\boldsymbol{k} + \mu\nabla^2\boldsymbol{V} \tag{3.2.55}$$

The vector identities

$$(\boldsymbol{V}\cdot\nabla)\boldsymbol{V} = \nabla\left(\frac{V^2}{2}\right) - \boldsymbol{V}\times(\nabla\times\boldsymbol{V}) \tag{3.2.56}$$

$$\nabla^2\boldsymbol{V} = \nabla(\nabla\cdot\boldsymbol{V}) - \nabla\times(\nabla\times\boldsymbol{V}) \tag{3.2.57}$$

together with the definition of *vorticity*

$$\boldsymbol{\zeta} \equiv \nabla\times\boldsymbol{V} \tag{3.2.58}$$

and the incompressible flow continuity equation, $\nabla\cdot\boldsymbol{V} = 0$, allow Equation (3.2.55) to be written

$$\rho\frac{\partial\boldsymbol{V}}{\partial t} + \nabla\left(p + \frac{1}{2}\rho V^2 + \rho g z\right) = \rho\boldsymbol{V}\times\boldsymbol{\zeta} - \mu\nabla\times\boldsymbol{\zeta} \tag{3.2.59}$$

The flow is said to be *irrotational* if

$$\boldsymbol{\zeta} \equiv \nabla\times\mathbf{V} = 0 \tag{3.2.60}$$

from which it follows that a *velocity potential* Φ can be defined

$$\boldsymbol{V} = \nabla\Phi \tag{3.2.61}$$

Setting $\boldsymbol{\zeta} = 0$ in Equation (3.2.59), using Equation (3.2.61), and integrating with respect to all the spatial variables leads to

$$\rho\frac{\partial\Phi}{\partial t}+\left(p+\frac{1}{2}\rho V^2+\rho gz\right)=F(t) \tag{3.2.62}$$

(The arbitrary function *F(t)* introduced by the integration can be absorbed into $\boldsymbol{\Phi}$, or is determined by the boundary conditions.)

Equation (3.2.62) is the unsteady *Bernoulli equation* for irrotational, incompressible flow. *Irrotational flows* are always *potential flows*, even if the flow is compressible. Because the viscous term in Equation (3.2.59) vanishes identically for $\boldsymbol{\zeta} = 0$, it would appear that the preceding Bernoulli equation is valid even for viscous flow. Potential solutions of hydrodynamics are in fact exact solutions of the full Navier–Stokes equations. Such solutions, however, are not valid near solid boundaries or bodies because the no-slip condition generates vorticity and causes nonzero $\boldsymbol{\zeta}$; the potential flow solution is invalid in all those parts of the flow field that have been "contaminated" by the spread of the vorticity by convection and diffusion. (See following discussion.)

The curl of Equation (3.2.59), noting that the curl of any gradient is zero, leads to

$$\rho\frac{\partial\boldsymbol{\zeta}}{\partial t}=\rho\nabla\times\left(\boldsymbol{V}\times\boldsymbol{\zeta}\right)-\mu\nabla\times\nabla\times\boldsymbol{\zeta} \tag{3.2.63}$$

but

$$\nabla^2\boldsymbol{\zeta}=\nabla(\nabla\cdot\boldsymbol{\zeta})-\nabla\times\nabla\times\boldsymbol{\zeta}=-\nabla\times\nabla\times\boldsymbol{\zeta} \tag{3.2.64}$$

because div curl () ≡ 0, and therefore also

$$\nabla\times\left(\boldsymbol{V}\times\boldsymbol{\zeta}\right)\equiv\boldsymbol{\zeta}\left(\nabla\boldsymbol{V}\right)+\boldsymbol{V}\nabla\cdot\boldsymbol{\zeta}-\boldsymbol{V}\nabla\boldsymbol{\zeta}-\boldsymbol{\zeta}\nabla\cdot\boldsymbol{V} \tag{3.2.65}$$

$$=\boldsymbol{\zeta}\left(\nabla\boldsymbol{V}\right)-\boldsymbol{V}\nabla\boldsymbol{\zeta} \tag{3.2.66}$$

Equation (3.2.63) can then be written

$$\frac{D\boldsymbol{\zeta}}{Dt}=\left(\boldsymbol{\zeta}\cdot\nabla\right)\boldsymbol{V}+\nu\nabla^2\boldsymbol{\zeta} \tag{3.2.67}$$

where $\nu = \mu/\rho$ is the *kinematic viscosity.*

Equation (3.2.67) is the vorticity equation for incompressible flow. The first term on the right, an inviscid term, represents the rate of change of vorticity by stretching and tilting of vortex lines. For $\nu \neq 0$, the second term on the right-hand side represents the rate of change of $\boldsymbol{\zeta}$ due to diffusion of vorticity, which may have been present in the flow from the beginning, or generated, for example, at solid boundaries due to the no-slip condition. (Vorticity can also be generated by *Coriolis effects* in a rotating frame and by *baroclinicity.*[4] For the vorticity equation including these effects, see Kundu and Cohen, 2004.)

In inviscid, two-dimensional flow both terms on the right-hand side vanish, and the equation reduces to $D\boldsymbol{\zeta}/Dt = 0$, from which it follows that the vorticity of a fluid particle remains constant as it moves.

---

[4] A flow is called *barotropic* if ρ is a function of p only, i.e., $\rho = f(p)$. Flows that are not barotropic are called *baroclinic.*

This is *Helmholtz's theorem.* As a consequence, it also follows that if $\boldsymbol{\zeta} = 0$ initially, $\boldsymbol{\zeta} = 0$ always; i.e., *initially irrotational flows remain irrotational* (for inviscid flows). Similarly, it can be proved that $D\Gamma/Dt = 0$; i.e., the *circulation* around a material closed circuit remains constant, which is *Kelvin's theorem.*

Also, for steady flow, the Bernoulli equation (Equation 3.2.62) reduces to

$$p + \frac{1}{2}\rho V^2 + \rho g z = \text{constant} \tag{3.2.68}$$

which is valid for steady, irrotational, incompressible flow.

Stream Function

For two-dimensional planar, incompressible flows [$\boldsymbol{V} = (u, v)$], the continuity equation,

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \tag{3.2.69}$$

is identically satisfied by introducing a *stream function* ψ, defined by

$$u = \frac{\partial \psi}{\partial y}, \qquad v = -\frac{\partial \psi}{\partial x} \tag{3.2.70}$$

Physically, ψ is a measure of the volume flow rate between streamlines. (Stream functions can be similarly defined to satisfy identically the continuity equations for incompressible cylindrical and spherical axisymmetric flows and for these flows, as well as the preceding planar flow, also when they are *compressible*, but then only if they are *steady.*)

Continuing with the planar case, note that, in such flows, there is only a single nonzero component of vorticity, given by

$$\boldsymbol{\zeta} = (0, 0, \zeta_z) = \left(0, 0, \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right) \tag{3.2.71}$$

With Equation (3.2.70), this sole nonzero component of vorticity is related to ψ by

$$\zeta_z = -\frac{\partial^2 \psi}{\partial x^2} - \frac{\partial^2 \psi}{\partial y^2} = -\nabla^2 \psi \tag{3.2.72}$$

For this two-dimensional flow, Equation (3.2.67) reduces to the single scalar equation:

$$\frac{\partial \zeta_z}{\partial t} + u\frac{\partial \zeta_z}{\partial x} + v\frac{\partial \zeta_z}{\partial y} = v\left(\frac{\partial^2 \zeta_z}{\partial x^2} + \frac{\partial^2 \zeta_z}{\partial y^2}\right) \equiv v\nabla^2 \zeta_z \tag{3.2.73}$$

Substitution of Equation (3.2.72) into Equation (3.2.73) yields an equation for the stream function alone:

$$\frac{\partial(\nabla^2 \psi)}{\partial t} + \frac{\partial \psi}{\partial y}\frac{\partial(\nabla^2 \psi)}{\partial x} - \frac{\partial \psi}{\partial x}\frac{\partial(\nabla^2 \psi)}{\partial y} = v\nabla^4 \psi \tag{3.2.74}$$

where $\nabla^4 \equiv \nabla^2 (\nabla^2)$. For uniform flow (aligned with the x-axis) past a solid body, for example, this equation for ψ would be solved subject to the boundary conditions:

$$\begin{aligned} &\frac{\partial}{\partial x} = 0, \quad \frac{\partial}{\partial y} = V_\bullet \quad \text{at infinity} \\ &\frac{\partial}{\partial x} = 0, \quad \frac{\partial}{\partial y} = 0 \quad \text{at the body (no penetration, no slip)} \end{aligned} \tag{3.2.75}$$

For the special case of irrotational flow, it follows immediately from Equation (3.2.70) and Equation (3.2.71) with $\zeta_z = 0$, that ψ satisfies the *Laplace equation*:

$$\nabla^2 \psi = \frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = 0 \tag{3.2.76}$$

Inviscid Irrotational Flow: Potential Flow

For irrotational flows, it has already been noted that a velocity potential Φ can be defined such that $\boldsymbol{V} = \nabla\Phi$. If the flow is also incompressible, so that $\nabla \cdot \boldsymbol{V} = 0$, it then follows that

$$\nabla \cdot (\nabla \Phi) = \nabla^2 \Phi = 0 \tag{3.2.77}$$

so Φ satisfies Laplace's equation. Note that unlike the stream function ψ, which can only be defined for two-dimensional flows, the preceding considerations for Φ apply to flows in two and three dimensions. On the other hand, the existence of ψ does not require the flow to be irrotational, whereas the existence of Φ does.)

Because Equation (3.2.77), with appropriate conditions on $\boldsymbol{V}$ at boundaries of the flow, completely determines the velocity field, and the momentum equation plays no role in this determination, inviscid irrotational flow — *potential theory* — is a purely *kinematic theory*. The momentum equation is used after Φ is known to calculate the pressure field consistent with the velocity field $\boldsymbol{V}$.

For two- as well as three-dimensional flows, the determination of Φ makes use of the powerful techniques of potential theory, well developed in the mathematical literature. For two-dimensional planar flows, the techniques of complex variable theory are available because Φ may be considered as the real or the imaginary part of an *analytic function*. (The same is true for ψ because, for such two-dimensional flows, Φ and ψ are conjugate variables.)

Because the Laplace equation, obeyed by Φ and ψ, is linear, complex flows may be built up from the *superposition* of *simple flows*; this property of inviscid irrotational flows is the basis of many of the solution techniques in this area of fluid mechanics.

Problem

A two-dimensional inviscid irrotational flow has the velocity potential

$$\Phi = x^2 - y^2 \tag{P.3.2.6}$$

What two-dimensional potential flow does this represent?

Solution. It follows from Equation (3.2.61) and Equation (3.2.70) that, for two-dimensional flows in general,

$$u = \frac{\partial \Phi}{\partial x} = \frac{\partial \psi}{\partial y}, \quad v = \frac{\partial \Phi}{\partial y} = -\frac{\partial \psi}{\partial x} \tag{P.3.2.7}$$

From Equation (P.3.2.6)

$$u = \frac{\partial \psi}{\partial y} = 2x, \quad v = -\frac{\partial \psi}{\partial x} = -2y \tag{P.3.2.8}$$

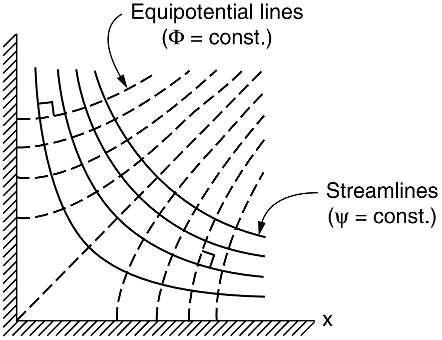

FIGURE 3.2.3 Potential flow in a 90° corner.

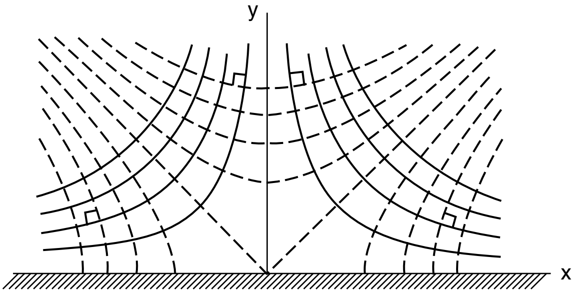

FIGURE 3.2.4 Potential flow impinging against a flat (180°) wall (plane stagnation-point flow).

integration of which yields

$$\psi = 2xy \tag{P.3.2.9}$$

The streamlines, ψ = constant, and equipotential lines, Φ = constant, both families of hyperbolas and each family the orthogonal trajectory of the other, are shown in Figure 3.2.3. Because the x and y axes are streamlines, Equation (P.3.2.6) and Equation (P.3.2.9) represent the inviscid irrotational flow in a right-angle corner. By symmetry, they also represent the planar flow in the upper half-plane directed toward a stagnation point at $x = y = 0$ (Figure 3.2.4). In polar coordinates (r,θ), with corresponding velocity components (u_r,u_θ), this flow is represented by

$$\Phi = r^2 \cos 2\theta, \quad \psi = \mathrm{r}^2 \sin 2\theta \tag{P.3.2.10}$$

with

$$u_r = \frac{\partial \Phi}{\partial r} = \frac{1}{r}\frac{\partial \psi}{\partial \theta} = 2r\cos 2\theta, \quad u_\theta = \frac{1}{r}\frac{\partial \Phi}{\partial \theta} = -\frac{\partial \psi}{\partial r} = -2r\sin 2\theta \tag{P.3.2.11}$$

For two-dimensional planar potential flows, one may also use *complex variables*, writing the *complex potential* $f(z) = \Phi + i\psi$ as a function of the complex variable $z = x + iy$, where the *complex velocity* is given by $f'(\mathrm{z}) = \mathrm{w}(\mathrm{z}) = u - \mathrm{i}\nu$. For the flow above

$$f(z) = z^2 \tag{P.3.2.12}$$

Expressions such as Equation (P.3.2.12), where the right-hand side is an analytic function of z, may also be regarded as a *conformal mapping*, which makes available as an aid in solving two-dimensional potential problems all the tools and techniques of that branch of mathematics.

3.3 Similitude: Dimensional Analysis and Data Correlation

Stuart W. Churchill

Dimensional Analysis

Similitude refers to the formulation of a description for physical behavior that is general and independent of the individual dimensions, physical properties, forces, etc. In this subsection the treatment of similitude is restricted to *dimensional analysis*; for a more general treatment see Zlokarnik (1991). The full power and utility of dimensional analysis is often underestimated and underutilized by engineers. This technique may be applied to a complete mathematical model or to a simple listing of the variables that define the behavior. Only the latter application is described here. For a description of the application of dimensional analysis to a mathematical model see Hellums and Churchill (1964).

General Principles

Dimensional analysis is based on the principle that all additive or equated terms of a complete relationship between the variables must have the same net dimensions. The analysis starts with the preparation of a list of the individual dimensional variables (dependent, independent, and parametric) that are presumed to define the behavior of interest. The performance of dimensional analysis in this context is reasonably simple and straightforward; the principal difficulty and uncertainty arise from the identification of the variables to be included or excluded. If one or more important variables are inadvertently omitted, the reduced description achieved by dimensional analysis will be incomplete and inadequate as a guide for the correlation of a full range of experimental data or theoretical values. The familiar band of plotted values in many graphical correlations is more often a consequence of the omission of one or more variables than of inaccurate measurements. If, on the other hand, one or more irrelevant or unimportant variables are included in the listing, the consequently reduced description achieved by dimensional analysis will result in one or more unessential dimensionless groupings. Such excessive dimensionless groupings are generally less troublesome than missing ones because the redundancy will ordinarily be revealed by the process of correlation. Excessive groups may, however, suggest unnecessary experimental work or computations, or result in misleading correlations. For example, real experimental scatter may inadvertently and incorrectly be correlated in all or in part with the variance of the excessive grouping.

In consideration of the inherent uncertainty in selecting the appropriate variables for dimensional analysis, it is recommended that this process be interpreted as a *speculative* and subject to correction of the basis of experimental data or other information. Speculation may also be utilized as a formal technique to identify the effect of eliminating a variable or of combining two or more. The latter aspect of speculation, which may be applied either to the original listing of dimensional variables or to the resulting set of dimensionless groups, is often of great utility in identifying possible limiting behavior or dimensionless groups of marginal significance. The systematic speculative elimination of all but the most certain variables, one at a time, followed by regrouping, is recommended as a general practice. The additional effort as compared with the original dimensional analysis is minimal, but the possible return is very high. A general discussion of this process may be found in Churchill (1981).

The minimum number of independent dimensionless groups i required to describe the fundamental and parametric behavior is (Buckingham, 1914)

$$i = n - m \tag{3.3.1}$$

where n is the number of variables and m is the number of fundamental dimensions such as mass M, length L, time θ, and temperature T that are introduced by the variables. The inclusion of redundant dimensions such as force F and energy E that may be expressed in terms of mass, length, time, and temperature is at the expense of added complexity and is to be avoided. (Of course, mass could be replaced by force or temperature by energy as alternative fundamental dimensions.) In some rare cases i is actually greater than $n - m$. Then

$$i = n - k \tag{3.3.2}$$

where k is the maximum number of the chosen variables that cannot be combined to form a dimensionless group. Determination of the minimum number of dimensionless groups is helpful if the groups are to be chosen by inspection, but is unessential if the algebraic procedure described below is utilized to determine the groups themselves since the number is then obvious from the final result.

The *particular* minimal set of dimensionless groups is arbitrary in the sense that two or more of the groups may be multiplied together to any positive, negative, or fractional power as long as the number of independent groups is unchanged. For example, if the result of a dimensional analysis is

$$\phi\left\{XY^{1/2}, Z/Y^2, Z\right\} = 0 \tag{3.3.3}$$

where X, Y, and Z are independent dimensionless groups, an equally valid expression is

$$\phi\{X, Y, Z\} = 0 \tag{3.3.4}$$

Dimensional analysis itself does not provide any insight as to the best choice of equivalent dimensionless groupings, such as between those of Equation (3.3.3) and Equation (3.3.4). However, isolation of each of the variables that are presumed to be the most important in a separate group may be convenient in terms of interpretation and correlation. Another possible criterion in choosing between alternative groupings may be the relative invariance of a particular one. The functional relationship provided by Equation (3.3.3) may equally well be expressed as

$$X = \phi\{Y, Z\} \tag{3.3.5}$$

where X is implied to be the dependent grouping and Y and Z to be independent or parametric groupings.

Three primary methods of determining a minimal set of dimensionless variables are (1) by inspection; (2) by combination of the residual variables, one at a time, with the set of chosen variables that cannot be combined to obtain a dimensionless group; and (3) by an algebraic procedure. These methods are illustrated in the examples that follow.

Example 3.3.1: Fully Developed Flow of Water Through a Smooth Round Pipe

Choice of Variables. The shear stress τ_w on the wall of the pipe may be postulated to be a function of the density ρ and the dynamic viscosity μ of the water, the inside diameter D of the pipe, and the space-mean of the time-mean velocity u_m. The limitation to fully developed flow is equivalent to a postulate of independence from distance x in the direction of flow, and the specification of a smooth pipe is equivalent to the postulate of independence from the roughness e of the wall. The choice of τ_w rather than the pressure drop per unit length $-dP/dx$ avoids the need to include the acceleration due to gravity g and the elevation z as variables. The choice of u_m rather than the volumetric rate of flow V, the mass rate of flow w, or the mass rate of flow per unit area G is arbitrary but has some important consequences as noted below. The postulated dependence may be expressed functionally as $\phi\{\tau_w, \rho, \mu, D, u_m\} = 0$ or $\tau_w = \phi\{\rho, \mu, D, u_m\}$.

Tabulation

Next prepare a tabular listing of the variables and their dimensions:

	τ_w	ρ	μ	D	u_m
M	1	1	1	0	0
L	–1	–3	–1	1	1
θ	–2	0	–1	0	–1
T	0	0	0	0	0

Minimal Number of Groups

The number of postulated variables is 5. Since the temperature does not occur as a dimension for any of the variables, the number of fundamental dimensions is 3. From Equation (3.3.1), the minimal number of dimensionless groups is 5 – 3 = 2. From inspection of the above tabulation, a dimensionless group cannot be formed from as many as three variables such as D, μ, and ρ. Hence, Equation (3.3.2) also indicates that $i = 5 - 3 = 2$.

Method of Inspection

By inspection of the tabulation or by trial and error it is evident that only two independent dimensionless groups may be formed. One such set is

$$\phi\left\{\frac{\tau_w}{\rho u_m^2}, \frac{Du_m\rho}{\mu}\right\} = 0$$

Method of Combination

The residual variables τ_w and μ may be combined in turn with the noncombining variables ρ, D, and u_m to obtain two groups such as those above.

Algebraic Method

The algebraic method makes formal use of the postulate that the functional relationship between the variables may in general be represented by a power series. In this example such a power series may be expressed as

$$\tau_w = \sum_{i=1}^{N} A_i \rho^{a_i} \mu^{b_i} D^{c_i} u_m^{d_i}$$

where the coefficients A_i are dimensionless. Each additive term on the right-hand side of this expression must have the same net dimensions as τ_w. Hence, for the purposes of dimensional analysis, only the first term need be considered and the indexes may be dropped. The resulting highly restricted expression is $\tau_w = A\rho^a\mu^bD^c u_m^d$. Substituting the dimensions for the variables gives

$$\frac{M}{L\theta^2} = A\left(\frac{M}{L^3}\right)^a\left(\frac{M}{L\theta}\right)^b L^c\left(\frac{L}{\theta}\right)^d$$

Equating the sum of the exponents of M, L, and θ on the right-hand side of the above expression with those of the left-hand side produces the following three simultaneous linear algebraic equations: $1 = a + b$; $-1 = -3a - b + c + d$; and $-2 = -b - d$, which may be solved for a, c, and d in terms of b to obtain $a = 1 - b$, $c = -b$, and $d = 2 - b$. Substitution then gives $\tau_w = A\rho^{1-b}\mu^b D^{-b} u_m^{2-b}$ which may be regrouped as

$$\frac{\tau_w}{\rho u_m^2} = A\left(\frac{\mu}{Du_m\rho}\right)^b$$

Since this expression is only the first term of a power series, it should *not* be interpreted to imply that $\tau_w/\rho u_m^2$ is necessarily proportional to some power at $\mu/Du_m\rho$ but instead only the equivalent of the expression derived by the method of inspection. The inference of a power dependence between the dimensionless groups is the most common and serious error in the use of the algebraic method of dimensional analysis.

Speculative Reductions

Eliminating ρ as a variable on speculative grounds to

$$\phi\left\{\frac{\tau_w D}{\mu u_m}\right\} = 0$$

or its exact equivalent:

$$\frac{\tau_w D}{\mu u_m} = A$$

The latter expression with $A = 8$ is actually the exact solution for the laminar regime ($Du_m\rho/\mu < 1800$). A relationship that does not include ρ may alternatively be derived directly from the solution by the method of inspection as follows. First, ρ is eliminated from one group, say $\tau_w/\rho u_m^2$, by multiplying it with $Du_m\rho/\mu$ to obtain

$$\phi\left\{\frac{\tau_w D}{\mu u_m}, \frac{Du_m\rho}{\mu}\right\} = 0$$

The remaining group containing ρ is now simply dropped. Had the original expression been composed of three independent groups each containing ρ, that variable would have to be eliminated from two of them before dropping the third one.

The relationships that are obtained by the speculative elimination of μ, D, and u_m, one at a time, do not appear to have any range of physical validity. Furthermore, if w or G had been chosen as the independent variable rather than u_m, the limited relationship for the laminar regime would not have been obtained by the elimination of ρ.

Alternative Forms

The solution may also be expressed in an infinity of other forms such as

$$\phi\left\{\frac{\tau_w D^2\rho}{\mu^2}, \frac{Du_m\rho}{\mu}\right\} = 0$$

If τ_w is considered to be the principal dependent variable and u_m the principal independent variable, this latter form is preferable in that these two quantities do not then appear in the same grouping. On the other hand, if D is considered to be the principal independent variable, the original formulation is preferable. The variance of $\tau_w/\rho u_m^2$ is less than that of $\tau_w D/\mu u_m$ and $\tau_w D^2\rho/\mu^2$ in the turbulent regime while that of $\tau_w D/\mu u_m$ is zero in the laminar regime. Such considerations may be important in devising convenient graphical correlations.

Alternative Notations

The several solutions above are more commonly expressed as

$$\phi\left\{\frac{f}{2}, \mathrm{Re}\right\} = 0$$

$$\phi\left\{\frac{f\,\mathrm{Re}}{2}, \mathrm{Re}\right\} = 0$$

or

$$\phi\left\{\frac{f\,\mathrm{Re}^2}{2}, \mathrm{Re}\right\} = 0$$

where $f = 2\,\tau_w/\rho u_m^2$ is the *Fanning friction factor* and $Re = Du_m\rho/\mu$ is the *Reynolds number.*

The more detailed forms, however, are to be preferred for purposes of interpretation or correlation because of the explicit appearance of the individual, physically measurable variables.

Addition of a Variable

The above results may readily be extended to incorporate the roughness e of the pipe as a variable. If two variables have the same dimensions, they will always appear as a dimensionless group in the form of a ratio, in this case e appears most simply as e/D. Thus, the solution becomes

$$\phi\left\{\frac{\tau_w}{\rho u_m^2}, \frac{Du_m\rho}{\mu}, \frac{e}{D}\right\} = 0$$

Surprisingly, as contrasted with the solution for a smooth pipe, the speculative elimination of μ and hence of the group $Du_m\rho/\mu$ now results in a valid asymptote for $Du_m\rho/\mu \rightarrow \infty$ and all finite values of e/D, namely,

$$\phi\left\{\frac{\tau_w}{\rho u_m^2}, \frac{e}{D}\right\} = 0$$

Example 3.3.2: Fully Developed Forced Convection in Fully Developed Flow in a Round Tube

It may be postulated for this process that $h = \phi\{D, u_m, \rho, \mu, k, c_p\}$, where here h is the local heat transfer coefficient, and c_p and k are the specific heat capacity and thermal conductivity, respectively, of the fluid. The corresponding tabulation is

	h	D	u_m	ρ	μ	k	c_p
M	1	0	0	1	1	1	0
L	0	1	1	–3	–1	1	2
θ	–3	0	–1	0	–1	–3	–2
T	–1	0	0	0	0	–1	–1

The number of variables is 7 and the number of independent dimensions is 4, as is the number of variables such as D, u_m, ρ, and k that cannot be combined to obtain a dimensionless group. Hence, the minimal number of dimensionless groups is 7 – 4 = 3. The following acceptable set of dimensionless groups may be derived by any of the procedures illustrated in Example 1:

$$\frac{hD}{k} = \phi\left\{\frac{Du_m\rho}{\mu}, \frac{c_p\mu}{k}\right\}$$

Speculative elimination of μ results in

$$\frac{hD}{k} = \phi\left\{\frac{Du_m\rho c_p}{k}\right\}$$

which has often erroneously been inferred to be a valid asymptote for $c_p\mu/k \to 0$. Speculative elimination of D, u_m, ρ, k, and c_p individually also does not appear to result in expressions with any physical validity. However, eliminating c_p and ρ or u_m gives a valid result for the laminar regime, namely,

$$\frac{hD}{k} = A$$

The general solutions for flow and convection in a smooth pipe may be combined to obtain

$$\frac{hD}{k} = \phi\left\{\frac{\tau_w D^2\rho}{\mu^2}, \frac{c_p\mu}{k}\right\}$$

which would have been obtained directly had u_m been replaced by τ_w in the original tabulation. This latter expression proves to be superior in terms of speculative reductions. Eliminating D results in

$$\frac{h\mu}{k(\tau_w\rho)^{1/2}} = \phi\left\{\frac{c_p\mu}{k}\right\}$$

which may be expressed in the more conventional form of

$$\text{Nu} = \text{Re}\left(\frac{f}{2}\right)^{1/2}\phi\{\text{Pr}\}$$

where Nu = hD/k is the *Nusselt number* and Pr = $c_p\mu/k$ is the *Prandtl number*. This result appears to be a valid asymptote for Re → ∞ and a good approximation for even moderate values (>5000) for large values of Pr. Elimination of μ as well as D results in

$$\frac{h}{c_p(\tau_w\rho)^{1/2}} = A$$

or

$$\mathrm{Nu} = A\,\mathrm{Re}\,\mathrm{Pr}\left(\frac{f}{2}\right)^{1/2}$$

which appears to be an approximate asymptote for Re → ∞ and Pr → 0. Elimination of both c_p and ρ again yields the appropriate result for laminar flow, indicating that ρ rather than u_m is the meaningful variable to eliminate in this respect.

The numerical value of the coefficient A in the several expressions above depends on the mode of heating, a true variable, but one from which the purely functional expressions are independent. If j_w the heat flux density at the wall, and $T_w - T_m$, the temperature difference between the wall and the bulk of the fluid, were introduced as variables in place of $h \equiv j_w/(T_w - T_m)$, another group such as $c_p(T_w - T_m)(D\rho/\mu)^2$ or $\rho c_p(T_w - T_m)/\tau_w$ or $c_p(T_w - T_m)/u_m^2$, which represents the effect of viscous dissipation, would be obtained. This effect is usually but not always negligible. (See Chapter 4.)

Example 3.3.3: Free Convection from a Vertical Isothermal Plate

The behavior for this process may be postulated to be represented by

$$h = \phi\left\{g, \beta, T_w - T_\infty, x, \mu, \rho, c_p, k\right\}$$

where g is the acceleration due to gravity, β is the volumetric coefficient of expansion with temperature, T_∞ is the unperturbed temperature of the fluid, and x is the vertical distance along the plate. The corresponding tabulation is

	h	g	β	$T_w - T_\infty$	x	μ	ρ	c_p	k
M	1	0	0	0	0	1	1	0	1
L	0	1	0	0	1	–1	–3	2	1
θ	–3	–2	0	0	0	–1	0	–2	–3
T	–1	0	–1	1	0	0	0	–1	1

The minimal number of dimensionless groups indicated by both methods is 9 – 4 = 5. A satisfactory set of dimensionless groups, as found by any of the methods illustrated in Example 1 is

$$\frac{hx}{k} = \phi\left\{\frac{\rho^2 g x^3}{\mu^2}, \frac{c_p\mu}{k}, \beta(T_w - T_\infty), c_p(T_w - T_\infty)\left(\frac{\rho x}{\mu}\right)^2\right\}$$

It may be reasoned that the buoyant force which generates the convective motion must be proportional to $\rho g\beta(T_w - T_\infty)$, thus, g in the first term on the right-hand side must be multiplied by $\beta(T_w - T_\infty)$, resulting in

$$\frac{hx}{k} = \phi\left\{\frac{\rho^2 g\beta(T_w - T_\infty)x^3}{\mu^2}, \frac{c_p\mu}{k}, \beta(T_w - T_\infty), c_p(T_w - T_\infty)\left(\frac{\rho x}{\mu}\right)^2\right\}$$

The effect of expansion other than on the buoyancy is now represented by $\beta(T_w - T_\infty)$, and the effect of viscous dissipation by $c_p(T_w - T_\infty)(\rho x/\mu)^2$. Both effects are negligible for all practical circumstances. Hence, this expression may be reduced to

$$\frac{hx}{k} = \phi\left\{\frac{\rho^2 g\beta(T_w - T_\infty)x^3}{\mu^2}, \frac{c_p\mu}{k}\right\}$$

or

$$\mathrm{Nu}_x = \phi\left\{\mathrm{Gr}_x, \mathrm{Pr}\right\}$$

where $\mathrm{Nu}_x = hx/k$ and $\mathrm{Gr}_x = \rho^2 g\beta(T_w - T_\infty)x^3/\mu^2$ is the *Grashof number.*

Elimination of x speculatively now results in

$$\frac{hx}{k} = \left(\frac{\rho^2 g\beta(T_w - T_\infty)x^3}{\mu^2}\right)^{1/3} \phi\{\mathrm{Pr}\}$$

or

$$\mathrm{Nu}_x = \mathrm{Gr}_\mathrm{x}^{1/3}\phi\{\mathrm{Pr}\}$$

This expression appears to be a valid asymptote for $\mathrm{Gr}_x \to \infty$ and a good approximation for the entire turbulent regime. Eliminating μ speculatively rather than x results in

$$\frac{hx}{k} = \phi\left\{\frac{\rho^2 c_p^2 g\beta(T_w - T_\infty)x^3}{k^2}\right\}$$

or

$$\mathrm{Nu}_x = \phi\left\{\mathrm{Gr}_x \mathrm{Pr}^2\right\}$$

The latter expression appears to be a valid asymptote for $\mathrm{Pr} \to 0$ for all Gr_x, that is, for both the laminar and the turbulent regimes. The development of a valid asymptote for large values of Pr requires more subtle reasoning. First $c_p\mu/k$ is rewritten as $\mu/\rho\alpha$ where $\alpha = k/\rho c_p$. Then ρ is eliminated speculatively except as it occurs in $\rho g\beta(T_w - T_\infty)$ and $k/\rho c_p$. The result is

$$\frac{hx}{k} = \phi\left\{\frac{c_p\rho^2 g\beta(T_w - T_\infty)x^3}{\mu k}\right\}$$

or

$$\mathrm{Nu}_x = \phi\left\{\mathrm{Ra}_x\right\}$$

where

$$\mathrm{Ra}_x = \frac{c_p\rho^2 g\beta(T_w - T_\infty)x^3}{\mu k} = \mathrm{Gr}_x\,\mathrm{Pr}$$

is the *Rayleigh number.* The expression appears to be a valid asymptote for $\mathrm{Pr} \to \infty$ and a reasonable approximation for even moderate values of Pr for all Gr_x, that is, for both the laminar and the turbulent regimes.

Eliminating x speculatively from the above expressions for small and large values of Pr results in

$$\mathrm{Nu}_x = A\left(\mathrm{Gr}_x\,\mathrm{Pr}^2\right)^{1/3} = A\left(\mathrm{Ra}_x\,\mathrm{Pr}\right)^{1/3}$$

and

$$\mathrm{Nu}_x = B\left(\mathrm{Gr}_x\,\mathrm{Pr}\right)^{1/3} = B\left(\mathrm{Ra}_x\right)^{1/3}$$

The former appears to be a valid asymptote for Pr → 0 and $\mathrm{Gr}_x \to \infty$ and a reasonable approximation for very small values of Pr in the turbulent regime, while the latter is well confirmed as a valid asymptote for Pr → ∞ and $\mathrm{Gr}_x \to \infty$ and as a good approximation for moderate and large values of Pr over the entire turbulent regime. The expressions in terms of Gr_x are somewhat more complicated than those in terms of Ra_x, but are to be preferred since Gr_x is known to characterize the transition from laminar to turbulent motion in natural convection just as Re_D does in forced flow in a channel. The power of speculation combined with dimensional analysis is well demonstrated by this example in which valid asymptotes are thereby attained for several regimes.

Correlation of Experimental Data and Theoretical Values

Correlations of experimental data are generally developed in terms of dimensionless groups rather than in terms of the separate dimensional variables in the interests of compactness and in the hope of greater generality. For example, a complete set of graphical correlations for the heat transfer coefficient h of Example 3.3.2 above in terms of each of the six individual independent variables and physical properties might approach book length, whereas the dimensionless groupings both imply that a single plot with one parameter should be sufficient. Furthermore, the reduced expression for the turbulent regime implies that a plot of $\mathrm{Nu}/\mathrm{Re}\, f^{1/2}$ vs. Pr should demonstrate only a slight parametric dependence on Re or $\mathrm{Re}\, f^{1/2}$. Of course, the availability of a separate correlation for f as a function of Re is implied.

Theoretical values, that is, ones obtained by numerical solution of a mathematical model in terms of either dimensional variables or dimensionless groups, are presumably free from imprecision. Even so, because of their discrete form, the construction of a correlation or correlations for such values may be essential for the same reasons as for experimental data.

Graphical correlations have the merit of revealing general trends, of providing a basis for evaluation of the choice of coordinates, and most of all of displaying visually the scatter of the individual experimental values about a curve representing a correlation or their behavior on the mean. (As mentioned in the previous subsection, the omission of a variable may give the false impression of experimental error in such a plot.) On the other hand, correlating equations are far more convenient as an input to a computer than is a graphical correlation. These two formats thus have distinct and complementary roles; both should generally be utilized. The merits and demerits of various graphical forms of correlations are discussed in detail by Churchill (1979), while the use of logarithmic and arithmetic coordinates, the effects of the appearance of a variable in both coordinates, and the effects of the distribution of error between the dependent and independent variable are further illustrated by Wilkie (1985).

Churchill and Usagi (1972; 1974) proposed general usage of the following expression for the formulation of correlating equations:

$$y^n\{x\} = y_0^n\{x\} + y_\infty^n\{x\} \tag{3.3.6}$$

where $y_o\{x\}$ and $y_\infty\{x\}$ denote asymptotes for small and large values of x, respectively, and n is an arbitrary exponent. For convenience and simplicity, Equation (3.3.6) may be rearranged in either of the following two forms:

$$\left(Y(x)\right)^n = 1 + Z^n\{x\} \tag{3.3.7}$$

or

$$\left(\frac{Y\{x\}}{Z\{x\}}\right)^n = 1 + \frac{1}{Z^n\{x\}} \tag{3.3.8}$$

where $Y\{x\} \equiv y\{x\}/y_o\{x\}$ and $Z\{x\} \equiv y_\infty\{x\}/y_o\{x\}$. Equation (3.3.6), Equation (3.3.7), and Equation (3.3.9) are hereafter denoted collectively as the CUE (Churchill–Usagi equation). The principle merits of the CUE as a canonical expression for correlation are its simple form, generality, and minimal degree of explicit empiricism, namely, only that of the exponent n, since the asymptotes $y_o\{x\}$ and $y_\infty\{x\}$ are ordinarily known in advance from theoretical considerations or well-established correlations. Furthermore, as will be shown, the CUE is quite insensitive to the numerical value of n. Although the CUE is itself very simple in form, it is remarkably successful in representing closely very complex behavior, even including the dependence on secondary variables and parameters, by virtue of the introduction of such dependencies through $y_o\{x\}$ and $y_\infty\{x\}$. In the rare instances in which such dependencies are not represented in the asymptotes, n may be correlated as a function of the secondary variables and/or parameters. Although the CUE usually produces very close representations, it is empirical and not exact. In a few instances, numerical values of n have been derived or rationalized on theoretical grounds, but even then some degree of approximation is involved. Furthermore, the construction of a correlating expression in terms of the CUE is subject to the following severe limitations:

1. The asymptotes $y_o\{x\}$ and $y_\infty\{x\}$ must intersect once and only once;
2. The asymptotes $y_o\{x\}$ and $y_\infty\{x\}$ must be free of singularities. Even though a singularity occurs beyond the asserted range of the asymptote, it will persist and disrupt the prediction of the CUE, which is intended to encompass all values of the independent variable x; and
3. The asymptotes must both be upper or lower bounds.

In order to avoid or counter these limitations it may be necessary to modify or replace the asymptotes with others. Examples of this process are provided below. A different choice for the dependent variable may be an option in this respect. The suitable asymptotes for use in Equation (3.3.6) may not exist in the literature and therefore may need to be devised or constructed. See, for example, Churchill (1988b) for guidance in this respect. Integrals and derivatives of the CUE are generally awkward and inaccurate, and may include singularities not present or troublesome in the CUE itself. It is almost always preferable to develop a separate correlating equation for such quantities using derivatives or integrals of $y_o\{x\}$ and $y_\infty\{x\}$, simplified or modified as appropriate.

The Evaluation of *n*

Equation (3.3.6) may be rearranged as

$$n = \frac{\ln\left\{1 + \left(\frac{y_\infty\{x\}}{y_0\{x\}}\right)^n\right\}}{\ln\left\{\frac{y\{x\}}{y_0\{x\}}\right\}} \tag{3.3.9}$$

and solved for n by iteration for any known value of $y\{x\}$, presuming that $y_o\{x\}$ and $y_\infty\{x\}$ are known. If $y\{x^*\}$ is known, where x^* represents the value of x at the point of intersection of the asymptotes, that is, for $y_o\{x\} = y_\infty\{x\}$, Equation (3.3.9) reduces to

$$n = \frac{\ln\{2\}}{\ln\left\{\frac{y\{x^*\}}{y_0\{x^*\}}\right\}} \tag{3.3.10}$$

and iterative determination of n is unnecessary.

A graphical and visual method of evaluation of n is illustrated in Figure 3.3.1 in which $Y\{Z\}$ is plotted vs. Z for $0 \le Z \le 1$ and $Y\{Z\}/Z$ vs. $1/Z$ for $0 \le 1/Z \le 1$ in arithmetic coordinates with n as a parameter. Values of $y\{x\}$ may be plotted in this form and the best overall value of n selected visually (as illustrated in Figure 3.3.2). A logarithmic plot of $Y\{Z\}$ vs. Z would have less sensitivity relative to the dependence on n. (See, for example, Figure 1 of Churchill and Usagi, 1972.) Figure 3.3.1 explains in part the success of the CUE. Although y and x may both vary from 0 to ∞, the composite variables plotted in Figure 3.3.1

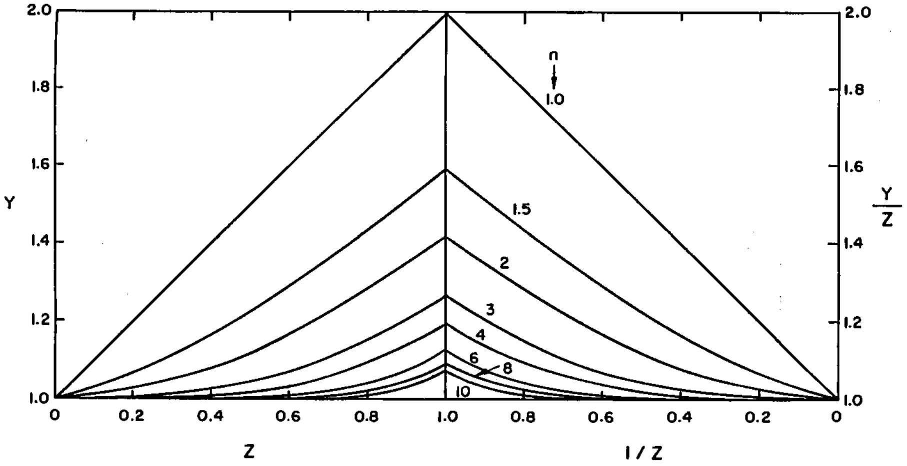

FIGURE 3.3.1 Arithmetic, split-coordinate plot of Equation 3.3.10. (From Churchill, S.W. and Usagi, R. *AIChE J.* 18(6), 1123, 1972. With permission from the American Institute of Chemical Engineers.)

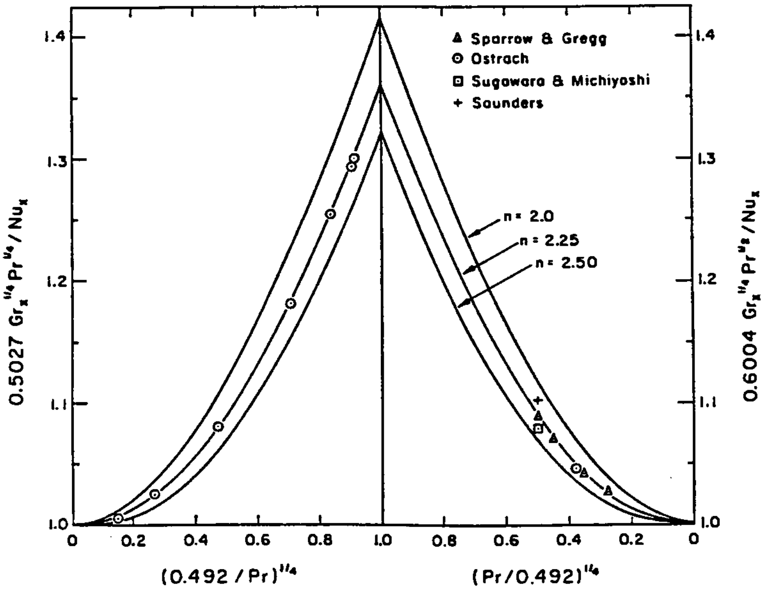

FIGURE 3.3.2 Arithmetic, split-coordinate plot of computed values and experimental data for laminar free convection from an isothermal vertical plate. (From Churchill, S.W. and Usagi, R. *AIChE J.* 18(6), 1124, 1972. With permission from the American Institute of Chemical Engineers.)

are highly constrained in that the compound independent variables Z and $1/Z$ vary only between 0 and 1, while for $n \geq 1$, the compound dependent variables $Y\{Z\}$ and $Y\{Z\}/Z$ vary only from 1 to 2.

Because of the relative insensitivity of the CUE to the numerical value of n, an integer or a ratio of two small integers may be chosen in the interest of simplicity and without significant loss of accuracy. For example, the maximum variance in Y (for $0 \leq Z \leq 1$) occurs at $Z = 1$ and increases only $100(2^{1/20} - 1) = 3.5\%$ if n is decreased from 5 to 4. If $y_o\{x\}$ and $y_\infty\{x\}$ are both lower bounds, n will be positive, and if they are both upper bounds, n will be negative. To avoid extending Figure 3.3.1 for negative values of n, $1/y\{x\}$ may simply be interpreted as the dependent variable.

Intermediate Regimes

Equation (3.3.6), Equation (3.3.7), and Equation (3.3.8) imply a slow, smooth transition between $y_o\{x\}$ and $y_\infty\{x\}$ and, moreover, one that is symmetrical with respect to $x^*(Z = 1)$. Many physical systems demonstrate instead a relatively abrupt transition, as for example from laminar to turbulent flow in a channel or along a flat plate. The CUE may be applied serially as follows to represent such behavior if an expression $y_i\{x\}$ is postulated for the intermediate regime. First, the transition from the initial to the intermediate regime is represented by

$$y_1^n = y_0^n + y_i^n \tag{3.3.11}$$

Then the transition from this combined regime to the final regime by

$$y^m = y_1^m + y_\infty^m = \left(y_0^n + y_i^n\right)^{m/n} + y_\infty^m \tag{3.3.12}$$

Here, and throughout the balance of this subsection, in the interests of simplicity and clarity, the functional dependence of all the terms on x is implied rather written out explicitly. If y_o is a lower bound and y_i is implied to be one, y_1 and y_∞ must be upper bounds. Hence, n will then be positive and m negative. If y_o and y_i are upper bounds, y_1 and y_∞ must be lower bounds; then n will be negative and m positive. The reverse formulation starting with y_∞ and y_1 leads by the same procedure to

$$y^n = y_0^n + \left(y_i^m + y_\infty^m\right)^{n/m} \tag{3.3.13}$$

If the intersections of y_i with y_o and y_∞ are widely separated with respect to x, essentially the same pair of values for n and m will be determined for Equation (3.3.12) and Equation (3.3.13), and the two representations for y will not differ significantly. On the other hand, if these intersections are close in terms of x, the pair of values of m and n may differ significantly and one representation may be quite superior to the other. In some instances a singularity in y_o or y_∞ may be tolerable in either Equation (3.3.12) or (3.3.13) because it is overwhelmed by the other terms. Equation (3.3.12) and Equation (3.3.13) have one hidden flaw. For $x \to 0$, Equation (3.3.12) reduces to

$$y \to y_0\left[1 + \left(\frac{y_\infty}{y_0}\right)^m\right]^{1/m} \tag{3.3.14}$$

If y_o is a lower bound, m is necessarily negative, and values of y less than y_o are predicted. If y_o/y_∞ is sufficiently small or if m is sufficiently large in magnitude, this discrepancy may be tolerable. If not, the following alternative expression may be formulated, again starting from Equation (3.3.11):

$$\left(y^n - y_0^n\right)^m = y_i^{nm} + \left(y_\infty^n - y_0^n\right)^m \tag{3.3.15}$$

Equation (3.3.15) is free from the flaw identified by means of Equation (3.3.14) and invokes no additional empiricism, but a singularity may occur at $y_\infty = y_o$, depending on the juxtapositions of y_o, y_i, and y_∞. Similar anomalies occur for Equation (3.3.13) and the corresponding analog of Equation (3.3.14), as well as for behavior for which $n < 0$ and $m > 0$. The preferable form among these four is best chosen by trying each of them.

One other problem with the application of the CUE for a separate transitional regime is the formulation of an expression for $y_i\{x\}$, which is ordinarily not known from theoretical considerations. Illustrations of the empirical determination of such expressions for particular cases may be found in Churchill and Usagi (1974), Churchill and Churchill (1975), and Churchill (1976; 1977), as well as in Example 3.3.5 below.

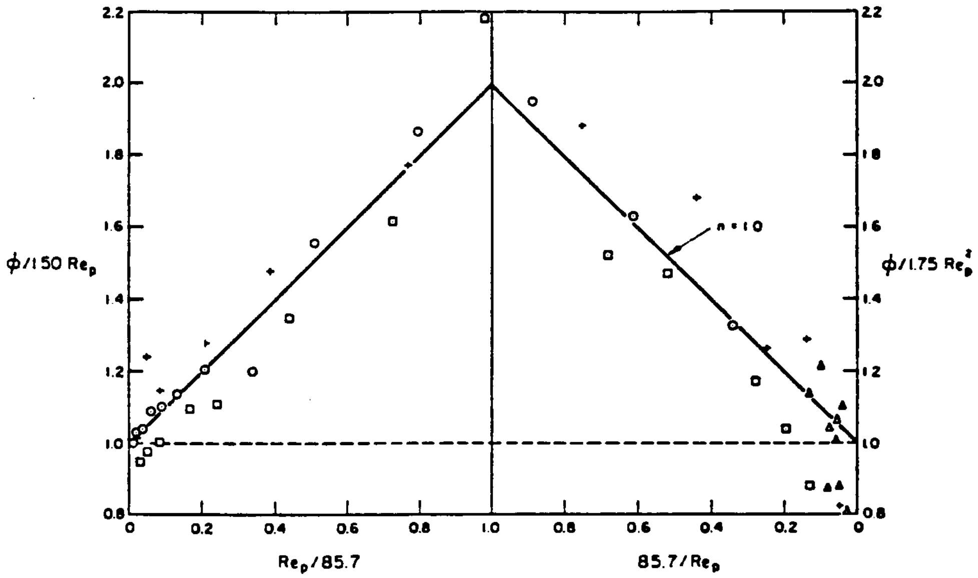

FIGURE 3.3.3 Arithmetic, split-coordinate plot of experimental data for the pressure drop in flow through a packed bed of spheres. (From Churchill, S.W. and Usagi, R. *AIChE J.* 18(6), 1123, 1972. With permission from the American Institute of Chemical Engineers.)

Example 3.3.4: The Pressure Gradient in Flow through a Packed Bed of Spheres

The pressure gradient at asymptotically low rates of flow (the creeping regime) can be represented by the Kozeny–Carman equation, $\Phi = 150\ \mathrm{Re}_p$, and at asymptotically high rates of flow (the inertial regime) by the Burke–Plummer equation, $\Phi = 1.75\ (\mathrm{Re}_p)^2$, where $\Phi = \rho\varepsilon^2 d_p(-dP_f/dx)\mu^2(1-\varepsilon)$, $\mathrm{Re}_p = d_p u_o \rho/\mu(1-\varepsilon)$, d_p = diameter of spherical particles, m, ε = void fraction of bed of spheres, dP_f/dx = dynamic pressure gradient (due to friction), Pa/m, and u_o = superficial velocity (in absence of the spheres), m/sec. For the origin of these two asymptotic expressions see Churchill (1988a). They both have a theoretical structure, but the numerical coefficients of 150 and 1.75 are basically empirical. These equations are both lower bounds and have one intersection. Experimental data are plotted in Figure 3.3.3, which has the form of Figure 3.3.1 with $Y = \Phi/150\ \mathrm{Re}_p$, $Y/Z = \Phi/(1.75\ \mathrm{Re}_p)^2$ and $Z = 1.75\ \mathrm{Re}_p^2/150\,\mathrm{Re}_p = \mathrm{Re}_p/85.7$. A value of $n = 1$ is seen to represent these data reasonably well on the mean, resulting in

$$\Phi = 150\mathrm{Re}_p + 1.75\left(\mathrm{Re}_p\right)^2$$

which was originally proposed as a correlating equation by Ergun (1952) on the conjecture that the volumetric fraction of the bed in "turbulent" flow is proportional to Re_p. The success of this expression in conventional coordinates is shown in Figure 3.3.4. The scatter, which is quite evident in the arithmetic split coordinates of Figure 3.3.3, is strongly suppressed in a visual sense in the logarithmic coordinates of Figure 3.3.4.

Example 3.3.5: The Friction Factor for Commercial Pipes for All Conditions

The serial application of the CUE is illustrated here by the construction of a correlating equation for both smooth and rough pipes in the turbulent regime followed by combination of that expression with ones for the laminar and transitional regimes.

The Turbulent Regime

The Fanning friction factor, f_F, for turbulent flow in a smooth round pipe for asymptotically large rates of flow (say $\mathrm{Re}_D > 5000$) may be represented closely by the empirical expression:

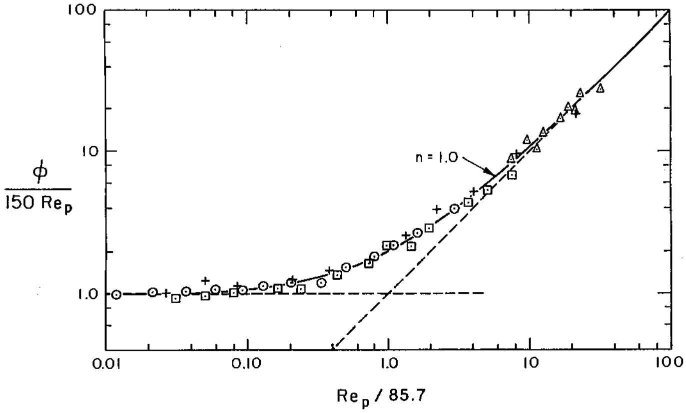

FIGURE 3.3.4 Logarithmic correlation of experimental data for the pressure drop in flow through a packed bed of spheres. (From Churchill, S.W. and Usagi, R. *AIChE J.* 18(6), 1123, 1972. With permission from the American Institute of Chemical Engineers.)

$$\left(\frac{2}{f_F}\right)^{1/2} = 0.256 + 2.5\ln\left\{\left(\frac{f_F}{2}\right)^{1/2}\mathrm{Re}_D\right\}$$

A corresponding empirical representation for naturally rough pipe is

$$\left(\frac{2}{f_F}\right)^{1/2} = 3.26 + 2.5\ln\left\{\frac{D}{e}\right\}$$

Direct combination of these two expressions in the form of the CUE does not produce a satisfactory correlating equation, but their combination in the following rearranged forms:

$$e^{(1/2.5)(2/f_F)^{1/2}} = 1.108\left(\frac{f_F}{2}\right)^{1/2}\mathrm{Re}_D$$

and

$$e^{(1/2.5)(2/f_F)^{1/2}} = 3.68\left(\frac{D}{e}\right)$$

with $n = -1$ results in, after the reverse rearrangement,

$$\left(\frac{2}{f_F}\right)^{1/2} = 0.256 + 2.5\ln\left\{\frac{\left(\frac{f_F}{2}\right)^{1/2}\mathrm{Re}_D}{1 + 0.3012\left(\frac{e}{D}\right)\left(\frac{f_F}{2}\right)^{1/2}\mathrm{Re}_D}\right\}$$

The exact equivalent of this expression in structure but with the slightly modified numerical coefficients of 0.300, 2.46, and 0.304 was postulated by Colebrook (1938–1939) to represent his own experimental data. The coefficients of the expression given here are presumed to be more accurate, but the difference in the predictions of f_F with the two sets of coefficients is within the band of uncertainty of the experimental data. The turbulent regime of the “friction-factor” plot in most current textbooks and handbooks is simply a graphical representation of the Colebrook equation. Experimental values are not included in such plots since e, the effective roughness of commercial pipes, is simply a correlating factor that forces agreement with the Colebrook equation. Values of e for various types of pipe in various services are usually provided in an accompanying table, that thereby constitutes an integral part of the correlation.

The Laminar Region

The Fanning friction factor in the laminar regime of a round pipe ($\mathrm{Re}_d < 1800$) is represented exactly by the following theoretical expression known as Poiseuille’s law: $f_F = 16/\mathrm{Re}_D$. This equation may be rearranged as follows for convenience in combination with that for turbulent flow:

$$\left(\frac{2}{f_F}\right)^{1/2} = \frac{\mathrm{Re}_D\left(f_F/2\right)^{1/2}}{8}$$

The Transitional Regime

Experimental data as well as semitheoretical computed values for the limiting behavior in the transition may be represented closely by $(f_F/2) = (\mathrm{Re}_D/37500)^2$. This expression may be rewritten, in terms of $(2/f_F)^{1/2}$ and $\mathrm{Re}_D(f_F/2)^{1/2}$, as follows:

$$\left(\frac{f_F}{2}\right)^{1/2} = \left(\frac{37500}{\mathrm{Re}_D\left(f_F/2\right)^{1/2}}\right)^{1/2}$$

Overall Correlation

The following correlating equation for all $\mathrm{Re}_D(f_F/2)^{1/2}$ and e/D may now be constructed by the combination of the expressions for the turbulent and transition regimes in the form of the CUE with $n = 8$, and then that expression and that for the laminar regime with $n = -12$, both components being chosen on the basis of experimental data and predicted values for the full regime of transition:

$$\left(\frac{2}{f_F}\right)^{1/2} = \left[\left(\frac{8}{\mathrm{Re}_D\left(f_F/2\right)^{1/2}}\right)^{12} + \left(\left[\frac{37500}{\mathrm{Re}_D\left(f_F/2\right)^{1/2}}\right]^4 + \left|2.5\ln\left\{\frac{1.108\,\mathrm{Re}_D\left(f_F/2\right)^{1/2}}{1+0.3012\left(\frac{e}{a}\right)\mathrm{Re}_D\left(f_F/2\right)^{1/2}}\right\}\right|^8\right)^{-3/2}\right]^{-1/12}$$

The absolute value signs are only included for aesthetic reasons; the negative values of the logarithmic term for very small values of $\mathrm{Re}_D(f_F/2)^{1/2}$ do not affect the numerical value of $(2/f_F)^{1/2}$ in the regime in which they occur. This overall expression appears to have a complicated structure, but it may readily be recognized to reduce to its component parts when the corresponding term is large with respect to the other two. It is insensitive to the numerical values of the two arbitrary exponents. For example, doubling their values would have almost no effect on the predictions of $(f_F/2)^{1/2}$. The principal uncertainty is associated with the expression for the transition regime, but the overall effect of the corresponding term is very small. The uncertainties associated with this correlating equation are common to most graphical correlations and algebraic expressions for the friction factor, and are presumed to be fairly limited in magnitude and to be associated primarily with the postulated value of e. Although the overall expression is explicit in $\mathrm{Re}_D(f_F/2)^{1/2}$ rather than Re_D, the latter quantity may readily be obtained simply by multiplying the postulated value of $\mathrm{Re}_D(f_F/2)^{1/2}$ by the computed values of $(2/f_F)^{1/2}$.

3.4 Hydraulics of Pipe Systems

J. Paul Tullis and Blake P. Tullis

Principles involved in the design and operation of pipelines include:

- Establish the required flow for present and future demands, determining the route, profile, and elevation differences, as well as need for and benefits of storage capabilities.
- Determine whether the flow will be supplied by gravity, pumps, or a combination.
- Select the appropriate pipe material and pressure class, considering fluid type; soil conditions; system pressure; pipe size; whether the pipe will be buried; etc.
- Consider the possibility of crushing from external loads and collapse due to internal vacuum pressures.
- Select the optimum pipe diameter.
- Select valves and pumps that have performance characteristics compatible with the system.
- Establish operating procedures for the pumps and valves to avoid excessive hydraulic transients.
- Analyze the cavitation potential of the valves and pumps.
- Select appropriate type, size, and location of air valves and check valves.
- Establish procedures for filling, flushing, and draining the system.

Basic Equations

Solving fluid flow problems involves the application of one or more of the three basic equations: continuity, momentum, and energy. These three basic tools are developed from the law of conservation of mass, Newton's second law of motion, and the first law of thermodynamics. The simplest form of the continuity equation is for one-dimensional incompressible steady flow in a closed conduit. Applying continuity between any two sections gives:

$$A_1V_1 = A_2V_2 = Q \tag{3.4.1}$$

For a variable density, the equation can be written:

$$\rho_1A_1V_1 = \rho_2A_2V_2 - \dot{m} \tag{3.4.2}$$

in which A is the cross-sectional area of the pipe; V is the mean velocity at that same location; Q is the flow rate; ρ is the fluid density; and $\dot{m}$ is the mass flow rate. The equations are valid for steady flow in any rigid conduit as long as there is no addition or loss of liquid between sections 1 and 2.

For steady-state pipe flow, the momentum equation relates the sum of forces in a given direction acting on a control volume (a section of the fluid inside the pipe), to the net momentum flux through the control volume in the same direction. The most common forces are pressure and friction.

$$\Sigma F_x = \rho_2A_2V_2V_{2x} - \rho_1A_1V_1V_{1x} \tag{3.4.3}$$

For incompressible flow, this equation can be reduced to:

$$\Sigma F_x = \rho Q\left(V_{2x} - V_{1x}\right) \tag{3.4.4}$$

These equations can easily be applied to a three-dimensional flow problem by adding equations in the y and z directions.

A general form of the energy equation applicable to incompressible pipe flow is:

$$\frac{P_I}{\gamma} + Z_1 + \frac{V_1^2}{2g} = \frac{P_2}{\gamma} + Z_2 + \frac{V_2^2}{2g} - H_p + H_t + H_f \tag{3.4.5}$$

The units are energy per unit weight of liquid: ft-lb/lb or $N\text{-}m/N$, or simply length.

The first three terms are pressure head (P/γ); elevation head (Z) (above some datum); and velocity head ($V^2/2g$). The last three terms on the right side of the equation are the total dynamic head added by a pump (H_p), removed by a turbine (H_t), and the total friction and minor head losses (H_f). The sum of the first three terms in Equation (3.4.5) is defined as the total head and the sum of the pressure and elevation heads is referred to as the piezometric head.

Fluid Friction

This subsection discusses pressure changes resulting from incompressible flow for pipes with circular geometry. However, the results can be generalized for a pipe of noncircular geometry by substituting for the diameter D in any of the equations, the hydraulic diameter, D_h, defined as $D_h = A/P$. A is the cross-sectional area of the conduit and P is the wetted perimeter (πD for a circular pipe flowing full).

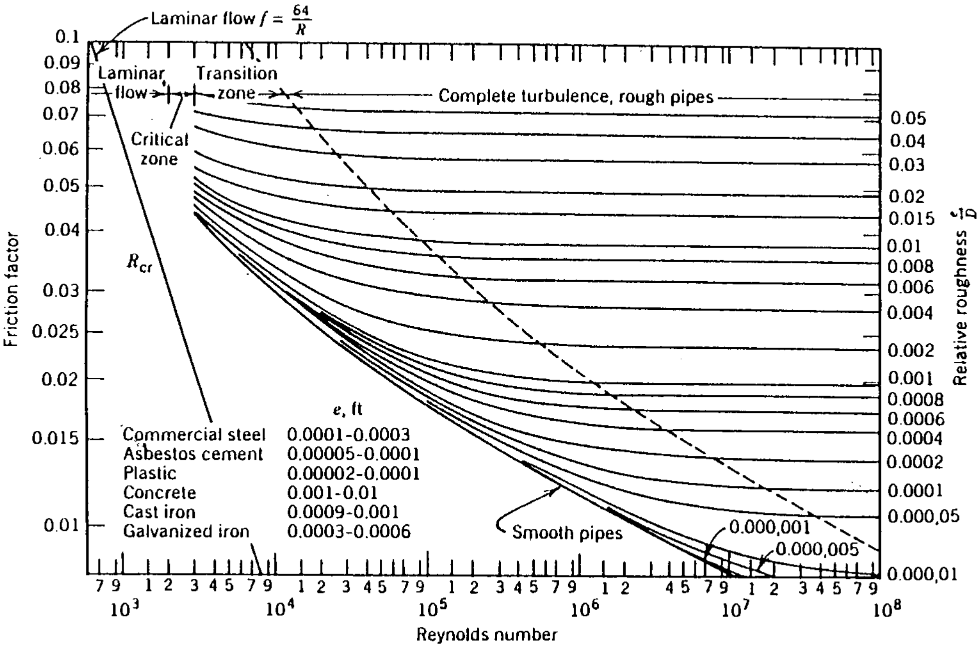

FIGURE 3.4.1 The Moody diagram.

The analysis in this subsection can also be applied to gases and vapors, provided the Mach number in the duct does not exceed 0.3. For greater values of the Mach number, the compressibility effect becomes significant and the reader should see Section 3.7 on compressible flow.

Friction loss (H_f) depends on pipe diameter (D); length (L); pipe roughness (e); fluid density (ρ) or specific weight (γ); viscosity (ν); and flow velocity (V). Dimensional analysis can be used to provide a functional relationship among the friction loss H_f, pipe dimensions, fluid properties, and flow parameters. The resulting equation is called the Darcy-Weisbach equation:

$$H_f = \frac{fLV^2}{2gD} = \frac{fLQ^2}{1.23gD^5} \tag{3.4.6}$$

The friction factor f is a measure of pipe roughness and has been evaluated experimentally for numerous pipes. The data were used to create the Moody friction factor chart shown as Figure 3.4.1. The friction factor f and the subsequent friction loss of a flowing liquid depend on whether the flow is laminar or turbulent. Laminar flow exists when viscous forces are large compared to inertial forces. The Reynolds number is the ratio of inertia forces to viscous forces and is a convenient parameter for determining whether a flow condition will be laminar or turbulent. The Reynolds number is defined as:

$$\mathrm{Re} = \frac{\rho V d}{\mu} = \frac{Vd}{\nu} \tag{3.4.7a}$$

V is the mean flow velocity; d is diameter; ρ is fluid density; μ is dynamic viscosity; and ν is kinematic viscosity.

For laminar flow (Re < 2000), f is only a function of Re and is calculated by $f = 64/\mathrm{Re}$. Laminar flow in pipes is unusual for practical applications. To illustrate this, the velocity of water flowing in a 1-m diameter pipe at 20°C would need to be less than or equal to 2 mm/sec to be laminar. Most practical pipe flow problems are in the turbulent region.

At Reynolds numbers between about 2000 and 4000, the flow is unstable as a result of the onset of turbulence (critical zone in Figure 3.4.1). In this range, friction loss calculations are difficult because it is impossible to determine a unique value of *f*. Fortunately, few pipe flow problems involve Reynolds numbers below 4000. For Re > 4000, the flow becomes turbulent and *f* is a function of Re and relative pipe roughness (e/D), where *e* is the equivalent roughness height and *D* is pipe diameter. At high Re, *f* eventually depends only on the relative roughness height, e/D. This region is defined as fully turbulent flow. The Reynolds number at which this occurs depends on the relative roughness of the pipe

Using the Moody chart in Figure 3.4.1 to get *f* requires that Re and e/D be known. Calculating Re is direct if the water temperature, flow, and pipe diameter are known. The problem then reduces to one of obtaining a good value for *e*. The values of *e* listed in Figure 3.4.1 should be considered as approximate and used only if more accurate values cannot be obtained from the pipe supplier.

For noncircular pipes, the only change in the friction loss equation is replacing the diameter with the hydraulic radius (R). R is the ratio of the flow area to the wetter perimeter. For a circular pipe, $D = 4R$,

The Moody diagram (Figure 3.4.1) is a graphical representation of the Colebrook and White equation:

$$\frac{1}{\sqrt{f}} = 1.74 - 0.869 \ln\left(\frac{2e}{D} + \frac{18.7}{\mathrm{Re}\sqrt{f}}\right) \tag{3.4.7b}$$

The Colebrook and White equation requires a trial-and-error or iterative solution because *f* appears on both sides of the equation.

Haaland (1983) developed an explicit relationship that approximates the Colebrook and White equation. The relationship provides reasonable accuracy in the range of $4000 < \mathrm{Re} < 10^8$ and $0 < e/d < 0.05$

$$\frac{1}{\sqrt{f}} = -0.782 \ln\left[\frac{6.9}{\mathrm{Re}} + \left(\frac{e}{3.7D}\right)^{1.11}\right] \tag{3.4.8}$$

If the flow or pipe diameter is not known, the solution to the Darcy–Weisbach or Haaland equations becomes a trial-and-error or iterative process.

For long gravity flow pipelines, the criterion for selecting the pipe diameter is simply finding the smallest pipe that can pass the required flow without the friction and minor losses exceeding the available head. For pumped systems, optimizing the pipe diameter is based on an economic analysis that compares the installed pipe cost with the cost of building and operating the pumping plant. Pipe cost is proportional to *D* and pumping cost is inversely proportional to *D*. The optimum pipe diameter is selected as the one that provides the lowest total cost.

The pipe roughness usually varies with time due to buildup of solid deposits or organic growths. Manufacturing methods and tolerances also cause variations in the surface roughness. Consequently, the friction factor for any pipe can only be approximated and proper allowance should be made for these uncertainties.

Minor Losses

Flow through valves, orifices, elbows, transitions, etc. causes flow separation, which results in the generation and dissipation of turbulent eddies. The resulting head loss, H_m, referred to as a minor loss, is proportional to the velocity head:

$$H_m = K_l \frac{Q^2}{\left(2gA_m^2\right)} \tag{3.4.9}$$

in which K_l is the minor loss coefficient and A_m is the flow area at the inlet to the minor loss element. Although these types of losses are referred to as minor, in short piping systems; long piping systems with small velocity heads; or other systems in which the friction loss is relatively small, the minor losses can be responsible for the majority of the system head loss. The minor loss coefficient K_l is analogous to fL/D in Equation (3.4.6).

The summation of all friction and minor losses in a pipe system can be expressed as:

$$H_l = H_f + H_m \tag{3.4.10}$$

$$H_l = \left[\sum \left(\frac{fL}{2gDA_p^2} \right) + \sum \left(\frac{K_l}{2gA_m^2} \right) \right] Q^2 = CQ^2 \tag{3.4.11}$$

in which:

$$C = \sum \left(\frac{fL}{2gDA_p^2} \right) + \sum \left(\frac{K_l}{2gA_m^2} \right) \tag{3.4.12}$$

It is important to use the correct pipe inside diameter for each pipe section and minor loss. The variation of the actual inside pipe diameters from the nominal is a function of size and pressure class.

In an effort to simplify calculations, some have expressed the minor losses as an equivalent pipe length parameter: $L_{\text{equ}} = K_l D/f$. It represents the length of pipe that produces the same head loss as the local or minor loss. This is a simple, but potentially inaccurate, method of including minor losses. The problem is that the friction coefficient varies from pipe to pipe, so the equivalent length will not have a unique value. When minor losses are truly minor, this problem becomes academic. However, when local losses are an important part of the analysis, it is recommended that the minor loss coefficients K_l be used rather than an equivalent length.

The following summarizes the testing programs conducted to evaluate the loss coefficients of pipe fittings. The documents are only available from ASHRAE.

- Reducing Ells, and Pipe Reducers (ASHRAE 2002 H-1405)
  Number: 250
  Radius: short and long
  Sizes: 2 and 4 in. (5 and 10 cm)
  Materials: threaded iron and welded steel
  Manufacturers: 11
- Threaded and Forged Weld Pipe Tees (ASHRAE 2002 H-1404)
  Number: 142
  Sizes: 2 and 4 in. (5 and 10 cm)
  Materials: threaded iron and welded steel
  Manufacturers: 11
- Large Pipe Ells, Reducers and Expansions (ASHRAE 2002 H-1672a)
  Number: 32
  Radius: long
  Sizes: 12, 16, 20, and 24 in. (30.5, 40.6, 50.8, and 61 cm)
  Materials: welded steel
  Manufacturers: 4
- Large Pipe Tees (ASHRAE 2002 H-1672b)
  Number: 328
  Sizes: 12 and 16 in. (30.5 and 40.6 cm)
  Materials: welded steel
  Manufacturers: 4

- Close Coupled Pipe Ells (ASHRAE 2002 H-1673)
    Sizes: 2 and 4 in. (5 and 10 cm)
    Radius: Short
    Spacing: 0, 1, 2, 3, 4, 5, 10, 20, and 50 pipe dia.
    Materials: threaded iron and welded steel
- PVC Pipe Elbows, Reducers and Expansions, RP-1193 (ASHRAE 2003,TECH-00034-2003)
    Number: 170
    Schedule: 80
    Sizes: 2, 4, 6, and 8 in. (5.08, 10.16, 15.25, and 20.32 cm)
    Materials: injection molded and fabricated PVC
    Manufacturers: 7
- PVC Pipe Tees, RP-1193 (ASHRAE 2003 TECH-00035-2003)
    Number: 61
    Schedule: 80
    Sizes: 2, 4, 6, and 8 in. (5.08, 10.16, 15.25, 20.32 cm)
    Materials: injection molded and fabricated PVC
    Manufacturers: 7

Test results show that the loss coefficients for fittings vary with material; manufacturer; method of fabrication; accuracy of installation; and, for tees, with the percent flow distribution between the branches. The loss coefficient consistently reduced as the size of the fitting increased. Currently, such variations in minor loss coefficients are not accounted for in published minor loss data.

The ASHRAE study also looked at the effect of closely spaced elbows in series (Rahmeyer, 2002e, Technical Paper H-1673). The testing included two sizes of elbows, four different alignments, and spacing from 0 to 20 pipe diameters. The results showed that the combined loss coefficient for the two elbows was never greater than the sum of the individual loss coefficients. At a spacing of 20 diameters, there was no effect. At 10 diameters, the combined loss coefficients were between 2 and 6% lower than the sum of the individual coefficients. At 3 diameters, the combined coefficient was 10 to15% lower. For close-coupled elbows, the combined loss coefficient was between 5 and 28% lower, depending on the orientation of the elbows.

Comparing the magnitude of ($\Sigma(fL/2gA_p^2)$ to $\Sigma(K_l/2gA_m^2)$) will determine how much care should be given to the selection of the K_l values. Typical values of K_l are listed in Table 3.4.1 with a range of values from the recent ASHRAE studies. For details on the loss coefficient for a specific fitting and for loss coefficients not found in the table, the reader is referred to Rahmeyer (2002a,b,c; 2003a,b) and Miller (1990).

Pipe Selection

Materials commonly used for pressure pipe transporting liquids are ductile iron; concrete; steel; fiberglass; PVC; and polyolefin (polyethylene and polypropylene). For each of these pipe materials, national committees have developed specifications that discuss external loads; internal design pressure; available sizes; quality of materials; corrosive environments; installation practices; and linings. Standards are available from the following organizations:

- American Water Works Association (AWWA)
- American Society of Mechanical Engineers (ASME)
- American Society for Testing and Materials (ASTM)
- American National Standards Institute (ANSI)
- Canadian Standards Association (CSA)
- Federal Specifications (FED)
- Plastic Pipe Institute (PPI)

In addition, manuals and other standards have been published by various manufacturers and manufacturers' associations. These specifications and standards should be used to guide the selection of pipe

TABLE 3.4.1 Minor Loss Coefficients

Item	K_l
Pipe inlets	
Projecting pipe	0.5–0.9
Sharp corner-flush	0.50
Slightly rounded	0.04–0.5
Bell mouth	0.03–0.1
Sudden expansions[a] (based on inlet velocity, V_1)	$(1\text{-}A_1/A_2)^2$
Sudden contractions[b] (based on outlet velocity, V_2)	$(1/C_c\text{-}1)^2$

A_2/A_1	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9
C_c	0.624	0.632	0.643	0.659	0.681	0.712	0.755	0.813	0.892

Item	K_l
Steel bell reducers[e] (welded, $D1/D2$ = 1.2–1.33)	0.053–0.23
Steel bell expanders[e] (welded, $D2/D1$ = 1.2–1.33)	0.02–0.11
PVC fabricated reducers[e] ($D1/D2$ = 1.33–1.5)	0.12–0.68
PVC fabricated expanders[e] ($D2/D1$ = 1.2–1.33)	0.07–1.19

Bends	ASHRAE[e]	Typical Values[c]
Short radius, r/d = 1		
90	0.33–0.74	0.3–0.6
45		0.10
30		0.06
Long radius, r/d = 1.5		
90	0.089–0.26	0.07–0.33
45		0.09
30		0.06
Mitered (one miter)		
90	1.10	
60	0.40–0.59	
45	0.35–0.44	
30	0.11–0.19	
PVC injection molded elbows[e]	0.68–1.00	
PVC fabricated type I elbows[e]	0.40–0.42	
PVC fabricated type II elbows[e]	0.73–0.76	
Tees[e]		

Valves	Average Values	Range
Check valves[d]		
Swing check	1.0	0.29–2.2
Tilt disc	1.2	0.27–2.62
Lift	4.6	0.85–9.1
Double door	1.32	1.0–1.8
Full open gate	0.15	0.1–0.3
Full open butterfly	0.40	0.2–0.6
Full open globe	4.0	3–10

material. ASCE (1992) contains a description of most of these pipe materials and a list of the specifications for the various organizations, which apply to each material. The document also discusses the various pipe-linings available for corrosion protection. The following are relevant publications for selecting the proper type and pressure class of pipe: (ASCE 1992, 1993; AWWA 1995 (M9), 1989 (M11), 2003 (M41); PPI 1980 (M23).

For air and low-pressure liquid applications, available pipe materials include unreinforced concrete; corrugated steel; smooth sheet metal; spiral rib (sheet metal); and HDPE (high-density polyethylene). The choice of a material for a given application depends on pipe size, pressure requirements, resistance to collapse from internal vacuums or external loads, resistance to internal and external corrosion, ease of handling and installing, useful life, and economics.

Valve Selection

Valves serve a variety of functions; including, isolation; flow control; pressure regulation; preventing reverse flow; limiting maximum pressures; and releasing/admitting air. This section discusses characteristics of and principles for selecting and operating control valves, check valves, air valves, and pressure relief valves. For a description of various types of valves and details regarding their function, see Tullis 2005.

Control Valves

Valve selection and operation rarely receive the same detailed engineering attention given to other components of piping systems. Their function is often not demanding and detailed attention to valve selection may not be necessary. However, in some applications, the lack of attention to selecting the proper type and size valve can lead to excessive maintenance, poor performance, and other serious consequences.

To find the right valve, the user often relies on the valve vendors for engineering advice, and rightly so, because they should be the most familiar with their product. However, when the system requirements are nonstandard, or severe, few vendors have enough engineering experience or performance data on their valves to enable them to provide reliable information. To minimize valve problems, one must identify the valves in the system that need special attention. For such valves, the engineer needs tools for making a correct analysis. The following subsections provide information for selecting and operating valves when special engineering is required to avoid problems.

When analyzing a flow control valve, the following criteria should be considered:

- The valve should not produce excessive pressure drop when full open.
- The valve should control the flow rate over approximately 50% of its movement.
- The maximum operating torque must not exceed the capacity of the operator or valve shaft and connections for any flow condition.
- The cavitation intensity should be limited to the appropriate level.
- The valve should be operated so that the resulting pressure transients do not exceed the safe limits of the system.

Excessive Pressure Drop

What constitutes excessive pressure drop for a control valve depends on the overall purpose of the piping system and on the magnitude of the other losses in the system. A valve considered to have an excessive loss in one system might be totally acceptable in another. To determine the acceptability of the full open pressure loss of the control valve, the magnitude of the loss valve coefficient ($K_l/2gA_m^2$) should be compared to the total system loss coefficient C (Equation 3.4.12). For example, the loss coefficient for a full-open globe valve can be 10 times higher than a full-open butterfly valve. However, if the loss coefficient for the globe valve is small compared to the total system loss coefficient, the globe valve would be an acceptable choice.

Controllability

For many flow control applications, it is desirable to select a valve that has linear control characteristics. Some valve vendors advertise that their valves are linear. The problem with such a claim is that the linearity of a control valve depends on the system in which it is installed. In a short pipe, a valve may linearly control the flow. However, the same valve installed in a long pipe will only control the flow near the closed position.

The flow in a pipeline can be calculated using the energy equation (Equation 3.4.5) and the system loss equation (Equation 3.4.11). The result is:

$$Q = \sqrt{\frac{\Delta Z}{\left[\Sigma\left(\frac{fL}{2gDA_p^2}\right) + \Sigma\left(\frac{K_l}{2gA_m^2}\right)\right]}} \qquad (3.4.13)$$

The ability of the valve to control flow depends on the relative values of the valve's loss coefficient ($K_l/2gA_m^2$) compared to the pipe's friction coefficient ($fL/2gdA_p^2$). For a short system, a valve can almost linearly reduce the flow because the valve loss becomes large compared to the friction loss as the valve closes. In contrast, for a long pipeline $K_l/2gA_m^2$ will be small compared to $fL/2gdA_p^2$ until the valve is near its closed position.

To demonstrate the relationship between a valve and system, consider a butterfly valve that will be used to control the flow between two reservoirs with an elevation difference of ΔZ. System A is a short pipe (0.3 m dia., 100 m long, $\Delta Z = 10$ m, $f = 0.0138$) where pipe friction is small ($fL/2gdA_p^2 = 46.9$). System B is a long pipe (0.3 m dia., 10,000 m long, $\Delta Z = 200$ m, $f = 0.0138$) with high friction ($fL/2gdA_p^2 = 4690$). Initially, assume that the same butterfly valve will be used in both pipes and it will be the same size as the pipe diameter.

For the valve, assume that the K_l full open is 0.187 and at 50% open it is 8.4. Correspondingly, $K_l/2gA_m^2 = 1.905$ and 85.7. For system A, the flow with the valve full open will be 0.453 m^3/sec and at 50% open 0.275 m^3/sec, a reduction of 39%. Repeating these calculations over the full range of valve openings would show that the flow for system A reduces almost linearly as the valve closes.

For system B, the flow with the valve full open will be 0.206 m^3/sec and at 50% open 0.205 m^3/sec, a reduction of less than 1%. The valve in system B will not start to control the flow until it has closed more than 50%. A line-size butterfly valve is obviously not a good choice for a control valve in system B. One solution to this problem is to use a smaller valve. If the butterfly valve installed in system B were half the pipe diameter, it would control the flow over most of its stroke.

The range of opening over which the valve controls the flow also has a significant effect on the magnitude of the transient pressures caused by closing the valve. The valve closure time must be long enough to avoid excessive transient pressures. If the valve is oversized and does not start reducing the flow until it is more than 50% closed, over half of the closing time is wasted and the effective valve closure time is less than half the actual closing time. The solution to this problem is to reduce the valve size so it provides control over most of its movement.

The size of the control valve, as well as its associated open/close time, can also have an impact on the overall system control logic. The closing time for the valve must be fast enough to match the changing flow requirements for the rest of the system without generating excessive transient pressures. For example, if the valve controls the water level in a storage tank and is actuated by a level sensor, the valve must close fast enough that the tank does not overfill.

A case study of a pipeline rupture illustrates the need for selecting the proper size of control valve. The pipeline was 6 ft (2 m) in diameter, about 30 miles (51 km) long, and supplied water to two storage tanks. The pipes to the storage tanks each contained a 5-ft (1.52-m) diameter butterfly valve. The combined area of the two 5-ft (1.52-m) valves is equivalent to one 7-ft (2.13-m) valve. Because the valves were oversized, they only controlled flow over the last 25% of their movement. The pipeline ruptured due to a pressure transient that resulted from closing the valves too fast. If smaller control valves had been installed, the pipeline may not have ruptured during initial flow tests.

Torque

Selection of the correct operator for a specific quarter-turn valve and application requires knowing the maximum torque that the operator will be required to supply. This requires analyzing the system for the entire range of expected flow conditions so that the maximum flow torque can be identified. The maximum torque is also needed when selecting the valve to be sure that the valve shaft and connections are adequately designed. It is the responsibility of the valve manufacturer to provide the flow and torque characteristics and limits for their valve. It is the responsibility of the system engineers and/or operators to see that the valves are operated within these limits.

The four primary sources of torques for quarter-turn valves are seating torque; bearing friction torque; packing friction torque; and hydrodynamic (flow) torque. These torque values are usually determined experimentally and should be available from the valve manufacturer. All four torques should be evaluated to determine the maximum torque for a given valve.

Seating friction torque develops when the plug or disk moves in or out of the seat (sealing surface). For small valves with soft seats, the seating torque can be larger than the other three torques combined. Bearing friction torque develops when a load is placed on the bearing surface by the valve shaft when there is a pressure differential across the valve. Because the pressure drop significantly increases as a valve closes, the bearing torque is greatest at small openings. Packing friction torque is caused by the valve shaft rubbing against the packing material. Packing is the material placed between the valve shaft and valve body to prevent leakage. Packing friction torque can be particularly troublesome because the packing conditions can be modified in the field. If a packing leaks, the normal procedure is to tighten the packing until the leak stops. This can significantly increase the packing torque and may prevent the operator from opening the valve. When valve packing is adjusted, the ability of the actuator to close the valve under all operating conditions should be confirmed.

Forces induced by the fluid flowing through the valve cause a hydrodynamic torque, which usually acts to close the valve. The magnitude of the torque varies with flow rate, pressure drop, and valve opening. The valve opening, where maximum hydrodynamic torque occurs, depends on the valve design and system characteristics. In short systems, in which friction loss is low and velocities are high, a quarter-turn valve will see maximum torques at large openings where the flow rate is high. In long systems with high friction losses and lower velocities, the same valve will see maximum torque at smaller openings where the pressure drop is high. The hydrodynamic forces should be evaluated over the entire valve operating range and corresponding system flow conditions to identify the maximum operating torque. Operating torque is normally greater when the valve is being opened because the hydrodynamic torque usually acts to close the valve and the bearing and packing torques oppose the direction of valve motion. During closure, the bearing and packing torques act in the direction opposite to that of the hydrodynamic torque.

Cavitation

Cavitation is a process in which vapor bubbles form, grow, become unstable, and collapse. This causes excessive noise, vibrations, erosion damage; the valve can lose capacity if subjected to the most severe stage of cavitation. Evaluating the intensity of cavitation and limiting it to an acceptable level are important in control valve selection.

The first step in a cavitation evaluation is to decide on the acceptable level of cavitation. Three cavitation limits typically used to quantify the intensity of cavitation for a control valve are: critical, incipient damage, and choking cavitation. The cavitation design limit appropriate for a given application varies with valve type, valve function, details of the piping layout and location, and the frequency and duration of operation.

Critical cavitation is typically considered a conservative design limit. It corresponds to the onset of light but constant cavitation noise and is appropriate as a design limit for valves that need to operate essentially free of adverse cavitation effects. Incipient damage corresponds to onset of pitting (material removal). It is an appropriate design limit when significant noise and vibrations can be tolerated but no damage is desired. Choking cavitation (sometimes called flashing) represents the condition in which the mean pressure immediately downstream from the valve drops to vapor pressure and the flow rate is at its maximum for a given upstream pressure. Between critical and incipient damage, the noise level can become objectionable. Between incipient damage and choking cavitation, the erosion damage and vibration levels can be severe. Using choking as a design condition may be appropriate for a pressure relief valve, where valve operation is short lived and infrequent; maximum flow rate through the valve is required; and cavitation damage can be tolerated for short periods of time. It should not be used for valves intended for long-term, low-maintenance operation.

One of the challenges with cavitation has been a lack of consistent terminology between industries. For example, some industries define the onset of cavitation as the condition in which the performance of the valve begins to drop off due to heavy cavitation. This is a correct definition for onset of choking cavitation, but it is misleading to imply that it represents onset of cavitation. Choking is, in fact, the final stage of cavitation — well beyond the point at which damage begins. Promoting this incorrect definition of "onset of cavitation" has resulted in many valves suffering extensive damage. A similar definition of onset of cavitation exists in the pump industry, where the cavitation index NPSHr is often assumed to be the point at which cavitation begins. In reality, it represents onset of choking cavitation. Pump cavitation is discussed in more detail later in the chapter.

The intensity of cavitation and the corresponding noise, vibration, and erosion damage at the valve are at their maximum just before a valve chokes. If the valve operates at a flow condition beyond choking (sometimes referred to as supercavitation), the cavitation events create one large vapor cavity and the mean pressure in the pipe is essentially vapor pressure. The collapse of the large vapor cavity usually occurs at the first significant downstream flow disturbance — such as an elbow, tee, valve, or orifice — or when the frictional forces in the pipe are sufficient to generate the necessary pressure recovery. During supercavitation, damage may not occur inside the valve, but there will be serious vibration and material erosion problems farther downstream where the collapse occurs.

The cavitation intensity for valves is quantified with a cavitation index σ, which represents the ratio of forces preventing cavitation (high local pressure) to forces causing cavitation (high pressure differential).

$$\sigma = \frac{(Pd + Pb - Pv)}{(Pu - Pd)} \tag{3.4.14}$$

Pu and *Pd* are the gage pressures upstream and downstream from the valve; *Pb* is the barometric pressure; and *Pv* is the absolute vapor pressure.

The smaller the σ value is, the greater the chance that cavitation will occur. To evaluate the potential for cavitation of a valve or other minor loss element at a particular flow condition, the value of the system σ (Equation 3.4.14 evaluated at system pressure conditions) must be calculated and compared with σ values corresponding to the various cavitation intensity levels, i.e., critical, incipient damage, and choking. These cavitation intensity level values vary with valve type and valve opening and must be determined experimentally.

Numerous valves have been tested to evaluate critical cavitation and onset of choking. Consequently, many valve manufacturers should be able to provide experimental data for these limits. Only limited data, however, are available identifying onset of cavitation damage because of the difficulty and labor-intensive nature of laboratory damage testing. This is unfortunate because onset of damage is the most important cavitation limit. Experimental data for several types of valves are available in the literature (Tullis, 1989, 1993). Information from these sources can be used if information from the valve manufacturer is not available. It is important to note that most valves have unique cavitation characteristics and that valve-specific cavitation data should be used for design purposes.

As an example, if an incipient damage level of cavitation intensity were selected as the limiting operating condition, the experimentally determined σ-incipient damage would be compared with the σ-system. If the σ-system is larger than σ-incipient damage, then the level of cavitation for that condition is acceptable. Because some level of uncertainty is associated with the experimentally determined cavitation intensity parameters, designers may wish to include a factor of safety when limiting the cavitation intensity of the valve or other minor loss device. Cavitation characteristics of a valve can be and typically are subject to size and pressure scale effects. A discussion on cavitation scale effects is presented by Tullis (1989, 1993).

If the cavitation analysis indicates that the valve, orifice, or other device will be operating at a cavitation level greater than can be tolerated, various techniques can be used to limit the level of cavitation. One is to select a different type of valve. Recent developments have produced several new valves better suited for limiting the levels of cavitation or reducing the potential for cavitation damage. Some of these valves operate on the principle of dropping the pressure in stages. They have multiple paths with numerous sharp turns or sudden expansions in series and are sometimes referred to as “stack valves.” The number of restrictions depends on the total pressure drop required and the system pressure downstream from the last restriction. Because the pressure downstream from each restriction is progressively smaller, for cavitation purposes, each stage is designed so the pressure drop across each subsequent restriction is less than the preceding one (by approximately 50%). Consequently, the first stage (on the high-pressure inlet side) will be able to provide a pressure drop many times the pressure drop at the last stage, with both stages operating near the same level of cavitation intensity. As a result, these types of valves can operate at very large pressure differentials without experiencing cavitation damage. One limitation of stack valves is that they are only usable in clean systems.

For untreated water systems, the stack valve is not appropriate because of plugging problems. As an alternative, conventional valves and orifices can be installed in series to reduce the cavitation in stages. Proper spacing of valves and orifices is important. The spacing between valves depends upon the type. For most quarter-turn valves, a spacing of five to eight pipe diameters is needed for pressure recovery and uniform flow re-establishment between each valve. This prevents disk flutter and ensures normal pressure drop characteristics at each valve. Globe valves, however, can be installed with no piping between them and have satisfactory operation. The primary disadvantages of locating conventional valves in series are the space requirement, increased complexity of the control logic, and cost. For details on this type of application, see Tullis (1989, 1993).

Another recent advance in the fight against cavitation is the development of the sleeve valve. These valves use a perforated cylindrical sleeve to create multiple jets that discharge radially inward. An external sliding collar controls the number of holes exposed. These have excellent cavitation characteristics because they can operate at fairly heavy cavitation levels without damaging the valve or outlet pipe. The valve’s success is attributed to two things. Small holes discharging into a large chamber is the optimum configuration to suppress cavitation in a single-stage device. The other factor is that the jets from the multiple holes converge toward the center of the outlet sleeve, keeping the collapsing cavitation events away from the boundary until just before the valve chokes. These valves can operate at σ values below 0.2 without damage. Conventional valves typically experience cavitation damage at σ values greater than 1.0.

The cavitation performance of conventional valves varies considerably. For example, skirted cone valves and solid ball valves generate significantly less cavitation than unskirted cone and nonsolid ball valves. This is because, for valves with a solid plug, all the flow goes through two ports in series (one at the inlet side and one at the outlet side of the plug). Similarly to stack valves, reducing the pressure in stages provides superior cavitation performance, compared to a single-stage control valve. The unskirted cone and nonsolid ball valves have two throttling ports in series, but they also allow flow to pass around the plug. The flow passage around the plug experiences only a single-stage pressure drop, resulting in increased cavitation potential. Skirted cone and solid ball valves also have better cavitation performance than butterfly, gate, and segmented ball valves because those valves only have a single stage of pressure drop. See Tullis (1989, 1993, 2003) for descriptions of the different types of valves and their cavitation characteristics.

For some applications, cavitation can be avoided by using a free discharge valve. Fixed cone valves are specifically designed for this application. However, these are specially designed valves and are relatively expensive. Some conventional valves can also be used for free discharge, if they can be adequately vented.

Injecting air to suppress cavitation is a technique that has been used for many years with varying degrees of success to suppress cavitation damage. If an adequate amount of air is injected into the proper region, noise, vibrations, and erosion damage can be significantly reduced. For systems that can tolerate some air injection, aeration is often the cheapest and most effective remedy for cavitation.

If all else fails, cavitation damage can be suppressed by plating critical areas of the pipe and valve with cavitation-resistant materials. The final option is simply to replace damaged valves as needed. For additional information on valve cavitation, see AWWA (2001, M49); Knapp et al. (1970); ISA (2000); and Tullis (1989, 1993).

Transients

Hydraulic transients refer to the dynamic pressure waves that result from rapid acceleration or deceleration of flow and are common in pipeline operation. They can be generated as a result of pipeline filling and air-flushing techniques; valve operation techniques, pump startup and shutdown, and pipe ruptures. Transient pressures can exceed the safe operating limit of the pipe if adequate design provisions and operational procedures are not established. The larger the incremental velocity change is and the faster the changes occur, the larger the resulting pressure change will be.

Transients caused by slow velocity changes, such as the rise and fall of the water level in a tank, are called surges. Surge analysis, or "rigid column theory," involves the numerical solution of a simple ordinary differential equation (force = mass × acceleration). The compressibility of the fluid and the elasticity of the conduit are ignored and the entire column of fluid is assumed to move as a rigid body. When changes in velocity occur rapidly, the compressibility of the liquid and the elasticity of the pipe become important and must be included in the analysis. This procedure is often called "elastic" or "water hammer" analysis and involves tracking acoustic pressure waves through the pipe. The analysis requires solving partial differential equations.

An equation predicting the head rise ΔH caused by a sudden change of velocity $\Delta V = V2 - V1$ can be derived by applying the unsteady momentum equation to a control volume of a section of the pipe at which the change of flow occurred. Consider a partial valve closure, which instantly reduces the velocity by an amount ΔV. Reduction of the velocity can only be accomplished by an increase in the pressure upstream of the valve of magnitude ΔH. The pressure wave of magnitude ΔH travels in the upstream direction of the pipe at the acoustic velocity, $\boldsymbol{a}$, which is a function of the fluid and pipe material properties. The increased pressure compresses the liquid and slightly expands the pipe. The transient head rise due to an incremental change in velocity is described as

$$\Delta H = -\boldsymbol{a}\,\Delta V/g, \text{ for } \boldsymbol{a} >> \Delta V \tag{3.4.15}$$

This equation can be used to account for the accumulative effect of multiple incremental changes of velocity until the initial pressure wave returns to the point of origin.

The wave speed depends on the pipe material, wall thickness, diameter, type of liquid, and the amount of air in the system. For a steel pipe with no entrained or trapped air, the wave speed is typically about 3000 fps (1000 m/sec). Based on this wave speed, Equation (3.4.15) predicts that an instant velocity change of 3 fps (1 m/sec) causes a transient pressure of about 300 ft (100 m). This illustrates why transient pressures can easily damage pipes.

The derivation of Equation (3.4.15) was based on an assumption of an instantaneous incremental velocity change or an instant valve closure. Instant closure actually refers to a finite time. It is the longest time over which a valve can be closed and still cause a pressure rise equal to that of an instant closure. It is the time required for the initial transient pressure wave to travel from the point of origin to the next upstream (or downstream) boundary condition and return to the point of origin. This wave travel time equals $2L/\boldsymbol{a}$ seconds, where L is the pipe length between the point of origin and the adjacent boundary condition and $\boldsymbol{a}$ is the acoustic wave speed. The maximum transient pressure rise associated with an instant valve closer will occur at the valve if the closure time is less than or equal to $2L/\boldsymbol{a}$ seconds.

Computational techniques for estimating transient pressures are too complex to be done with simple hand calculations. The solution involves solving partial differential equations derived from the equations of motion and continuity. These partial differential equations are normally solved by the method of characteristics — a technique that transforms the equations into ordinary differential equations. After integration, the equations can be solved numerically by finite differences (Tullis, 1989; Wiley and Streeter, 1993).

To complete the analysis, equations describing the boundary conditions are required. Typical boundary conditions are the connection of a pipe to a reservoir, a valve, changes in pipe diameter or material, pipe junctions, etc. Friction loss is included in the development of the basic equations and minor losses are handled as boundary conditions.

Every pipe system should have at least a cursory transient analysis performed to identify the possibility of serious transients and decide whether a detailed analysis is necessary. If an analysis indicates that transients are a problem, methods of controlling them include:

- Increasing the closing time of the control valve
- Using a smaller valve to provide better control
- Designing special facilities for filling, flushing, and removing air from pipelines
- Increasing the pressure class of the pipeline
- Using pressure relief valves, surge tanks, air chambers, etc.

Restricted Valve Opening

Many conventional control valves cannot safely and/or accurately regulate flow near the closed and full-open positions. Near the closed position, two of the potential problems are seat damage due to high velocities and inability to set the valve opening accurately when the connections between the control element and the operator are loose.

Near full open, some valves lose control, meaning that flow does not change as the valve position is changed. For globe style valves, this occurs when the stroke is too long. For a butterfly valve, it is due to the shape of the disk and changes in the flow pattern around the disk at large openings. For some disk shapes, the flow can actually decrease at valve openings greater than about 90%. This problem is magnified when the valve is installed in a long system in which the valve loss is small compared to the system friction loss (see the section on "Controllability").

Another reason that some quarter-turn valves should not be operated at large openings is that some valves experience torque reversals, which result in disk flutter that can lead to fatigue of the shaft and/or connections. Torque reversals are a function of the plug or disk design and usually only occur for flow in one direction. Valve vendors usually indicate a preferred flow direction for valve installation to avoid torque reversal problems.

Check Valves

Selecting the wrong type or size of check valve can result in poor performance, severe transients, and frequent repairs (Kalsi Engineering and Tullis Engineering Consultants, 1993). Proper check valve selection requires understanding the characteristics of the various types of check valves and analyzing how they will function as a part of the system in which they will be installed. For a description of the characteristics of common types of check valves, see Kalsi Engineering and Tullis Engineering Consultants (1993) and Tullis (2003). A check valve that operates satisfactorily in one system may be totally inadequate in another. Each type has unique characteristics that give it advantages or disadvantages compared with the others. The characteristics of check valves that should be considered in the selection process include:

- Closure speed of check valves relative to the rate of flow reversal of the system
- Stability of the disk and its sensitivity to upstream disturbances
- The flow required to fully open and firmly backseat the disc
- The pressure drop at maximum flow
- Sealing effectiveness and ease of maintenance

Disk stability varies with flow rate, disk position, and upstream disturbances and is an important factor in determining the useful life of a check valve. For most applications, it is preferable to size the check valve (especially swing check valve) so that the disk is fully open and firmly back-seated at normal flow rates. It is a mistake to oversize a swing check valve that is located just downstream from a disturbance such as a pump, elbow, or control valve. The disk will not firmly back seat and it will be subjected to severe motion and accelerate wear. Reducing the valve size reduces this problem.

The transient pressure rise generated at check valve closure is another important consideration. The pressure rise is a function of how fast the check valve closes compared to the speed of flow reversal (Thorley, 1989). Systems in which rapid flow reversals occur include parallel pumps, where one pump is stopped while the others are still operating; systems that have air chambers or surge tanks close to the check valve; and short systems with high elevation heads. For these systems, a high-energy source downstream from the check valve causes the flow to reverse quickly. As the disk nears its seat, it starts to restrict the reverse flow. This builds the pressure, accelerates the disk, and slams it into the seat.

Results of laboratory experiments, field tests, and computer simulations show that dramatic reductions in the transient pressures can be achieved by replacing a slow-closing swing check valve with a fast-acting check valve. For example, in a system containing parallel pumps in which the transient was generated by stopping one of the pumps, the peak transient pressure was reduced from 745 to 76 kPa when the swing check was replaced with a nozzle check valve.

The closing speed of a valve is determined by the mass of the disk, the forces closing the disk, and the travel distance from fully open to fully closed. Fast-closing valves have the following properties: the disk (including all moving parts) is lightweight, closure is assisted by springs, and the full stroke of the disk is short. Swing check valves are the slowest closing valves because they violate all three of these criteria: they have heavy disks, no springs, and long disk travel. The nozzle check valve is one of the fastest closing valves because the closing element is light, spring loaded, and has a short stroke. The silent, duo, double door, and lift check valves with springs are similar to nozzle valves in their closing times, mainly because of the closing force of the spring.

Air Valves

There are three types of automatic air valves:

- *Air/vacuum valves* are designed for releasing large quantities of air while the pipe is being filled and for admitting air when the pipe is being drained. Air/vacuum valves typically contain a float, which rises and closes the orifice as the valve body fills with water. Once the line is pressurized, the float cannot reopen to remove air that may subsequently accumulate. If the pressure becomes negative during a transient or while draining, the float drops and admits air into the line. At least

one of the air/vacuum valves should be sized for maximum flow from a full pipe break. It must be large enough for its air flow rate under vacuum conditions to equal the maximum drainage rate of the water from a pipe break and at an internal pipe pressure above the pipe collapse pressure. When sized for vacuum service, the air/vacuum valves will actually be oversized for filling the pipe. However, this does not cause any problems because the filling rate must be controlled by the water inflow rate and not by the discharge capacity of the air/vacuum valves.
- *Air release valves* contain a small orifice and are designed to release small quantities of pressurized air not released by the air/vacuum valves and small quantities of air that accumulate after initial filling and pressurization. The small orifice is controlled by a plunger activated by a float at the end of a lever arm. As air accumulates in the valve body, the float drops and opens the orifice. As the air is expelled, the float rises and closes off the orifice.
- *Combination valves* are made up of two valves, a large valve that functions as an air/vacuum valve and a small one that functions as an air release valve. The installation can consist of an air/vacuum valve and an air release valve plumbed in parallel, or the two can be housed in a single valve body. Most air valve installations require combination valves. Guidelines for sizing air valves are available from valve manufacturers and AWWA (2001, M51).

The use of large manual air release valves should be avoided because they can cause severe transients. If the pipeline is filled with the manual air valves closed, the trapped air will be pressurized to full system pressure. When the manual air valve is manually opened, the pressurized air escapes at sonic velocity, causing rapid acceleration of the liquid toward the air valve. When the last of the air is released and the water hits the air valve, the velocity of the water is suddenly reduced and high transient pressures can be generated. If manual air valves are installed, they should be small so that the air release rate is properly controlled.

Air valves should be placed at prominent high points or at intervals if there are few or no high points. The pipe profile needs to be studied relative to possible pipe ruptures so that the largest air/vacuum valves can be located at the high points where they can protect against pipe collapse. At other high points, smaller air/vacuum valves can be installed.

Velocity of the flow during filling is important. A safe way to fill a pipe is to limit the fill rate to an average flow velocity of about 0.3 m/sec (1 ft/sec) until the air/vacuum valves close. Once they are closed, the fill rate can be increased to about 1 m/sec (3 ft/sec), keeping the system pressure as low as possible. This will move the remaining air to the air release valve. When possible, the system should not be pressurized until all of the air has been removed. Trapped air at high pressure can generate severe transients if the air is allowed to pass through a control valve or manual air release valve.

Relief Valves

Pressure relief valves (PRVs) are installed to limit maximum system pressures. They can automatically open when the system pressure exceeds a set pressure or they can be programmed to open in anticipation of a transient or surge. The two general types of relief valves are: nonpilot activated and pilot activated. The selection of which type is appropriate depends on the size of valve required and if the opening and/or closing rate needs to be controlled.

The characteristics of nonpilot-activated valves are:

- They are only available in small sizes.
- The valve is held closed with a spring.
- The valve opens when line pressure exceeds the spring setting.
- They are fast acting but the speed of opening and closing is not controlled.
- They automatically close when the pressure drops below the spring setting.
- Only small changes can be made in the pressure setting by adjusting the compression of the spring.

Pilot-activated relief valves are opened and closed by system pressure and a restoring spring. The characteristics of pilot-activated valves are:

- The main valve is generally a globe-style valve that is controlled by a small pilot valve.
- There is no size limitation.
- The valves are held closed by a spring and fluid pressure.
- The pilot valve is a miniature PRV and opens the main PRV by bleeding fluid from the hydraulic pressure chamber of the main valve.
- Opening and closing speeds are controlled by throttling valves in the pilot system.
- The range of pressures can be adjusted by changing the pilot PRV.
- They are generally slow acting, so they do not protect against rapid pressure transients.
- They can be programmed to be "surge anticipators."

The pressure setting of the PRV can be adjusted over a small range by changing the compression of the spring in the pilot valve. However, it is important that the spring not be overcompressed. It is possible to compress the pilot spring completely if the adjusting rod is screwed in all the way. If this is done, the pilot PRV will remain closed and the main PRV cannot open. It was this type of improper adjustment that caused the failure of a major pipeline. Large pressure range changes require changing the spring and piston size of the pilot valve.

For added safety, multiple PRVs should be installed. Typical options include two identical valves, each with 100% capacity, or three valves, each with 50% capacity. PRVs need to be serviced periodically to ensure that they are functional. Foreign matter in the liquid can plug the pilot valves and render them inoperable.

Centrifugal Pump Selection and Performance

Optimizing the life of a piping system requires proper selection, operation, and maintenance of the pumps. During the selection process, the designer must be concerned about matching the pump performance to the system requirements and anticipate problems that will be encountered when the pumps are started or stopped and when the pipe is filled and drained. The design should also consider the effect of variations in present and future flow demands. Selection of the pumps should not be based on the least initial cost but rather on the least total cost, considering pump performance and reliability. This subsection deals with pump selection and selected operational problems.

Single Pump Selection

Selecting a pump for a particular service requires matching the system requirements to the capabilities of the pump. The process consists of developing a system equation by applying the energy equation to evaluate the pumping head required to overcome the elevation difference between reservoirs friction, and minor losses. For a pump supplying water between two reservoirs or tanks, the pump head required to produce a given discharge can be expressed as

$$H_p = \Delta Z + H_l \text{ or } H_p = \Delta Z + CQ^2 \tag{3.4.16}$$

in which Q is flow rate, ΔZ is the downstream reservoir elevation minus the upstream reservoir elevation, and the constant C is defined by Equation (3.4.12).

The total dynamic head of a pump is defined by:

$$H_p = \frac{(V_2^2 - V_1^2)}{2g} + \frac{(P_2 - P_1)}{\gamma} + Z_2 - Z_1 + H_l \tag{3.4.17}$$

Figure 3.4.2 shows a system curve for a pipe having an elevation lift of 82 ft (25 m) and moderate friction losses. When the elevations of the upstream and/or downstream reservoirs are variable, a family of system curves can be developed using different values of ΔZ.

The three pump curves shown in Figure 3.4.2 represent different impeller diameters. The intersections of the system curve with the pump curves identify the flow rate that each impeller would supply if

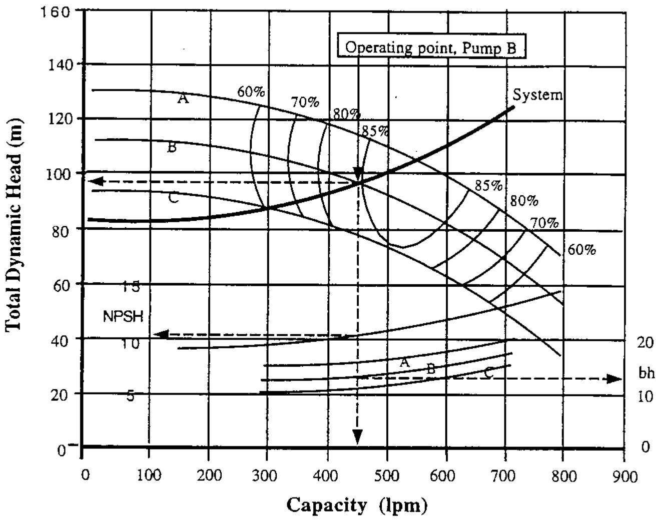

FIGURE 3.4.2 Pump selection for a single pump.

installed in that system. For this system, A and B impellers would be a good choice because they operate at or near their best efficiency range. Figure 3.4.2 shows the head and flow produced by the B pump when operating in that system are 97 ft (30 m) and 450 gpm (28.4 l/s), respectively. The net positive suction head (NPSH) and brake horsepower (bhp) are obtained as shown in the figure.

Multiple Pump Selection

The selection process is more complex when the system demand varies due to variations in reservoir elevation or to changing flow requirements. If the system must operate over a range of reservoir elevations, the pump should be selected so that the system curve, based on the mean water level (or that most frequently encountered), intersects the pump curve to the right of the midpoint of the best efficiency range. If the water level variation is not too great, the pump may not be able to operate efficiently over the complete flow range.

If the flow range is large, multiple pumps or variable-speed drives may be needed. Selection of multiple pumps and the decision about installing them in parallel or in series depend on the amount of friction in the system. Parallel installations are most effective for low-friction systems. Series pumps work best in high-friction systems.

For parallel constant speed pump operation, the combined two-pump curve is constructed by adding the flow of each pump. Such a curve is shown in Figure 3.4.3 (labeled 2 pumps). The intersection of the two-pump curve with the system curve identifies the head and combined flow for the two pumps. The pump efficiency for each pump is determined by projecting horizontally to the left to intersect the single-pump curve. For this example, a C pump, when operating by itself, will have an efficiency of 83%. With two C pumps operating, the efficiency of each will be about 72%. For the pumps to operate most efficiently for a one- or two-pump operation, the pump curve should intersect the system curve to the right of its best efficiency point.

Variable-Speed Pumps

Recent improvements in reliability and reductions in cost have made variable-speed pumps a viable option for installations in which a wide range of flow is required. Several variable speed technologies are available. One that is increasing in popularity, especially in the water and wastewater industries, is the variable-frequency drive (VFD). These are electronic controllers that adjust the speed of the electric pump motor by modulating the power delivered. VFD units can be retrofitted to existing pumps, as well as being supplied with new units.

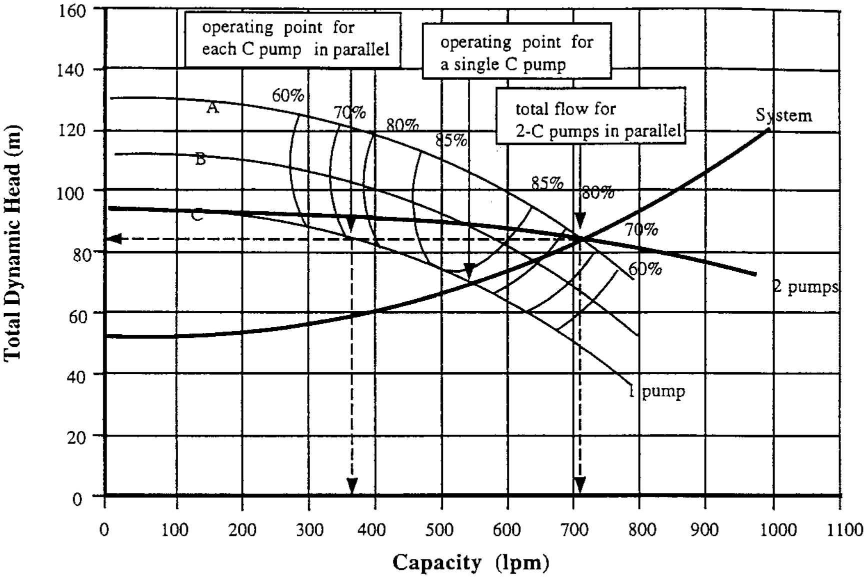

FIGURE 3.4.3 Selection of parallel pumps.

For a specific centrifugal pump, head/capacity curves for different motor speeds and/or different diameter impellers (shaved impellers) for noncavitating conditions can be estimated using the following affinity laws (Karassik et al., 1976). (Note: *D* represents impeller diameter, not pump diameter.)

$$Q_2 = Q_1 \left(\frac{N_2}{N_1} \right) \left(\frac{D_2}{D_1} \right) \tag{3.4.18}$$

$$H_2 = H_1 \left(\frac{N_2}{N_1} \right)^2 \left(\frac{D_2}{D_1} \right)^2 \tag{3.4.19}$$

$$P_2 = P_1 \left(\frac{N_2}{N_1} \right)^3 \left(\frac{D_2}{D_1} \right)^3 \tag{3.4.20}$$

To approximate pump curves for a family of geometrically similar pumps for noncavitating conditions, the following set of affinity equations can be used:

$$Q_2 = Q_1 \left(\frac{N_2}{N_1} \right) \left(\frac{D_2}{D_1} \right)^3 \tag{3.4.21}$$

$$H_2 = H_1 \left(\frac{N_2}{N_1} \right)^2 \left(\frac{D_2}{D_1} \right)^2 \tag{3.4.22}$$

$$P_2 = P_1 \left(\frac{N_2}{N_1} \right)^3 \left(\frac{D_2}{D_1} \right)^5 \tag{3.4.23}$$

The D ratios in Equation (3.4.21) through Equation (3.4.23) can be the pump or the impeller diameter. This is because the equations are only valid for geometrically similar pumps where the ratio of pump diameter to impeller diameter is constant. Either set of equations can be used to compute changes due to motor speed variations.

Figure 3.4.4 and Figure 3.4.5 show pump curves for different motor speeds and different systems for a pump with a constant impeller diameter but operating at different motor speeds. The curves for the different speeds are generated by scaling Q and H values from the 1770-rpm curve and using Equation (3.4.18) and Equation (3.4.19) or Equation (3.4.20) and Equation (3.4.22) to obtain the adjusted values of Q and H.

The variable-speed drive can operate at any speed from almost zero to full motor speed (and even higher). Assume that a 10:1 flow range is desired. The speed range required by the pump to provide a given flow range is controlled by the system. Figure 3.4.4 shows a system with a significant elevation change and relatively low friction. The pump can provide a 10:1 flow range at motor speeds between 1770 and 1310 rpm. For the high-friction system with a small elevation change shown in Figure 3.4.5, the speed variation will be between 1770 and 800 rpm for a flow range of 10:1.

Variable-speed drives offer several advantages. Single-speed drives start the motor abruptly, subjecting the rotating element to high torque and electrical current surges several times the full load current. For a constant speed deep well pump, rapid start of the motor can also cause transient and vibration problems related to compression and release of air trapped in the pump column between the water level and check valve. In contrast, variable-speed drives provide a "soft" start, gradually ramping up the motor to operating speed. This allows the air to be released slowly and reduces electrical and mechanical stress on the rotating elements, reduces maintenance, and extends motor and pump life. Because the speed can be controlled to a fraction of a percent variation, variable-speed units provide fine control of the system operating conditions.

One of the primary justifications for using a variable speed drive is cost savings resulting from reduced power demands and reduced maintenance of the motor, pump, and discharge control valves. For constant-speed pumps, reduced flow is achieved by throttling the discharge valve. This can be compared to operating an automobile at full throttle and trying to control speed by braking. The pressure drop across the valve required to reduce the flow results in wasted energy and creates the possibility of cavitation. Cavitation problems are more problematic for high-friction systems with small elevation changes due to the lack of back pressure at small flows and high-pressure differentials across the valve. Figure 3.4.4 and Figure 3.4.5 demonstrate the difference in cavitation potential and energy wasted by the throttled discharge control valve in two systems.

In the figures, the lines labeled "throttled" represent conditions in which the discharge control valve is throttled to provide a flow of 400 gpm (25.2 l/s) with the motor at full speed. The pump and system curves show that the head upstream from the valve will be 194 ft (59 m) and the back pressure provided by the system to the downstream side of the valve will be 108 ft (33 m). The head loss across the valve is therefore 194 – 108 = 86 ft (26.2 m). Using Equation (3.4.14) with $P_V = 32$ ft (9.8 m) gives $\sigma = 1.63$.

For the system shown in Figure 3.4.5, the head upstream from the valve is again 194 ft (59 m) and the back pressure provided by the system is 47 ft (14.3 m), so the head loss across the valve is 147 ft (44.8 m) and $\sigma = 0.54$. Because σ for the valve installed in the high-friction system (Figure 3.4.5) is one-third as much as the σ for the valve in the low-friction system, the valve in the high-head system will experience considerably more cavitation.

For the high-friction system (Figure 3.4.5), a variable speed pump provides more power savings than the system with low friction. In the former, the variable-speed pump would operate at a head of 47 ft (14.3 m) (compared to 194 ft (59.1 m) for a constant-speed pump), so the power consumption at a flow rate of 400 gpm (25.2 l/s) would be only 24% of the power consumption of a constant-speed pump.

Pump Operation

Starting a constant-speed pump with the pipeline empty can result in filling at a rapid rate because there is little frictional resistance initially to build back pressure. As a result, the pump will operate at a flow

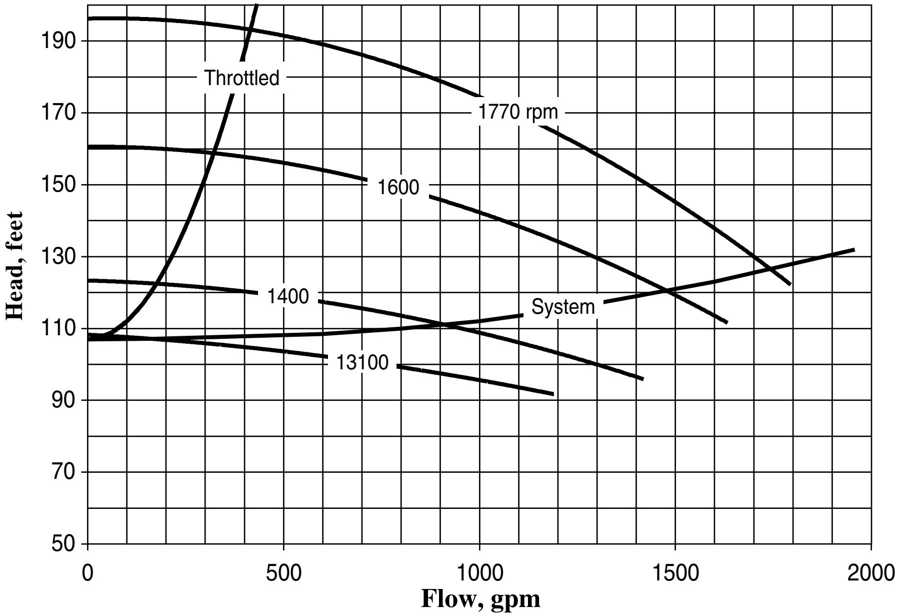

FIGURE 3.4.4 Variable-speed pump operating in a low-friction system.

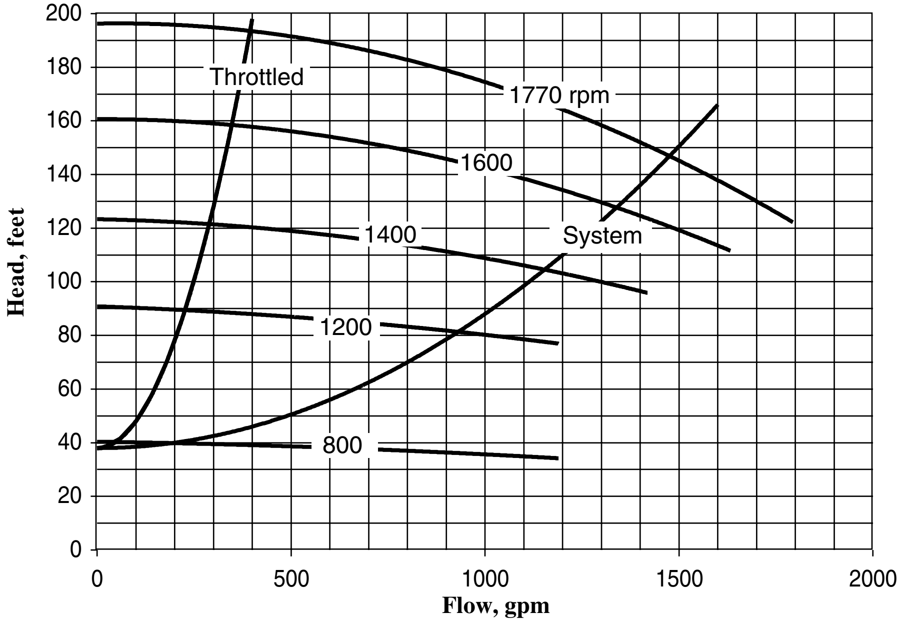

FIGURE 3.4.5 Variable-speed pump operating in a high-friction system.

greater than its design flow. This may cause the pump to cavitate, but the more serious problem is the possibility of high pressures generated by the rapid filling of the pipe. Provisions should be made to control the rate of filling. This can be done by starting the pump against a partially open discharge control valve and bypassing some of the flow around the pump, which allows the system to be filled slowly and safely. If the pipe remains full after a pump is shut down and no air is trapped in the pipe, subsequent start-up of the pumps generally does not create serious transient problems. If the pump has a VFD drive, the pipeline can be filled slowly without throttling the discharge valve and using a bypass.

For some systems, uncontrolled shutdown of the pumps due to power failures can generate high transient pressures. The problem is more severe for pipelines that have a large elevation change and multiple high points. The magnitude of the transient is related to the pipe length, the magnitude of the elevation change, the pump characteristics, and the type of check valve used. Computer simulations are needed to develop solutions to this transient problem.

Numerous mechanical devices and techniques have been used to suppress pump shut-down transients. These include increasing the rotational inertia of the pump, using surge tanks or air chambers near the pump, pressure relief valves, vacuum-breaking valves, and surge-anticipating valves. Selection of the proper transient control device will improve reliability, extend the economic life of the system, and reduce maintenance.

Pump Cavitation

The cavitation potential of a pump is quantified by a term referred to as the net positive suction head (NPSH). The available NPSH (NPSHa) is the total head at the pump suction relative to the liquid vapor pressure. For a wet-pit pump installation, NPSHa can be calculated by:

$$\text{NPSHa} = H_b - H_v + Z_s - H_l \tag{3.4.24}$$

in which, H_b is the barometric pressure at the pump installation; H_v is the absolute vapor pressure head of the liquid; Z_s is the elevation of the water level in the wet well; and H_l is the friction loss in the suction piping. Note that Z_s is negative if the liquid level in the wet well is below the elevation of the pump.

For dry-pit pumps, NPSHa can be calculated by:

$$\text{NPSHa} = H_b + H_v + \frac{P_s}{} + \frac{V_s^2}{2g} \tag{3.4.25}$$

The NPSH required by the pump (NPSHr), as defined by ANSI/HI (1998), corresponds to the flow condition in which the pump efficiency is reduced by 3% due to heavy cavitation. NPSHr is evaluated experimentally by maintaining a constant flow and reducing the pressure in the suction pipe (or lowering the level in the wet well) until the pump's efficiency is reduced by 3%. NPSHr varies with flow rate; for some pumps, NPSHr increases with flow rate and, for others, it decreases with flow rate. The intensity of cavitation generally increases when the pump is operated significantly above or below the best efficiency point even if the NPSHr reduces.

It is important to understand the intensity of the cavitation when a pump is operating at or near NPSHr. It is common practice to assume that if NPSHa > NPSHr, no cavitation will occur. This is not true. In order for the pump's efficiency to reduce by 3%, the cavitation must be heavy enough that part of the impeller is engulfed in a large vapor cavity.

Research has shown that, for some pumps, cavitation begins when the NPSH is several times higher than NPSHr (Grist, 1974). When cavitation first begins, it is manifest by individual cavitation events that create a light crackling sound. The noise is not objectionable and the cavitation does not cause vibrations or damage to the pump. As NPSH is reduced, the noise and vibrations increase. At some point, the cavitation is heavy enough that it causes erosion damage to the impeller and pump casing. Once the cavitation is in the damaging region, it often sounds like gravel passing through the pump.

As the suction pressure reduces and the system NPSH approaches NPSHr, the cavitation no longer consists of individual events. It has entered the most advanced stage in which so many cavitation events occur that they form into large vapor cavities that envelope part of the impeller. This condition is similar to the choked-flow or super-cavitating condition described in the section on control valves, in which a large vapor cavity extends into the downstream pipe. When choking cavitation occurs in a pump, the efficiency reduces because the pump is no longer pumping just a liquid but is pumping a mixture of liquid and vapor.

Consequently, even if NPSHa > NPSHr, the pump may not be operating cavitation-damage free. Adding a factor of safety of at least 5 to 10 ft (1.5 to 3 m) to the published NPSHr values is recommended to reduce the risk of severe vibrations and cavitation damage. There is a relationship between vibrations and cavitation. First, the forces caused by implosion of the cavitation events induce vibrations. Second, once measurable erosion damage occurs on the impeller, it becomes unbalanced. This further increases the intensity of the vibrations and accelerates bearing wear. The cavitation damage is also progressive. Once material is removed from the leading edge or from the impeller surface, the resulting roughened areas become sources of additional cavitation.

Suction Conditions

Pump installations can be classified as booster, dry pit, or wet pit. Booster pump installations refer to systems in which no wet well is close to the pump and suction conditions are controlled by the suction piping. Dry pit refers to installations in which the liquid is supplied from a wet well or vessel and the pump is connected via a short length of pipe and fittings. Wet pit identifies installations in which the impeller or the entire pump is submerged. Such installations are also commonly referred to as wet wells, pump sumps, or pumping pits.

Pump impellers are designed assuming that the approach flow will be relatively steady, uniform, and one-dimensional. Consequently, for acceptable pump operation, the flow needs to enter the pump free of undesirable flow conditions. Standards have been developed that identify the amount of circulation, degree of flow nonuniformity, unsteadiness of the flow, and strength of vortices acceptable for pump installations (IR, 1985; ANSI/HI, 1998).

Circulation and nonuniform flow distribution can cause the flow to approach the impeller blades at the wrong velocity and/or the wrong angle, thus causing flow separation on the impeller blades. Organized vortices and high levels of turbulence cause the impeller blades to respond much like the wings of an aircraft flying through a storm. These undesirable flow conditions can result in vibrations, cavitation, accelerated wear, and loss of efficiency. Considerable care should be used to provide good suction flow conditions to the pumps.

Hydraulic model studies are routinely performed for large wet-well pump installations to develop modifications to improve the flow approaching the pump (Sweeney and Rockwell, 1982; Tullis, 1979). These studies have shown that designing pumping pits based only on published guidelines does not guarantee acceptable suction conditions. Modifications to the pumping pits are usually required to provide acceptable flow conditions, even if the sump meets the ANSI/HI guidelines.

On the other hand, field experience has shown that some pumps with suction conditions that do not meet the ANSI/HI standards still operate without problems. This seems to be a function of the quality of the pump. For example, the authors are aware of one installation in which two variable-speed dry-pit pumps (built by different manufacturers) were installed side by side and connected to the same wet well with similar piping. The larger of the two pumps had higher suction velocities but operated normally. The smaller pump experienced severe cavitation and vibrations at all motor speeds. The difference in performance was attributed to differences in the quality of the two pumps.

Other Considerations

External Loads

In some situations, the external load is the controlling factor determining whether the pipe will collapse. The magnitude of the external load and the resistance of the pipe to collapse depend on numerous factors, including:

- Pipe diameter
- Pipe material
- Pipe deformation (deviation from circular cross section)
- Trench width
- Depth of cover
- Specific weight of the soil
- Degree of soil saturation

- Type of backfill material
- Method used to backfill
- Degree of compaction
- Live loads

The cumulative effect of all these sources of external loading requires considerable study and analysis, beyond the scope of this chapter. Because no simple guidelines for evaluating external pipe loads are available, the reader is referred to Watkins and Anderson (2000) and Spangler and Handy (1973) for details on how to perform calculations of earth loading.

Limiting Velocities

There are concerns about maximum and minimum velocity limits. If the velocity is too low, problems may develop due to settling of suspended solids and air being trapped at high points and along the crown of the pipe. The safe lower velocity limit to avoid collecting air and sediment depends on the amount and type of sediment and on the pipe diameter and pipe profile. Generally, velocities greater than about 1 m/sec (3 ft/sec) are sufficient to move trapped air to air release valves and keep the sediment in suspension.

Problems associated with high velocities are:

- Erosion of the pipe wall or liner (especially if coarse, abrasive suspended sediment is present)
- Cavitation at control valves and other restrictions
- Increased pumping costs
- Removal of air at air release valves
- Increased operator size requirements and concern about valve shaft failures due to excessive flow torques
- Increased risk of hydraulic transients

Each of these should be considered before making the final pipe diameter selection. A typical upper velocity for many applications is 20 ft/sec (6 m/sec). However, with proper pipe design and analysis, higher velocities can be tolerated.

Nomenclature

$\dot{m}$	Mass flow rate
ρ	Density
γ	Specific weight
μ	Dynamic viscosity
υ	Kinematic viscosity
ΔH	Transient head rise
ΔV	Velocity change
A	Area
a	Wave speed
A_m	Area at inlet to pipe fitting for minor losses
A_p	Area of pipe
C	Total system loss coefficient, (Equation 3.4.12)
C_c	Contraction coefficient
D	Diameter
e	Pipe roughness
F	Momentum force
f	Friction factor
g	Acceleration of gravity
H	Pressure head
H_b	Barometric pressure head

H_f	Total head loss, friction and local
h_f	Friction loss
h_l	Minor loss
H_p	Pump head
H_t	Turbine head
H_v	Absolute vapor pressure head of liquid
k	Relative roughness, e/D
K_l	Minor loss coefficient
L	Pipe length
L_{equ}	Equivalent length for minor loss
N	Motor speed
NPSHa	Available net positive suction head
NPSHr	Required net positive suction head
P	Pressure
P_b	Barometric pressure
P_d	Pressure downstream from valve
P_u	Pressure upstream from valve
P_v	Absolute vapor pressure
Q	Flow rate
R	Hydraulic radius, ratio of the flow area to the wetted perimeter
r	Radius
Re	Reynolds number
V	Velocity
Z	Elevation
Z_s	Elevation of liquid level in pump suction well (negative when below pump)
ΔZ	Elevation change
σ	Cavitation index

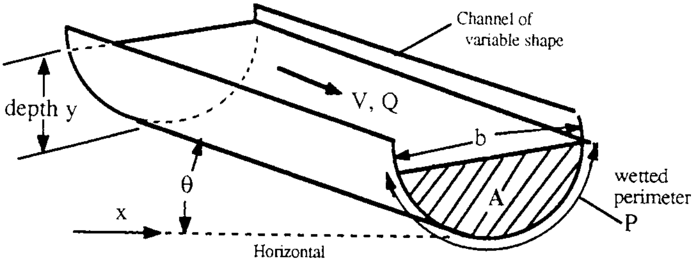

FIGURE 3.5.1 Definition sketch for an open channel.

3.5 Open Channel Flow

Frank M. White

Definition

The term *open channel flow* denotes the gravity-driven flow of a liquid with a free surface. Technically, we may study any flowing liquid and any gas interface. In practice, the vast majority of open channel flows concern water flowing beneath atmospheric air in artificial or natural channels.

The geometry of an arbitrary channel is shown in Figure 3.5.1. The area A is for the water cross section only, and b is its top width. The wetted perimeter P covers only the bottom and sides, as shown, not the surface (whose air resistance is neglected). The water depth at any location is y, and the channel slope is θ, often denoted as $S_o = \sin\theta$. All of these parameters may vary with distance x along the channel. In unsteady flow (not discussed here) they may also vary with time.

Uniform Flow

A simple reference condition, called *uniform flow,* occurs in a long straight prismatic channel of constant slope S_o. There is no acceleration, and the water flows at constant depth with fluid weight exactly balancing the wetted wall shear force: $\rho gLA \sin\theta = \tau_w PL$, where L is the channel length. Thus, $\tau_w = \rho g R_h S_o$, where $R_h = A/P$ is called the *hydraulic radius* of the channel. If we relate wall shear stress to the Darcy friction factor f, $\tau_w = (f/8)\rho V^2$, we obtain the basic uniform flow open channel relation:

$$\text{Uniform flow:}\quad V = \sqrt{\frac{8g}{f}}\sqrt{R_h S_o}\,,\quad \text{where}\quad \sqrt{\frac{8g}{f}} = C = \text{Chézy coefficient} \tag{3.5.1}$$

Antoine Chézy first derived this formula in 1769. It is satisfactory to base f upon the pipe-flow Moody diagram (Figure 3.4.1) using the hydraulic diameter, $D_h = 4R_h$, as a length scale. That is, $f = fcn\ (VD_h/\nu, \varepsilon/D_h)$ from the Moody chart. In ordinary practice, however, engineers assume fully rough, high-Reynolds-number flow and use Robert Manning's century-old correlation:

$$C \approx \frac{\zeta}{n} R_h^{1/6},\quad \text{or}\quad V_{\text{uniform}} \approx \frac{\zeta}{n} R_h^{2/3} S_o^{1/2}\quad \text{and}\quad Q = VA \tag{3.5.2}$$

where ζ is a conversion factor equal to 1.0 in SI units and 1.486 in English units. The quantity n is Manning's roughness parameter, with typical values, along with the associated roughness heights ε, listed in Table 3.5.1.

TABLE 3.5.1 Average Roughness Parameters for Various Channel Surfaces

Critical Flow

Since the surface is always atmospheric, pressure head is not important in open channel flows. Total energy *E* relates only to velocity and elevation:

$$\text{Specific energy } E = y + \frac{V^2}{2g} = y + \frac{Q^2}{2gA^2}$$

At a given volume flow rate *Q*, the energy passes through a minimum at a condition called *critical flow*, where $dE/dy = 0$, or $dA/dy = b = gA^3/Q^2$:

$$A_{\text{crit}} = \left(\frac{bQ^2}{g}\right)^{1/3} \qquad V_{\text{crit}} = \frac{Q}{A_{\text{crit}}} = \left(\frac{gA_{\text{crit}}}{b}\right)^{1/2} \tag{3.5.3}$$

where *b* is the top-surface width as in Figure 3.5.1. The velocity V_{crit} equals the speed of propagation of a surface wave along the channel. Thus, we may define the Froude number *Fr* of a channel flow, for any cross section, as $Fr = V/V_{\text{crit}}$. The three regimes of channel flow are

Fr < 1: subcritical flow; Fr = 1: critical flow; Fr > 1: supercritical flow

There are many similarities between Froude number in channel flow and Mach number in variable-area duct flow (see Section 3.6).

For a rectangular duct, $A = by$, we obtain the simplified formulas

$$V_{\text{crit}} = \sqrt{gy} \qquad \text{Fr} = \frac{V}{\sqrt{gy}} \tag{3.5.4}$$

independent of the width of the channel.

Example 3.5.1

Water ($\rho = 998$ kg/m^3, $\mu = 0.001$ kg/m · sec) flows uniformly down a half-full brick 1-m-diameter circular channel sloping at 1°. Estimate (a) Q; and (b) the Froude number.

Solution 3.5.1 (a). First compute the geometric properties of a half-full circular channel:

$$A = \frac{\pi}{8}(1\text{ m})^2 = 0.393\text{ m}^2; \quad P = \frac{\pi}{2}(1\text{ m}) = 1.57\text{ m}; \quad R = \frac{A}{P} = \frac{0.393}{1.57} = 0.25\text{ m}$$

From Table 3.5.1, for brickwork, $n \approx 0.015$. Then, Manning's formula, Equation (3.5.2) predicts

$$V = \frac{\zeta}{n}R_h^{1/6}S_o^{1/2} = \frac{1.0}{0.015}(0.25)^{1/6}(\sin 1°)^{1/2} \approx 3.49\frac{\text{m}}{\text{sec}}; \quad Q = 3.49(0.393) \approx \mathbf{1.37}\frac{\mathbf{m^3}}{\mathbf{sec}} \quad \textit{Solution 3.5.1(a)}$$

The uncertainty in this result is about ±10%. The flow rate is quite large (21,800 gal/min) because 1°, although seemingly small, is a substantial slope for a water channel.

One can also use the Moody chart. with $V \approx 3.49$ m/sec, compute $\text{Re} = \rho V D_h/\mu \approx 3.49$ E6 and $\varepsilon/D_h \approx 0.0037$, then compute $f \approx 0.0278$ from the Moody chart. Equation (3.5.1) then predicts

$$V = \sqrt{\frac{8g}{f}R_h S_o} = \sqrt{\frac{8(9.81)}{0.0278}(0.25)(\sin 1°)} \approx 3.51\frac{\text{m}}{\text{sec}}; \quad Q = VA \approx \mathbf{1.38}\frac{\mathbf{m^3}}{\mathbf{sec}}$$

Solution 3.5.1 (b). With Q known from part (a), compute the critical conditions from Equation (3.5.3):

$$A_{\text{crit}} = \left(\frac{bQ^2}{g}\right)^{1/3} = \left[\frac{1.0(1.37)^2}{9.81}\right]^{1/3} = 0.576\text{ m}^2, \quad V_{\text{crit}} = \frac{Q}{A_{\text{crit}}} = \frac{1.37}{0.576} = 2.38\ \frac{\text{m}}{\text{sec}}$$

Hence

$$\text{Fr} = \frac{V}{V_{\text{crit}}} = \frac{3.49}{2.38} \approx \mathbf{1.47}\ \ (\text{supercritical}) \quad \textit{Solution 3.5.1(b)}$$

Again the uncertainty is approximately ±10%, primarily because of the need to estimate the brick roughness.

Hydraulic Jump

In gas dynamics (Section 3.6), a supersonic gas flow may pass through a thin normal shock and exit as a subsonic flow at higher pressure and temperature. By analogy, a supercritical open channel flow may pass through a *hydraulic jump* and exit as a subcritical flow at greater depth, as in Figure 3.5.2. Application of continuity and momentum to a jump in a rectangular channel yields

$$V_2 = V_1\frac{y_1}{y_2} \qquad y_2 = \frac{y_1}{2}\left[-1 + \sqrt{1 + 8\text{Fr}_1^2}\right] \text{ where } \text{Fr}_1 = \frac{V_1}{\sqrt{gy_1}} > 1 \tag{3.5.5}$$

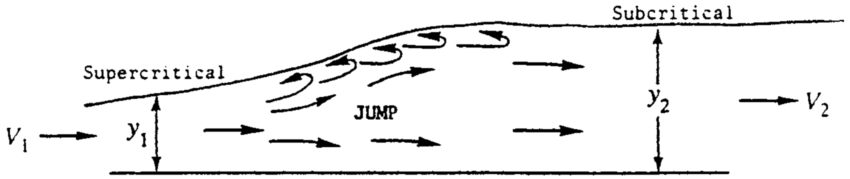

FIGURE 3.5.2 A two-dimensional hydraulic jump.

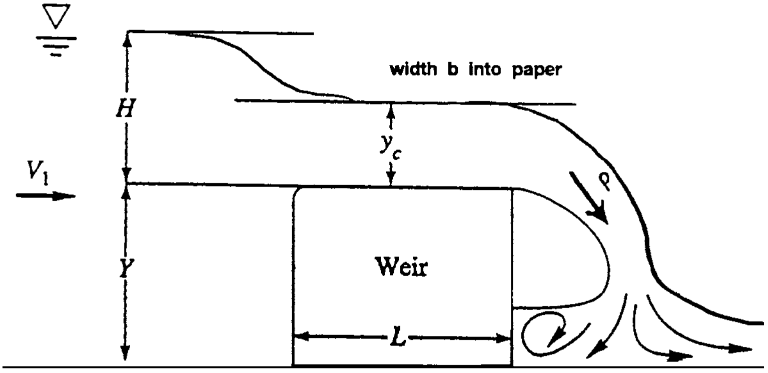

FIGURE 3.5.3 Geometry and notation for flow over a weir.

Both the normal shock and the hydraulic jump are dissipative processes: the entropy increases and the effective energy decreases. For a rectangular jump,

$$\Delta E = E_1 - E_2 = \frac{(y_2 - y_1)^3}{4y_1y_2} > 0 \tag{3.5.6}$$

For strong jumps, this loss in energy can be up to 85% of E_1. The second law of thermodynamics requires $\Delta E > 0$ and $y_2 > y_1$ or, equivalently, $\mathrm{Fr}_1 > 1$,

Note from Figure 3.5.2 that a hydraulic jump is not thin. Its total length is approximately four times the downstream depth. Jumps also occur in nonrectangular channels, and the theory is much more algebraically laborious.

Weirs

If an open channel flow encounters a significant obstruction, it will undergo rapidly varied changes which are difficult to model analytically but can be correlated with experiment. An example is the *weir* in Figure 3.5.3 (colloquially called a *dam*), which forces the flow to deflect over the top. If $L << Y$, the weir is termed *sharp-crested*; if $L = O(Y)$ it is *broad-crested*. Small details, such as the upper front corner radius or the crest roughness, may be significant. The crest is assumed level and of width b into the paper.

If there is a free overfall, as in Figure 3.5.3, the flow accelerates from subcritical upstream to critical over the crest to supercritical in the overfall. There is no flow when the excess upstream depth $H = 0$. A simple Bernoulli-type analysis predicts that the flow rate Q over a wide weir is approximately proportional to $bg^{1/2}H^{3/2}$. An appropriate correlation is thus

$$Q_{\text{weir}} = C_d b g^{1/2} H^{3/2}, \quad \text{where} \quad C_d = \text{dimensionless weir coefficient} \tag{3.5.7}$$

If the upstream flow is turbulent, the weir coefficient depends only upon geometry, and Reynolds number effects are negligible. If the weir has sidewalls and is narrow, replace width b by $(b - 0.1H)$.

Two recommended empirical correlations for Equation (3.5.7) are as follows:

$$\begin{aligned} &\text{Sharp-crested:} \quad C_d \approx 0.564 + 0.0846\frac{H}{Y} \quad \text{for} \quad \frac{L}{Y} < 0.07 \\ &\text{Broad-crested:} \quad C_d \approx 0.462 \quad \text{for} \quad 0.08 < \frac{H}{L} < 0.33 \end{aligned} \tag{3.5.8}$$

These data are for wide weirs with a sharp upper corner in front. Many other weir geometries are discussed in the references for this section. Of particular interest is the sharp-edged vee-notch weir, which has no length scale b. If 2θ is the total included angle of the notch, the recommended correlation is

$$\text{Vee-notch, angle } 2\theta: \quad Q \approx 0.44 \tan\theta\, g^{1/2} H^{5/2} \quad \text{for} \quad 10° < \theta \le 50° \tag{3.5.9}$$

The vee-notch is more sensitive at low flow rates (large H for a small Q) and thus is popular in laboratory measurements of channel flow rates.

A weir in the field will tend to spring free and form a natural *nappe*, or air cavity, as in Figure 3.5.3. Narrow weirs, with sidewalls, may need to be aerated artificially to form a nappe and keep the flow from sliding down the face of the weir. The correlations above assume nappe formation.

Gradually Varied Flow

Return to Figure 3.5.1 and suppose that (y, A, b, P, S_o) are all variable functions of horizontal position x. If these parameters are slowly changing, with no hydraulic jumps, the flow is termed *gradually varied* and satisfies a simple one-dimensional first-order differential equation if Q = constant:

$$\frac{dy}{dx} \approx \frac{S_o - S}{1 - \dfrac{V^2 b}{gA}}, \quad \text{where} \quad V = \frac{Q}{A} \quad \text{and} \quad S = \frac{f}{D_h}\frac{V^2}{2g} = \frac{n^2 V^2}{\zeta^2 R_h^{4/3}} \tag{3.5.10}$$

The conversion factor $\zeta^2 = 1.0$ for SI units and 2.208 for English units. If flow rate, bottom slope, channel geometry, and surface roughness are known, we may solve for $y(x)$ for any given initial condition $y = y_o$ at $x = x_o$. The solution is computed by any common numerical method, e.g., Runge–Kutta.

Recall from Equation (3.5.3) that the term $V^2b/(gA) \equiv \mathrm{Fr}^2$, so the sign of the denominator in Equation (3.5.10) depends upon whether the flow is sub- or supercritical. The mathematical behavior of Equation (3.5.10) differs also. If Fr is near unity, the change dy/dx will be very large, which probably violates the basic assumption of "gradual" variation.

For a given flow rate and local bottom slope, two reference depths are useful and may be computed in advance:

(a) The *normal* depth y_n for which Equation (3.5.2) yields the flow rate:
(b) The *critical* depth y_c for which Equation (3.5.3) yields the flow rate.

Comparison of these two, and their relation to the actual local depth y, specifies the type of solution curve being computed. The five bottom-slope regimes (mild M, critical C, steep S, horizontal H, and adverse A) create 12 different solution curves, as illustrated in Figure 3.5.4. All of these may be readily generated by a computer solution of Equation 3.5.10. The following example illustrates a typical solution to a gradually varied flow problem.

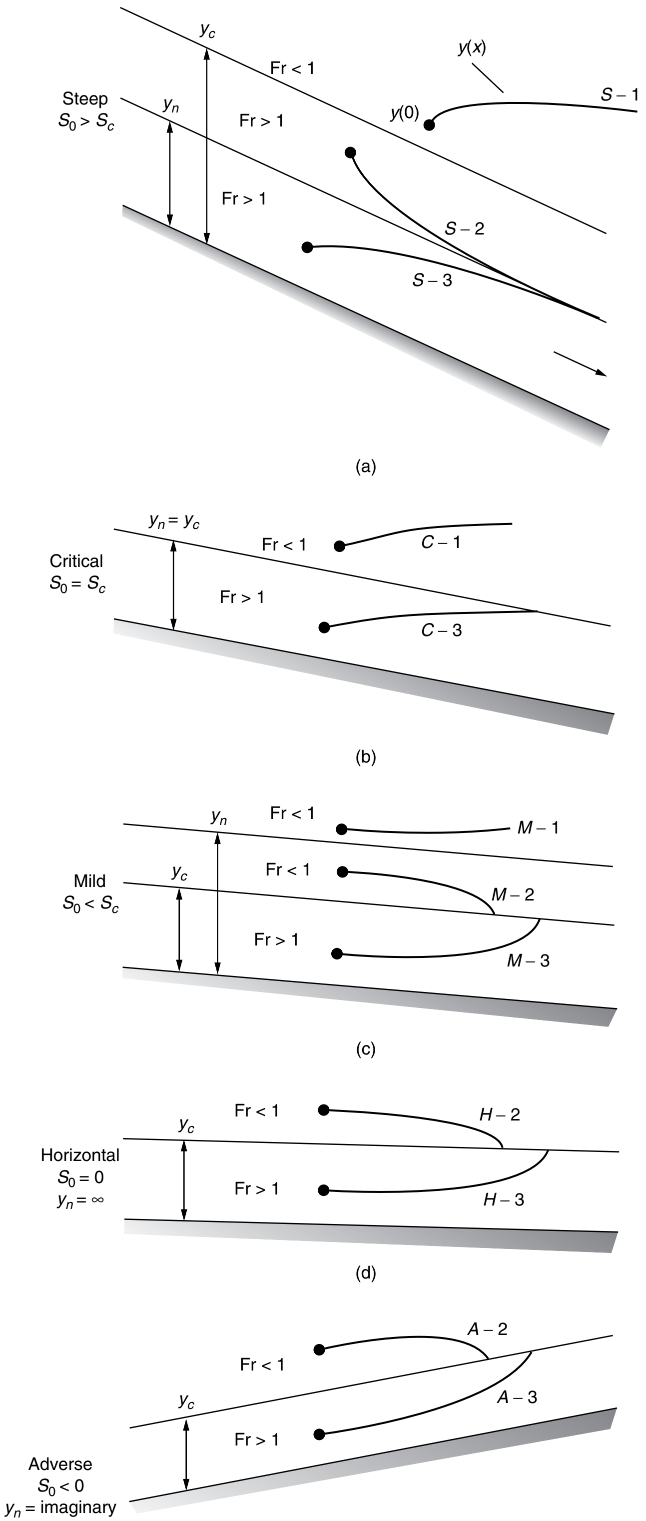

FIGURE 3.5.4 Classification of solution curves for gradually varied flow.

Example 3.5.2

Water, flowing at 2.5 m^3/sec in a rectangular gravelly earth channel 2 m wide, encounters a broad-crested weir 1.5 m high. Using gradually varied theory, estimate the water depth profile back to 1 km upstream of the weir. The bottom slope is 0.1^0.

Solution. We are given Q, $Y = 1.5$ m, and $b = 2$ m. We may calculate excess water level H at the weir (see Figure 3.5.3) from Equation (3.5.7) and Equation (3.5.8):

$$Q = 2.5\frac{\text{m}^3}{\text{sec}} = C_d b_{\text{eff}} g^{1/2} H^{3/2} = 0.462(2.0 - 0.1H)(9.81)^{1/2} H^{3/2}, \quad \text{solve for} \quad H \approx \mathbf{0.94}\ \text{m}$$

Since the weir is not too wide, we have subtracted 0.1 H from b as recommended. The weir serves as a "control structure" which sets the water depth just upstream. This is our initial condition for gradually varied theory: $y(0) = Y + H = 1.5 + 0.94 \approx 2.44$ m at $x = 0$. Before solving Equation (3.5.10), we find the normal and critical depths to get a feel for the problem:

$$\text{Normal depth:} \qquad Q = 2.5\frac{\text{m}^3}{\text{sec}} = \frac{1.0}{0.025}(2.0y_n)\left(\frac{2.0y_n}{2.0 + 2y_n}\right)^{3/2}\sqrt{\sin 0.1°}, \quad \text{solve} \quad y_n \approx \mathbf{1.14}\ \text{m}$$

$$\text{Critical depth:} \qquad A_c = 2.0y_c - \left(\frac{bQ^2}{g}\right)^{1/3} = \left[\frac{2.0(2.5)^2}{9.81}\right]^{1/3}, \quad \text{solve} \quad y_c \approx \mathbf{0.54}\ \text{m}$$

We have taken $n \approx 0.025$ for gravelly earth, from Table 3.5.1. Since $y(0) > y_n > y_c$, we are on a mild slope $M - 1$ "backwater" curve, as in Figure 3.5.4. For our data, Equation (3.5.10) becomes

$$\frac{dy}{dx} \approx \frac{S_o - n^2Q^2/\left(\zeta^2 A^2 R_h^{4/3}\right)}{1 - Q^2 b/\left(gA^3\right)}$$

where $Q = 2.5$, $b = 2$, $\zeta = 1$, $A = 2y$, $S_o = \sin 0.1°$, $R_h = 2y/(2 + 2y)$, $g = 9.81$, $y(0) = 2.44$ at $x = 0$.

Integrate numerically backward, that is, for $\Delta x < 0$, until $x = -1$ km $= -1000$ m. The complete solution curve is shown in Figure 3.5.5. The water depth decreases upstream and is approximately $y \approx 1.31$ m at $x = -1000$ m. If slope and channel width remain constant, the water depth asymptotically approaches the normal depth y_n far upstream.

Nomenclature

English symbols

A = water cross section area
b = channel upper-surface width
C = Chézy coefficient, Equation (3.5.1)
C_d = weir discharge coefficient, Equation (3.5.7)
D_h = hydraulic diameter, $= 4R_h$
E = specific energy, $= y + V^2/2g$
f = Moody friction factor
Fr = Froude number, $= V/V_{\text{crit}}$
g = acceleration of gravity
H = excess water level above weir, Figure 3.5.3
L = weir length, Figure 3.5.3
n = Manning roughness factor, Table 3.5.1
P = wetted perimeter

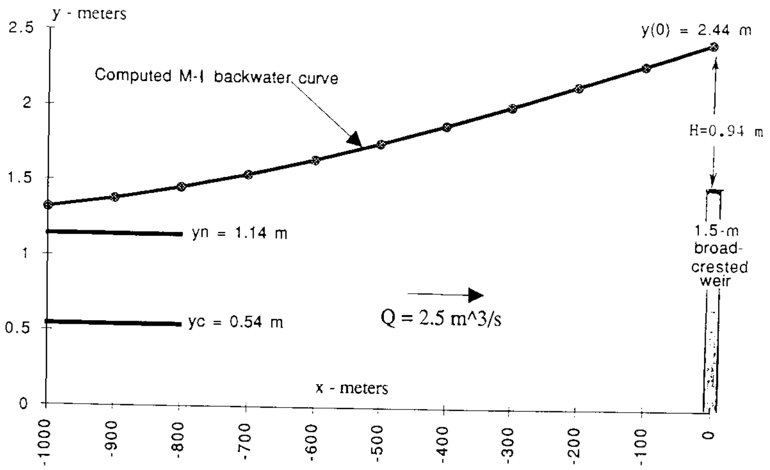

FIGURE 3.5.5 Backwater solution curve for Example 3.5.2.

Q = volume flow rate
R_h = hydraulic radius, = A/P
S = frictional slope, Equation (3.5.10)
S_o = bottom slope
V = average velocity
x = horizontal distance along the channel
y = water depth
Y = weir height, Figure (3.5.3)

Greek Symbols

ε = wall roughness height, Table 3.5.1
ρ = fluid density
μ = fluid viscosity
ν = fluid kinematic viscosity, = μ/ρ
ζ = conversion factor, = 1.0 (SI) and 1.486 (English)

Subscripts

c,crit = critical, at Fr = 1
n = normal, in uniform flow

3.6 External Incompressible Flows

Alan T. McDonald

Introduction and Scope

Potential flow theory (Section 3.2) treats an incompressible *ideal fluid* with zero viscosity. There are no shear stresses; pressure is the only stress acting on a fluid particle. Potential flow theory predicts no drag force when an object moves through a fluid; this is obviously incorrect because all real fluids are viscous and cause drag forces. The objective of this section is to consider the behavior of viscous, incompressible fluids flowing over objects.

A number of phenomena that occur in external flow at high Reynolds number over an object are shown in Figure 3.6.1. The freestream flow divides at the stagnation point and flows around the object. Fluid at the object surface takes on the velocity of the body as a result of the no-slip condition. Boundary layers form on the upper and lower surfaces of the body; flow in the boundary layers is initially laminar, then **transition** to turbulent flow may occur (points "T").

Boundary layers thickening on the surfaces cause only a slight displacement of the streamlines of the external flow (their thickness is greatly exaggerated in the figure). **Separation** may occur in the region of increasing pressure on the rear of the body (points "S"); after separation, boundary layer fluid no longer remains in contact with the surface. Fluid that was in the boundary layers forms the viscous *wake* behind the object.

The Bernoulli equation is valid for steady, incompressible flow without viscous effects. It may be used to predict pressure variations outside the boundary layer. Stagnation pressure is constant in the uniform inviscid flow far from an object, and the Bernoulli equation reduces to

$$p_\infty + \frac{1}{2}\rho V^2 = \text{constant} \tag{3.6.1}$$

where p_∞ is pressure far upstream, ρ is density, and V is velocity. Therefore, the local pressure can be determined if the local freestream velocity, U, is known.

Boundary Layers

The Boundary Layer Concept

The **boundary layer** is the thin region near the surface of a body in which viscous effects are important. By recognizing that viscous effects are concentrated near the surface of an object, Prandtl showed that only the Euler equations for inviscid flow need be solved in the region outside the boundary layer. Inside

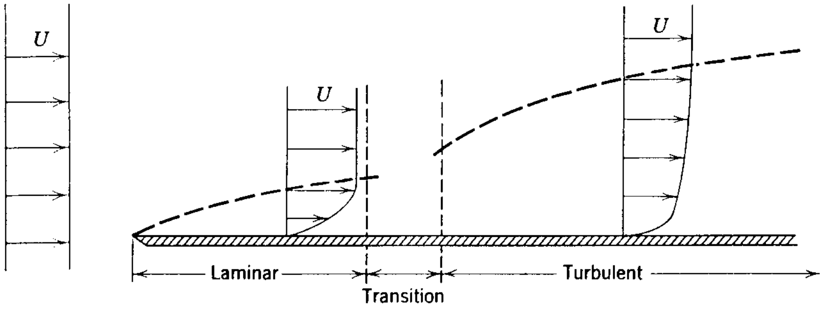

FIGURE 3.6.2 Boundary layer on a flat plate (vertical thickness exaggerated for clarity).

the boundary layer, the elliptic Navier–Stokes equations are simplified to boundary layer equations with parabolic form that are easier to solve. The thin boundary layer has negligible pressure variation across it; pressure from the freestream is impressed upon the boundary layer.

Basic characteristics of all laminar and turbulent boundary layers are shown in the developing flow over a flat plate in a semi-infinite fluid. Because the boundary layer is thin, disturbance of the inviscid flow outside the boundary layer is negligible, and the **pressure gradient** along the surface is close to zero. Transition from laminar to turbulent boundary layer flow on a flat plate occurs when Reynolds number based on x exceeds $\mathrm{Re}_x = 500{,}000$. Transition may occur earlier if the surface is rough, pressure increases in the flow direction, or separation occurs. Following transition, the turbulent boundary layer thickens more rapidly than the laminar boundary layer as a result of increased shear stress at the body surface.

Boundary Layer Thickness Definitions

Boundary layer disturbance thickness, δ, is usually defined as the distance, y, from the surface to the point where the velocity within the boundary layer, u, is within 1% of the local freestream velocity, U. As shown in Figure 3.6.2, the boundary layer velocity profile merges smoothly and asymptotically into the freestream, making δ difficult to measure. For this reason and for their physical significance, two integral measures of boundary layer thickness are defined. Displacement thickness, δ^*, is defined as

$$\frac{\delta^*}{\delta} = \int_0^\infty \left(1 - \frac{u}{U}\right) d\left(\frac{y}{\delta}\right) \tag{3.6.2}$$

Physically, δ^*, is the distance the solid boundary would need to be displaced into the freestream in a frictionless flow to produce the mass flow deficit caused by the viscous boundary layer. Momentum thickness, θ, is defined as

$$\frac{\theta}{\delta} = \int_0^\infty \frac{u}{U}\left(1 - \frac{u}{U}\right) d\left(\frac{y}{\delta}\right) \tag{3.6.3}$$

Physically, θ is the thickness of a fluid layer with velocity U, for which the momentum flux is the same as the deficit in momentum flux within the boundary layer (momentum flux is momentum per unit time passing a cross section).

Because δ^* and θ are defined in terms of integrals for which the integrand vanishes in the freestream, they are easier to evaluate experimentally than disturbance thickness δ.

Exact Solution of the Laminar Flat-Plate Boundary Layer

Blasius obtained an exact solution for laminar boundary layer flow on a flat plate. He assumed a thin boundary layer to simplify the streamwise momentum equation. He also assumed *similar* velocity profiles in the boundary layer so that, when written as $u/U = f(y/\delta)$, velocity profiles do not vary with x. He used a similarity variable to reduce the partial differential equations of motion and continuity to a single third-order ordinary differential equation.

Blasius used numerical methods to solve the ordinary differential equation. Unfortunately, the velocity profile must be expressed in tabular form. The principal results of the Blasius solution may be expressed as

$$\frac{\delta}{x} = \frac{5}{\sqrt{\mathrm{Re}_x}} \tag{3.6.4}$$

and

$$C_f = \frac{\tau_w}{\frac{1}{2}\rho U^2} = \frac{0.664}{\sqrt{\mathrm{Re}_x}} \tag{3.6.5}$$

These results characterize the laminar boundary layer on a flat plate; they show that laminar boundary layer thickness varies as $x^{1/2}$ and wall shear stress varies as $1/x^{1/2}$.

Approximate Solutions

The Blasius solution cannot be expressed in closed form and is limited to laminar flow. Therefore, approximate methods that give solutions for laminar and turbulent flow in closed form are desirable. One such method is the *momentum integral equation* (MIE), which may be developed by integrating the boundary layer equation across the boundary layer or by applying the streamwise momentum equation to a differential control volume (Fox et al., 2004). The result is the ordinary differential equation

$$\frac{d\theta}{dx} = \frac{\tau_w}{\rho U^2} - \left(\frac{\delta^*}{\theta} + 2\right)\frac{\theta}{U}\frac{dU}{dx} \tag{3.6.6}$$

The first term on the right side of Equation (3.6.6) contains the influence of wall shear stress. Because τ_w is always positive, it always causes θ to increase. The second term on the right side contains the pressure gradient, which can have either sign. Therefore, the effect of the pressure gradient can be to increase or to decrease the rate of growth of boundary layer thickness.

Equation (3.6.6) is an ordinary differential equation that can be solved for θ as a function of x on a flat plate (zero pressure gradient), provided a reasonable shape is assumed for the boundary layer velocity profile and shear stress is expressed in terms of the other variables. Results for laminar and turbulent flat-plate boundary layer flows are discussed next.

Laminar Boundary Layers — A reasonable approximation to the laminar boundary layer velocity profile is to express u as a polynomial in y. The resulting solutions for δ and τ_w have the same dependence on x as the exact Blasius solution. Numerical results are presented in Table 3.6.1. Comparing the approximate and exact solutions shows remarkable agreement in view of the approximations used in the analysis. The trends are predicted correctly and the approximate values are within 10% of the exact values.

Turbulent Boundary Layers — The turbulent velocity profile may be expressed well using a power law, $u/U = (y/\delta)^{1/n}$, where n is an integer between 6 and 10 (frequently 7 is chosen). For turbulent flow, it is not possible to express shear stress directly in terms of a simple velocity profile; an empirical correlation is required. Using a pipe flow data correlation gives

$$\frac{\delta}{x} = \frac{0.382}{\mathrm{Re}_x^{1/5}} \tag{3.6.7}$$

Note: BL = boundary layer.

and

$$C_f = \frac{\tau_w}{\frac{1}{2}\rho U^2} = \frac{0.0594}{\mathrm{Re}_x^{1/5}} \tag{3.6.8}$$

These results characterize the turbulent boundary layer on a flat plate. They show that turbulent boundary layer thickness varies as $x^{4/5}$ and wall shear stress varies as $1/x^{1/5}$.

Approximate results for laminar and turbulent boundary layers are compared in Table 3.6.2. At a Reynolds number of 1 million, wall shear stress for the turbulent boundary layer is nearly six times as large as for the laminar layer. For a turbulent boundary layer, thickness increases five times faster with distance along the surface than for a laminar layer. These approximate results give a physical feel for relative magnitudes in the two cases.

The MIE cannot be solved in closed form for flows with nonzero pressure gradients. However, the role of the pressure gradient can be understood qualitatively by studying the MIE.

Effect of Pressure Gradient

Boundary layer flow with favorable, zero, and adverse pressure gradients is depicted schematically in Figure 3.6.3. (Assume a thin boundary layer, so that flow on the lower surface behaves as external flow on a surface, with the pressure gradient impressed on the boundary layer.) The pressure gradient is favorable when $\partial p/\partial x < 0$; zero when $\partial p/\partial x = 0$; and adverse when $\partial p/\partial x > 0$, as indicated for regions 1, 2, and 3.

Viscous shear always causes a net retarding force on any fluid particle within the boundary layer. For zero pressure gradient, shear forces alone can never bring the particle to rest. (Recall that for laminar and turbulent boundary layers, the shear stress varied as $1/x^{1/2}$ and $1/x^{1/5}$, respectively; shear stress never becomes zero for finite x.) Because shear stress is given by $\tau_w = \mu\, \partial u/\partial y)_{y=0}$, the velocity gradient cannot

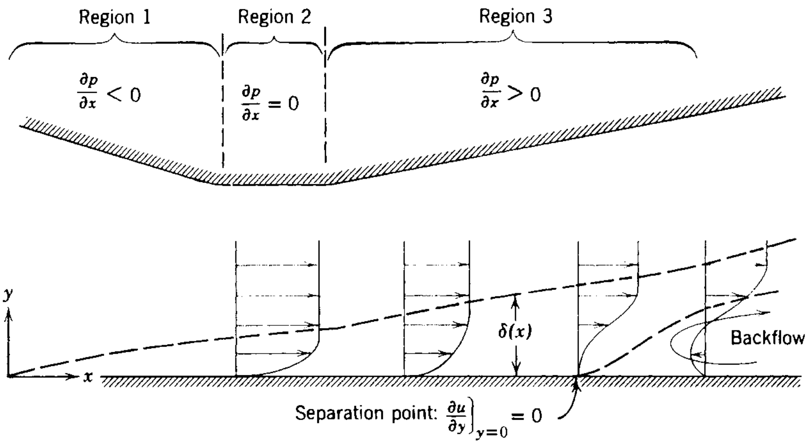

FIGURE 3.6.3 Boundary layer flow with pressure gradient (thickness exaggerated for clarity).

be zero. Therefore, flow cannot separate in a zero pressure gradient; shear stresses alone can never cause flow separation.

In the favorable pressure gradient of region 1, pressure forces tend to maintain the motion of the particle, so flow cannot separate. In the adverse pressure gradient of region 3, pressure forces oppose the motion of a fluid particle. An adverse pressure gradient is a necessary condition for flow separation.

Velocity profiles for laminar and turbulent boundary layers are shown in Figure 3.6.2. It is easy to see that the turbulent velocity profile has much more momentum than the laminar profile. Therefore, the turbulent velocity profile can resist separation in an adverse pressure gradient better than the laminar profile.

The freestream velocity distribution must be known before the MIE can be applied. A first approximation is obtained by applying potential flow theory to calculate the flow field around the object. Much effort has been devoted to calculation of velocity distributions over objects of known shape (the "direct" problem) and to determination of shapes to produce a desired pressure distribution (the "inverse" problem). Detailed discussion of such calculation schemes is beyond the scope of this section; the state of the art continues to progress rapidly.

Drag

Any object immersed in a viscous fluid flow experiences a net force from the shear stresses and pressure differences caused by the fluid motion. *Drag* is the force component parallel to, and *lift* is the force component perpendicular to, the flow direction. *Streamlining* is the art of shaping a body to reduce fluid dynamic drag. Airfoils (hydrofoils) are designed to produce lift in air (water); they are streamlined to reduce drag and thus to attain high lift–drag ratios.

In general, lift and drag cannot be predicted analytically for flows with separation, but progress continues on computational fluid dynamics methods. For many engineering purposes, drag and lift forces are calculated from experimentally derived coefficients, discussed next.

Drag coefficient is defined as

$$C_D = \frac{F_D}{\frac{1}{2}\rho V^2 A} \tag{3.6.9}$$

where $\frac{1}{2}\rho V^2$ is dynamic pressure and A is the area upon which the coefficient is based. Common practice is to base drag coefficients on projected *frontal area* (Fox et al., 2004).

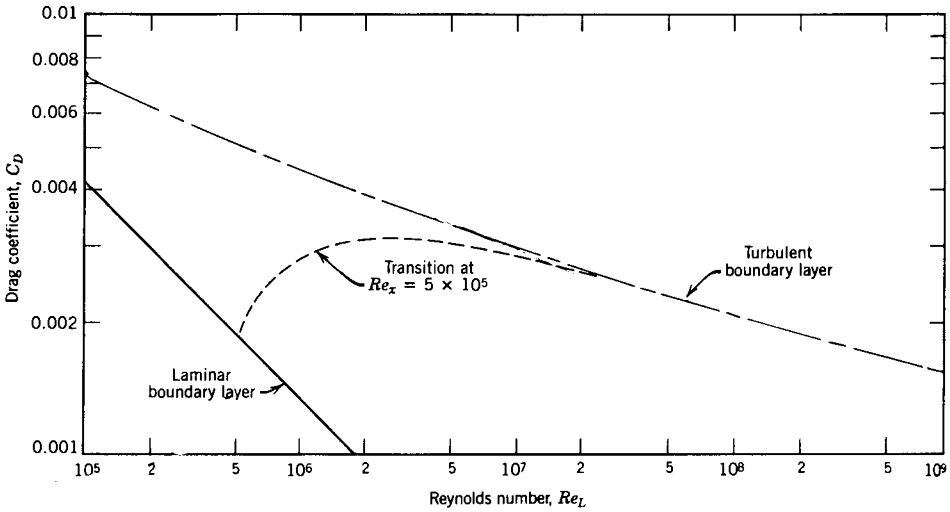

FIGURE 3.6.4 Drag coefficient vs. Reynolds number for a smooth flat plate parallel to the flow.

Similitude was treated in Section 3.3. In general, the drag coefficient may be expressed as a function of Reynolds number; Mach number; Froude number; relative roughness; submergence divided by length; and so forth. This section considers neither high-speed flow nor free-surface effects; only Reynolds number and roughness effects on drag coefficient will be considered.

Friction Drag

The total friction drag force acting on a plane surface aligned with the flow direction can be found by integrating the shear stress distribution along the surface. The drag coefficient for this case is defined as friction force divided by dynamic pressure and *wetted area* in contact with the fluid. Because shear stress is a function of Reynolds number, so is drag coefficient (see Figure 3.6.4). In Figure 3.6.4, transition occurs at $\mathrm{Re}_x = 500{,}000$; the dashed line represents the drag coefficient at larger Reynolds numbers. A number of empirical correlations may be used to model the variation in C_D shown in Figure 3.6.4 (Schlichting, 1979).

Extending the laminar boundary layer line to higher Reynolds numbers shows that it is beneficial to delay transition to the highest possible Reynolds number. Some results are presented in Table 3.6.3; drag is reduced more than 50% by extending laminar boundary layer flow to $\mathrm{Re}_L = 10^6$.

Pressure Drag

A thin flat surface normal to the flow has no area parallel to the flow direction. Therefore, there can be no friction force parallel to the flow; all drag is caused by pressure forces. Drag coefficients for objects with sharp edges tend to be independent of Reynolds number (for Re > 1000) because the separation points are fixed by the geometry of the object. Drag coefficients for selected objects are shown in Table 3.6.4.

Rounding the edges that face the flow reduces drag markedly. Compare the drag coefficients for the hemisphere and C-section shapes facing into and away from the flow. Also note that the drag coefficient for a two-dimensional object (long square cylinder) is about twice that for the corresponding three-dimensional object (square cylinder with $b/h = 1$).

Friction and Pressure Drag: Bluff Bodies

Friction and pressure forces contribute to the drag of *bluff bodies* (see Shapiro, 1960, for a good discussion of the mechanisms of drag). As an example, consider the drag coefficient for a smooth sphere shown in Figure 3.6.5. Transition from laminar to turbulent flow in the boundary layers on the forward portion of the sphere causes a dramatic dip in drag coefficient at the *critical Reynolds number* ($\mathrm{Re}_D \approx 2 \times 10^5$). The turbulent boundary layer is better able to resist the adverse pressure gradient on the rear of the

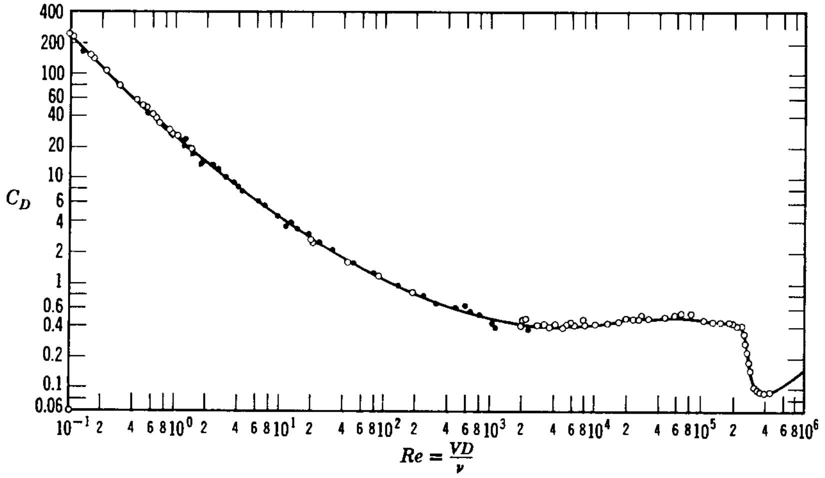

FIGURE 3.6.5 Drag coefficient vs. Reynolds number for a smooth sphere. (From Schlichting, H. 1979. *Boundary Layer Theory,* 7th ed., McGraw–Hill, New York. With permission.)

sphere, so separation is delayed and the wake is smaller, causing less pressure drag. Surface roughness (or freestream disturbances) can reduce the critical Reynolds number. For example, dimples on a golf ball cause the boundary layer to become turbulent and, therefore, lower the drag coefficient in the range of speeds encountered in a drive.

Streamlining

Streamlining is adding a faired tail section to reduce the extent of separated flow on the downstream portion of an object (at high Reynolds number where pressure forces dominate drag). The adverse pressure gradient is taken over a longer distance, delaying separation. However, adding a faired tail increases surface area, causing skin friction drag to increase. Thus, streamlining must be optimized for each shape. For example, front contours are of principal importance in road vehicle design; the angle of the back glass also is important (in most cases the entire rear end cannot be made long enough to control separation and reduce drag significantly).

Lift

Lift coefficient is defined as

$$C_L = \frac{F_L}{\frac{1}{2}\rho V^2 A} \tag{3.6.10}$$

Note that lift coefficient is based on projected *planform area.*

Airfoils

Airfoils are shaped to produce lift efficiently by accelerating flow over the upper surface to produce a low-pressure region. Because the flow must again decelerate, inevitably a region of adverse pressure gradient must be near the rear of the upper surface (pressure distributions are shown clearly in Hazen, 1965).

Lift and drag coefficients for airfoil sections depend on Reynolds number and *angle of attack* between the chord line and the undisturbed flow direction. The *chord line* is the straight line joining the leading and trailing edges of the airfoil (Abbott and von Doenhoff, 1959). As the angle of attack is increased, the minimum pressure point moves forward on the upper surface and the minimum pressure becomes lower. This increases the adverse pressure gradient. At some angle of attack, the adverse pressure gradient is strong enough to cause the boundary layer to separate completely from the upper surface, causing the airfoil to *stall*. The separated flow alters the pressure distribution, reducing lift sharply.

Increasing the angle of attack also causes the drag coefficient to increase. At some angle of attack below "stall," the ratio of lift to drag — the *lift–drag* ratio — reaches a maximum value.

Drag Due to Lift

For wings (airfoils of finite span), lift and drag also are functions of aspect ratio. Lift is reduced and drag increased compared with infinite span because end effects cause the lift vector to rotate rearward. For a given geometric angle of attack, this reduces effective angle of attack, reducing lift. The additional component of lift acting in the flow direction increases drag; the increase in drag due to lift is called *induced drag*.

The effective aspect ratio includes the effect of planform shape. When written in terms of effective aspect ratio, the drag of a finite-span wing is

$$C_D = C_{D,\infty} + \frac{C_L^2}{\pi ar} \tag{3.6.11}$$

where ar is effective aspect ratio and the subscript ∞ refers to the infinite section drag coefficient at C_L. For further details consult the references.

The lift coefficient must increase to support aircraft weight as speed is reduced. Therefore, induced drag can increase rapidly at low flight speeds. For this reason, minimum allowable flight speeds for commercial aircraft are closely controlled by the FAA.

Boundary Layer Control

The major part of the drag on an airfoil or wing is caused by skin friction. Therefore, it is important to maintain laminar flow in the boundary layers as far aft as possible; laminar flow sections are designed to do this. It also is important to prevent flow separation and to achieve high lift to reduce takeoff and landing speeds. These topics fall under the general heading of boundary layer control.

Profile Shaping

Boundary layer transition on a conventional airfoil section occurs almost immediately after the minimum pressure at about 25% chord aft the leading edge. Transition can be delayed by shaping the profile to maintain a favorable pressure gradient over more of its length. The U.S. National Advisory Committee for Aeronautics (NACA) has developed several series of profiles that delayed transition to 60 or 65% of chord, reducing drag coefficients (in the design range) 60% compared with conventional sections of the same thickness ratio (Abbott and von Doenhoff, 1959).

Flaps and Slats

Flaps are movable sections near the trailing edge of a wing. They extend and/or deflect to increase wing area and/or increase wing camber (curvature), to provide higher lift than the clean wing. Many aircraft also are fitted with leading edge slats that open to expose a slot from the pressure side of the wing to the upper surface. The open slat increases the effective radius of the leading edge, improving maximum lift coefficient. The slot allows energized air from the pressure surface to flow into the low-pressure region atop the wing, energizing the boundary layers and delaying separation and stall.

Suction and Blowing

Suction removes low-energy fluid from the boundary layer, reducing the tendency for early separation. Blowing via high-speed jets directed along the surface reenergizes low-speed boundary layer fluid. The objective of both approaches is to delay separation, thus increasing the maximum lift coefficient the wing can achieve. Powered systems add weight and complexity; they also require bleed air from the engine compressor, reducing thrust or power output.

Moving Surfaces

Many schemes have been proposed to utilize moving surfaces for boundary layer control. Motion in the direction of flow reduces skin friction and thus the tendency to separate; motion against the flow has the opposite effect. The aerodynamic behavior of sports balls — baseballs, golf balls, and tennis balls — depends significantly on aerodynamic side force (lift, down force, or side force) produced by spin. These effects are discussed at length in Fox et al. (2004) and its references.

Computation vs. Experiment

Experiments cannot yet be replaced completely by analysis. Progress in modeling, numerical techniques, and computer power continues to be made, but the role of the experimentalist likely will remain important for the foreseeable future.

Computational Fluid Dynamics (CFD)

Computation of fluid flow requires accurate mathematical modeling of flow physics and accurate numerical procedures to solve the equations. The basic equations for laminar boundary layer flow are well known. For turbulent boundary layers, it is not generally possible to resolve the solution space into sufficiently small cells to allow direct numerical simulation. Instead, empirical models for the turbulent stresses must be used. Advances in computer memory storage capacity and speed (e.g., through use of massively parallel processing) continue to increase the resolution that can be achieved.

A second source of error in CFD work results from the numerical procedures required to solve the equations. Even if the equations are exact, approximations must be made to discretize and solve them using finite-difference or finite-volume methods. Whichever is chosen, the solver must guard against introducing numerical instability, round-off errors, and numerical diffusion (Hoffman, 2001).

Role of the Wind Tunnel

Traditionally, wind tunnel experiments have been conducted to verify the design and performance of components and complete aircraft. Design verification of a modern aircraft may require expensive scale models, several thousand hours of wind tunnel time at many thousands of dollars an hour, and additional full-scale flight testing. New wind tunnel facilities continue to be built and old ones refurbished. This indicates a need for continued experimental work in developing and optimizing aircraft configurations.

Many experiments are designed to produce baseline data to validate computer codes. Such systematic experimental data can help to identify the strengths and weaknesses of computational methods. CFD tends to become only indicative of trends when massive zones of flow separation are present. Takeoff and landing configurations of conventional aircraft, with landing gear, high-lift devices, and flaps extended, tend to need final experimental confirmation and optimization. Many studies of vertical takeoff and vectored thrust aircraft require testing in wind tunnels.

Defining Terms

Boundary layer: Thin layer of fluid adjacent to a surface where viscous effects are important; viscous effects are negligible outside the boundary layer.

Drag coefficient: Force in the flow direction exerted on an object by the fluid flowing around it, divided by dynamic pressure and area.

Lift coefficient: Force perpendicular to the flow direction exerted on an object by the fluid flowing around it, divided by dynamic pressure and area.

Pressure gradient: Variation in pressure along the surface of an object. For a *favorable* pressure gradient, pressure *decreases* in the flow direction; for an *adverse* pressure gradient, pressure *increases* in the flow direction.

Separation: Phenomenon that occurs when fluid layers adjacent to a solid surface are brought to rest and boundary layers depart from the surface contour, forming a low-pressure *wake* region. Separation can occur only in an *adverse pressure gradient*.

Transition: Change from laminar to turbulent flow within the boundary layer. The location depends on distance over which the boundary layer has developed; pressure gradient; surface roughness; freestream disturbances; and heat transfer.

3.7 Compressible Flow

Ajay Kumar and Jessica Todd

Introduction

This section deals with compressible flow. Only one- or two-dimensional steady, inviscid flows under perfect gas assumption are considered. Readers are referred to other sources of information for unsteady effects, viscous effects, and three-dimensional flows.

The term *compressible flow* is routinely used to define variable density flow which is in contrast to incompressible flow, where the density is assumed to be constant throughout. In many cases, these density variations are principally caused by the pressure changes from one point to another. Physically, the *compressibility* can be defined as the fractional change in volume of the gas element per unit change in pressure. It is a property of the gas and, in general, can be defined as

$$\tau = \frac{1}{\rho}\frac{d\rho}{dp}$$

where τ is the compressibility of the gas, ρ is the density, and p is the pressure being exerted on the gas. A more precise definition of compressibility is obtained if we take into account the thermal and frictional losses. If during the compression the temperature of the gas is held constant, it is called the isothermal compressibility and can be written as

$$\tau_T = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial p}\right)_T$$

However, if the compression process is reversible, it is called the isentropic compressibility and can be written as

$$\tau_s = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial p}\right)_s$$

Gases in general have high compressibility (τ_T for air is 10^{-5} $\mathrm{m^2/N}$ at 1 atm) as compared with liquids (τ_T for water is 5×10^{-10} $\mathrm{m^2/N}$ at 1 atm).

Compressibility is a very important parameter in the analysis of compressible flow and is closely related to the *speed of sound*, a, which is the velocity of propagation of small pressure disturbances and is defined as

$$a^2 = \left(\frac{\partial p}{\partial \rho}\right)_s \quad \text{or} \quad a = \sqrt{\left(\frac{\partial p}{\partial \rho}\right)_s}$$

In an isentropic process of a perfect gas, the pressure and density are related as

$$\frac{p}{\rho^\gamma} = \text{constant}$$

Using this relation along with the perfect gas relation $p = \rho RT$, we can show that for a perfect gas

$$a = \sqrt{\gamma RT} = \sqrt{\frac{\gamma p}{\rho}}$$

where γ is the ratio of specific heats at constant pressure and constant volume, R is the gas constant, and T is the temperature. For air under normal conditions, γ is 1.4 and R is 287 $\mathrm{m^2/sec^2\ K}$ so that the speed of sound for air becomes $a = 20.045\sqrt{T}$ m/sec where T is in kelvin.

Another important parameter in compressible flows is the *Mach number, M,* which is defined as the ratio of the gas velocity to the speed of sound or

$$M = \frac{V}{a}$$

where V is the velocity of gas. Depending upon the Mach number of the flow, we can define the following flow regimes:

$M \ll 1$ Incompressible flow

$M < 1$ Subsonic flow

$M \approx 1$ Transonic flow

$M > 1$ Supersonic flow

$M \gg 1$ Hypersonic flow

Subsonic through hypersonic flows are compressible in nature. In these flows, the velocity is appreciable compared with the speed of sound, and the fractional changes in pressure, temperature, and density are all of significant magnitude. We will restrict ourselves in this section to subsonic through flows only.

Before we move on to study these flows, let us define one more term. Let us consider a gas with static pressure p and temperature T, traveling at some velocity V and corresponding Mach number M. If this gas is brought isentropically to stagnation or zero velocity, the pressure and temperature which the gas achieves are defined as *stagnation pressure* p_0 and *stagnation temperature* T_0 (also called total pressure and total temperature). The speed of sound at stagnation conditions is called the *stagnation speed of sound* and is denoted as a_0.

One-Dimensional Flow

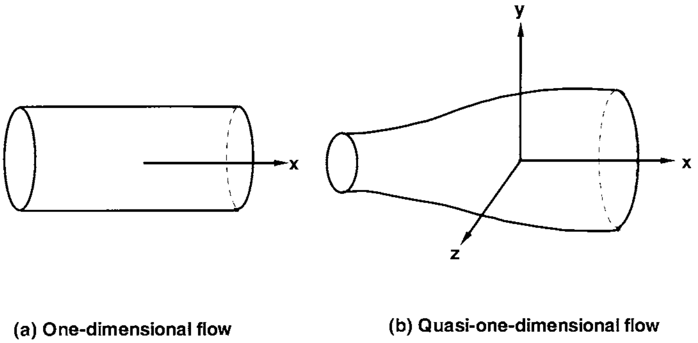
In one-dimensional flow, the flow properties vary only in one coordinate direction. Figure 3.7.1 shows two streamtubes in a flow. In a *truly one-dimensional flow* illustrated in Figure 3.7.1(a), the flow variables are a function of x only and the area of the stream tube is constant. On the other hand, Figure 3.7.1(b) shows a flow where the area of the stream tube is also a function of x but the flow variables are still a function of x only. This flow is defined as the *quasi-one-dimensional flow.* We will first discuss the truly one-dimensional flow.

In a steady, truly one-dimensional flow, conservation of mass, momentum, and energy leads to the following simple algebraic equations.

$$\begin{gathered}\rho u = \text{constant}\\ p + \rho u^2 = \text{constant}\\ h + \frac{u^2}{2} + q = \text{constant}\end{gathered} \tag{3.7.1}$$

where q is the heat added per unit mass of the gas. These equations neglect body forces, viscous stresses, and heat transfer due to thermal conduction and diffusion. These relations given by Equation 3.7.1, when applied at points 1 and 2 in a flow with no heat addition, become

$$\begin{gathered}\rho_1 u_1 = \rho_2 u_2\\ p_1 + \rho_1 u_1^2 = p_2 + \rho_2 u_2^2\\ h_1 + \frac{u_1^2}{2} = h_2 + \frac{u_2^2}{2}\end{gathered} \tag{3.7.2}$$



(a) One-dimensional flow

(b) Quasi-one-dimensional flow

FIGURE 3.7.1 (a) One-dimensional flow; (b) quasi-one-dimensional flow.

The energy equation for a calorically perfect gas, where $h = c_pT$, becomes

$$c_pT_1 + \frac{u_1^2}{2} = c_pT_2 + \frac{u_2^2}{2}$$

Using $c_p = \gamma R/(\gamma - 1)$ and $a^2 = \gamma RT$, the above equation can be written as

$$\frac{a_1^2}{\gamma - 1} + \frac{u_1^2}{2} = \frac{a_2^2}{\gamma - 1} + \frac{u_2^2}{2} \tag{3.7.3}$$

Since Equation (3.7.3) is written for no heat addition, it holds for an adiabatic flow. If the energy equation is applied to the stagnation conditions, it can be written as

$$c_pT + \frac{u^2}{2} = c_pT_0$$

$$\frac{T_0}{T} = 1 + \frac{\gamma - 1}{2}M^2 \tag{3.7.4}$$

It is worth mentioning that in arriving at Equation (3.7.4), only adiabatic flow condition is used whereas stagnation conditions are defined as those where the gas is brought to rest isentropically. Therefore, the definition of stagnation temperature is less restrictive than the general definition of stagnation conditions. According to the general definition of isentropic flow, it is a reversible adiabatic flow. This definition is needed for the definition of stagnation pressure and density. For an isentropic flow,

$$\frac{p_0}{p} = \left(\frac{\rho_0}{\rho}\right)^{\gamma} = \left(\frac{T_0}{T}\right)^{\gamma/(\gamma-1)} \tag{3.7.5}$$

From Equation (3.7.4) and Equation (3.7.5), we can write

$$\frac{p_0}{p} = \left(1 + \frac{\gamma - 1}{2}M^2\right)^{\gamma/(\gamma-1)} \tag{3.7.6}$$

$$\frac{\rho_0}{\rho} = \left(1 + \frac{\gamma - 1}{2}M^2\right)^{1/(\gamma-1)} \tag{3.7.7}$$

Values of stagnation conditions are tabulated in Anderson (1982) as a function of M for $\gamma = 1.4$.

Normal Shock Wave

A shock wave is a very thin region (of the order of a few molecular mean free paths) across which the static pressure, temperature, and density increase whereas the velocity decreases. If the shock wave is perpendicular to the flow, it is called a *normal shock wave*. The flow is supersonic ahead of the normal shock wave and subsonic behind it. Figure 3.7.2 shows the flow conditions across a normal shock wave which is treated as a discontinuity. Since there is no heat added or removed, the flow across the shock wave is adiabatic. By using Equations (3.7.2) the normal shock equations can be written as

$$\begin{gathered} \rho_1u_1 = \rho_2u_2 \\ p_1 + \rho_1u_1^2 = p_2 + \rho_2u_2^2 \\ h_1 + \frac{u_1^2}{2} = h_2 + \frac{u_2^2}{2} \end{gathered} \tag{3.7.8}$$

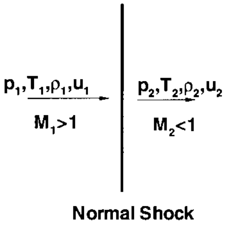


FIGURE 3.7.2 Flow conditions across a normal shock.

Equations (3.7.8) are applicable to a general type of flow; however, for a calorically perfect gas, we can use the relations $p = \rho RT$ and $h = c_p T$ to derive a number of equations relating flow conditions downstream of the normal shock to those at upstream. These equations (also known as Rankine–Hugoniot relations) are

$$\frac{p_2}{p_1} = 1 + \frac{2\gamma}{\gamma+1}\left(M_1^2 - 1\right)$$

$$\frac{\rho_2}{\rho_1} = \frac{u_1}{u_2} = \frac{(\gamma+1)M_1^2}{2+(\gamma-1)M_1^2} \tag{3.7.9}$$

$$\frac{T_2}{T_1} = \frac{h_2}{h_1} = \left[1 + \frac{2\gamma}{\gamma+1}\left(M_1^2 - 1\right)\right]\left[\frac{2+(\gamma-1)M_1^2}{(\gamma+1)M_1^2}\right]$$

$$M_2^2 = \frac{1 + \frac{\gamma-1}{2}M_1^2}{\gamma M_1^2 - \frac{\gamma-1}{2}}$$

Again, the values of p_2/p_1, ρ_2/ρ_1, T_2/T_1, etc. are tabulated in Anderson (1982) as a function of M_1 for $\gamma = 1.4$. Let us examine some limiting cases. As $M_1 \to 1$, Equations (3.7.9) yield $M_2 \to 1$, $p_2/p_1 \to 1$, $\rho_2/\rho_1 \to 1$, and $T_2/T_1 \to 1$. This is the case of an extremely weak normal shock across which no finite changes occur. This is the same as the sound wave. On the other hand, as $M_1 \to \infty$, Equations (3.7.9) yield

$$M_2 \to \sqrt{\frac{\gamma-1}{2\gamma}} = 0.378; \quad \frac{\rho_2}{\rho_1} \to \frac{\gamma+1}{\gamma-1} = 6; \quad \frac{p_2}{p_1} \to \infty; \quad \frac{T_2}{T_1} \to \infty$$

However, the calorically perfect gas assumption no longer remains valid as $M_1 \to \infty$.

Let us now examine why the flow ahead of a normal shock wave must be supersonic even though Equations (3.7.8) hold for $M_1 < 1$ as well as $M_1 > 1$. From the second law of thermodynamics, the entropy change across the normal shock can be written as

$$s_2 - s_1 = c_p \ln\frac{T_2}{T_1} - R\ln\frac{p_2}{p_1}$$

By using Equations (3.7.9) it becomes

$$s_2 - s_1 = c_p \ln\left\{\left[1 + \frac{2\gamma}{\gamma+1}\left(M_1^2 - 1\right)\right]\left[\frac{2+(\gamma-1)M_1^2}{(\gamma+1)M_1^2}\right]\right\} - R\ln\left[1 + \frac{2\gamma}{\gamma+1}\left(M_1^2 - 1\right)\right] \tag{3.7.10}$$

Equation (3.7.10) shows that the entropy change across the normal shock is also a function of M_1 only. Using Equation (3.7.10) we see that

$$\begin{aligned} s_2 - s_1 &= 0 \quad \text{for} \quad M_1 = 1 \\ &< 0 \quad \text{for} \quad M_1 < 1 \\ &> 0 \quad \text{for} \quad M_1 > 1 \end{aligned}$$

Since it is necessary that $s_2 - s_1 \geqslant 0$ from the second law, $M_1 \geq 1$. This, in turn, requires that $p_2/p_1 \geqslant 1$, $\rho_2/\rho_1 \geqslant 1$, $T_2/T_1 \geqslant 1$, and $M_2 \leqslant 1$.

We now examine how the stagnation conditions change across a normal shock wave. For a calorically perfect gas, the energy equation in Equations (3.7.9) gives

$$c_p T_{01} = c_p T_{02} \quad \text{or} \quad T_{01} = T_{02}$$

In other words, the total temperature remains constant across a stationary normal shock wave.

Let us now apply the entropy change relation across the shock using the stagnation conditions.

$$s_2 - s_1 = c_p \ln \frac{T_{02}}{T_{01}} - R \ln \frac{p_{02}}{p_{01}}$$

Note that entropy at stagnation conditions is the same as at the static conditions since to arrive at stagnation conditions, the gas is brought to rest isentropically. Since $T_{02} = T_{01}$,

$$s_2 - s_1 = -R \ln \frac{p_{02}}{p_{01}}$$

$$\frac{p_{02}}{p_{01}} = e^{-(s_2 - s_1)/R} \tag{3.7.11}$$

Since $s_2 > s_1$ across the normal shockwave, Equation (3.7.11) gives $P_{02} < P_{01}$ or, in other words, the total pressure decreases across a shock wave.

One-Dimensional Flow with Heat Addition

Consider one-dimensional flow through a control volume as shown in Figure 3.7.3. Flow conditions going into this control volume are designated by 1 and coming out by 2. A specified amount of heat per unit mass, q, is added to the control volume. The governing equations relating conditions 1 and 2 can be written as

$$\begin{gathered} \rho_1 u_1 = \rho_2 u_2 \\ p_1 + \rho_1 u_1^2 = p_2 + \rho_2 u_2^2 \\ h_1 + \frac{u_1^2}{2} + q = h_2 + \frac{u_2^2}{2} \end{gathered} \tag{3.7.12}$$

The following relations can be derived from Equation (3.7.12) for a calorically perfect gas

$$q = c_p \left(T_{02} - T_{01} \right) \tag{3.7.13}$$

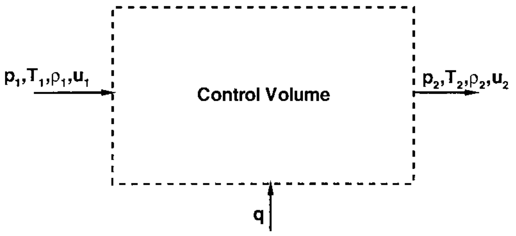

FIGURE 3.7.3 One-dimensional control volume with heat addition.

$$\frac{p_2}{p_1} = \frac{1+\gamma M_1^2}{1+\gamma M_2^2} \tag{3.7.14}$$

$$\frac{T_2}{T_1} = \left(\frac{1+\gamma M_1^2}{1+\gamma M_2^2}\right)^2 \left(\frac{M_2}{M_1}\right)^2 \tag{3.7.15}$$

$$\frac{\rho_2}{\rho_1} = \left(\frac{1+\gamma M_2^2}{1+\gamma M_1^2}\right)^2 \left(\frac{M_1}{M_2}\right)^2 \tag{3.7.16}$$

Equation (3.7.13) indicates that the effect of heat addition is to directly change the stagnation temperature T_0 of the flow. Table 3.7.1 shows some physical trends which can be obtained with heat addition to subsonic and supersonic flow. With heat extraction the trends in Table 3.7.1 are reversed.

Figure 3.7.4 shows a plot between enthalpy and entropy, also known as the Mollier diagram, for one-dimensional flow with heat addition. This curve is called the Rayleigh curve and is drawn for a set of

TABLE 3.7.1 Effect of Heat Addition on Subsonic and Supersonic Flow

T_{02}	Increases	Increases
p_{02}	Decreases	Decreases

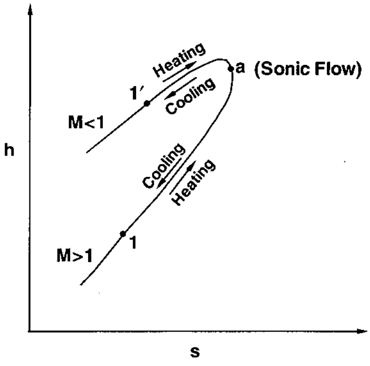

FIGURE 3.7.4 The Rayleigh curve.

given initial conditions. Each point on this curve corresponds to a different amount of heat added or removed. It is seen from this curve that heat addition always drives the Mach numbers toward 1. For a certain amount of heat addition, the flow will become sonic. For this condition, the flow is said to be *choked*. Any further increase in heat addition is not possible without adjustment in initial conditions. For example, if more heat is added in region 1, which is initially supersonic, than allowed for attaining Mach 1 in region 2, then a normal shock will form inside the control volume which will suddenly change the conditions in region 1 to subsonic. Similarly, in case of an initially subsonic flow corresponding to region 1′, any heat addition beyond that is needed to attain Mach 1 in region 2, the conditions in region 1′ will adjust to a lower subsonic Mach number through a series of pressure waves.

Similar to the preceding heat addition or extraction relationships, we can also develop relationships for one-dimensional steady, adiabatic flow but with frictional effects due to viscosity. In this case, the momentum equation gets modified for frictional shear stress. For details, readers are referred to Anderson (1982).

Quasi-One-Dimensional Flow

In quasi-one-dimensional flow, in addition to flow conditions, the area of duct also changes with *x*. The governing equations for quasi-one-dimensional flow can be written in a differential form as follows using an infinitesimal control volume shown in Figure 3.7.5.

$$d(\rho u A) = 0 \tag{3.7.17}$$

$$dp + \rho u\, du = 0 \tag{3.7.18}$$

$$dh + u\, du = 0 \tag{3.7.19}$$

Equation (3.7.17) can be written as

$$\frac{d\rho}{\rho} + \frac{du}{u} + \frac{dA}{A} = 0 \tag{3.7.20}$$

which can be further written as follows for an isentropic flow:

$$\frac{dA}{A} = \left(M^2 - 1\right)\frac{du}{u} \tag{3.7.21}$$

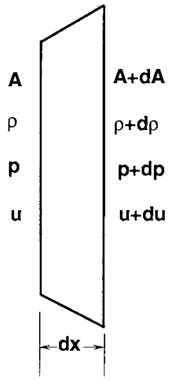

FIGURE 3.7.5 Control volume for quasi-one-dimensional flow.

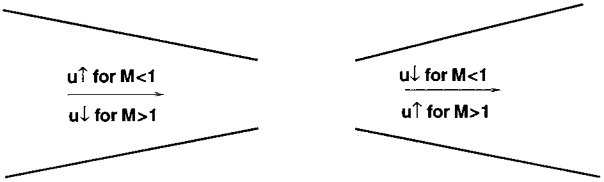

FIGURE 3.7.6 Compressible flow in converging and diverging ducts.

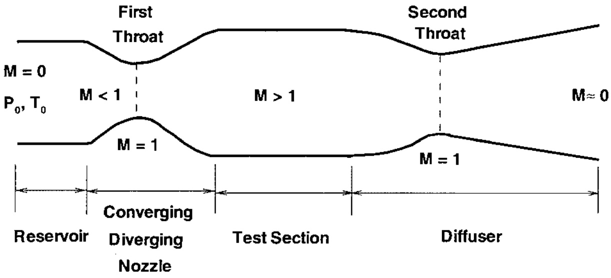

FIGURE 3.7.7 Schematic of a typical supersonic wind tunnel.

Some very useful physical insight can be obtained from this area–velocity relation.

- For subsonic flow ($0 \le M < 1$), an increase in area results in decrease in velocity, and vice versa.
- For supersonic flow ($M > 1$), an increase in area results in increase in velocity, and vice versa.
- For sonic flow ($M = 1$), $dA/A = 0$, which corresponds to a minimum or maximum in the area distribution, but it can be shown that a minimum in area is the only physical solution.

Figure 3.7.6 shows the preceding results in a schematic form.

It is obvious from this discussion that for a gas to go isentropically from subsonic to supersonic, and vice versa, it must flow through a convergent–divergent nozzle, also known as the de Laval nozzle. The minimum area of the nozzle at which the flow becomes sonic is called the throat. This physical observation forms the basis of designing supersonic wind tunnels shown schematically in Figure 3.7.7. In general, in a supersonic wind tunnel, a stagnant gas is first expanded to the desired supersonic Mach number. The supersonic flow enters the test section where it passes over a model being tested. The flow then is slowed down by compressing it through a second convergent–divergent nozzle, also known as a diffuser, before it is exhausted to the atmosphere.

Now, using the equations for quasi-one-dimensional flow and the isentropic flow conditions, we can derive a relation for the area ratio that is needed to accelerate or decelerate the gas to sonic conditions. Denoting the sonic conditions by an asterisk, we can write $u^* = a^*$. The area is denoted as A^*, and it is obviously the minimum area for the throat of the nozzle. From Equation (3.7.17) we have

$$\rho u A = \rho^* u^* A^*$$

$$\frac{A}{A^*} = \frac{\rho^* u^*}{\rho u} = \frac{\rho^*}{\rho_0} \frac{\rho_0}{\rho} \frac{u^*}{u} \qquad (3.7.22)$$

Under isentropic conditons,

$$\frac{\rho_0}{\rho} = \left(1 + \frac{\gamma - 1}{2} M^2\right)^{1/(\gamma-1)} \qquad (3.7.23)$$

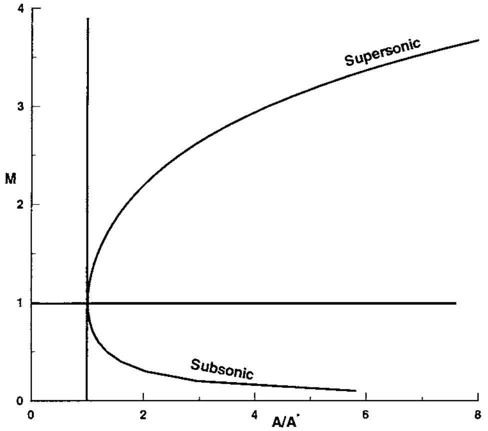

FIGURE 3.7.8 Variation of area ratio A/A* as a function of Mach number for a quasi-one-dimensional flow.

$$\frac{\rho_0}{\rho^*} = \left(1 + \frac{\gamma - 1}{2}\right)^{1/(\gamma-1)} = \left(\frac{\gamma + 1}{2}\right)^{1/(\gamma-1)} \tag{3.7.24}$$

Also, $u^*/u = a^*/u$. Let us define a Mach number $M^* = u/a^*$. M^* is known as the *characteristic Mach number* and it is related to the local Mach number by the following relation:

$$M^{*2} = \frac{\frac{\gamma+1}{2}M^2}{1 + \frac{\gamma - 1}{2}M^2} \tag{3.7.25}$$

Using Equation (3.7.23) through Equation (3.7.25) in Equation (3.7.22) we can write

$$\left(\frac{A}{A^*}\right)^2 = \frac{1}{M^2}\left[\left(\frac{2}{\gamma+1}\right)\left(1 + \frac{\gamma-1}{2}M^2\right)\right]^{(\gamma+1)/(\gamma-1)} \tag{3.7.26}$$

Equation (3.7.26) is called the area Mach number relation. Figure 3.7.8 shows a plot of A/A^* against Mach number. A/A^* is always ≥ 1 for physically viable solutions.

The area Mach number relation says that for a given Mach number, there is only one area ratio A/A^*. This is a very useful relation and is frequently used to design convergent–divergent nozzles to produce a desired Mach number. Values of A/A^* are tabulated as a function of M in Anderson (1982).

Equation (3.7.26) can also be written in terms of pressure as follows:

$$\frac{A}{A^*} = \frac{\left[1 - \left(\frac{p}{p_0}\right)^{(\gamma-1)/\gamma}\right]^{1/2}\left(\frac{p}{p_0}\right)^{1/\gamma}}{\left(\frac{\gamma-1}{2}\right)^{1/2}\left(\frac{2}{\gamma+1}\right)^{(\gamma+1)/2(\gamma-1)}} \tag{3.7.27}$$

Nozzle Flow

Using the area relations, we can now plot the distributions of Mach number and pressure along a nozzle. Figure 3.7.9 shows pressure and Mach number distributions along a given nozzle and the wave config-

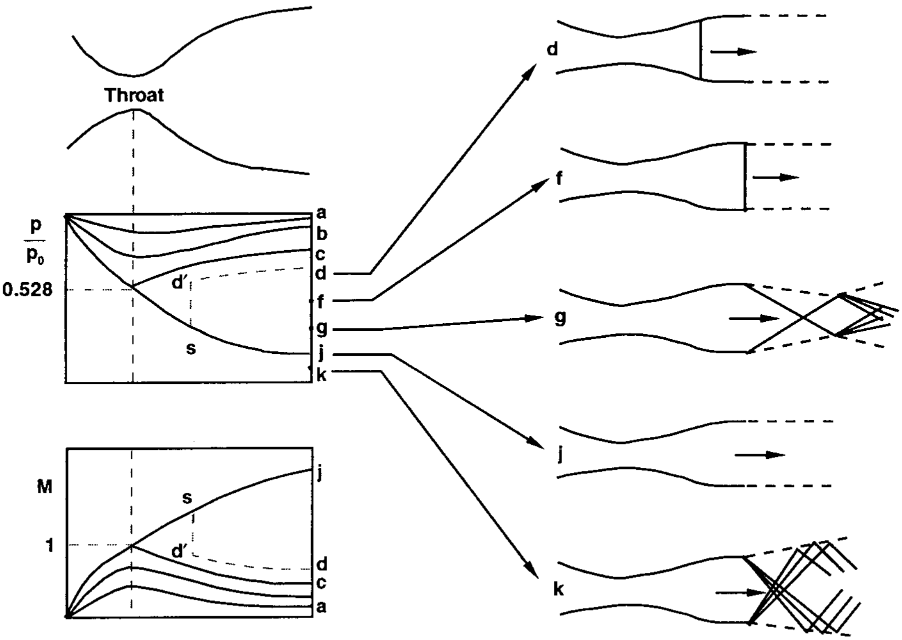

FIGURE 3.7.9 Effect of exit pressure on flow through a nozzle.

urations for several exit pressures. For curves a and b, the flow stays subsonic throughout and the exit pressure controls the flow in the entire nozzle. On curve c, the throat has just become sonic, and so the pressure at the throat, and upstream of it, can decrease no further. There is another exit pressure corresponding to curve j ($p_j < p_c$) for which a supersonic isentropic solution exists. But if the pressure lies between p_c and p_j, there is no isentropic solution possible. For example, for an exit pressure p_d, a shock will form in the nozzle at location *s* which will raise the pressure to $p_{d'}$ and turn the flow subsonic. The pressure will then rise to p_d as the subsonic flow goes through an increasing area nozzle. The location, *s*, depends on the exit pressure. Various possible situations are shown in Figure 3.7.9. It is clear that if the exit pressure is equal to or below p_f, the flow within the nozzle is fully supersonic. This is the principle used in designing supersonic wind tunnels by operating from a high-pressure reservoir or into a vacuum receiver, or both.

Diffuser

If a nozzle discharges directly into the receiver, the minimum pressure ratio for full supersonic flow in the test section is

$$\left(\frac{p_0}{p_E}\right)_{\min} = \frac{p_0}{p_f}$$

where p_f is the value of p_E at which the normal shock stands right at the nozzle exit. However, by adding an additional diverging section, known as a diffuser, downstream of the test section as shown in Figure 3.7.10 it is possible to operate the tunnel at a lower pressure ratio than p_0/p_f. This happens because the diffuser can now decelerate the subsonic flow downstream of the shock isentropically to a stagnation pressure p_0'. The pressure ratio required then is the ratio of stagnation pressures across a normal shock wave at the test section Mach number. In practice, the diffuser gives lower than expected recovery as a result of viscous losses caused by the interaction of shock wave and the boundary layer which are neglected here.

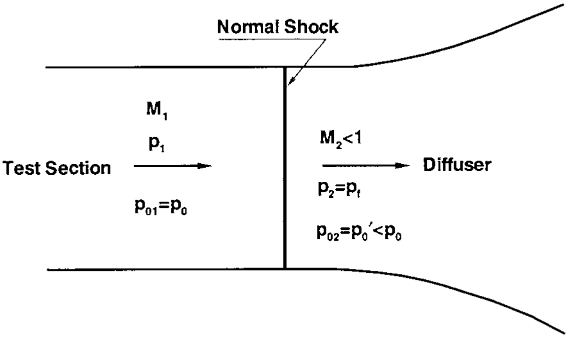

FIGURE 3.7.10 Normal shock diffuser.

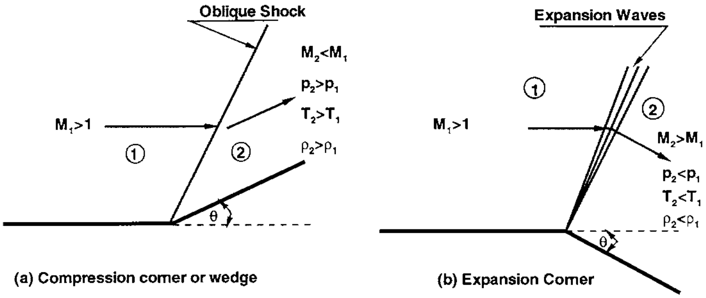

(a) Compression corner or wedge

(b) Expansion Corner

FIGURE 3.7.11 Supersonic flow over a corner.

The operation of supersonic wind tunnels can be made even more efficient; i.e., they can be operated at even lower pressure ratios than p_0/p_0', by using the approach shown in Figure 3.7.7 where the diffuser has a second throat. It can slow down the flow to subsonic Mach numbers isentropically and, ideally, can provide complete recovery, giving $p_0' = p_0$. However, due to other considerations, such as the starting process of the wind tunnel and viscous effects, it is not realized in real life.

Two-Dimensional Supersonic Flow

When supersonic flow goes over a wedge or an expansion corner, it goes through an oblique shock or expansion waves, respectively, to adjust to the change in surface geometry. Figure 3.7.11 shows the two flow situations. In Figure 3.7.11(a) an oblique shock abruptly turns the flow parallel to the wedge surface. The Mach number behind the shock is less than ahead of it, whereas the pressure, temperature, and density increase. In the case of an expansion corner, oblique expansion waves smoothly turn the flow to become parallel to the surface downstream of the expansion corner. In this case, the Mach number increases, but the pressure, temperature, and density decrease as the flow goes through the expansion corner. Oblique shocks and expansion waves occur in two- and three-dimensional supersonic flows. In this section, we will restrict ourselves to steady, two-dimensional supersonic flows only.

Oblique Shock Waves

The oblique shock can be treated in the same way as the normal shock by accounting for the additional velocity component. If a uniform velocity v is superimposed on the flow field of the normal shock, the resultant velocity ahead of the shock can be adjusted to any flow direction by adjusting the magnitude and direction of v. If v is taken parallel to the shock wave, as shown in Figure 3.7.12, the resultant velocity ahead of the shock is $w_1 = \sqrt{u_1^2 + v_1^2}$ and its direction from the shock is given by $\beta = \tan^{-1}(u_1/v)$. On the downstream side of the shock, since u_2 is less than u_1, the flow always turns toward the shock. The magnitude of u_2 can be determined by the normal shock relations corresponding to velocity u_1 and the

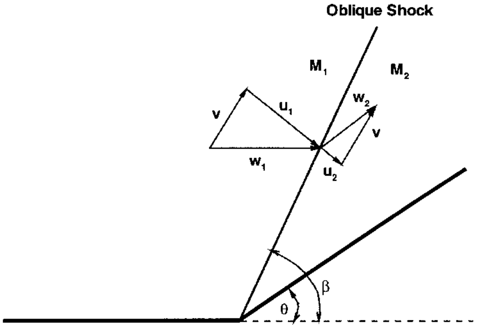

FIGURE 3.7.12 Oblique shock on a wedge.

magnitude of v is such that the flow downstream of the shock turns parallel to the surface. Since imposition of a uniform velocity does not affect the pressure, temperature, etc., we can use normal shock relations with Mach number replaced in them to correspond to velocity u_1 or u_1/a_1, which is nothing but $M_1 \sin\beta$. Thus, oblique shock relations become

$$\frac{p_2}{p_1} = 1 + \frac{2\gamma}{\gamma+1}\left(M_1^2 \sin^2\beta - 1\right) \tag{3.7.28}$$

$$\frac{\rho_2}{\rho_1} = \frac{(\gamma+1)M_1^2 \sin^2\beta}{(\gamma-1)M_1^2 \sin^2\beta + 2} \tag{3.7.29}$$

$$\frac{T_2}{T_1} = \frac{a_2^2}{a_1^2} = \left[1 + \frac{2\gamma}{\gamma+1}\left(M_1^2 \sin^2\beta - 1\right)\right]\left[\frac{2 + (\gamma-1)M_1^2 \sin^2\beta}{(\gamma+1)M_1^2 \sin^2\beta}\right] \tag{3.7.30}$$

The Mach number M_2 (= w_2/a_2) can be obtained by using a Mach number corresponding to velocity u_2 (= $w_2 \sin(\beta - \theta)$) in the normal shock relation for the Mach number. In other words,

$$M_2^2 \sin^2(\beta-\theta) = \frac{1 + \frac{\gamma-1}{2}M_1^2 \sin^2\beta}{\gamma M_1^2 \sin^2\beta - \frac{\gamma-1}{2}} \tag{3.7.31}$$

To derive a relation between the wedge angle θ and the wave angle β, we have from Figure 3.7.12

$$\tan\beta = \frac{u_1}{v} \quad \text{and} \quad \tan(\beta-\theta) = \frac{u_2}{v}$$

so that

$$\frac{\tan(\beta-\theta)}{\tan\beta} = \frac{u_2}{u_1} = \frac{\rho_1}{\rho_2} = \frac{(\gamma-1)M_1^2 \sin^2\beta + 2}{(\gamma+1)M_1^2 \sin^2\beta}$$

This can be simplified to

$$\tan\theta = 2\cot\beta \frac{M_1^2 \sin^2\beta - 1}{M_1^2(\gamma + \cos 2\beta) + 2} \tag{3.7.32}$$

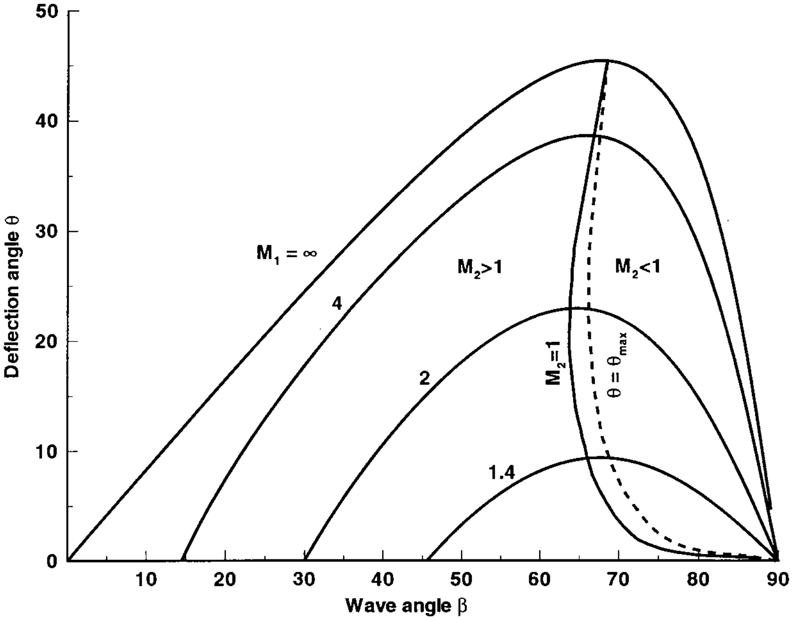

FIGURE 3.7.13 Oblique shock characteristics.

Dennard and Spencer (1964) have tabulated oblique shock properties as a function of M_1. Let us now make some observations from the preceding relations.

From the normal shock relations, $M_1 \sin\beta \geqslant 1$. This defines a minimum wave angle for a given Mach number. The maximum wave angle, of course, corresponds to the normal shock or $\beta = \pi/2$. Therefore, the wave angle β has the following range

$$\sin^{-1}\frac{1}{M} \leq \beta \leq \frac{\pi}{2} \tag{3.7.33}$$

Equation (3.7.32) becomes zero at the two limits of β. Figure 3.7.13 shows a plot of θ against β for various values of M_1. For each value of M_1, there is a maximum value of θ. For $\theta < \theta_{max}$, there are two possible solutions having different values of β. The larger value of β gives the stronger shock in which the flow becomes subsonic. A locus of solutions for which $M_2 = 1$ is also shown in the figure. It is seen from the figure that with weak shock solution, the flow remains supersonic except for a small range of θ slightly smaller than θ_{max}.

Let us now consider the limiting case of θ going to zero for the weak shock solution. As θ decreases to zero, β decreases to the limiting value μ, given by

$$M_1^2 \sin^2\mu - 1 = 0$$

$$\mu = \sin^{-1}\frac{1}{M_1} \tag{3.7.34}$$

For this angle, the oblique shock relations show no jump in flow quantities across the wave or, in other words, there is no disturbance generated in the flow. This angle μ is called the *Mach angle* and the lines at inclination μ are called *Mach lines.*

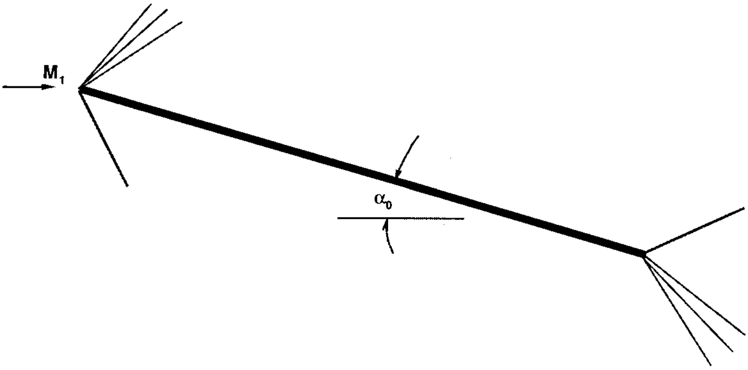

FIGURE 3.7.14 Lifting flat plate.

Thin-Airfoil Theory

For a small deflection angle $\Delta\theta$, it can be shown that the change in pressure in a flow at Mach M_1 is given approximately by

$$\frac{\Delta p}{p_1} \approx \frac{\gamma M_1^2}{\sqrt{M_1^2 - 1}} \Delta\theta \tag{3.7.35}$$

This expression holds for both compression and expansion. If Δp is measured with respect to the freestream pressure, p_1, and all deflections to the freestream direction, we can write Equation (3.7.35) as

$$\frac{p - p_1}{p_1} = \frac{\gamma M_1^2}{\sqrt{M_1^2 - 1}} \theta \tag{3.7.36}$$

where θ is positive for a compression and negative for expansion. Let us define a pressure coefficient C_p, as

$$C_p = \frac{p - p_1}{q_1}$$

where q_1 is the dynamic pressure and is equal to $\gamma p_1 M_1^2/2$. Equation (3.7.36) then gives

$$C_p = \frac{2\theta}{\sqrt{M_1^2 - 1}} \tag{3.7.37}$$

Equation (3.7.37) states that the pressure coefficient is proportional to the local flow deflection. This relation can be used to develop supersonic thin-airfoil theory. As an example, for a flat plate at angle of attack α_0 (shown in Figure 3.7.14), the pressure coefficients on the upper and lower surfaces are

$$C_p = \mp \frac{2\alpha_0}{\sqrt{M_1^2 - 1}}$$

The lift and drag coefficients can be written as

$$C_L = \frac{\left(p_L - p_U\right) c \cos\alpha_0}{q_1 c} = \left(C_{p_L} - C_{p_U}\right)\cos\alpha_0$$

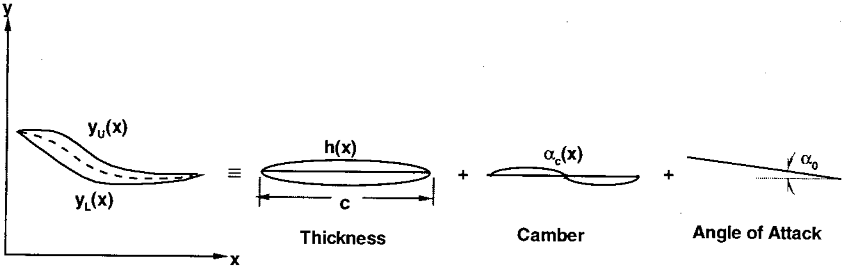

FIGURE 3.7.15 Arbitrary thin airfoil and its components.

$$C_D = \frac{(p_L - p_U)c\sin\alpha_0}{q_1 c} = \left(C_{p_L} - C_{p_U}\right)\sin\alpha_0$$

where c is the chord length of the plate. Since α_0 is small, we can write

$$C_L = \frac{4\alpha_0}{\sqrt{M_1^2 - 1}}, \qquad C_D = \frac{4\alpha_0^2}{\sqrt{M_1^2 - 1}} \tag{3.7.38}$$

A similar type of expression can be obtained for an arbitrary thin airfoil that has thickness, camber, and angle of attack. Figure 3.7.15 shows such an airfoil. The pressure coefficients on the upper and lower surfaces can be written as

$$C_{p_U} = \frac{2}{\sqrt{M_1^2 - 1}}\frac{dy_U}{dx}, \qquad C_{p_L} = \frac{2}{\sqrt{M_1^2 - 1}}\left(-\frac{dy_L}{dx}\right) \tag{3.7.39}$$

For the thin airfoil, the profile may be resolved into three separate components as shown in Figure 3.7.15. The local slope of the airfoil can be obtained by superimposing the local slopes of the three components as

$$\frac{dy_U}{dx} = -\left(\alpha_0 + \alpha_c(x)\right) + \frac{dh}{dx} = -\alpha(x) + \frac{dh}{dx}$$

$$\frac{dy_L}{dx} = -\left(\alpha_0 + \alpha_c(x)\right) - \frac{dh}{dx} = -\alpha(x) - \frac{dh}{dx} \tag{3.7.40}$$

where $\alpha = \alpha_0 + \alpha_c(x)$ is the local total angle of attack of the camber line. The lift and drag for the thin airfoil are given by

$$L = q_1 \int_0^c \left(C_{p_L} - C_{p_U}\right) dx$$

$$D = q_1 \int_0^c \left[C_{p_L}\left(-\frac{dy_L}{dx}\right) + C_{p_U}\left(\frac{dy_U}{dx}\right)\right] dx$$

Let us define an average value of $\alpha(x)$ as

$$\bar{\alpha} = \frac{1}{c}\int_0^c \alpha(x)\, dx$$

Using Equation (3.7.40) and the fact that $\overline{\alpha}_0 = \alpha$ and $\overline{\alpha}_c = 0$ by definition, the lift and drag coefficients for the thin airfoil can be written as

$$C_L = \frac{4\alpha_0}{\sqrt{M_1^2 - 1}}$$

$$C_D = \frac{4}{\sqrt{M_1^2 - 1}}\left[\overline{\left(\frac{dh}{dx}\right)^2} + \overline{\alpha_C^2(x)} + \alpha_0^2\right] \qquad (3.7.41)$$

Equations (3.7.41) show that the lift coefficient depends only on the mean angle of attack whereas the drag coefficient is a linear combination of the drag due to thickness, drag due to camber, and drag due to lift (or mean angle of attack).

3.8 Multiphase Flow

John C. Chen

Introduction

Classic study of fluid mechanics concentrates on the flow of a single homogeneous phase, e.g., water, air, steam. However, many industrially important processes involve simultaneous flow of multiple phases, e.g., gas bubbles in oil, wet steam, dispersed particles in gas or liquid. Examples include vapor–liquid flow in refrigeration systems, steam–water flows in boilers and condensers, vapor–liquid flows in distillation columns, and pneumatic transport of solid particulates. In spite of their importance, multiphase flows are often neglected in standard textbooks. Fundamental understanding and engineering design procedures for multiphase flows are not nearly so well developed as those for single-phase flows. An added complexity is the need to predict the relative concentrations of the different phases in the multiphase flows, a need that doesn't exist for single-phase flows.

Inadequate understanding not withstanding, a significant amount of data have been collected and combinations of theoretical models and empirical correlations are used in engineering calculations. This knowledge base is briefly summarized in this section and references are provided for additional information. While discussions are provided of solid–gas flows and solid–liquid flows, primary emphasis is placed on multiphase flow of gas–liquids since this is the most often encountered class of multiphase flows in industrial applications.

A multiphase flow occurs whenever two or more of the following phases occur simultaneously: gas/vapor, solids, single-liquid phase, multiple (immiscible) liquid phases. Every possible combination has been encountered in some industrial process, the most common being the simultaneous flow of vapor/gas and liquid (as encountered in boilers and condensers). All multiphase flow problems have features which are characteristically different from those found in single-phase problems. First, the relative concentration of different phases is usually a dependent parameter of great importance in multiphase flows, while it is a parameter of no consequence in single-phase flows. Second, the spatial distribution of the various phases in the flow channel strongly affects the flow behavior, again a parameter that is of no concern in single-phase flows. Finally, since the density of various phases can differ by orders of magnitude, the influence of gravitational body force on multiphase flows is of much greater importance than in the case of single-phase flows. In any given flow situation, the possibility exists for the various phases to assume different velocities, leading to the phenomena of slip between phases and consequent interfacial momentum transfer. Of course, the complexity of laminar/turbulent characteristics occurs in multiphase flows as in single-phase flows, with the added complexity of interactions between phases altering the laminar/turbulent flow structures. These complexities increase exponentially with the number of phases encountered in the multiphase problem. Fortunately, a large number of applications occur with just two phase flows, or can be treated as pseudo-two-phase flows.

Two types of analysis are used to deal with two-phase flows. The simpler approach utilizes homogeneous models which assume that the separate phases flow with the same identical local velocity at all points in the fluid. The second approach recognizes the possibility that the two phases can flow at different velocities throughout the fluid, thereby requiring separate conservation equations for mass and momentum for each phase. Brief descriptions of both classes of models are given below.

Fundamentals

Consider *n* phases in concurrent flow through a duct with cross-sectional area A_c. Fundamental quantities that characterize this flow are

$\dot{m}_i$ = mass flow rate of ith phase

u_i = velocity of ith phase

α_i = volume fraction of ith phase in channel

Basic relationships between these and related parameters are

$$G_i = \text{mass flux of } i\text{th phase}$$

$$= \frac{\dot{m}_i}{A_c} \tag{3.8.1}$$

$$v_i = \text{superficial velocity of } i\text{th phase}$$

$$= \frac{G_i}{\rho_i} \tag{3.8.2}$$

$$u_i = \text{actual velocity of } i\text{th phase}$$

$$= \frac{v_i}{\alpha_i} \tag{3.8.3}$$

$$x_i = \text{flow quality of } i\text{th phase}$$

$$= \frac{\dot{m}_i}{\sum_i^n m_i} = \frac{G_i}{\sum_{i=1}^n G_i} \tag{3.8.4}$$

$$\alpha_i = \text{volume fraction of } i\text{th phase}$$

$$= \frac{\left(\dfrac{x_i}{\rho_i u_i}\right)}{\sum_{i=1}^n \left(\dfrac{x_i}{\rho_i u_i}\right)} \tag{3.8.5}$$

In most engineering calculations, the above parameters are defined as average quantities across the entire flow area, A_c. It should be noted, however, that details of the multiphase flow could involve local variations across the flow area. In the latter situation, G_i, v_i, and α_i are often defined on a local basis, varying with transverse position across the flow area.

Pressure drop along the flow channel is associated with gravitational body force, acceleration forces, and frictional shear at the channel wall. The total pressure gradient along the flow axis can be represented as

$$\frac{dP}{dz} = \left(\frac{dP}{dz}\right)_g + \left(\frac{dP}{dz}\right)_a + \left(\frac{dP}{dz}\right)_f \tag{3.8.6}$$

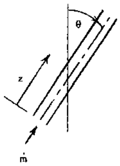
where

$$\left(\frac{dP}{dz}\right)_g = -g\cos\theta \cdot \sum_{i=1}^n \alpha_i \rho_i \tag{3.8.7}$$

θ = angle of channel from vertical

and

$$\left(\frac{dP}{dz}\right)_a = -\sum_{i=1}^{n} G_i \frac{du_i}{dz} \tag{3.8.8}$$



$$\left(\frac{dP}{dz}\right)_f = -\frac{\rho u^2}{2D} f \tag{3.8.9}$$

ρ = density of multiphase mixture

$$= \sum_{i=1}^{n} \rho_i \alpha_i \tag{3.8.10}$$

u = an average mixture velocity

$$= \frac{1}{\rho} \sum_{i=1}^{n} G_i \tag{3.8.11}$$

f = equivalent Darcy friction factor for the multiphase flow

In applications, the usual requirement is to determine pressure gradient (*dP*/*dz*) and the volume fractions (α_i). The latter quantities are of particular importance since the volume fraction of individual phases affects all three components of the pressure gradient, as indicated in Equation (3.8.7) to Equation (3.8.11). Correlations of various types have been developed for prediction of the volume fractions, all but the simplest of which utilize empirical parameters and functions.

The simplest flow model is known as the homogeneous equilibrium model (HEM), wherein all phases are assumed to be in neutral equilibrium. One consequence of this assumption is that individual phase velocities are equal for all phases everywhere in the flow system:

$$u_i = u \quad \text{for all} \quad i \tag{3.8.12}$$

This assumption permits direct calculation of the volume fractions from known mass qualities:

$$\alpha_i = \frac{x_i}{\rho_i \sum_{i=1}^{n} \left(\frac{x_i}{\rho_i}\right)} \tag{3.8.13}$$

The uniform velocity for all phases is the same as mixture velocity:

$$u = \frac{1}{\rho} \sum_{i=1}^{n} G_i \tag{3.8.14}$$

where

$$\frac{1}{\rho} = \sum_{i=1}^{n} \left(\frac{x_i}{\rho_i}\right) \tag{3.8.15}$$

This homogeneous model permits direct evaluation of all three components of axial pressure gradient, if flow qualities (x_i) are known:

$$\left(\frac{dP}{dz}\right)_g = -\frac{g\cos\theta}{\sum_{i=1}^{n}\left(\frac{x_i}{\rho_i}\right)} \tag{3.8.16}$$

$$\left(\frac{dP}{dz}\right)_a = -\left(\sum_{i=1}^{n} G_i\right)\cdot\frac{du}{dz} \tag{3.8.17}$$

$$\left(\frac{dP}{dz}\right)_f = -\frac{\rho u^2}{2D_f}\cdot f \tag{3.8.18}$$

where u and ρ are given by Equation (3.8.14) and Equation (3.8.15).

Predicting the coefficient of friction (f to clear) remains a problem, even in the homogeneous model. For cases of fully turbulent flows, experience has shown that a value of 0.02 may be used as a first-order approximation for (f to clear). More-accurate estimates require empirical correlations, specific to particular classes of multiphase flows and subcategories of flow regimes.

The following parts of this section consider the more common situations of two-phase flows and describe improved design methodologies specific to individual situations.

Gas–Liquid Two-Phase Flow

The most common case of multiphase flow is two-phase flow of gas and liquid, as encountered in steam generators and refrigeration systems. A great deal has been learned about such flows, including delineation of flow patterns in different flow regimes, methods for estimating volume fractions (gas void fractions), and two-phase pressure drops.

Flow Regimes

A special feature of multiphase flows is their ability to assume different spatial distributions of the phases. These different flow patterns have been classified in flow regimes, which are themselves altered by the direction of flow relative to gravitational acceleration. Figure 3.8.1 and Figure 3.8.2 (Delhaye, 1981) show the flow patterns commonly observed for co-current flow of gas and liquid in vertical and horizontal channels, respectively. For a constant liquid flow rate, the gas phase tends to be distributed as small bubbles at low gas flow rates. Increasing gas flow rate causes agglomeration of bubbles into larger slugs and plugs. Further increasing gas flow rate causes separation of the phases into annular patterns wherein liquid concentrates at the channel wall and gas flows in the central core for vertical ducts. For horizontal ducts, gravitational force tends to drain the liquid annulus toward the bottom of the channel, resulting in stratified and stratified wavy flows. This downward segregation of the liquid phase can be overcome by kinetic forces at high flow rates, causing stratified flows to revert to annular flows. At high gas flow rates, more of the liquid tends to be entrained as dispersed drops; in the limit one obtains completely dispersed mist flow.

Flow pattern maps are utilized to predict flow regimes for specific applications. The first generally successful flow map was that of Baker (1954) for horizontal flow, reproduced here in Figure 3.8.3. For vertical flows, the map of Hewitt and Roberts (1969), duplicated in Figure 3.8.4, provides a simple method for determining flow regimes. Parameters used for the axial coordinates of these flow maps are defined as follows:

$$\lambda = \left(\frac{\rho_g \rho_\ell}{\rho_a \rho_w}\right)^{1/2} \tag{3.8.19}$$

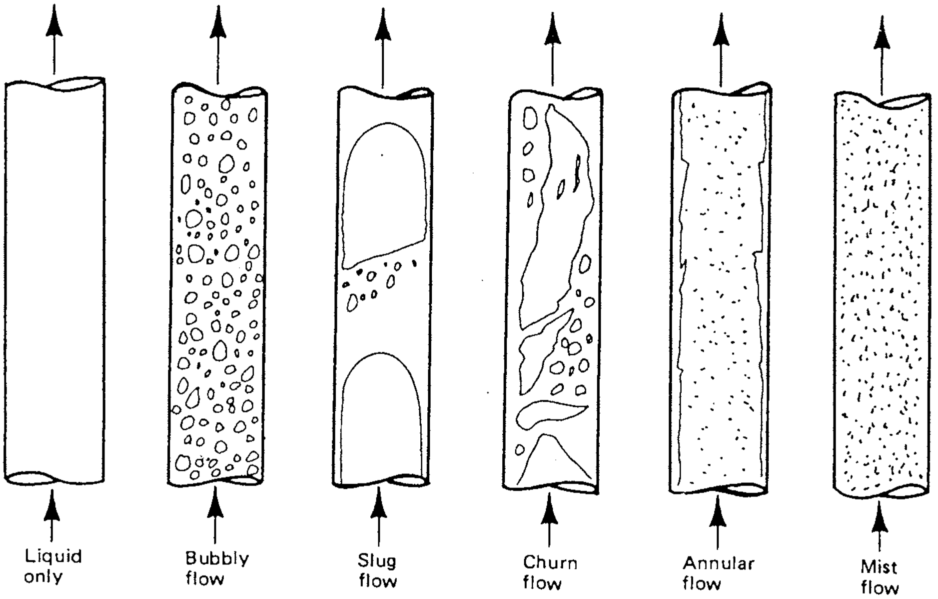


FIGURE 3.8.1 Flow patterns in gas–liquid vertical flow. (From Lahey, R.T., Jr. and Moody, F.I. 1977. *The Thermal Hydraulics of a Boiling Water Nuclear Reactor,* The American Nuclear Society, LaGrange, IL. With permission.)

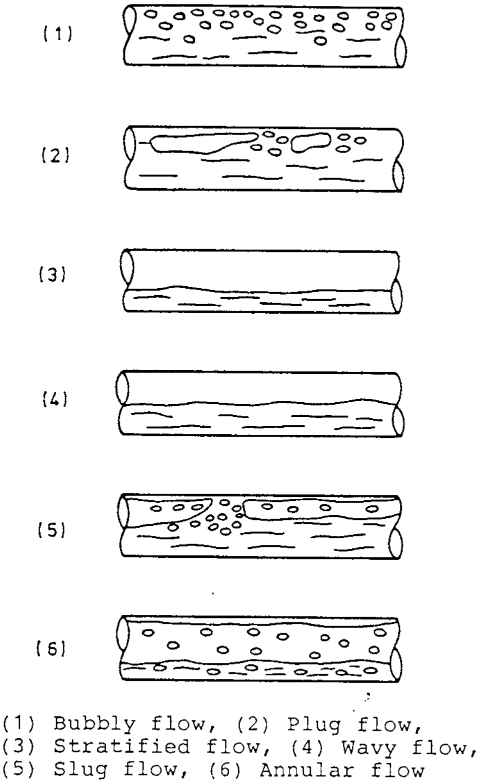

FIGURE 3.8.2 Flow patterns in gas–liquid horizontal flow.

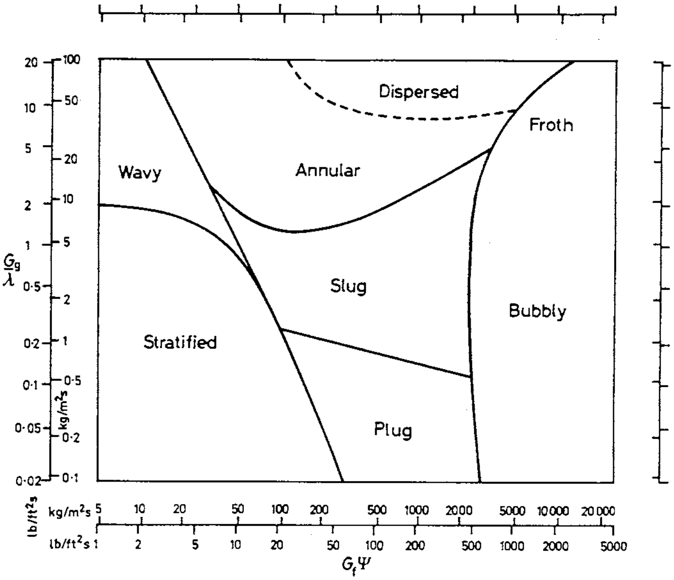

FIGURE 3.8.3 Flow pattern map for horizontal flow (Baker, 1954). (From Collier, J.G. 1972. *Convective Boiling and Condensation,* McGraw-Hill, London. With permission.)

$$\psi = \left(\frac{\sigma_w}{\sigma}\right)\left[\left(\frac{\mu_\ell}{\mu_w}\right)\left(\frac{\rho_w}{\rho_\ell}\right)^2\right]^{1/3} \tag{3.8.20}$$

$$j = \text{volumetric flux, } \frac{G}{\rho} \tag{3.8.21}$$

Void Fractions

In applications of gas–liquid flows, the volume fraction of gas (α_g) is commonly called “void fraction” and is of particular interest. The simplest method to estimate void fraction is by the HEM. From Equation (3.8.13), the void fraction can be estimated as

$$\alpha_g = \frac{x_g}{x_g + \left(1 - x_g\right)\dfrac{\rho_g}{\rho_\ell}} \tag{3.8.22}$$

where α_g, x_g, ρ_g, ρ_ℓ are cross-sectional averaged quantities.

In most instances, the homogenous model tends to overestimate the void fraction. Improved estimates are obtained by using separated-phase models which account for the possibility of slip between gas and liquid velocities. A classic separated-phase model is that of Lockhart and Martinelli (1949). The top portion of Figure 3.8.5 reproduces the Lockhart–Martinelli correlation for void fraction (shown as α) as a function of the parameter X which is defined as

$$X = \left[\left(\frac{dP}{dz}\right)_{f\ell} \div \left(\frac{dP}{dz}\right)_{fg}\right]^{1/2} \tag{3.8.23}$$

where

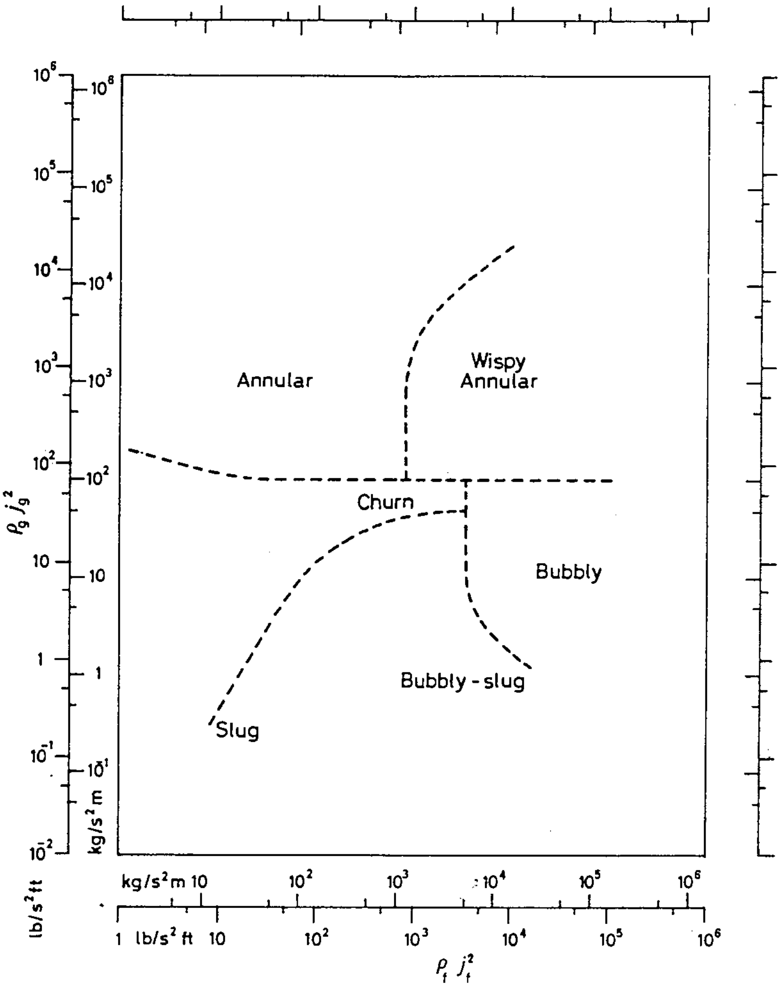

FIGURE 3.8.4 Flow pattern map for vertical flow (Hewitt and Roberts, 1969). (From Collier, J.G. 1972. *Convective Boiling and Condensation,* McGraw-Hill, London. With permission.)

$\left(\frac{dP}{dz}\right)_{f\ell}$ = frictional pressure gradient of liquid phase flowing alone in channel

$\left(\frac{dP}{dz}\right)_{fg}$ = frictional pressure gradient of gas phase flowing alone in channel

Often, flow rates are sufficiently high such that each phase if flowing alone in the channel would be turbulent. In this situation the parameter X can be shown to be

$$X_{tt} = \left(\frac{1-x_g}{x_g}\right)^{0.9}\left(\frac{\rho_g}{\rho_\ell}\right)^{0.5}\left(\frac{\mu_\ell}{\mu_g}\right)^{0.1} \tag{3.8.24}$$

Another type of separated-phase model is the drift-flux formulation of Wallis (1969). This approach focuses attention on relative slip between phases and results in slightly different expressions depending

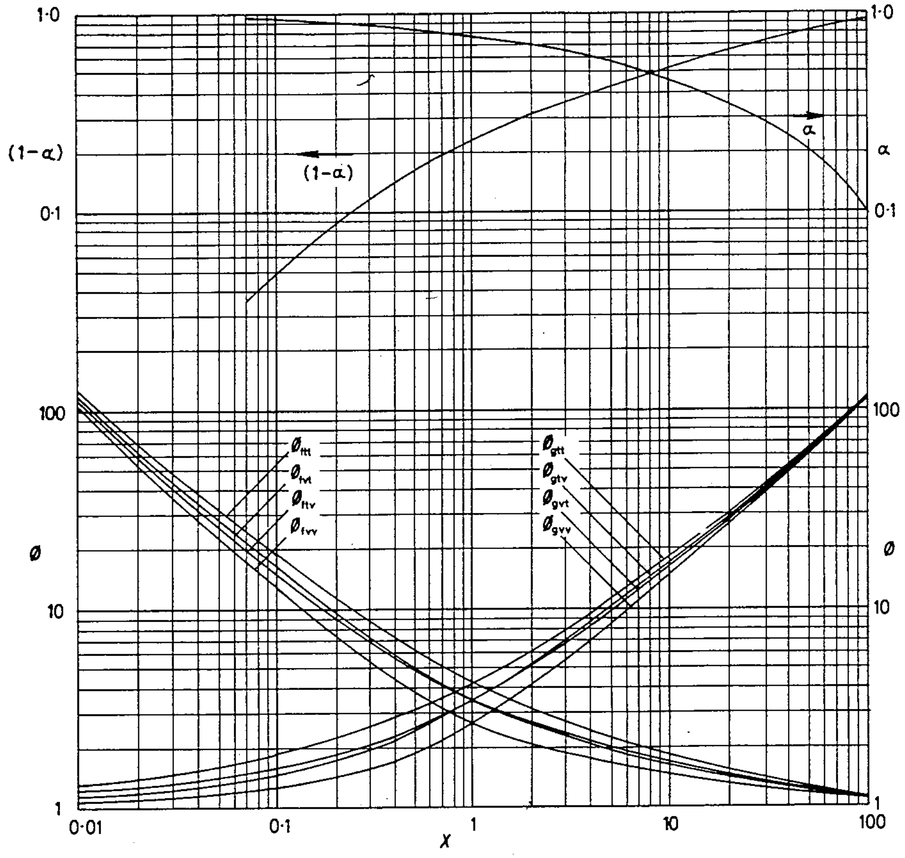

FIGURE 3.8.5 Correlations for void fraction and frictional pressure drop (Lockhart and Martinelli, 1949). (From Collier, J.G. 1972. *Convective Boiling and Condensation,* McGraw-Hill, London. With permission.)

on the flow regime. For co-current upflow in two of the more common regimes, the drift-flux model gives the following relationships between void fraction and flow quality:

Bubbly flow or churn-turbulent flow:

$$\alpha_g = \frac{x_g}{\left(\frac{u_o \rho_g}{G}\right) + C_o\left[x_g + \left(1 - x_g\right)\frac{\rho_g}{\rho_\ell}\right]} \tag{3.8.25}$$

Dispersed drop (mist) flow:

$$x_g = \frac{1 - \left(1 - \alpha_g\right)\left(\frac{u_o \rho_\ell}{G}\alpha_g^2 + 1\right)}{1 - \left(1 - \alpha_g\right)\left(1 - \frac{\rho_\ell}{\rho_g}\right)} \tag{3.8.26}$$

where

u_o = terminal rise velocity of bubble, in bubbly flow, or terminal fall velocity of drop in churn-turbulent flow

C_o = an empirical distribution coefficient $\simeq$ 1.2

Pressure Drop

Equation (3.8.16) through Equation (3.8.18) permit calculation of two-phase pressure drop by the homogeneous model, if the friction coefficient (f) is known. One useful method for estimating (f) is to treat the entire two-phase flow as if it were all liquid, except flowing at the two-phase mixture velocity. By this approach the frictional component of the two-phase pressure drop becomes

$$\left(\frac{dP}{dz}\right)_f = \left[1 + x_g\left(\frac{\rho_\ell}{\rho_g} - 1\right)\right] \cdot \left(\frac{dP}{dz}\right)_{f\ell G} \tag{3.8.27}$$

where $(dP/dz)_{f\ell G}$ = frictional pressure gradient if entire flow (of total mass flux G) flowed as liquid in the channel.

The equivalent frictional pressure drop for the entire flow as liquid, $(dP/dz)_{f\ell g}$, can be calculated by standard procedures for single-phase flow. In using Equation (3.8.16) through Equation (3.8.18), the void fraction would be calculated with the equivalent homogeneous expression Equation (3.8.13).

A more accurate method to calculate two-phase pressure drop is by the separated-phases model of Lockhart and Martinelli (1949). The bottom half of Figure 3.8.5 shows empirical curves for the Lockhart–Martinelli frictional multiplier, ϕ:

$$\phi_i = \left[\left(\frac{dP}{dz}\right)_f \div \left(\frac{dP}{dz}\right)_{fi}\right]^{1/2} \tag{3.8.28}$$

where (i) denotes either the fluid liquid phase (f) or gas phase (g). The single-phase frictional gradient is based on the ith phase flowing alone in the channel, in either viscous laminar (v) or turbulent (t) modes. The most common case is where each phase flowing alone would be turbulent, whence one could use Figure 3.8.5 to obtain

$$\begin{aligned}\left(\frac{dP}{dz}\right)_f &= \text{frictional pressure gradient for two-phase flow}\\ &= \phi_{gtt}^2 \cdot \left(\frac{dP}{dz}\right)_{fg}\end{aligned} \tag{3.8.29}$$

where $(dP/dz)_{fg}$ is calculated for gas phase flowing alone and $X = X_{tt}$ as given by Equation (3.8.24).

The correlation of Lockhart–Martinelli has been found to be adequate for two-phase flows at low-to-moderate pressures, i.e., with reduced pressures less than 0.3. For applications at higher pressures, the revised models of Martinelli and Nelson (1948) and Thom (1964) are recommended.

Gas–Solid, Liquid–Solid Two-Phase Flows

Two-phase flows can occur with solid particles in gas or liquid. Such flows are found in handling of granular materials and heterogeneous reaction processing. Concurrent flow of solid particulates with a fluid phase can occur with various flow patterns, as summarized below.

Flow Regimes

Consider vertical upflow of a fluid (gas or liquid) with solid particles. Figure 3.8.6 illustrates the major flow regimes that have been identified for such two-phase flows. At low flow rates, the fluid phase percolates between stationary particles; this is termed flow through a fixed bed. At some higher velocity a point is reached when the particles are all suspended by the upward flowing fluid, the drag force between particles and fluid counterbalancing the gravitational force on the particles. This is the point of minimum

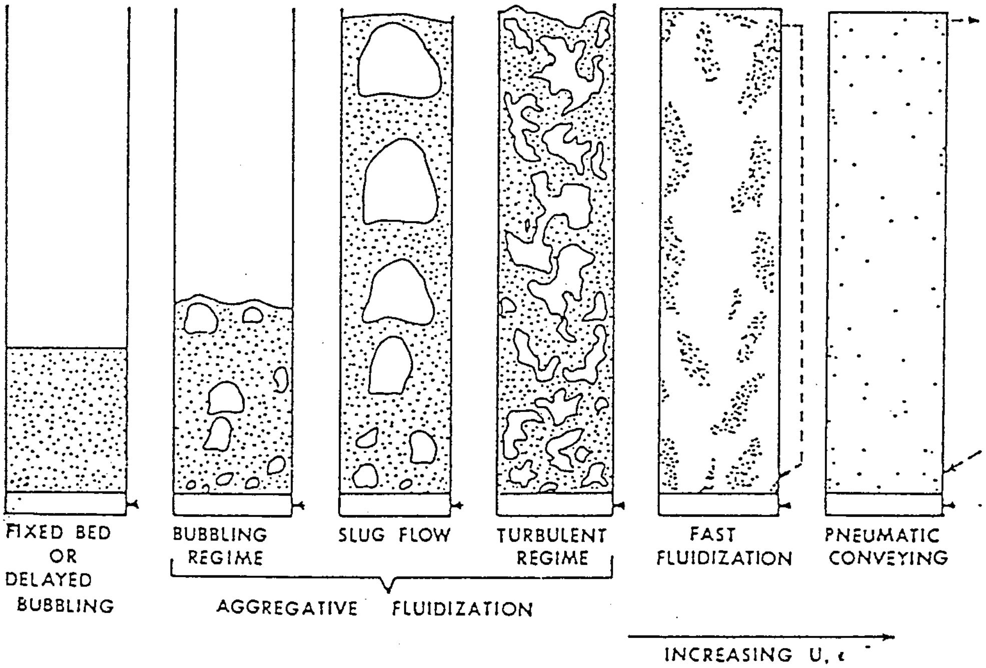

FIGURE 3.8.6 Flow patterns for vertical upflow of solid particles and gas or liquid. (From Chen, J.C. 1994. *Proc. Xth Int. Heat Transfer Conf.*, Brighton, U.K., 1:369–386. With permission.)

fluidization, marking the transition from fixed to fluidized beds. Increase of fluid flow rate beyond minimum fluidization causes instabilities in the two-phase mixture, and macroscopic bubbles or channels of fluid are observed in the case of gaseous fluids. In the case of liquid fluids, the two-phase mixture tends to expand, often without discrete bubbles or channels. Further increase of fluid velocity causes transition to turbulent fluidization wherein discrete regions of separated phases (fluid slugs or channels and disperse suspensions of particles) can coexist. Depending on specific operating conditions (e.g., superficial fluid velocity, particle size, particle density, etc.), net transport of solid particles with the flowing fluid can occur at any velocity equal to or greater than that associated with slug flow and turbulent flow. Further increases in fluid velocity increase the net transport of solid particles. This can occur with large-scale clusters of solid particles (as exemplified by the fast fluidization regime) or with dilute dispersions of solid particles (as often utilized in pneumatic conveying). For engineering application of fluid–solid two-phase flows, the important thresholds between flow regimes are marked by the fluid velocity for minimum fluidization, terminal slip, and saltation threshold.

Minimum Fluidization

The transition from flow through packed beds to the fluidization regime is marked by the minimum fluidization velocity of the fluid. On a plot pressure drop vs. superficial fluid velocity, the point of minimum fluidization is marked by a transition from a linearly increasing pressure drop to a relatively constant pressure drop as shown in Figure 3.8.7 for typical data, for two-phase flow of gas with sand particles of 280 μm mean diameter (Chen, 1996). The threshold fluid velocity at minimum fluidization is traditionally derived from the Carman–Kozeny equation,

$$U_{mf} = \frac{\left(\rho_s - \rho_f\right)\left(\phi\, dp\right)^2 g}{150\mu_f} \cdot \frac{\alpha_{mf}^2}{\left(1 - \alpha_{mf}\right)} \qquad (3.8.30)$$

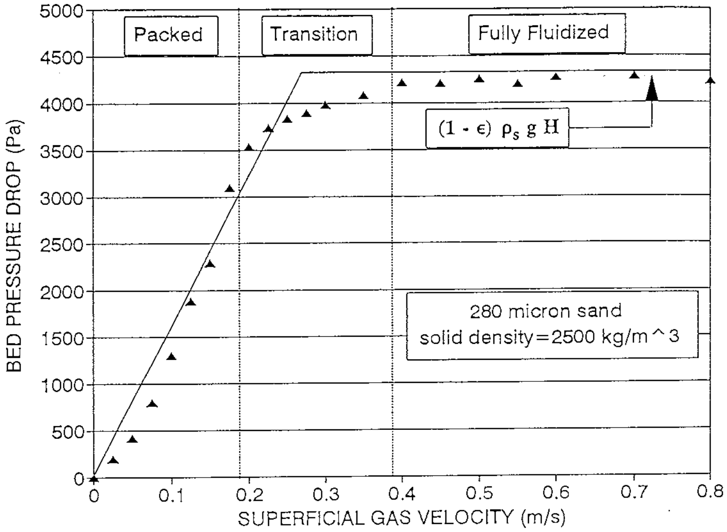

FIGURE 3.8.7 Transition at minimum fluidization. (From Chen, J.C. 1996. In *Annual Review of Heat Transfer*, Vol. VII, Begal House, Washington, D.C. With permission.)

where

ϕ = sphericity of particles (unity for spherical particles)
α_{mf} = volumetric fraction of fluid at minimum fluidization

Small, light particles have minimum fluidization voidage (α_{mf}) of the order 0.6, while larger particles such as sand have values closer to 0.4.

An alternative correlation for estimating the point of minimum fluidization is that of Wen and Yu (1966):

$$\frac{U_{mf} d_p \rho_f}{\mu_f} = (33.7 + 0.041 Ga)^{0.5} - 33.7 \tag{3.8.31}$$

where $Ga = \rho_f d_p^3 (\rho_s - \rho_f) g / \mu_f^2$.

When the fluid velocity exceeds U_{mf}, the two-phase mixture exists in the fluidized state in which the pressure gradient is essentially balanced by the gravitational force on the two-phase mixture:

$$\frac{dP}{dz} = g\left[\alpha_s \rho_s + \alpha_f \rho_f\right] \tag{3.8.32}$$

This fluidized state exists until the fluid velocity reaches a significant fraction of the terminal slip velocity, beyond which significant entrainment and transport of the solid particles occur.

Terminal Slip Velocity

For an isolated single particle the maximum velocity relative to an upflowing fluid is the terminal slip velocity. At this condition, the interfacial drag of the fluid on the particle exactly balances the gravitational body force on the particle:

$$U_t = \left(U_f - U_s\right)_t = \left[\frac{4 d_p \left(\rho_s - \rho_f\right)}{3 \rho_f} \cdot \frac{1}{C_D}\right]^{1/2} \tag{3.8.33}$$

where C_D = coefficient of drag on the particle.

The coefficient of drag on the particle (C_D) depends on the particle Reynolds number:

$$\mathrm{Re}_p = \frac{\rho_f d_p \left(U_f - U_s\right)}{\mu_f} \tag{3.8.34}$$

The following expressions may be used to estimate C_D as appropriate:

$$\begin{aligned} C_D &= \frac{32}{\mathrm{Re}_p}, && \mathrm{Re}_p \le 1 \\ C_D &= \frac{18.5}{\mathrm{Re}_p^{0.67}}, && 1 \le \mathrm{Re}_p \le 10^3 \end{aligned} \tag{3.8.35}$$

Pneumatic Conveying

A desirable mode of pneumatic conveying is two-phase flow with solid particles dispersed in the concurrent flowing fluid. Such dispersed flows can be obtained if the fluid velocity is sufficiently high. For both horizontal and vertical flows, there are minimum fluid velocities below which saltation of the solid particles due to gravitational force occurs, leading to settling of the solid particles in horizontal channels and choking of the particles in vertical channels. Figure 3.8.8 and Figure 3.8.9 for Zenz and Othmer (1960) show these different regimes of pneumatic conveying for horizontal and vertical transport, respectively. Figure 3.8.8 shows that for a given rate of solids flow (W) there is a minimum superficial fluid velocity below which solid particles tend to settle into a dense layer at the bottom of the horizontal channels. Above this saltation threshold, fully dispersed two-phase flow is obtained. In the case of vertical

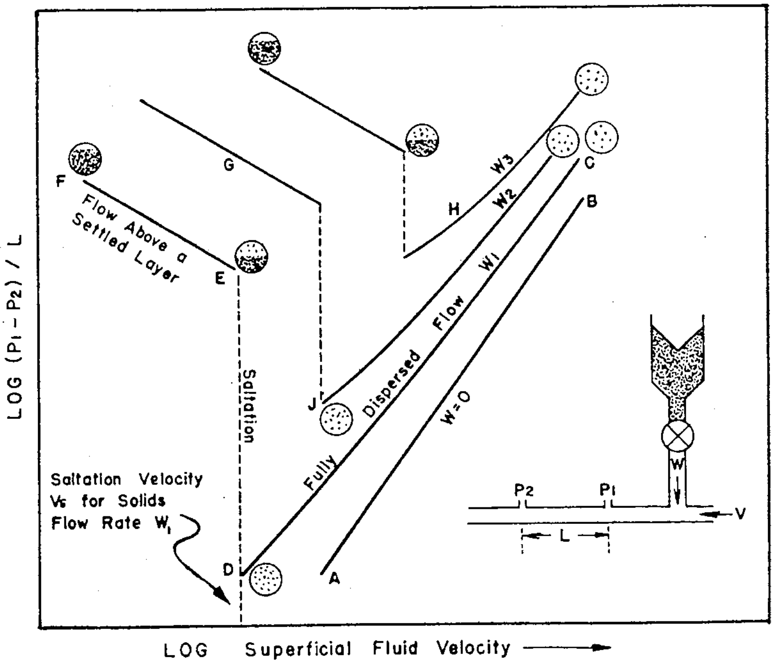

FIGURE 3.8.8 Flow characteristics in horizontal pneumatic conveying. (From Zeng, F.A. and Othmer, D.F. 1960. *Fluidization and Fluid-Particle Systems,* Reinhold, New York. With permission.)

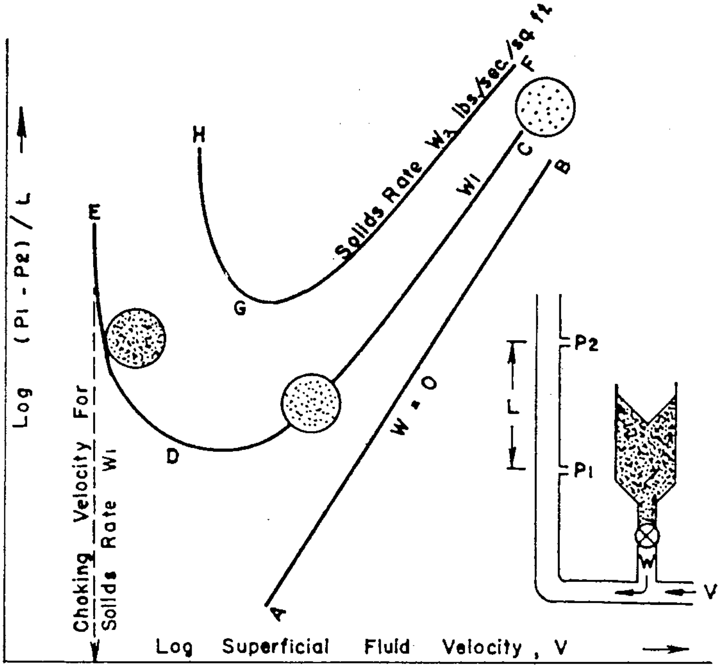

FIGURE 3.8.9 Flow characteristics in vertical pneumatic conveying. (From Zeng, F.A. and Othmer, D.F. 1960. *Fluidization and Fluid-Particle Systems,* Reinhold, New York. With permission.)

transport illustrated in Figure 3.8.9, there is a minimum fluid velocity below which solid particles tend to detrain from the two-phase suspension. This choking limit varies not only with particle properties but also with the actual rate of particle flow. Well-designed transport systems must operate with superficial fluid velocities greater than these limiting saltation and choking velocities.

Zenz and Othmer (1960) recommend the empirical correlations represented in Figure 3.8.10 estimating limiting superficial fluid velocities at incipient saltation or choking, for liquid or gas transport of uniformly sized particles. Note that these correlations are applicable for either horizontal or vertical concurrent flow. Figure 3.8.10 is duplicated from the original source and is based on parameters in engineering units, as noted in the figure. To operate successfully in dispersed pneumatic conveying of solid particles, the superficial fluid velocity must exceed that determined from the empirical correlations of Figure 3.8.10.

Nomenclature

A_c	cross-sectional flow area of channel
C_o	Wallis' distribution coefficient
d_p	diameter of solid particles
f_D	Darcy friction factor
G	mass flow flux, kg/m^2 · sec
j	volumetric flow flux, m/sec
$\dot{m}$	mass flow rate, kg/sec
P	pressure, N/m^2
u	velocity in axial flow direction, m/sec
v	superficial velocity in axial flow direction, m/sec
x	mass flow quality
z	axial coordinate

3.9 New-Newtonian Flows

Thomas F. Irvine Jr. and Massimo Capobianchi

Introduction

An important class of fluids exists which differ from Newtonian fluids in that the relationship between the shear stress and the flow field is more complicated. Such fluids are called non-Newtonian or rheological fluids. Examples include various suspensions such as coal–water or coal–oil slurries, food products, inks, glues, soaps, polymer solutions, etc.

An interesting characteristic of rheological fluids is their large "apparent viscosities". This results in laminar flow situations in many applications, and consequently the engineering literature is concentrated on laminar rather than turbulent flows. It should also be mentioned that knowledge of non-Newtonian fluid mechanics and heat transfer is still in an early stage and many aspects of the field remain to be clarified.

In the following sections, we will discuss the definition and classification of non-Newtonian fluids, the special problems of thermophysical properties, and the prediction of pressure drops in both laminar and turbulent flow in ducts of various cross-sectional shapes for different classes of non-Newtonian fluids.

Classification of Non-Newtonian Fluids

It is useful to first define a Newtonian fluid since all other fluids are non-Newtonian. Newtonian fluids possess a property called viscosity and follow a law analogous to the Hookian relation between the stress applied to a solid and its strain. For a one-dimensional Newtonian fluid flow, the shear stress at a point is proportional to the rate of strain (called in the literature the *shear rate*) which is the velocity gradient at that point. The constant of proportionality is the dynamic viscosity, i.e.,

$$\tau_{y,x} = \mu \frac{du}{dy} = \mu \dot{\gamma} \tag{3.9.1}$$

where x refers to the direction of the shear stress y the direction of the velocity gradient, and $\dot{\gamma}$ is the shear rate. The important characteristic of a Newtonian fluid is that the dynamic viscosity is independent of the shear rate.

Equation (3.9.1) is called a constitutive equation, and if $\tau_{x,y}$ is plotted against $\dot{\gamma}$, the result is a linear relation whose slope is the dynamic viscosity. Such a graph is called a *flow curve* and is a convenient way to illustrate the viscous properties of various types of fluids.

Fluids which do not obey Equation (3.9.1) are called non-Newtonian. Their classifications are illustrated in Figure 3.9.1 where they are separated into various categories of purely viscous time-independent or time-dependent fluids and viscoelastic fluids. Viscoelastic fluids, which from their name possess both viscous and elastic properties (as well as memory), have received considerable attention because of their ability to reduce both drag and heat transfer in channel flows. They will be discussed in a later subsection.

Purely viscous time-dependent fluids are those in which the shear stress in a function only of the shear rate but in a more complicated manner than that described in Equation (3.9.1). Figure 3.9.2 illustrates the characteristics of purely viscous time-independent fluids. In the figure, (a) and (b) are fluids where the shear stress depends only on the shear rate but in a nonlinear way. Fluid (a) is called pseudoplastic (or shear thinning), and fluid (b) is called dilatant (or shear thickening). Curve (c) is one which has an initial yield stress after which it acts as a Newtonian fluid, called Buckingham plastic, and curve (d), called Hershel-Buckley, also has a yield stress after which it becomes pseudoplastic. Curve (e) depicts a Newtonian fluid.

Figure 3.9.3 shows flow curves for two common classes of purely viscous time-dependent non-Newtonian fluids. It is seen that such fluids have a hysteresis loop or memory whose shape depends upon

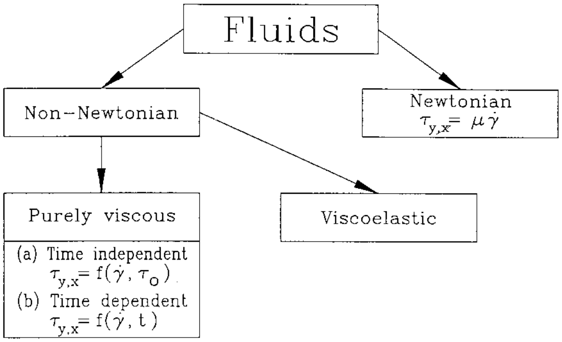

FIGURE 3.9.1 Classification of fluids.

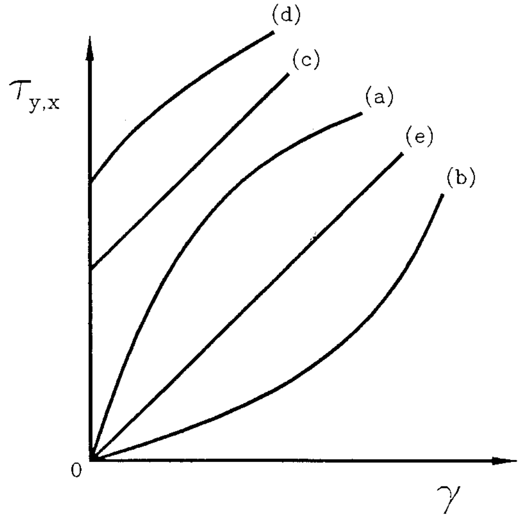

FIGURE 3.9.2 Flow curves of purely viscous, time-independent fluids: (a) pseudoplastic; (b) dilatant; (c) Bingham plastic; (d) Hershel–Buckley; (e) Newtonian.

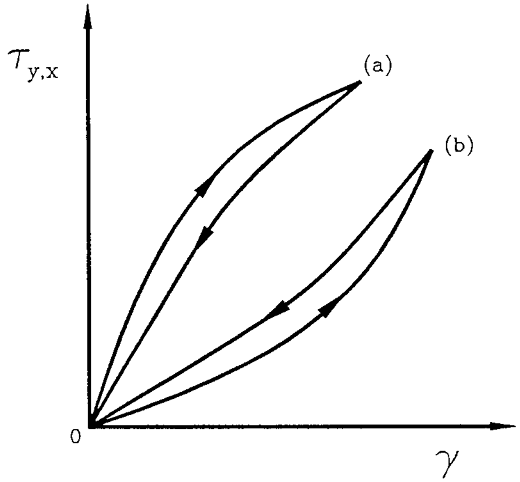

FIGURE 3.9.3 Flow curves for purely viscous, time-dependent fluids: (a) thixotropic; (b) rheopectic.

the time-dependent rate at which the shear stress is applied. Curve (a) illustrates a pseudoplastic time-dependent fluid and curve (b) a dilatant time-dependent fluid. They are called, respectively, thixotropic and rheopectic fluids and are complicated by the fact that their flow curves are difficult to characterize for any particular application.

Apparent Viscosity

Although non-Newtonian fluids do not have the property of viscosity, in the Newtonian fluid sense, it is convenient to define an apparent viscosity which is the ratio of the local shear stress to the shear rate at that point.

$$\mu_a = \frac{\tau}{\dot{\gamma}} \tag{3.9.2}$$

The apparent viscosity is not a true property for non-Newtonian fluids because its value depends upon the flow field, or shear rate. Nevertheless, it is a useful quantity and flow curves are often constructed with the apparent viscosity as the ordinate and shear rate as the abscissa. Such a flow curve will be illustrated in a later subsection.

Constitutive Equations

A constitutive equation is one that expresses the relation between the shear stress or apparent viscosity and the shear rate through the rheological properties of the fluid. For example, Equation (3.9.1) is the constitutive equation for a Newtonian fluid.

Many constitutive equations have been developed for non-Newtonian fluids with some of them having as many as five rheological properties. For engineering purposes, simpler equations are normally satisfactory and two of the most popular will be considered here.

Since many of the non-Newtonian fluids in engineering applications are pseudoplastic, such fluids will be used in the following to illustrate typical flow curves and constitutive equations. Figure 3.9.4 is a qualitative flow curve for a typical pseudoplastic fluid plotted with logarithmic coordinates. It is seen in the figure that at low shear rates, region (a), the fluid is Newtonian with a constant apparent viscosity of μ_o (called the *zero shear rate viscosity*). At higher shear rates, region (b), the apparent viscosity begins to decrease until it becomes a straight line, region (c). This region (c) is called the power law region and is an important region in fluid mechanics and heat transfer. At higher shear rates than the power law region, there is another transition region (d) until again the fluid becomes Newtonian in region (e). As discussed below, regions (a), (b), and (c) are where most of the engineering applications occur.

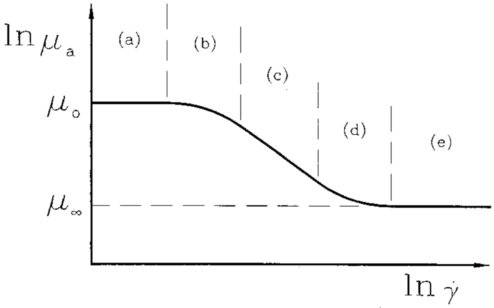

FIGURE 3.9.4 Illustrative flow curve for a pseudoplastic fluid (a) Newtonian region; (b) transition region I; (c) power law region; (d) transition region II; (e) high-shear-rate Newtonian region.

Power Law Constitutive Equation

Region (c) in Figure 3.9.4, which was defined above as the power law region, has a simple constitutive equation:

$$\tau = K\dot{\gamma}^{n} \tag{3.9.3}$$

or, from Equation (3.9.2):

$$\mu_a = K\dot{\gamma}^{n-1} \tag{3.9.4}$$

Here, K is called the fluid consistency and n the flow index. Note that if $n = 1$, the fluid becomes Newtonian and K becomes the dynamic viscosity. Because of its simplicity, the power law constitutive equation has been most often used in rheological studies, but at times it is inappropriate because it has several inherent flaws and anomalies. For example, if one considers the flow of a pseudoplastic fluid ($n < 1$) through a circular duct, because of symmetry at the center of the duct the shear rate (velocity gradient) becomes zero and thus the apparent viscosity from Equation (3.9.4) becomes infinite. This poses conceptual difficulties especially when performing numerical analyses on such systems. Another difficulty arises when the flow field under consideration is not operating in region (c) of Figure 3.9.4 but may have shear rates in region (a) and (b). In this case, the power law equation is not applicable and a more general constitutive equation is needed.

Modified Power Law Constitutive Equation

A generalization of the power law equation which extends the shear rate range to regions (a) and (b) is given by

$$\mu_a = \frac{\mu_o}{1 + \dfrac{\mu_o}{K}\dot{\gamma}^{1-n}} \tag{3.9.5}$$

Examination of Equation (3.9.5) reveals that at low shear rates, the second term in the denominator becomes small compared with unity and the apparent viscosity becomes a constant equal to μ_O. This represents the Newtonian region in Figure 3.9.4. On the other hand, as the second term in the denominator becomes large compared with unity, Equation (3.9.5) becomes Equation (3.9.4) and represents region (c), the power law region. When both denominator terms must be considered, Equation (3.9.5) represents region (b) in Figure 3.9.4.

An important advantage of the modified power law equation is that it retains the rheological properties K and n of the power law model plus the additional property μ_o. Thus, as will be shown later, in the flow and heat transfer equations, the same dimensionless groups as in the power law model will appear plus an additional dimensionless parameter which describes in which of the regions (a), (b), or (c) a particular system is operating. Also, solutions using the modified power law model will have Newtonian and power law solutions as asymptotes.

Equation (3.9.5) describes the flow curve for a pseudoplastic fluid ($n < 1$). For a dilatant fluid, ($n > 1$), an appropriate modified power law model is given by

$$\mu_a = \mu_o\left[1 + \frac{K}{\mu_o}\dot{\gamma}^{n-1}\right] \tag{3.9.6}$$

Many other constitutive equations have been proposed in the literature (Skelland, 1967; Cho and Hartnett, 1982; Irvine and Karni, 1987), but the ones discussed above are sufficient for a large number of engineering applications and agree well with the experimental determinations of rheological properties.

TABLE 3.9.1 Rheological Properties Used in the Modified Power Law Equations in Figure 3.9.5 for Three Polymer Solutions of CMC-7H4

CMC	K (N · sec^n/m^2)	n	μ_o (N · sec/m^2)n

Rheological Property Measurements

For non-Newtonian fluids, specifying the appropriate rheological properties for a particular fluid is formidable because such fluids are usually not pure substances but various kinds of mixtures. This means that the properties are not available in handbooks or other reference materials but must be measured for each particular application. A discussion of the various instruments for measuring rheological properties is outside the scope of the present section, but a number of sources are available which describe different rheological property measurement techniques and instruments: Skelland (1967), Whorlow (1980), Irvine and Karni (1987), and Darby (1988). Figure 3.9.5 is an illustration of experimental flow curves measured with a falling needle viscometer and a square duct viscometer for polymer solutions of different concentrations. Also known in the figure as solid lines is the modified power law equation used to represent the experimental data. It is seen that Equation (3.9.5) fits the experimental data within ±2%. Table 3.9.1 lists the rheological properties used in the modified power law equations in Figure 3.9.5. It must be emphasized that a proper knowledge of these properties is vital to the prediction of fluid mechanics and heat transfer phenomena in rheological fluids.

Fully Developed Laminar Pressure Drops for Time-Independent Non-Newtonian Fluids

Modified Power Law Fluids

This important subject will be considered by first discussing modified power law fluids. The reason is that such solutions include both friction factor–Reynolds number relations and a shear rate parameter. The latter allows the designer to determine the shear rate region in which his system is operating and thus the appropriate solution to be used, i.e., regions (a), (b), or (c) in Figure 3.9.4.

For laminar fully developed flow of a modified power law fluid in a circular duct, the product of the friction factor and a certain Reynolds number is a constant depending on the flow index, n, and the shear rate parameter, β.

$$f_D \cdot \mathrm{Re}_m = \mathrm{constant}(n,\beta) \tag{3.9.7}$$

where f_D is the Darcy friction factor and Re_m the modified power law Reynolds number, i.e.,

$$f_D = \frac{2\dfrac{\Delta p}{L}D_H}{\rho \bar{u}^2} \quad \text{(Darcy friction factor)}^5$$

$$\mathrm{Re}_m = \frac{\rho \bar{u} D_H}{\mu^*}$$

---

[5] It should be noted that the Fanning friction factor is also used in the technical literature. The Fanning friction factor is ¼ of the Darcy friction factor, and will be characterized by the symbol f_F.

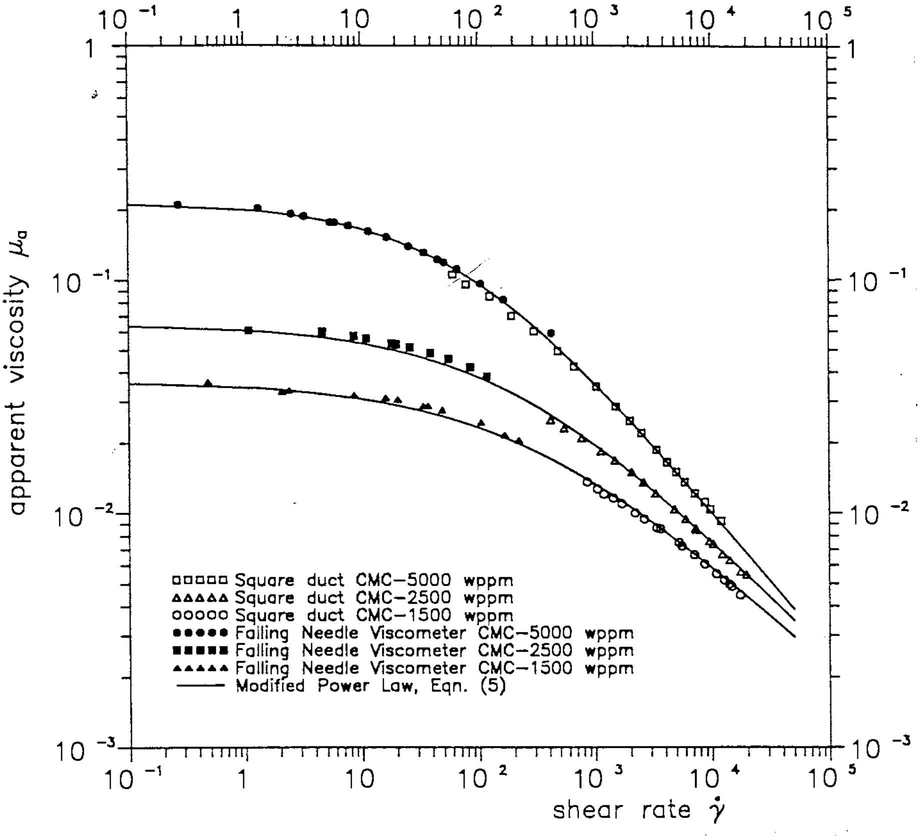

FIGURE 3.9.5 Experimental measurements of apparent viscosity vs. shear rate for polymer solutions (CMC-7H4) at different concentrations. (From Park, S. et al., in *Proc. Third World Conf. Heat Transfer, Fluid Mechanics, and Thermodynamics,* Vol. 1, Elsevier, New York, 1993, 900–908.

$$\mu^* = \frac{\mu_o}{1+\beta}$$

$$\beta = \frac{\mu_o}{K}\left(\frac{\bar{u}}{D_H}\right)^{1-n}$$

where β is the shear rate parameter mentioned previously which can be calculated by the designer for a certain operating duct ($\bar{u}$ and d) and a certain pseudoplastic fluid (μ_o, K, n). The solution for a circular tube has been calculated by Brewster and Irvine (1987) and the results are shown in Figure 3.9.6 and in Table 3.9.2. Referring to 3.9.6, we can see that when the $\log_{10} \beta$ is less than approximately –2, the duct is operating in region (a) of Figure 3.9.4 which is the Newtonian region and therefore classical Newtonian solutions can be used. Note that in the Newtonian region, Re_m reverts to the Newtonian Reynolds number given by

$$\mathrm{Re}_N = \frac{\rho \bar{u} D_H}{\mu_o} \tag{3.9.8}$$

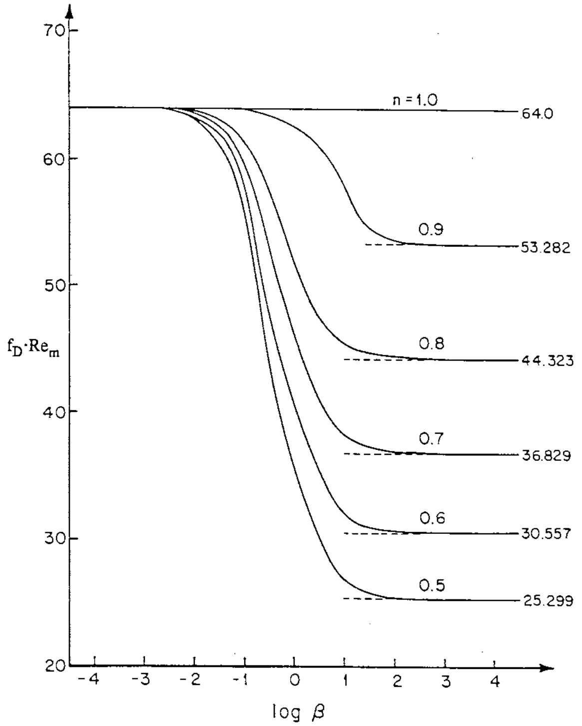

FIGURE 3.9.6 Product of friction factor and modified Reynolds number vs. $\log_{10} \beta$ for a circular duct. (From Brewster, R.A. and Irvine, T.F., Jr., *Wärme und Stoffübertragung,* 21, 83–86, 1987.

Source: Brewster, R.A. and Irvine, T.F., Jr., *Wärme und Stoffübertragung,* 21, 83–86, 1987. With permission.

When the value of $\log_{10} \beta$ is approximately in the range $-2 \leq \log_{10} \beta \leq 2$, the duct is operating in the transition region (b) of Figure 3.9.4 and the values of $f_D \cdot \mathrm{Re}_m$ must be obtained from Figure 3.9.6 or from Table 3.9.2.

When $\log_{10} \beta$ is greater than approximately 2, the duct is operating in the power law region (c) of Figure 3.9.4 and power law friction factor Reynolds number relations can be used. They are also indicated in Figure 3.9.6 and Table 3.9.2. In this region, Re_m becomes the power law Reynolds number given by

$$\mathrm{Re}_g = \frac{\rho \bar{u}^{2-n} D_H^n}{K} \tag{3.9.9}$$

For convenience, Brewster and Irvine (1987) have presented a correlation equation which agrees within 0.1% with the results tabulated in Table 3.9.2.

$$f_D \cdot \mathrm{Re}_m = \frac{1+\beta}{\dfrac{1}{64} + \dfrac{\beta}{2^{3n+3}\left(\dfrac{3n+1}{4n}\right)^n}} \tag{3.9.10}$$

Thus, Equation (3.9.10) contains all of the information required to calculate the circular tube laminar fully developed pressure drop for a pseudoplastic fluid depending upon the shear rate region(s) under consideration, i.e., regions (a), (b), or (c) of Figure 3.9.4. Note that in scaling such non-Newtonian systems, both Re_m and β must be held constant. Modified power law solutions have been reported for two other duct shapes. Park et al. (1993) have presented the friction factor–Reynolds number relations for rectangular ducts and Capobianchi and Irvine (1992) for concentric annular ducts.

Power Law Fluids

Since the power law region of modified power law fluids ($\log_{10} \beta \geq 2$) is often encountered, the friction factor–Reynolds number relations will be discussed in detail in this subsection.

An analysis of power law fluids which is most useful has been presented by Kozicki et al. (1967). Although the method is approximate, its overall accuracy (±5%) is usually sufficient for many engineering calculations. His expression for the friction factor–Reynolds number product is given by

$$f_D \cdot \mathrm{Re}^* = 2^{6n} \tag{3.9.11}$$

where

$$\mathrm{Re}^* = \text{Kozicki Reynolds number}, \quad \mathrm{Re}^* = \frac{\mathrm{Re}_g}{\left[\dfrac{a+bn}{n}\right]^n 8^{n-1}} \tag{3.9.12}$$

and a and b are geometric constants which depend on the cross-sectional shape of the duct. For example, for a circular duct, $a = 0.25$ and $b = 0.75$. Values of a and b for other duct shapes are tabulated in Table 3.9.3. For additional duct shapes in both closed and open channel flows, Kozicki et al. (1967) may be consulted.

Fully Developed Turbulent Flow Pressure Drops

In a number of engineering design calculations for turbulent flow, the shear rate range falls in region (c) of Figure 3.9.4. Thus, power law relations are appropriate for such pressure drop calculations.

Hartnett and Kostic (1990) have investigated the various correlations which have appeared in the literature for circular tubes and have concluded that for a circular tube the relation proposed by Dodge and Metzner (1959) is the most reliable for pseudoplastic fluids. It is given by

$$\frac{1}{f_F^{1/2}} = \frac{4.0}{n^{0.75}} \cdot \log_{10}\left[\mathrm{Re}'_g \left(f_F\right)^{1-(1/2n)}\right] - \frac{0.40}{n^{1.2}} \tag{3.9.13}$$

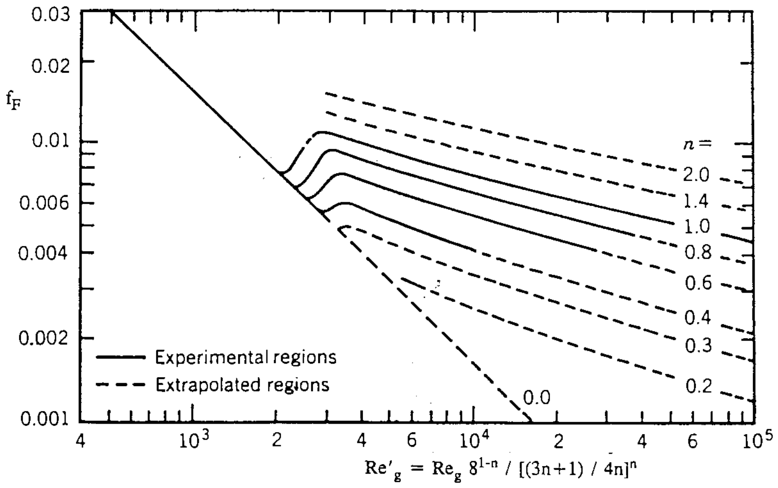

FIGURE 3.9.7 Dodge and Metzner relation between Fanning friction factor and Re'_g. (From Dodge, D.W. and Metzner, A.B., *AIChE J.*, 5, 189–204, 1959.)

where f_F is the Fanning friction factor and

$$\mathrm{Re}'_g = \mathrm{Re}_g \left[\frac{8^{1-n}}{\left[\dfrac{3n+1}{4n}\right]^n} \right] \tag{3.9.14}$$

Figure 3.9.7 is a graphical representation of Equation (3.9.13) which indicates the Dodge and Metzner experimental regions by solid lines, and by dashed lines where the data are extrapolated outside of their experiments.

For noncircular ducts in turbulent fully developed flow, only a limited amount of experimental data are available. Kostic and Hartnett (1984) suggest the correlation:

$$\frac{1}{f_F^{1/2}} = \frac{4}{n^{0.75}} \cdot \log_{10}\left[\mathrm{Re}^*\left(f_F\right)^{1-(1/2n)}\right] - \frac{0.40}{n^{0.5}} \tag{3.9.15}$$

where f_F is again the Fanning friction factor and Re^* is the Kozicki Reynolds number:

$$\mathrm{Re}^* = \frac{\mathrm{Re}_g}{\left[\dfrac{a+bn}{n}\right]^n 8^{n-1}} \tag{3.9.16}$$

and a and b are geometric constants given in Table 3.9.3.

Viscoelastic Fluids

Fully Developed Turbulent Flow Pressure Drops

Viscoelastic fluids are of interest in engineering applications because of reductions of pressure drop and heat transfer which occur in turbulent channel flows. Such fluids can be prepared by dissolving small amounts of high-molecular-weight polymers, e.g., polyacrylamide, polyethylene oxide (Polyox), etc., in

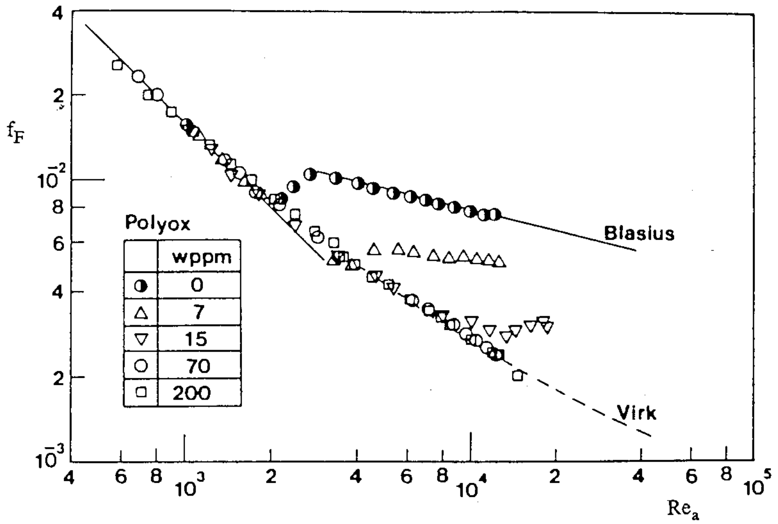

FIGURE 3.9.8 Reduction in friction factors for polyethylene oxide (Polyox) solutions in a small-diameter capillary tube. (From Cho, Y.I. and Harnett, J.P., *Adv. Heat Transfer,* 15, 59–141, 1982. With permission.)

water. Concentrations as low as 5 parts per million by weight (wppm) result in significant pressure drop reductions. Figure 3.9.8 from Cho and Hartnett (1982) illustrates the reduction in friction factors for Polyox solutions in a small-diameter capillary tube. It is seen that at zero polymer concentration the data agree with the Blasius equation for Newtonian turbulent flow. With the addition of only 7 wppm of Polyox, there is a significant pressure drop reduction and for concentrations of 70 wppm and greater all the data fall on the Virk line which is the maximum drag-reduction asymptote. The correlations for the Blasius and Virk lines as reported by Cho and Hartnett (1982) are

$$f_F = \frac{0.079}{\text{Re}^{1/4}} \quad \text{(Blasius)} \tag{3.9.17}$$

$$f_F = 0.20\,\text{Re}_a^{-0.48} \quad \text{(Virk)} \tag{3.9.18}$$

At the present time, no generally accepted method exists to predict the drag reduction between the Blasius and Virk lines. Kwack and Hartnett (1983) have proposed that the amount of drag reduction between those two correlations is a function of the Weissenberg number, defined as

$$w_s = \frac{\lambda \bar{u}}{D_H} \tag{3.9.19}$$

where λ = characteristic time of the viscoelastic fluid. They present correlations which allow the friction factor to be estimated at several Reynolds numbers between the Blasius and Virk lines.

Fully Developed Laminar Flow Pressure Drops

The above discussion on viscoelastic fluids has only considered fully developed turbulent flows. Laminar fully developed flows can be considered as nonviscoelastic but purely viscous non-Newtonian. Therefore, the method of Kozicki et al. (1967) may be applied to such situations once the appropriate rheological properties have been determined.

Nomenclature

a = duct shape geometric constant
b = duct shape geometric constant
c = duct width (see Table 3.9.3) (m)
d_i = concentric annuli inner diameter (see Table 3.9.3) (m)
d_o = concentric annuli outer diameter (see Table 3.9.3) (m)
f_D = Darcy friction factor
f_F = Fanning friction factor
h = duct height (see Table 3.9.3) (m)
K = fluid consistency ($\mathrm{Ns^n/m^2}$)
n = flow index
N = number of sides in polygon (see Table 3.9.3)
Re_g = generalized Reynolds number,

$$\mathrm{Re}_g = \frac{\rho \bar{u}^{2-n} D_H^n}{K}$$

Re_m = modified power law Reynolds number,

$$\mathrm{Re}_m = \frac{\rho \bar{u} D_H}{\mu^*}$$

Re_N = modified power law Reynolds number Newtonian asymptote,

$$\mathrm{Re}_N = \frac{\rho \bar{u} D_H}{\mu_o}$$

Re_a = apparent Reynolds number

$$\mathrm{Re}_a = \frac{\mathrm{Re}_g}{\left(\frac{3n+1}{4n}\right)^{n-1} 8^{n-1}}$$

Re^* = Kozicki Reynolds number

$$\mathrm{Re}^* = \frac{\rho \bar{u}^{2-n} D_H^n}{K\left[\frac{a+bn}{n}\right]^n 8^{n-1}}$$

Re'_g = Metzner Reynolds number

$$\mathrm{Re}'_g = \mathrm{Re}_g\left[\frac{8^{1-n}}{\left[\frac{3n+1}{4n}\right]^n}\right]$$

$\bar{u}$ = average streamwise velocity (m/sec)
t = time (sec)
w_s = Weissenberg number
x = direction of shear stress (m)
y = direction of velocity gradient (m)

Greek

α^* = duct aspect ratio in Table 3.9.3
β = shear rate parameter

$$\beta = \frac{\mu_o}{K}\left(\frac{\bar{u}}{D_H}\right)^{1-n}$$

$\dot{\gamma}$ = shear rate (L/sec)
ΔP = presure drop (N/m^2)
λ = characteristic time of viscoelastic fluid (sec)
μ_a = apparent viscosity (N · sec/m^2)
μ_o = zero shear rate viscosity (N · sec/m^2)
μ_∞ = high shear rate viscosity (N · sec/m^2)
μ^* = reference viscosity

$$\mu^* = \frac{\mu_o}{1+\beta} \quad \left(\mathrm{N\cdot sec/m^2}\right)$$

τ_o = yield stress (N/m^2)
$\tau_{y,x}$ = shear stress (N/m^2)
ϕ = half apex angle (see Table 3.9.3) (°)

Further Information

It is not possible to include all of the interesting non-Newtonian topics in a section of this scope. Other items which may be of interest and importance are listed below along with appropriate references: hydrodynamic and thermal entrance lengths, Cho and Hartnett (1982); non-Newtonian flow over external surfaces, Irvine and Karni (1987); chemical, solute, and degradation effects in viscoelastic fluids, Cho and Harnett (1982); general references, Skelland (1967), Whorlow (1980), and Darby (1988).

3.10 Tribology, Lubrication, and Bearing Design

Francis E. Kennedy, E. Richard Booser, and Donald F. Wilcock

Introduction

Tribology — the science and technology of contacting surfaces involving friction, wear, and lubrication — is extremely important in nearly all mechanical components. A major focus of the field is on friction, its consequences, especially wear, and its reduction through lubrication and material surface engineering. The improper solution of tribological problems is responsible for huge economic losses in society, including shortened component lives, excessive equipment down time, and large expenditures of energy. It is particularly important that engineers use appropriate means to reduce friction and wear in mechanical systems through the proper selection of bearings, lubricants, and materials for all contacting surfaces. The aim of this chapter is to assist in that endeavor.

Sliding Friction and Its Consequences

Coefficient of Friction

If two stationary contacting bodies are held together by a normal force W, and if a tangential force is applied to one of them, the tangential force can be increased until it reaches a magnitude sufficient to initiate sliding. The ratio of the friction force at incipient sliding to the normal force is known as the static coefficient of friction, f_s. After sliding begins, the friction force always acts in the direction opposing motion and the ratio between that friction force and the applied normal force is the kinetic coefficient of friction, f_k.

Generally, f_k is slightly smaller than f_s and both coefficients are independent of the size or shape of the contacting surfaces. Both coefficients are very much dependent on the materials and cleanliness of the two contacting surfaces. For ordinary metallic surfaces, the friction coefficient is not very sensitive to surface roughness. For ultrasmooth or very rough surfaces, however, the friction coefficient can be larger. Typical friction coefficient values are given in Table 3.10.1. Generally, friction coefficients are greatest

TABLE 3.10.1 Some Typical Friction Coefficients[a]

Material Pair	Static Friction Coefficient, f_s		Kinetic Friction Coefficient, f_k	
	In Air	In Vacuo	In Air, Dry	Oiled
Mild steel vs. mild steel	0.75		0.57	0.16
Mild steel vs. copper	0.53	0.5 (oxidized) 2.0 (clean)	0.36	0.18
Copper vs. copper	1.3	21.0	0.8	0.1
Tungsten carbide vs. copper	0.35		0.4	
Tungsten carbide vs. tungsten carbide	0.2	0.4	0.15	
Mild steel vs. PTFE	0.04		0.05	0.04

[a] The friction coefficient values listed in this table were compiled from several of the references listed at the end of this section.

when the two surfaces are identical metals, slightly lower with dissimilar but mutually soluble metals, still lower for metal against nonmetal, and lowest for dissimilar nonmetals.

The kinetic coefficient of friction, f_k, for metallic or ceramic surfaces is relatively independent of sliding velocity at low and moderate velocities, although often a slight decrease occurs in f_k at higher velocities. With polymers and soft metals, the friction coefficient may increase with increasing velocity until a peak is reached, after which the friction may decrease with further increases in velocity or temperature. The decrease in kinetic friction coefficient with increasing velocity, which may become especially pronounced at higher sliding velocities, can be responsible for friction-induced vibrations (stick-slip oscillations) of the sliding systems. Such vibrations are an important design consideration for clutches and braking systems; they can also be important in the accurate control and positioning of robotic mechanisms and precision manufacturing systems.

Wear

Wear is the unwanted removal of material from solid surfaces by mechanical means; it is one of the leading reasons for the failure and replacement of manufactured products. It has been estimated that the costs of wear, which include repair and replacement along with equipment downtime, constitute up to 6% of the U.S. gross national product (Rabinowicz, 1995). Wear can be classified into four primary types: sliding wear, abrasion, erosion, and corrosive wear. Owing to its importance, wear and its control have been the subject of several handbooks (Peterson and Winer, 1980; Blau, 1992) that the interested reader may consult for further information.

Types of Wear

Sliding wear occurs to some degree whenever solid surfaces are in sliding contact; the two predominant sliding wear mechanisms are adhesion and surface fatigue. *Adhesive wear* is caused by strong adhesive forces between the two surfaces within the real area of contact. It results in the removal of small particles from at least one of the surfaces, usually the softer one. These particles can then transfer to the other surface or mix with other material from both surfaces before being expelled as loose wear debris. Adhesive wear can be particularly severe for surfaces that have a strong affinity for each other, such as those made from identical metals. *Surface fatigue wear* occurs when repeated sliding or rolling/sliding over a wear track results in the initiation of surface or subsurface cracks and the propagation of those cracks produces wear particles in ductile materials by a process called delamination. With brittle materials, sliding wear often occurs by a *surface fracture* process.

After an initial transition or "running-in" period, sliding wear tends to reach a steady-state rate, which is approximated by the following Archard (or Holm–Archard) wear equation:

$$V = K * W * s/H \tag{3.10.1}$$

where V = volume of worn material; K = dimensionless wear coefficient; s = sliding distance; W = normal load between the surfaces; and H = hardness of the softer of the two contacting surfaces.

The dimensionless wear coefficient gives an indication of the tendency of a given material combination to wear; relative wear coefficient values are given in Figure 3.10.1. In general, wear coefficients are highest for identical metals sliding without lubrication, and wear is decreased by adding a lubricant and by having dissimilar material pairs.

Abrasive wear occurs when a hard, rough surface slides against a softer surface (*two-body abrasion*) or when hard particles slide between softer surfaces (*three-body abrasion*). This process usually results in material removal by plowing or chip formation, especially when the abraded surface is metallic; surface fracture can occur during abrasion of brittle surfaces. In fact, abrasion mechanisms are similar to those of grinding and lapping, which could be considered intentional abrasion. Consideration of the cutting and plowing processes shows that abrasive wear obeys the same equation (Equation 3.10.1) as sliding wear does (Archard, 1980; Rabinowicz, 1995). Typical wear coefficients for abrasive wear are given in Figure 3.10.1. Because the relative size, hardness, and sharpness of the abrading particles, or surface

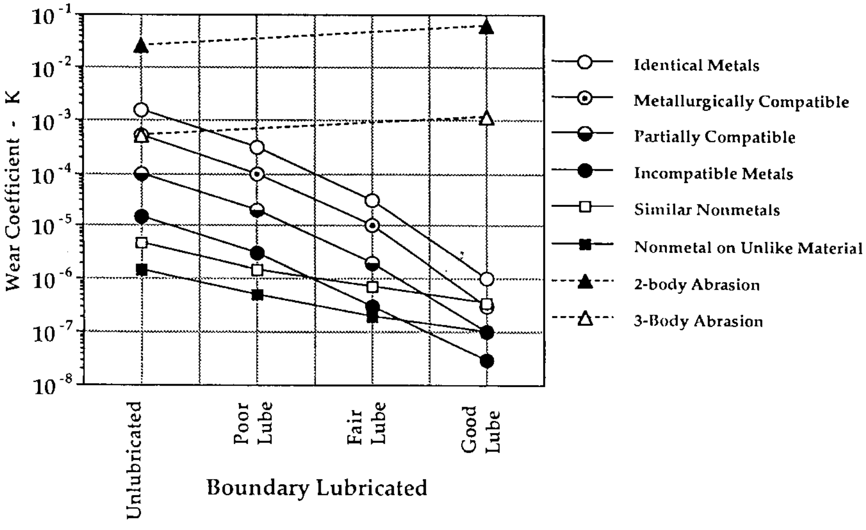

FIGURE 3.10.1 Typical values of wear coefficient for sliding and abrasive wear. (Modified from Rabinowicz, E., in *Wear Control Handbook*, M.B. Peterson and W.O. Winder, Eds., 475–506, ASME, New York, 1980, and Rabinowicz, E., *Friction and Wear of Materials*, 2nd ed., John Wiley & Sons, New York, 1995.)

asperities, also affect abrasive wear rates, the wear coefficients for abrasion must include recognition of those factors (Rabinowicz, 1995).

Erosion occurs when solid particles or liquid droplets impinge on a solid surface. When impingement is on a ductile metallic surface, the wear process is similar to that caused by abrasion and is dominated by plastic deformation. Brittle surfaces, on the other hand, tend to erode by surface fracture mechanisms. The material removal rate is dependent on the angle of attack of the particles, with erosion reaching a peak at low angles (about 20°) for ductile surfaces and at high angles (90°) for brittle materials. In either case, the wear rate is proportional to the mass rate of flow of the particles and to their kinetic energy; it is inversely proportional to the hardness of the surface and the energy-absorbing potential (or toughness) of the impinged surface (Schmitt, 1980). Although erosion is usually detrimental, it can be used beneficially in such material removal processes as sand blasting and abrasive water-jet machining.

Corrosive wear results from a combination of chemical and mechanical action. It involves the synergistic effects of chemical attack (corrosion) of the surface, followed by removal of the corrosion products by a wear mechanism to expose the metallic surface, and then repetition of those processes. Because many corrosion products act to protect the surfaces from further attack, the removal of those films by wear acts to accelerate the rate of material removal. Corrosive wear can become particularly damaging when it acts in a low-amplitude oscillatory contact, which may be induced by vibration, in which case it is called *fretting corrosion.*

Means for Wear Reduction

The following actions can be taken to limit *sliding wear*:

- Ensure that the sliding surfaces are well lubricated. This can best be accomplished by a liquid lubricant; however, grease or solid lubricants such as graphite or molybdenum disulfide can sometimes be effective when liquid lubricants cannot be used.
- Choose dissimilar materials for sliding pairs.
- Use hardened surfaces.
- Add wear-resistant coatings to the contacting surfaces (see the following subsection).
- Reduce normal loads acting on the contact.
- Reduce surface temperatures (particularly important for polymer surfaces).

To reduce *abrasive wear*:

- Use hardened surfaces.
- Add a hard surface coating.
- Reduce the roughness of hard surfaces in contact with softer surfaces.
- Provide for the removal of abrasive particles from contacting surfaces. This can be done by flushing surfaces with liquid and/or filtering liquid coolants and lubricants.
- Reduce the size of abrasive particles.

To reduce *erosion*:

- Modify the angle of impingement of solid particles or liquid droplets.
- Provide for the removal of solid particles from the impinging stream of fluid.
- Use hardened surfaces.
- Use tough materials for surfaces.
- Add protective coating to surfaces.

Surface Engineering for Friction and Wear Reduction

Surface treatments have long been an important remedy for wear problems —an importance that has grown in recent years with the introduction of new techniques to harden surfaces or apply hard surface coatings (Bhushan, 1999). Available processes and characteristics for treating a steel substrate are listed in Table 3.10.2.

Thermal transformation hardening processes are used to harden ferrous (primarily steel) surfaces by heating the surface rapidly, transforming it to austenite, and then quenching it to form martensite. The source of heat can be one of the following: an oxyacetylene or oxypropane flame (*flame hardening*); eddy currents induced by a high-frequency electric field (*induction hardening*); a beam from a high-power laser (*laser hardening*); or a focused electron beam (*electron beam hardening*). The depth and uniformity of the hard layer depend on the rate and method of heating. These processes are characterized by a short process time and all except electron beam hardening (which requires a moderate vacuum) can be done in air.

Thermal diffusion processes involve the diffusion of atoms into surfaces to create a hard layer. In the most widely used of these processes — *carburizing* (or case hardening) — carbon diffuses into a low-carbon steel surface to produce a hard, carbon-rich “case.” The hardness and thickness of the case depend

TABLE 3.10.2 Characteristics of Surface Treatment Processes for Steel

	Coating or Treated Layer		Substrate
Process	Hardness (HV)	Thickness (μm)	Temperature (°C)
Surface hardening			
Flame or induction hardening	500–700	250–6000	800–1000
Laser or electron beam hardening	500–700	200–1000	950–1050
Carburizing	650–900	50–1500	800–950
Carbonitriding	650–900	25–500	800–900
Citriding	700–1200	10–200	500–600
Boronizing	1400–1600	50–100	900–1100
Coating			
Chrome plating	850–1250	1–500	25–100
Electroless nickel	500–700	0.1–500	25–100
Hardfacing	800–2000	500–50000	1300–1400
Thermal spraying	400–2000	50–1500	<250
PVD	100–3000	0.05–10	100–300
CVD	1000–3000	0.5–100	150–2200
PACVD	1000–5000	0.5–10	<300
Ion implantation	750–1250	0.01–0.25	<200

on the temperature, exposure time, and source of carbon (a hydrocarbon gas, salt bath, or packed bed of carbon). *Carbonitriding* is a process similar to carburizing that involves simultaneous diffusion of carbon and nitrogen atoms into carbon steel surfaces. In the *nitriding* process, nitrogen atoms diffuse into the surface of steel that contains nitride-forming elements (such as Al, Cr, Mo, V, W, or Ti) and form fine precipitates of nitride compounds in a near-surface layer. The hardness of the surface layer depends on the types of nitrides formed. The source of nitrogen can be a hot gas (usually ammonia) or a plasma. *Nitrocarburizing* and *boronizing* are related processes in which nitrogen or boron atoms diffuse into steel surfaces and react with the iron to form a hard layer of iron carbonitride or iron boride, respectively.

Thin, hard metallic coatings can be very effective in friction and wear reduction and can be applied most effectively by *electroplating processes* (Weil and Sheppard, 1992). The most common of such coatings are *chromium*, which is plated from a chromic acid bath, and *electroless nickel*, which is deposited without electric current from a solution containing nickel ions and a reducing agent. Chromium coatings generally consist of fine-grained chromium with oxide inclusions, while electroless nickel coatings contain up to 10% of phosphorus or boron, depending on the reducing agent used.

Thermal spray processes (Kushner and Novinski, 1992) enable a large variety of coating materials, including metals, ceramics, and polymers, to be deposited rapidly on a wide range of substrates. Four different thermal spray processes are commercially available: *oxyfuel* (or flame) spraying of metallic wire or metallic or ceramic powder; *electric arc* spraying of metallic wire; *plasma* arc spraying of powder (metallic or ceramic); and *high-velocity oxyfuel* (or detonation gun) powder spray. In each of the thermal spray processes, the coating material, in wire or powder form, is heated to a molten or plastic state, and the heated particles are propelled toward the surface to be coated where they adhere and rapidly solidify to form a coating. The hardness of the coating depends on the sprayed material and the process parameters.

Weld hardfacing processes (Crook and Farmer, 1992) involve the application of a wear-resistant material to the surface of a part by means of a weld overlay. Weld overlay materials include ferrous alloys (such as martensitic air-hardening steel or high chromium cast iron); nonferrous alloys (primarily cobalt- or nickel-based alloys containing hard carbide, boride, or intermetallic particles); and cemented carbides (usually tungsten carbide/cobalt cermets). In each case, the surface being coated is heated to the same temperature as the molten weld layer, thus posing a limitation to the process. Weld hardfacing is best used when abrasion or sliding wear cannot be avoided (as with earthmoving or mining equipment) and the goal is to limit the wear rate.

Vapor deposition processes for wear-resistant coatings include *physical vapor deposition* (PVD), *chemical vapor deposition* (CVD), and several variants of those basic processes (Bhushan and Gupta, 1991; Holmberg and Matthews, 1994). Each of the processes consists of three steps:

1. Creation of a vapor phase of the coating material
2. Transportation of the vapor from source to substrate
3. Condensation of the vapor phase on the substrate and growth of a thin solid film

In PVD processes, the vapor is produced by evaporation (by heating of the coating source) or sputtering (in which coating material is dislodged and ejected from the source due to bombardment by energetic particles). In some PVD processes, the vapor becomes ionized or reacts with a gas or plasma en route to the substrate, thus modifying the structure or composition of the deposited film. In CVD processes, a gas composed of a volatile component of the coating material is activated thermally or by other means in the vicinity of the substrate, and it reacts to form a solid deposit on the surface of the hot substrate.

PVD and CVD methods can be used to produce a wide variety of coatings, including metals, alloys, and refractory compounds. Among the most popular vapor-deposited hard coatings for wear resistance are titanium nitride, titanium carbide, and hard amorphous carbon (diamond-like carbon). Deposition rates are relatively low compared to some other coating processes, ranging from <0.1 μm/min for some ion beam sputtering or ion plating processes, up to 25 μm/min or more for activated reactive evaporation or CVD processes.

Most PVD processes are done in a vacuum, while CVD processes are done in a reaction chamber that may be at atmospheric pressure. *Plasma-assisted chemical vapor deposition* (PACVD) is a hybrid process in which the constituents of the vapor phase react to form a solid film when assisted by a glow discharge plasma. The advantages of PACVD over other CVD processes include lower substrate temperatures, higher deposition rates, and a wider variety of coating possibilities.

Ion implantation (Fenske, 1992) is a process in which charged particles are created in an ion source, accelerated toward the surface at high velocity, and then injected into the substrate surface. The most commonly implanted ions for surface engineering are nitrogen, carbon, boron, and titanium, although virtually any element could be implanted. The microstructure of the near-surface region is changed by the presence of the implanted ions and the result can be high near-surface hardness and wear resistance. The affected layer is very thin (<1 μm).

Effect of Lubrication on Friction and Wear

Whenever lubricated surfaces slide together at low sliding speeds or with a high applied normal load, the lubricant may not separate the two solid surfaces completely. However, it can still significantly reduce the friction coefficient by reducing the shear strength of adhesive junctions between the two surfaces. In this so-called "boundary lubrication" regime, the effectiveness of the lubricant can be improved if the lubricant molecules adhere well to the solid surfaces. This is best accomplished by introducing a lubricant or additive that forms a surface film through adsorption, chemisorption, or chemical reaction with the surface. The ensuing reduced shear strength of the surface film can lower the friction coefficient by as much as an order of magnitude from the dry friction value.

When a good supply of a viscous lubricant is available, the separation between the surfaces will increase as the sliding speed increases or the normal load decreases. As the separation increases, the amount of solid–solid contact between the surfaces will decrease, as will the friction coefficient and wear rate. In this "mixed friction" regime, friction is determined by the amount of plowing deformation on the softer surface by the harder surface asperities and by adhesion within the solid–solid contacts. When the surfaces become completely separated by a self-acting or externally pressurized lubricant film, the lubricating regime is hydrodynamic, wear is reduced to nearly zero, and friction reaches a low value governed by viscous shear of the lubricant. Friction coefficients in such cases can be 0.001 or lower, depending on the surface velocities and the lubricant viscosity. This is the case for most journal or thrust bearings (see the subsection on fluid film bearings).

Bearings for Friction Reduction

Most mechanical systems contain moving components, such as shafts, which must be supported and held in position by stationary members. This is best done by appropriate design or selection of bearings to be used wherever the moving member is to be supported. Most bearings may be classified as fluid film bearings, dry or semilubricated bearings, or rolling element bearings.

Fluid film bearings (see subsection below) have a conformal geometry, with a thin film of fluid separating the two surfaces. The fluid lubricant could be a liquid, such as oil, or a gas, such as air. Fluid film bearings are commonly used to support rotating cylindrical shafts, and the load on such a bearing could be radial, in which case the bearing is called a journal bearing, or axial, for a thrust bearing. In most cases, the fluid film is generated by the motion within the bearing, so the bearing is called self-acting or hydrodynamic.

Whether a self-acting bearing can develop a fluid film sufficient to separate and support the two surfaces is determined by magnitude of the quantity $\mu U/W$, where μ is the (absolute) fluid viscosity; U is the relative sliding velocity; and W is the normal load. If that quantity is too small, the fluid film will be too thin and high friction will occur. Although this can be a problem during start-up of equipment when sliding velocities are low, it can be overcome by pressurizing the fluid film from an external pressure source to create a hydrostatic bearing. Whether the fluid film is externally pressurized (hydrostatic) or self-acting (hydrodynamic), separation of the solid surfaces allows wear to be essentially eliminated and friction to be very low, even when very large loads are carried by the pressurized lubricant.

TABLE 3.10.3 Bearing Characteristics

	Fluid Film Bearings	Dry Bearings	Semilubricated	Rolling Element Bearings
Start-up friction coefficient	0.25	0.15	0.10	0.002
Running friction coefficient	0.001	0.10	0.05	0.001
Velocity limit	High	Low	Low	Medium
Load limit	High	Low	Low	High
Life limit	Unlimited	Wear	Wear	Fatigue
Lubrication requirements	High	None	Low/none	Low
High temperature limit	Lubricant	Material	Lubricant	Lubricant
Low temperature limit	Lubricant	None	None	Lubricant
Vacuum	Not applicable	Good	Lubricant	Lubricant
Damping capacity	High	Low	Low	Low
Noise	Low	Medium	Medium	High

Dry and semilubricated bearings (see subsection below) have conformal surfaces in direct contact with each other. This category includes bearings that run dry (without liquid lubrication) or those that have been impregnated with a lubricant. Dry bearings are made of a material such as a polymer or carbon-graphite, which has a low friction coefficient; they are generally used in low-load and low-speed applications. Semilubricated bearings are made of a porous material, usually metal, and are impregnated with a lubricant that resides within the pores. The lubricant, which could be oil or grease, cannot provide a complete fluid film, but usually acts as a boundary lubricant. Semilubricated bearings can carry greater loads at greater speeds than dry bearings, but not as high as fluid film or rolling element bearings. The failure mechanism for dry and semilubricated bearings is wear.

Rolling element bearings (see subsection below) take advantage of the fact that rolling friction is usually lower than sliding friction. These bearings include rolling elements, either balls or rollers, between hardened and ground rings or plates. Their main advantage over fluid film bearings is that they have low friction during startup and at operating velocities, although the friction can be higher than that of fluid film bearings during steady-state operation. Ball and roller bearings are most commonly lubricated by oil or grease. In either case, the lubricating film at the concentrated contacts between rolling elements and rings is very thin and the pressures in the film are very high; this is a condition known as elastohydrodynamic lubrication. Rolling element bearings fail by a number of mechanisms, often stemming from improper installation, use, or poor lubrication, but the overriding failure mechanism is rolling contact fatigue.

Each type of bearing has advantages and disadvantages, which are summarized in Table 3.10.3. The Engineering Sciences Data Unit (1965, 1967) has developed some general guides to the selection of bearing type for different load and speed conditions. Those guides for journal and thrust bearing selection are given in Figure 3.10.2 and Figure 3.10.3.

Lubricant Properties

Petroleum Oils

The vast majority of lubricants in use today are mineral oils obtained through the distillation of crude petroleum. Mineral oils are composed primarily of three types of hydrocarbon structures: paraffinic, aromatic, and alicyclic (naphthenic). The molecular weights of the hydrocarbons range from about 250, for low viscosity grades, up to nearly 1000 for more viscous lubricants. Mineral oils by themselves do not have all of the properties required of modern lubricants. For that reason, almost all current lubricants are fortified with a chemical additive package consisting of some of the following (Rudnick, 2003; Totten, 2003):

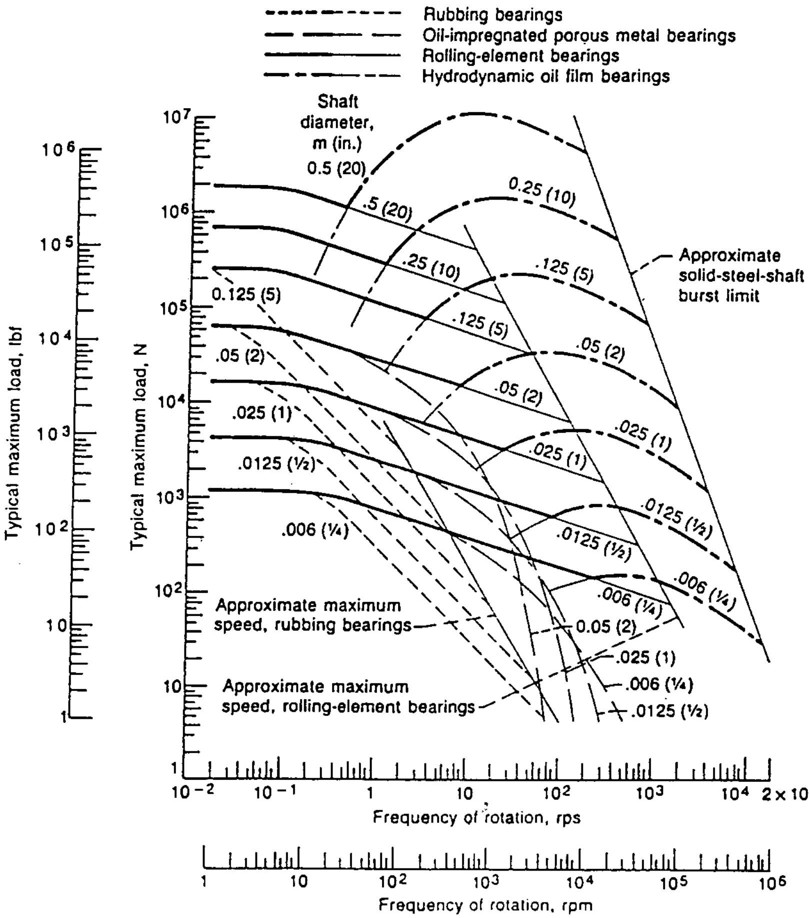

FIGURE 3.10.2 General guide to journal bearing type selection. Except for rolling element bearings, curves are drawn for bearings with width/diameter = 1. A medium viscosity mineral oil is assumed for hydrodynamic bearings. (ESDU, *General Guide to the Choice of Journal Bearing Type*, item 65007, Institution of Mechanical Engineers, London, 1965.)

- *Oxidation inhibitors* limit oxidation of hydrocarbon molecules by interrupting the hydroperoxide chain reaction.
- *Rust inhibitors* are surface-active additives that preferentially adsorb on iron or steel surfaces and prevent their corrosion by moisture.
- *Antiwear and extreme pressure agents* form low shear strength films on metallic surfaces, which limit friction and wear, particularly in concentrated contacts.
- *Friction modifiers* form adsorbed or chemisorbed surface films that are effective in reducing friction of bearings during low-speed operation (boundary lubrication regime).
- *Detergents* and *dispersants* reduce deposits of oil-insoluble compounds (e.g., sludge) in internal combustion engines.
- *Pour-point depressants* lower the temperature at which petroleum oils become immobilized by crystallized wax.
- *Foam inhibitors* are silicone polymers, which enhance the separation of air bubbles from the oil.
- *Viscosity-index improvers* are long chain polymer molecules that reduce the effect of temperature on viscosity. They are used in multigrade lubricants.

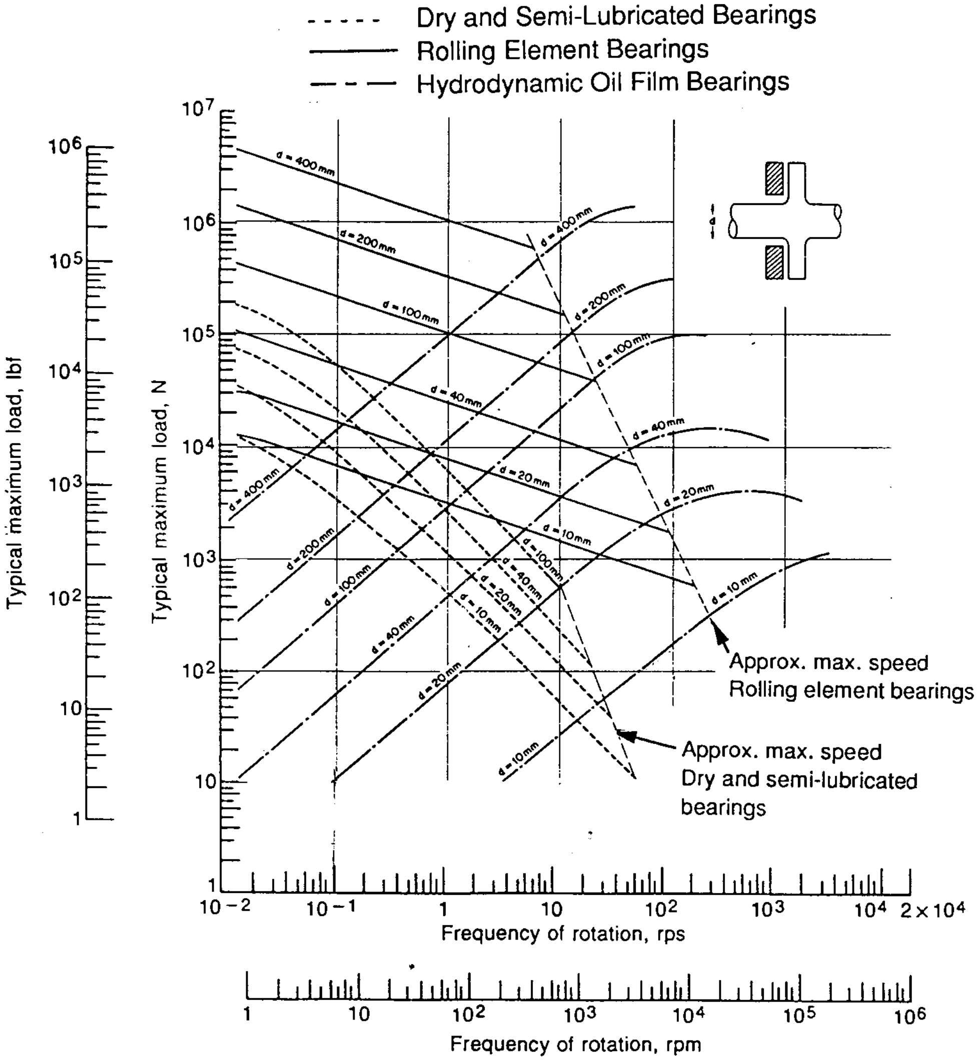

FIGURE 3.10.3 General guide to thrust bearing type selection. Except for rolling element bearings, curves are drawn for a ratio of inside diameter to outside diameter equal to 2 and for a nominal life of 10,000 h. A medium viscosity mineral oil is assumed for hydrodynamic bearings. (Based on ESDU, *General Guide to the Choice of Thrust Bearing Type*, item 67073, Institution of Mechanical Engineers, London, 1967, and Neale, M.J., *Bearings*, Butterworth–Heinemann, Oxford, U.K., 1993.)

Properties of Petroleum Oils

The lubricating oil property of most significance to bearing performance is viscosity. The absolute viscosity, designated as μ, could be given in SI units as Pascal second (Pa·sec = N•sec/m^2) or centiPoise (1 cP = 0.001 Pa·sec) or in English units as lb·sec/in.^{2} or reyn. Kinematic viscosity, designated here as ν, is defined as absolute viscosity divided by density. It is given in SI units as m^2/sec or centiStokes (1 cSt = 10^{-6} m^2/sec) and in English units as in.^{2}/sec.

Viscosity data in Table 3.10.4 are representative of typical petroleum “turbine” and “hydraulic” oils widely used in industry; they closely correspond to properties of most other commercially available petroleum oils. Table 3.10.5 gives equivalent viscosity grades for common automotive (SAE); gear (SAE

TABLE 3.10.4 Representative Oil Properties

	Viscosity				Density

and AGMA); and reciprocating aircraft engine (SAE) oils (Booser, 1995). Equivalent ISO viscosity grades are listed for the single-graded SAE automotive oils such as SAE 10W and SAE 30. For multigrade oils such as SAE 10W-30, however, the added viscosity-index improvers provide unique viscosity-temperature characteristics. Typical properties of a number of these multigrade SAE oils are included in Table 3.10.4.

ISO viscosity grade 32 and the equivalent SAE 10W are most widely used industrially. Lower viscosity oils often introduce evaporation and leakage problems, along with diminished load capacity. Higher viscosity may lead to high temperature rise, unnecessary power loss, and start-up problems at low temperature. For low-speed machines, however, higher viscosity oils ranging up to ISO 150, SAE 40, and sometimes higher are often used to obtain higher load capacity.

Oil viscosity decreases significantly with increasing temperature as shown in Figure 3.10.4. Although this figure provides viscosity data suitable for most bearing calculations, oil suppliers commonly provide

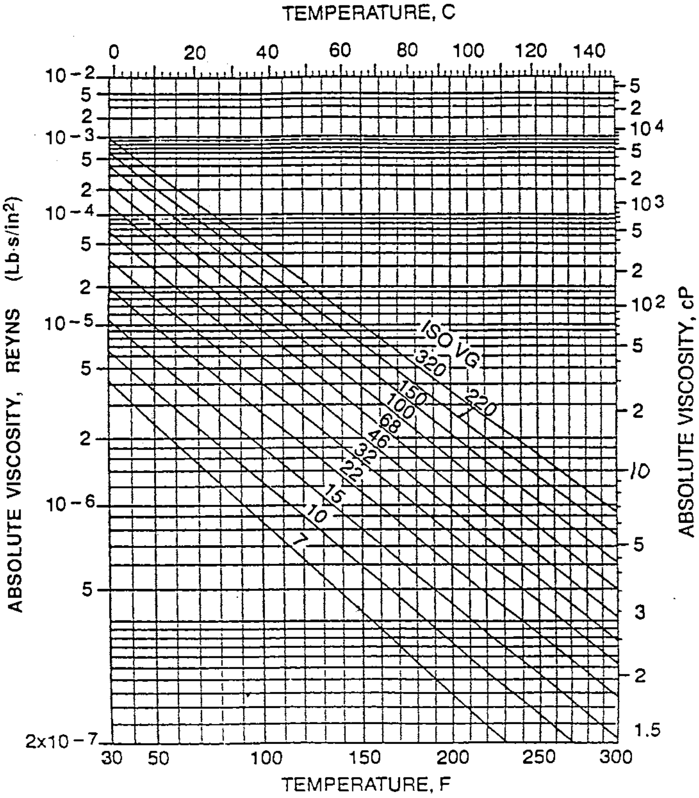

FIGURE 3.10.4 Viscosity-temperature chart for industrial petroleum oils. (Based on Raimondi, A.A. and Szeri, A.A., in *Handbook of Lubrication*, vol. 2, 413–462, CRC Press, Boca Raton, FL, 1984.)

only the 40 and 100°C values of kinematic viscosity in centistokes (mm²/sec). The viscosity at other temperatures can be found by the following ASTM D341 equation relating kinematic viscosity ν in centistokes (mm²/sec) to temperature T in degrees F:

$$\text{loglog}\,(\nu + 0.7) = A - B\log\,(460 + T) \tag{3.10.2}$$

where A and B are constants for any particular (petroleum or synthetic) oil. For ISO VG-32 oil in Table 3.10.4, for example, $A = 10.54805$ and $B = 3.76834$, based on the 104 and 212°F (40 and 100°C) viscosities. This gives a viscosity of 10.78 cSt at a bearing operating temperature of 160°F.

Conversion of kinematic to absolute viscosity requires use of density, which also varies with temperature. A coefficient of expansion of 0.0004/°F is typical for most petroleum oils, so the variation of density with temperature is in accordance with the following relation:

$$\rho_T = \rho_{104}\,[1 - 0.0004\,(T - 104)] \tag{3.10.3}$$

For the ISO-VG-32 oil with its density of 0.857 gm/cc at 100°F (40°C), this equation gives 0.838 gm/cc at 160°F. Multiplying 10.78 cSt by 0.838 then gives an absolute viscosity of 9.03 cP. Multiplying by the conversion factor of 1.45×10^{-7} gives 1.31×10^{-6} lb·sec/in.² (Reyns).

Heat capacity C_p of petroleum oils used in bearing calculations is given by (Klaus and Tewksbury, 1984):

$$C_p = 3860 + 4.5(T) \quad \text{in-lb/lb-°F} \tag{3.10.4}$$

The viscosity of petroleum oils is also affected significantly by pressure, and that increase can become important in concentrated contacts such as rolling element bearings where elastohydrodynamic lubrication occurs. The following relationship can be used for many oils to find the viscosity at elevated pressure:

$$\mu_p = \mu_o \, e^{\alpha p} \tag{3.10.5}$$

where μ_o is the viscosity at atmospheric pressure; μ_p is the viscosity at pressure p; and α is the pressure-viscosity exponent. This exponent, available from lubricant suppliers, generally ranges from about 1.0×10^{-4} psi^{-1} for low viscosities up to about 2.0×10^{-4} psi^{-1} at higher viscosities for many mineral and synthetic oils.

Synthetic Oils

Synthetic oils of widely varying characteristics are finding increasing use for applications at extreme temperatures and for their unique physical and chemical characteristics (Rudnick and Shubkin, 1999). Table 3.10.6 gives a few representative examples of commercially available synthetic oils. Cost of the synthetics, ranging up to many times that of equivalent petroleum oils, is a common deterrent to their use in situations in which petroleum products give satisfactory performance.

Greases

Grease is essentially a suspension of oil in a thickening agent, along with appropriate additives. The oil generally makes up between 75 and 90% of a grease's weight, and it is held in place by the gel structure of the thickener to carry out its lubricating function. The simplicity of the lubricant supply system, ease of sealing, and corrosion protection make grease the first choice for many ball and roller bearings, small gear drives, and slow-speed sliding applications (Booser, 1995). Consistencies of greases vary from soap-thickened oils that are fluid at room temperature to hard brick types that may be cut with a knife. Greases of NLGI grade 2 stiffness (ASTM D217) are most common. Softer greases down to grade 000 provide easier feeding to multiple row roller bearings and gear mechanisms. Stiffer grade 3 is used in some prepacked ball bearings to avoid mechanical churning as the seals hold the grease in close proximity with the rotating balls.

Petroleum oils are used in most greases; the oils generally are in the SAE 30 range, with a viscosity of about 100 to 130 cSt at 40°C. Lower viscosity oil grades are used for some high-speed applications and for temperatures below about –20°C. Higher viscosity oils are used in greases for high loads and low speeds. Synthetic oils are used only when their higher cost is justified by the need for special properties, such as capability for operation below –20°C or above 125 to 150°C.

The most common gelling agents are the fatty acid metallic soaps of lithium, calcium, sodium, or aluminum in concentrations of 8 to 25%. Of these, the most popular is lithium 12-hydroxystearate; greases based on this lithium thickener are suitable for use at temperatures up to 110°C, where some lithium soaps undergo a phase change. Greases based on calcium or aluminum soaps generally have an upper temperature limit of 65 to 80°C, but this limit can be significantly raised to the 120 to 125°C range through new complex soap formulations. Calcium complex soaps with improved high temperature stability, for instance, are prepared by reacting a high molecular weight fatty acid (e.g., stearic acid) and at a low molecular weight fatty acid (acetic acid) with calcium hydroxide dispersed in mineral oil.

Inorganic thickeners, such as fine particles of bentonite clay, are inexpensively applied by simple mixing with oil to provide nonmelting greases for use up to about 140°C. Polyurea nonmelting organic powders are used in premium petroleum greases for applications up to about 150 to 170°C.

Additives, such as those mentioned in the subsection on petroleum oils, are added to grease to improve oxidation resistance, rust protection, or extreme pressure properties. Owing to the incompatibility of oils, thickeners, and additives, greases of different types should be mixed with caution.

Solid Lubricants

Solid lubricants provide thin solid films on sliding or rolling/sliding surfaces to reduce friction and wear. They are particularly useful for applications involving high operating temperatures, vacuum, nuclear radiation, or other environments that limit the use of oils or greases. Solid lubricant films do not prevent moving surfaces from contacting each other, so they cannot eliminate wear and their lives are limited by wear. The properties of some of the most common solid lubricants are given in Table 3.10.7.

The most important inorganic solid lubricants are layer-lattice solids such as molybdenum disulfide (MoS_2) and graphite. These materials are characterized by strong covalent or ionic bonding between atoms in individual layers, but relatively weak van der Waals' bonds between layers, thus enabling the layers to slide easily relative to one another. Graphite is a very effective lubricant film when moisture or water vapor is present because adsorbed water vapor lubricates the sliding layers; however, it has poor friction properties in vacuum or other low-humidity applications. Molybdenum disulfide does not require the presence of adsorbed water vapor, so it is widely used in vacuum or space applications.

The most commonly used organic solid lubricant is polytetrafluoroethylene (PTFE), which can be used as a fused surface coating or as a self-lubricating material (see subsection on plastics). Its low friction is attributed to the smooth profile of the PTFE molecule. The chemical inertness of PTFE makes it attractive for chemical and food processing applications.

TABLE 3.10.7 Properties of Selected Solid Lubricants

Material	Acceptable Usage Temperature, °C				Average Friction Coefficient, f		Remarks
	Minimum		Maximum				
	In Air	In N_2 or Vacuum	In Air	In N_2 or Vacuum	In Air	In N_2 or Vacuum	
Molybedenum disulfide, MoS_2	–240	–240	370	820	0.10–0.25	0.05–0.10	Low f, carries high load, good overall lubricant, can promote metal corrosion
Graphite	–240	—	540	Unstable in vacuum	0.10–0.30	0.02–0.45	Low f and high load capacity in air, high f and wear in vacuum, conducts electricity
PTFE	–70	–70	290	290	0.02–0.15	0.02–0.15	Lowest f of solid lubricants, load capacity moderate and decreases at elevated temperature
Calcium flouride–barium fluoride eutectic, CaF_2-BaF_2	430	430	820	820	0.10–0.25 above 540°C 0.25–0.40 below 540°C	Same as in air	Can be used at higher temperature than other solid lubricants, high f below 540°C

Source: Modified from Booser, E.R., in *Encyclopedia of Chemical Technology*, 4th ed., Vol. 15, 463–517, John Wiley & Sons, New York, 1995.

New ceramic-based solid lubricants have been developed for high-temperature applications, such as heat engines or space uses. One of the most promising of these is a calcium fluoride–barium fluoride eutectic, which can be used at temperatures exceeding 800°C.

Fluid Film Bearings

Journal Bearings

A journal bearing consists of an approximately cylindrical bearing body or sleeve around a rotating cylindrical shaft. In general, journal bearings are found in motors, pumps, generators, appliances, and internal combustion engines in which a fluid lubricant is used; they are also in smaller mechanisms such as switches, clocks, small motors, and circuit breakers in which a solid lubricant such as graphite, grease, or certain plastics serves to reduce friction. Air (gas) bearings are designed to utilize both fluid mechanics principles when operating, and solid lubricant surfaced materials for start, stop, and emergency operations.

A hydrodynamic journal bearing maintains separation of shaft from bearing because the lubricant viscosity and the speed of the shaft create pressure in the converging portion of the fluid film that carries load. The governing equations were first developed by Reynolds (1886). Their solution has led to numerous computer solutions, including those used for this chapter.

Journal Bearing Design

Figure 3.10.5 shows schematics of frequently used types of journal bearing in which one or more lobes of cylindrical shape are positioned around the shaft; their axis is assumed to be parallel to the shaft axis. The features of each design as well as applications in which it is often found are listed in Table 3.10.8. Noncontact journal bearings are designed to assure a continuous supply of lubricant to the load-carrying section, and the bearing grooves in Figure 3.10.5 are designed for that purpose. Oil must be resupplied to the bearing because of the continuous loss of lubricant as it is forced from the bearing by the load-carrying pressures generated within it. The subsection on lubricant supply methods describes some of the many systems designed to assure this supply and to cool the lubricant at the same time.

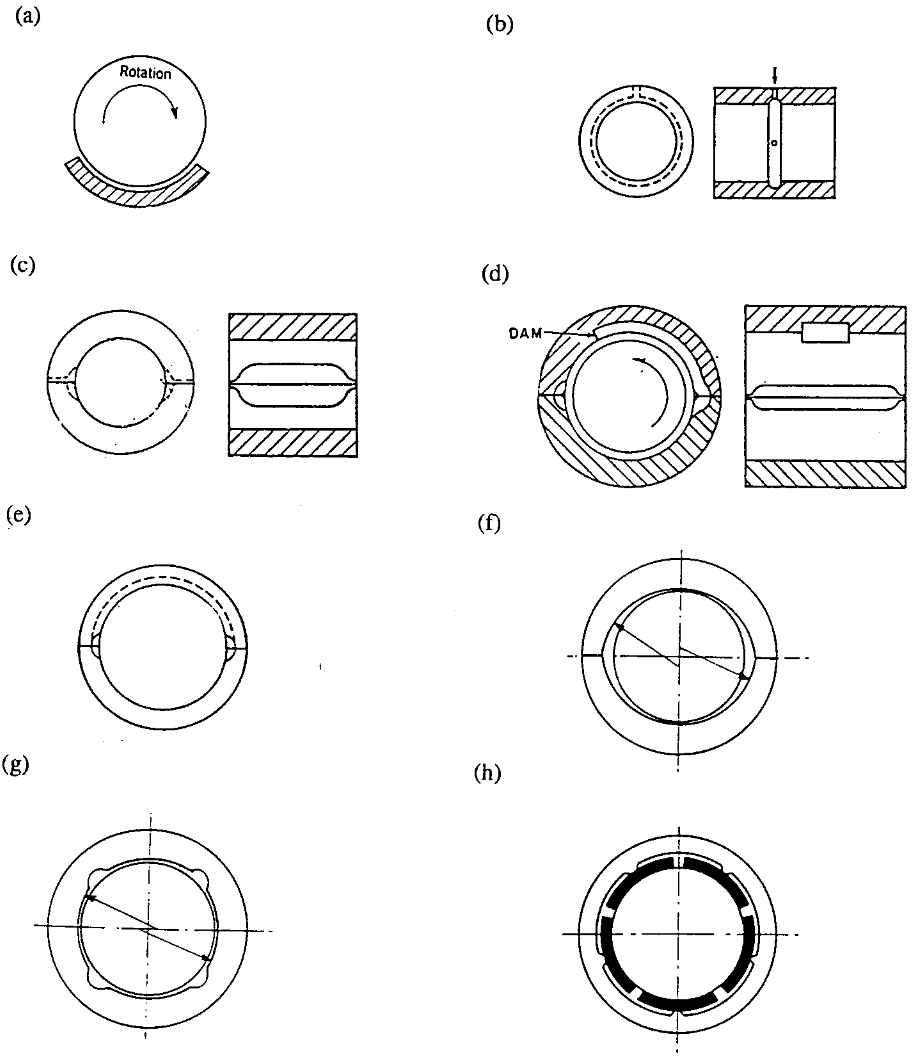

FIGURE 3.10.5 Types of pressure-fed journal bearings: (a) partial arc; (b) circumferential groove; (c) cylindrical bearing — axial groove; (d) pressure dam; (e) cylindrical overshot; (f) elliptical; (g) multilobe; (h) tilting pad.

Controlling variables. Definitions of the variables involved in journal bearing analysis are contained in Table 3.10.9. Because of the large range of many variables, nondimensional quantities are often used that are independent of the dimensional unit system involved. Examples are given are in the English system unless otherwise stated.

Calculating Bearing Performance

Journal bearing performance can be calculated directly from dedicated computer codes, which take account of load, speed, oil type, and delivery system as well as bearing dimensions. This subsection presents two approximate solutions: a simple thermal approach and a set of interpolation tables based on computer solutions.

Thermal Approach. It is assumed that the bearing is operating at a constant but elevated temperature. A predicted operating temperature can then be found as a function of an assumed viscosity. A solution is found when the assumed viscosity equals the lubricant viscosity at that temperature.

Three equations are used for this method. For radial loads, the power dissipation is:

$$H_p = j\pi^3 \mu \left(N/60\right)^2 D^3 L/C \text{ in}\cdot\text{lb/s} \tag{3.10.6}$$

where j = 1 for a shaft-centered design. The lubricant flow rate is:

$$Q = Q_o + q\,CR^2\omega/2 \text{ in.}^3/\text{s} \tag{3.10.7}$$

where q is the proportion of side flow to circulating flow, and the zero speed flow, Q_o (gpm), represents other flows such as from the ends of feed grooves not related to the load-carrying film. Q_o can usually be neglected for rough estimation, and this approximation is useful for eccentricities as high as 0.7. Note that q and j are functions of specific design as well as load and speed. The average operating temperature for a given viscosity is:

$$T_2 = T_f + \frac{\left(H_p - \Phi\right)}{\left(\rho C_p Q\right)} \ {}^\circ\text{F} \tag{3.10.8}$$

where T_f is the feed temperature and Φ is the energy loss due to conduction and radiation. For diameters of 2 in. or more, Φ can usually be assumed to be 0. Plotting T_2 vs. viscosity for several values of μ on a plot of the viscosity vs. T for the lubricant shows the operating temperature for the bearing as the intersection.

Flow dynamics solution. A more general solution for journal bearing performance is based on prediction of flow characteristics in the bearing and of physical behavior of the bearing based on Reynolds equation. A common two-pad journal bearing with pressurized oil feed will be used to provide specific design information.

Reynolds equation is the differential equation expressing the physical behavior of the fluid film between shaft and bearing, as written for cylindrical bearings:

$$1/R^2\left[\partial/\partial\theta\left(h^3/\mu\right)\partial p/\partial\theta\right] + \partial/\partial z\left(h^3/\mu\right)\partial p/\partial z = 6\left(U/R\right)\partial h/\partial\theta \tag{3.10.9}$$

where z is the axial coordinate and θ is the angular coordinate.

Bearing configuration. A cross section through a common type of two-pad cylindrical bearing is shown in Figure 3.10.6. Two pads having a radius of $R + C$ and an angular extent of 150°, and, with load applied vertically to the lower half through a shaft, comprise the bearing. Lubricant is admitted under moderate feed pressure to the two 30° grooves formed at the split as shown in Figure 3.10.6. The shaft rotates counterclockwise, and lubricant pressures are balanced when the shaft center is displaced down and to the right.

Lubricant properties. Pressures in the lubricant film are generated as a function of the local shear rates and the local viscosities as described by Reynolds equation.

The local temperature rise is given by the local energy dissipation divided by the local flow rate:

$$\Delta T = \left[2\mu\omega R^2\Delta\theta\right]/\left[h^2\rho C_p\right] \tag{3.10.10}$$

As an alternative to Equation (3.10.2), an exponential relation between viscosity and temperature is used:

$$\mu = \mu_0 e^{-\beta\left(T - T_0\right)} \tag{3.10.11}$$

Assuming an ISO 32 oil of viscosity μ_o at 104°F is 3.98 Reyns, density is 0.0310, and β is 0.0170 for the range from 104 to 212°F. The value for β may be determined from Figure 3.10.4.

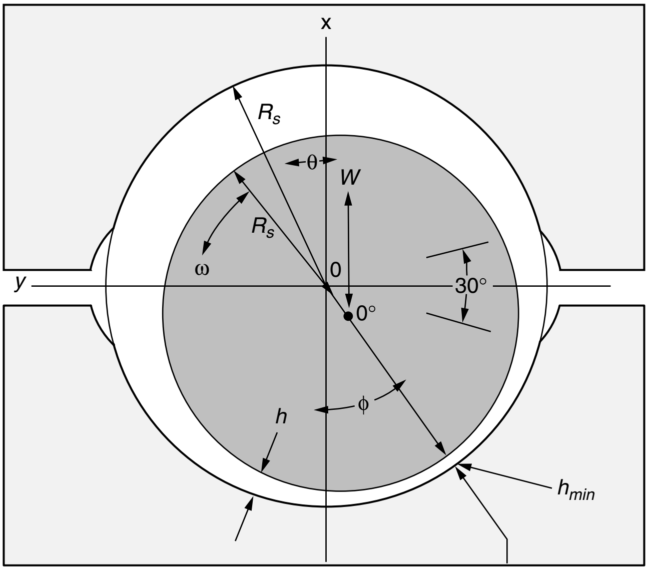

FIGURE 3.10.6 Geometry of split cylindrical journal bearing.

A nondimensional coefficient, C_α, the *adiabatic coefficient*, is used as an indicator of the severity of thermal heating in a design. It contains the several factors responsible for temperature rise.

$$C_\alpha = 2\mu_f \beta\omega \left(R/C\right)^2 \big/ \rho C_p \tag{3.10.12}$$

Bearing performance tables. Using computer-generated solutions of the Reynolds equation for the pressure field over the bearing surface, the relevant performance properties of the bearing/lubricant system can be determined. A number of programs are commercially available for this purpose. In order to illustrate how the behavior of a journal bearing can be determined, a two-pad split cylindrical bearing with an *L*/*D* of 0.5 has been selected, and a proprietary computer code has been used to develop a group of performance quantities for such a bearing. The code accounts for the internal lubricant circulation, including mixing in the inlet groove of feed lubricant with warm lubricant from the upper half, resulting in the viscosity μ_f.

The primary characteristics of the bearing are load, stiffness, and damping. Each of these factors is presented in nondimensional terms in Table 3.10.10; the corresponding dimensional and other quantities are given as follows:

Film thickness (in.): $$h = C\left(1 + e\cos\Theta\right) \tag{3.10.13a}$$

Shaft eccentricity (in.): $$e = \varepsilon C \tag{3.10.13b}$$

Load (lb): $$W = w\left[6\mu\omega\left(R/C\right)^2 DL\right] \tag{3.10.13c}$$

Flow (in.^{3}/sec): $$Q = q\left(CR^2\omega/2\right) \tag{3.10.13d}$$

Power loss (in.·lb/sec): $$H_p = j\left(2\pi\,\mu\omega^2 R^3 L/C\right) \tag{3.10.13e}$$

Stiffness (lb/in.): $$S_{xx} = K_{xx}\, 6\mu\omega R\left(R/C\right)^2 \qquad (3.10.13f)$$

Damping (lb·sec/in.): $$D_{xx} = B_{xx}\, 12\mu R\left(R.C\right)^3 \qquad (3.10.13g)$$

The axial length/diameter ratio also influences the performance of a journal bearing. To illustrate this, Table 3.10.11 presents the performance of longer bearings (L/D = 0.75 and 1.00) for comparison to the more common L/D = 1/2 results in Table 3.10.10. Comparing Table 3.10.10 and Table 3.10.11, the use of longer bearings has several important effects on operation and performance. Comparing key variables, the effects at an eccentricity of ratio of 0.7 are as follows:

Variable	$L/D = 0.5$	$L/D = 0.75$	$L/D = 1.00$
Load, w	0.28	0.69	1.21
Flow, q	0.69	0.82	0.88
Attitude angle, ϕ	36.4	36.1	35.8
Power ratio, j	1.00	1.15	1.17
Stiffness, K_{xx}	1.38	3.06	5.03
Damping, B_{xx}	0.99	2.52	4.31

Effect of Turbulence

Turbulence is a mixing phenomenon that occurs in larger high-speed bearings. When this behavior occurs, the simple viscous drag behavior assumed previously is broken up by numerous eddies which increase the drag. The Reynolds number is a nondimensional quantity that expresses this factor:

$$R_e = h\, U\, \rho/\mu \qquad (3.10.14)$$

where h is the local film thickness; U is the relative velocity of one surface with respect to the other; ρ is the fluid density; and μ is the local viscosity. The influence of turbulence on an L/D = 0.5 bearing is shown in Table 3.10.12.

Examination of Table 3.10.12 shows that the principal effects of operation in the turbulent regime with Reynolds number above about 1000 are in the greater power required (j) and the maximum bearing temperature. Load capacity and flow are only moderately affected.

Example Calculation

The problem is to design a two-pad cylindrical bearing for support of a rotor having a bearing load of 8000 lb, a shaft diameter of 6 in., and a speed of 3600 rpm. Assume use of ISO VG-32 oil fed at a temperature of 120°F. Compute operating characteristics for a 3-in. long bearing. Assume a radial clearance of 0.0044 in.

Feed viscosity: $\mu_f = 3.98 \times 10^{-6} e^{-0.00170(120-104)} = 3.03 \times 10^{-6}$ Reyn
Angular velocity: $\omega = 3600 \times 2\pi/60 = 377$ rad/sec
Adiabatic coefficient: $C_\alpha = 2 \times 3.03 \times 10^{-6} \times 0.0170 \times 377 \times (3/0.0044)^2/0.0310/4320 = 0.1345$
Load coefficient (from Equation 3.10.13c): $w = 8000/[6 \times 3.03 \times 10^{-6} \times 377 \times 3 \times 6 \times (33/0.0044)^2] = 0.139$

The desired solution lies between part 2 and part 3 of Table 3.10.10. Using linear interpolation between the tabulated values for C_α of 0.1 and 0.2, and values for ε of 0.7 and 0.8, an approximate operating point of $C_\alpha = 0.1345$ yields the following coefficients: $\varepsilon = 0.729$; $w = 0.279$; $q = 0.733$; $j = 0.860$; and $\Delta T_b = 0.915$.

Using Equation 13.10.13a through Equation 13.10.13g, the dimensional operating results are:

Shaft velocity: $\omega = 3600 \times 2\pi/60 = 377$ rad/sec
Flow: $Q = 0.733 \times .0044 \times 3^2 \times 377 = 5.47$ in.^{3}/sec
Power loss: $H_p = 0.860 \times 2\pi \times 3.03 \times 10^{-6} \times 377^2 \times 3^3 \times 3/0.0044 = 42.8$ in.·lb/sec
Oil temperature: $T_b = 120 + 0.915/0.0170 = 174$°F

Thrust Bearings

Types of Thrust Bearings

Oil film thrust bearings range from coin-size flat washers to sophisticated assemblies many feet in diameter (Khonsari and Booser, 2002). Of the six common types of thrust bearings shown in Table 3.10.13, the first five are hydrodynamic. As with journal bearings, each of these generates oil film pressure when a rotating thrust face pumps oil by shear into a zone of reduced downstream clearance. When thrust load increases, film thickness drops until a new balance is reached between inflow and outflow, raising pressure until the higher bearing load is balanced. The hydrostatic bearing uses a separate oil pump to supply the pressurized flow.

[a] $\varepsilon = 0.7$; $C_\alpha = 0.2$; arc = 150°.

Flat-land bearings, simplest to fabricate and least costly, are the first choice for simple positioning of a rotor and for light loads in electric motors, appliances, pumps, crankshafts, and other machinery. They carry less of a load than the other types because flat parallel planes do not directly provide the required pumping action. Instead, their action depends on thermal expansion of the oil and warping of the bearing material induced by heating from the passing oil film. The resulting slight oil wedge then gives a load rating of about 10 to 20% of that for the other types.

Step bearings also offer relatively simple design. With a coined or etched step, they lend themselves to mass production as small-size bearings and thrust washers. Step height for optimum load capacity approximately equals the minimum film thickness, often 0.001 in. or less. Circumferential length beyond the step is ideally 45% of the total bearing segment (Wilcock and Booser, 1956).

Step thrust bearings are well suited for low-viscosity fluids such as water, gasoline, fuels, and solvents. Minimum film thickness in these applications is so small that features such as pivots and tapers are usually impractical. Step height must be small enough for good load capacity, yet large enough to accommodate some wear without becoming worn away. Step erosion by contaminants is sometimes a problem.

Tapered-land bearings provide reliable, compact designs for mid- to large-size high-speed machines such as turbines, compressors, and pumps. Taper height normally should be about one to three times the minimum film thickness. For greater load capacity and to minimize wear during starting, stopping, and at low speeds, a flat land is commonly machined at the trailing edge to occupy from 10 to 30% of the circumferential length of each segment. Because operation of these bearings is sensitive to load, speed, and lubricant viscosity, they are typically designed for the rated range of operating conditions for specific machines.

Tilting-pad thrust bearings are used increasingly in turbines, compressors, pumps, and marine drives in much the same range of applications as tapered-land designs. They usually have a central supporting pivot for each of their three to ten bearing segments. Each of these thrust pad segments is free to adjust its position to form a nearly optimum oil wedge with widely varying loads, speeds, and lubricants, and with rotation in both directions. A secondary leveling linkage system is commonly introduced to support the individual pads; this provides a further advantage over tapered-land designs by accommodating some misalignment. Off-the-shelf units are available to match rotor shaft diameters from about 2 to 12 in., and custom designs range from 120 to 170 in. outside diameter.

Recent trends to increase load capacity have led to offsetting pivots from the circumferential midpoint of a pad to about 60% beyond the leading edge; to substituting copper for steel as the backing for a tin babbitt bearing surface; and to nonflooded lubrication to minimize parasitic power loss from useless churning of oil passing through the bearing housing.

Springs or other flexible supports for thrust segments are employed for bearings ranging up to 10 ft or more in outside diameter and carrying millions of pounds of thrust. This flexible mounting avoids the

TABLE 3.10.13 Common Thrust Bearings and Their Range of Application

Type	O.D. in.	Unit load, psi

	3–50	500–3000

Source: Booser, E.R. and Wilcock, D.F., *Machine Design*, June 20, 69–72, 1991.

high load concentration encountered by pivots in supporting large tilting-pads. Rubber backing can provide this flexible mounting for smaller thrust pads.

Hydrostatic thrust bearings are used when sufficient load support cannot be generated by oil film action within the bearing. This may be the case with low viscosity fluids, or for load support on an oil film at standstill and very low speeds. The fluid is first pressurized by an external pump and then introduced into pockets in the bearing surface to float the load.

A compact hydrostatic thrust bearing can sometimes be constructed with a single pocket at the end of a rotor. Larger bearings usually use three or more pressurized pockets to resist misalignment or to support off-center loads. Hydraulic flow resistance in the supply line to each pocket or constant flow to each pocket (as with ganged gear pumps) then provides any asymmetric pressure distribution needed to support an off-center load. Bearing unit load is commonly limited to about 0.5 (0.75 with fixed flow systems) times the hydrostatic fluid supply pressure — up to 5000 psi with conventional lubricating oils.

Design Factors for Thrust Bearings

In preliminary sizing, the inside diameter *d* of a thrust bearing is made sufficiently larger than the shaft to allow for assembly and to provide for any required oil flow to the thrust bearing inside diameter. This clearance typically ranges from about 1/8 in. for a 2-in. shaft to 1/2 in. for a 10-in. shaft. Bearing outside diameter *D* is then set to provide bearing area sufficient to support total thrust load *W* (pounds or Newtons) with an average loading *P* (psi or N/m²), using typical values from Table 3.10.13:

$$D = \left(\frac{4W}{\pi k_g P} + d^2 \right)^{0.5} \tag{3.10.15}$$

where k_g (typically 0.80 to 0.85) is the fraction of area between *d* and *D* not occupied by oil-distributing grooves. This bearing area is then divided by radial oil-feed groove passages, usually into "square" sectors with circumferential breadth *B* at their mean diameter equal to their radial length *L*.

Although square pads usually produce optimum oil film performance, other proportions may be advantageous. With very large bearing diameters, for instance, square sectors may involve such a long circumferential dimension that the oil film overheats before reaching the next oil-feed groove. On a radially narrow thrust face, on the other hand, square sectors may become so numerous as to introduce excessive oil groove area; thus, their short circumferential length would interfere with hydrodynamic oil film action.

Performance Analysis

Performance analyses for sector thrust bearings using a fixed taper also hold approximately for most thrust bearing shapes (other than flat lands) with the same ratio of inlet to outlet oil film thickness (Wilcock and Booser, 1956; Khonsari and Booser, 2002; Fuller, 1984). For centrally pivoted-pad thrust bearings and for spring-supported thrust bearings, use of an inlet-to-outlet film thickness ratio of two is usually appropriate in such an analysis.

Computer analyses in polar coordinates and with local oil film viscosity calculated over the whole oil film area give more exact solutions; however, the following constant viscosity approximations are made by relating a rectangular bearing sector (width B, length L) to the circular configuration of Figure 3.10.7.

After Khonsari, M.M., *Tribology Data Handbook*, CRC Press, Boca Raton, FL, 1997.

This rectangular representation allows more ready evaluation of a range of variables and gives results quite similar to those of a more accurate polar coordinate analysis.

Employing the nomenclature of Figure 3.10.7, the following relations give minimum film thickness h_2, frictional power loss H, and oil flow into a sector Q. The dimensionless coefficients involved are given in Table 3.10.14 for a range of sector proportions L/B and ratios of inlet-to-outlet film thicknesses h_1/h_2.

$$h_2 = K_h \left(\mu UB/P\right)^{0.5} \qquad \text{in. (m)} \tag{3.10.16a}$$

$$H = K_f \, \mu U^2 BL/h_2 \qquad \text{lb} - \text{in./sec (N} - \text{m/sec)} \tag{3.10.16b}$$

$$Q = K_q ULh_2 \qquad \text{in.}^3\text{/sec (m}^3\text{/sec)} \tag{3.10.16c}$$

$$\Delta T = H\Big/\left(Q\rho C_p\right) = \frac{K_f}{K_q K_h^2 \rho C_p} P \qquad {}^\circ\text{F (}^\circ\text{C)} \tag{3.10.16d}$$

where:

B = circumferential breadth of sector at mean radius, in (m).
K_h, K_f, K_q = dimensionless coefficients.
L = radial length of sector, in (m).
P = unit loading on projected area of sector, W/BL, lb/in.^{2} (N/m^2).
U = surface velocity at mean diameter of sector, in./sec (m/sec).
W = load on a sector, lb. (N).
C_p = oil specific heat, in. – lb/(lb – °F) (J(kg – °C))
h_1, h_2 = leading edge and trailing edge film thicknesses, in (m)
ρ = oil density, lb/in.^{3} (N/m^3)
μ = oil viscosity at the operating temperature, lb·sec/in.^{2} (N·sec/m^2)

Example

The following example involves a bearing for 25,000 lb thrust load in a 1200 rpm compressor whose rotor has a 5-in. diameter journal. ISO-32 viscosity grade oil is to be fed at 120°F. Allowing 3/8-in. radial clearance along the shaft sets thrust bearing bore d = 5.75 in. Taking unit loading P = 300 psi allows a margin for uncertainty in expected thrust load; outside diameter D is given by Equation (3.10.14):

$$D=\left(\frac{4\times 25000}{\pi(0.85)(300)}+5.75^2\right)^{0.5}=12.6\text{ in.}$$

With 15% of the area used for oil feed passages, k_g= 0.85. Thrust bearing segment radial length L = (12.6 – 5.75)/2 = 3.425 in. With mean diameter (5.75 + 12.6)/2 = 9.175 in., total circumferential breadth of all pads at the mean diameter = $\pi D_m k_g$ = 24.5 in. The number of sectors (and grooves) for $B = L$ is then 24.5/3.425 = 7.2. Using seven lands, adjusted circumferential breadth B for each sector = 24.5/7 = 3.5 in. (For simpler fabrication, six or eight sectors should also be considered.) Runner velocity at the mean diameter, $U = \pi(9.175(1200/60)$ = 576.5 in./sec.

For square pads (L/B = 1) in a pivoted-pad bearing with h_1/h_2 = 2, which represents experience with centrally pivoted pads, Table 3.10.14 gives the following performance coefficients:

$$K_h = 0.261;\ K_f = 0.727;\ K_q = 0.849$$

The rise in temperature is given by Equation (3.10.16d), which assumes that the total frictional power loss H goes into heating the total oil flow Q passing over the pad.

$$\Delta T=\frac{K_f P}{K_q K_h^2 \rho C_p}=\frac{0.727(300)}{0.849(0.261)^2(0.0313)(4535)}=27^\circ\text{F}$$

Adding this ΔT to the 120°F feed temperature gives 147°F as the representative oil-operating temperature with a viscosity of 1.6×10^{-6} lb·sec/in.^{2} from Figure 3.10.4. Temperature rise to the maximum oil film temperature would be expected to be about 53°F, twice the 27°F. If this bearing were in a housing fully flooded with oil, feed temperature to each pad would become the housing oil temperature — essentially, the same as oil draining from the housing.

Minimum film thickness h_2 becomes from Equation (3.10.16a):

$$h_2=0.261\left[\left(1.6\times 10^{-6}\right)(576.5)(3.5)/300\right]^{0.5}=0.00086\text{ in.}$$

With a fixed tapered land, rather than a centrally pivoted pad for which it could be assumed that h_1/h_2 = 2, several iterations might be required with different assumed values of the h_1/h_2 ratio in order to determine the performance coefficients in Table 3.10.14. The proper value of h_1/h_2 will be the one that gives the same final calculated value of h_2 from the preceding equation as was assumed in the preliminary selection of K_h, K_f, and K_q.

After finding the values for h_2 and K_f, the power loss H can be determined using Equation (3.10.16b). For this example, the power loss would be $H = 5510$ lb·in./sec.

The total oil feed to the bearing should satisfy two requirements: (1) provide a full oil film over the bearing segment; and (2) maintain reasonably cool operation with no more than 30 to 40°F rise in the oil temperature from feed to drain. Equation (3.10.16c) can be used to find the oil feed Q needed at the sector inlet to form a full film. The oil feed needed for a 40°F rise is given by the following heat balance using typical density and specific heat values for petroleum oil:

$$Q = H\left(\rho C_p \, \Delta T\right) \tag{3.10.17}$$

The required oil feed will be the larger of the values determined by Equation (3.10.16c) and Equation (3.10.17).

The preceding calculations are for a single sector; power loss and oil feed would be multiplied by the number of sectors (seven) to obtain values for the total bearing. Consideration would normally follow for other pad geometries, and possibly other lubricants and oil flow patterns, in a search for the most promising design. More detailed calculations of film thickness, film temperatures, oil flow, and power loss could then be obtained by one of a number of computer codes available from bearing suppliers or other sources.

Oil-Film Bearing Materials

Selection of the material for use in a journal or thrust bearing depends on matching its properties to the load, temperature, contamination, lubricant, and required life.

Babbitts. Of the common bearing materials listed in Table 3.10.15, first consideration for rotating machines is usually a babbitt alloy containing about 85% tin or lead together with suitable alloying elements. With their low hardness, they have excellent ability to embed dirt, conform to shaft misalignment, and rate highest for compatibility with steel journals. Tin babbitts, which contain about 3 to 8% copper and 5 to 8% antimony, are usually the first choice for their excellent corrosion resistance. SAE

TABLE 3.10.15 Characteristics of Oil-Film Bearing Materials

Material	Brinell Hardness	Load Capacity, psi	Max Operating Temp., °F	Compatibility[a]	Conformability and Embedability[a]	Corrosion Resistance[a]	Fatigue Strength[a]
Tin babbitt	20–30	800–1500	300	1	1	1	5
Lead babbitt	15–25	800–1200	300	1	1	3	5
Copper lead	20–30	1500–2500	350	2	2	5	4
Leaded bronze	60–65	3000–4500	450	3	4	4	3
Tin bronze	65–80	5000+	500	5	5	2	2
Aluminum alloy	45–65	4000+	300	4	3	1	2
Zinc alloy	90–125	3000	250	4	5	5	3
Silver overplated		5000+	300	2	4	2	1
Two-component, babbitt surfaced		3000+	300	2	4	2	3
Three-component, babbitt surfaced		4000+	300	1	2	2	1

[a] Arbitrary scale: 1 = best, 5 = worst.

12 (ASTM grade 2) tin babbitt is widely used in automotive and industrial bearings. The much lower cost of lead babbitt, however, with 9 to 16% antimony and up to 12% tin for improved corrosion resistance, brings SAE 13, 14, and 15 grades into wide use for general automotive and industrial applications (Booser, 1992).

To achieve the high fatigue strength needed in reciprocating engines, only a very thin layer (commonly 0.001 in.) of babbitt is used so that much of the reciprocating load is taken on a stronger backing material (Kingsbury, 1992; DeHart, 1983). For bimetal bushings such as those used in automobile engines, oil grooves and feed holes are formed in continuous steel strip coated with babbitt. The strip is then cut to size and the individual segments are rolled into finished bearings.

For heavy-duty reciprocating engines, three-layer bearings are common. Using a steel strip backing, a thin overlay of SAE 19 or 190 lead babbitt is electroplated or precision cast on an intermediate layer about 0.1 to 0.3 in. thick of copper–nickel, copper–lead, leaded bronze, aluminum, or electroplated silver.

Copper Alloys. Copper–lead alloys containing 20 to 50% lead, cast or sintered on a steel back, provide good fatigue resistance for heavy-duty main and connecting rod bearings for auto, truck, diesel, and aircraft engines. The 10% lead–10% tin leaded bronze has been a traditional selection for bearings in steel mills, appliances, pumps, automotive piston pins, and trunions. This has been replaced in many applications by CA932 (SAE 660) containing 3% zinc for easier casting. The harder tin bronzes require reliable lubrication, good alignment, and 300 to 400 Brinell minimum shaft hardness. Cast tin bronze bushings are used at high loads and low speeds in farm machinery, earth-moving equipment, rolling mills, and in automotive engines for connecting rod bearings.

Utility of copper alloy bearings is limited to relatively low surface speeds by the tendency to form a copper transfer film on a steel shaft. Above about 1500 to 3000 ft/min, selective plucking of softer copper material from hotter load zones in the bearing may result in welded lumps forming on the cooler, stronger transfer layer on the mating steel shaft.

Zinc Alloys. Zinc alloys containing about 10 to 30% aluminum find some use for lower cost and better wear life in replacing leaded bronzes. They are used for oscillating and rotating applications involving speeds up to 1400 ft/min and temperatures up to 250°F.

Aluminum Alloys. Although finding only minor use in general industrial applications because of their limited compatibility with steel journals, aluminum alloys containing 6.5% tin, 1% copper, and up to 4% silicon are used as solid, bimetal, and trimetal bearings in automotive engines, reciprocating compressors, and aircraft equipment. Good journal finish and shaft hardness of Rockwell B 85 or higher are required. The good fatigue and corrosion resistance of aluminum alloys have led to use of a number of unique alloys containing major additions of silicon, lead, or tin to provide better compatibility characteristics (DeHart, 1983; Shabel et al., 1992).

Dry and Semilubricated Bearings

Various plastics, porous bronze and porous iron, carbon–graphite, rubber, and wood are widely used for bearings operating dry or with sparse lubrication (Booser, 1992). Unique properties of these materials have led to their broad use in applications once employing oil-film and ball and roller bearings. Although these materials provide good performance under conditions of poor or nonexistent lubrication at low speeds, performance commonly improves the closer the approach to full-film lubrication.

Plastics

Most commercial plastics find some dry or lubricated use in slow-speed bearings at light loads (Jamison, 1994). The most commonly used thermoplastics for bearings are polytetrafluorethylene (PTFE), nylon, and acetal resins. Thermosetting plastics used for bearings include phenolics, polyesters, and polyimides. Table 3.10.16 compares characteristics of typical plastic bearings with those of carbon–graphite, wood, and rubber, which are used in similar applications.

TABLE 3.10.16 Representative Limiting Conditions for Nonmetallic Bearing Materials

[c] 15% glass fiber.

In addition to the maximum temperature that can be tolerated, three operating limits shown in Table 3.10.16 are normally defined for plastic bearings (Blanchet, 1997): (1) maximum load at low speed, which reflects the compressive yield strength; (2) maximum speed for running under very light load; and (3) a $P\nu$ load-speed limit at intermediate speeds, which serves as a measure of the maximum tolerable surface temperature. Because wear volume in dry sliding is approximately proportional to total load and the distance of sliding, $P\nu$ also gives a measure of wear depth d in the modified form of Archard's relation (3.10.1), $d = k(P\nu)t$, where t is the operating time and wear factor k = wear coefficient K/hardness H.

Typical values of this wear factor k are given in Table 3.10.17. Because k values involve substantial variability, prototype tests are highly desirable for any planned application. Added fillers can reduce the wear factor for the base polymer by a factor of 10 to 1000 and more (Blanchet and Kennedy, 1992). Common fillers include inorganic powders such as clay, glass fibers, graphite, molybdenum disulfide, and powdered metal, and also silicone fluid as an internally available lubricant.

TABLE 3.10.18 Operating Limits for Porous Metal Bearings

Porous Metal	Nominal Composition, wt%	Pressure Limit, P, MN/m^2 Static	Dynamic	Speed Limit, v, m/sec	Pv Limit $MN/(m.sec)$
Bronze	Cu 90, Sn 10	59	28	6.1	1.8[a]

Aluminum		28	14	6.1	1.8

Note: To convert MN/m^2 to psi, multiply by 145.

[a] Approximately equivalent to 50,000 psi × ft/min limit often quoted by U.S. suppliers.

Porous Metals

Bearings of compressed and sintered bronze, iron, and aluminum alloy powder are produced at the rate of millions per week for shaft sizes ranging from about 1.6 to 150 mm. These sleeve bearings and thrust washers are used in a wide variety of small electric motors, appliances, business machines, machine tools, automotive accessories, and farm and construction equipment (Cusano, 1994; Morgan, 1984). Traditional powder metal bearings consist of 90% copper and 10% tin (Table 3.10.18). The common pore volume of 20 to 30% is usually impregnated with a petroleum oil of SAE 30 viscosity. To promote formation of an oil film, high porosity with its high oil content is employed for higher speeds, often with an oil wick or grease providing a supplementary lubricant supply. Lower porosity with up to 3.5% added graphite is used for lower speeds and oscillation where oil film formation is difficult.

Porous iron bearings are used for lower cost, often with some copper and graphite added for high load capacity at low speed. Iron with up to 40% of added 90-10 bronze powder provides many of the characteristics of porous bronze bearings while enjoying the lower cost of the iron. Porous aluminum containing 3 to 5% copper, tin, and lead finds limited use for providing cooler operation, better conformability, and lower weight.

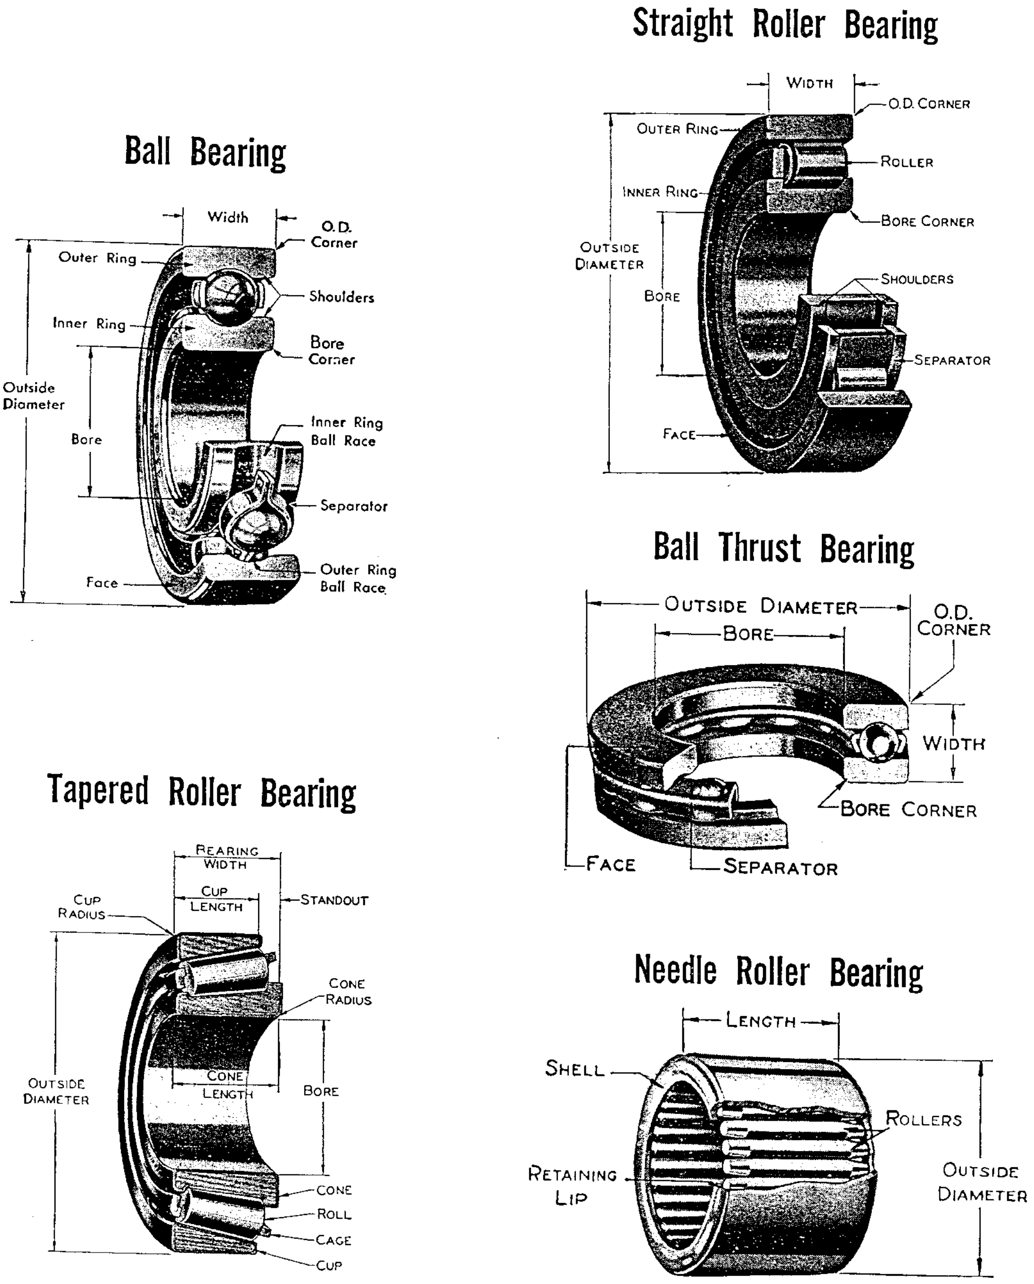
Table 3.10.18 gives approximate operating limits for porous metal bearings. Generally, maximum Pv values for sleeve bearings range up to 50,000 psi·ft/min. Pv levels for thrust bearings should generally not exceed about 20% of this value.

Rolling Element Bearings

Types of Rolling Element Bearings

Rolling element bearings may be classified according to the type of rolling element, i.e., ball or roller, and the loading direction. Ball and roller bearings can be designed to carry radial or thrust loads, or a combination of the two. Standard rolling element bearing configurations are shown in Figure 3.10.8, and the capabilities of the different types are summarized in Figure 3.10.9.

Ball bearings usually consist of a number of hardened and precisely ground balls interposed between two grooved and hardened rings or races. A cage or separator is used to keep the balls equally spaced around the groove. The most common *radial ball bearing* is a deep groove, or Conrad, type designed to carry large radial loads, with a small thrust load capability. The radial capacity of a deep groove bearing can be increased by inserting more balls in the bearing by means of a face-located filling notch (which decreases the thrust capacity) or a split inner or outer ring (which requires a means to hold the ring halves axially together). The thrust capability of a radial ball bearing can be increased by inducing angular contact between ball and rings. A single-row angular contact bearing can carry thrust load in only one direction; the thrust load capacity is dependent on the contact angle (angle between the line of action of the force and the plane perpendicular to the shaft axis). Duplex angular contact bearings consist of two angular contact bearings mounted together so they can carry thrust loads in either direction with little axial play, or they can be mounted in tandem to double the axial and radial load-carrying capacity.



Ball Bearing

Straight Roller Bearing

Tapered Roller Bearing

Ball Thrust Bearing

Needle Roller Bearing

FIGURE 3.10.8 Major types of rolling element bearings.

Self-aligning ball bearings are designed to accommodate more shaft misalignment than is possible with other radial ball bearings.

Thrust ball bearings are used primarily in machinery with a vertically oriented shaft, which requires a stiff axial support. Many such bearings have a 90° contact angle and as a result can carry essentially no radial load; they also have limited high speed capability. If thrust loads in both directions are to be carried, a second row of balls must be added.

Roller bearings can be made with cylindrical, tapered, or spherical rollers. As with ball bearings, the rollers are contained between two rings, with a cage or separator used to keep the rollers separated. The

	TYPE	SIZE RANGE IN INCHES		AVERAGE RELATIVE RATINGS				DIMENSIONS

FIGURE 3.10.9 Characteristics of standard rolling element bearing configurations.

cage can be guided by the rollers or one of the rings. Because roller bearings operate with line contacts, as opposed to the point (or elliptical) contacts that occur in ball bearings, roller bearings are stiffer (less radial displacement per unit load) and have a greater load-carrying capacity than a ball bearing of similar size. Roller bearings are more expensive than ball bearings of comparable size.

Radial cylindrical roller bearings are designed to carry primarily radial loads. Cylindrical roller bearings have a high radial load capacity and low friction, so they are suitable for high speed operation. Their thrust load capacity is limited to that which can be carried by contact (sliding) between the ends of the rollers and the flange or shoulder on the ring that contains them.

The rollers in many cylindrical roller bearings are actually slightly crowned to relieve stress concentrations that would otherwise occur at the ends of the rollers and to compensate for misalignment of the bearing. In order to increase the load-carrying capacity of roller bearings, a second row of rollers is added instead of using longer rollers. This is because long rollers (i.e., length/diameter > 1.7) tend to skew in the roller path, thus limiting their high speed capability and sometimes shortening their life. Needle bearings have long rollers, however, and they are useful when there are severe radial space limitations and when neither high load capacity nor high speeds are required.

Spherical roller bearings usually have an outer ring with a spherical inside diameter, within which are barrel-shaped rollers. This makes these bearings self-aligning and also gives them a contact area between roller and ring larger than those of other rolling element bearings. Because of this, spherical roller bearings have a very high radial load-carrying capacity, along with some ability to carry thrust loads. They have higher friction between roller and ring and this limits their high-speed capability.

Tapered roller bearings have tapered rollers, ideally shaped like truncated cones, contained between two mating cones of different angles: the inner cone and the outer cup. The contact angle of the bearing determines its thrust load capability; a steeper angle is chosen for more thrust capacity. If a single row of rollers is used, the bearing is separable and can carry thrust loads in only one direction. If the thrust is double-acting, a second bearing can be mounted in a back-to-back configuration or a double row bearing can be selected. In tapered roller bearings there is sliding contact between the ends of the rollers and the guide flange on the inner cone; this requires lubrication to prevent wear and reduce friction.

Thrust roller bearings can be cylindrical, needle, tapered, or spherical (Figure 3.10.9). In each case, load-carrying capacity is high; however, the sliding that occurs between rollers and rings requires lubrication and cooling.

Rolling Element Bearing Materials

Ball and roller bearings require materials with excellent resistance to rolling contact fatigue and wear, as well as good dimensional stability and impact resistance. The rolling elements are subjected to cyclic contact pressures that can range from 700 to 3500 MPa (100 to 500 ksi) or more, and the bearing materials must be hard enough to resist surface fatigue under those conditions. Of the through-hardening steels that meet these requirements, the most popular is AISI 52100, which contains about 1% carbon and 1.5% chromium. In general, balls and rollers made from 52100 are hardened to about Rockwell C60.

Standard bearings made from 52100 may suffer from unacceptable dimensional changes resulting from metallurgical transformations at operating temperatures above 140°C (285°F). Special stabilization heat treatments enable operation at higher temperatures, with successful operation at temperatures as high as 200°C (390°F) achieved in cases involving low loads. However, the material's strength and fatigue resistance diminish if the bearing temperature increases above about 175°C (350°F), so above that temperature materials with better hot-hardness, such as M50 tool steel, are required. Carburizing steels such as AISI 8620 have been developed for tapered roller bearings and other heavily loaded types that benefit from the tougher core and case compressive residual stress developed during carburizing. For applications in oxidative or corrosive environments, a hardened martensitic stainless steel such as SAE 440C may be chosen.

For the highest operating temperatures, ceramic materials may be used in bearings. The most promising of the ceramics for rolling element bearing applications is silicon nitride. Its major use so far in

TABLE 3.10.19 Temperature Limits for Rolling Element Bearing Materials

Material	Maximum Operating Temperature °C	Maximum Operating Temperature °F
AISI 52100	140–175	285–350
AISI 8620 (carburized)	150	300
440C stainless steel	170	340
M50 tool steel	315	600
Hybrid Si_3N_4–M50	425	800
All-ceramic (Si_3N_4)	650	1200

bearings has been in hybrid bearings with ceramic balls or rollers and metallic rings, but all-ceramic bearings have also been developed.

The temperature limits of these bearing materials are given in Table 3.10.19. For all bearing materials, great care must be taken in the processing and production stages to ensure that no defects or inclusions are present that could serve as an initiation site for fatigue cracks. For most high-performance metallic bearings, this requires a very clean steel production process, such as vacuum arc remelting. Heat treatment of the material is also important to produce the required dimensional stability. The production process for ceramic bearings is even more critical because a defect in a ceramic bearing element could result in catastrophic fracture of the brittle material.

Bearing cages or retainers have the separation of the rolling elements as their primary purpose. In some cases, they also provide some solid lubrication to the bearing. Low carbon steel is the most common cage material, but bronze (silicon iron bronze or aluminum bronze) and polymers (particularly nylon 6-6) are used in many applications.

Selection of Rolling Element Bearings

It has been stated that if a rolling element bearing in service is properly lubricated; properly aligned; kept free of abrasive particles, moisture, and corrosive agents; and properly loaded, then all causes of damage will be eliminated except one — contact fatigue (Harris, 2000). The fatigue process results in a spall, which may originate on or just beneath the contact surface. Studies of rolling contact fatigue life by Lundberg and Palmgren (1947, 1952) and others showed that most rolling element bearings have fatigue lives that follow a Weibull statistical distribution: the dependence of strength on volume is explained by the dispersion in material strength. Most bearings today are designed according to the Lundberg–Palmgren model, which has been standardized by international (ISO, 2000) and national (e.g., ANSI/AFBMA, 1990) standards.

The basic rating life of rolling element bearings is the L_{10} life, which is the number of revolutions at constant speed for which there is a 10% probability of failure (or 90% reliability). The basic dynamic load-carrying capacity, or load rating, of a bearing is the constant load C, which corresponds to an L_{10} life of 1 million revolutions. For any other bearing load F, the L_{10} life can be determined by the following relationship:

$$L_{10} = (C/F)^n \tag{3.10.18}$$

where the load-life exponent $n = 3$ for ball bearings, and $n = 10/3$ for roller bearings.

For light loads, fatigue life may extend well beyond that predicted by Equation (3.10.18) (Ioannides and Harris, 1985). Even infinite fatigue life is possible with Hertz elastic contact stresses below 150 ksi (ASME 2003), or with oil film thickness in loaded contacts greater than about six times the composite surface roughness. This limiting stress varies with different steels, drops for operating temperatures above 80°C, and reaches 258 ksi with silicon nitride ceramics.

The equivalent bearing load includes contributions from radial as well as thrust loads and can be calculated by the following expression:

$$F = XF_r + YF_a \tag{3.10.19}$$

where X is a radial load factor; Y is a thrust load factor; F_r is the radial load applied to the bearing; and F_a is the applied thrust (or axial) load.

Values for the dynamic load rating C, as well as the load factors X and Y for any bearing configuration, can be found in manufacturers' catalogs, or they can be calculated according to formulas given in bearing texts by Harris (2000) or Brandlein et al. (2002). Life adjustment factors can be used to adjust the desired L_{10} life to account for special operating conditions, special material selections, special lubrication conditions, or reliability different from 90% (ASME, 2003).

The bearing user will generally select a commercially available bearing by the following procedure:

1. Determine the axial and thrust loads acting at the bearing location.
2. Determine the required bearing life (L_{10}).
3. Select the most appropriate bearing type from among those given in Figure 3.10.9.
4. Use the X and Y values appropriate to the type of bearing and loading conditions in Equation (3.10.19) to find the equivalent dynamic bearing load F.
5. Determine the required dynamic load capacity C from Equation (3.10.18).
6. Select a bearing with a dynamic load capacity at least as large as the required value from a manufacturer's catalog.
7. Provide an appropriate mounting arrangement for the bearing. Manufacturers' catalogs can be consulted for guidance in designing the mounting and selecting appropriate fits for the bearing. The importance of the fit cannot be overemphasized; improper fit can result in considerable reduction in bearing life.
8. Provide adequate lubrication for the bearing (see below). Seals and/or shields may be integrated into the bearing to retain or protect the lubricant in the bearing.

Despite their selection on the basis of fatigue life, lives of most ball bearings in industrial service appear to be limited by wear from factors such as misalignment, dried grease, or contamination (Khonsari and Booser, 2002).

Rolling Bearing Lubrication

The primary load-carrying contacts between rolling elements and rings exhibit nearly pure rolling. There are many sliding contacts in rolling element bearings, however, including those in which roller ends contact the internal flanges of rings; rolling elements contact separator/cage; and the separator contacts the guiding (piloting) ring of the bearing. All of those contacts must be lubricated to limit friction and wear; a grease or an oil can be used for that purpose.

Under most normal operating conditions, rolling element bearings can be grease lubricated. *Greases* coat surfaces with a thin boundary lubricant film of oil, thickener, and additive molecules, thus providing protection against sliding wear, and provide oil to lubricate the concentrated rolling contacts (see below). The selection of a grease depends on its effective temperature range, oil viscosity, consistency, and rust-inhibiting properties. For normal applications, a bearing should be filled with grease up to 30 to 50% of its free volume. Overfilling will cause overheating, particularly at high speeds. Grease will deteriorate with time and leak out. For that reason, a relubrication schedule should be developed, with grease added at intervals that can be estimated by the following expression (Neale, 1993):

$$\text{relubrication interval}\left(\text{hours}\right)=\left(k/d^{1/2}\right)\left[\left(14\times10^{-6}/n\right)-4d^{1/2}\right] \tag{3.10.20}$$

where k = 10 for radial ball bearings, = 5 for cylindrical roller bearings, and = 1 for spherical or tapered roller bearings; d = bearing bore diameter (mm); and n = speed (rpm).

Oil lubrication is required when high speed or high operating temperatures preclude the use of grease. It is necessary to choose an oil of proper viscosity and appropriate viscosity–temperature characteristics

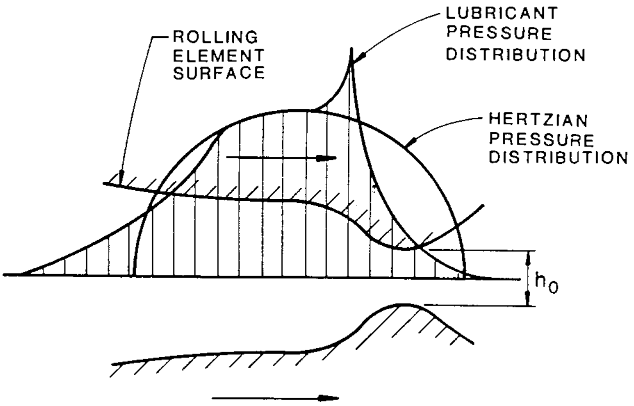

FIGURE 3.10.10 Typical pressure and film thickness distributions in elastohydrodynamic contact.

in order to ensure sufficient thickness of oil film in the lubricated concentrated contacts. If viscosity is too low, the film thickness will not prevent metal–metal contact; if the viscosity is too high, excessive friction will occur. Oil can be applied to a bearing by one of several methods (listed in order of increasing effectiveness at increasing bearing speed):

- *Oil bath* — the rolling elements carry the oil through the bearing.
- *Oil circulating system* — the oil is pumped from the bearing through an external filter and heat exchanger and back to the bearing.
- *Oil mist* — an air stream carries oil droplets to the bearing.
- *Oil jets* — the oil is injected into the bearing through carefully positioned nozzles.

The quantity and entry velocity of the oil must be carefully selected and controlled in order to dissipate the heat generated in the bearing.

The lubrication mechanism in the concentrated contacts of rolling element bearings is *elastohydrodynamic lubrication* (EHL). EHL typically occurs in lubricated, nonconforming elastic contacts, such as the elliptical contact that occurs between ball and raceway or the rectangular contact between roller and ring. These lubricated contacts have a very small area and the pressures are very high. Because of those high pressures, the contacting surfaces deform and the lubricant viscosity increases, thereby aiding its ability to sustain heavy loading without oil-film breakdown. A diagram of these phenomena is shown in Figure 3.10.10. The most important parameter of the concentrated contact, from the point of view of rolling-element bearing performance, is minimum EHL film thickness, h_o. The following expression can be used to find minimum film thickness in most rolling-element bearing contacts (Hamrock and Dowson, 1977):

$$h_o = 3.63\, R_x\, U^{0.68}\, G^{-0.49}\, W_p^{-0.73} \left(1 - e^{-0.68\kappa}\right) \tag{3.10.21}$$

where $R_x = (R_{x1}\, R_{x2})/(R_{x1} + R_{x2})$, $R_y = (R_{y1}\, R_{y2})/(R_{y1} + R_{y2})$, ellipticity parameter $\kappa = R_x/R_y$, $U = \mu\,(u_1 + u_2)/2E'R_x$, μ = absolute viscosity, u_1 and u_2 = velocities of rolling element and ring, respectively, $E' = E/(1 - \nu^2)$, E = modulus of elasticity, ν = Poisson's ratio, $G = \alpha E'$, α =pressure-viscosity exponent, $W_p = W/E'R_x^2$, and W = radial load.

The minimum film thickness must be large enough to prevent metal–metal contact within the lubricated conjunctions. The criterion for this is stated as:

$$h_0 \geq 1.5\left(r_{q1}^2 + r_{q2}^2\right)^{0.5} \tag{3.10.22}$$

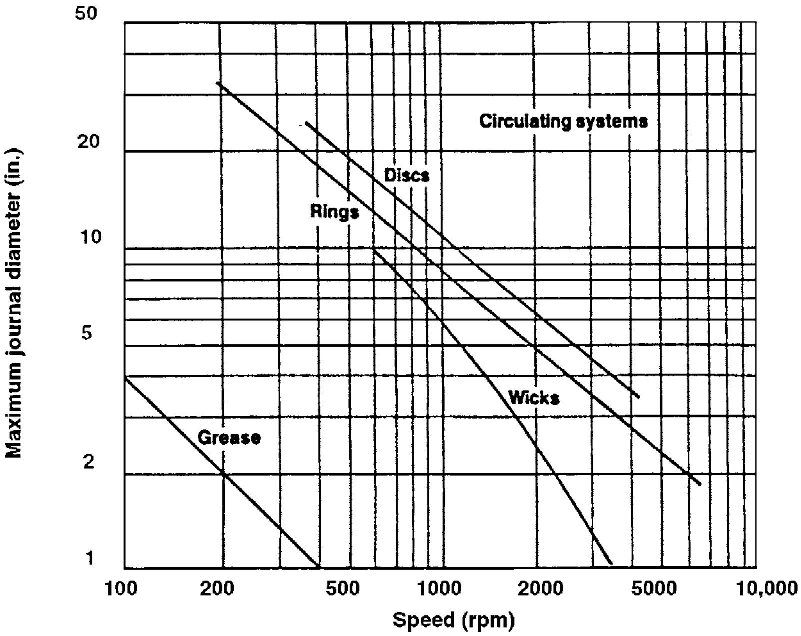

FIGURE 3.10.11 Upper limits for journal bearing lubrication methods. (From Wilcock, D.F. and Booser, E.R., *Bearing Design and Application*, McGraw–Hill, New York, 1987.)

where r_{q1} and r_{q2} are the rms surface roughness of the rolling element and ring, respectively. If the minimum film thickness is less than this value, complete elastohydrodynamic lubrication will not occur, and this could result in wear, surface fatigue, and eventual early bearing failure (i.e., well before the predicted L_{10} life). This drop in life can be minimized at low speeds with oils and greases incorporating certain antiwear additives.

An alternative to oil or grease lubrication for rolling element bearings operating under severe conditions is *solid lubrication*. Solid lubricants can be used effectively in high temperatures or vacuum conditions in which liquid lubricants are impractical or would provide marginal performance. Solid lubricants do not prevent solid–solid contact, so wear of the lubricant coating can be expected; bearing life is governed by the depletion of the solid lubricant film.

Lubricant Supply Methods

Lubrication systems for oil-film bearings can generally be grouped into three classifications: self-contained devices for small machines; centralized systems (common in manufacturing plants); and circulating systems dedicated to a single piece of equipment such as a motor, turbine, or compressor. Upper speed limits for common journal bearing lubrication methods are indicated in Figure 3.10.11 (Wilcock and Booser, 1987). Submerging the bearing directly in an oil bath is a common alternative for vertical machines.

Self-Contained Units

Lifting oil by *capillary action* from a small reservoir is used to feed small bearings in business machines, household appliances, electrical instruments, controls, and timer motors. In capillary tubes, the height h to which oil will rise is (Wilcock and Booser, 1987; Khonsari and Booser, 2002):

$$h = 2\sigma\cos\theta/(r\rho) \tag{3.10.23}$$

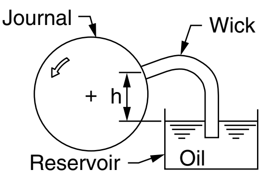

FIGURE 3.10.12 Wick-lubricated journal bearing. (From Elwell, R.C., in *Handbook of Lubrication and Tribology*, Vol. III, 515–533, CRC Press, Boca Raton, FL, 1994.)

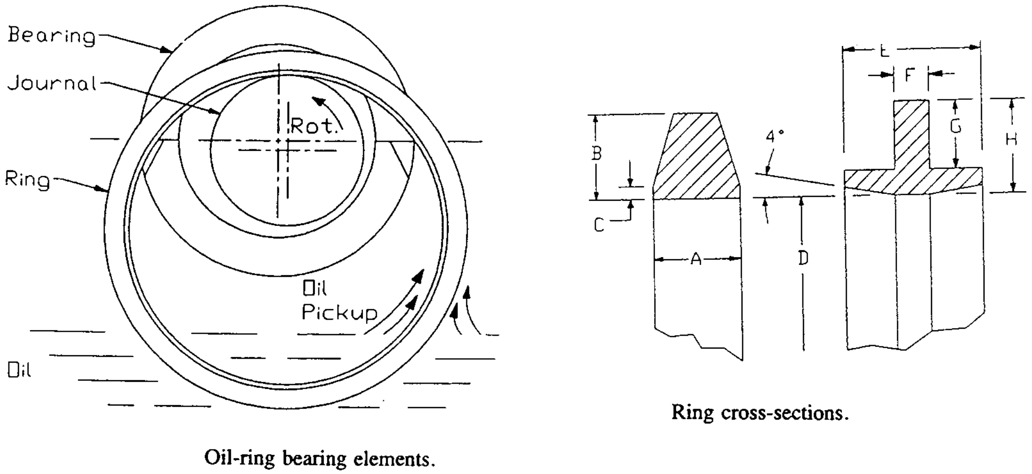

FIGURE 3.10.13 Oil-ring bearing elements and ring cross-sections. (From Elwell, R.C., in *Handbook of Lubrication and Tribology*, Vol. III, 515–533, CRC Press, Boca Raton, FL, 1994.)

where σ = surface tension, lb/in.; r = capillary radius (or spacing between two parallel plates), in.; and ρ =oil density, lb/in.^{3}. Because oils wet most surfaces readily, the cosine of the contact angle can be taken as unity. As an example, with $\sigma = 1.7 \times 10^{-4}$ lb/in. for a petroleum oil, the rise in an 0.005-in. radius capillary will be: $h = 2(1.7 \times 10^{-4})(1)/(0.005)(0.0307) = 2.2$ in.

Wick lubrication is applied in millions of fractional horsepower motors annually. Although wicks generally are not efficient at raising oil more than about 2 in., lift may be up to 5 in. in railway journal bearings. Referring to Figure 3.10.12, petroleum oil delivery by a typical wick can be estimated by the following equation (Elwell, 1994):

$$Q = kAF_o\left(h_u - h\right)/\left(\mu L\right) \quad \text{in.}^3/\text{min} \tag{3.10.24}$$

where the constant k reflects the capillary spacing in the wick and the surface tension of the oil; A is the wick cross section area, in.^{2}; F_o is volume fraction of oil in the saturated wick (often about 0.75); h_u is the ultimate wicking height, about 7.5 in. for SAE Grade F-1 felt; h is oil delivery height above the reservoir surface, in; L is wick length, in.; μ is viscosity at the wick temperature, lb.sec/in.$^2 \times 10^6$; k is approximately 0.26 for SAE Grade F-1 felt.

Oil rings hanging over a journal, as illustrated in Figure 3.10.13 and Table 3.10.20, are used to lift oil to journal bearings in electric motors, pumps, and medium-size industrial machines (Elwell, 1994). At very low journal surface speeds below about 2 to 3 ft/sec, the ring will run synchronously with its journal. At higher speeds, increasing viscous drag on the ring in its reservoir will slow the ring surface velocity; oil ring rpm at higher speeds is often in the range of 1/10 the journal rpm. Above about 45 ft/sec journal surface velocity, oil delivery drops to an unusably low level as centrifugal throw-off and windage interfere.

TABLE 3.10.20 Typical Oil-Ring Dimensions[a]

A	B	C	D	E	F	G	H
6 (0.24)	6 (0.24)	1 (0.04)	100 (3.94)

8 (0.31)	8 (0.31)	2 (0.08)	165 (6.50)				
16 (0.63)	13 (0.51)	2 (0.08)	200 (7.87)	16 (0.63)	5 (0.20)	11 (0.43)	10 (0.39)
			335 (13.2)	21 (0.83)	6 (0.24)	13 (0.51)	14 (0.55)
			585 (23.0)	25 (1.0)	7 (0.28)	14 (0.55)	20 (0.79)
			830 (32.7)	32 (1.3)	8 (0.31)	16 (0.63)	27 (1.06)

[a] mm (in.).

TABLE 3.10.21 Typical Oil Circulating Systems

Application	Duty	Oil Viscosity at 40°C (cSt)	Oil Feed (gpm)	Pump Type	Reservoir Dwell Time (min)	Type	Rating (μm)
Electrical machinery	Bearings	32–68	2	Gear	5	Strainer	50
General	Bearings	68	10	Gear	8	Dual cartridge	100
Paper mill dryer section	Bearings, gears	150–220	20	Gear	40	Dual cartridge	120
Steel mill	Bearings	150–460	170	Gear	30	Dual cartridge	150
	Gears	68–680	240	Gear	20	Dual cartridge	
Heavy duty gas turbines	Bearings, controls	32	600	Gear	5	Pleated paper	5
Steam turbine-generators	Bearings	32	1000	Centrifugal	5	By-pass 15%/h	10

These self-contained systems usually supply much less oil to a bearing than needed to form a full hydrodynamic oil film (Elwell, 1994). With the starved oil supply generating an oil wedge of reduced circumferential extent, power loss will be lowered at the expense of reduced load capacity (smaller minimum film thickness).

Centralized Distribution Systems

Limitations with individual localized lubricating devices have led to widespread use of centralized systems for factory production-line equipment, construction and mining machines, and similar applications. Oil or soft grease is pumped from a central reservoir in pulses or as metered continuous feed. Oil mist is piped for distances up to 300 ft for machines in petrochemical plants and steel mills. Polymer additives in the 50,000 to 150,000 mol wt range greatly reduce the escape of stray oil mist into the atmosphere.

Circulating Systems

When bearing design, reliability requirements, or equipment considerations preclude use of simpler oil feed, a circulating system involving an oil reservoir, pump, cooler, and filter (Twidale and Williams, 1984) is employed. These systems become quite compact with the space limitations in aircraft, marine, or automobile engines — the reservoir may simply be the machine sump with capacity to hold only a 20 to 60-sec oil supply. Characteristics of typical oil-circulating systems for industrial use are given in Table 3.10.21 (Wilcock and Booser, 1987).

Dynamic Seals

To control leakage of lubricating oil and process fluids and to minimize contamination, fluid seals commonly accompany bearings in a wide variety of machinery. Static seals, such as O-rings and gaskets,

TABLE 3.10.22 Characteristics of Dynamic Seals

Type of Seal	Type of Motion		Extent	Friction of Use	Leakage	Life
	Rotating	Reciprocating				
Contact

Source: Modified from Stair, W., in *Handbook of Lubrication*, vol. 2, 581–622, CRC Press, Boca Raton, FL, 1984.

provide sealing between surfaces that do not move relative to each other. Dynamic seals, which will be the focus of this discussion, restrain flow of fluid between surfaces in relative motion. Most dynamic seals could be classified as contact or as clearance seals. Contact seals are used when surfaces are in sliding contact, while clearance seals imply that surfaces are in close proximity to each other but do not contact. The major types of dynamic seals are listed in Table 3.10.22. Further details about the design and analysis of dynamic sealing elements can be found in the handbook article by Stair (1984) and in the book by Lebeck (1991).

As an example of a contact seal, ball bearings are often sealed to retain their lubricant and to keep out contaminants over a long lifetime. For small grease-lubricated bearings, the sealing function is often accomplished by lightly loaded contact between a rubber lip seal component and the bearing ring. For shafts ranging up to about 2 in. (5 cm) in diameter, the lip seal may be replaced by a closely fitted, but noncontacting, shield; this helps contain the grease and restricts intrusion of dirt and other contaminants. For more severe sealing requirements in rolling element bearings, labyrinth clearance seals may be used (Harris, 2000).

The most common seals for rotating shafts passing through fixed housings, such as pumps or gearboxes, are radial lip seals and mechanical face seals. These contact seals can be designed to handle a wide range of sealed fluids, temperatures, velocities, and pressures (Lebeck, 1991; Stair, 1984). Material selection and surface finish considerations are similar to those discussed in the subsections on sliding friction and its consequences and on dry and semilubricated bearings.

When high surface speeds are encountered, wear and frictional heating may prohibit use of rubbing contact seals. For such applications, clearance seals such as close-fitting labyrinth seals or controlled-clearance fluid-film seals can be used. Fluid-film seals can be hydrostatic or hydrodynamic; both types have a pressurized film of fluid that prevents contact between the sealed surfaces and uses pressure balancing to restrain leakage. The principles governing their operation are similar to those discussed in the subsection on fluid film bearings. Details of fluid-film seals can be found in the article by Shapiro (1995).

3.11 Pumps and Fans

Robert F. Boehm

Introduction

Pumps are devices that impart a pressure increase to a liquid. Fans are used to increase the velocity of a gas, but this is also accomplished through an increase in pressure. The pressure rise found in pumps can vary tremendously, and this is a very important design parameter, along with the liquid flow rate. This pressure rise can range from simply increasing the elevation of the liquid to increasing the pressure by hundreds of atmospheres. Fan applications, on the other hand, generally deal with small pressure increases. In spite of this seemingly significant distinction between pumps and fans, the fundamentals of certain types of these machines, as well as their applications and theories of operation, share many similarities.

Pumps or fans can be used as a means of forcing flows into a region of interest or, alternatively, exhausting flows from a region of interest. For example, induced draft fans are those in which the inlet to the fan is attached to the region of interest. Forced draft fans are hooked with their exhaust side to the region of interest. Pumps are usually not denoted with this distinction except for vacuum pumps, which are always used to exhaust a fluid from a volume of interest.

The appropriate use of pumps and fans depends upon the satisfactory choice of device and the proper design and installation for the application. A check of sources of commercial equipment shows that varieties of pumps and fans are many. Each of these has special characteristics that must be appreciated for achieving proper function. Preliminary design criteria for choosing between different types are given by Boehm (1987).

As to be expected, the wise applications of pumps and fans require knowledge of fluid flow fundamentals. Unless the fluid mechanics of a particular application is understood, the design could be less than desirable.

In this section, pump and fan types are briefly defined. In addition, typical application information is given. Also, some ideas from fluid mechanics that are especially relevant to pump and fan operation are reviewed. For more details on this latter topic, see the section of this book that discusses fluid mechanics fundamentals.

Pumps

Raising water from wells and cisterns was the earliest form of pumping (a very detailed history of early applications is given by Ewbank, 1842). Modern applications are much broader, and these find a wide variety of machines in use. Modern pumps function on one of two principles. By far the majority of pump installations are of the *velocity head* type. In these devices, the pressure rise is achieved by giving the fluid movement. At the exit of the machine, this movement is translated into a pressure increase by slowing down the fluid. The other major type of pump is called *positive displacement*. These devices are designed to increase the pressure on the liquid while essentially trying to compress the volume. A categorization of pump types (with the exception of vacuum pumps) has been given by Krutzsch (1986); an adaptation is shown below.

- I. Velocity head
  - A. Centrifugal
    - 1. Axial flow (single or multistage)
    - 2. Radial flow (single or double suction)
    - 3. Mixed flow (single or double suction)
    - 4. Peripheral (single or multistage)
  - B. Special effect
    - 1. Gas lift
    - 2. Jet
    - 3. Hydraulic ram
    - 4. Electromagnetic
- II. Positive displacement
  - A. Reciprocating
    - 1. Piston, plunger
      - a. Direct acting (simplex or duplex)
      - b. Power (single or double acting, simplex, duplex, triplex, multiplex)
    - 2. Diaphragm (mechanically or fluid driven, simplex or multiplex)

B. Rotary
  1. Single rotor (vane, piston, screw, flexible member, peristaltic)
  2. Multiple rotor (gear, lobe, screw, circumferential piston)

In the next subsections, some of the more common pumps are described.

Centrifugal and Other Velocity-Head Pumps

Centrifugal pumps are used in more industrial applications than any other kind of pump, primarily because these pumps offer low initial and upkeep costs. Traditionally, pumps of this type have been limited to low-pressure-head applications; however, modern pump designs have overcome this problem unless very high pressures are required. Some of the other good characteristics of these types of devices include smooth (nonpulsating) flow and the ability to tolerate nonflow conditions.

The most important parts of the centrifugal pump are the *impeller* and *volute*. An impeller can take on many forms, ranging from essentially a spinning disc to designs with elaborate vanes. The latter is usual. Impeller design tends to be somewhat unique to each manufacturer, as well as finding a variety of designs for a range of applications. An example of an impeller is shown in Figure 3.11.1. This device imparts a radial velocity to the fluid that has entered the pump perpendicular to the impeller. The volute (there may be one or more) performs the function of slowing the fluid and increasing the pressure. A good discussion of centrifugal pumps is given by Lobanoff and Ross (1992).

The design of a pump and its performance are dependent upon a number of applicable variables. These will be noted in more detail later; they include the pump operating speed, flow rate, and developed head. Pump engineers generally combine these variables together into a parameter called the *specific speed*, N_s. This is given as

$$N_s = Q^{0.5}N/H^{0.75}$$

where

Q = volume rate of flow, gpm
N = operating speed of pump, rpm
H = pump head, ft

Historically, the efficiency is related to this parameter in a general way, showing a maximum efficiency of over 90% at a specific speed of about 2500 and very high flow rates (Yedidiah, 1996). For lower flows, the maximum efficiency is decreased and occurs at smaller values of N_s. Rishel (2000) reported on the results of a study of actual installations of “wire-to-water” efficiencies for pumps. These ranged from 20% for small systems (20 gpm) to 84% for systems at 2000 gpm. The head was varied in the study. A plot of his data is given in Figure 3.11.2.

An important factor in the specification of a centrifugal pump is the casing orientation and type. For example, the pump can be oriented vertically or horizontally. Horizontal mounting is most common.

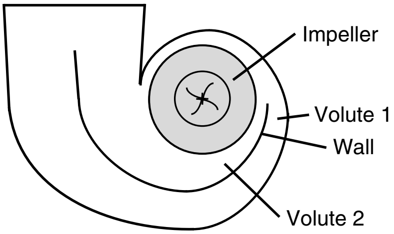

FIGURE 3.11.1 A schematic of a centrifugal pump is shown. The liquid enters perpendicular to the figure, and a radial velocity is imparted by clockwise spin of the impeller.

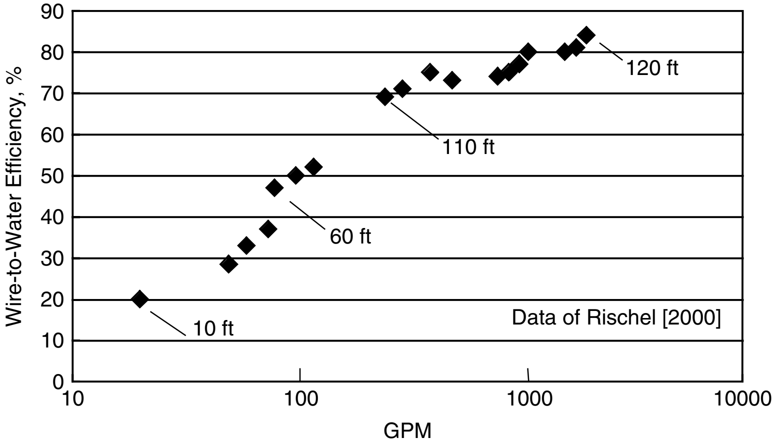

FIGURE 3.11.2 "Wire-to-water" efficiencies for centrifugal pumps are given. (Based upon the data of Rishel, J.B., 2000. *ASHRAE J.*, March, 48.) The head varies throughout the data within the range shown.

Vertical pumps usually offer benefits related to ease of priming and reduction in required NPSH (see discussion later). This type also requires less floor space. Submersible and immersible pumps are always of the vertical type. Another design factor is the way in which the casing is split, which has implications about ease of manufacture and repair. Casings split perpendicular to the shaft are called radially split, while those split parallel to the shaft axis are denoted as axially split. The latter can be horizontally split or vertically split. The number of stages in the pump greatly affects the pump-output characteristics. Several stages can be incorporated into the same casing, with an associated increase in pump output. Multistage pumps are often used for applications with total developed head over (about) 50 atm.

It can be important whether a pump is self-priming (the impeller of the pump must be immersed in the fluid to be pumped). In general, a centrifugal pump cannot begin pumping unless it is primed. If a centrifugal pump is filled with air when it is turned on, the initiation of pumping action may not be sufficient to bring the fluid into the pump. Pumps can be specified with features that can minimize priming problems.

Although not applicable to centrifugal pumps only, a major application here is the use of a *variable speed drive* (*VSD*). In many situations, the design condition is not the only one at which the pump may need to operate. For example, if the flow decreased for some reason, the head would go up, and vice versa. This may cause problems with the particular pump installation. A VSD will allow these situations, as well as part load operation, to be accommodated. Without VSD, for example, this would be accomplished by mechanical devices in order to throttle the flow. A VSD can greatly enhance system operational efficiency.

Other types of velocity-head pumps are available. *Gas lifts* accomplish a pumping action by a drag on gas bubbles that rise through a liquid. *Jet pumps* (eductors) increase pressure by imparting momentum from a high-velocity liquid stream to a low-velocity or stagnant body of liquid. The resulting flow then goes through a diffuser to achieve an overall pressure increase. Related designs that use a gas or a vapor to impart the momentum are called *jet ejectors*. An excellent summary of these types of devices has been given by Power (1994). In all cases in which eductors or ejectors are used, a separate high-pressure fluid stream needs to be available to power the device.

Positive-Displacement Pumps

Positive-displacement pumps demonstrate high discharge pressures and low flow rates. Usually, this is accomplished by some type of pulsating action. A piston pump is a classical example of a positive-displacement machine. Rotary pumps are one type of positive displacement device that does not impart pulsations to the exiting flow (a full description of these types of pumps is given by Turton, 1994). Several techniques are available for dealing with pulsating flows, including use of double-acting pumps (usually of the reciprocating type) and installation of pulsation dampeners.

Positive displacement pumps usually require special seals to contain the fluid. Costs are higher initially, as well as for maintenance, compared to most pumps that operate on the velocity-head basis. Positive-displacement pumps demonstrate an efficiency nearly independent of flow rate, in contrast to the velocity-head type.

Reciprocating pumps offer very high efficiencies, reaching 90% in larger sizes. These types of pumps are more appropriate for pumping abrasive liquids (e.g., slurries) than are centrifugal pumps.

Piston pumps are commonly applied positive-displacement devices. The piston-cylinder arrangement is familiar to most people who have used pumps. These pumps can be *single acting* or *double acting.* In the latter classification, the design is such that pumping takes place on both sides of the piston. Many application engineers recommend a maximum duty pressure of about 2000 psi. Higher pressures can be handled by a plunger-rod pump; a plunger rod moves inside a pipe of the same diameter. Because fluctuations are inherent in most positive displacement devices, a pulsation dampener may have to be used (Vandall and Foerg, 1993).

A possibly valuable characteristic of positive displacement pumps is that the output flow is proportional to pump speed. This allows this type of pump to be used for metering applications. Also, a positive aspect of these pumps is that they are self-priming, except at initial startup. *Very high head pressures (often damaging to the pump) can be developed in positive displacement pumps if the downstream flow is blocked.* For this reason, a pressure-relief-valve bypass must always be used with positive displacement pumps. Some designers recommend a bypass even for centrifugal pumps.

Selecting a Pump Based upon Flow Considerations

Performance characteristics of the pump must be considered in system design. Simple diagrams of pump applications are shown in Figure 3.11.3. First consider the left-hand figure, which represents a flow circuit; the pressure drops related to the piping, fittings, valves, and any other flow devices found in the circuit must be estimated using laws of fluid mechanics. Usually these resistances (pressure drops) are found to vary approximately with the square of the liquid flow rate.

Most pumps demonstrate a flow vs. pressure rise variation that is a positive value at zero flow and decreases to zero head at some larger flow. A variation typical of centrifugal pumps is shown on the left-hand side of Figure 3.11.4. One exception to this — an important one related to these types of pumps — is the so-called “drooping head” behavior. In this situation, the head at zero flow is less than the heads achieved at small positive flows. Described in some detail by Paugh (1994), this phenomenon is a result of high-efficiency design.

Positive displacement pumps, as shown on the right-hand side of Figure 3.11.4, are an exception to this characteristic behavior in that these devices usually cannot tolerate a zero flow. An important aspect

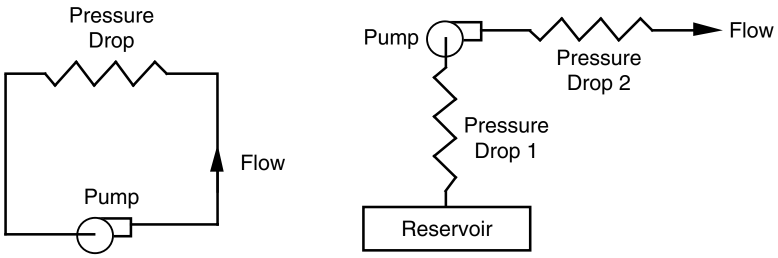

FIGURE 3.11.3 Typical pump applications, whether in circuits or once-through arrangements, can be represented as combined fluid resistances. The resistances are determined from fluid mechanics analyses.

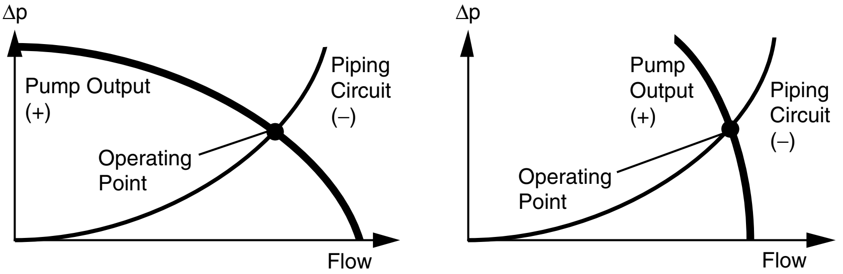

FIGURE 3.11.4 An overlay of the pump flow vs. head curve with the circuit piping characteristics gives the operating state of the circuit. A typical velocity-head pump characteristic is shown on the left, while a positive-displacement pump curve is shown on the right.

to note is that a closed system can presumably be pressurized by the pump to the detriment of the system and the pump.

The piping diagram shown on the right-hand side of Figure 3.11.3 is a once-through system, another frequently encountered installation. However, the leg of piping through "pressure drop 1" shown here can have some very important implications related to *net positive suction head*, often denoted as *NPSH*. In simple terms, NPSH indicates the difference between the local pressure and the thermodynamic saturation pressure at the fluid temperature. If NPSH = 0, the liquid can vaporize, thus resulting in a variety of outcomes from noisy pump operation to outright failure of components. This condition, called *cavitation*, must be eliminated by proper design.

Cavitation, if it occurs, will first take place at the lowest pressure point within the piping arrangement. Often this point is located at, or inside, the inlet to the pump. Most manufacturers specify how much NPSH is required for satisfactory operation of their pumps. Thus, the *actual NPSH* (often denoted as *NPSHA*) experienced by the pump must be larger than the manufacturer's *required NPSH* (which may be called *NPSHR*).

If a design indicates insufficient NPSH, changes should be made in the system, possibly including alternative piping layout. This might include lowering the pump location relative to the feed, changing sizes of the inlet piping and fittings, or slowing the pump speed. Some pumps have smaller NPSH requirements than others, possibly as a result of adding inducers to the inlet. Sometimes it is possible to cool the pump inlet fluid and this will increase the NPSHA. More extreme solutions could find a smaller pump installed prior to the inlet of the main pump whose purpose is to increase the NPSHA of the latter. Of course, if a pump is fed from a tank and vortices form there at typical flow conditions, this could greatly decrease the NPSHA beyond what would appear to be present.

Fluid properties can have a major impact on the choice of pump. One variable of concern is viscosity. This property can have high or extremely variable values in a given circuit. At the minimum, increases in viscosity will require more pumping power. However, the value of the viscosity may influence the type of pump used. For viscosities up to slightly over 3000 cP, centrifugal pumps will work quite well. Rotary pumps can handle less frequently encountered situations with considerably higher viscosities.

The manufacturer should be consulted for a map of operational information for a given pump. A typical set of these is shown in Figure 3.11.5 through Figure 3.11.7. This information will allow the designer to select a pump that satisfies the circuit operational requirements while meeting the necessary NPSH and most efficient operation criteria.

First consider Figure 3.11.5. This gives a map of overall performance for a given family of pumps. The specific operational ranges for each model within the family are shown. This range is due to use of various impeller sizes, pump speeds, and other design parameters in a particular configuration.

Once the general design conditions are located on an overall performance map, they will generally indicate a particular model for the application. This can then be referred to go determine the performance

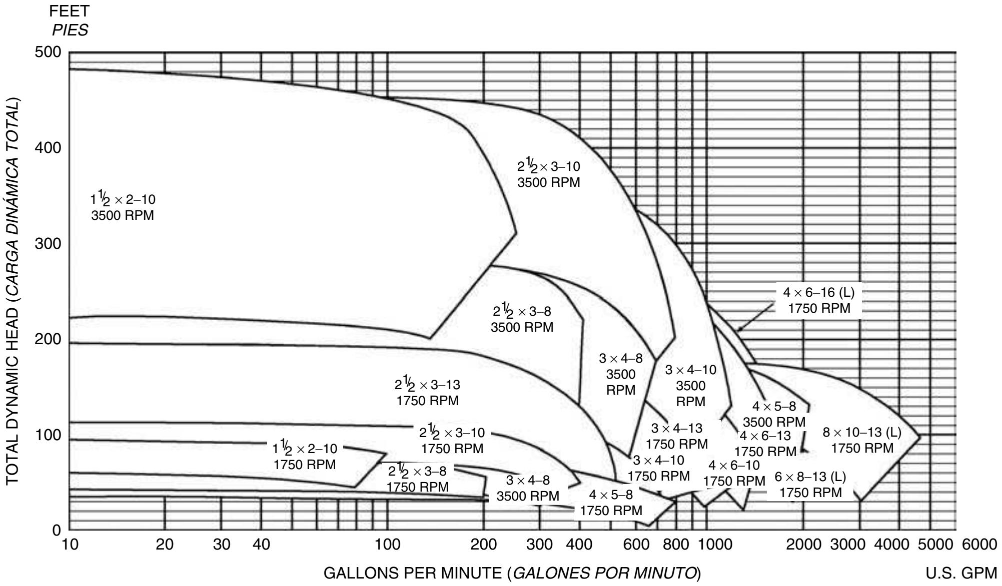

FIGURE 3.11.5 When a pump is selected for a given application, the starting point is a performance coverage map. From this, the model required to achieve a given performance can be selected. (Compliments of Goulds Pumps.)

FIGURE 3.11.6 Once the particular model of pump is determined (see Figure 3.11.5), the actual performance of that model can be examined from a plot of this type. This is given here for a particular speed. (Compliments of Goulds Pumps.)

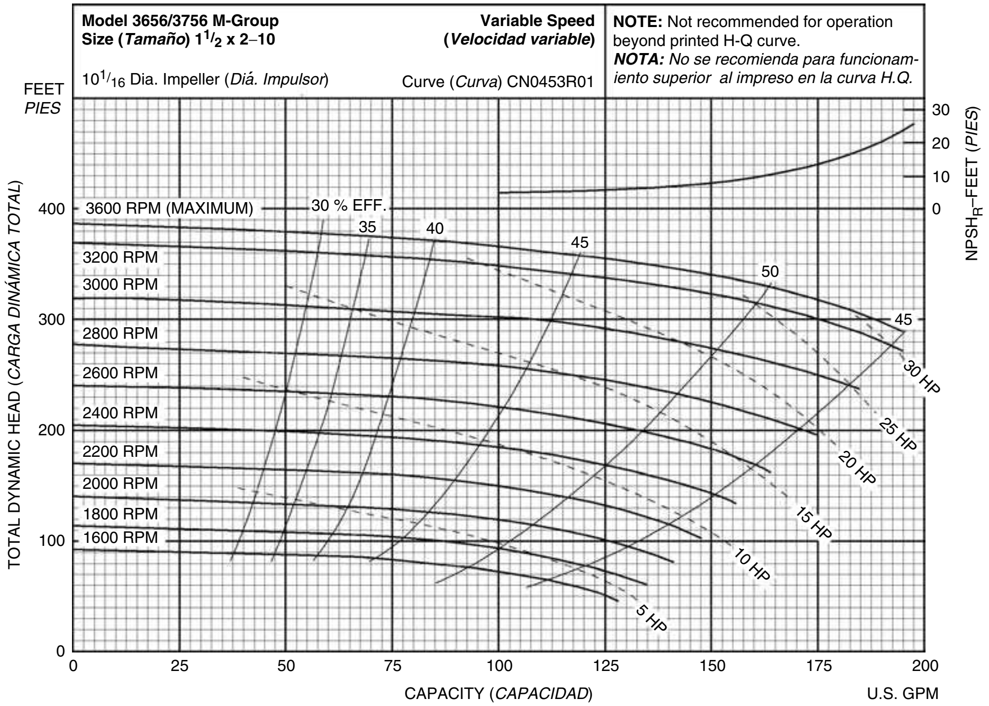

FIGURE 3.11.7 Impeller speed for a given model will have an impact on the pump performance (compare to Figure 3.11.6). (Compliments of Goulds Pumps.)

of the specific model. For example, if design conditions had fallen in the range of model 1½ × 2 – 10 3500 rpm, the details of this one would be examined (see Figure 3.11.6).

Note the following generally typical characteristics of centrifugal pumps. The produced head decreases with increasing flow over the specific range for this pump. Larger diameter impellers are required to move to higher level curves, and these conditions are associated with higher power requirements. NPSH requirements increase generally with increasing flow. Sometimes manufacturers give this information as a simple function of flow, or it can be specified in more definitive terms as shown in Figure 3.11.6. Pumping efficiency curves are also shown. It is desirable to operate near the maximum values of efficiency if that can be accommodated between the design requirements and the characteristics of the specific pumps. This is a lower-flow pump and, as was shown in Figure 3.11.2, this one demonstrates lower efficiencies than some larger units would be able to furnish within the same family of pumps.

Finally, consider Figure 3.11.7. This shows the impact of drive speed on the operation of the pump. Figure 3.11.6 was developed for a single speed; Figure 3.11.7 shows the effects of various speeds. Here the NPSH is shown as a simple function increasing with flow rate.

Several options are available to the designer for combining pumps in systems. Consider a comparison of the net effect between operating pumps in series or operating the same two pumps in parallel. Examples of this for pumps with characteristics like centrifugal units are shown in Figure 3.11.8. It is clear that one way to achieve high pumping pressures with centrifugal pumps is to place a number of units in series. This effect is related to what is found in multistage designs.

Vacuum Pumps

When pressures significantly below atmospheric are required, a vacuum pump should be applied. In fact, *vacuum* is defined as being a pressure below the surrounding atmosphere. These pumps are often used

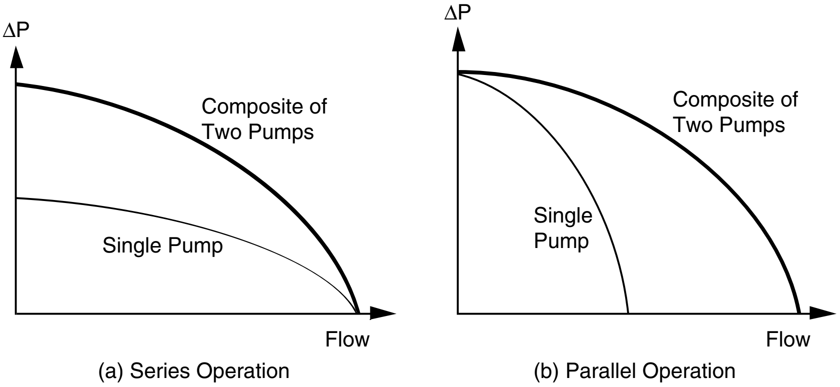

FIGURE 3.11.8 Series and parallel operations of centrifugal pumps are possible. The resultant characteristics for two identical pumps.

to remove a vapor or a gas from within a volume of interest. If most of the vapor or gas is removed, this is often called a "hard" or "high" vacuum.

Even though the pressure differential across a vacuum pump is typically less than 1 atm, the small value of pressure at the inlet to the pump complicates the performance of the device. A resulting high-pressure ratio usually exists across a vacuum pump. Because of this factor, as well as the characteristics of gases and vapors as they become rarefied, a large amount of vacuum is usually accomplished by using a sequence of vacuum pumps. To see how this is achieved, consider the general types of vacuum pumps available.

At coarse vacuums (not large pressure differences from atmospheric) a mechanical pump or blower might be used. These have designs very much like those of other pump and fan systems discussed in this chapter.

At higher vacuums, a *vapor jet* (or *diffusion*) pump may find a cost-effective application. The basic idea behind this approach is a concept illuminated by kinetic theory: gases can be pumped by the molecular drag effect. A separate pumping fluid is used to remove the vapor or gas of interest. Devices built on this concept demonstrate high pumping speeds at low pressures.

Using high-speed rotating machinery in several stages to accomplish necessary evacuation, *turbo* pumps reach levels of vacuums similar to those achieved by diffusion pumps.

Ion-getter and *sputter-ion pumps* are used for high- and ultrahigh-vacuum situations. In this approach, *gettering* is used, which denotes a concept of a chemical combination between a surface and the pumped gas. Although many types of gettering materials are available, a commonly used one is titanium. When chemically active gas atoms strike a getter surface, stable, solid compounds are formed there.

To achieve high- or ultrahigh-vacuums, a series of these pumps might be used. At moderate vacuums, a *roughing* pump is a good choice. As the absolute pressure decreases, a switch is made to another type of pump, for example, a cryopump or a diffusion pump. Finally, the very small pressures can then be reached using a getter or ion pump. Approximate ranges for each of these pumps are shown in Figure 3.11.9. Figure 3.11.10 shows the performance range of various types of coarse vacuum pumps. These figures were developed from information given by Hablanian (1997), whose text is an excellent source of information on all of these types of devices.

Fans

As noted earlier, fans are devices that cause air to move. This definition is broad and can even include a flapping palm branch, but the discussion here deals only with devices that impart air movement due to rotation of an impeller inside a fixed casing. In spite of this limiting definition, it includes a large variety of commercial designs.

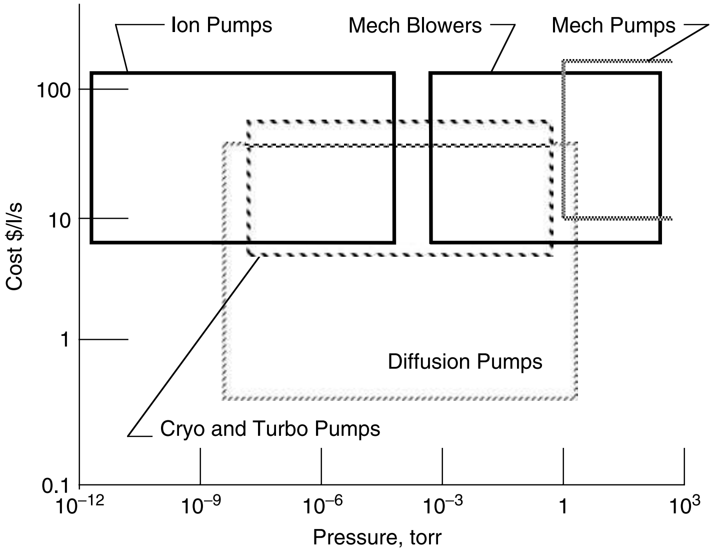

FIGURE 3.11.9 Approximate operational ranges in which various types of vacuum pumps are most cost effective (in 1985 prices). (Adapted from Hablanian, M., 1997. *High-Vacuum Technology — A Practical Guide*, 2nd ed., Marcel Dekker, New York.)

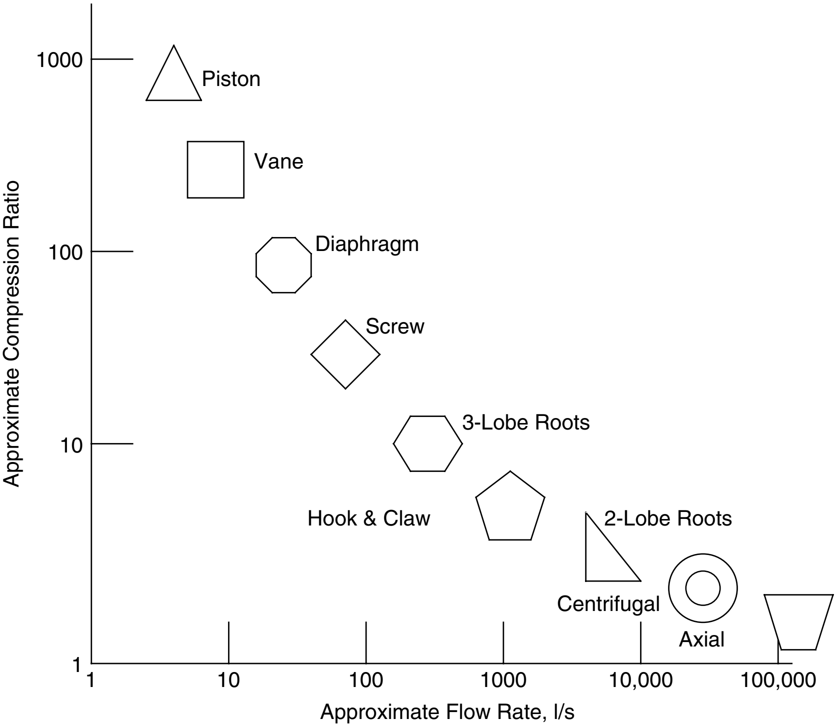

FIGURE 3.11.10 The operational ranges of coarse vacuum pumps. (Adapted from Hablanian, M., 1997. *High-Vacuum Technology — A Practical Guide*, 2nd ed., Marcel Dekker, New York.)

Fans find application in many engineering systems. Along with the chillers and boilers, they are the heart of heating, ventilating, and air conditioning (HVAC) systems. When large physical dimensions of a unit are not a design concern (usually the case), centrifugal fans are favored over axial flow units for

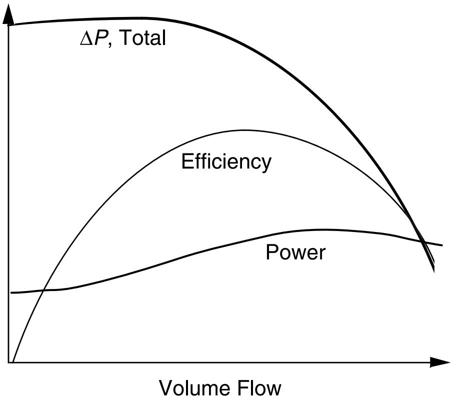

FIGURE 3.11.11 Characteristics of a centrifugal fan. The drawbacks to operating away from optimal conditions are obvious from the efficiency variation.

HVAC applications. Many types of fans are found in power plants (Stultz and Kitto, 1992). Very large fans are used to furnish air to the boiler as well to draw or force air through cooling towers and pollution control equipment. Electronic cooling finds applications for small units — automobiles have several fans in them. Because of the great engineering importance of fans, several organizations publish rating and testing criteria (see, for example, ASME, 1995).

Generally, fans are classified according to how the air flows through the impeller. These flows may be axial (essentially a propeller in a duct), radial (conceptually much like the centrifugal pumps discussed earlier), mixed, and cross. Although many other fan designations exist, all industrial units are one of these classifications. Mixed-flow fans are so named because axial and radial flow occurs on the vanes. Casings for these devices are essentially like those for axial flow machines, but the inlet has a radial flow component. On cross-flow impellers, the gas traverses the blading twice.

Generic characteristics of fans are shown in Figure 3.11.11. Because velocities can be high in fans, often the total and the static pressure increases are considered. Although both are not shown in this figure, the curves have similar variations. Of course, the total ΔP is greater than the static value; the difference is the velocity head and it increases as the volume flow increases. At zero flow (the *shut-off point*), the static and total pressure difference values are the same. Efficiency variation shows a sharp optimum value at the design point. For this reason, it is critical that fan designs be carefully tuned to the required conditions.

A variety of vane types are found on fans and the type of vane is also used for fan classification. Axial fans usually have vanes of airfoil shape or vanes of uniform thickness. Some vane types that might be found on a centrifugal (radial flow) fan are shown in Figure 3.11.12.

One issue in choosing fans for a particular application is fan efficiency. Typical efficiency comparisons of the effect of blade type on a centrifugal fan are shown in Figure 3.11.13. Because velocities can be high, the value of aerodynamic design is clear. Weighing against this is the increased cost.

An additional aspect that may be important in the choice of fans is noise generation, which may be most critical in HVAC applications. It is difficult to describe noise characteristics in brief terms because of the frequency-dependent nature of these phenomena. However, comparison of specific sound power levels (usually denoted by K_w) shows that backward-curved centrifugal fans with aerodynamic blades are among the best performing designs. Details of noise characteristics are given elsewhere (ASHRAE, 1999). Although each type of fan has some specific qualities for certain applications, most installations use centrifugal (radial flow) fans. A primary exception is for very-high-flow, low-pressure-rise situations in which axial (propeller) fans are used.

Similarities exist between fans and pumps because the fluid density essentially does not vary through either type of machine. Of course in pumps this is because a liquid can be assumed to be incompressible. In fans, a gas (typically air) is moved with little pressure change. As a result, the gas density can be taken

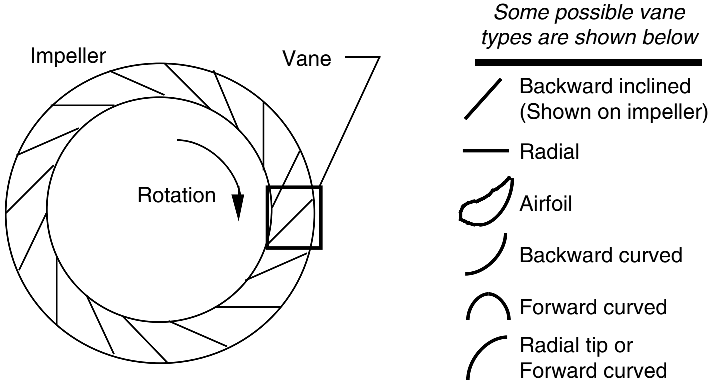

FIGURE 3.11.12 A variety of vane types that might be used on a centrifugal fan.

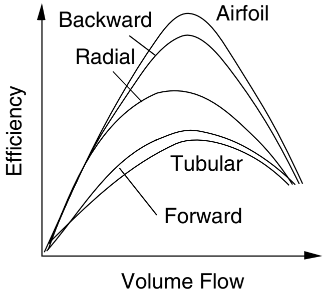

FIGURE 3.11.13 Efficiency variations with volume flow of centrifugal fans for a variety of vane types.

to be constant. Because most fans operate near atmospheric pressure, the ideal gas assumptions can be used in determining gas properties.

Flow control in fan applications, where needed, is a very important design concern. Methods for accomplishing this involve use of dampers (on the inlet or the outlet of the fan), variable pitch vanes, or variable speed control. Dampers are the least expensive to install but also the most inefficient in terms of energy use. Modern solid-state control for providing variable frequency power to the drive motor is becoming the preferred control method when a combination of initial and operating costs are considered.

3.12 Liquid Atomization and Spraying

Rolf D. Reitz

Sprays are involved in many practical applications, including in the process industries (e.g., spray drying, spray cooling, powdered metals); treatment applications (e.g., humidification, gas scrubbing); coating applications (e.g., surface treatment, spray painting and crop spraying); spray combustion (e.g., burners, furnaces, rockets, gas turbines, diesel and port fuel injected engines); and medicinal and printing applications. To be able to describe sprays it is necessary to obtain a detailed understanding of spray processes.

In the simplest case, the liquid to be sprayed is injected at a high velocity through a small orifice. Atomization is the process during which the injected liquid is broken up into droplets; it has a strong influence on spray vaporization rates because it increases the total surface area of the injected liquid greatly. Fast vaporization may be desirable in certain applications, but undesirable in others where the liquid is required to impinge on a target. The trajectories of the spray drops are governed by the drops' injected momentum, drag forces, and interactions between the drops and the surrounding gas. Control of these and other spray processes can lead to significant improvements in performance, quality of product, and reduction of emission of pollutants.

Spray Characterization

Practical atomizers generate sprays with a distribution of drop sizes with average sizes in the diameter range from a few microns (1 $\mu = 10^{-6}$ m) to as large as 0.5 mm. It is important to quantify the details of the distribution depending on the application. For example, the smaller drops in a spray vaporize fast, and this is helpful to control ignition processes in some combustion systems. On the other hand, the large drops carry most of the mass and momentum of the injected liquid; these drops are able to penetrate into the high-pressure gases in engine combustion chambers. Typical average drop sizes for broad classes of sprays are shown schematically in Figure 3.12.1. It should be noted that the terminology used to describe sprays in Figure 3.12.1 is qualitative and not universally agreed upon.

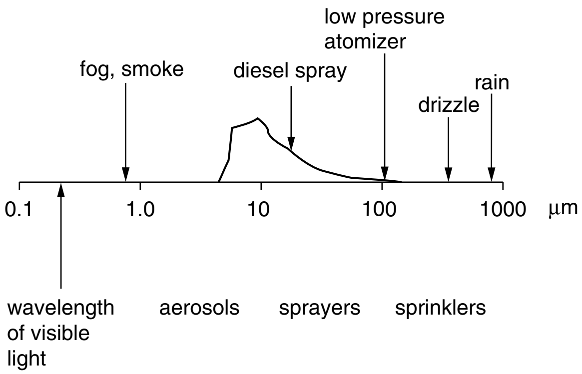

FIGURE 3.12.1 Typical average spray drop sizes for various classes of sprays. A representative size distribution is depicted for the diesel spray.

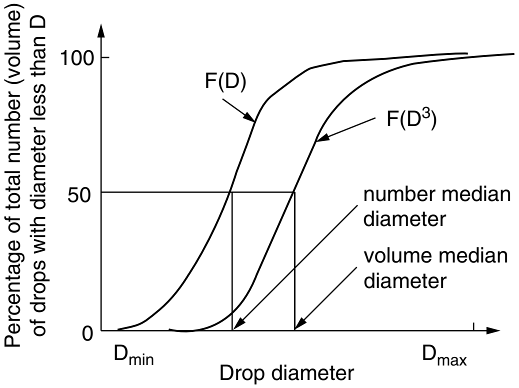

FIGURE 3.12.2 Cumulative spray drop number and volume distributions.

Methods for characterizing the size distribution of spray drops are discussed in American Society for Testing Materials (ASTM) Standard E799[1] and Mugele and Evans[2]. A probability distribution function, $F(D)$, is introduced that represents the fraction of drops per unit diameter range about the diameter, D, as shown in Figure 3.12.2. The spray drop sizes span a range from a minimum diameter, $D_{\min}$, to a maximum diameter, $D_{\max}$. It is also convenient to introduce a mean or average drop diameter instead of specifying the complete drop size distribution. The number median drop diameter (NMD) represents that drop whose diameter is such that 50% of the drops in the spray have sizes less than this size. Spray drop size distribution data can also be represented as a volume (or mass) distribution function, $F(D^3)$; this gives more weight to the large drops in the distribution. In this case a volume median diameter (VMD) or a mass median diameter (MMD) can also be defined, as indicated in Figure 3.12.2.

Various other mean diameters are also in common use. These are summarized using the standard notation of Mugele and Evens[2] as

$$\left(D_{jk}\right)^{j-k} = \frac{\int_{D_{\min}}^{D_{\max}} D^j f(D)dD}{\int_{D_{\min}}^{D_{\max}} D^k f(D)dD} \tag{3.12.1}$$

where $f(D) = dF(D)/dD$ is the drop size probability density function (usually normalized such that $\int_{D_{\min}}^{D_{\max}} f(D)dD = 1$).

Commonly used mean diameters are D_{10} (i.e., $j = 1$, $k = 0$, sometimes called the length mean diameter [3]) and D_{32} (i.e., $j = 3$, $k = 2$, called the Sauter mean diameter or SMD). The Sauter mean diameter has a useful physical interpretation in combustion applications because drop vaporization rates are proportional to the drop's surface area. It represents the size of the drop that has the same volume-to-surface area ratio as that of the entire spray.

Several distribution functions have been found to fit experimental data reasonably well. Among these are the Nukiyama–Tanasawa and the Rosin–Rammler distributions, which have the general form[3] $f(D) = cD^p \exp(-\{bD\}^q)$, where the constants c, p, b, and q characterize the size distribution. The higher the parameter, q, the more uniform the distribution is, and typically $1.5 < q < 4$. Other distributions have been proposed that consist of logarithmic transformations of the normal distribution, such as $f(D) = c\exp(-y^2/2)$, where $y = \delta \ln(\eta D/(D_{\max} - D))$, and c, δ, and η are constants. In this case, the smaller δ, is, the more uniform the size distribution. It should be noted that no theoretical justification for any of these size distributions exists. Spray drop size distributions can be measured nonintrusively by using optical laser diffraction and phase/Doppler instruments. A discussion of these techniques and their accuracy is reviewed by Chigier.[4]

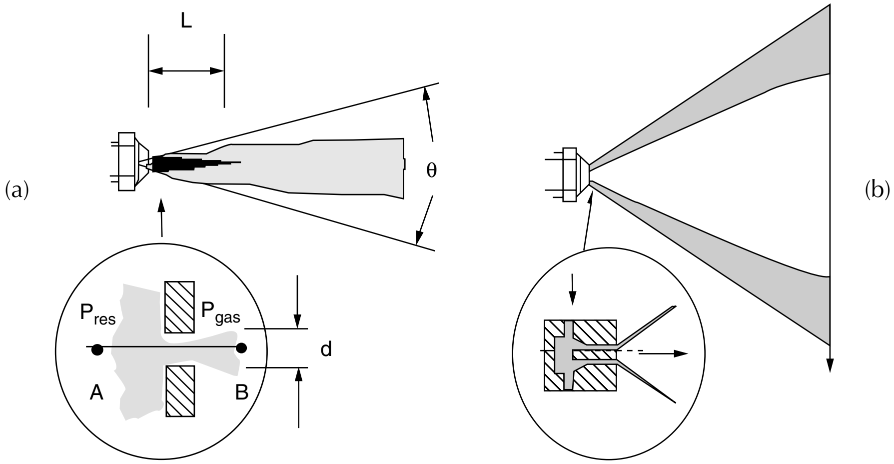

FIGURE 3.12.3 Schematic diagram of pressure atomizer sprays: (a) solid cone; and (b) hollow cone.

Atomizer Design Considerations

Atomization is generally achieved by forcing a liquid or a liquid–gas mixture through a small hole or slit under pressure to create thin liquid sheets or jets moving at a high relative velocity with respect to the surrounding ambient gas. Desirable characteristics of atomizers include: the ability to atomize the liquid over a wide range of flow rates, low power requirements, and low susceptibility to blockage or fouling. In addition, atomizers should produce consistent sprays with uniform flow patterns in operation.

Atomizers can be broadly characterized as those producing hollow cone or solid cone sprays, as depicted in Figure 3.12.3. In solid cone (or full cone) sprays, the spray liquid is concentrated along the spray axis (Figure 3.12.3a). These sprays are useful in applications requiring high spray penetration, such as in diesel engines. In hollow cone sprays, the axis region is relatively free of drops, giving wide spray dispersal (Figure 3.12.3b). These sprays are often used in furnaces, gas turbines, and spray coating applications.

Many different atomizer designs are found in applications. Common atomizer types include pressure; rotary; twin-fluid (air-assist, air-blast, effervescent); flashing; electrostatic; vibratory; and ultrasonic atomizers, as discussed next.

Atomizer Types

In *pressure atomizers* atomization is achieved by means of a pressure difference, $\Delta P = P_{\text{res}} - P_{\text{gas}}$, between the liquid in the supply reservoir pressure, P_{res}, and the ambient medium pressure, P_{gas}, across a nozzle. The simplest design is the plain orifice nozzle with exit hole diameter, *d*, depicted in Figure 3.12.3a. The liquid emerges at the theoretical velocity $U = \sqrt{2\Delta P / \rho_{liquid}}$ — the (Bernoulli) velocity along the streamline A–B in Figure 3.12.3a, where ρ_{liquid} is the density of the liquid. The actual injection velocity is less than the ideal velocity by a factor called the discharge coefficient, C_D, which is between 0.6 and 0.9 for plain hole nozzles. C_D accounts for flow losses in the nozzle.

Four main jet breakup regimes have been identified, corresponding to different combinations of liquid inertia, surface tension, and aerodynamic forces acting on the jet, as shown in Figure 3.12.4. At low injection pressures, the low velocity liquid jet breaks up due to the unstable growth of long wavelength waves driven by surface tension forces (Rayleigh regime). As the jet velocity is increased, the growth of disturbances on the liquid surface is enhanced due to the interaction between the liquid and the ambient gas (the first and second wind-induced breakup regimes). At high injection pressures, the high-velocity jet disintegrates into drops immediately after leaving the nozzle exit (atomization regime). Criteria for the boundaries between the regimes are available.[5] Aerodynamic effects have been found to become very

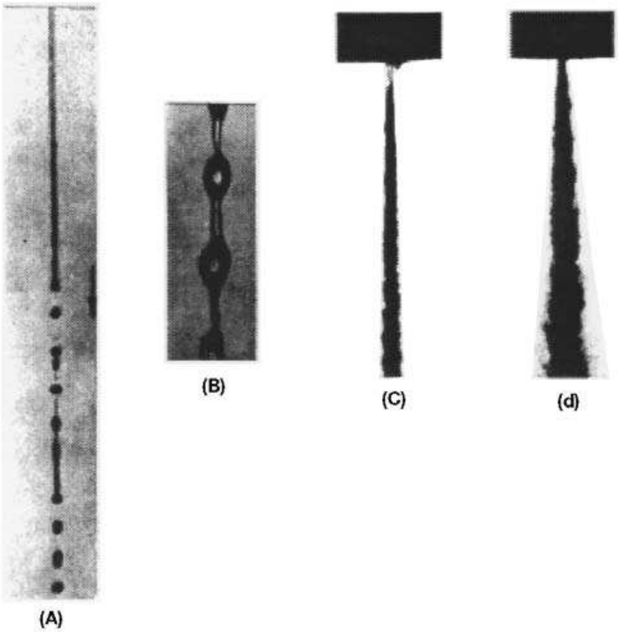

FIGURE 3.12.4 (a) Rayleigh breakup. Drop diameters are larger than the jet diameter. Breakup occurs many nozzle diameters downstream of nozzle. (b) First wind-induced regime. Drops with diameters of the order of jet diameter. Breakup occurs many nozzle diameters downstream of nozzle. (c) Second wind-induced regime. Drop sizes smaller than the jet diameter. Breakup starts some distance downstream of nozzle. (d) Atomization regime. Drop sizes much smaller than the jet diameter. Breakup starts at nozzle exit.‘

important relative to inertial effects when the jet Weber number, $\mathrm{We}_j > 40$, where $\mathrm{We}_j = \rho_{\mathrm{gas}} U^2 d/\sigma$; ρ_{gas} is the gas density; and σ is the liquid surface tension.

Experiments show that the unstable growth of surface waves is aided by high relative velocities between the liquid and the gas, high turbulence and other disturbances in the liquid and gas flows, and the use of spray liquids with low viscosity and low surface tension.

Liquid breakup characteristics such as the spray drop size, the jet breakup length, and spray angle have been related to the unstable wave growth mechanism. The wavelengths and growth rates of the waves can be predicted using results from a linear stability analysis, with[6]

$$\frac{\Lambda}{a} = 9.02\frac{\left(1+0.45Z^{0.5}\right)\left(1+0.4T^{0.7}\right)}{\left(1+0.87\,\mathrm{We}_2^{1.67}\right)^{0.6}} \tag{3.12.2a}$$

$$\Omega\left(\frac{\rho_1 a^3}{\sigma}\right)^{0.5} = \frac{0.34+0.38\ \mathrm{We}_2^{1.5}}{\left(1+Z\right)\left(1+1.4T^{0.6}\right)} \tag{3.12.2b}$$

where Λ is the wavelength and Ω is the growth rate of the most unstable surface wave, and a is the liquid jet radius. The maximum wave growth rate increases and the corresponding wavelength decreases with increasing Weber number, $\mathrm{We}_2 = \rho_{\mathrm{gas}} U^2 a/\sigma$, where U is the relative velocity between the liquid and the gas. The liquid viscosity appears in the Ohnesorge number, $Z = \mathrm{We}_1^{1/2}/\mathrm{Re}_1$. Here the Weber number We_1 is based on the liquid density; the Reynolds number is $\mathrm{Re}_1 = Ua/\nu_1$; ν_1 is the liquid viscosity; and the

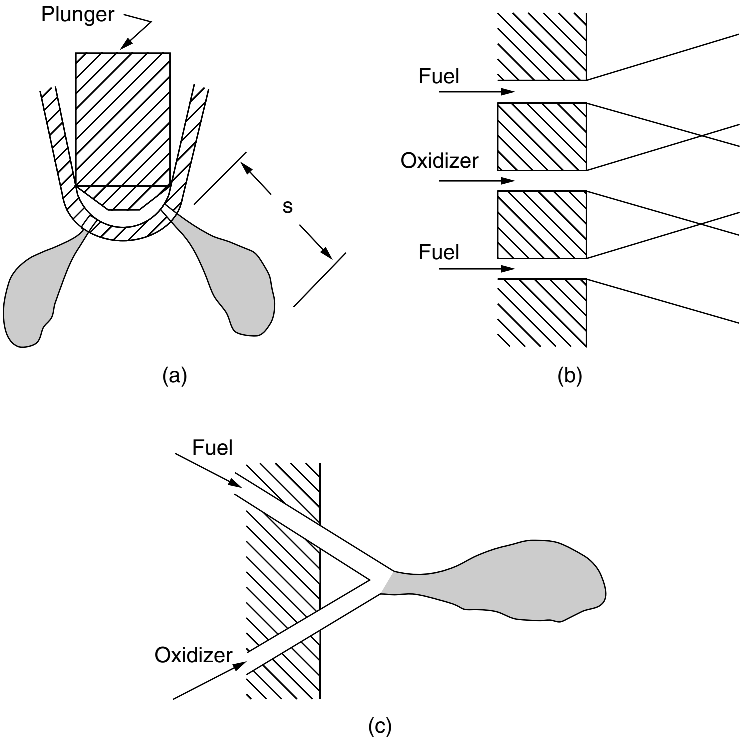

FIGURE 3.12.5 (a) Diesel injector multihole spray nozzle; (b) showerhead; and (c) doublet impingement nozzles.

parameter $T = Z\mathrm{We}_2^{1/2}$. The wave growth rate is reduced and the wave length is increased as the liquid viscosity increases.

The size of the drops formed from the breakup process is often assumed to be proportional to the wavelength of the unstable surface waves in modeling studies.[6] However, the drop sizes in the primary breakup region near the nozzle exit have also been found to be influenced by the length scale of the energy containing eddies in the turbulent liquid flow.[7]. There is uncertainty about atomization mechanisms because spray measurements are complicated by the high optical density of the spray in the breakup region (e.g., see Figure 3.12.4d). As the drops penetrate into the ambient gas, they interact with each other through collisions and coalescence, and the spray drop size changes dynamically within the spray due to secondary breakup and vaporization effects. The drop trajectories are determined by complex drop drag, breakup, and vaporization phenomena, and by interactions with the turbulent gas flow.[6]

High-pressure diesel sprays are intermittent and are required to start and stop quickly without dribble between injections. This is accomplished by means of a plunger arrangement actuated by a cam and spring system in mechanical "jerk" pump systems (see Figure 3.12.5a). Modern electronic injectors include electromagnetic solenoids that permit duration and injection pressure to be varied independently of each other and of engine speed. Experiments on diesel-type injector nozzles show that the penetration distance, S, of the tip of the spray at time, t, after the beginning of the injection is given by[8]

$$S = 0.39Ut \qquad \text{for} \quad t < t_b$$

$$S = 2.46\sqrt{U\,d\,t}\left(\rho_{liquid}/\rho_{gas}\right)^{1/4} \qquad \text{for} \quad t > t_b \tag{3.12.3}$$

where the "breakup time" is $t_b = 40.5d(\rho_{\text{liquid}}/\rho_{\text{gas}})^{1/2}/U$. The jet breakup length (see Figure 3.12.3a), $L = Ut_b$, is independent of the injection velocity. On the other hand, for low-speed jets, or for jets injected

TABLE 3.12.1 Representative Sauter Mean Diameter (SMD) Drop Size Correlations for Various Spray Devices

Device	Correlation	Notes
Plain orifice	$SMD = 3.08\nu_1^{0.385}\left(\rho_{liquid}\sigma\right)^{0.737}\rho_{gas}^{0.06}\Delta P^{-0.54}$	Use SI units
Fan spray	$SMD = 2.83\,d_h\left(\sigma\mu_{liquid}^2/\rho_{gas}d_h^3\Delta P^2\right)^{0.25}$ $+0.26d_h\left(\sigma\rho_{liquid}/\rho_{gas}d_h\Delta P\right)^{0.25}$	d_h = nozzle hydraulic diameter
Rotary atomizer	$SMD = 0.119Q^{0.1}\sigma^{0.5}/Nd^{0.5}\rho_{liquid}^{0.4}\mu_{liquid}^{0.1}$	N = rotational speed (rev/sec), Q = volumetric flow rate, A_{inj} U
Pressure swirl	$SMD = 4.52\left(\sigma\mu_{liquid}^2/\rho_{gas}\Delta P^2\right)^{0.25}\left(t\cos\theta\right)^{0.25}$ $+0.39\left(\sigma\rho_{liquid}/\rho_{gas}\Delta P\right)^{0.25}\left(t\cos\theta\right)^{0.75}$ $t = 0.0114\,A_{inj}\rho_{liquid}^{1/2}d\cos\theta$	t = film thickness, θ = cone angle, d = discharge orifice diameter
Twin fluid/air blast	$SMD = 0.48\,d\left(\sigma/\rho_{gas}U^2d\right)^{0.4}\left(1+1/ALR\right)^{0.4} +$ $0.15\,d\left(\mu_{liquid}^2/\sigma\rho_{liquid}d\right)^{0.5}\left(1+1/ALR\right)$	ALR = air-to-liquid mass ratio
Prefilming airblast	$SMD = \left(1+1/ALR\right)[0.33\,d_h\left(\sigma/\rho_{gas}U^2d_p\right)^{0.6} +$ $0.068\,d_h\left(\mu_{liquid}^2/\sigma\rho_{liquid}d_p\right)^{0.5}]$	d_h = hydraulic diameter, d_p = prefilmer diameter, Figure 3.12.7c
Ultrasonic	$SMD = \left(4\pi^3\sigma/\rho_{liquid}\omega^2\right)^{1/3}$	ω = vibration frequency

into a low gas density environment, $t_b = 1.04C(\rho_{\text{liquid}}d^3/\sigma)^{1/2}$, where C is a constant typically between 12 and 16, and σ is the surface tension. In this case, L increases with the injection velocity.[9] The functional form of the preceding jet breakup time and length correlations can be derived for an inviscid liquid in the limits of large and small Weber number, We_2 from the unstable wave growth rate in Equation (3.12.2b) with $t_b \sim \Omega^{-1}$.

For high-speed diesel-type jets in the atomization regime, the resulting spray diverges in the form of a cone with cone angle, θ, that is usually in the range from 5 to 20°. θ increases with gas density following $\text{Tan}\theta = A(\rho_{\text{gas}}/\rho_{\text{liquid}})^{1/2}$, where A is a constant that depends on the nozzle passage length and (weakly) on the injection velocity.[9] Very high injection pressures are required to produce small drops. In diesel engines, ΔP is typically as high as 200 MPa and drops are produced with mean diameters of the order of 10 µm (see Figure 3.12.1). Drop size correlations such as that presented in Table 3.12.1 have been proposed for plain-orifice sprays.[3] Note, however, that these correlations do not account for the fact that the spray drop size varies with time and from place to place in the spray. Moreover, experimental correlations often do not include some parameters known to influence spray drop sizes, such as the nozzle passage length and its entrance geometry. Therefore, overall drop size correlations should only be used with caution.

The plain orifice design is also used in twin-fluid-type liquid rocket engines in showerhead and doublet designs (Figure 3.12.5b and Figure 3.12.5c). In the case of doublet nozzles, shown in Figure 3.12.5c, the impinging jets create unstable liquid sheets that break up to produce the sprays. Drop size correlations are available for liquid sheets such as those formed by discharging the liquid through a rectangular slit (see *fan sprays* in Table 3.12.1). Thin liquid sheets or slits lead to the production of small drops. The

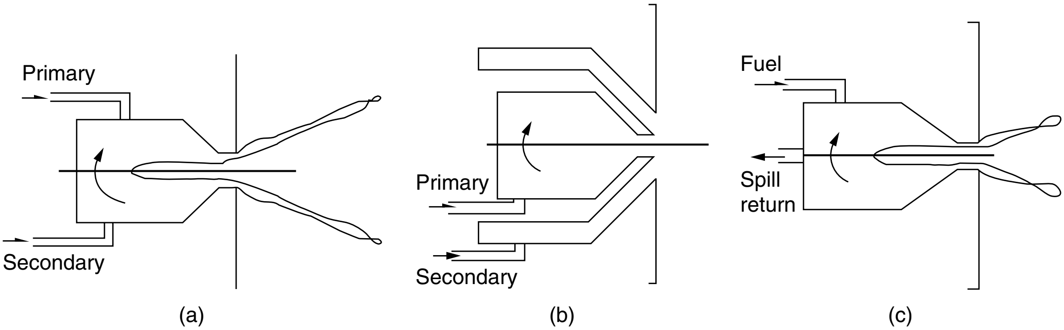

FIGURE 3.12.6 Nozzle designs: (a) duplex; (b) dual orifice; and (c) spill-return type.

breakup mechanism of liquid sheets is also thought to involve the unstable growth of surface waves due to surface tension and aerodynamic forces.[5]

In *rotary atomizers* centrifugal forces are used to further enhance the breakup process. In this case the liquid is supplied to the center of a spinning disk and liquid sheets or ligaments are thrown off the edges of the disk. The drop size depends on the rotational speed of the disk, as indicated in Table 3.12.1. A spinning wheel or cup (turbo-bell) is used in some spray-painting applications. The spray shape is controlled by supplying a coflowing stream of "shaping air."

Centrifugal forces also play a role in the breakup mechanism of *pressure swirl* atomizers (*simplex* nozzles). These atomizers give wider spray cone angles than plain-orifice nozzles and are available in hollow cone and solid cone designs. As depicted in Figure 3.12.3b, the spray liquid enters a swirl chamber tangentially to create a swirling liquid sheet. The air-core vortex within the swirl chamber plays an important role in determining the thickness of the liquid sheet or film at the nozzle exit. This type of nozzle produces relatively coarse sprays. A representative SMD correlation is listed in Table 3.12.1. The spray cone angle depends on the ratio of the axial and tangential liquid velocity components at the exit of the nozzle. This type of atomizer is not well suited for use in transient applications because it tends to dribble at startup and shut down when the air core is not fully formed.

The basic drawback of all pressure atomizers is that the flow rate depends on the square-root of ΔP. The volumetric flow rate is $Q = A_{inj}\, U$, where A_{inj} is the liquid flow area at the nozzle exit, so that a factor of 20 increase in flow rate (a typical turn-down ratio from idle- to full-load operation of a gas turbine engine) requires a factor of 400 increase in injection pressure.

This difficulty has led to so-called "wide-range" atomizer designs such as those shown in Figure 3.12.6. The *duplex* nozzle features two sets of tangential swirl ports: the primary (or pilot) supplies fuel at low flow rates, while the secondary ports become operational at high flow rates. Another variation is the *dual-orifice* nozzle, which is conceptually two simplex nozzles arranged concentrically, one supplying the primary flow and the other supplying the secondary flow. The *spill-return* nozzle is a simplex nozzle with a rear passage that returns fuel to the injection pump. In this design, the flow rate is controlled by the relative spill amount, and there are no small passages to become plugged. However, the fuel is always supplied at the maximum pressure, which increases the demands on the injection pump. However, high swirl is always maintained in the swirl chamber and good atomization is achieved even at low flow rates.

In *twin-fluid injectors* atomization is aided by a flow of high-velocity gas through the injector passages. The high-velocity gas stream impinges on a relatively low-velocity liquid internally (in *internal-mixing* nozzles, Figure 3.12.7a) or externally (in *external-mixing* designs, Figure 3.12.7b). The liquid and gas flows are typically swirled in opposite directions by means of swirl vanes to improve atomization. *Air-assist* refers to designs that use a relatively small amount of air at high (possibly sonic) velocities. *Air-blast* refers to designs that use large quantities of relatively low-velocity air that often supplies some of the air to help decrease soot formation in combustion systems.[3]

In *flashing* and *effervescent* atomizers, a two-phase flow is passed through the injector nozzle exit. In the former, the bubbles are generated by means of a phase change that occurs as the liquid, containing

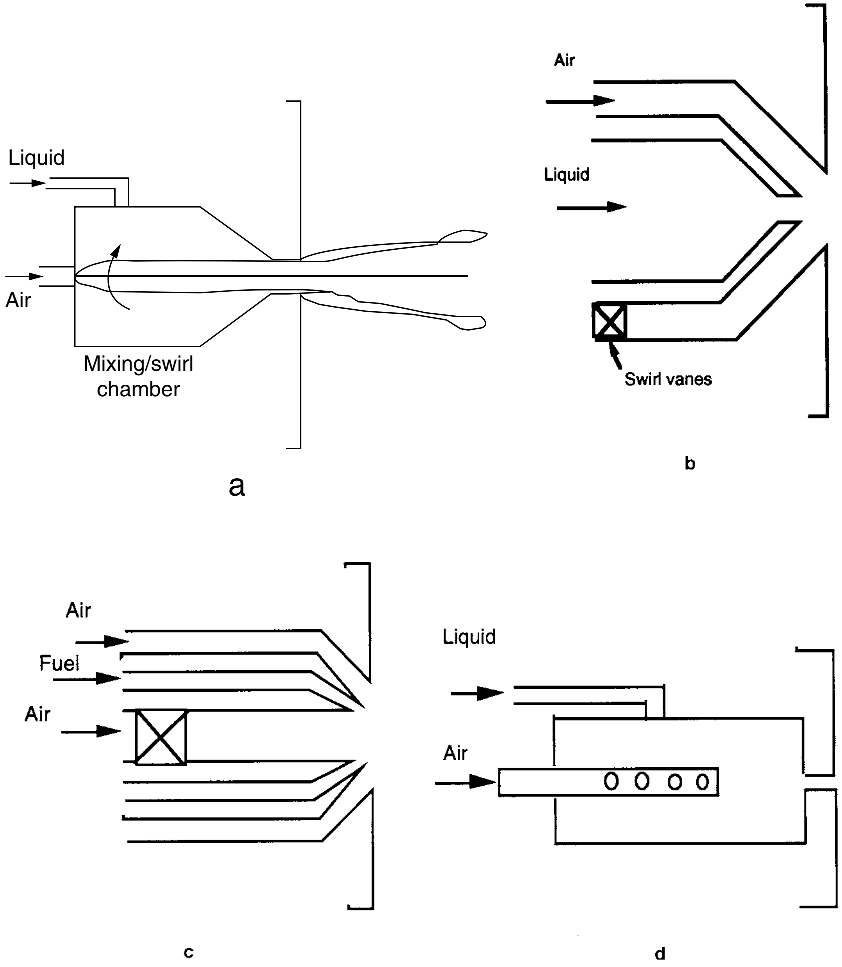

FIGURE 3.12.7 Twin-fluid injector designs: (a) internal mixing; and (b) external-mixing. Atomizers: (c) prefilming air blast; and (d) internal-mixing, effervescent atomizer.

a dissolved propellant gas or vapor, undergoes the pressure drop through the nozzle. This process is exploited in many household spray cans, but has the disadvantage of releasing the propellant gas required for atomization into the atmosphere. In the so-called effervescent atomizer, air bubbles are introduced into the liquid upstream of the exit orifice, as depicted in Figure 3.12.7d. The spray quality is found to depend weakly on the air bubble size and is independent of the nozzle exit diameter. This makes internal mixing, air-assist atomizers very attractive for use with high-viscosity fluids and slurries for which nozzle plugging would otherwise be a problem.[3]

In *electrostatic* atomizers, the spray liquid is charged by applying a high-voltage drop across the nozzle. The dispersion of the spray drops is increased by exploiting electrical repulsive forces between the droplets. An electrostatic charge on the drops is also helpful in spray-coating applications, such as in automotive spray painting using electrostatic turbo-bell sprayers, because the charged drops are attracted to an oppositely charged target surface.

Other atomizer types include *vibratory* and *ultrasonic* atomizers (or *nebulizers*) win which the drops are formed by vibrating the injector nozzle at high frequencies and at large amplitudes to produce short wavelength disturbances to the liquid flow. Ultrasonic atomizers are used in inhalation therapy where very fine sprays (submicron sizes) are required; an available representative drop size correlation is also listed in Table 3.12.1.

Nomenclature

a	liquid jet radius
A	spray angle constant, flow area
ALR	air-to-liquid mass ratio
b	Rosin–Rammler size distribution parameter
c	Rosin–Rammler size distribution parameter
C	jet breakup time constant
C_D	nozzle discharge coefficient
d	nozzle orifice exit diameter
D	drop diameter
f	drop probability density function
F	drop probability distribution function
L	jet breakup length
MMD	mass median drop diameter
N	rotational speed
NMD	number median diameter
p	Rosin–Rammler size distribution parameter
P	pressure
q	Rosin–Rammler size distribution parameter
Re	Reynolds number Ud/ν
Q	volumetric flow rate
S	spray tip penetration distance
SMD	Sauter mean drop diameter
t	time, liquid film thickness
T	Taylor number $Z\,\mathrm{We}^{1/2}$
U	liquid injection velocity, gas-liquid relative velocity
We	Weber number $\rho\, U^2\, d/\sigma$
y	normal drop size distribution parameter
Z	Ohnesorge number $\mathrm{We}^{1/2}/\mathrm{Re}$
δ	normal drop size distribution parameter
ΔP	liquid injection pressure
η	normal drop size distribution parameter
θ	spray cone angle
Λ	surface wave wavelength
μ	liquid kinematic viscosity
ν	liquid dynamic viscosity
ρ	density
σ	surface tension
ω	vibration frequency
Ω	surface wave growth rate

3.13 Flow Measurement

Jungho Kim, Sherif A. Sherif, and Alan T. McDonald

Introduction

Flow measurements are perhaps the most common type of measurements made. Many types of flow measuring devices are available. The choice of meter type depends on the required accuracy, range, cost, ease of reading or data reduction, and service life. The simplest and cheapest device that gives the required accuracy should be chosen.

Flow measurement can be classified into four broad types: (1) direct methods, (2) flow restriction methods, (3) linear flow meters, and (4) traversing methods. Each of these are discussed in the subsections below.

Direct Methods

Tanks can be used to determine the flow rate for steady liquid flows by measuring the volume or mass of liquid collected during a known time interval. If the time interval is long enough, flow rates may be determined precisely by using tanks. Compressibility must be considered in gas volume measurements. It is not practical to measure the mass of gas, but a volume sample can be collected by placing an inverted "bell" over water and holding the pressure constant by counterweights. No calibration is required when volume measurements are set up carefully; this is a great advantage of direct methods.

Restriction Flow Meters for Flow in Ducts

Most restriction flow meters for internal flow (except the laminar flow element) are based on acceleration of a fluid stream through some form of nozzle, shown schematically in Figure 3.13.1. Flow separating from the sharp edge of the nozzle throat forms a recirculation zone shown by the dashed lines downstream

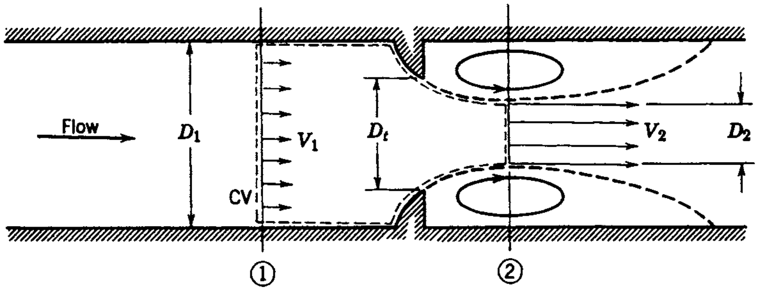

FIGURE 3.13.1 Internal flow through a generalized nozzle, showing control volume used for analysis.

from the nozzle. The main flow stream continues to accelerate from the nozzle throat to form a vena contracta at Section 2 and then decelerates again to fill the duct. At the vena contracta, the flow area is a minimum, the flow streamlines are essentially straight, and the pressure is uniform across the channel section. The theoretical flow rate is

$$\dot{m}_{\text{theoretical}} = \frac{A_2}{\sqrt{1-\left(A_2/A_2\right)^2}}\sqrt{2\rho\left(p_1-p_2\right)} \tag{3.13.1}$$

Equation 3.13.1 shows the general relationship for a restriction flow meter: Mass flow rate is proportional to the square root of the pressure differential across the meter taps. This relationship limits the flow rates that can be measured accurately to approximately a 4:1 range.

Several factors limit the utility of Equation 3.13.1 for calculating the actual mass flow rate through a meter. The actual flow area at Section 2 is unknown when the vena contracta is pronounced (e.g., for orifice plates when D_t is a small fraction of D_1). The velocity profiles approach uniform flow only at large Reynolds numbers. Frictional effects can become important (especially downstream from the meter) when the meter contours are abrupt. Finally, the location of the pressure taps influences the differential pressure reading, $p_1 - p_2$.

The actual mass flow rate is given by

$$\dot{m}_{\text{actual}} = \frac{CA_t}{\sqrt{1-\left(A_2/A_2\right)^2}}\sqrt{2\rho\left(p_1-p_2\right)} \tag{3.13.2}$$

where C is an empirical discharge coefficient.

If $\beta = D_t/D_1$, then $(A_t/A_1)^2 = (D_t/D_1)^4 = \beta^4$, and

$$\dot{m}_{\text{actual}} = \frac{CA_t}{\sqrt{1-\beta^4}}\sqrt{2\rho\left(p_1-p_2\right)} \tag{3.13.3}$$

where $1/(1 - \beta^4)^{1/2}$ is the velocity correction factor. Combining the discharge coefficient and velocity correction factor into a single *flow coefficient*,

$$K \equiv \frac{C}{\sqrt{1-\beta^4}} \tag{3.13.4}$$

TABLE 3.13.1 Characteristics of Orifice, Flow Nozzle, and Venturi Flow Meters

Flow Meter Type	Diagram	Head Loss	Cost
Orifice		High	Low
Flow nozzle		Intermediate	Intermediate
Venturi		Low	High

yields the mass flow rate in the form:

$$\dot{m}_{\text{actual}} = KA_t\sqrt{2\rho(p_1 - p_2)} \tag{3.13.5}$$

Test data can be used to develop empirical equations to predict flow coefficients vs. pipe diameter and Reynolds numbers for standard metering systems. The accuracy of the equations (within specified ranges) is often adequate enough to use the meter without calibration. Otherwise, the coefficients must be measured experimentally.

For the turbulent flow regime ($\text{Re}_\text{D} > 4000$), the flow coefficient may be expressed by an equation of the form:

$$K = K_\infty + \frac{1}{\sqrt{1-\beta^4}}\frac{b}{\text{Re}_{D_1}^n} \tag{3.13.6}$$

where subscript ∞ denotes the flow coefficient at infinite Reynolds numbers and constants b and n allow for scaling to finite Reynolds numbers. Correlating equations and curves of flow coefficients vs. Reynolds number are given for specific metering elements in the next three subsections following the general comparison of the characteristics of the orifice plate, flow nozzle, and venturi meters in Table 3.13.1 (see Fox and McDonald, 1992).

Flow meter coefficients reported in the literature have been measured with fully developed turbulent velocity distributions at the meter inlet. When a flow meter is installed downstream from a valve, elbow, or other disturbance, a straight section of pipe must be placed in front of the meter. Approximately 10 diameters of straight pipe upstream are required for venturi meters, and up to 40 diameters for orifice plate or flow nozzle meters. Some design data for incompressible flow are given below. The same basic methods can be extended to compressible flows.

Orifice Plates

The orifice plate (Figure 3.13.2) may be clamped between pipe flanges. Since its geometry is simple, it is low in cost and easy to install or replace. The sharp edge of the orifice will not foul with scale or suspended matter. However, suspended matter can build up at the inlet side of a concentric orifice in a horizontal pipe; an eccentric orifice may be placed flush with the bottom of the pipe to avoid this difficulty. The primary disadvantages of the orifice are its limited capacity and the high permanent head loss caused by uncontrolled expansion downstream from the metering element.

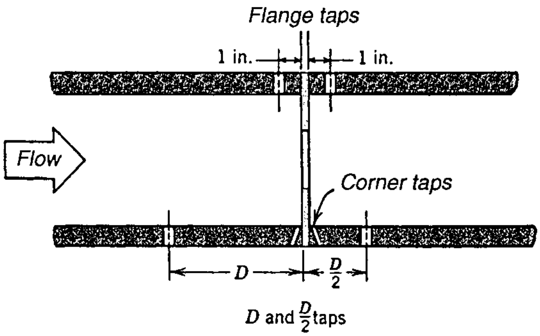

FIGURE 3.13.2 Orifice geometry and pressure tap locations. (From Miller, R.W., *Flow Measurement Engineering Handbook,* 3rd ed., McGraw-Hill, New York, 1996. With permission.)

Pressure taps for orifices may be placed in several locations as shown in Figure 3.13.2 (see Miller, 1996 for additional details). Since the location of the pressure taps influences the empirically determined flow coefficient, one must select handbook values of K consistent with the pressure tap locations.

The correlating equation recommended for a concentric orifice with corner taps is

$$C = 0.5959 + 0.0312\,\beta^{2.1} - 0.184\,\beta^{8} + \frac{91.71\,\beta^{2.5}}{\mathrm{Re}_{D_1}^{0.75}} \tag{3.13.7}$$

Equation 3.13.7 predicts orifice discharge coefficients within ±0.6% for $0.2 < \beta < 0.75$ and for $10^4 < \mathrm{Re}_{D1} < 10^7$. Some flow coefficients calculated from Equation 3.13.7 are presented in Figure 3.13.3. Flow coefficients are relatively insensitive to Reynolds number for $\mathrm{Re}_{D1} > 10^5$ when $\beta > 0.5$.

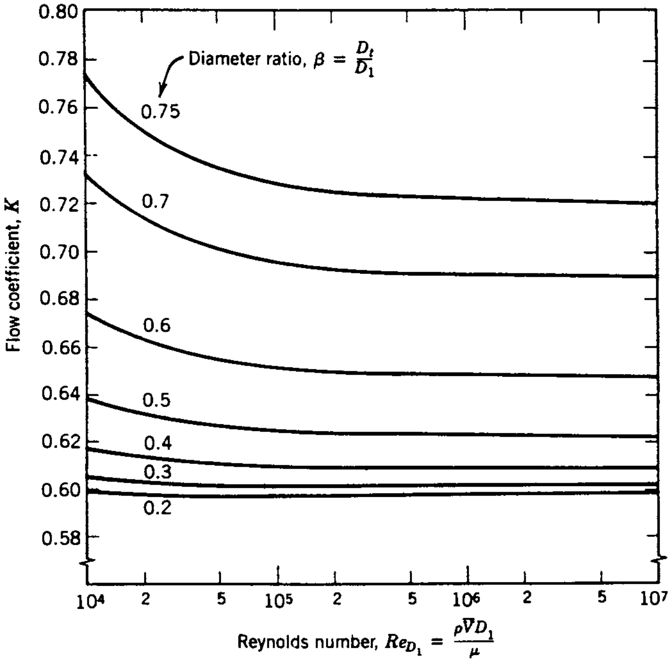

FIGURE 3.13.3 Flow coefficients for concentric orifices with corner taps.

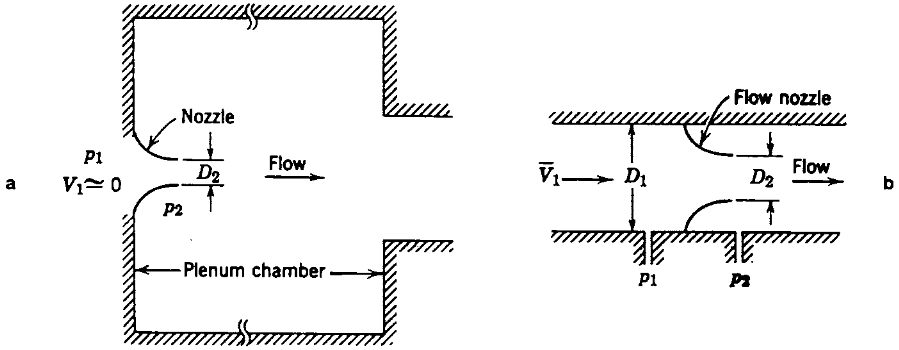

FIGURE 3.13.4 Typical installations of nozzle flow meters: (a) plenum, (b) in duct.

Flow Nozzles

Flow nozzles may be used as metering elements in either plenums or ducts, as shown in Figure 3.13.4; the nozzle section is approximately a quarter ellipse. Design details and recommended locations for pressure taps are given in *ASHRAE Handbook Fundamentals* (1981).

A similar correlating equation is available for orifice plates with D and D/2 taps. Flange taps require a different correlation for every line size. Pipe taps, located at 2 – 1/2 D and 8D, no longer are recommended. The correlating equation recommended for ASME long-radius flow nozzles is

$$C = 0.9975 - \frac{6.53\,\beta^{0.5}}{\mathrm{Re}_{D_1}^{0.5}} \tag{3.13.8}$$

Equation 3.13.8 predicts discharge coefficients for flow nozzles within ± 2.0% for $0.25 < \beta < 0.75$ for $10^4 < \mathrm{Re}_{D1} < 10^7$. Some flow coefficients calculated from Equation 3.13.8 are presented in Figure 3.13.5. (K can be greater than 1 when the velocity correction factor exceeds 1.) For plenum installation, nozzles may be fabricated from spun aluminum, molded fiberglass, or other inexpensive materials. Typical flow coefficients are in the range $0.95 < K < 0.99$; the larger values apply at high Reynolds numbers. Thus, the mass flow rate can be computed within approximately ±2% using $K = 0.97$.

Venturi Meters

Venturi meters are generally made from castings machined to close tolerances to duplicate the performance of the standard design, so they are heavy, bulky, and expensive. The conical diffuser section downstream from the throat gives excellent pressure recovery; overall head loss is low. Venturi meters are self-cleaning because of their smooth internal contours.

Experimentally measured discharge coefficients for venturi meters range from 0.980 to 0.995 at high Reynolds numbers ($\mathrm{Re}_{D1} > 2 \times 10^5$). Thus, $C = 0.99$ can be used to calculate mass flow rate within about ±1% at high Reynolds numbers. Consult manufacturers' literature for specific information at Reynolds numbers below 10^5.

Orifice plates, flow nozzles, and venturis all produce pressure drops proportional to the flow rate squared, according to Equation 3.13.4. In practice, a meter must be sized to accommodate the largest flow rate expected. Because the pressure drop vs. flow rate relationship is nonlinear, a limited range of flow rates can be measured accurately. Flow meters with single throats usually are considered for flow rates over a 4:1 range.

Unrecoverable head loss across a metering element may be expressed as a fraction of the differential pressure across the element. Unrecoverable head losses are shown in Figure 3.13.6.

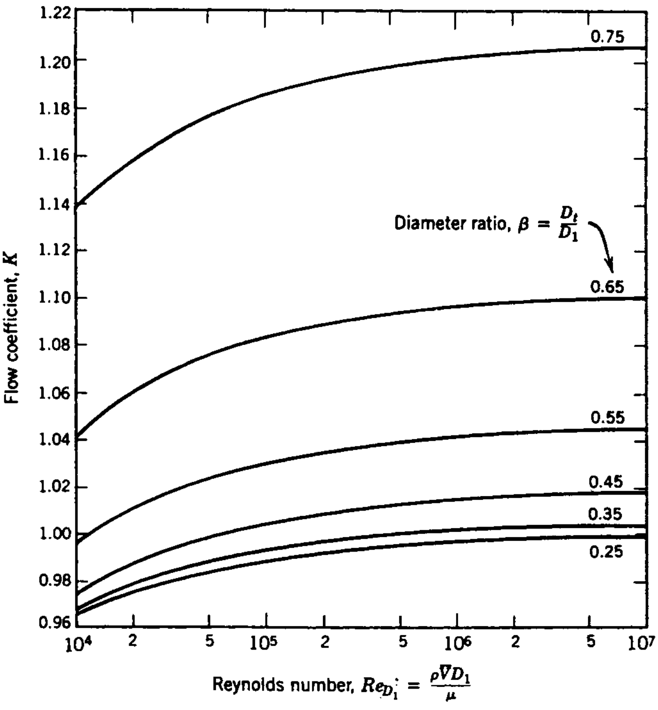

FIGURE 3.13.5 Flow coefficients for ASME long-radius flow nozzles.

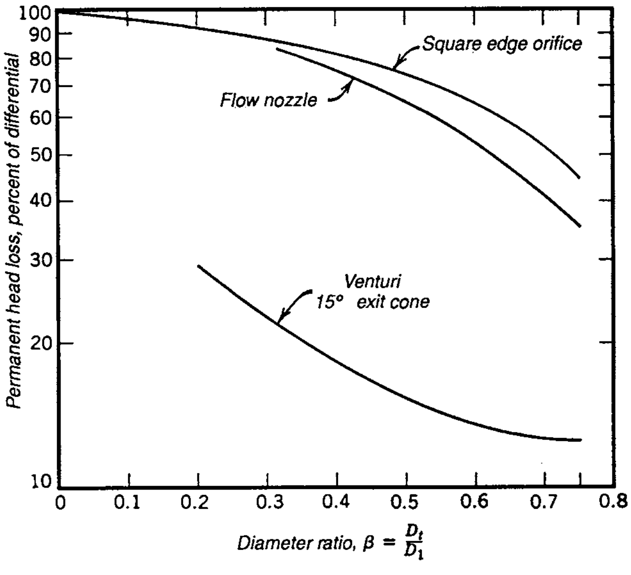

FIGURE 3.13.6 Permanent head loss produced by various flow metering elements. (From Miller, R.W., *Flow Measurement Engineering Handbook,* 3rd ed., McGraw-Hill, New York, 1996. With permission.)

Linear Flow Meters

The output of flow meters is typically calibrated to read a volume flow rate of a specified liquid or gas under certain conditions. For example, the volume flow rate of a liquid could be expressed in terms of liters per minute (LPM) of water, while that of a gas could be expressed in terms of standard cubic feet per minute (SCFM) of air. When using flow meters to determine flow rate at conditions different from the calibration conditions, corrections to the output must be made to obtain the true flow rate.

Rotameters

A typical rotameter consists of a float contained within a diverging tube (Figure 3.13.7). The float is raised by a combination of drag and buoyancy. The height to which the float rises in the tube can be made to vary by varying the shape of the diverging tube — tubes with linear or logarithmic variations can easily be fabricated.

Glass tube rotameters can be used to temperatures as high as 200°C and pressures up to 20 atm, depending on the diameter of the tube. Plastic tube rotameters are also available for use at lower temperatures and pressures. Flow rates at very high temperatures and pressures can be measured using metal tubes — detectors mounted on the outside of the tube are used to determine the float position.

Rotameters usually come with calibrations based on water or air at STP. The output is generally in SCFM of air or LPM of water. For measuring flow at other conditions or for other fluids, corrections must be made to determine the flow rate. The response of a rotameter can be determined by performing a force balance on the float. The height of the float is determined by a balance between the drag force on the float and the effective weight of the float:

$$F_D = \left(\rho_{float} - \rho_{fluid}\right) g V_{float} \tag{3.13.9}$$

where the drag force is given by

$$F_D = C_D A_{float} \frac{\rho_{fluid} u_{fluid}^2}{2} \tag{3.13.10}$$

Combining Equations 3.13.9 and 3.13.10 and solving for the fluid velocity u_{fluid} yields

$$u_{fluid} = \sqrt{\frac{2g\left(\rho_{float} - \rho_{fluid}\right)V_{float}}{C_d A_p \rho_{fluid}}} \tag{3.13.11}$$

The mass flow rate is given by

$$\dot{m} = \rho_{fluid} A_{meter} u_{fluid} \tag{3.13.12}$$

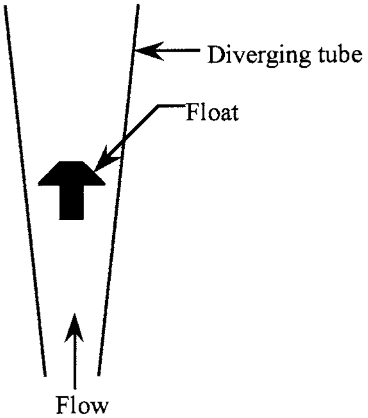

FIGURE 3.13.7 Schematic of rotameter operation.

where A_{meter} is the area between the float and the tube. Combining Equations 3.13.11 and 3.13.12 yields

$$\dot{m} = C\rho_{fluid} A_{meter} \sqrt{\frac{\rho_{float}}{\rho_{fluid}} - 1} \tag{3.13.13}$$

where it has been assumed that the drag coefficient, C_D, is constant. Many floats are designed for constant C_D over a wide flow range.

Consider now the case where a given flow meter indicates the same flow rate for two different fluid flows, i.e., A_{meter} is constant for both cases. Then,

$$\frac{\dot{m}_1}{\dot{m}_2} = \frac{\rho_{fluid,1}}{\rho_{fluid,2}} \frac{\sqrt{\rho_{float}/\rho_{fluid,1} - 1}}{\sqrt{\rho_{float}/\rho_{fluid,2} - 1}} \tag{3.13.14}$$

Since $\dot{m} = \rho_{fluid} \dot{V}$,

$$\frac{\dot{V}_1}{\dot{V}_2} = \frac{\sqrt{\rho_{float}/\rho_{fluid,1} - 1}}{\sqrt{\rho_{float}/\rho_{fluid,2} - 1}} \tag{3.13.15}$$

For cases where $\rho_{float} >> \rho_{fluid}$ (gas flows), the above equation reduces to

$$\frac{\dot{V}_1}{\dot{V}_2} = \frac{\sqrt{\rho_{fluid,2}}}{\sqrt{\rho_{fluid,1}}} \tag{3.13.16}$$

Example: Assume we have oil with a specific gravity of 0.8 flowing through a rotameter with a float made of steel. The steel has a specific gravity of 8.0. If the meter was calibrated for water, what is the correction that must be made to the indicated flow rate in order to obtain the true flow rate of oil?

Solution: Because the fluid density is not negligible compared to the float density, Equation 3.13.15 must be used.

$$\frac{\dot{V}_{oil}}{\dot{V}_{water}} = \frac{\sqrt{\rho_{float}/\rho_{oil} - 1}}{\sqrt{\rho_{float}/\rho_{water} - 1}} = \frac{\sqrt{8.0/0.8 - 1}}{\sqrt{8.0/1.0 - 1}} = 1.13$$

The true flow rate of oil, therefore, would be 1.13 times that indicated.

Target Flow Meters

These meters measure the drag force on a disk or target placed in the flow. The meter may consist simply of a hinged disk in the flow with a dial indicator showing the amount of deflection. More sophisticated meters use a strain gauge or a bellows to measure the force. Target meters can be used in dirty flows, and can also be used to sense the flow direction. Target meters are subject to the same corrections as for rotameters.

Turbine Flow Meters

Turbine flow meters consist of a free-running, vaned impeller mounted in a cylindrical section of tube. A cutaway of some turbine flow meters is shown in Figure 3.13.8. The rate of angular rotation is determined by counting the number of blade passages per unit time magnetically, mechanically, optically, or by some other method. No penetrations or seals in the duct are usually required, enabling turbine flow meters to measure flow rates in corrosive or toxic liquids. They are generally used for liquid flows,

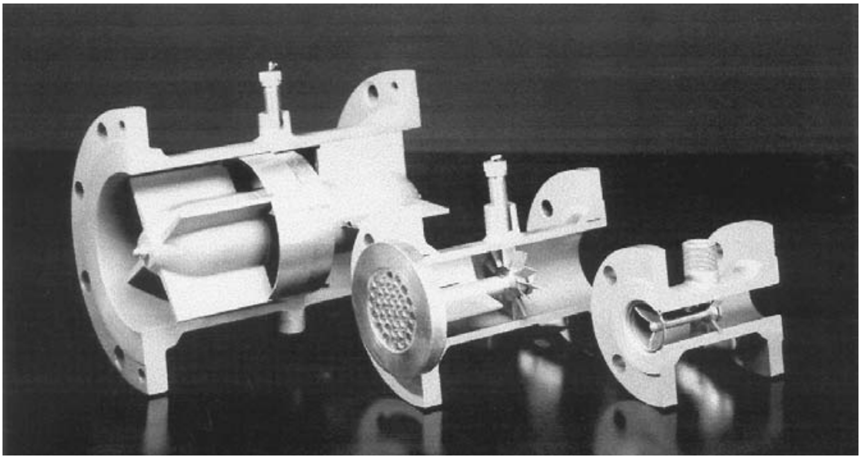

FIGURE 3.13.8 Some turbine flow meters. (Courtesy of Smith Meter, Erie, PA.)

and are characterized by high accuracy and wide dynamic range. Reading accuracies of 0.5% over a 30:1 range are common. If units with ball bearings are used, they should be inspected occasionally to check for bearing wear. The life of the unit can be dramatically increased by operating the unit well below the maximum rated speed, however. The response of turbine flow meters can be affected by viscosity. A field calibration should be performed when the working fluid has a viscosity significantly higher than that for water.

Paddlewheel flow meters are an inexpensive alternative to turbine flow meters when extreme accuracies are not required. The rate of rotation of a paddlewheel partially immersed in the flow is used as a measure of the flow rate. Unlike turbine flow meters, paddlewheels can be used in dirty flows.

Positive Displacement Meters

Positive displacement meters measure flow rate by separating the flow into discrete increments that are moved from one side of the flow meter to the other. An example of a positive displacement meter is shown in Figure 3.13.9. Positive displacement meters can be used to measure the flow rate of high-viscosity fluids.

Vortex Shedding Meters

When a bluff body is placed in a flow, vortices can be shed downstream of the body (Figure 3.13.10). Vortex shedding meters measure the frequency of the asymmetric pressure variations that occur on the body as the vortices are shed and relate this to the flow rate. The vortex shedding frequency is governed by the Strouhal number (St)

$$St = \frac{f_s d}{V} \tag{3.13.17}$$

where f_s = vortex shedding frequency
d = characteristic dimension of the body
V = velocity of the flow

Experiments have shown that St is constant within 1% for Reynolds numbers between 10^4 and 10^6. The frequency is directly proportional to the velocity (and thus the flow rate) around the body in this range. These flow meters are insensitive to dirty flows and can be used under a wide variety of conditions because they have no moving parts.

Thermal Mass Flow Meters

These determine flow rate of clean gases by passing the fluid through a precision tube that is heated in one section, and the temperature of the tube wall upstream and downstream of the heated section is measured (Figure 3.13.11). The difference in temperature between the two sensors is a measure of the mass flow rate. Calibration is usually performed using nitrogen and a correction factor is applied for other gases.

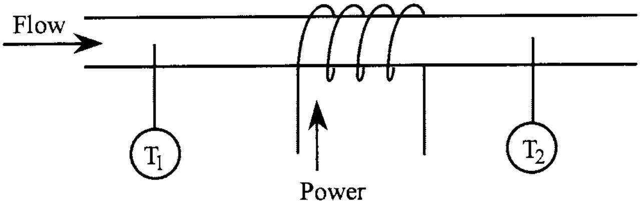

FIGURE 3.13.11 Schematic of thermal mass flow meter operation.

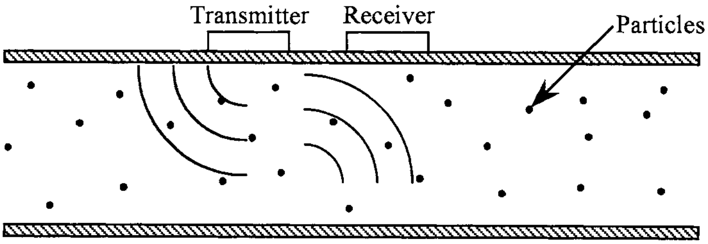

FIGURE 3.13.12 Schematic of ultrasonic flow meter.

An alternate scheme measures the temperature of the gas, and power is supplied to the downstream sensor such that its temperature is kept a fixed amount above the upstream sensor. The feedback circuit needed to do this is similar to that used in hot-wire anemometry. The amount of power supplied to the downstream sensor is a measure of the gas flow rate. The advantages of these meters are that they give a direct indication of the flow rate without requiring corrections for temperature or pressure variations, they have no moving parts, and are noninvasive.

Ultrasonic Flow Meters

These meters determine flow rate by measuring the Doppler shift of an ultrasonic signal due the movement of particles in the flow (Figure 3.13.12). Particles or bubbles in the fluid are usually required. Recently, meters have been developed that can measure the flow of clean fluids by measuring the velocity of turbulent swirls in the liquid. The meter is noninvasive, and can measure flow rate of dirty fluids or slurries.

The transit time method relies on measuring the difference in the time it takes for a signal to traverse the flow in one direction compared to a signal traveling in the opposite direction. Because the difference in transit times are so small, the time difference is usually measured as a phase difference between the two sound signals. When the particles move at flow speed, the frequency shift is proportional to flow speed. For a suitably chosen path, output is proportional to volume flow rate. Ultrasonic meters may require calibration in place. One or two transducers may be used.

Laminar Flow Elements (LFE)

Laminar flow meters operate by passing a gas through a bundle of tubes or a honeycomb (Figure 3.13.13). The small diameter of these flow passages in the matrix laminarize the flow, and the pressure drop between the inlet and exit of the tubes is measured. If the flow passages were circular, the pressure drop across the element would be

$$\Delta P = \frac{128\mu l\dot{V}}{\pi D^4} \tag{3.13.18}$$

and is linear with the volumetric flow rate. Because the flow passages are not necessarily circular, calibration of the flow meter is usually required. Corrections are also needed for changes in fluid viscosity and temperature. The gas must be clean. The LFE may be used with reasonable accuracy over a 10:1 flow rate range. A LFE costs approximately as much as a venturi, but is much lighter and smaller. Thus, the LFE is widely used in applications where compactness and extended range are important.

Coriolis Meters

These meters are true mass flow meters. The concept behind coriolis meters is shown in Figure 3.13.14. Consider the case where the flow moves through a U-tube that is vibrated at its resonant frequency using an electromagnetic coil. If fluid flows into the tube when the tube is moving upward, the fluid needs to be accelerated and will cause the tube to bend down. The fluid that has traveled around the bend at this

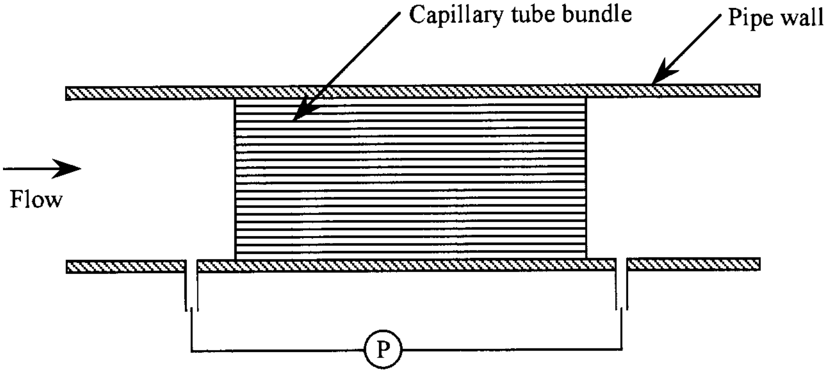

FIGURE 3.13.13 Schematic of laminar flow element.

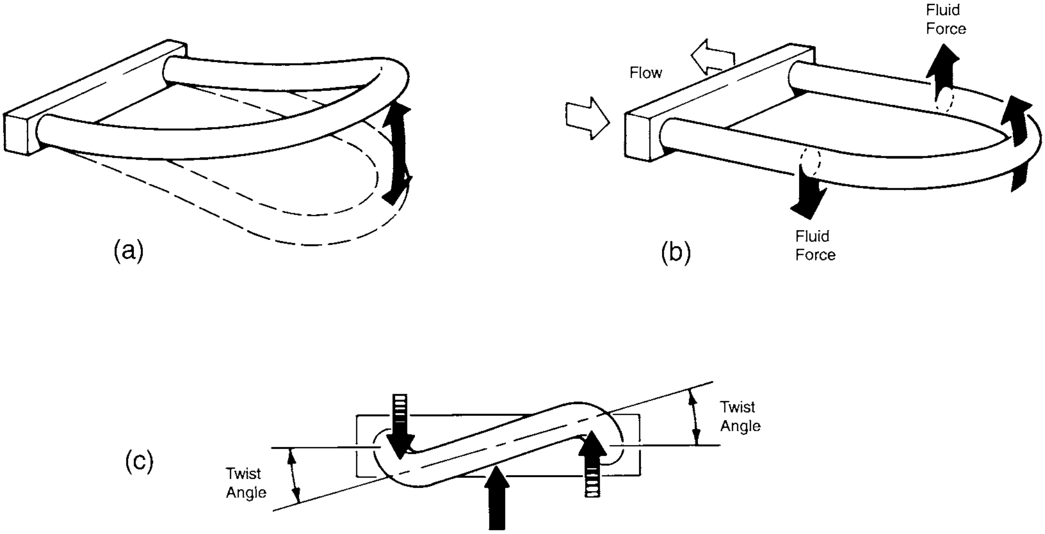

FIGURE 3.13.14 Principle of operation of a coriolis meter: (a) vibrating flow tube, (b) fluid forces reacting to vibration of flow tube, (c) end view of flow tube showing twist. (Courtesy of Micro Motion Inc., Boulder, CO.)

time already has an upward momentum and needs to be decelerated, causing this part of the tube to bend upward. The tube, therefore, will twist in the opposite direction during the downward motion. The difference in velocity of the two legs of the vibrating tubes is a measure of the mass flow rate. The density of the fluid flowing in the tube can be measured by measuring the change in resonant frequency of the tube. The instrument measures mass flow rate directly and, thus, is ideal for two-phase or liquid–solid flow measurements. Pressure drop across the coriolis meter may be high, but its useful flow rate range is 100:1.

Electromagnetic Flow Meters

Electromagnetic flow meters create a magnetic field across a pipe. When a conductive fluid passes through the field, a voltage is generated at right angles to the field and velocity vectors. Electrodes placed on a pipe detect the resulting signal voltage, which is proportional to the average axial velocity when the profile is axisymmetric. The minimum flow speed should be above about 0.3 m/s, but there are no restrictions on the Reynolds number. The flow rate range normally quoted is 10:1.7

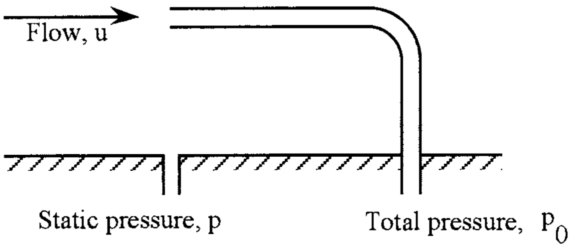

FIGURE 3.13.15 Basic total pressure probe setup.

Traversing Methods

In situations such as in air handling or refrigeration equipment, it may be impractical or impossible to install a fixed flow meter, but it may be possible to measure flow rate using a traversing technique. To measure flow rate by traverse, the duct cross section is subdivided into segments of equal area. The fluid velocity is measured at the center of each area segment, and the volume flow rate for each segment is approximated by the product of the measured velocity and segment area. Flow rate through the entire duct is the sum of these segmental flow rates. Methods for measuring the flow velocity are discussed below.

Pressure Probes

Perhaps the simplest and least expensive method of measuring velocity is through the use of Pitot probes. Consider the stagnating flow shown in Figure 3.13.15. Applying Bernoulli's equation to the flow between a point far upstream of the probe and the probe tip, assuming an incompressible flow, yields

$$p_0 = p + \frac{1}{2}\rho u^2 \tag{3.13.19}$$

The total pressure sensed by the tube (p_0) is greater than the freestream pressure (p) by the dynamic head $1/2\rho u^2$. The freestream velocity (u) thus can be determined by measuring the static and total pressures. Equation 3.13.19 can be applied to flows whose Mach number ($M = u/a$) is less than 0.2 with less than 0.5% uncertainty. The speed of sound is given by

$$a = \sqrt{\gamma R_g T} \tag{3.13.20}$$

where T is the static absolute temperature of the flow, R_g is the real gas constant, and γ is the ratio of specific heats. When the flow Mach number exceeds 0.2, the density of the fluid along the stagnation streamline changes and compressibility effects must be taken into account. For $0.2 < M < 1.0$, the relation between velocity and pressure difference is given by:

$$M^2 = \frac{2}{\gamma - 1}\left[\left(\frac{p_0}{p}\right)^{\frac{\gamma-1}{\gamma}} - 1\right] \tag{3.13.21}$$

When the flow is supersonic, the flow adjusts to the stagnation condition through a bow shock off the tip of the Pitot probe (Figure 3.13.16). The relationship between the static pressure ahead of the shock (measured by a static pressure tap) to the total pressure behind the shock (indicated by the probe) is given by

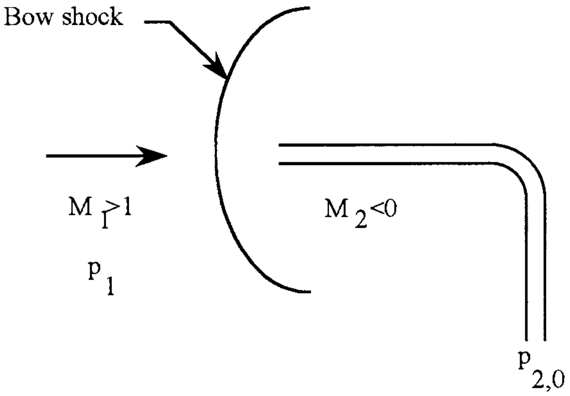

FIGURE 3.13.16 Supersonic flow around a total pressure probe.

$$\frac{p_1}{p_{2,0}} = \frac{\left(\frac{2\gamma}{\gamma+1} M_1^2 - \frac{\gamma-1}{\gamma+1}\right)^{\frac{1}{\gamma-1}}}{\left(\frac{\gamma+1}{2} M_1^2\right)^{\frac{\gamma}{\gamma-1}}} \tag{3.13.22}$$

The above equation can be solved to determine the Mach number and, hence, the flow velocity ahead of the shock.

Although the measurement of velocity using pressure probes is relatively straightforward, there are many situations where the ideal situation indicated in Figure 3.13.15 does not occur. Some factors that influence the measurement are

- Alignment of the probe with the flow
- Wall effects
- Turbulence effects
- Pitot probe design
- Static pressure tap geometry
- Streamline curvature

Each of these effects is briefly discussed below.

Alignment Effects

The change in stagnation pressure due to flow misalignment for various probes is shown in Figure 3.13.17. It is seen that an open-ended tube can be misaligned by up to ±10° without error in the pressure reading, while a tube with a chamfered opening can tolerate misalignments up to ±30°.

Wall Effects

The presence of a wall changes the flow around the probe, and this can result in pressure readings that are lower than when a wall is not present. For a round probe touching the wall, the velocity indicated can be up to 1.5% low (Moffatt).

Turbulence Effects

The effects of turbulence on velocity measurements are dependent on many factors such as turbulence scale and structure, fluctuation frequency, and internal geometry of the probe. The few studies that have been performed were inconclusive, with some studies indicating a decrease in the measured velocity with increasing turbulence and others indicating the opposite trend. A first-order analysis indicates that 20% turbulence intensities can result in a 2% increase in the measured velocity.

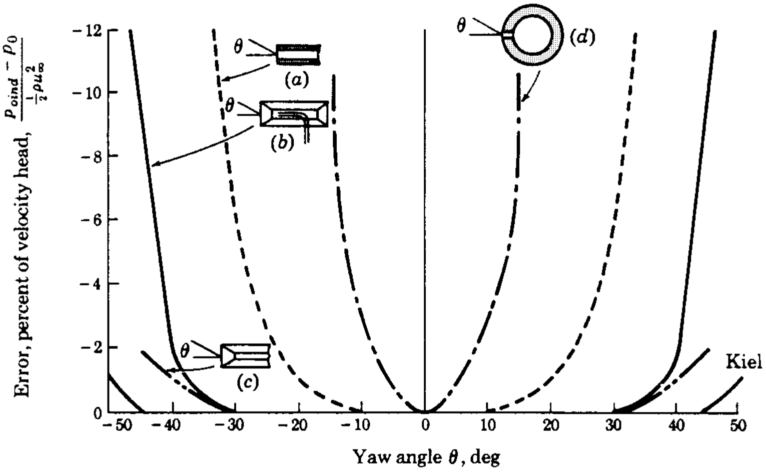

FIGURE 3.13.17 Error in stagnation pressure with changes in yaw angle for (a) open-ended tube, (b) channel tube, (c) chamfered tube, and (d) tube with orifice in side. (From Krause, L.N. and Gettleman, C.C., *ISA Proc.,* 7, 134, 1952. With permission.)

Static Pressure Taps

Static pressure taps should be drilled perpendicular to the wall, and no burrs or chamfers should be present. The holes should be made as small as possible without causing excessively slow response times at the transducer.

Streamline Curvature

If the streamlines in a flow are curved (perhaps due to obstacles in the flow), then velocity and pressure gradients can occur across the channel and the static pressure obtained from a wall pressure tap may not be representative of that where the total pressure is being measured. The local static pressure at the measuring location must either be measured or computed.

Design of Pitot-Static Probes

Pitot-static probes combine the measurement of total and static pressure in one unit. A commercially available Pitot-static probe is shown in Figure 3.13.18. The location of the static pressure taps is important. The static pressure taps should be located sufficiently far downstream of the tip so that flow acceleration effects can be ignored, and sufficiently far upstream of the support so that blockage effects are small. If the static pressure taps are located eight tube diameters downstream of the tip and eight tube diameters upstream of the support, then the effects of both acceleration and blockage will be below 1%.

Measurement of Flow Direction

The flow direction can be obtain by using prizm probes or probes with multiple sensing holes. Additional reading regarding the various types of pressure probes and the errors associated with them is given in Moffatt.

Hot-Wire Anemometry

Hot-wire anemometry is used when one wishes to measure rapidly varying velocities with good spatial resolution. Velocity fluctuations up to 50 kHz can easily be obtained. Typically a heated, thin wire is held in the flow, and the cooling effect on the wire due to velocity is measured. The disadvantages compared to pressure probes are that they are relatively expensive, they use frail wires, and they need to be calibrated in a known flow environment. Corrections also need to be made to account for freestream temperature variations and for flow along the wire for slanted wires. There are two types of hot-wire anemometry — constant temperature and constant current.

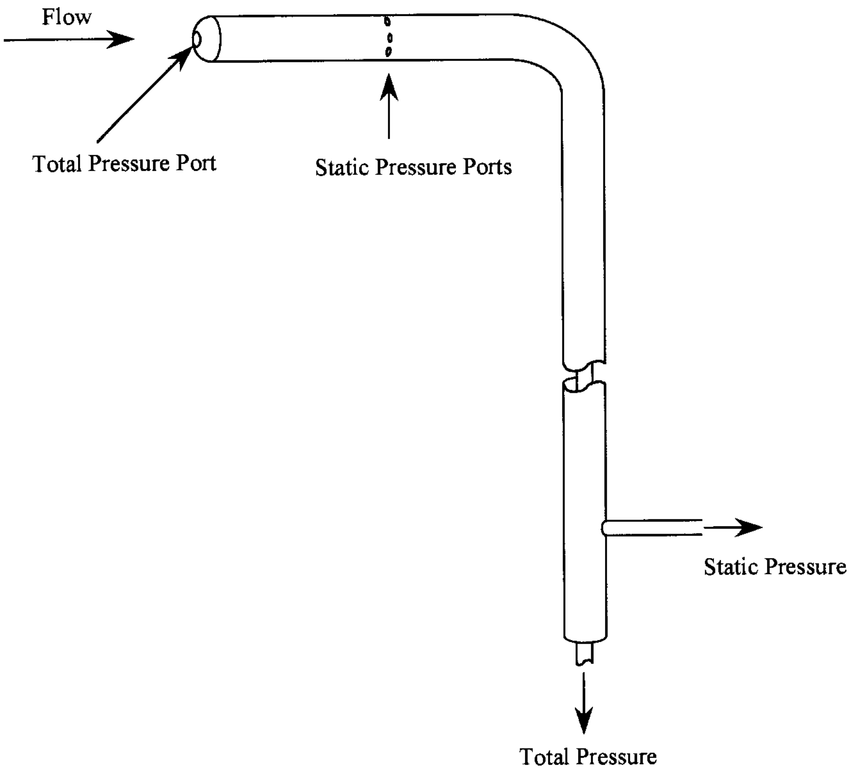

FIGURE 3.13.18 A pitot-static probe.

Constant Current Anemometry

This method consists of sending a constant current through a thin wire and measuring the change in resistance of the wire with velocity. Although much simpler than constant temperature anemometry, constant current anemometry has several disadvantages that has resulted in almost exclusive use of constant temperature anemometry today. These disadvantages include relatively low frequency response and the possibility of wire burnout at large currents and low velocities. However, they can be used when many channels of data need to be acquired, when turbulence information is not needed, or when the flow temperature needs to be measured. Numerous schemes for treating the resulting data have been published. Digital processing techniques, including fast Fourier transforms, can be used to obtain mean values and moments, and to analyze signal frequency content and correlations.

Constant Temperature Anemometry Fundamentals

The basic circuit is shown on Figure 3.13.19. The wire is represented by resistance R_w in a Wheatstone bridge. Resistors R_1, R_2, and R_c are very stable with temperature. The imbalance in the bridge is measured using an op-amp, and the op-amp outputs whatever voltage is necessary to bring the bridge back into balance. For example, consider the case where the bridge is balanced at a given flow velocity, i.e., $R_w/R_1 = R_c/R_2$ and $V_1 = V_2$. If the velocity over the wire increases, the wire temperature (and therefore its resistance) will decrease, causing the bridge to become unbalanced ($R_w/R_1 < R_c/R_2$ and $V_1 < V_2$). The op-amp senses this imbalance in the bridge and increases its output voltage causing more current to flow through the wire, bringing the bridge back into balance. The operating temperature of the wire is controlled by changing the value of R_c. The output voltage of the op-amp is a measure of the amount of cooling the wire experiences. Because the temperature of the wire does not change, the frequency response is not limited by the thermal mass of the wires and high frequency responses are possible.

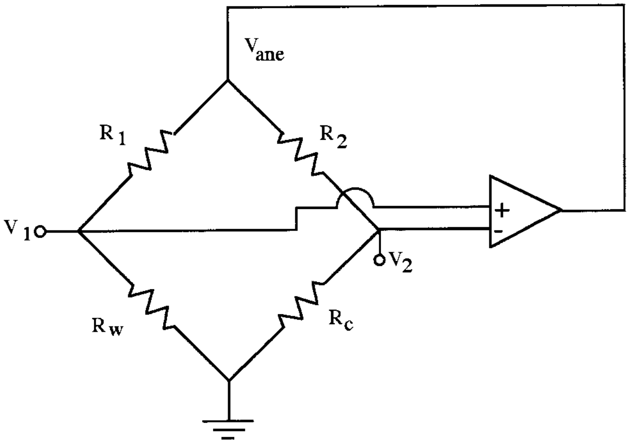

FIGURE 3.13.19 Schematic of hot-wire circuit.

Equations Governing Hot-Wire Anemometry

The cooling law is assumed to be of the form

$$Nu = A_0 + B_0 \operatorname{Re}^{0.5} \tag{3.13.23}$$

where Nu is the Nusselt number and Re is the Reynolds number; both are based on the wire diameter. The above equation is commonly known as King's law (King, 1914). Substituting in the definition of Nu and Re and solving for the heat transferred from the wire yields

$$q = A_1 \left(T_w - T_\infty\right) k + B_1 \left(\frac{P_\infty u_\infty}{T_\infty \mu}\right)^{0.5} \left(T_w - T_\infty\right) k \tag{3.13.24}$$

The heat transferred from the wire to the gas is balanced by the energy supplied by the anemometer:

$$q = i_w^2 R_w = \frac{V_{ane}^2 R_w}{\left(R_w + R_{ane}\right)^2} \tag{3.13.25}$$

or, since R_w and R_{ane} are constant,

$$q \propto V_{ane}^2 \tag{3.13.26}$$

Combining Equations 3.13.24 and 3.13.26 and solving for $P_\infty u_\infty$ yields

$$\left(P_\infty u_\infty\right)^{0.5} = A T_\infty^{0.5} \mu^{0.5} + B \frac{V_{ane}^2}{\left(T_w - T_\infty\right)} \frac{T_\infty^{0.5} \mu^{0.5}}{k} \tag{3.13.27}$$

For isothermal flows, the response equation reduces to

$$u^{0.5} = A + B V_{ane}^2 \tag{3.13.28}$$

Although it is theoretically possible to obtain the response curve without doing a calibration, the uncertainty in the wire diameter, wire length, and other errors make calibration of the wire mandatory at the conditions at which one wishes to operate.

Probe Design

Shown on Figure 3.13.20 are some typical probes used in anemometry. The curved prongs on the boundary layer probe (Figure 3.13.20b) are designed to minimize flow disturbance in the near-wall region. The two wires on this probe are used to obtain both u and v components of velocity.

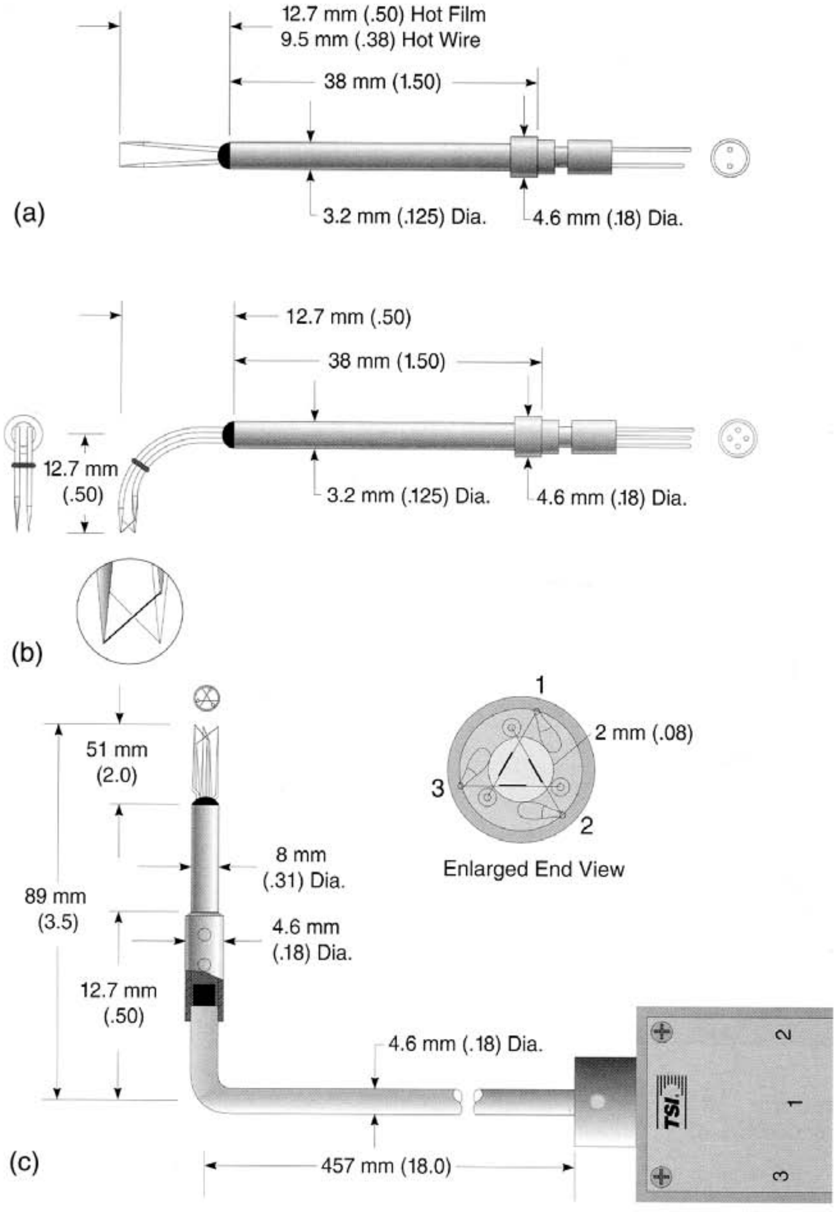

FIGURE 3.13.20 Some hot-wire probe configurations: (a) single-wire probe, (b) boundary layer cross-wire probe, (c) triple sensor cross-flow probe. (Courtesy of TSI Inc., St. Paul, MN.)

Platinum-plated tungsten wires 4 μm thick are typically used. Platinum is used to prevent oxidation of the wires during operation. The operating temperature for these wires is typically 250°C. Pure platinum wires are also used with the advantage of being able to operate at high temperatures (about 1000°C), thereby minimizing drift with ambient temperature changes, but they tend to be quite frail and their use is limited to low velocities. The ends of the wires where they attach to the prongs are usually copper-plated and the unplated length defines the sensitive portion of the wire. This is performed to isolate the sensing length from the disturbing effects of the prongs on the flow. The l/d of the sensing length is typically 200.

Platinum thin film probes are also available. These are made by depositing a thin layer of platinum onto a quartz substrate, typically a 50-μm-diameter quartz rod. The probe can be coated with a thin layer of oxide for use in electrically conductive liquids. The advantages of film sensors are their rigidity and strength. Rigidity is important for multisensor applications since the data reduction algorithms typically assume straight sensors. Film sensors are more resistant to damage by particles in the flow.

Multicomponent Probes

More than one component of velocity can be measured if multiple wires are present. Consider the case where a wire is inclined relative to the axis of the flow, as shown in Figure 3.13.21. Cross-wires (Figure 3.13.20b) inclined at θ_1 and θ_2 from the normal can be used to obtain the instantaneous U and V components of velocity. The cross-correlation between u′ and v′ (u′v′), also known as the turbulent shear stress, can be obtained if the instantaneous velocities U and V are known. The wires will be sensitive to the velocities according to

$$U_{eff,1} = U\cos(\theta_1) + V\sin(\theta_1) \tag{3.13.29}$$

$$U_{eff,2} = U\cos(\theta_2) - V\sin(\theta_2) \tag{3.13.30}$$

If the effective velocities over the two wires are known along with the probe geometry, then the velocities U and V can be determined. The instantaneous velocity can be broken down into the mean and fluctuating components:

$$U = \overline{U} + u' \tag{3.13.31}$$

$$V = \overline{V} + v' \tag{3.13.32}$$

Since

$$\overline{uv} = \overline{(\overline{U} + u')(\overline{V} + v')} = \overline{U}\overline{V} + \overline{u'v'} \tag{3.13.33}$$

the turbulent shear stress can be written as

$$\overline{u'v'} = \overline{uv} - \overline{U}\overline{V} \tag{3.13.34}$$

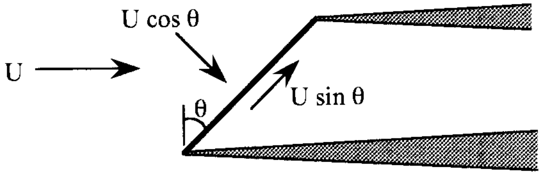

FIGURE 3.13.21 Normal and tangential components of velocity for a wire inclined to the flow.

The above results must be corrected to take into account the directional response of the wire, as discussed below. Three-wire probes to measure three components of velocity are also available (Figure 3.13.20c).

Directional Response

For small inclinations θ to the flow, the hot-wire will only respond to the velocity component normal to the wire or *Ucos*θ. For large inclinations, a significant axial flow develops along the wire resulting in additional cooling as a result of the finite length of the wire. The equation usually used to describe this effect is based on work by Champagne et al. (1967) and is given by

$$U_{eff}^2 = U^2\left(\cos^2\theta + k^2\sin^2\theta\right) \tag{3.13.35}$$

where k is a constant that varies linearly from 0.2 for a wire with $l/d = 200$ to zero for $l/d = 600$. Champagne et al. (1967) applied these results to estimate the overall error for a 45° cross-wire operated at constant temperature. They found that

$$\left(\frac{\overline{u'^2}}{U^2}\right)_m = \left(\frac{\overline{u'^2}}{U^2}\right)_i \tag{3.13.36}$$

$$\left(\frac{\overline{u'v'}}{U^2}\right)_m = \frac{1+k^2}{1-k^2}\left(\frac{\overline{u'v'}}{U^2}\right)_i \tag{3.13.37}$$

$$\left(\frac{\overline{v'^2}}{U^2}\right)_m = \frac{1+k^2}{1-3k^2+4k^4}\left(\frac{\overline{v'^2}}{U^2}\right)_i \tag{3.13.38}$$

where the subscript m is the measured value and the subscript i is the ideal value for a wire of infinite length.

Corrections Due to Temperature

Probably the most significant source of error when using a properly calibrated hot-wire occurs as a result of drifts in the flow temperature from the calibration temperature. If the flow temperature is higher than the calibration temperature, less energy is required to keep the wire at a constant temperature for a given velocity, and the indicated flow velocity will be lower than the true flow velocity. A first-order correction can be made to account for the drift in flow temperature as described below, however. The energy dissipated by the wire is proportional to the wire-to-flow temperature difference, and is also proportional to the voltage across the wire:

$$q_w \sim \Delta T \sim V^2 \tag{3.13.39}$$

The following equation can be used to correct for small changes in temperature:

$$V_{corr} = V_m\sqrt{\frac{T_w - T_{ref}}{T_w - T_\infty}} \tag{3.13.40}$$

where V_{corr} = corrected voltage
V_m = measured voltage
T_w = wire temperature
T_{ref} = temperature of the calibration flow
T_∞ = temperature of the flow

It should be noted that the sensitivity to ambient temperature changes decreases with higher wire temperatures — the wire should be operated at the highest possible temperature.

Laser Doppler Anemometry

LDV uses light to measure the velocity of particles in a flow through a small volume. If the particles faithfully follow the flow, then the velocity of the particle can be assumed to be the velocity of the flow itself. LDV has numerous advantages over other methods of measuring velocity. First, it is nonintrusive so it can be used in environments that are hostile to probes or where probes excessively disturb the flow. Second, it does not depend on temperature or pressure changes in the flow. Third, it can detect flow reversals. Fourth, it can measure very high velocities if sufficiently fast electronics are available. Fifth, velocity is measured directly and is unaffected by changes in temperature, density, or composition in the flow field. LDV has been used in flows ranging from natural convection to flows in IC engines and gas turbines. The disadvantages include the need for particles (seeded or naturally occurring) that follow the fluid motion, high cost, the need for optical access to the test section, and the need for careful alignment.

Principle of Operation

The basic setup for a popular type of LDV system is shown on Figure 3.13.22. A single, polarized, continuous-wave laser is split into two parallel beams using a beam splitter. The beams pass through a focusing lens that causes the beams to intersect in the focal plane of the lens, simultaneously reducing the beam diameter. The light beams approximate cylinders in the intersection region. The two beams constructively and destructively interfere with each other in the intersection regions, setting up alternating bright and dark fringes that are parallel to the axis of the laser beams. A particle moving through the measuring volume will scatter light, with the intensity of the scattered light depending on whether or not the particle is in a bright or dark fringe. Only the component of velocity perpendicular to the fringes and to the axis of the laser beams will be measured. The collecting lens collects some of the scattered light and focuses it onto a photodetector which outputs a signal dependent on the light intensity. Since the spacing between the fringes can be calculated or measured, the velocity of the particle traversing the measuring volume can be determined by measuring the frequency of the signal from the photomultiplier.

Measuring Volume Dimensions

The dimensions of the measuring volume can be computed from the following relations:

$$d_m = \frac{4 f \lambda}{\pi D_{e}^{-2}} \tag{3.13.41}$$

$$l_m = \frac{d_m}{\tan \kappa} \tag{3.13.42}$$

$$d_f = \frac{\lambda}{2 \sin \kappa} \tag{3.13.43}$$

where d_m = measuring volume diameter
l_m = measuring volume length
d_f = fringe spacing
f = focal length of the transmitting lens
D_{e}^{-2} = diameter of the laser beam at the e^{-2} intensity point entering the transmitting lens
λ = wavelength of the laser light
κ = half angle between the beams

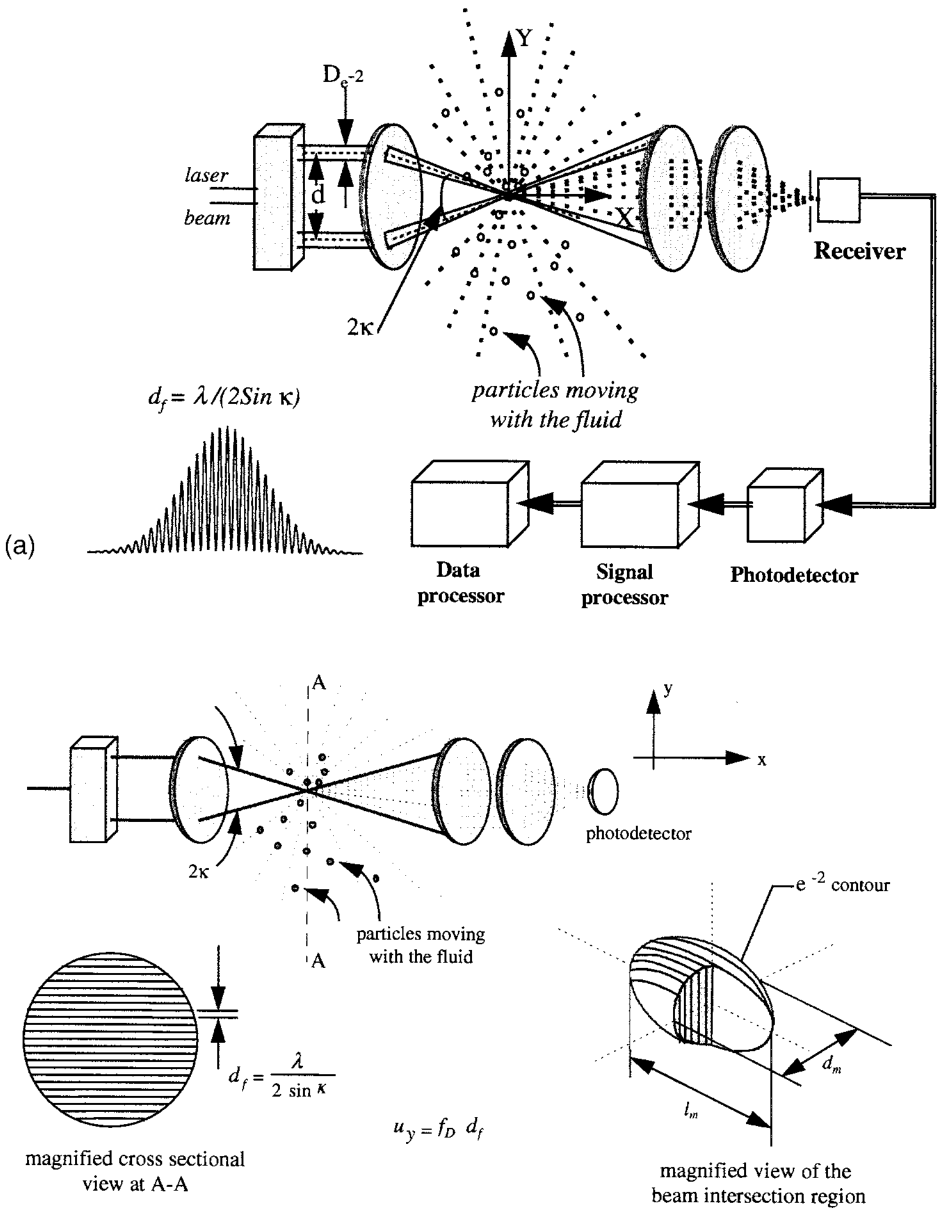

FIGURE 3.13.22 Basic setup for two-component LDV: (a) schematic of a dual beam system, (b) details of the beam crossing. (Courtesy of TSI Inc., St. Paul, MN.)

HeNe or argon-ion lasers are typically used. Note that in order to get a small measuring volume diameter, the focal length needs to be short, or the beam diameter needs to be large. Similar effects are seen for the measurement volume length. Ideally, one would like to have a measuring volume that is small compared to the scales of interest, with at least 10 fringes in the measuring volume.

Backscatter Mode

A configuration that is often used is shown in Figure 3.13.23. The backscatter configuration has the advantage that the optics can be made very compact, and because all the optics can be put in a single housing the optics need to be aligned only once. Much less light is scattered in the backward direction

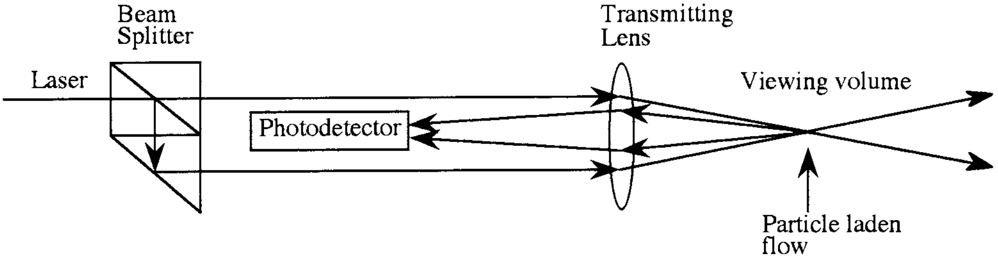

FIGURE 3.13.23. LDV configuration for backscatter.

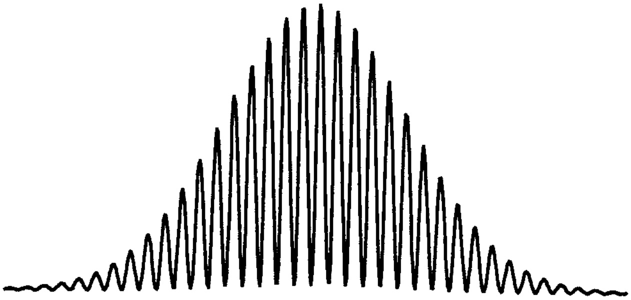

FIGURE 3.13.24 Typical photodetector signal due to scattering from a single particle. (Courtesy of TSI Inc., St. Paul, MN.)

than in the forward direction, however, so much more sensitive photodetectors are required to detect the weaker signal.

Photodetectors

Two types of photodetectors are generally used to convert the scattered light collected by the collecting lens to an electronic signal. In the photomultiplier, photons strike a coating of photoemissive material causing electrons to be emitted. These electrons are accelerated by a high-voltage field and impact onto a dynode that emits even more electrons. This amplification process is repeated, resulting in final gains of 10^3 to 10^7. Frequency responses up to 200 MHz can be obtained using photomultipliers.

Photodiodes are light-sensitive semiconductor junctions. An amplification process similar to that in PMTs occurs in photodiodes, but gains are limited to about 10^3. The frequency response tends to be lower as well. Photodiodes are much less expensive than photomultipliers, however.

Signal Processing

A typical output signal from a photodetector is shown on Figure 3.13.24. It is seen to consist of a pedestal along with the Doppler signal. Most commercial LDV systems currently on the market use FFT or correlation methods to determine the frequency.

Particle Tracking

It is important that the particles be able to follow the flow. Consider a spherical particle placed in a uniform flow. The drag force on the particle is due to the difference in speed between the particle and the carrier fluid, i.e.,

$$Force = ma = m\frac{dU_\infty}{dt} = \rho_P \frac{\pi D_P^3}{6}\frac{dU_\infty}{dt} = Drag \qquad (3.13.44)$$

The drag on a spherical particle is given by

$$Drag = C_d \frac{1}{2} \rho_\infty \frac{\pi D_P^2}{4} \left(U_\infty - U_P\right)^2 \tag{3.13.45}$$

where

$$C_d = \frac{24}{\text{Re}_P} = \frac{24\nu}{D_P\left(U_\infty - U_P\right)} \tag{3.13.46}$$

for $0 < Re_P < 100$. Combining Equations 3.13.44, 3.13.45, and 3.13.46 and integrating yields

$$\frac{\left(U_\infty - U_P\right)}{U_\infty} = \exp\left(-t/K\right) \tag{3.13.47}$$

where

$$K = \frac{D_P^2}{18\nu} \frac{\rho_P}{\rho_\infty} \tag{3.13.48}$$

Here, K is the time constant, and represents the time it takes for the initial velocity difference between the particle and the fluid to decay by $1/e$. Particles with K small compared to the time scales of interest will faithfully follow the flow.

Flow Reversal Measurements

If the fringes are stationary, as was assumed until now, one cannot tell the direction from which the particle passes the fringes, i.e., a particle moving with a velocity U will produce the same signal as a particle moving with velocity $-U$. While the direction of the flow is unambiguous in many cases, there are other flows (recirculating flows, flows with high turbulence intensity, impinging jets, shear flows) where the flow direction is not known. This problem can be easily rectified by shifting the frequency of one of the laser beams. If one of the beams is shifted in frequency, this will cause the fringes to move as well. If the fringes move at a speed faster than the maximum absolute flow velocity, then the indicated velocity will be the flow velocity plus the fringe velocity. Zero flow velocity would correspond to the fringe velocity, negative flow velocities would correspond to indicated velocities lower than the fringe velocity, and positive flow velocities would correspond to indicated velocities higher than the fringe velocity.

Frequency shifting is usually accomplished by inserting an acoustic-optic Bragg cell in one of the split beams. Typical shifts are 40 MHz, i.e., a 40-MHz signal would be seen at the output of the photodetector at zero flow velocity.

Multicomponent Systems

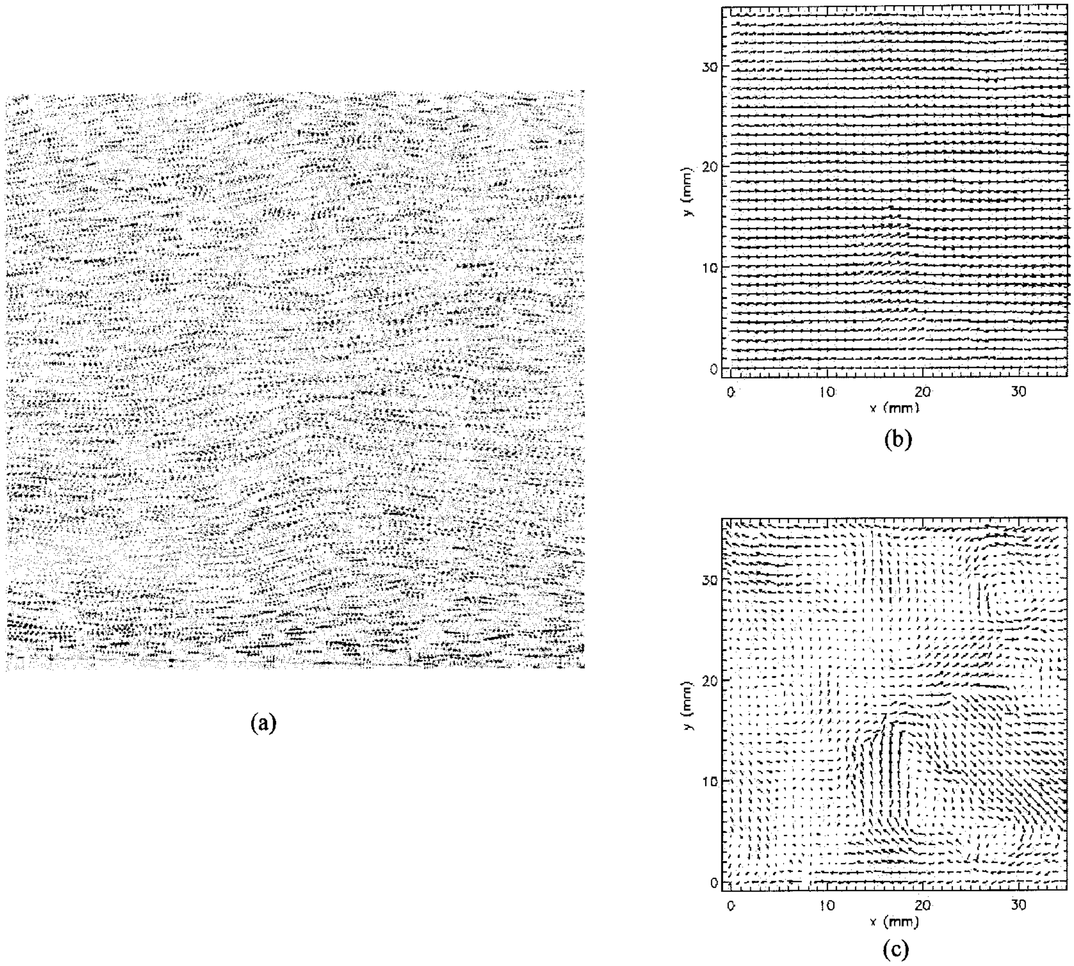
Measurement of more than one component of velocity is more difficult than simply having two one-component systems because the signals from the two beams interfere with each other. It is necessary to be able to distinguish which pair of beams the signal came from. One can either use two pairs of beams of different color or different polarities. In the two-color method, four beams consisting of two different colors are usually used. An argon-ion laser produces both blue and green lines. This light is split and converged to form two mutually orthogonal dual-beam systems. The scattered light is collected by a pair of receiving optics/photodetector systems, one of which accepts only blue light and one of which only accepts green light. The scattered light is separated using a dichroic mirror that transmits the blue light and reflects the green light.

Particle Image Velocimetry

A relatively new method of measuring velocity at many points in the flow is by particle image velocimetry (PIV). This method enables simultaneous measurement of velocity at many points in the flow by measuring the distance that particles carried by the flow travel over a known time interval. Accuracy and spatial resolution can be comparable to LDV.

Typical applications of PIV are to obtain the turbulent flow structure of complex steady flow fields where mapping is too difficult and time-consuming, and periodic flow fields where the velocity field can be obtained at different phases. An example of flow field velocity vectors obtained using PIV is shown on Figure 3.13.25.

The fundamental principle of PIV by optical imaging is the measurement of displacements δx, δy of image markers which travel with the fluid. In PIV, the time between the marks is fixed, while the distance between fringes is fixed in LDV. The time interval between marks in PIV must be small compared to the time scales of interest in the flow. Typical markers that have been used are H_2 bubbles, fluorescent particles, and naturally occurring small particles in liquids. The two main components of a PIV system are the imaging system which produces a double-exposed photographic image of the particles in the flow field, and the interrogation system which extracts and presents the velocity field information contained in the photograph.

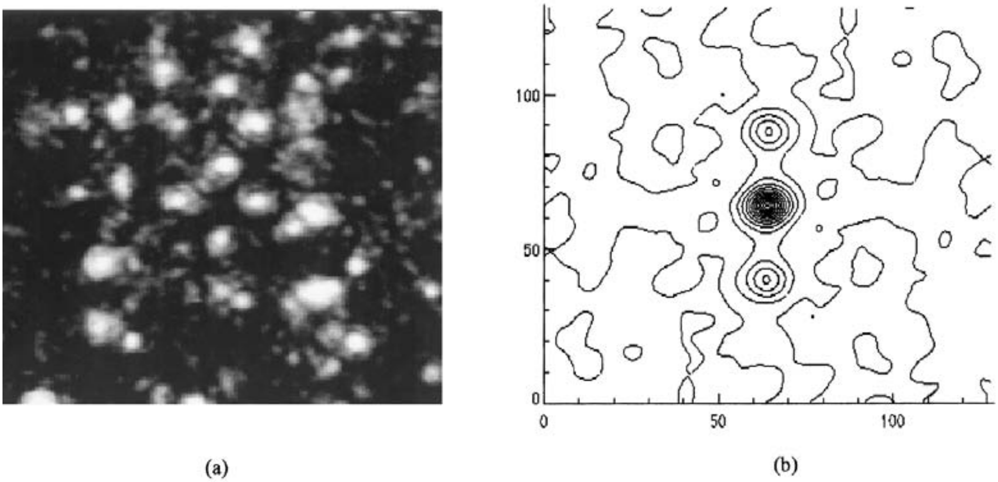


(a)

(b)

(c)

FIGURE 3.13.25 Example of velocity vectors obtained using PIV: (a) double exposure of particles in flowfield, (b) velocity vectors, (c) velocity vectors with mean velocity subtracted out. (Courtesy of Ken Kiger, University of Maryland, College Park, MD.)



(a) (b)

FIGURE 3.13.26 Example of (a) double-exposed image of particle shifted from one another, (b) the corresponding spatial autocorrelation. (Courtesy of Ken Kiger, University of Maryland, College Park, MD.)

Imaging System

Typically, the beam from a doubly pulsed laser is converted into a sheet of laser light using a cylindrical lens, which is then used to illuminate the markers in the flow. A camera located perpendicular to the flow records the doubly exposed image onto film. Typical light sources are pulsed lasers or shuttered continuous wave (CW) lasers. Because pulsed lasers have larger energy output than CW lasers, they are generally used to illuminate small particles in the flow. Single CW laser beams swept across the flow using a rotating, faceted mirror produce a pseudo light sheet and can also be used to illuminate particles.

Film is usually necessary to resolve the markers if reasonable spatial resolution is desired. Larger markers in conjunction with high-resolution video cameras can be used, but care must be taken to ensure that the markers faithfully follow the flow. High-resolution cameras do have the advantage that near on-line processing of the data can be performed, however, with the appropriate digitizing and computing equipment.

The result of the imaging system is to produce two sets of markers that are displaced in time. The two sets can be on a single sheet of film, or can be recorded separately on different frames of a video camera. An example of two sets of markers is shown on Figure 3.13.26a.

Interrogation System

To obtain the velocity vectors, the doubly exposed image is first divided up into small sub-areas over which the average velocity vector will be computed. The size of the sub-areas should be as small as possible to obtain the highest number of velocity vectors, but they should not be so small that an insufficient number of particle pairs results. A good rule of thumb is to choose a sub-area size that contains about 10 particle pairs. The position of each of the particles is then determined, and a spatial autocorrelation performed (Figure 3.13.26b). The location of the peaks in the spatial correlation plane yields the average particle displacement over that sub-area. The largest peak results from a self-correlation and is not of interest. Two other peaks, one in the positive direction and the other in the negative direction, indicate the possible average particle displacement over that sub-area.

Flow Direction

It is not possible to determine the *direction* of the velocity vector from a doubly exposed photograph alone. This is not a problem if the main flow direction is known *a priori*, but it does present problems in highly turbulent flows or if flow reversals occur. Image shifting of the second set of particles relative to the first can be used to resolve this directional ambiguity. Suppose the second set of images is shifted by a positive amount. A stationary marker will be displaced by this amount. A moving marker will have an additional displacement as a result of its movement. A shift greater than that expected at the largest negative flow velocity then eliminates ambiguity regarding flow direction, since the second image is always on the positive side of the first image. This technique is analogous to using frequency shifting in LDV measurements to determine the direction of the particle movement.

Rotating mirrors and crystals have been used to produce this shift in images. More recently, cameras have been developed specifically for PIV that electronically shift the first set of images by a certain number of pixels before acquiring the second set, eliminating any additional mechanical complexity.

Viscosity Measurements

Viscometry is the technique of measuring the viscosity of a fluid. Viscometers are classified as rotational, capillary, or miscellaneous, depending on the technique employed. Rotational viscometers use the principle that a rotating body immersed in a liquid experiences a viscous drag which is a function of the viscosity of the liquid, the shape and size of the body, and the speed of its rotation. Rotational viscometers are widely used because measurements can be carried out for extended periods of time.

Capillary viscometry uses the principle that when a liquid passes in laminar flow through a tube, the viscosity of the liquid can be determined from measurements of the volume flow rate, the applied pressure, and the tube dimensions. Viscometers that cannot be classified either as rotational or capillary include the falling ball viscometer. Its method of operation is based on Stokes' law which relates the viscosity of a Newtonian fluid to the velocity of a sphere falling through it. Falling-ball viscometers are often employed for reasonably viscous fluids. Rising bubble viscometers utilize the principle that the rise of an air bubble through a liquid medium gives a visual measurement of liquid viscosity. Because of their simplicity, rising bubble viscometers are commonly used to estimate the viscosity of varnish, lacquer, and other similar media.

Defining Terms

Flow meter: Device used to measure mass flow rate or volume flow rate of fluid flowing in a duct.

Restriction flow meter: Flow meter that causes flowing fluid to accelerate in a nozzle, creating a pressure change that can be measured and related to flow rate.

Thermal anemometer: Heated sensor used to infer local fluid velocity by sensing changes in heat transfer from a small electrically heated surface exposed to the fluid flow.

Traverse: Systematic procedure used to traverse a probe across a duct cross section to measure flow rate through the duct.

3.14 Pressure Measurements

Jungho Kim

Pressure is defined as force per unit area. Pressure transducers measure pressure relative to an absolute pressure p_a (relative to vacuum) or gage pressure p_g (relative to atmosphere). Gage pressure can be positive or negative depending on whether the measured pressure is above or below atmospheric. This atmospheric pressure can change depending on location. In some cases, pressure is measured relative to a sealed cavity which is at 1 bar regardless of the local atmospheric pressure. Some common units of pressure are Pa, mmHg, inches of water, torr, and bars. There are many types of pressure gages. Some can be considered standards which are accurate, repeatable, and fundamental pressure measuring instruments. Other gages must be calibrated against the standards.

Standards

Pressure standards use as force the weight of a solid or liquid mass. The two most common pressure standards are manometers and deadweight gages.

Manometers. A manometer (Figure 3.14.1) uses the deflection of a liquid column to measure pressure. A U-tube manometer measures pressure differences by balancing the forces on a liquid column in a U-shaped tube. A static force balance on the liquid gives

$$p_1 - p_2 = \rho_m g h$$

where ρ_m is the density of the manometer fluid column and h is the difference in the heights of the column. Because of surface tension and capillary effects, the meniscus (the liquid/air interference) is curved and the same point on the meniscus should be used when reading capillary height. The most common fluids are water, oil, alcohol, and mercury. Mercury is attractive because of its high density. Oil is good because evaporation losses and corrosion effects are minimized. Alcohol is attractive because the meniscus is flatter than with other fluids.

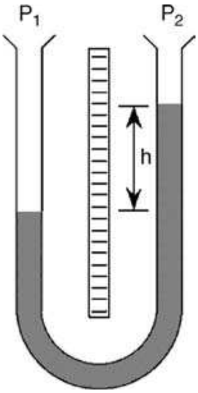

FIGURE 3.14.1 Manometer.

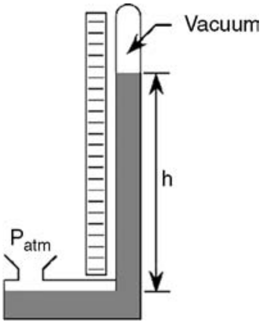

FIGURE 3.14.2 Barometer.

The manometer should be oriented along with the gravity vector, and the local gravitational acceleration must be known accurately. Corrections should be made that take into difference the recording temperature and the temperature at which the scale was calibrated since temperature variations can affect the manometer reading by causing the scale to expand and the density of the manometer fluid to change. The tube walls must be clean so that the meniscus shape does not change along the tube.

There are many variations on the U-tube manometer. A barometer (Figure 3.14.2) is used to measure atmospheric pressure by effectively connecting one side of a U-tube manometer to a vacuum and exposing the other side to the atmosphere. The evacuated space cannot be at zero pressure due to the vapor pressure of the fluid, so corrections are made for this. Inclined manometers have one leg tilted, and are used to increase the sensitivity of the measurement by decreasing the uncertainty in measurement of the liquid height. Systems that allow very small pressure differences to be measured are called micromanometers. In one scheme, the fluid level is found precisely using an electric circuit. A micrometer mounted on a pointer is lowered until it contacts the manometer fluid level, closing a circuit. Fluid level changes can be measured with a precision of 0.01 mm. Manometers can be used to measure pressures about 1 atm and lower, but the height of the liquid column becomes excessive at higher pressures and deadweight gages must be used.

Deadweight gages. A deadweight gage (Figure 3.14.3) consists of a piston-cylinder arrangement upon which standard weights are placed, and is used primary to calibrate other pressure transducers. Readings are taken when the piston is floating, and the pressure below the piston is equal to the sum of the weight of the piston and the added standard weights, divided by the piston area. Friction between the piston and cylinder is eliminated by rotating the piston. For absolute gages, the atmospheric pressure needs to be accurately measured and added to the reading. Pressures up to 350 atmospheres can be produced using deadweight gages.

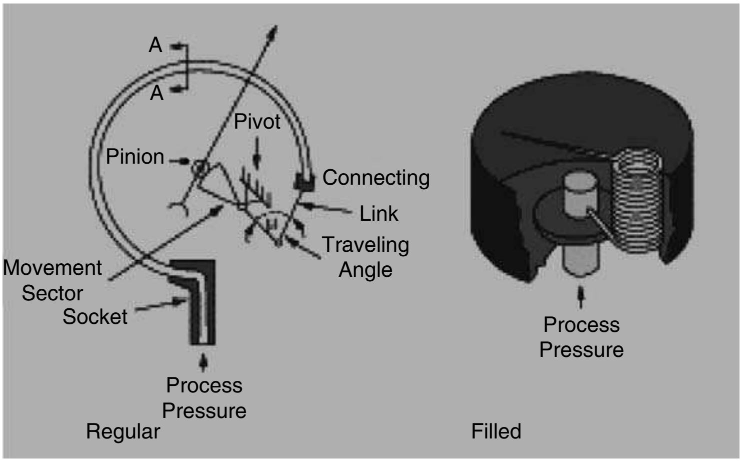

FIGURE 3.14.4 Bourdon gage (Omega). AMATEK: 727-536-7831 (Call on Monday)

Other Pressure Gages

Factors that need to be taken into consideration when choosing a pressure transducer include the pressure range, compatibility between the fluid and the transducer, the temperature, size, output type, and cost.

Bourdon tubes. The Bourdon tube (Figure 3.14.4) consists of a flattened tube bent into a circular arc. A pressure difference between the inside and outside of the tube tends to straighten the tube, and causes the free end to deflect and rotate a pointer. The angular position of the pointer is proportional to the pressure applied. A wide range of pressures from vacuum to over 10,000 atmospheres can be measured using Bourdon tubes. C-type Bourdon tubes with a tube bent over a 270° arc are used for higher pressures while spiral and helical type tubes are typically used below 70 bars in order to amplify the motion. Typical accuracies range from 0.1% to 5% full scale. Temperature change must be accounted for in order to obtain accurate measurements. Variations in indicated pressure are typically 0.3% to 0.4% over 10 K.

Bellows gages. These use elastic deformation to measure pressure. The deflection of the free end of the bellows is read on a dial driven by linkages and gears. Since small pressure difference can cause large forces when applied over a large area, bellows gages can be used to measure very low pressures or where high sensitivity is needed. Bellows can be made from bronze, copper, stainless steel, brass, or rubber.

Diaphragm gages. Diaphragm gages measure the deflection of a diaphragm when subjected to a pressure difference. Flat-diaphragm pressure elements can have strain gages attached to them to measure the amount of deflection the diaphragm undergoes for a given pressure. Very small gages in silicon with very high frequency response (100 kHz) have been made using VLSI technology. The strain in a micromachined silicon diaphragm is measured by four piezoresistive transducers arranged in a Wheatstone bridge. Transducers with pressure ranges up to 2000 atm are available.

Piezoelectric transducers. When a force is applied across a piezoelectric material, displaced electrical charges accumulate on the faces. The voltage produced is approximately proportional to the force applied. Because of charge leakage, piezoelectric transducers can only be used to make dynamic measurements. A static pressure will produce a signal initially, but this signal will slowly decay. These transducers are very rugged, hare high frequency response, and very low pressures (microphones) to very large pressures (e.g., pressure in gun barrels or shock tubes) can be measured. Typical frequency response is on the order of 100 kHz.

Capacitive transducers. These record movement of plates separated by a dielectric. Changes in capacitance are detected by change in resonance of a RC oscillator. Advantages include high sensitivity to diaphragm movement, minimum hysteresis due to friction, nd relatively fast response. Disadvantages include nonlinearity of output, charge leakage, and cost of the output sensing equipment. They are also somewhat sensitive to temperature changes.

Bridgeman-type gages. These gages measure the resistance change of a wire (manganin or gold with 2.1% chromium) when subjected to high pressure. A thin wire is wound into a coil, and the resistance change is measured using a Wheatstone bridge. A second coil that is not subject to the high pressure is used as an adjacent arm in the bridge and compensates for large temperature variations. Care must be taken to make sure the wire is free of internal stresses and corrections should be made for changes in temperature. These gages have been used to measure very high pressures (up to 27,000 bar).

Vacuum measurements. the unit of pressure commonly used in vacuum measurements is torr (1 mmHg) or microns (10^{-6} m Hg). Broudon gages can be used to about 10 torr, manometers and bellows gages down to about 0.1 torr, and diaphragm gages down to about 10^{-3} torr. At lower pressures, gages built specifically for vacuum measurements are needed. The McLeod gage is a standard for vacuum measurements because the pressure can be computed from the gage dimensions. It can be used to measure pressures as low as 0.01 microns when used tilted. In this gage, a low-pressure gas sample is sealed in a container, then compressed through a liquid seal to a pressure high enough that it can be read with a manometer.

Thermal conductivity gages utilize the finding that a linear relationship exists between thermal conductivity and pressure for pressures below 10^{-2} torr. Above 10^{-2} torr, the thermal conductivity varies approximately logarithmically until about 1 torr, after which it remains constant. The gages have an element which is electrically heated with a constant energy input. This element will attain a temperature at which the energy input balances the heat transfer away by conduction and radiation. For a given gas composition, this equilibrium temperature is a measure of the gas pressure. the emissivity of the surface is minimized to maximize the sensitivity. In the Pirani-type (Figure 3.14.5) thermal conductivity gage, two elements consisting of tungsten wires inside glass tubes are used One element is exposed to the gas,

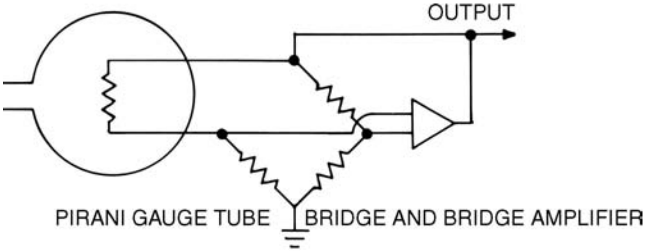

FIGURE 3.14.5 Schematic of Pirani gage. (Courtesy of MKS Instruments.)

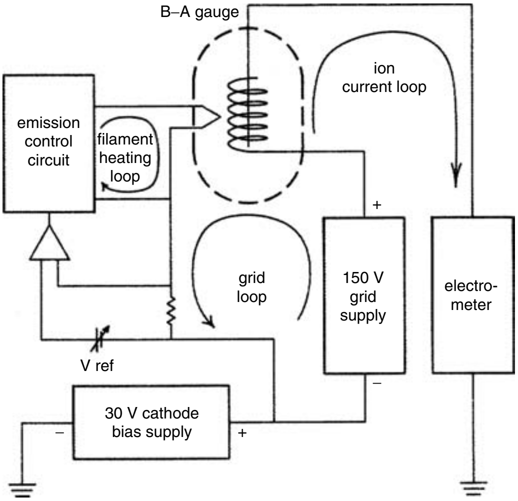

FIGURE 3.14.6 Schematic of ionization gage. (Courtesy of MKS Instruments.)

while the other is sealed in an evacuated tube. These two elements form adjacent arms in a Wheatstone bridge. When a voltage is applied to the bridge, the wires will be heated. The wire in the tube with the gas sample will be cooled by gas conduction and radiation, while the wire in the evacuated tube is cooled by radiation only. The imbalance of the Wheatstone bridge serves as a measure of gas pressure. Because gases vary in thermal conductivity, calibration must be performed for each gas that is tested.

the ionization gage (Figure 3.14.6) is one of the oldest and most widely used gages to measure gas pressure under high-vacuum conditions. Electrons emitted from a hot cathode into the vacuum is used to create ions when they collide with gas molecules. If the electron strikes a gas molecule, a positive ion can be created, freeing a secondary electron. These positive ions are accelerated to a collector where they combine with electrons. Recombination produces a current that is proportional the gas pressure. Conventional ionization gages are suitable for use below 1 torr. Cold cathodes replace the hot cathode with a voltage potential that accelerates electrons. Problems with decomposition of filament gases and filament burnout are thus avoided. A magnetic filed is sometimes used to deflect the electrons causing them to spiral as they move across the field, increasing their chances of colliding with a gas molecule and increasing the sensitivity of the instrument.

3.15 Micro/Nanotribology

Bharat Bhushan

Introduction

The emerging field of micro/nanotribology is concerned with processes ranging from atomic and molecular scales to microscale, occurring during adhesion, friction, wear, and thin-film lubrication at sliding surfaces (Bhushan, 1995, 1997; Bhushan et al., 1995). The differences between conventional tribology or macrotribology and micro/nanotribology are contrasted in Figure 3.15.1. In macrotribology, tests are conducted on components with relatively large mass under heavily loaded conditions. In these tests, wear is inevitable and the bulk properties of mating components dominate the tribological performance. In micro/nanotribology, measurements are made on at least one of the mating components, with relatively small mass under lightly loaded conditions. In this situation, negligible wear occurs and the surface properties dominate the tribological performance.

Micro/nanotribological investigations are needed to develop fundamental understanding of interfacial phenomena on a small scale and to study interfacial phenomena in the micro- and nanostructures used

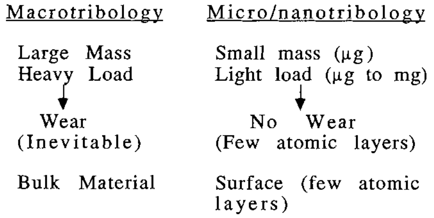

FIGURE 3.15.1 Comparison between macrotribology and microtribology.

in magnetic storage systems, microelectromechanical systems (MEMS), and other industrial applications (Bhushan, 1995, 1996, 1997). Friction and wear of lightly loaded micro/nanocomponents are highly dependent on the surface interactions (few atomic layers). These structures are generally lubricated with molecularly thin films. Micro- and nanotribological studies are also valuable in fundamental understanding of interfacial phenomena in macrostructures to provide a bridge between science and engineering (Bowden and Tabor, 1950, 1964; Bhushan and Gupta, 1997; Bhushan, 1996).

In 1985, Binnig et al. (1986) developed an "atomic force microscope" (AFM) to measure ultrasmall forces (less than 1 μN) present between the AFM tip surface and the sample surface. AFMs can be used for measurement of *all engineering surfaces* of any surface roughness, which may be either electrically conducting or insulating. AFM has become a popular surface profiler for topographic measurements on micro- to nanoscale. These are also used for scratching, wear, and nanofabrication purposes. AFMs have been modified in order to measure both normal and friction forces and this instrument is generally called a friction force microscope (FFM) or a lateral force microscope (LFM). New transducers in conjunction with an AFM can be used for measurements of elastic/plastic mechanical properties (such as load-displacement curves, indentation hardness, and modulus of elasticity) (Bhushan et al., 1996). A surface force apparatus (SFA) was first developed in 1969 (Tabor and Winterton, 1969) to study both static and dynamic properties of molecularly thin liquid films sandwiched between two molecularly smooth surfaces. SFAs are being used to study rheology of molecularly thin liquid films; however, the liquid under study has to be confined between molecularly smooth surfaces with radii of curvature on the order of 1 mm (leading to poorer lateral resolution as compared with AFMs) (Bhushan, 1995). Only AFMs/FFMs can be used to study *engineering surfaces* in the *dry and wet conditions* with *atomic resolution*. The scope of this section is limited to the applications of AFMs/FFMs.

At most solid–solid interfaces of technological relevance, contact occurs at numerous asperities with a range of radii; a sharp AFM/FFM tip sliding on a surface simulates just one such contact. Surface roughness, adhesion, friction, wear, and lubrication at the interface between two solids with and without liquid films have been studied using the AFM and FFM. The status of current understanding of micro/nanotribology of engineering interfaces follows.

Experimental Techniques

An AFM relies on a scanning technique to produce very high resolution, three-dimensional images of sample surfaces. The AFM measures ultrasmall forces (less than 1 nN) present between the AFM tip surface and a sample surface. These small forces are measured by measuring the motion of a very flexible cantilever beam having an ultrasmall mass. The deflection can be measured to with ±0.02 nm, so for a typical cantilever force constant of 10 N/m, a force as low as 0.2 nN can be detected. An AFM is capable of investigating surfaces of both conductors and insulators on an atomic scale. In the operation of a high-resolution AFM, the sample is generally scanned; however, AFMs are also available where the tip is scanned and the sample is stationary. To obtain atomic resolution with an AFM, the spring constant of the cantilever should be weaker than the equivalent spring between atoms. A cantilever beam with a spring constant of about 1 N/m or lower is desirable. Tips have to be sharp as possible. Tips with a radius ranging from 10 to 100 nm are commonly available.

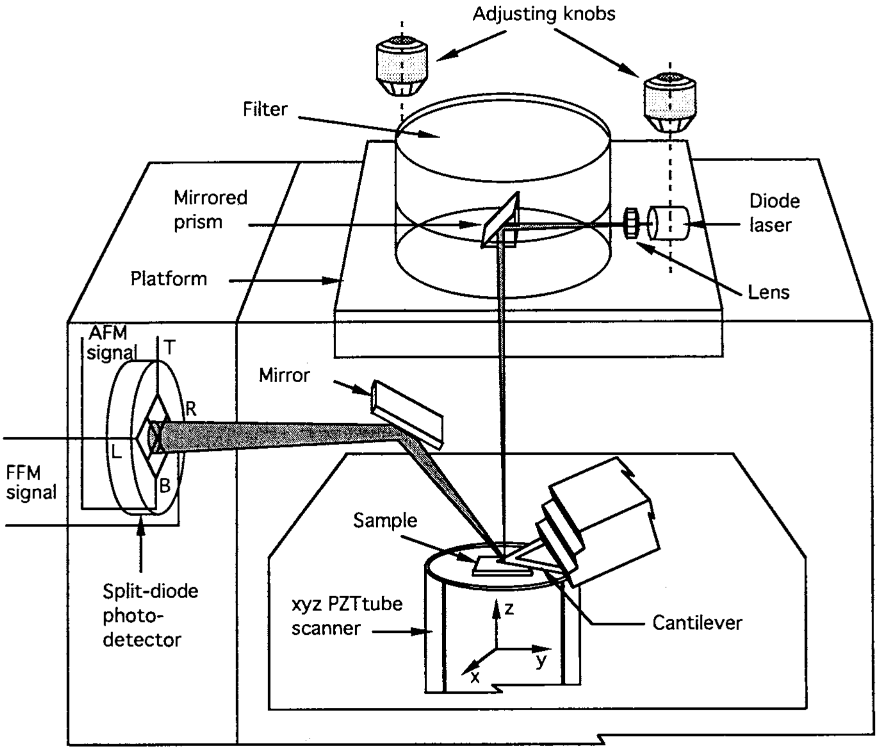

FIGURE 3.15.2 Schematic of a commercial AFM/FFM using laser beam deflection method.

In the AFM/FFM shown in Figure 3.15.2, the sample is mounted on a PZT tube scanner which consists of separate electrodes to precisely scan the sample in the *X–Y* plane in a raster pattern and to move the sample in the vertical (*Z*) direction. A sharp tip at the end of a flexible cantilever is brought in contact with the sample. Normal and frictional forces being applied at the tip–sample interface are measured simultaneously, using a laser beam deflection technique.

Topographic measurements are typically made using a sharp tip on a cantilever beam with normal stiffness on the order of 0.5 N/m at a normal load of about 10 nN, and friction measurements are carried out in the load range of 10 to 150 nN. The tip is scanned in such a way that its trajectory on the sample forms a triangular pattern. Scanning speeds in the fast and slow scan directions depend on the scan area and scan frequency. A maximum scan size of 125 × 125 μm and scan rate of 122 Hz typically can be used. Higher scan rates are used for small scan lengths.

For nanoscale boundary lubrication studies, the samples are typically scanned over an area of 1 × 1 μm at a normal force of about 300 nN, in a direction orthogonal to the long axis of the cantilever beam (Bhushan, 1997). The samples are generally scanned with a scan rate of 1 Hz and the scanning speed of 2 μm/sec. The coefficient of friction is monitored during scanning for a desired number of cycles. After the scanning test, a larger area of 2 × 2 μm is scanned at a normal force of 40 nN to observe for any wear scar.

For microscale scratching, microscale wear, and nano-scale indentation hardness measurements, a sharp single-crystal natural diamond tip mounted on a stainless steel cantilever beam with a normal stiffness on the order of 25 N/m is used at relatively higher loads (1 to 150 μN). For wear studies, typically an area of 2 × 2 μm is scanned at various normal loads (ranging from 1 to 100 μN) for a selected number of cycles. For nanoindentation hardness measurements the scan size is set to zero and then normal load is applied to make the indents. During this procedure, the diamond tip is continuously pressed against the sample surface for about 2 sec at various indentation loads. The sample surface is scanned before and after the scratching, wear, or indentation to obtain the initial and the final surface topography, at a low normal load of about 0.3 μN using the same diamond tip. An area larger than the indentation region is scanned to observe the indentation marks. Nanohardness is calculated by dividing the indentation load by the projected residual area of the indents.

In measurements using conventional AFMs, the hardness value is based on the projected residual area after imaging the incident. Identification of the boundary of the indentation mark is difficult to accomplish with great accuracy, which makes the direct measurement of contact area somewhat inaccurate. A capacitive transducer with the dual capability of depth sensing as well as *in situ* imaging is used in conjunction with an AFM (Bhushan et al., 1996). This indentation system, called nano/picoindention, is used to make load-displacement measurements and subsequently carry out *in situ* imaging of the indent, if necessary. Indenter displacement at a given load is used to calculate the projected indent area for calculation of the hardness value. Young's modulus of elasticity is obtained from the slope of the unloading portion of the load-displacement curve.

Surface Roughness, Adhesion, and Friction

Solid surfaces, irrespective of the method of formation, contain surface irregularities or deviations from the prescribed geometrical form. When two nominally flat surfaces are placed in contact, surface roughness causes contact to occur at discrete contact points. Deformation occurs in these points and may be either elastic or plastic, depending on the nominal stress, surface roughness, and material properties. The sum of the areas of all the contact points constitutes the real area that would be in contact, and for most materials at normal loads this will be only a small fraction of the area of contact if the surfaces were perfectly smooth. In general, real area of contact must be minimized to minimize adhesion, friction, and wear (Bhushan and Gupta, 1997; Bhushan, 1996). Characterizing surface roughness is therefore important for predicting and understanding the tribological properties of solids in contact.

Surface roughness most commonly refers to the variations in the height of the surface relative to a reference plane (Bowden and Tabor, 1950; Bhushan, 1996). Commonly measured roughness parameters, such as standard deviation of surface heights (rms), are found to be scale dependent and a function of the measuring instrument, for any given surface, Figure 3.15.3 (Poon and Bhushan, 1995). The topography of most engineering surfaces is fractal, possessing a self-similar structure over a range of scales. By using fractal analysis one can characterize the roughness of surfaces with two scale-independent fractal parameters *D* and *C* which provide information about roughness at all length scales (Ganti and Bhushan, 1995; Bhushan, 1995). These two parameters are instrument independent and are unique for each surface. *D* (generally ranging from 1 to 2) primarily relates to distribution of different frequencies in the surface profile, and *C* to the amplitude of the surface height variations at all frequencies. A fractal model of elastic plastic contact has been used to predict whether contacts experience elastic or plastic deformation and to predict the statistical distribution of contact points.

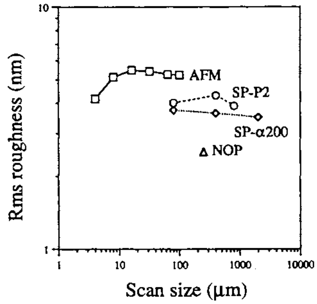

FIGURE 3.15.3 Scale dependence of standard deviation of surface heights (rms) for a glass–ceramic substrate, measured using an AFM, a stylus profiler (SP-P2 and SP-α200), and a noncontact optical profiler (NOP). (From Poon, C.Y. and Bhushan, B., *Wear*, 190, 76–88, 1995. With permission.)

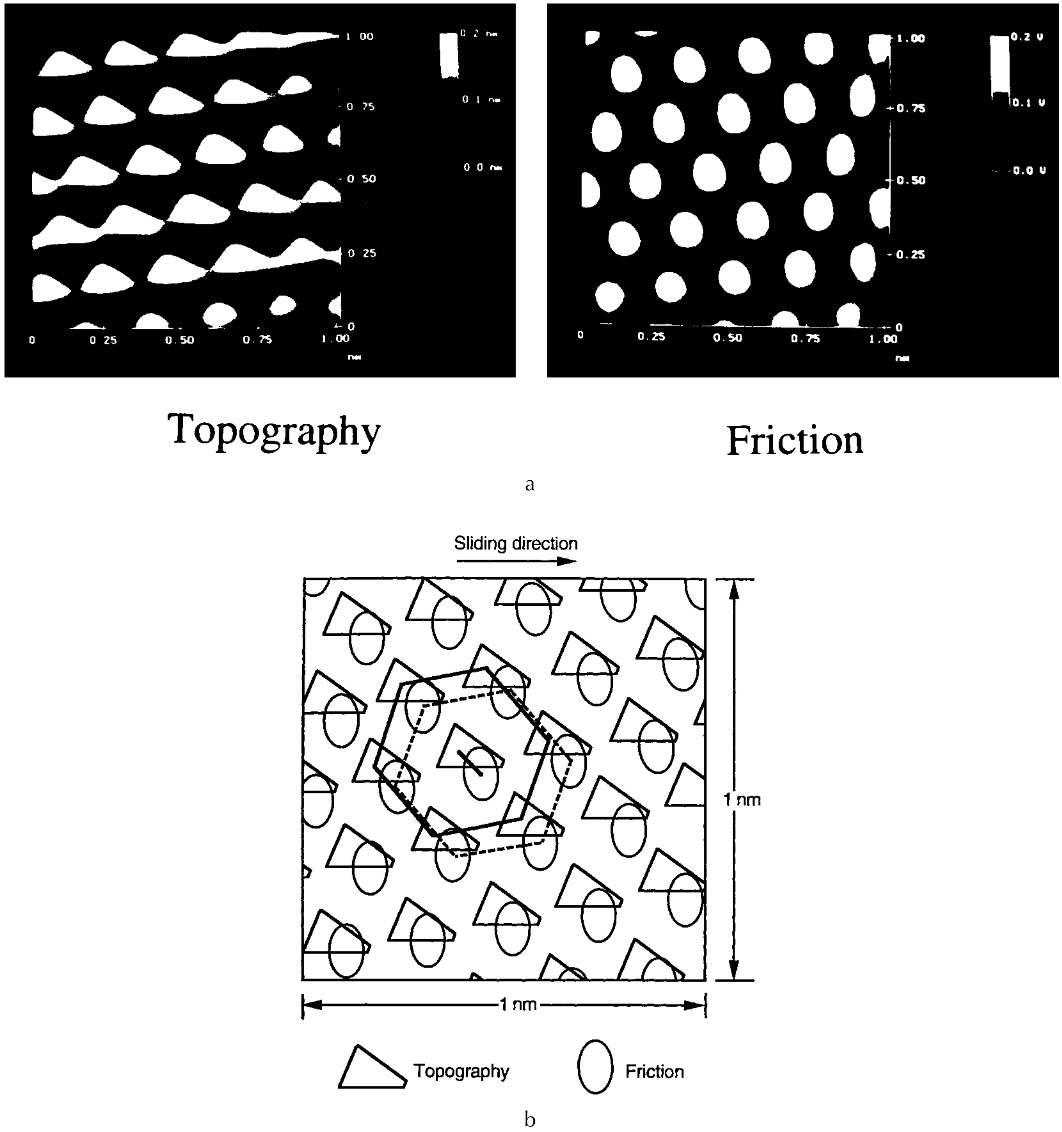

FIGURE 3.15.4 (a) Gray-scale plots of surface topography (left) and friction profiles (right) of a 1 × 1 nm area of freshly cleaved HOPG, showing the atomic-scale variation of topography and friction, (b) diagram of superimposed topography and friction profiles from (a); the symbols correspond to maxima. Note the spatial shift between the two profiles. (From Bhushan, B., *Handbook of Micro/Nanotribology*, CRC Press, Boca Raton, FL, 1995. With permission.)

Based on atomic-scale friction measurements of a well-characterized freshly cleaved surface of highly oriented pyrolytic graphite (HOPG), the atomic-scale friction force of HOPG exhibits the same periodicity as that of corresponding topography (Figure 3.15.4(a)), but the peaks in friction and those in topography were displaced relative to each other (Figure 3.15.4(b)). A Fourier expansion of the interatomic potential has been used to calculate the conservative interatomic forces between atoms of the FFM tip and those of the graphite surface. Maxima in the interatomic forces in the normal and lateral directions do not occur at the same location, which explains the observed shift between the peaks in the lateral force and those in the corresponding topography. Furthermore, the observed local variations in friction force were explained by variation in the intrinsic lateral force between the sample and the FFM tip, and these variations may not necessarily occur as a result of an atomic-scale stick–slip process.

TABLE 3.15.1 Surface Roughness and Micro- and Macroscale Coefficients of Friction of Various Samples

Material	rms Roughness, nm	Microscale Coefficient of Friction vs. Si_3N_4 Tip[a]	Macroscale Coefficient of Friction vs. Alumina Ball[b]
Si(111)	0.11	0.03	0.18
C^+-implanted Si	0.33	0.02	0.18

[a] Tip radius of about 50 nm in the load range of 10 to 150 nN (2.5 to 6.1 GPa), a scanning speed of 5 m/sec and scan area of 1 × 1 μm.

[b] Ball radius of 3 mm at a normal load of 0.1 N (0.3 GPa) and average sliding speed of 0.8 mm/sec.

Friction forces of HOPG have also been studied. Local variations in the microscale friction of cleaved graphite are observed, which arise from structural changes that occur during the cleaving process. The cleaved HOPG surface is largely atomically smooth, but exhibits line-shaped regions in which the coefficient of friction is more than an order of magnitude larger. Transmission electron microscopy indicates that the line-shaped regions consist of graphite planes of different orientation, as well as of amorphous carbon. Differences in friction can also be seen for organic mono- and multilayer films, which again seem to be the result of structural variations in the films. These measurements suggest that the FFM can be used for structural mapping of the surfaces. FFM measurements can be used to map chemical variations, as indicated by the use of the FFM with a modified probe tip to map the spatial arrangement of chemical functional groups in mixed organic monolayer films. Here, sample regions that had stronger interactions with the functionalized probe tip exhibited larger friction. For further details, see Bhushan (1995).

Local variations in the microscale friction of scratched surfaces can be significant and are seen to depend on the local surface slope rather than on the surface height distribution (Bhushan, 1995). Directionality in friction is sometimes observed on the macroscale; on the microscale this is the norm (Bhushan, 1995). This is because most "engineering" surfaces have asymmetric surface asperities so that the interaction of the FFM tip with the surface is dependent on the direction of the tip motion. Moreover, during surface-finishing processes material can be transferred preferentially onto one side of the asperities, which also causes asymmetry and directional dependence. Reduction in local variations and in the directionality of frictional properties therefore requires careful optimization of surface roughness distributions and of surface-finishing processes.

Table 3.15.1 shows the coefficient of friction measured for two surfaces on micro- and macroscales. The coefficient of friction is defined as the ratio of friction force to the normal load. The values on the microscale are much lower than those on the macroscale. When measured for the small contact areas and very low loads used in microscale studies, indentation hardness and modulus of elasticity are higher than at the macroscale. This reduces the degree of wear. In addition, the small apparent areas of contact reduce the number of particles trapped at the interface, and thus minimize the "ploughing" contribution to the friction force.

At higher loads (with contact stresses exceeding the hardness of the softer material), however, the coefficient of friction for microscale measurements increases toward values comparable with those obtained from macroscale measurements, and surface damage also increases (Bhushan et al., 1995; Bhushan and Kulkarni, 1996). Thus, Amontons' law of friction, which states that the coefficient of friction is independent of apparent contact area and normal load, does not hold for microscale measurements. These findings suggest that microcomponents sliding under lightly loaded conditions should experience very low friction and near zero wear.

Scratching, Wear, and Indentation

The AFM can be used to investigate how surface materials can be moved or removed on micro- to nanoscales, for example, in scratching and wear (Bhushan, 1995) (where these things are undesirable) and, in nanomachining/nanofabrication (where they are desirable). The AFM can also be used for measurements of mechanical properties on micro- to nanoscales. Figure 3.15.5 shows microscratches

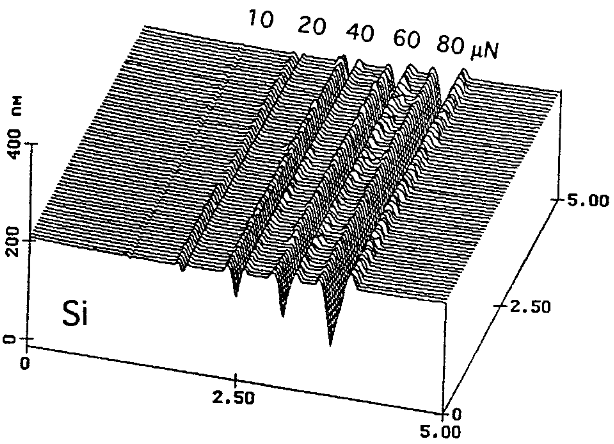

FIGURE 3.15.5 Surface profiles of Si(111) scratched at various loads. Note that the *x* and *y* axes are in micrometers and the *z* axis is in nanometers. (From Bhushan, B., *Handbook of Micro/Nanotribology*, CRC Press, Boca Raton, FL, 1995. With permission.)

made on Si(111) at various loads after 10 cycles. As expected, the depth of scratch increases with load. Such microscratching measurements can be used to study failure mechanisms on the microscale and to evaluate the mechanical integrity (scratch resistance) of ultrathin films at low loads.

By scanning the sample in two dimensions with the AFM, wear scars are generated on the surface. The evolution of wear of a diamond-like carbon coating on a polished aluminum substrate is showing in Figure 3.15.6 which illustrates how the microwear profile for a load of 20 μN develops as a function of the number of scanning cycles. Wear is not uniform, but is initiated at the nanoscratches indicating that surface defects (with high surface energy) act as initiation sites. Thus, scratch-free surfaces will be relatively resistant to wear.

Mechanical properties, such as load-displacement curves, hardness, and modulus of elasticity can be determined on micro- to picoscales using an AFM and its modifications (Bhushan, 1995; Bhushan et al., 1995, 1996). Indentability on the scale of picometers can be studied by monitoring the slope of cantilever deflection as a function of sample traveling distance after the tip is engaged and the sample is pushed against the tip. For a rigid sample, cantilever deflection equals the sample traveling distance; but the former quantity is smaller if the tip indents the sample. The indentation hardness on nanoscale of bulk materials and surface films with an indentation depth as small as 1 nm can be measured. An example of hardness data as a function of indentation depth is shown in Figure 3.15.7. A decrease in hardness with an increase in indentation depth can be rationalized on the basis that, as the volume of deformed materials increases, there is a higher probability of encountering material defects. AFM measurements on ion-implanted silicon surfaces show that ion implantation increases their hardness and, thus, their wear resistance (Bhushan, 1995). Formation of surface alloy films with improved mechanical properties by ion implantation is growing in technological importance as a means of improving the mechanical properties of materials.

Young's modulus of elasticity is calculated from the slope of the indentation curve during unloading (Bhushan, 1995; Bhushan et al., 1996). AFM can be used in a *force modulation mode* to measure surface elasticities: an AFM tip is scanned over the modulated sample surface with the feedback loop keeping the average force constant. For the same applied force, a soft area deforms more, and thus causes less cantilever deflection, than a hard area. The ratio of modulation amplitude to the local tip deflection is then used to create a *force modulation image*. The force modulation mode makes it easier to identify soft areas on hard substrates.

Detection of the transfer of material on a nanoscale is possible with the AFM. Indentation of C_{60}-rich fullerene films with an AFM tip has been shown to result in the transfer of fullerene molecules to the

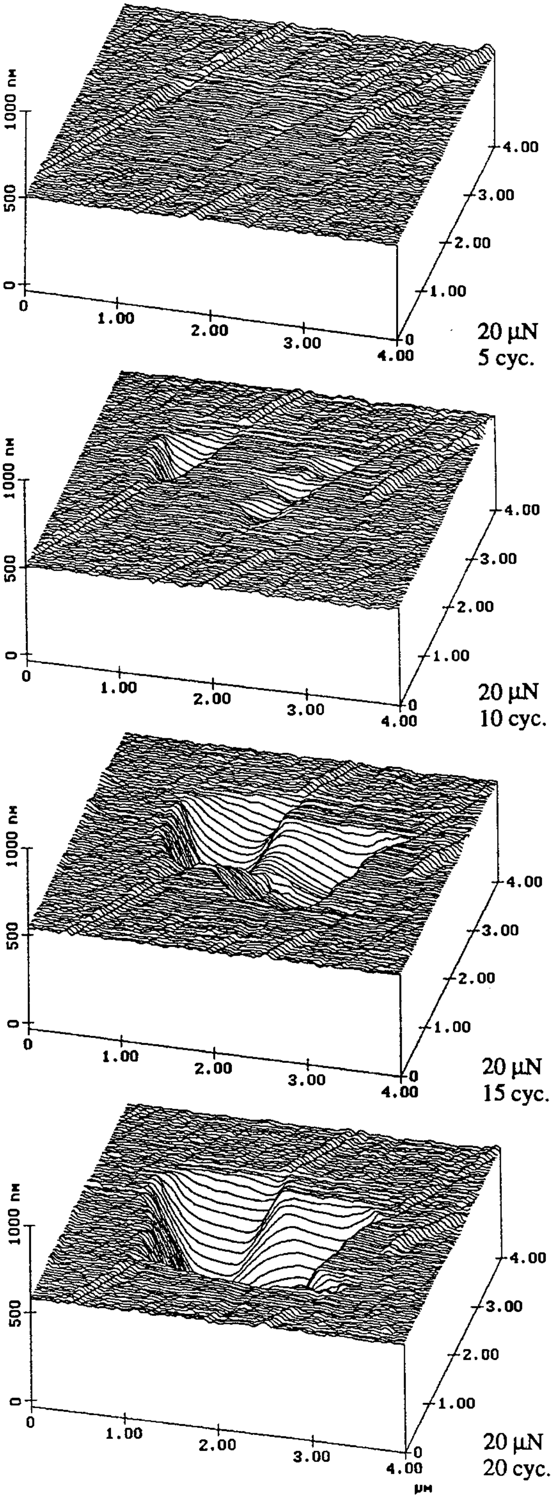

FIGURE 3.15.6 Surface profiles of diamond-like carbon-coated thin-film disk showing the worn region; the normal load and number of test cycles are indicated. (From Bhushan, B., *Handbook of Micro/Nanotribology*, CRC Press, Boca Raton, FL, 1995. With permission.)

AFM tip, as indicated by discontinuities in the cantilever deflection as a function of sample traveling distance in subsequent indentation studies (Bhushan, 1995).

Boundary Lubrication

The "classical" approach to lubrication uses freely supported multimolecular layers of liquid lubricants (Bowden and Tabor, 1950, 1964; Bhushan, 1996). The liquid lubricants are chemically bonded to improve their wear resistance (Bhushan, 1995, 1996). To study depletion of boundary layers, the microscale friction measurements are made as a function of the number of cycles. For an example of the data of virgin Si(100) surface and silicon surface lubricated with about 2-nm-thick Z-15 and Z-Dol perfluoropolyether (PEPE) lubricants, see Figure 3.15.8. Z-Dol is PFPE lubricant with hydroxyl end groups. Its lubricant film was thermally bonded. In Figure 3.15.8, the unlubricated silicon sample shows a slight increase in friction force followed by a drop to a lower steady state value after some cycles. Depletion of native oxide and possible roughening of the silicon sample are responsible for the decrease in this friction force. The initial friction force for the Z-15-lubricated sample is lower than that of the unlubricated silicon and

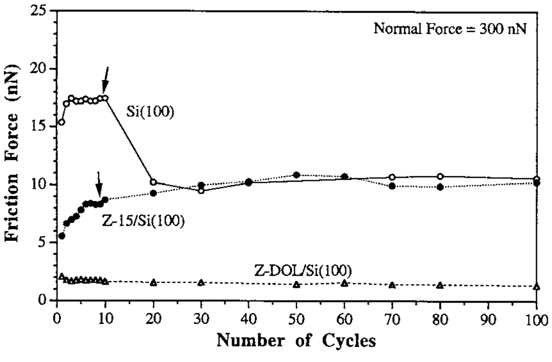

FIGURE 3.15.8 Friction force as a function of number of cycles using a silicon nitride tip at a normal force of 300 nN for the unlubricated and lubricated silicon samples. (From Bhushan, B., *Micro/Nanotribology and Its Applications*, Kluwer, Dordrecht, The Netherlands, 1997. With permission.)

increases gradually to a friction force value comparable with that of the silicon after some cycles. This suggests the depletion of the Z-15 lubricant in the wear track. In the case of the Z-Dol-coated silicon sample, the friction force starts out to be low and remains low during the entire test. It suggests that Z-Dol does not get displaced/depleted as readily as Z-15. Additional studies of freely supported liquid lubricants showed that either increasing the film thickness or chemically bonding the molecules to the substrate with a mobile fraction improves the lubrication performance (Bhushan, 1997).

For lubrication of microdevices, a more effect approach involves the deposition of organized, dense molecular layers of long-chain molecules on the surface contact. Such monolayers and thin films are commonly produced by Langmuir–Blodgett (LB) deposition and by chemical grafting of molecules into self-assembled monolayers (SAMs). Based on the measurements, SAMs of octodecyl (C_{18}) compounds based on aminosilanes on a oxidized silicon exhibited a lower coefficient of friction of (0.018) and greater durability than LB films of zinc arachidate adsorbed on a gold surface coated with octadecylthiol (ODT) (coefficient of friction of 0.03) (Bhushan et al., 1995). LB films are bonded to the substrate by weak van der Waals attraction, whereas SAMs are chemically bound via covalent bonds. Because of the choice of chain length and terminal linking group that SAMs offer, they hold great promise for boundary lubrication of microdevices.

Measurement of ultrathin lubricant films with nanometer lateral resolution can be made with the AFM (Bhushan, 1995). The lubricant thickness is obtained by measuring the force on the tip as it approaches, contacts, and pushes through the liquid film and ultimately contacts the substrate. The distance between the sharp “snap-in” (owing to the formation of a liquid of meniscus between the film and the tip) at the liquid surface and the hard repulsion at the substrate surface is a measure of the liquid film thickness. This technique is now used routinely in the information-storage industry for thickness measurements (with nanoscale spatial resolution) of lubricant films, a few nanometers thick, in rigid magnetic disks.

4.1 Conduction Heat Transfer

Robert F. Boehm

Introduction

Conduction heat transfer phenomena are found throughout virtually all of the physical world and the industrial domain. The analytical description of this heat transfer mode is one of the best understood. Some of the bases of understanding of conduction date back to early history. It was recognized that by invoking certain relatively minor simplifications, mathematical solutions resulted directly. Some of these were very easily formulated. What transpired over the years was a very vigorous development of applications to a broad range of processes. Perhaps no single work better summarizes the wealth of these studies than does the book by Carslaw and Jaeger (1996). They gave solutions to a broad range of problems, from topics related to the cooling of the Earth to the current-carrying capacities of wires. The general analyses given there have been applied to a range of modern-day problems, from laser heating to temperature-control systems.

Today conduction heat transfer is still an active area of research and application. A great deal of interest has developed in recent years in topics like contact resistance, where a temperature difference develops between two solids that do not have perfect contact with each other. Additional issues of current interest include non-Fourier conduction, where the processes occur so fast that the equation described below does not apply. Also, the problems related to transport in miniaturized systems are garnering a great deal of interest. Increased interest has also been directed to ways of handling composite materials, where the ability to conduct heat is very directional.

Much of the work in conduction analysis is now accomplished by use of sophisticated computer codes. These tools have given the heat transfer analyst the capability of solving problems in nonhomogeneous media, with very complicated geometries, and with very involved boundary conditions. It is still important to understand analytical ways of determining the performance of conducting systems. At the minimum these can be used as calibrations for numerical codes.

Fourier's Law

The basis of conduction heat transfer is **Fourier's Law**. This law involves the idea that the heat flux is proportional to the temperature gradient in any direction *n*. **Thermal conductivity**, *k*, a property of materials that is temperature dependent, is the constant of proportionality.

$$q_k = -kA\frac{\partial T}{\partial n} \tag{4.1.1}$$

In many systems the area *A* is a function of the distance in the direction *n*. One important extension is that this can be combined with the first law of thermodynamics to yield the **heat conduction equation**. For constant thermal conductivity, this is given as

$$\nabla^2 T + \frac{\dot{q}_G}{k} = \frac{1}{\alpha}\frac{\partial T}{\partial t} \tag{4.1.2}$$

In this equation, α is the thermal diffusivity and $\dot{q}_G$ is the internal heat generation per unit volume. Some problems, typically steady-state, one-dimensional formulations where only the heat flux is desired, can be solved simply from Equation (4.1.1). Most conduction analyses are performed with Equation (4.1.2). In the latter, a more general approach, the temperature distribution is found from this equation and appropriate boundary conditions. Then the heat flux, if desired, is found at any location using Equation (4.1.1). Normally, it is the temperature distribution that is of most importance. For example, it may be desirable to know through analysis if a material will reach some critical temperature, like its melting point. Less frequently the heat flux is desired.

While there are times when it is simply desired to understand what the temperature response of a structure is, the engineer is often faced with a need to increase or decrease heat transfer to some specific level. Examination of the thermal conductivity of materials gives some insight into the range of possibilities that exist through simple conduction.

Of the more common engineering materials, pure copper exhibits one of the higher abilities to conduct heat with a thermal conductivity approaching 400 W/mK. Aluminum, also considered to be a good conductor, has a thermal conductivity a little over half that of copper. To increase the heat transfer above values possible through simple conduction, more-involved designs are necessary that incorporate a variety of other heat transfer modes like convection and phase change.

Decreasing the heat transfer is accomplished with the use of insulations. A separate discussion of these follows.

Insulations

Insulations are used to decrease heat flow and to decrease surface temperatures. These materials are found in a variety of forms, typically *loose fill*, *batt*, and *rigid*. Even a gas, like air, can be a good insulator if it can be kept from moving when it is heated or cooled. A vacuum is an excellent insulator. Usually, though, the engineering approach to insulation is the addition of a low-conducting material to the surface. While there are many chemical forms, costs, and maximum operating temperatures of common forms of insulations, it seems that when a higher operating temperature is required, many times the thermal conductivity and cost of the insulation will also be higher.

Loose-fill insulations include such materials as milled alumina-silica (maximum operating temperature of 1260°C and thermal conductivities in the range of 0.1 to 0.2 W/mK) and perlite (maximum operating temperature of 980°C and thermal conductivities in the range of 0.05 to 1.5 W/mK). Batt-type insulations include one of the more common types — glass fiber. This type of insulation comes in a variety of densities, which, in turn, have a profound affect on the thermal conductivity. Thermal conductivities for glass fiber insulations can range from about 0.03 to 0.06 W/mK. Rigid insulations show a very wide range of forms and performance characteristics. For example, a rigid insulation in foam form, polyurethane, is very lightweight, shows a very low thermal conductivity (about 0.02 W/mK), but has a maximum operating temperature only up to about 120°C. Rigid insulations in refractory form show quite different characteristics. For example, high-alumina brick is quite dense, has a thermal conductivity of about 2 W/mK, but can remain operational to temperatures around 1760°C. Many insulations are characterized in the book edited by Guyer (1999).

Often, commercial insulation systems designed for high-temperature operation use a layered approach. Temperature tolerance may be critical. Perhaps a refractory is applied in the highest temperature region, an intermediate-temperature foam insulation is used in the middle section, and a high-performance, low-temperature insulation is used on the outer side near ambient conditions.

Analyses can be performed including the effects of temperature variations of thermal conductivity. However, the most frequent approach is to assume that the thermal conductivity is constant at some temperature between the two extremes experienced by the insulation.

The Plane Wall at Steady State

Consider steady-state heat transfer in a plane wall of thickness L, but of very large extent in both other directions. The wall has temperature T_1 on one side and T_2 on the other. If the thermal conductivity is considered to be constant, then Equation (4.1.1) can be integrated directly to give the following result:

$$q_k = \frac{kA}{L}\left(T_1 - T_2\right) \tag{4.1.3}$$

This can be used to determine the steady-state heat transfer through slabs.

An electrical circuit analog is widely used in conduction analyses. This is realized by considering the temperature difference to be analogous to a voltage difference, the heat flux to be like current flow, and the remainder of Equation (4.1.3) to be like a thermal resistance. The latter is seen to be

$$R_k = \frac{L}{kA} \tag{4.1.4}$$

Heat transfer through walls made of layers of different types of materials can be easily found by summing the resistances in series or parallel form, as appropriate.

In the design of systems, seldom is a surface temperature specified or known. More often, the surface is in contact with a bulk fluid, whose temperature is known at some distance from the surface. Convection from the surface is then represented by Newton's law of cooling:

$$q = \bar{h}_c A\left(T_s - T_\infty\right) \tag{4.1.5}$$

This equation can also be represented as a temperature difference divided by a thermal resistance, which is $1/\bar{h}_c A$. It can be shown that a very low surface resistance, as might be represented by phase change phenomena, has the effect of imposing the fluid temperature directly on the surface. Hence, usually a *known* surface temperature results from a fluid temperature being imposed directly on the surface through a very high heat transfer coefficient. For this reason, in the later results given here, particularly those for transient systems, a convective boundary will be assumed. For steady results this is less important because of the ability to add resistances through the circuit analogy.

Long, Cylindrical Systems at Steady State

For long (L) annular systems at steady-state conditions with constant thermal conductivities, the following two equations are the appropriate counterparts to Equation (4.1.3) and Equation (4.1.4). The heat transfer can be expressed as

$$q_k = \frac{2\pi Lk}{\ln\left[r_2/r_1\right]}\left(T_1 - T_2\right) \tag{4.1.6}$$

Here, r_1 and r_2 represent the radii of annular section. A thermal resistance for this case is as shown below.

$$R_k = \frac{\ln\left[r_2/r_1\right]}{2\pi Lk} \tag{4.1.7}$$

The Overall Heat Transfer Coefficient

The **overall heat transfer coefficient** concept is valuable in several aspects of heat transfer. It involves a modified form of Newton's law of cooling, as noted above, and it is written as

$$Q = \bar{U}A\Delta T \tag{4.1.8}$$

In this formulation $\bar{U}$ is the overall heat transfer coefficient based upon the area A. Because the area for heat transfer in a problem can vary (as with a cylindrical geometry), it is important to note that the $\bar{U}$ is dependent upon which area is selected. The overall heat transfer coefficient is usually found from a combination of thermal resistances. Hence, for a common series-combination-circuit analog, the $\bar{U}A$ product is taken as the sum of resistances.

$$\bar{U}A = \frac{1}{\sum_{i=1}^{n} R_i} = \frac{1}{R_{\text{total}}} \tag{4.1.9}$$

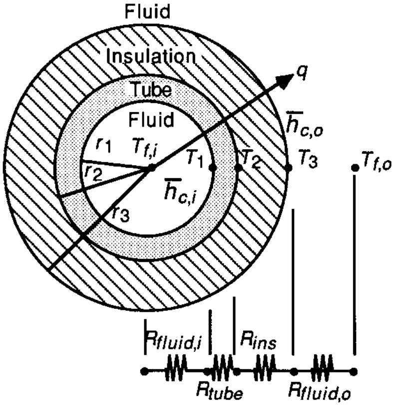

FIGURE 4.1.1 An insulated tube with convective environments on both sides.

To show an example of the use of this concept, consider Figure 4.1.1.

For steady-state conditions, the product $\bar{U}A$ remains constant for a given heat transfer and overall temperature difference. This can be written as

$$\bar{U}_1 A_1 = \bar{U}_2 A_2 = \bar{U}_3 A_3 = \bar{U}A \tag{4.1.10}$$

If the inside area, A_1, is chosen as the basis, the overall heat transfer coefficient can then be expressed as

$$\bar{U}_1 = \frac{1}{\dfrac{1}{\bar{h}_{c,i}} + \dfrac{r_1 \ln(r_2/r_1)}{k_{\text{pipe}}} + \dfrac{r_1 \ln(r_3/r_2)}{k_{\text{ins}}} + \dfrac{r_1}{r_3 \bar{h}_{c,o}}} \tag{4.1.11}$$

Critical Thickness of Insulation

Sometimes insulation can cause an increase in heat transfer. This circumstance should be noted in order to apply it when desired and to design around it when an insulating effect is needed. Consider the circumstance shown in Figure 4.1.1. Assume that the temperature is known on the outside of the tube (inside of the insulation). This could be known if the inner heat transfer coefficient is very large and the thermal conductivity of the tube is large. In this case, the inner fluid temperature will be almost the same as the temperature of the inner surface of the insulation. Alternatively, this could be applied to a coating (say an electrical insulation) on the outside of a wire. By forming the expression for the heat transfer in terms of the variables shown in Equation (4.1.11), and examining the change of heat transfer with variations in r_3 (that is, the thickness of insulation) a maximum heat flow can be found. While simple results are given many texts (showing the critical radius as the ratio of the insulation thermal conductivity to the heat transfer coefficient on the outside), Sparrow (1970) has considered a heat transfer coefficient that varies as $\bar{h}_{c,o} \sim r_3^{-m} |T_3 - T_{f,o}|^n$. For this case, it is found that the heat transfer is maximized at

$$r_3 = r_{\text{crit}} = \left[(1-m)/(1+n)\right]\frac{k_{\text{ins}}}{\bar{h}_{c,o}} \tag{4.1.12}$$

By examining the order of magnitudes of m, n, k_{ins}, and $\bar{h}_{c,o}$ the critical radius is found to be often on the order of a *few millimeters*. Hence, additional insulation on small-diameter cylinders such as small-gauge electrical wires could actually increase the heat dissipation. On the other hand, the addition of insulation to large-diameter pipes and ducts will almost always decrease the heat transfer rate.

Internal Heat Generation

The analysis of temperature distributions and the resulting heat transfer in the presence of volume heat sources is required in some circumstances. These include phenomena such as nuclear fission processes, joule heating, and microwave deposition. Consider first a slab of material $2L$ thick but otherwise very large, with internal generation. The outside of the slab is kept at temperature T_1. To find the temperature distribution within the slab, the thermal conductivity is assumed to be constant. Equation (4.1.2) reduces to the following:

$$\frac{d^2T}{dx^2} + \frac{\dot{q}_G}{k} = 0 \tag{4.1.13}$$

Solving this equation by separating variables, integrating twice, and applying boundary conditions gives

$$T(x) - T_1 = \frac{\dot{q}_G L^2}{2k}\left[1 - \left(\frac{x}{L}\right)^2\right] \tag{4.1.14}$$

A similar type of analysis for a long, cylindrical element of radius r_1 gives

$$T(r) - T_1 = \frac{\dot{q}_G r_1^2}{4k}\left[1 - \left(\frac{r}{r_1}\right)^2\right] \tag{4.1.15}$$

Two additional cases will be given. Both involve the situation when the heat generation rate is dependent upon the local temperature in a linear way (defined by a slope β), according to the following relationship:

$$\dot{q}_G = \dot{q}_{G,o}\left[1 + \beta\left(T - T_o\right)\right] \tag{4.1.16}$$

For a plane wall of $2L$ thickness and a temperature of T_1 specified on each surface

$$\frac{T(x) - T_o + 1/\beta}{T_1 - T_o + 1/\beta} = \frac{\cos \mu x}{\cos \mu L} \tag{4.1.17}$$

For a similar situation in a long cylinder with a temperature of T_1 specified on the outside radius r_1

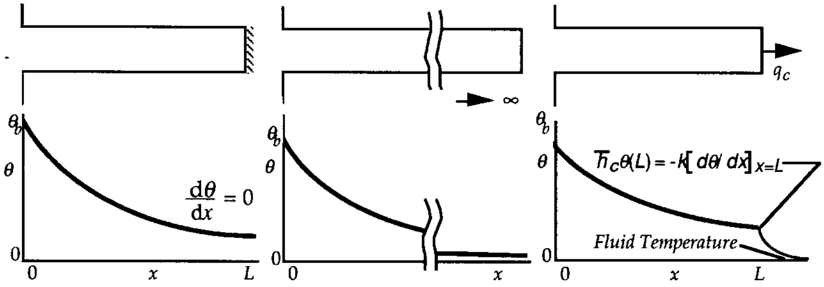
$$\frac{T(r) - T_o + 1/\beta}{T_1 - T_o + 1/\beta} = \frac{J_o(\mu r)}{J_o(\mu r_1)} \tag{4.1.18}$$

In Equation (4.1.18), the J_o is the typical notation for the Bessel function. Variations of this function are tabulated in Abramowitz and Stegun (1964). In both cases the following holds:

$$\mu \equiv \sqrt{\frac{\beta \dot{q}_{G,o}}{k}}$$

Fins

Fins are widely used to enhance the heat transfer (usually convective, but it could also be radiative) from a surface. This is particularly true when the surface is in contact with a gas. Fins are used on air-cooled engines, electronic cooling forms, as well as for a number of other applications. Since the heat transfer coefficient tends to be low in gas convection, area is added in the form of fins to the surface to decrease the convective thermal resistance.



CASE I: Insulated Tip CASE II: Infinitely Long CASE III: Convecting Tip

FIGURE 4.1.2 Three typical cases for one-dimensional, constant-cross-section fins are shown.

The simplest fins to analyze, and which are usually found in practice, can be assumed to be one-dimensional and constant in cross section. In simple terms, to be one-dimensional, the fins have to be long compared with a transverse dimension. Three cases are normally considered for analysis, and these are shown in Figure 4.1.2. They are the insulated tip, the infinitely long fin, and the convecting tip fin.

For Case, I, the solution to the governing equation and the application of the boundary conditions of the known temperature at the base and the insulated tip yields

$$\text{Case I:} \qquad \theta = \theta_b = \frac{\cosh m(L-x)}{\cosh mL} \tag{4.1.19}$$

For the infinitely long case, the following simple form results:

$$\text{Case II:} \qquad \theta(x) = \theta_b e^{-mx} \tag{4.1.20}$$

The final case yields the following result:

$$\text{Case III:} \qquad \theta(x) = \theta_b \frac{mL\cosh m(L-x) + \mathrm{Bi}\sinh m(L-x)}{mL\cosh mL + \mathrm{Bi}\sinh mL} \tag{4.1.21}$$

where

$$\mathrm{Bi} \equiv \bar{h}_c L/k$$

In all three of the cases given, the following definitions apply:

$$\theta \equiv T(x) - T_\infty, \quad \theta_b \equiv T(x=0) - T_\infty, \quad \text{and} \quad m^2 \equiv \frac{\bar{h}_c P}{kA}$$

Here A is the cross section of the fin parallel to the wall; P is the perimeter around that area.

To find the heat removed in any of these cases, the temperature distribution is used in Fourier's law, Equation (4.1.1). For most fins that truly fit the one-dimensional assumption (i.e., long compared with their transverse dimensions), all three equations will yield results that do not differ widely.

Two performance indicators are found in the fin literature. The **fin efficiency** is defined as the ratio of the actual heat transfer to the heat transfer from an ideal fin.

$$\eta \equiv \frac{q_{\text{actual}}}{q_{\text{ideal}}} \tag{4.1.22}$$

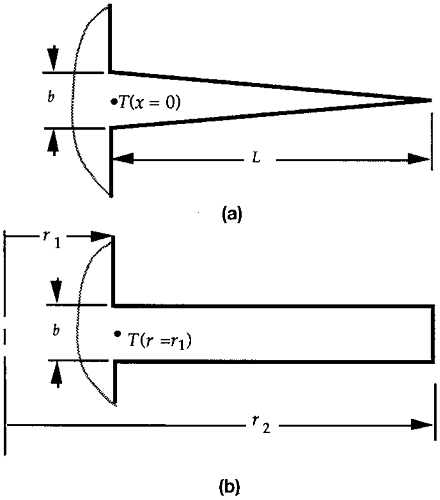


FIGURE 4.1.3 Two examples of fins with a cross-sectional area that varies with distance from the base. (a) Straight triangular fin. (b) Annular fin of constant thickness.

The ideal heat transfer is found from convective gain or loss from an area the same size as the fin surface area, all at a temperature T_b. Fin efficiency is normally used to tabulate heat transfer results for various types of fins, including ones with nonconstant area or which do not meet the one-dimensional assumption. An example of the former can be developed from a result given by Arpaci (1966). Consider a straight fin of triangular profile, as shown in Figure 4.1.3. The solution is found in terms of modified Bessel functions of the first kind. Tabulations are given in Abramowitz and Stegun (1964).

$$\eta = \frac{I_1\left(2\tilde{m}L^{1/2}\right)}{\tilde{m}L^{1/2}I_o\left(2\tilde{m}L^{1/2}\right)} \tag{4.1.23}$$

Here, $\tilde{m} \equiv \sqrt{2\bar{h}_c L/kb}$.

The **fin effectiveness**, ε, is defined as the heat transfer from the fin compared with the bare-surface transfer through the same base area.

$$\varepsilon = \frac{q_{\text{actual}}}{q_{\text{bare base}}} = \frac{q_f}{\bar{h}_c A\left(T_b - T_\infty\right)} \tag{4.1.24}$$

Carslaw and Jaeger (1959) give an expression for the effectiveness of a fin of constant thickness around a tube (see Figure 4.1.3) This is given as $(\tilde{\mu} \equiv \sqrt{2\bar{h}_c/kb})$.

$$\varepsilon = \frac{2}{\tilde{\mu}b}\,\frac{I_1\left(\tilde{\mu}r_2\right)K_1\left(\tilde{\mu}r_1\right) - K_1\left(\tilde{\mu}r_2\right)I_1\left(\tilde{\mu}r_1\right)}{I_o\left(\tilde{\mu}r_1\right)K_1\left(\tilde{\mu}r_2\right) + K_o\left(\tilde{\mu}r_1\right)I_1\left(\tilde{\mu}r_2\right)} \tag{4.1.25}$$

Here the notations I and K denote Bessel functions that are given in Abramowitz and Stegun (1964).

Fin effectiveness can be used as one indication whether or not fins should be added. A rule of thumb indicates that if the effectiveness is less than about three, fins should not be added to the surface.

Transient Systems

Negligible Internal Resistance

Consider the transient cooling or heating of a body with surface area A and volume V. This is taking place by convection through a heat transfer coefficient $\bar{h}_c$ to an ambient temperature of T_∞. Assume the thermal resistance to conduction inside the body is significantly less than the thermal resistance to convection (as represented by Newton's law of cooling) on the surface of the body. This ratio is denoted by the **Biot number**, Bi.

$$\mathrm{Bi} = \frac{R_k}{R_c} = \frac{\bar{h}_c (V/A)}{k} \tag{4.1.26}$$

The temperature (which will be uniform throughout the body at any time for this situation) response with time for this system is given by the following relationship. Note that the shape of the body is not important — only the ratio of its volume to its area matters.

$$\frac{T(t) - T_\infty}{T_o - T_\infty} = e^{-\bar{h}_c A t/\rho V c} \tag{4.1.27}$$

Typically, this will hold for the Biot number being less than (about) 0.1.

Bodies with Significant Internal Resistance

When a body is being heated or cooled transiently in a convective environment, but the internal thermal resistance of the body cannot be neglected, the analysis becomes more complicated. Only simple geometries (a symmetrical plane wall, a long cylinder, a composite of geometric intersections of these geometries, or a sphere) with an imposed step change in ambient temperature are addressed here.

The first geometry considered is a large slab of minor dimension $2L$. If the temperature is initially uniform at T_o, and at time 0+ it begins convecting through a heat transfer coefficient to a fluid at T_∞, the temperature response is given by

$$\theta = 2\sum_{n=1}^{\infty} \left(\frac{\sin \lambda_n L}{\lambda_n L + \sin \lambda_n L \cos \lambda_n L} \right) \exp\left(-\lambda_n^2 L^2 \mathrm{Fo}\right) \cos\left(\lambda_n x\right) \tag{4.1.28}$$

and the λ_n are the roots of the transcendental equation: $\lambda_n L \tan \lambda_n L = \mathrm{Bi}$. The following definitions hold:

$$\mathrm{Bi} \equiv \frac{\bar{h}_c L}{k} \qquad \mathrm{Fo} \equiv \frac{\alpha t}{L^2} \qquad \theta \equiv \frac{T - T_\infty}{T_o - T_\infty}$$

The second geometry considered is a very long cylinder of diameter $2R$. The temperature response for this situation is

$$\theta = 2\mathrm{Bi} \sum_{n=1}^{\infty} \frac{\exp\left(-\lambda_n^2 R^2 \mathrm{Fo}\right) J_o\left(\lambda_n r\right)}{\left(\lambda_n^2 R^2 + \mathrm{Bi}^2\right) J_o\left(\lambda_n R\right)} \tag{4.1.29}$$

Now the λ_n are the roots of $\lambda_n R\, J_1(\lambda_n R) + \mathrm{Bi}\, J_o(\lambda_n R) = 0$, and

$$\mathrm{Bi} = \frac{\bar{h}_c R}{k} \qquad \mathrm{Fo} = \frac{\alpha t}{R^2} \qquad \theta = \frac{T - T_\infty}{T_o - T_\infty}$$

The common definition of Bessel's functions applies here.

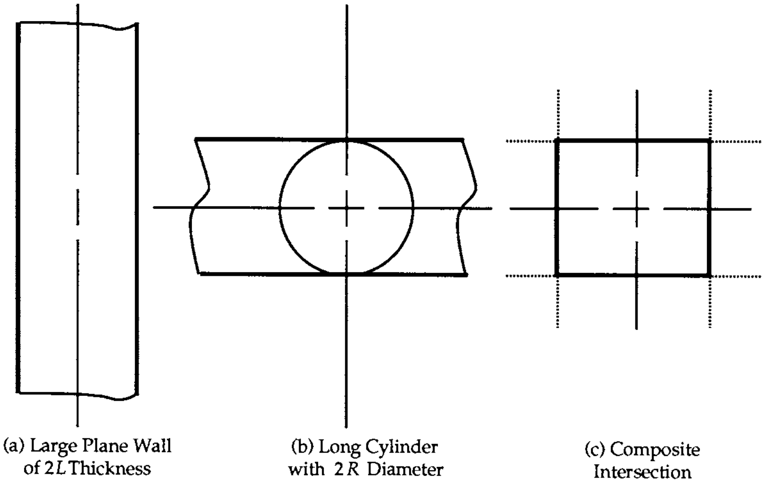

FIGURE 4.1.4 Three types of bodies that can be analyzed with results given in this section. (a) Large plane wall of 2*L* thickness; (b) long cylinder with 2*R* diameter; (c) composite intersection.

For the similar situation involving a solid sphere, the following holds:

$$\theta = 2\sum_{n=1}^{\infty} \frac{\sin(\lambda_n R) - \lambda_n R\cos(\lambda_n R)}{\lambda_n R - \sin(\lambda_n R)\cos(\lambda_n R)} \exp\left(-\lambda_n^2 R^2 \text{Fo}\right) \frac{\sin(\lambda_n r)}{\lambda_n r} \tag{4.1.30}$$

and the λ_n are found as the roots of $\lambda_n R \cos \lambda_n R = (1 - \text{Bi}) \sin \lambda_n R$. Otherwise, the same definitions as were given for the cylinder hold.

Solids that can be envisioned as the geometric intersection of the simple shapes described above can be analyzed with a simple product of the individual-shape solutions. For these cases, the solution is found as the product of the dimensionless temperature functions for each of the simple shapes with appropriate distance variables taken in each solution. This is illustrated as the right-hand diagram in Figure 4.1.4. For example, a very long rod of rectangular cross section can be seen as the intersection of two large plates. A short cylinder represents the intersection of an infinitely long cylinder and a plate. The temperature at any location within the short cylinder is

$$\theta_{2R,2L\text{ Rod}} = \theta_{\text{Infinite }2R\text{ Rod}}\,\theta_{2L\text{ Plate}} \tag{4.1.31}$$

Details of the formulation and solution of the partial differential equations in heat conduction are found in the text by Arpaci (1966).

Finite-Difference Analysis of Conduction

Today, numerical solution of conduction problems is the most-used analysis approach. Two general techniques are applied for this: those based upon finite-difference ideas and those based upon finite-element concepts. General numerical formulations are introduced in other sections of this book. In this section, a special, physical formulation of the finite-difference equations to conduction phenomena is briefly outlined.

Attention is drawn to a one-dimensional slab (very large in two directions compared with the thickness). The slab is divided across the thickness into smaller subslabs, and this is shown in Figure 4.1.5. All subslabs are thickness Δx except for the two boundaries where the thickness is $\Delta x/2$. A characteristic temperature for each slab is assumed to be represented by the temperature at the slab

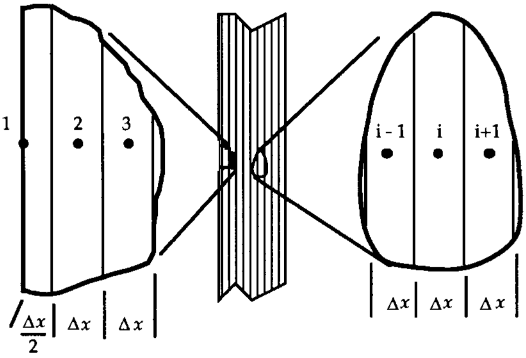

FIGURE 4.1.5 A one-dimensional finite differencing of a slab with a general interior node and one surface node detailed.

center. Of course, this assumption becomes more accurate as the size of the slab becomes smaller. With the two boundary-node centers located exactly on the boundary, a total of n nodes are used ($n - 2$ full nodes and one half node on each of the two boundaries).

In the analysis, a general interior node i (this applies to all nodes 2 through $n - 1$) is considered for an overall energy balance. Conduction from node $i - 1$ and from node $i + 1$ as well as any heat generation present is assumed to be energy per unit time flowing into the node. This is then equated to the time rate of change of energy within the node. A backward difference on the time derivative is applied here, and the notation $T_i' \equiv T_i(t + \Delta t)$ is used. The balance gives the following on a per-unit-area basis:

$$\frac{T_{i-1}' - T_i'}{\Delta x/k_-} + \frac{T_{i+1}' - T_i'}{\Delta x/k_+} + \dot{q}_{G,i}\Delta x = \rho \Delta x c_p \frac{T_i' - T_i}{\Delta t} \tag{4.1.32}$$

In this equation different thermal conductivities have been used to allow for possible variations in properties throughout the solid.

The analysis of the boundary nodes will depend upon the nature of the conditions there. For the purposes of illustration, convection will be assumed to be occurring off of the boundary at node 1. A balance similar to Equation (4.1.32) but now for node 1 gives the following:

$$\frac{T_\infty' - T_1'}{1/\bar{h}_c} + \frac{T_2' - T_1'}{\Delta x/k_+} + \dot{q}_{G,1}\frac{\Delta x}{2} = \rho \frac{\Delta x}{2} c_p \frac{T_1' - T_1}{\Delta t} \tag{4.1.33}$$

After all n equations are written, it can be seen that there are n unknowns represented in these equations: the temperature at all nodes. If one or both of the boundary conditions are in terms of a specified temperature, this will decrease the number of equations and unknowns by one or two, respectively. To determine the temperature as a function of time, the time step is arbitrarily set, and all the temperatures are found by simultaneous solution at $t = 0 + \Delta t$. The time is then advanced by Δt and the temperatures are then found again by simultaneous solution.

The finite difference approach just outlined using the backward difference for the time derivative is termed the *implicit* technique, and it results in an $n \times n$ system of linear simultaneous equations. If the forward difference is used for the time derivative, then only one unknown will exist in each equation. This gives rise to what is called an *explicit* or "marching" solution. While this type of system is more straightforward to solve because it deals with only one equation at a time with one unknown, a *stability criterion* must be considered which limits the time step relative to the distance step.

Two- and three-dimensional problems are handled in conceptually the same manner. One-dimensional heat fluxes between adjoining nodes are again considered. Now there are contributions from each of the dimensions represented. Details are outlined in the book by Jaluria and Torrance (2003).

Defining Terms

Biot number: Ratio of the internal (conductive) resistance to the external (convective) resistance from a solid exchanging heat with a fluid.

Fin: Additions of material to a surface to increase area and thus decrease the external thermal resistance from convecting and/or radiating solids.

Fin effectiveness: Ratio of the actual heat transfer from a fin to the heat transfer from the same cross-sectional area of the wall without the fin.

Fin efficiency: Ratio of the actual heat transfer from a fin to the heat transfer from a fin with the same geometry but completely at the base temperature.

Fourier's law: The fundamental law of heat conduction. Relates the local temperature gradient to the local heat flux, both in the same direction.

Heat conduction equation: A partial differential equation in temperature, spatial variables, time, and properties that, when solved with appropriate boundary and initial conditions, describes the variation of temperature in a conducting medium.

Overall heat transfer coefficient: The analogous quantity to the heat transfer coefficient found in convection (Newton's law of cooling) that represents the overall combination of several thermal resistances, both conductive and convective.

Thermal conductivity: The property of a material that relates a temperature gradient to a heat flux. Dependent upon temperature.

4.2 Convection Heat Transfer

Natural Convection

George D. Raithby and K.G. Terry Hollands

Introduction

Natural convection heat transfer occurs when the convective fluid motion is induced by density differences that are themselves caused by the heating. An example is shown in Figure 4.2.1(A), where a body at surface temperature T_s transfers heat at a rate q to ambient fluid at temperature $T_\infty < T_s$.

In this section, correlations for the average Nusselt number are provided from which the heat transfer rate q from surface area A_s can be estimated. The Nusselt number is defined as

$$\mathrm{Nu} = \frac{\bar{h}_c L}{k} = \frac{qL}{A_s \Delta T k} \tag{4.2.1}$$

where $\Delta T = T_s - T_\infty$ is the temperature difference driving the heat transfer. A dimensional analysis leads to the following functional relation:

$$\mathrm{Nu} = f(\mathrm{Ra},\ \mathrm{Pr},\ \text{geometric shape, boundary conditions}) \tag{4.2.2}$$

For given thermal boundary conditions (e.g., isothermal wall and uniform T_∞), and for a given geometry (e.g., a cube), Equation (4.2.2) states that Nu depends only on the Rayleigh number, Ra, and Prandtl number, Pr. The length scales that appear in Nu and Ra are defined, for each geometry considered, in a separate figure. The fluid properties are generally evaluated at T_f, the average of the wall and ambient

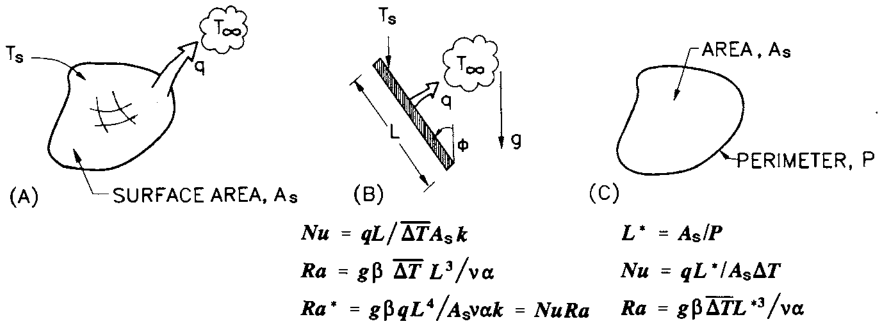

FIGURE 4.2.1 (A) Nomenclature for external heat transfer. (A) General sketch; (B) is for a tilted flat plate, and (C) defines the length scale for horizontal surfaces.

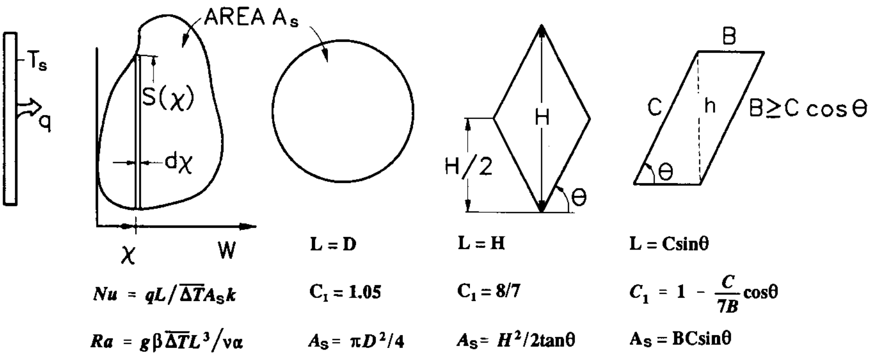

FIGURE 4.2.2 Nomenclature for heat transfer from planar surfaces of different shapes.

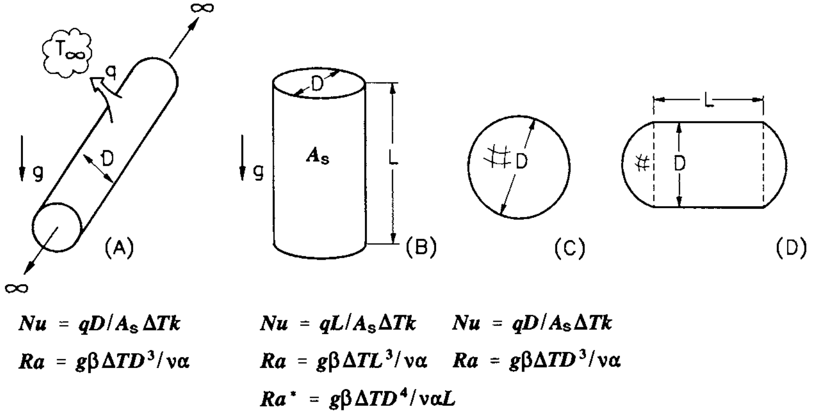

FIGURE 4.2.3 Definitions for computing heat transfer from a long horizontal circular cylinder (A), from the lateral surface of a vertical circular cylinder (B), from a sphere (C), and from a compound body (D).

temperatures. The exception is that β, the temperature coefficient of volume expansion, is evaluated at T_∞ for external natural convection(Figure 4.2.1 to Figure 4.2.3) in a *gaseous* medium.

The functional dependence on Pr is approximately independent of the geometry, and the following Pr-dependent function will be useful for laminar heat transfer (Churchill and Usagi, 1972):

$$\overline{C}_\ell = 0.671\Big/\left(1+(0.492/\mathrm{Pr})^{9/16}\right)^{4/9} \tag{4.2.3}$$

C_t^V and C_t^H are functions that will be useful for turbulent heat transfer:

$$C_t^V = 0.13\mathrm{Pr}^{0.22}\Big/\left(1+0.61\mathrm{Pr}^{0.81}\right)^{0.42} \tag{4.2.4}$$

$$C_t^H = 0.14\left(\frac{1+0.0107\mathrm{Pr}}{1+0.01\mathrm{Pr}}\right) \tag{4.2.5}$$

The superscripts *V* and *H* refer to the vertical and horizontal surface orientation.

The Nusselt numbers for fully laminar and fully turbulent heat transfer are denoted by Nu_ℓ and Nu_t, respectively. Once obtained, these are blended (Churchill and Usagi, 1972) as follows to obtain the equation for Nu:

$$\mathrm{Nu} = \left(\left(\mathrm{Nu}_\ell \right)^m + \left(\mathrm{Nu}_t \right)^m \right)^{1/m} \tag{4.2.6}$$

The blending parameter m depends on the body shape and orientation.

The equation for Nu_ℓ in this section is usually expressed in terms of Nu^T, the Nusselt number that would be valid if the thermal boundary layer were thin. The difference between Nu_ℓ and Nu^T accounts for the effect of the large boundary layer thicknesses encountered in natural convection.

It is assumed that the wall temperature of a body exceeds the ambient fluid temperature ($T_s > T_\infty$). For $T_s < T_\infty$ the same correlations apply with ($T_\infty - T_s$) replacing ($T_s - T_\infty$) for a geometry that is rotated 180° relative to the gravitational vector; for example, the correlations for a horizontal heated upward-facing flat plate applies to a cooled downward-facing flat plate of the same planform.

Correlations for External Natural Convection

This section deals with problems where the body shapes in Figure 4.2.1 to Figure 4.2.3 are heated while immersed in a quiescent fluid. Different *cases* are enumerated below.

1. *Isothermal Vertical (ϕ = 0) Flat Plate, Figure 4.2.1B.* For heat transfer from a vertical plate (Figure 4.2.1B), for $1 < \mathrm{Ra} < 10^{12}$,

$$\mathrm{Nu}^T = \overline{C}_\ell \mathrm{Ra}^{1/4} \qquad \mathrm{Nu}_\ell = \frac{2.0}{\ln\left(1 + 2.0/\mathrm{Nu}^T\right)} \tag{4.2.7}$$

$$\mathrm{Nu}_t = C_t^V \mathrm{Ra}^{1/3} \Big/ \left(1 + 1.4 \times 10^9 \,\mathrm{Pr}/\mathrm{Ra}\right)$$

$\overline{C}_\ell$ and C_t^V are given by Equation (4.2.3) and Equation (4.2.4). Nu is obtained by substituting Equation (4.2.7) expressions for Nu_ℓ and Nu_t into Equation (4.2.6) with $m = 6$.

2. *Vertical Flat Plate with Uniform Heat Flux, Figure 4.2.1B.* If the plate surface has a constant (known) heat flux, rather than being isothermal, the objective is to calculate the average temperature difference, $\overline{\Delta T}$, between the plate and fluid. For this situation, and for $15 < \mathrm{Ra}^* < 10^5$,

$$\mathrm{Nu}^T = \overline{G}_\ell \left(\mathrm{Ra}^*\right)^{1/5} \qquad \mathrm{Nu}_\ell = \frac{1.83}{\ln\left(1 + 1.83/\mathrm{Nu}^T\right)} \qquad \mathrm{Nu}_t = \left(C_t^V\right)^{3/4} \left(\mathrm{Ra}^*\right)^{1/4} \tag{4.2.8a}$$

$$\overline{G}_\ell = \frac{6}{5}\left(\frac{\mathrm{Pr}}{4 + 9\sqrt{\mathrm{Pr}} + 10\mathrm{Pr}} \right)^{1/5} \tag{4.2.8b}$$

Ra^* is defined in Figure 4.2.1B and C_t^V is given by Equation (4.2.4). Find Nu by inserting these expressions for Nu_ℓ and Nu_t into Equation (4.2.6) with $m = 6$. The $\overline{G}_\ell$ expression is due to Fujii and Fujii (1976).

3. *Horizontal Upward-Facing (ϕ = 90°) Plates, Figure 4.2.1C.* For horizontal isothermal surfaces of various platforms, correlations are given in terms of a lengthscale L^* (Goldstein et al., 1973), defined in Figure 4.2.1C. For $\mathrm{Ra} \geq 1$,

$$\mathrm{Nu}^T = 0.835\overline{C}_\ell \mathrm{Ra}^{1/4} \qquad \mathrm{Nu}_\ell = \frac{1.4}{\ln\left(1 + 1.4/\mathrm{Nu}^T\right)} \qquad \mathrm{Nu}_t = C_t^H \mathrm{Ra}^{1/3} \tag{4.2.9}$$

Nu is obtained by substituting Nu_ℓ and Nu_t from Equation 4.2.9 into Equation 4.2.6 with $m = 10$. For non-isothermal surfaces, replace ΔT by $\overline{\Delta T}$.

4. *Horizontal Downward-Facing ($\phi = -90°$) Plates, Figure 4.2.1C*. For horizontal downward-facing plates of various planforms, the main buoyancy force is into the plate so that only a very weak force drives the fluid along the plate; for this reason, only laminar flows have been measured. For this case, the following equation applies for Ra < 10^{10}, Pr ≥ 0.7:

$$\mathrm{Nu}^T = H_\ell \mathrm{Ra}^{1/5} \qquad \mathrm{H}_\ell = \frac{0.527}{\left[1+(1.9/\mathrm{Pr})^{9/10}\right]^{2/9}} \qquad \mathrm{Nu} = \frac{2.45}{\ln\left(1+2.45/\mathrm{Nu}^T\right)} \tag{4.2.10}$$

   H_ℓ fits the analysis of Fujii et al. (1973).

5. *Inclined Plates, Downward Facing ($-90° \le \phi \le 0$), Figure 4.2.1B*. First calculate q from *Case 1* with g replaced by $g \cos \phi$; then calculate q from *Case 4* (horizontal plate) with g replaced by $g \sin(-\phi)$, and use the maximum of these two values of q.
6. *Inclined Plates, Upward Facing ($0 \le \phi \le 90$), Figure 4.2.1B*. First calculate q from *Case 1* with g replaced by $g \cos \phi$; then calculate q from *Case 3* with g replaced by $g \sin \phi$, and use the maximum of these two values of q.
7. *Vertical and Tilted Isothermal Plates of Various Planform, Figure 4.2.2.* The line of constant χ in Figure 4.2.2 is the line of steepest ascent on the plate. Provided all such lines intersect the plate edges just twice, as shown in the figure, the thin-layer (Nu^T) heat transfer can be found by subdividing the body into strips of width $\Delta\chi$, calculating the heat transfer from each strip, and adding. For laminar flow from an isothermal vertical plate, this results in

$$\mathrm{Nu}^T = C_1 \bar{C}_\ell \mathrm{Ra}^{1/4} \qquad C_1 \equiv \left(\frac{L^{1/4}}{A}\int_0^W S^{3/4}\, d\chi\right) \tag{4.2.11}$$

   Symbols are defined in Figure 4.2.2, along with L and calculated C_1 values for some plate shapes. If the plate is vertical, follow the procedure in *Case 1* above (isothermal vertical flat plate) except replace the expression for Nu^T in Equation (4.2.7) by Equation (4.2.11). If the plate is tilted, follow the procedure described in *Case 5* or *6* (as appropriate) but again use Equation (4.2.11) for Nu^T in Equation (4.2.7)
8. *Horizontal Cylinders, Figure 4.2.3A*. For a long, horizontal circular cylinder use the following expressions for Nu_ℓ and Nu_t:

$$\mathrm{Nu}^T = 0.772 \bar{C}_\ell \mathrm{Ra}^{1/4} \qquad \mathrm{Nu}_\ell = \frac{2f}{\left(1+2f/\mathrm{Nu}^T\right)} \qquad \mathrm{Nu}_t = \bar{C}_t \mathrm{Ra}^{1/3} \tag{4.2.12}$$

   $\bar{C}_t$ is given in the table below. For Ra > 10^{-2}, $f = 0.8$ can be used, but for 10^{-10} < Ra < 10^{-2} use $f = 1 - 0.13/(\mathrm{Nu}^T)^{0.16}$. To find Nu, the values of Nu_ℓ and Nu_t from Equation (4.2.12) are substituted into Equation (4.2.6) with $m = 15$ (Clemes et al., 1994).

   $\bar{C}_t$ for Various Shapes and Prandtl Numbers

Pr→	0.01	0.022	0.10	0.71	2.0	6.0	50	100	2000
Horizontal cylinder	0.077	0.81	0.90	0.103	0.108	0.109	0.100	0.097	0.088
Spheres	0.074	0.078	0.088	0.104	0.110	0.111	0.101	0.097	0.086

9. *Vertical Cylinders ($\phi = 90°$), Figure 4.2.3B*. For high Ra values and large diameter, the heat transfer from a vertical cylinder approaches that for a vertical flat plate. Let the Nu^T and Nu_ℓ equations for a vertical flat plate of height L, Equation (4.2.7), be rewritten here as Nu_p^T and Nu_p, respectively.

At smaller Ra and diameter, transverse curvature plays a role which is accounted for in the following equations:

$$\mathrm{Nu}_{\ell} = \frac{0.9\xi \mathrm{Nu}_p}{\ln(1+0.9\xi)} \qquad \xi = \frac{2L/D}{Nu_p^T} \tag{4.2.13}$$

These equations are valid for purely laminar flow. To obtain Nu, blend Equation (4.2.13) for Nu_ℓ with Equation (4.2.7) for Nu_t using Equation (4.2.6) with $m = 10$.

10. *Spheres, Figure 4.2.3C.* For spheres use Equation (4.2.6), with $m = 6$, and with

$$\mathrm{Nu}_{\ell} = 2 + 0.878\overline{C}_{\ell}\mathrm{Ra}^{1/4} \quad \text{and} \quad \mathrm{Nu}_t = \overline{C}_t\mathrm{Ra}^{1/3} \tag{4.2.14}$$

The table above contains $\overline{C}_t$ values.

11. *Combined Shapes, Figure 4.2.3D.* For combined shapes, such as the cylinder in Figure 4.2.3D with spherical end caps, calculate the heat transfer from the cylinder of length L (*Case 8*), the heat transfer from a sphere of diameter D (*Case 10*) and add to obtain the total transfer. Other shapes can be treated in a similar manner.

Correlations for Open Cavities

Examples of this class of problem are shown in Figure 4.2.4. Walls partially enclose a fluid region (cavity) where boundary openings permit fluid to enter and leave. Upstream from its point of entry, the fluid is at the ambient temperature, T_∞. Since access of the ambient fluid to the heated surfaces is restricted, some of the heated surface is starved of cool ambient to which heat can be transferred. As the sizes of the boundary openings are increased, the previous class of problems is approached; for example, when the plate spacing in Figure 4.2.4A (*Case 12*) becomes very large, the heat transfer from each vertical surface is given by *Case 1*.

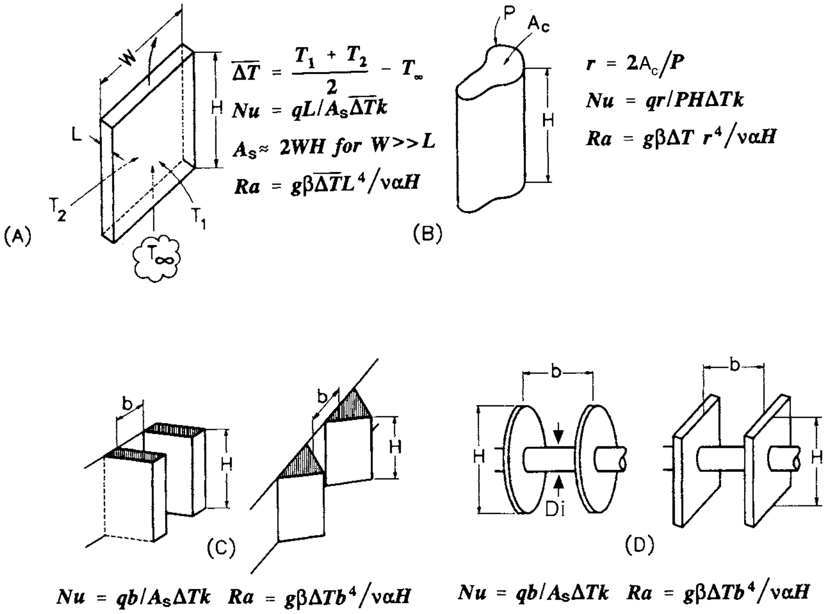

FIGURE 4.2.4 Nomenclature for various open-cavity problems.

12. *Isothermal Vertical Channels, Figure 4.2.4A and B.* Figure 4.2.4A shows an open cavity bounded by vertical walls and open at the top and bottom. The large opposing plates are isothermal, at temperatures T_1 and T_2, respectively, and the spacing between these plates is small. $\overline{\Delta T}$ is the average temperature difference between the plates and T_∞, as shown in Figure 4.2.4A, but T_1 and T_2 must not straddle T_∞. For this case

$$\mathrm{Nu} = \left(\left(\frac{\mathrm{Ra}}{f\mathrm{Re}} \right)^m + \left(C_1 \bar{C}_\ell \mathrm{Ra}^{1/4} \right)^m \right)^{1/m} \qquad \mathrm{Ra} \le 10^5 \tag{4.2.15}$$

where fRe is the product of friction factor and Reynolds number for fully developed channel flow, and C_1 is a constant that accounts for the augmentation of heat transfer, relative to a vertical flat plate (*Case 1*), due to the chimney effect. The fRe factor accounts for the cross-sectional shape (Elenbaas, 1942a). Symbols are defined in Figure 4.2.4A and B; in the Nu equation, q is the total heat transferred to the ambient fluid from all heated surfaces.

For the parallel plate channel shown in Figure 4.2.4(A), use $f\mathrm{Re} = 24$, $m = -1.9$, and for gases $C_1 \approx 1.2$. It should be noted, however, that C_1 must approach 1.0 as Pr increases or as the plate spacing increases. For channels of circular cross section (Figure 4.2.4B) $f\mathrm{Re} = 16$, $m = -1.03$, and for gases $C_1 \approx 1.17$. For other cross-sectional shapes like the square ($f\mathrm{Re} = 14.23$), hexagonal ($f\mathrm{Re} = 15.05$), or equilateral triangle ($f\mathrm{Re} = 13.3$), use Equation (4.2.15) with the appropriate fRe, and with $m = -1.5$, and $C_1 \approx 1.2$ for gases.

The heat transfer per unit cross-sectional area, q/A_c, for a given channel length H and temperature difference, passes through a maximum at approximately $\mathrm{Ra}_{\max}$, where

$$\mathrm{Ra}_{\max} = \left(\frac{f\mathrm{Re}\, C_1 \bar{C}_\ell}{2^{1/m}} \right)^{4/3} \tag{4.2.16}$$

$\mathrm{Ra}_{\max}$ provides the value of hydraulic radius $r = 2A_c/P$ at this maximum.

13. *Isothermal Triangular Fins, Figure 4.2.4C.* For a large array of triangular fins (Karagiozis et al., 1994) in air, for $0.4 < \mathrm{Ra} < 5 \times 10^5$

$$\mathrm{Nu} = \bar{C}_\ell \mathrm{Ra}^{1/4} \left[1 + \left(\frac{3.26}{\mathrm{Ra}^{0.21}} \right)^3 \right]^{-1/3} \qquad 0.4 < \mathrm{Ra} < 5 \times 10^6 \tag{4.2.17}$$

In this equation, b is the average fin spacing (Figure 4.2.4C), defined such that bL is the cross-sectional flow area between two adjacent fin surfaces up to the plane of the fin tips. For $\mathrm{Ra} < 0.4$, Equation (4.2.17) underestimates the convective heat transfer. When such fins are mounted horizontally (vertical baseplate, but the fin tips are horizontal), there is a substantial reduction of the convective heat transfer (Karagiozis et al., 1994).

14. *U-Channel Fins, Figure 4.2.4C.* For the fins most often used as heat sinks, there is uncertainty about the heat transfer at low Ra. By using a conservative approximation applying for $\mathrm{Ra} < 100$ (that underestimates the real heat transfer), the following equation may be used:

$$\mathrm{Nu} = \left[\left(\frac{\mathrm{Ra}}{24} \right)^{-2} + \left(C_1 \bar{C}_\ell \mathrm{Ra} \right)^{-2} \right]^{-0.5} \tag{4.2.18}$$

For air C_1 depends on aspect ratio of the fin as follows (Karagiozis, 1991):

$$C_1 = \left[1 + \left(\frac{H}{b}\right), 1.16\right]_{\min} \tag{4.2.19}$$

Equation (4.2.18) agrees well with measurements for Ra > 200, but for smaller Ra it falls well below data because the leading term does not account for heat transfer from the fin edges and for three-dimensional conduction from the entire array.

15. *Circular Fins on a Horizontal Tube, Figure 4.24D.* For heat transfer from an array of circular fins (Edwards and Chaddock, 1963), for $H/D_i = 1.94$, $5 < \text{Ra} < 10^4$, and for air,

$$\text{Nu} = 0.125\text{Ra}^{0.55}\left[1 - \exp\left(-\frac{137}{\text{Ra}}\right)\right]^{0.294} \tag{4.2.20}$$

A more general, but also more complex, relation is reported by Raithby and Hollands (1998).

16. *Square Fins on a Horizontal Tube, Figure 4.2.4D.* Heat transfer (Elenbaas, 1942b) from the square fins (excluding the cylinder that connects them) is correlated for gases by

$$\text{Nu} = \left[\left(\text{Ra}^{0.89}/18\right)^m + \left(0.62\text{Ra}^{1/4}\right)^m\right]^{1/m} \qquad m = -2.7 \tag{4.2.21}$$

Heat Transfer in Enclosures

This section deals with cavities where the bounding walls are entirely closed, so that no mass can enter or leave the cavity. The fluid motion inside the cavity is driven by natural convection, which enhances the heat transfer among the interior surfaces that bound the cavity.

17. *Extensive Horizontal Layers, Figure 4.2.5A.* If the heated plate, in a horizontal parallel-plate cavity, is on the top (θ = 180°), heat transfer is by conduction alone, so that Nu = 1. For heat transfer from below, θ = 0° (Hollands, 1984):

$$\text{Nu} = 1 + \left[1 - \frac{1708}{\text{Ra}}\right]^{\bullet}\left[k_1 + 2\left(\frac{\text{Ra}^{1/3}}{k_2}\right)^{1-\ln\left(\text{Ra}^{1/3}/k_2\right)}\right] + \left[\left(\frac{\text{Ra}}{5830}\right)^{1/3} - 1\right]^{\bullet} \tag{4.2.22}$$

where

$$[x]^{\bullet} = (x,0)_{\max} \qquad k_1 = \frac{1.44}{1 + 0.018/\text{Pr} + 0.00136/\text{Pr}^2} \qquad k_2 = 75\exp\left(1.5\text{Pr}^{-1/2}\right) \tag{4.2.23}$$

The equation has been validated for $\text{Ra} < 10^{11}$ for water, $\text{Ra} < 10^8$ for air, and over a smaller Ra range for other fluids. Equation (4.2.22) applies to extensive layers: $W/L \geq 5$. Correlations for nonextensive layers are provided by Raithby and Hollands (1998).

18. *Vertical Layers, Figure 4.2.5(A), with $\theta = 90°$.* W/L > *5*. For a vertical, gas-filled (Pr ≈ 0.7) cavity with $H/L \geq 5$, the following equation closely fits the data, for example that of Shewen et al. (1996) for $\text{Ra}(H/L)^3 \leq 5 \times 10^{10}$ and $H/L \geq 40$.

$$\text{Nu}_1 = \left[1 + \left(\frac{0.0665\text{Ra}^{1/3}}{1 + \left(\frac{9000}{\text{Ra}}\right)^{1.4}}\right)^2\right]^{1/2} \qquad \text{Nu}_2 = 0.242\left(\text{Ra}\frac{L}{H}\right)^{0.273} \qquad \text{Nu} = \left[\text{Nu}_1, \text{Nu}_2\right]_{\max} \tag{4.2.24}$$

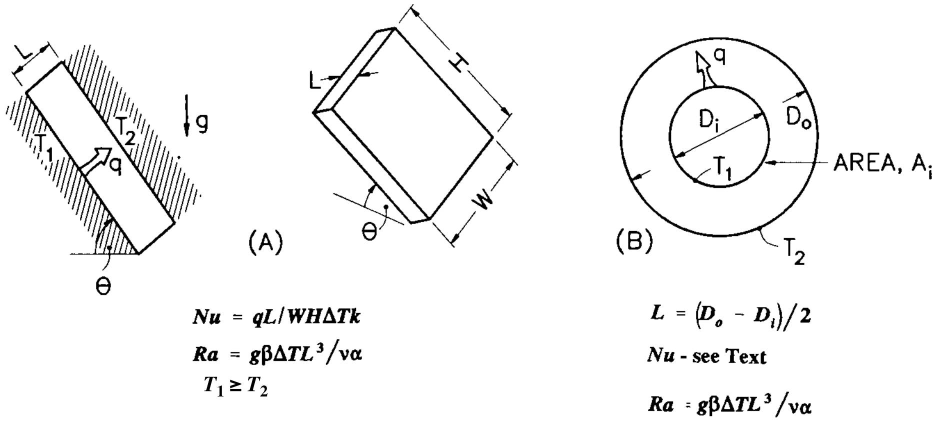

FIGURE 4.2.5 Nomenclature for enclosure problems.

For Pr ≥ 4, the following equation is recommended (Seki et al., 1978) for $\mathrm{Ra}(H/L)^3 < 4 \times 10^{12}$

$$\mathrm{Nu} = \left[1, 0.36\mathrm{Pr}^{0.051}\left(\frac{L}{H}\right)^{0.36}\mathrm{Ra}^{0.25}, 0.084\mathrm{Pr}^{0.051}\left(\frac{L}{H}\right)^{0.1}\mathrm{Ra}^{0.3}\right]_{\max} \tag{4.2.25a}$$

and for $\mathrm{Ra}\,(H/L)^3 > 4 \times 10^{12}$

$$\mathrm{Nu} = 0.039\mathrm{Ra}^{1/3} \tag{4.2.25b}$$

19. *Tilted Layers, Figure 4.25A, with 0 ≤ θ ≤ 90°,* W/L *> 8.* For gases (Pr ≈ 0.7), 0 ≤ θ ≤ 60° and $\mathrm{Ra} \le 10^5$ (Hollands et al., 1976), use

$$\mathrm{Nu} = 1 + 1.44\left[1 - \frac{1708}{\mathrm{Ra}\cos\theta}\right]^{\bullet}\left[1 - \frac{1708(\sin 1.8\theta)^{1.6}}{\mathrm{Ra}\cos\theta}\right] + \left[\left(\frac{\mathrm{Ra}\cos\theta}{5830}\right)^{1/3} - 1\right]^{\bullet} \tag{4.2.26}$$

See equation (4.2.23) for definition of $[x]^{\bullet}$. For 60° ≤ θ ≤ 90° linear interpolation is recommended using Equation (4.2.24) for θ = 90° and Equation (4.2.26) for θ = 60°.

20. *Concentric Cylinders, Figure 4.2.5B.* For heat transfer across the gap between horizontal concentric cylinders, the Nusselt number is defined as $\mathrm{Nu} = q' \ln(D_o/D_i)/2\pi k \Delta T$ where q' is the heat transfer per unit length of cylinder. For $\mathrm{Ra} \le 8 \times 10^7$, $0.7 \le \mathrm{Pr} \le 6000$, $1.15 \le D/D_i \le 8$ (Raithby and Hollands, 1975)

$$\mathrm{Nu} = \left[0.603\bar{C}_\ell \frac{\ln(D_o/D_i)\mathrm{Ra}^{1/4}}{\left[(L/D_i)^{3/5} + (L/D_o)^{3/5}\right]^{5/4}}, 1\right]_{\max} \tag{4.2.27}$$

For eccentric cylinders, see Raithby and Hollands (1998).

21. *Concentric Spheres, Figure 4.2.5B.* The heat transfer between concentric spheres is given by the following equation (Raithby and Hollands, 1975) for $\mathrm{Ra} \le 6 \times 10^8$, $5 \le \mathrm{Pr} \le 4000$, $1.25 < D_o/D_i \le 2.5$,

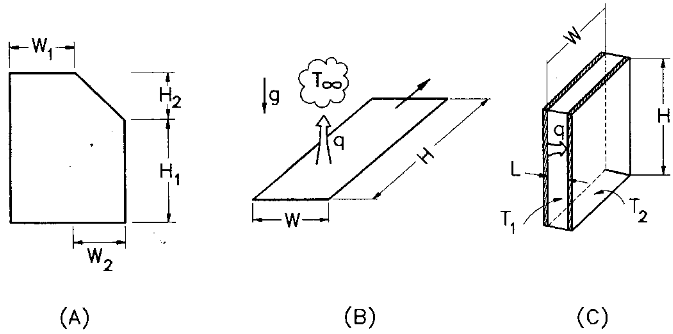

FIGURE 4.2.6 Sketches for example problems.

$$\mathrm{Nu} = \frac{qL}{\pi D_i D_o k \Delta T} = \left[1.16\bar{C}_\ell \left(\frac{L}{D_i}\right)^{1/4} \frac{\mathrm{Ra}^{1/4}}{\left[\left(D_i/D_o\right)^{3/5} + \left(D_o/D_i\right)^{4/5}\right]^{5/4}}, 1 \right]_{\max} \tag{4.2.28}$$

For eccentric spheres, see Raithby and Hollands (1985).

Example Calculations

Problem 1. Heat Transfer from Vertical Plate, Figure 4.2.6A. For the vertical isothermal surface in Figure 4.2.6A with $T_s = 40°\text{C}$, $H_1 = 1$ m, $H_2 = 1$ m, $W_1 = 1$ m, $W_2 = 1$ m and for an ambient air temperature of $T_\infty = 20°\text{C}$ (at 1 atm), find the heat transfer from one side of the plate.

Properties. At $T_f = (T_w + T_\infty)/2 = 30°\text{C}$ and atmospheric pressure for air: $\nu = 1.59 \times 10^{-5}$ m²/sec, $\alpha = 2.25\times10^{-5}$ m²/sec, Pr = 0.71, k = 0.0263 W/mK. At T_∞, $\beta \approx 1/T_\infty = 1/(273 + 20) = 0.00341\ \text{K}^{-1}$.

Solution. For the geometry shown in Figure 4.2.6A and using Equation (4.2.11):

$$A_s = \left(H_1 + H_2\right)W_1 + \left(H_1 + \frac{H_2}{2}\right)W_2 = 3.5\ \text{m}^2 \quad \text{(plate surface area)}$$

$$\int_0^{W_1+W_2} S^{3/4}\, d\chi = \left(H_1 + H_2\right)^{3/4} W_1 + \frac{4}{7}\frac{W_2}{H_2}\left[\left(H_1 + H_2\right)^{7/4} - H_1^{7/4}\right] = 3.03\ \text{m}^{7/4}$$

$$\mathrm{L}^{1/4} = \left(H_1 + H_2\right)^{1/4} = 1.19\ \text{m}^{1/4} \quad \text{(see comments below)}$$

$$C_1 = \frac{\mathrm{L}^{1/4}\displaystyle\int_0^{W_1+W_2} S^{3/4}\, d\chi}{A_s} = \frac{1.19\times3.03}{3.5} = 1.03$$

$$\mathrm{Ra} = \frac{g\beta_\infty L^3\left(T_w - T_\infty\right)}{\nu\alpha} = \frac{9.81\times0.00341\times2^3\times(40-20)}{1.59\times10^{-5}\times2.25\times10^{-5}} = 1.50\times10^{10}$$

$\bar{C}_\ell = 0.514$ from Equation (4.2.3); $C_t = C_t^V = 0.103$ from Equation (4.2.4). $\mathrm{Nu}^T = C_1\,\bar{C}_\ell\,\mathrm{Ra}^{1/4} = 185$ from Equation (4.2.11).

$$\left.\begin{aligned}\mathrm{Nu}_\ell &= \frac{2.0}{\ln\left(1+2.0/\mathrm{Nu}^T\right)} = 186\\ \mathrm{Nu}_t &= C_t^V \mathrm{Ra}^{1/3}\Big/\left(1+1.4\times10^9\,\mathrm{Pr/Ra}\right) = 238\end{aligned}\right\}\text{(from Equation (4.2.7))}$$

$$\mathrm{Nu} = \frac{qL}{A\Delta Tk} = \left(\mathrm{Nu}_\ell^6 + \mathrm{Nu}_t^6\right)^{1/6} = 246$$

from Equation (4.2.6) with $m = 6$.

$$q = \frac{A_s \Delta Tk\mathrm{Nu}}{\mathrm{L}} = \frac{3.5\times20\times0.0263\times246}{2} = 226W$$

Comments on Problem 1: Results are independent of the length scale L. Since $\mathrm{Nu}_\ell < \mathrm{Nu}_t$, the heat transfer is primarily turbulent. Do not neglect radiation. Had the surface been specified to be at constant heat flux, rather than isothermal, the equations in this section can be used to find the approximate average temperature difference between the plate and fluid.

Problem 2. Heat Transfer from Horizontal Strip, Figure 4.2.6B. Find the rate of heat loss per unit length from a very long strip (H → ∞) of width W = 0.1 m with a surface temperature of $T_s = 70°\mathrm{C}$ in water at $T_\infty = 30°\mathrm{C}$.

Properties. At $T_f = (T_s + T_\infty)1/2 = 50°\mathrm{C}$

$$v = 5.35\times10^{-7}\ \mathrm{m^2/sec} \qquad \alpha = 1.56\times10^{-7}\ \mathrm{m^2/sec} \qquad \mathrm{Pr} = 3.42$$

$$k = 0.645\ \mathrm{W/mK} \qquad \beta = 2.76\times10^{-4}\ \mathrm{K^{-1}}$$

Solution. This problem corresponds to *Case 3* and Figure 4.2.1C.

$$C_t^H = 0.14$$

from Equation 4.2.5 and $\overline{C}_l = 0.590$ from Equation (4.2.3).

$$L^* = \lim_{H\to\infty}\left(\frac{WH}{2W+2H}\right) = \frac{W}{2} = 0.05\ \mathrm{m}$$

from Figure 4.2.1C.

$$\mathrm{Ra} = \frac{g\beta\Delta TL^{*3}}{v\alpha} = 1.62\times10^8 \quad \mathrm{Nu}^T = 0.835\overline{C}_\ell \mathrm{Ra}^{1/4} = 55.6$$

$$\mathrm{Nu}_\ell = \frac{1.4}{\ln\left(1+1.4/\mathrm{Nu}^T\right)} = 54.2 \qquad \mathrm{Nu}_t = C_t^H \mathrm{Ra}^{1/3} = 76.3$$

$$\mathrm{Nu} = \frac{1}{WH\Delta T}\frac{L^*}{k} = \left(\mathrm{Nu}_\ell^{10} + \mathrm{Nu}_t^{10}\right)^{0.1} = 76.6$$

$$q/H = \frac{W\Delta Tk\mathrm{Nu}}{L^*} = 3950\ \text{W/m-length}$$

Comments: Turbulent heat transfer is dominant. Radiation can be ignored (since it lies in the far infrared region where it is not transmitted by the water).

Problem 3. Heat Loss across a Window Cavity, Figure 4.2.6C. The interior glazing is at temperature T_1 = 10°C, the exterior glazing at $T_2 = -10°C$, the window dimensions are W = 1 m, H = 1.7 m, and the air gap between the glazings is L = 1 cm and is at atmospheric pressure. Find the heat flux loss across the window.

Properties. At $\bar{T} = T_1 + T_2/2 = 0°C = 273K$

$$v = 1.35 \times 10^{-5} \text{ m}^2/\text{sec} \qquad \alpha = 1.89 \times 10^{-5} \text{ m}^2/\text{sec} \qquad \text{Pr} = 0.71$$

$$k = 0.024 \text{ W/mK} \qquad \beta = 1/273 = 3.66 \times 10^{-3} \text{ K}^{-1}$$

Solution. The appropriate correlations are given in *Case 18* and by Equation (4.2.24).

$$\text{Ra} = \frac{g\beta(T_1 - T_2)L^3}{v\alpha} = \frac{9.81 \times 3.66 \times 10^{-3} \times 20 \times (0.01)^3}{1.35 \times 10^{-5} \times 1.89 \times 10^{-5}} = 2.81 \times 10^3$$

$$\text{Nu}_1 = \left[1 + \left\{\frac{0.0665\text{Ra}^{1/3}}{1 + \left(\frac{9000}{\text{Ra}}\right)^{1.4}}\right\}^2\right]^{1/2} = 1.01$$

$$\text{Nu}_2 = 0.242\left(\text{Ra}\frac{L}{H}\right)^{0.273} = 0.242\left(2.81 \times 10^3 \times \frac{0.01}{1.7}\right)^{0.273} = 0.520$$

$$\text{Nu} = \frac{qL}{WH(T_1 - T_2)k} = \left(\text{Nu}_1, \text{Nu}_2\right)_{\max} = 1.01$$

$$q/WH = \frac{\text{Nu}(T_1 - T_2)k}{L} = \frac{1.01 \times 20 \times 0.024}{0.01} = 48.5 \text{ W/m}^2$$

Comments. For pure conduction across the air layer, Nu = 1.0. For the calculated value of Nu = 1.01, convection must play little role. For standard glass, the heat loss by radiation would be roughly double the natural convection value just calculated.

Special Nomenclature

Note that nomenclature for each geometry considered is provided in the figures that are referred to in the text.

$\bar{C}_\ell$ = function of Prandtl number, Equation (4.2.3)
C_t^V = function of Prandtl number, Equation (4.2.4)
C_t^H = function of Prandtl number, Equation (4.2.5)
$\underline{C}_t$ = surface averaged value of C_t, page 4–38
$\underline{\Delta T}$ = surface averaged value of $T_w - T_\infty$

Further Information

There are several heat transfer textbooks that provide fundamental information and correlations for natural convection heat transfer (e.g., Kreith and Bohn, 2000; Incropera and DeWitt, 2001). The correlations in this section closely follow the recommendations of Raithby and Hollands (1998), but that reference considers many more problems. Alternative equations are provided by Churchill (1983).

Forced Convection — External Flows

N.V. Suryanarayana

Introduction

In this section we consider heat transfer between a solid surface and an adjacent fluid which is in motion relative to the solid surface. If the surface temperature is different from that of the fluid, heat is transferred as forced convection. If the bulk motion of the fluid results solely from the difference in temperature of the solid surface and the fluid, the mechanism is natural convection. The velocity and temperature of the fluid far away from the solid surface are the free-stream velocity and free-stream temperature. Both are usually known or specified. We are then required to find the heat flux from or to the surface with specified surface temperature or the surface temperature if the heat flux is specified. The specified temperature or heat flux either may be uniform or may vary. The convective heat transfer coefficient *h* is defined by

$$q'' = h\left(T_s - T_\infty\right) \tag{4.2.29}$$

In Equation (4.2.29) with the local heat flux, we obtain the local heat transfer coefficient, and with the average heat flux with a uniform surface temperature we get the average heat transfer coefficient. For a specified heat flux the local surface temperature is obtained by employing the local convective heat transfer coefficient.

Many correlations for finding the convective heat transfer coefficient are based on experimental data which have some uncertainty, although the experiments are performed under carefully controlled conditions. The causes of the uncertainty are many. Actual situations rarely conform completely to the experimental situations for which the correlations are applicable. Hence, one should not expect the actual value of the heat transfer coefficient to be within better than ±10% of the predicted value.

Many different correlations to determine the convective heat transfer coefficient have been developed. In this section only one or two correlations are given. For other correlations and more details, refer to the books given in the bibliography at the end of this section.

Flat Plate

With a fluid flowing parallel to a flat plate, changes in velocity and temperature of the fluid are confined to a thin region adjacent to the solid boundary — the boundary layer. Several cases arise:

1. Flows without or with pressure gradient
2. Laminar or turbulent boundary layer
3. Negligible or significant viscous dissipation (effect of frictional heating)
4. $\mathrm{Pr} \geq 0.7$ or $\mathrm{Pr} \ll 1$

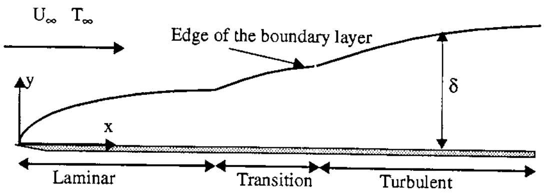

FIGURE 4.2.7 Flow of a fluid over a flat plate with laminar, transition, and turbulent boundary layers.

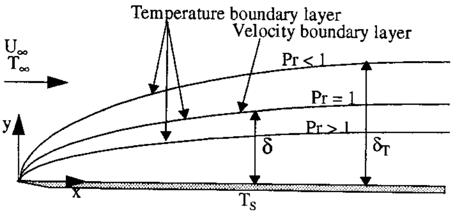

FIGURE 4.2.8 Temperature boundary layer thickness relative to velocity boundary layer thickness.

Flows with Zero Pressure Gradient and Negligible Viscous Dissipation

When the free-stream pressure is uniform, the free-stream velocity is also uniform. Whether the boundary layer is laminar or turbulent depends on the Reynolds number Re_X ($\rho U_\infty x/\mu$) and the shape of the solid at entrance. With a sharp edge at the leading edge (Figure 4.2.7) the boundary layer is initially laminar but at some distance downstream there is a transition region where the boundary layer is neither totally laminar nor totally turbulent. Farther downstream of the transition region the boundary layer becomes turbulent. For engineering applications the existence of the transition region is usually neglected and it is assumed that the boundary layer becomes turbulent if the Reynolds number, Re_X, is greater than the critical Reynolds number, Re_{cr}. A typical value of 5×10^5 for the critical Reynolds number is generally accepted, but it can be greater if the free-stream turbulence is low and lower if the free-stream turbulence is high, the surface is rough, or the surface does not have a sharp edge at entrance. If the entrance is blunt, the boundary layer may be turbulent from the leading edge.

Temperature Boundary Layer

Analogous to the velocity boundary layer there is a temperature boundary layer adjacent to a heated (or cooled) plate. The temperature of the fluid changes from the surface temperature at the surface to the free-stream temperature at the edge of the temperature boundary layer (Figure 4.2.8).

The velocity boundary layer thickness δ depends on the Reynolds number Re_X. The thermal boundary layer thickness δ_T depends both on Re_X and Pr

$\mathrm{Re}_x < \mathrm{Re}_{cr}$:

$$\frac{\delta}{x} = \frac{5}{\sqrt{\mathrm{Re}_x}} \qquad \mathrm{Pr} > 0.7 \qquad \frac{\delta}{\delta_T} = \mathrm{Pr}^{1/3}$$
$$\mathrm{Pr} \ll 1 \qquad \frac{\delta}{\delta_T} = \mathrm{Pr}^{1/2} \tag{4.2.30}$$

$\mathrm{Re}_{cr} < \mathrm{Re}_x$:

$$\frac{\delta}{x} = \frac{0.37}{\mathrm{Re}_x^{0.2}} \qquad \delta \approx \delta_T \tag{4.2.31}$$

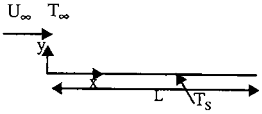

FIGURE 4.2.9 Heated flat plate with heating from the leading edge.

Viscous dissipation and high-speed effects can be neglected if $\Pr^{1/2}\,\mathrm{Ec}/2 \ll 1$. For heat transfer with significant viscous dissipation see the section on flow over flat plate with zero pressure gradient: Effect of High Speed and Viscous Dissipation. The Eckert number Ec is defined as $\mathrm{Ec} = U_\infty^2 / C_p(T_s - T_\infty)$.

With a rectangular plate of length L in the direction of the fluid flow the average heat transfer coefficient h_L with uniform surface temperature is given by

$$h_L = \frac{1}{L}\int_0^L h_x \, dx$$

Laminar Boundary Layer ($Re_x < Re_{cr}$, $Re_L < Re_{cr}$): With heating or cooling starting from the leading edge the following correlations are recommended. Note: in all equations evaluate fluid properties at the film temperature defined as the arithmetic mean of the surface and free-stream temperatures unless otherwise stated (Figure 4.2.9).

Local Heat Transfer Coefficient (Uniform Surface Temperature)
The Nusselt number based on the local convective heat transfer coefficient is expressed as

$$\mathrm{Nu}_x = f_{\Pr}\mathrm{Re}_x^{1/2} \tag{4.2.32}$$

The classical expression for $f_{\Pr}$ is $0.564\,\Pr^{1/2}$ for liquid metals with very low Prandtl numbers, $0.332\Pr^{1/3}$ for $0.7 < \Pr < 50$ and $0.339\Pr^{1/3}$ for very large Prandtl numbers. Correlations valid for all Prandtl numbers developed by Churchill (1976) and Rose (1979) are given below.

$$\mathrm{Nu}_x = \frac{0.3387\mathrm{Re}_x^{1/2}\Pr^{1/3}}{\left[1+\left(\frac{0.0468}{\Pr}\right)^{2/3}\right]^{1/4}} \tag{4.2.33}$$

$$\mathrm{Nu}_x = \frac{\mathrm{Re}^{1/2}\Pr^{1/2}}{\left(27.8+75.9\Pr^{0.306}+657\Pr\right)^{1/6}} \tag{4.2.34}$$

In the range $0.001 < \Pr < 2000$, Equation (4.2.33) is within 1.4% and Equation (4.2.34) is within 0.4% of the exact numerical solution to the boundary layer energy equation.

Average Heat Transfer Coefficient
The average heat transfer coefficient is given by

$$\mathrm{Nu}_L = 2\mathrm{Nu}_{x=L} \tag{4.2.35}$$

From Equation 4.2.35 it is clear that the average heat transfer coefficient over a length L is twice the local heat transfer coefficient at x = L.

Uniform Heat Flux

Local Heat Transfer Coefficient

Churchill and Ozoe (1973) recommend the following single correlation for all Prandtl numbers.

$$\mathrm{Nu}_x = \frac{0.886\,\mathrm{Re}_x^{1/2}\,\mathrm{Pr}^{1/2}}{\left[1+\left(\dfrac{\mathrm{Pr}}{0.0207}\right)^{2/3}\right]^{1/4}} \tag{4.2.36}$$

Note that for surfaces with uniform heat flux the local convective heat transfer coefficient is used to determine the local surface temperature. The total heat transfer rate being known, an average heat transfer coefficient is not needed and not defined.

Turbulent Boundary Layer ($Re_x > Re_{cr}$, $Re_L > Re_{cr}$): For turbulent boundary layers with heating or cooling starting from the leading edge use the following correlations:

Local Heat Transfer Coefficient

$\mathrm{Re}_{cr} < \mathrm{Re}_x < 10^7$:

$$\mathrm{Nu}_x = 0.0296\,\mathrm{Re}_x^{4/5}\,\mathrm{Pr}^{1/3} \tag{4.2.37}$$

$10^7 < \mathrm{Re}_x$:

$$\mathrm{Nu}_x = 1.596\,\mathrm{Re}_x\left(\ln \mathrm{Re}_x\right)^{-2.584}\mathrm{Pr}^{1/3} \tag{4.2.38}$$

Equation (4.2.38) is obtained by applying Colburn's *j* factor in conjunction with the friction factor suggested by Schlicting (1979).

In laminar boundary layers, the convective heat transfer coefficient with uniform heat flux is approximately 36% higher than with uniform surface temperature. With turbulent boundary layers, the difference is very small and *the correlations for the local convective heat transfer coefficient can be used for both uniform surface temperature and uniform heat flux.*

Average Heat Transfer Coefficient

If the boundary layer is initially laminar followed by a turbulent boundary layer at $\mathrm{Re}_x = \mathrm{Re}_{cr}$, the following correlations for $0.7 < \mathrm{Pr} < 60$ are suggested:

$\mathrm{Re}_{cr} < \mathrm{Re}_L < 10^7$:

$$\mathrm{Nu}_L = \left[0.664\,\mathrm{Re}_L^{1/2} + 0.037\left(\mathrm{Re}_L^{4/5} - \mathrm{Re}_{cr}^{4/5}\right)\right]\mathrm{Pr}^{1/3} \tag{4.2.39}$$

If $\mathrm{Re}_{cr} < \mathrm{Re}_L < 10^7$ and $\mathrm{Re}_{cr} = 10^5$, Equation 4.2.39 simplifies to

$$\mathrm{Nu}_L = \left(0.037\,\mathrm{Re}_L^{4/5} - 871\right)\mathrm{Pr}^{1/3} \tag{4.2.40}$$

$10^7 < \mathrm{Re}_L$ and $\mathrm{Re}_{cr} = 5 \times 10^5$:

$$\mathrm{Nu}_L = \left[1.963\,\mathrm{Re}_L\left(\ln \mathrm{Re}_L\right)^{-2.584} - 871\right]\mathrm{Pr}^{1/3} \tag{4.2.41}$$

Uniform Surface Temperature — Pr > 0.7: Unheated Starting Length

If heating does not start from the leading edge as shown in Figure 4.2.10, the correlations have to be modified. Correlation for the local convective heat transfer coefficient for laminar and turbulent boundary

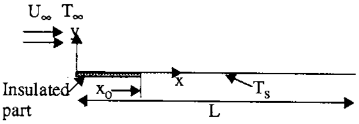

FIGURE 4.2.10 Heated flat plate with unheated starting length.

layers are given by Equation (4.2.42) and Equation (4.2.43) (Kays and Crawford, 1993) — the constants in Equation (4.2.42) and Equation (4.2.43) have been modified to be consistent with the friction factors. These correlations are also useful as building blocks for finding the heat transfer rates when the surface temperature varies in a predefined manner. Equation (4.2.44) and Equation (4.2.45), developed by Thomas (1977), provide the average heat transfer coefficients based on Equation (4.2.42) and Equation (4.2.43).

Local Convective Heat Transfer Coefficient

$\mathrm{Re}_x < \mathrm{Re}_{\mathrm{cr}}$:

$$\mathrm{Nu}_x = \frac{0.332\mathrm{Re}_x^{1/2}\mathrm{Pr}^{1/3}}{\left[1-\left(\frac{x_o}{x}\right)^{3/4}\right]^{1/3}} \tag{4.2.42}$$

$\mathrm{Re}_x > \mathrm{Re}_{\mathrm{cr}}$:

$$\mathrm{Nu}_x = \frac{0.0296\mathrm{Re}_x^{4/5}\mathrm{Pr}^{3/5}}{\left[1-\left(\frac{x_o}{x}\right)^{9/10}\right]^{1/9}} \tag{4.2.43}$$

Average Heat Transfer Coefficient over the Length (L – x_o)

$\mathrm{Re}_L < \mathrm{Re}_{\mathrm{cr}}$:

$$\begin{aligned} h_{L-x_o} &= \frac{0.664\mathrm{Re}_L^{1/2}\mathrm{Pr}^{1/3}\left[1-\left(\frac{x_o}{L}\right)^{3/4}\right]^{2/3} k}{L-x_o} \\ &= 2\frac{1-\left(\frac{x_o}{L}\right)^{3/4}}{1-x_o/L} h_{x=L} \end{aligned} \tag{4.2.44}$$

In Equation (4.2.44) evaluate $h_{x=L}$ from Equation (4.2.42).

$\mathrm{Re}_{\mathrm{cr}} = 0$:

$$\begin{aligned} h_{L-x_o} &= \frac{0.037\mathrm{Re}_L^{4/5}\mathrm{Pr}^{3/5}\left[1-\left(\frac{x_o}{L}\right)^{9/10}\right]^{8/9} k}{L-x_o} \\ &= 1.25\frac{1-\left(x_o/L\right)^{9/10}}{1-x_o/L} h_{x=L} \end{aligned} \tag{4.2.45}$$

In Equation (4.2.45) evaluate $h_{x=L}$ from Equation (4.2.43).

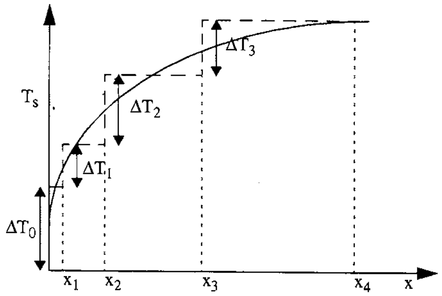

FIGURE 4.2.11 Arbitrary surface temperature approximated as a finite number of step changes.

Flat Plate with Prescribed Nonuniform Surface Temperature

The linearity of the energy equation permits the use of Equation (4.2.42) through Equation (4.2.45) for uniform surface temperature with unheated starting length to find the local heat flux and the total heat transfer rate by the principle of superposition when the surface temperature is not uniform. Figure 4.2.11 shows the arbitrarily prescribed surface temperature with a uniform free-stream temperature of the fluid. If the surface temperature is a differentiable function of the coordinate *x*, the local heat flux can be determined by an expression that involves integration (refer to Kays and Crawford, 1993). If the surface temperature can be approximated as a series of step changes in the surface temperature, the resulting expression for the local heat flux and the total heat transfer rate is the summation of simple algebraic expressions. Here the method using such an algebraic simplification is presented.

The local convective heat flux at a distance *x* from the leading edge is given by

$$q_x'' = \sum_1^n h_{xi} \Delta T_{si} \tag{4.2.46}$$

where h_{xi} denotes the local convective heat transfer coefficient at x due to a single step change in the surface temperature ΔT_{si} at location $x_i (x_i < x)$. Referring to Figure 4.2.11, the local convective heat flux at x ($x_3 < x < x_4$) is given by

$$q_x'' = h_x(x,0)\Delta T_o + h_x(x,x_1)\Delta T_1 + h_x(x,x_2)\Delta T_2 + h_x(x,x_3)\Delta T_3$$

where $h_x(x, x_1)$ is the local convective heat transfer coefficient at x with heating starting from x_1; the local convective heat transfer is determined from Equation (4.2.42) if the boundary layer is laminar and Equation (4.2.43) if the boundary layer is turbulent from the leading edge. For example, $h_x(x, x_2)$ in the third term is given by

$$\mathrm{Re}_x < \mathrm{Re}_{\mathrm{cr}} \qquad h_x(x,x_2) = \frac{0.332\left(\dfrac{\rho U_\infty x}{\mu}\right)^{1/2} \mathrm{Pr}^{1/3}}{\left[1-\left(\dfrac{x_2}{x}\right)^{3/4}\right]^{1/3}} \frac{k}{x}$$

$$\mathrm{Re}_{\mathrm{cr}} = 0 \qquad h_x(x,x_2) = \frac{0.0296\left(\dfrac{\rho U_\infty x}{\mu}\right)^{4/5} \mathrm{Pr}^{3/5}}{\left[1-\left(\dfrac{x_2}{x}\right)^{9/10}\right]^{1/9}} \frac{k}{x}$$

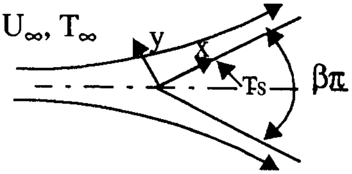

FIGURE 4.2.12 Flow over a wedge. βπ is the wedge angle.

The procedure for finding the total heat transfer rate from $x = 0$ to $x = L$ is somewhat similar. Denoting the width of the plate by W,

$$\frac{q}{W} = \sum h_{L-x_i} \Delta T_i \left(L - x_i\right) \tag{4.2.47}$$

where h_{L-x_i} is the average heat transfer coefficient over the length $L - x_i$ due to a step change ΔT_i in the surface temperature at x_i. For example, the heat transfer coefficient in the third term in Equation (4.2.47) obtained by replacing x_o by x_2 in Equation (4.2.44) or (4.2.45) depending on whether $\mathrm{Re}_L < \mathrm{Re}_{\mathrm{cr}}$ or $\mathrm{Re}_{\mathrm{cr}} = 0$.

Flows with Pressure Gradient and Negligible Viscous Dissipation

Although correlations for flat plates are for a semi-infinite fluid medium adjacent to the plate, most applications of practical interest deal with fluid flowing between two plates. If the spacing between the plates is significantly greater than the maximum boundary layer thickness, the medium can be assumed to approach a semi-infinite medium. In such a case if the plates are parallel to each other and if the pressure drop is negligible compared with the absolute pressure, the pressure gradient can be assumed to be negligible. If the plates are nonparallel and if the boundary layer thickness is very much smaller than the spacing between the plates at that location, the medium can still be considered as approaching a semi-infinite medium with a non-negligible pressure gradient. In such flows the free-stream velocity (core velocity outside the boundary layer) is related to the pressure variation by the Bernoulli equation:

$$\frac{p}{\rho} + \frac{U_\infty^2}{2} + zg = \text{constant}$$

Another situation where the free-stream velocity varies in the direction of flow giving rise to a pressure gradient is flow over a wedge. For the family of flows for which the solutions are applicable, the free-stream velocity at the edge of the boundary layer is related to the x-coordinate by a power law, $U_\infty = cx^m$. Flows over semi-infinite wedges (Figure 4.2.12) satisfy that condition. The exponent m is related to the wedge angle βπ

$$\beta = \frac{2m}{1+m} \qquad m = \frac{\beta}{2-\beta}$$

With laminar boundary layers, the boundary layer thickness, friction factor, and Nusselt numbers are defined by

$$\frac{\delta}{x} = \frac{c_1}{\sqrt{\mathrm{Re}_x}} \qquad \frac{C_{fx}}{2} = \frac{\tau_w}{\rho U_\infty^2} = \frac{c_2}{\sqrt{\mathrm{Re}_x}} \qquad \mathrm{Nu}_x = c_3 \mathrm{Re}_x^{1/2}$$

The values of c_1, c_2, and c_3 are available in Burmeister (1993). For example, for $\beta = 0.5$ (wedge angle = 90°), $m = 1/3$, $c_1 = 3.4$, $c_2 = 0.7575$, and $c_3 = 0.384$ for $\mathrm{Pr} = 0.7$, and $c_3 = 0.792$ for $\mathrm{Pr} = 5$. Re_x is based on $U_\infty = cx^m$; the free-stream velocity is not uniform.

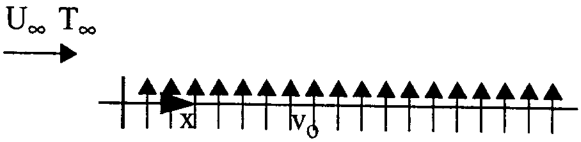

FIGURE 4.2.13 Flat plate with transpiration injection.

Uniform Temperature: Flat Plate with Injection or Suction with External Flows of a Fluid Parallel to the Surface

Injection or suction has engineering applications. When the free-stream temperature of the fluid is high, as in gas turbines, a cooling fluid is introduced into the mainstream to cool the surface. If the cooling fluid is introduced at discrete locations (either perpendicular to the surface or at an angle), it is known as film cooling. If a fluid is introduced or withdrawn through a porous medium, it is known as transpiration (Figure 4.2.13). An application of suction is to prevent boundary layer separation (Figure 4.2.13).

Analytical solutions for a laminar boundary layer with transpiration suction or blowing are available if the velocity perpendicular to the surface varies in the following manner:

$$\mathbf{v}_o = \text{constant } x^{(m-1)/2}$$

Solutions are limited to the cases of the injected fluid being at the same temperature as the surface and the injected fluid being the same as the free-stream fluid. Positive values of v_o indicate blowing and negative values indicate suction. Values of $\text{Nu}_x/\text{Re}_x^{1/2}$ for different values of Pr and for different values of blowing or suction parameter are given in Kays and Crawford (1993).

For example, for a laminar boundary layer over a flat plate with a fluid (Pr = 0.7) the value of $\text{Nu}_x/\text{Re}_x^{1/2}$ is 0.722 for $(v_o/U_\infty)\sqrt{\rho U_\infty x/\mu} = -0.75$ (suction) and 0.166 for $(v_o/U_\infty)\sqrt{\rho U_\infty x/\mu} = 0.25$ (blowing). Heat transfer coefficient increases with suction which leads to a thinning of the boundary layer. Blowing increases the boundary layer thickness and decreases the heat transfer coefficient.

For *turbulent boundary layers* Kays and Crawford (1993) suggest the following procedure for finding the friction factor and convective heat transfer coefficient. Define friction blowing parameter B_f and heat transfer blowing parameter B_h as

$$B_f = \frac{\mathbf{v}_o/U_\infty}{C_f/2} \tag{4.2.48}$$

$$B_h = \frac{\mathbf{v}_o/U_\infty}{\text{St}} = \frac{\dot{m}''/G_\infty}{\text{St}} \tag{4.2.49}$$

where

v_o = velocity normal to the plate
U_∞ = free-stream velocity
$\dot{m}''$ = mass flux of the injected fluid at the surface (ρv_o)
G_∞ = mass flux in the free stream (ρU_∞)
St = Stanton number = $\text{Nu}_x/\text{Re}_x\text{Pr} = h/\rho U_\infty c_p$

The friction factors and Stanton number with and without blowing or suction are related by

$$\frac{C_f}{C_{fo}} = \frac{\ln\left(1 + B_f\right)}{B_f} \tag{4.2.50}$$

$$\frac{\mathrm{St}}{\mathrm{St}_o} = \frac{\ln\left(1 + B_h\right)}{B_h} \tag{4.2.51}$$

In Equation (4.2.50) and Equation (4.2.51) C_{fo} and St_o are the friction factor and Stanton number with $v_o = 0$ (no blowing or suction), and C_f and St are the corresponding quantities with blowing or suction at the same $\mathrm{Re}_x(\rho U_\infty x/\mu)$.

For the more general case of variable free-stream velocity, temperature difference, and transpiration rate, refer to Kays and Crawford (1993).

Flow over Flat Plate with Zero Pressure Gradient: Effect of High-Speed and Viscous Dissipation

In the boundary layer the velocity of the fluid is reduced from U_∞ to zero at the plate leading to a reduction in the kinetic energy of the fluid. Within the boundary layer there is also the work done by viscous forces; the magnitude of the such viscous work is related to the velocity of the fluid, the velocity gradient, and the viscosity of the fluid. The effect of such a reduction in the kinetic energy and the viscous work is to increase the internal energy of the fluid in the boundary layer. The increase in the internal energy may be expected to lead to an increase in the temperature; but because of the heat transfer to the adjacent fluid the actual increase in the internal energy (and the temperature) will be less than the sum of the decrease in the kinetic energy and viscous work transfer; the actual temperature increase depends on the decrease in the kinetic energy, the viscous work transfer, and the heat transfer from the fluid. The maximum temperature in the fluid with an adiabatic plate is known as the adiabatic wall temperature (which occurs at the wall) and is given by

$$T_{aw} = T_\infty + r\frac{U_\infty^2}{2C_p} \tag{4.2.52}$$

In Equation (4.2.52) r is the recovery factor and is given by Eckert and Drake (1986).

Laminar boundary layer	$0.6 < \mathrm{Pr} < 15$	$r = \mathrm{Pr}^{1/2}$
Turbulent boundary layer		$r = \mathrm{Pr}^{1/3}$

Equation (4.2.52) can be recast as

$$\frac{T_{aw} - T_\infty}{T_s - T_\infty} = \frac{r}{2}\frac{U_\infty^2}{C_p\left(T_s - T_\infty\right)} \tag{4.2.53}$$

From Equation (4.2.53) the maximum increase in the fluid temperature as a fraction of the difference between the plate and free-stream temperatures is given by $r\,\mathrm{Ec}/2$. With air flowing over a plate at 500 m/sec, the increase in the temperature of the air can be as high as 105°C. With $T_s = 40°\mathrm{C}$ and $T_\infty = 20°\mathrm{C}$, the temperature of the air close to the plate can be higher than the plate temperature. It is thus possible that although the plate temperature is higher than the free-stream temperature, the heat transfer is from the air to the plate. At a Mach number greater than 0.1 for gases, viscous dissipation becomes significant.

The temperature profiles for high-speed flows for different values of T_s are shown in Figure 4.2.14. In high-speed flows, as heat transfer can be to the plate even if the plate temperature is greater than the fluid temperature, the definition of the convective heat transfer coefficient given in Equation (4.2.29) is not adequate. On the other hand, as the heat transfer is always from the plate if $T_s > T_{aw}$, the adiabatic wall temperature is more appropriate as the reference temperature. Thus, in high-speed flows the definition of the convective heat transfer coefficient is given by

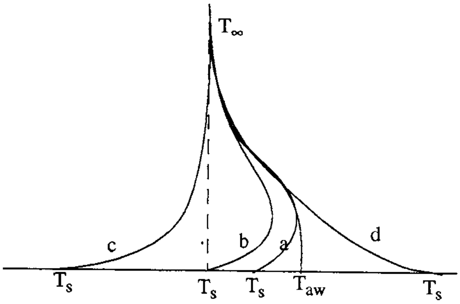

FIGURE 4.2.14 Temperature profiles for high-speed flows: (a) $T_\infty < T_s < T_{aw}$; (b) $T_s = T_\infty$; (c) $T_s \ll T_\infty$; (d) $T_s > T_{aw}$.

$$q'' = h\left(T_s - T_{aw}\right) \tag{4.2.54}$$

Equation (4.2.54) is consistent with Equation (4.2.29) as the adiabatic wall temperature equals the free-stream temperature if the effects of viscous dissipation and reduced kinetic energy in the boundary layer are neglected. With the adiabatic wall temperature as the fluid reference temperature for the definition of the convective heat transfer coefficient, equations for low speeds can also be used for high-speed flows. Because of the greater variation in the fluid temperature in the boundary layer, the variation of properties due to temperature variation becomes important. It is found that the correlations are best approximated if the properties are evaluated at the reference temperature T^* defined by Eckert (1956):

$$T^* = 0.5\left(T_s + T_\infty\right) + 0.22\left(T_{aw} - T_\infty\right) \tag{4.2.55}$$

With properties evaluated at the reference temperature given by Equation (4.2.55), Equation (4.2.56) through (4.2.61) are applicable to high-speed flows with Prandtl numbers less than 15. It should be noted that the adiabatic wall temperatures in the laminar and turbulent regions are different affecting both the temperature at which the properties are evaluated and the temperature difference for determining the local heat flux. Therefore, when the boundary layer is partly laminar and partly turbulent, an average value of the heat transfer coefficient is not defined as the adiabatic wall temperatures in the two regions are different. In such cases the heat transfer rate in each region is determined separately to find the total heat transfer rate.

Evaluate properties at reference temperature given by Equation (4.2.55):

Laminar Local: $\mathrm{Re}_x < \mathrm{Re}_{cr}$ $$\mathrm{Nu}_x = 0.332\mathrm{Re}_x^{1/2}\mathrm{Pr}^{1/3} \tag{4.2.56}$$

Average: $\mathrm{Re}_L < \mathrm{Re}_{cr}$ $$\mathrm{Nu}_L = 0.664\mathrm{Re}_L^{1/2}\mathrm{Pr}^{1/3} \tag{4.2.57}$$

Turbulent Local: $10^7 > \mathrm{Re}_x > \mathrm{Re}_{cr}$ $$\mathrm{Nu}_x = 0.0296\mathrm{Re}_x^{4/5}\mathrm{Pr}^{1/3} \tag{4.2.58}$$

Local: $10^7 < \mathrm{Re}_x < 10^9$ $$\mathrm{Nu}_x = 1.596\mathrm{Re}_x\left(\ln\mathrm{Re}_x\right)^{-2.584}\mathrm{Pr}^{1/3} \tag{4.2.59}$$

Average: $\mathrm{Re}_{cr} = 0,\ \mathrm{Re}_L < 10^7$ $$\mathrm{Nu}_L = 0.037\mathrm{Re}_L^{4/5}\mathrm{Pr}^{1/3} \tag{4.2.60}$$

Average: $\mathrm{Re}_{cr} = 0,\ 10^7 < \mathrm{Re}_L < 10^9$ $$\mathrm{Nu}_L = 1.967\mathrm{Re}_L\left(\ln\mathrm{Re}_L\right)^{-2.584}\mathrm{Pr}^{1/3} \tag{4.2.61}$$

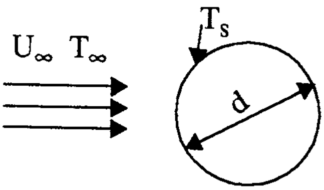

FIGURE 4.2.15 A fluid stream in cross flow over a cylinder.

When the temperature variation in the boundary layer is large, such that the assumption of constant specific heat is not justified, Eckert (1956) suggests that the properties be evaluated at a reference temperature corresponding to the specific enthalpy i^* given by

$$i^* = 0.5(i_s + i_\infty) + 0.22(i_s - i_\infty) \tag{4.2.62}$$

where i is the specific enthalpy of the fluid evaluated at the temperature corresponding to the subscript. Equation (4.2.62) gives the same values as Equation (4.2.55) if C_p is constant or varies linearly with temperature.

At very high speeds the gas temperature may reach levels of temperatures that are sufficient to cause disassociation and chemical reaction; these and other effects need to be taken into account in those cases.

Flow over Cylinders, Spheres, and Other Geometries

Flows over a flat plate and wedges were classified as laminar or turbulent, depending on the Reynolds number, and correlations for the local and average convective heat transfer coefficients were developed. But flows over cylinders (perpendicular to the axis) and spheres are more complex. In general, the flow over cylinders and spheres may have a laminar boundary layer followed by a turbulent boundary layer and a wake region depending on the Reynolds number with the diameter as the characteristic length. Because of the complexity of the flow patterns, only correlations for the average heat transfer coefficients have been developed (Figure 4.2.15).

Cylinders: Use the following correlation proposed by Churchill and Bernstein (1977): $\mathrm{Re}_d\,\mathrm{Pr} > 0.2$. Evaluate properties at $(T_s + T_\infty)/2$:

$$\mathrm{Re}_d > 400{,}000: \qquad \mathrm{Nu}_d = 0.3 + \frac{0.62\mathrm{Re}_d^{1/2}\mathrm{Pr}^{1/3}}{\left[1+(0.4/\mathrm{Pr})^{2/3}\right]^{1/4}}\left[1+\left(\frac{\mathrm{Re}_d}{282{,}000}\right)^{5/8}\right]^{4/5} \tag{4.2.63}$$

$$10{,}000 < \mathrm{Re}_d < 400{,}000: \quad \mathrm{Nu}_d = 0.3 + \frac{0.62\mathrm{Re}_d^{1/2}\mathrm{Pr}^{1/3}}{\left[1+(0.4/\mathrm{Pr})^{2/3}\right]^{1/4}}\left[1+\left(\frac{\mathrm{Re}_d}{282{,}000}\right)^{1/2}\right] \tag{4.2.64}$$

$$\mathrm{Re}_d < 10{,}000: \qquad \mathrm{Nu}_d = 0.3 + \frac{0.62\mathrm{Re}_d^{1/2}\mathrm{Pr}^{1/3}}{\left[1+(0.4/\mathrm{Pr})^{2/3}\right]^{1/4}} \tag{4.2.65}$$

For flow of liquid metals, use the following correlation suggested by Ishiguro et al. (1979):

$$1 < \mathrm{Re}_d\mathrm{Pr} < 100 \qquad \mathrm{Nu}_d = 1.125(\mathrm{Re}_d\mathrm{Pr})^{0.413} \tag{4.2.66}$$

For more information on heat transfer with flow over cylinders, refer to Morgan (1975) and Zukauskas (1987).

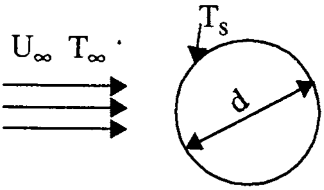

FIGURE 4.2.16 A fluid flowing over a sphere.

Spheres: For flows over spheres (Figure 4.2.16) use one of the following two correlations.

1. Whitaker (1972): Evaluate properties at T_∞ except μ_s at T_s.

$$3.5 < \mathrm{Re}_d < 76{,}000 \qquad 0.71 < \mathrm{Pr} < 380 \qquad 1 < \mu/\mu_s < 3.2$$

$$\mathrm{Nu}_d = 2.0 + \left(0.4\mathrm{Re}_d^{1/2} + 0.06\mathrm{Re}_d^{2/3}\right)\mathrm{Pr}^{2/5}\left(\frac{\mu}{\mu_s}\right)^{1/4} \tag{4.2.67}$$

2. Achenbach (1978): Evaluate properties at $(T_s + T_\infty)/2$:

$$100 < \mathrm{Re}_d < 2\times10^5 \qquad \mathrm{Pr} = 0.71$$

$$\mathrm{Nu}_d = 2 + \left(0.25\mathrm{Re}_d + 3\times10^{-4}\mathrm{Re}_d^{1.6}\right)^{1/2} \tag{4.2.68}$$

$$4\times10^5 < \mathrm{Re}_d < 5\times10^6 \qquad \mathrm{Pr} = 0.71$$

$$\mathrm{Nu}_d = 430 + 5\times10^{-3}\mathrm{Re}_d + 0.25\times10^{-9}\mathrm{Re}_d^2 - 3.1\times10^{-17}\mathrm{Re}_d^3 \tag{4.2.69}$$

3. Liquid Metals: From experimental results with liquid sodium, Witte (1968) proposed

$$3.6\times10^4 < \mathrm{Re}_d < 1.5\times10^5 \qquad \mathrm{Nu}_d = 2 + 0.386\left(\mathrm{Re}_d\mathrm{Pr}\right)^{1/2} \tag{4.2.70}$$

Other Geometries: For geometries other than cylinders and spheres, use Equation (4.2.71) with the characteristic dimensions and values of the constants given in the Table 4.2.1.

$$\mathrm{Nu}_D = c\mathrm{Re}_D^m \tag{4.2.71}$$

Although Equation (4.2.71) is based on experimental data with gases, its use can be extended to fluids with moderate Prandtl numbers by multiplying Equation (4.2.71) by $(\mathrm{Pr}/0.7)^{1/3}$.

Heat Transfer across Tube Banks

When tube banks are used in heat exchangers, the flow over the tubes in the second subsequent rows of tubes is different from the flow over a single tube. Even in the first row the flow is modified by the presence of the neighboring tubes. The extent of modification depends on the spacing between the tubes. If the spacing is very much greater than the diameter of the tubes, correlations for single tubes can be used. Correlations for flow over tube banks when the spacing between tubes in a row and a column is not much greater than the diameter of the tubes have been developed for use in heat-exchanger applications. Two arrangements of the tubes are considered — aligned and staggered as shown in Figure 4.2.17. The nomenclature used in this section is shown in the figure.

TABLE 4.2.1 Values of *c* and *m* in Equation (4.2.71)

Geometry	Re_D	c	m
	5000-100 000	0.092	0.675
	2500-8000	0.160	0.699
	5000-100 000	0.222	0.588
	2500-7500	0.261	0.624
	5000-19500 19 500-100 000	0.144 0.035	0.638 0.782
	5000-100 000	0.138	0.638
	2500-15 000	0.224	0.612
	3000-15 000	0.085	0.804
	4000-15 000	0.205	0.731

Charcteristic dimension is the equivalent circular diameter = Perimeter/π
For example, for a square rod with each side a, D = 4a/π

From Jakob, 1949. With permission.

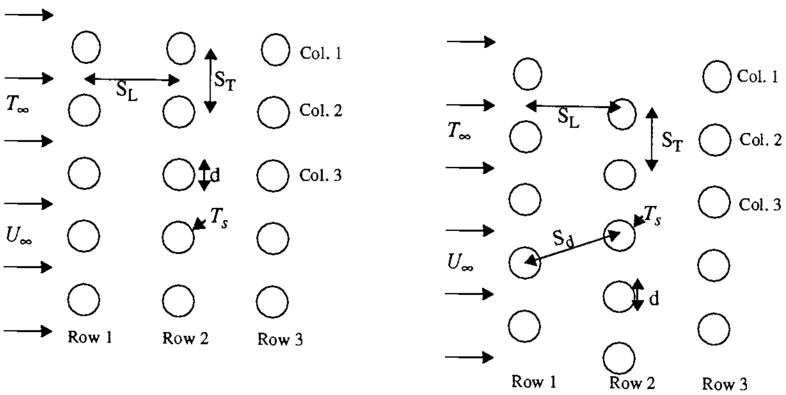

FIGURE 4.2.17 Two arrangements of tube banks. In-line or aligned arrangement on the left and staggered arrangement on the right. ($a = S_T/d$; $b = S_L/d$.)

TABLE 4.2.2 In-Line Arrangement — Values of Constants in Equation (4.2.72) ($p = 0$ in all cases)

Re_d	c	m	n
1–100	0.9	0.4	0.36
100–1000	0.52	0.5	0.36
10^3–2×10^5	0.27	0.63	0.36
$2 \times 10^5 - 2 \times 10^6$	0.033	0.8	0.4

TABLE 4.2.3 Staggered Arrangement — Values of Constants in Equation (4.2.72)

Re_d	c	p	m	n
1–500	1.04	0	0.4	0.36
500–1000	0.71	0	0.5	0.36
10^3–2×10^5	0.35	0.2	0.6	0.36
$2 \times 10^5 - 2 \times 10^6$	0.031	0.2	0.8	0.36

For the average convective heat transfer coefficient with tubes at uniform surface temperature, from experimental results, Zukauskas (1987) recommends correlations of the form:

$$\mathrm{Nu}_d = c\left(\frac{a}{b}\right)^p \mathrm{Re}_d^m \mathrm{Pr}^n \left(\frac{\mathrm{Pr}}{\mathrm{Pr}_s}\right)^{0.25} \tag{4.2.72}$$

In Equation (4.2.72) all properties are evaluated at the arithmetic mean of the inlet and exit temperatures of the fluid, except Pr_s which is evaluated at the surface temperature T_s. The values of the constants c, p, m, and n are given in Table 4.2.2 for in-line arrangement and in Table 4.2.3 for staggered arrangement.

In computing Re_d, the maximum average velocity between tubes is used. The maximum velocities for the in-line and staggered arrangements are given by

$$\text{In-line:} \qquad U_{\max} = \frac{U_\infty S_T}{S_T - d} \tag{4.2.73}$$

$$\text{Staggered:} \qquad S_d > \frac{S_T + d}{2} \qquad U_{\max} = \frac{U_\infty S_T}{S_T - d} \tag{4.2.74}$$

$$\text{Staggered:} \qquad S_d < \frac{S_T + d}{2} \qquad U_{\max} = \frac{U_\infty S_T}{2(S_d - d)}$$

$$S_d = \left[S_L^2 + \left(\frac{S_T}{2}\right)^2\right]^{1/2} \tag{4.2.75}$$

Equation (4.2.72) is for tube banks with 16 or more rows. When there are fewer than 16 rows, the heat transfer coefficient given by Equation (4.2.72) is multiplied by the correction factor c_1 defined by Equation (4.2.76) and given in Table 4.2.4.

$$\frac{h_N}{h_{16}} = c_1 \tag{4.2.76}$$

TABLE 4.2.4 Correction Factor c_1 to Be Used with Equation (4.2.76)

Tube Arrangement	Number of Rows (N) 1	2	3	4	5	7	10	13
In-line	0.70	0.80	0.86	0.90	0.93	0.96	0.98	0.99
Staggered	0.64	0.76	0.84	0.89	0.93	0.96	0.98	0.99

where

h_N = heat transfer coefficient with N rows (fewer than 16)
h_{16} = heat transfer coefficient with 16 or more rows

Pressure Drop: With tube banks, pressure drop is a significant factor, as it determines the fan power required to maintain the fluid flow. Zukauskas (1987) recommends that the pressure drop be computed from the relation

$$\Delta p = p_i - p_e = N\chi \frac{\rho U_{\max}^2}{2} f \tag{4.2.77}$$

where p_i and p_e are the fluid pressures at inlet and exit of the tube banks. The values of χ and f are presented in Figure 4.2.18A. In Figure 4.2.18A the friction factor f for in-line arrangement is presented for different values of b (S_L/d) for $S_L = S_T$. For values of S_L/S_T other than 1, the correction factor χ is given in the inset for different values of $(a - 1)/(b - 1)$. Similarly, the friction factor for staggered arrangement (for equilateral triangle arrangement) and a correction factor for different values of a/b are also given in Figure 4.2.18b. The value of f is for one row of tubes; the total pressure drop is obtained by multiplying the pressure drop for one row by the number of rows, N.

The temperature of the fluid varies in the direction of flow, and, therefore, the value of the convective heat transfer coefficient (which depends on the temperature-dependent properties of the fluid) also varies in the direction of flow. However, it is common practice to compute the total heat transfer rate with the assumption of uniform convective heat transfer coefficient evaluated at the arithmetic mean of the inlet and exit temperatures of the fluid. With such an assumption of uniform convective heat transfer coefficient, uniform surface temperature and constant specific heat (evaluated at the mean fluid temperature), the inlet and exit fluid temperatures are related by

$$\ln\left(\frac{T_s - T_e}{T_s - T_i}\right) = -\frac{hA_s}{\dot{m}c_p} \tag{4.2.78}$$

The heat transfer rate to the fluid is related by the equation

$$q = \dot{m}c_p\left(T_i - T_e\right) \tag{4.2.79}$$

Example

A heat exchanger with aligned tubes is used to heat 40 kg/sec of atmospheric air from 10 to 50°C with the tube surfaces maintained at 100°C. Details of the heat exchanger are

Diameter of tubes	25 mm
Number of columns	20
Length of each tube	3 m
$S_L = S_T$	75 mm

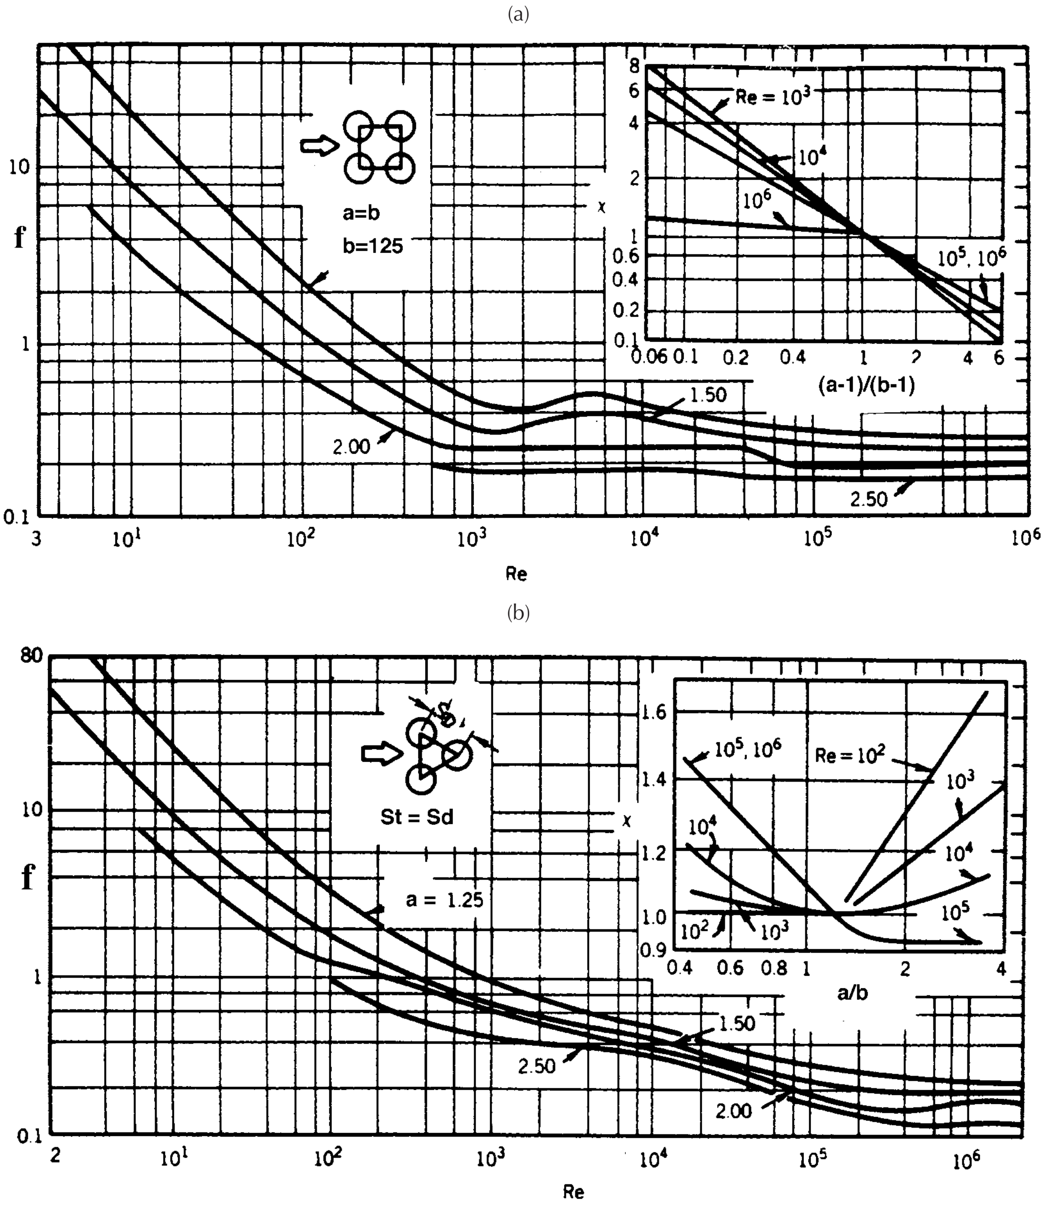

FIGURE 4.2.18 Friction factors for tube banks. (a) In-line arrangement; (b) Staggered arrangement. (From Zukauskas, A., in *Handbook of Single-Phase Convective Heat Transfer*, Kakac, S. et al., Eds., Wiley Interscience, New York, 1987. With permission.)

Determine the number of rows required.

Solution. Average air temperature = $(T_i + T_e)/2 = 30°\text{C}$. Properties of atmospheric air (from Suryanarayana, 1995):

$$\rho = 1.165 \text{ kg/m}^3 \qquad c_p = 1007 \text{ J/kg K}$$

$$\mu = 1.865 \times 10^{-5} \text{ N sec/m}^3 \qquad k = 0.0264 \text{ W/mK}$$

$$\text{Pr} = 0.712 \qquad \text{Pr}_s(\text{at } 100°\text{C}) = 0.705$$

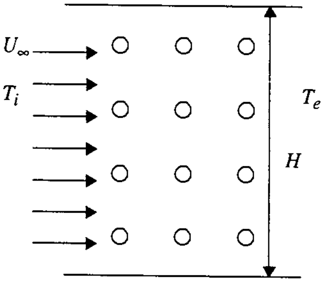

FIGURE 4.2.19 Aligned tube heat exchanger (only a few of the 20 columns and rows are shown).

To find $U_{\max}$ we need the minimum area of cross section for fluid flow (Figure 4.2.19).

$$H = 20 \times 0.075 = 1.5 \text{ m}$$

$$A_{\min} = 20(0.075 - 0.025) \times 3 = 3 \text{ m}^2$$

$$U_{\max} = \frac{\dot{m}}{\rho A_{\min}} = \frac{40}{1.165 \times 3} = 11.44 \text{ m/sec}$$

$$\text{Re}_d = \frac{\rho U_{\max} d}{\mu} = \frac{1.165 \times 11.44 \times 0.025}{1.865 \times 10^{-5}} = 17{,}865$$

With values from Table 4.2.2,

$$\text{Nu}_d = 0.27 \times 17{,}865^{0.63} \times 0.712^{0.36} \left(\frac{0.712}{0.705}\right)^{0.25} = 114.3$$

$$h = \frac{114.3 \times 0.0264}{0.025} = 120.7 \text{ W/m}^2 \text{ K}$$

From Equation 4.2.78,

$$\ln\left(\frac{100-50}{100-10}\right) = -\frac{120.7 \times A_s}{40 \times 1007} \qquad A_s = \pi \times 0.025 \times 3 \times 20 \times N$$

$$\underline{N = \text{number of rows} = 42}$$

Fan Power: From the first law of thermodynamics (see Chapter 2), the fan power is

$$\dot{W}_F = \dot{m}\left(\frac{p_i}{\rho_i} + \frac{p_e}{\rho_e} + \frac{\mathbf{v}_e^2}{2}\right)$$

p_i and p_e are the pressures at inlet and exit of the heat exchanger and $\mathbf{v}_e$ is the fluid velocity at exit. Assuming constant density evaluated at $(T_i + T_e)/2$ the pressure drop is found from Figure 4.2.18a.

$$\text{Re}_p = 17{,}865: \qquad a = b = S_T/d = 75/25 = 3$$

In Figure 4.2.18, although the friction factor is available for values of b up to 2.5, we will estimate the value of f for $b = 3$. From Figure 4.2.18, $f \approx 0.11$. The correction factor $c = 1$.

$$p_i - p_e = N\chi \frac{\rho U_{\max}^2}{2} f = 42 \times 1 \frac{1.165 \times 11.44^2}{2} \times 0.11 = 352.2 \text{ kPa}$$

$$\mathbf{v}_e = \frac{11.44 \times 50}{75} = 7.63 \text{ m/sec}$$

$$\dot{W}_F = 40\left(352.2 + \frac{7.63^2}{2}\right) = \underline{15{,}250 \text{ W}}$$

Heat Transfer with Jet Impingement

Jet impingement (Figure 4.2.20) on a heated (or cooled) surface results in high heat transfer rates, and is used in annealing of metals, tempering of glass, cooling of electronic equipment, internal combustion engines, and in a wide variety of industries — textiles, paper, wood, and so on. Usually, the jets are circular, issuing from a round nozzle of diameter d, or rectangular, issuing from a slot of width w. They may be used singly or in an array. The jets may impinge normally to the heated surface or at an angle. If there is no parallel solid surface close to the heated surface, the jet is said to be free; in the presence of a parallel surface close to the heated surface, the jet is termed confined. In this section only single, free jets (round or rectangular) impinging normally to the heated surface are considered.

Jets may be submerged with the fluid from the nozzle exiting into a body of a fluid (usually the same fluid), for example, air impinging on a surface surrounded by atmospheric air. In submerged jets entrained fluid (the part of the surrounding fluid dragged by the jet) has a significant effect on the flow and heat transfer characteristics of the jet, but the effect of gravity is usually negligible. In free-surface jets — a liquid jet in an atmosphere of air is a good approximation to a free-surface jet — the entrainment effect is usually negligible, but the effect of gravity may be significant.

A jet is usually divided into three regions, a free-jet region, a stagnation region, and a wall-jet region. In the free-jet region the effect of the target surface on the flow is negligible. In the stagnation region the target surface affects the flow field, and the velocity parallel to the surface increases while the velocity component normal to the surface decreases. At the beginning of the stagnation region, the axial velocity of the fluid is very much greater than the radial component (or the x-component) of the velocity. The stagnation region is followed by the wall-jet region where the radial component (or the x-component) of the velocity is much greater than the axial velocity.

The heat transfer coefficient is a function of H/d (or H/w), $\mathrm{Re}_d(\rho v_j d/\mu)$ or $(\rho v_j 2w/\mu)$, and Pr and depends on the region (stagnation or wall jet), whether it is submerged or nonsubmerged and whether

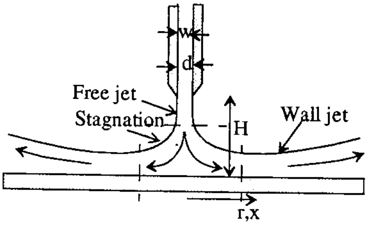

FIGURE 4.2.20 Circular jet of diameter d or a rectangular jet of width w.

the flow adjacent to the plate is laminar or turbulent. Some of the heat transfer correlations suggested by different researchers are given below. All the correlations are for single jets.

Submerged Jets: Single Circular Jets

$$\mathrm{Re}_d = \frac{4\dot{m}}{\pi d \mu} \qquad \mathrm{Nu}_d = \frac{hd}{k} \qquad \dot{m} = \text{mass rate of flow of fluid}$$

Average heat transfer coefficients up to radius r (Martin, 1990):

$$\mathrm{Nu}_d = 2\frac{d}{r}\frac{1-1.1d/r}{1+0.1(H/d-6)d/r}\left[\mathrm{Re}_d\left(1+\frac{\mathrm{Re}_d^{0.55}}{200}\right)\right]^{1/2}\mathrm{Pr}^{0.42} \tag{4.2.80}$$

Range of validity:

$$2000 \le \mathrm{Re}_d \le 400{,}000 \qquad 2.5 \le r/d \le 7.5 \qquad 2 \le H/d \le 12$$

Local convective heat transfer coefficient at radius r (Webb and Ma, 1995):

$$\mathrm{Nu}_d = 1.29\mathrm{Re}_d^{1/2}\mathrm{Pr}^{0.4}\left\{\left[\frac{\tanh(0.88r/d)}{r/d}\right]^{-8.5}+\left[1.69\left(\frac{r}{d}\right)^{-1.07}\right]^{-17}\right\}^{-1/17} \tag{4.2.81}$$

Submerged Jets: Single Rectangular Jet

$$\mathrm{Re}_w = \frac{\rho \mathbf{v}_j 2w}{\mu} = \frac{2\dot{m}}{\mu} \qquad \dot{m} = \text{mass rate of flow per unit length of jet}$$

$$\mathrm{Nu}_w = \frac{h2w}{k}$$

Average heat transfer coefficient (Martin, 1990):

$$\mathrm{Nu}_w = \frac{1.53\mathrm{Pr}^{0.42}\mathrm{Re}_w^m}{\dfrac{x}{2w}+\dfrac{H}{2w}+1.39} \tag{4.2.82}$$

$$m = 0.695 - \left[\frac{x}{2w}+\left(\frac{H}{2w}\right)^{1.33}+3.06\right]^{-1}$$

Free-Surface Jets: Single Circular Jet. Correlations are given in Table 4.2.5 (Liu et al., 1991 and Webb and Ma, 1995).

For more information on jet impingement heat transfer, refer to Martin (1977) and Webb and Ma (1995) and the references in the two papers.

TABLE 4.2.5 Correlations for Free-Surface Jets $r_v/d = 0.1773\,\text{Re}_d^{1/3}$

		Nu_d	
$r/d < 0.787$	$0.15 \le \text{Pr} \le 3$	$0.715\text{Re}_d^{1/2}\text{Pr}^{0.4}$	(4.2.83)
	$\text{Pr} > 3$	$0.797\text{Re}_d^{1/2}\text{Pr}^{1/3}$	(4.2.84)
$0.787 < r/d < r_v/d$		$0.632\text{Re}_d^{1/2}\text{Pr}^{1/3}\left(\dfrac{d}{r}\right)^{1/2}$	(4.2.85)
$r_v/d < r/d < r_t/d$		$\dfrac{0.407\text{Re}_d^{1/3}\text{Pr}^{1/3}(d/r)^{2/3}}{\left[\dfrac{0.1713}{(r/d)^2}+\dfrac{5.147}{\text{Re}_d}\dfrac{r}{d}\right]^{2/3}\left[\dfrac{(r/d)^2}{2}+C\right]^{1/3}}$ where $C = -5.051\times10^{-5}\text{Re}_d^{2/3}$ $\dfrac{r_t}{d} = \left\{-\dfrac{s}{2}+\left[\left(\dfrac{s}{2}\right)^2+\left(\dfrac{p}{3}\right)^3\right]^{1/2}\right\}^{1/3} + \left\{-\dfrac{s}{2}+\left[\left(\dfrac{s}{2}\right)^2-\left(\dfrac{p}{3}\right)^3\right]^{1/2}\right\}^{1/3}$ $p = \dfrac{-2C}{0.2058\text{Pr}-1} \qquad s = \dfrac{0.00686\text{Re}_d\text{Pr}}{0.2058\text{Pr}-1}$	(4.2.86)
$r > r_t$	$\text{Pr} < 4.86$	$\dfrac{0.25}{\dfrac{1}{\text{Re}_d\text{Pr}}\left[1-\left(\dfrac{r_t}{r}\right)^2\right]\left(\dfrac{r}{d}\right)^2+0.13\dfrac{h}{d}+0.0371\dfrac{h_t}{d}}$ where $h_t = h$ at r_t and $\dfrac{h}{d} = \dfrac{0.1713}{r/d}+\dfrac{5.147}{\text{Re}_d}\left(\dfrac{r}{d}\right)^2$	(4.2.87)

Forced Convection — Internal Flows

N.V. Suryanarayana

Introduction

Heat transfer to (or from) a fluid flowing inside a tube or duct is termed *internal forced convection*. The fluid flow may be laminar or turbulent. If the Reynolds number based on the average velocity of the fluid and diameter of the tube ($\rho vd/\mu$) is less than 2100 (Reynolds numbers in the range of 2000 to 2300 are cited in different sources), the flow is laminar. If the Reynolds number is greater than 10,000, the flow is turbulent. The flow with a Reynolds number in the range 2100 to 10,000 is considered to be in the transitional regime. With heating or cooling of the fluid, there may or may not be a change in the phase of the fluid. Here, only heat transfer to or from a single-phase fluid is considered.

Fully Developed Velocity and Temperature Profiles. When a fluid enters a tube from a large reservoir, the velocity profile at the entrance is almost uniform as shown in Figure 4.2.21. The fluid in the immediate vicinity of the tube surface is decelerated and the velocity increases from zero at the surface to u_c at a distance δ from the surface; in the region $r = 0$ to $(R - \delta)$ the velocity is uniform. The value of δ increases in the direction of flow and with constant fluid density the value of the uniform velocity u_c increases. At some location downstream, δ reaches its maximum possible value, equal to the radius of the tube, and from that point onward the velocity profile does not change.

The region where δ increases, i.e., where the velocity profile changes, is known as the entrance region or hydrodynamically developing region. The region downstream from the axial location where δ reaches its maximum value and where the velocity profile does not change is the fully developed velocity profile or hydrodynamically fully developed region. Similarly, downstream of the location where heating or cooling of the fluid starts, the temperature profile changes in the direction of flow. But beyond a certain distance the dimensionless temperature profile does not change in the direction of flow. The region where

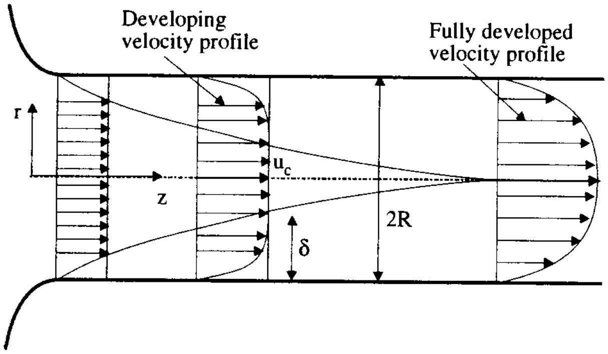

FIGURE 4.2.21 Developing and fully developed velocity profiles.

the dimensionless temperature profile changes is the thermally developing region or the thermal entrance region, and the region where the dimensionless temperature profile does not change is the thermally fully developed region. For simultaneously developing velocity and temperature profiles in laminar flows, the hydrodynamic and thermal entrance lengths are given by

$$\frac{L_e}{d} = 0.0565\text{Re}_d \tag{4.2.88}$$

$$\frac{L_{e,th}}{d} = 0.053\text{Re}_d\text{Pr} \qquad \text{Uniform heat flux} \tag{4.2.89}$$

$$\frac{L_{e,th}}{d} = 0.037\text{RePr} \qquad \text{Uniform surface temperature} \tag{4.2.90}$$

In most engineering applications, with turbulent flows, correlations for fully developed conditions can be used after about 10 diameters from where the heating starts.

Convective Heat Transfer Coefficient and Bulk Temperature. The reference temperature for defining the convective heat transfer coefficient is the bulk temperature T_b and the convective heat flux is given by

$$q'' = h\left(T_s - T_b\right) \tag{4.2.91}$$

The bulk temperature T_b is determined from the relation

$$T_b = \frac{\int_{A_c} \rho v C_p T dA_c}{\int_{A_c} \rho v C_p dA_c} \tag{4.2.92}$$

where A_c is the cross-sectional area perpendicular to the axis of the tube.

If the fluid is drained from the tube at a particular axial location and mixed, the temperature of the mixed fluid is the bulk temperature. It is also know as the mixing cup temperature. With heating or cooling of the fluid the bulk temperature varies in the direction of flow. In some cases we use the term *mean fluid temperature*, T_m, to represent the arithmetic mean of the fluid bulk temperatures at inlet and exit of the tube.

Heat Transfer Correlations

Laminar Flows — Entrance Region. For laminar flows in a tube with uniform surface temperature, in the entrance region the correlation of Sieder and Tate (1936) is

$$\overline{\text{Nu}_d} = 1.86\left(\frac{\text{Re}_d\text{Pr}}{L/d}\right)^{1/3}\left(\frac{\mu}{\mu_s}\right)^{0.14} \tag{4.2.93}$$

valid for

$$\frac{L}{d} < \frac{\text{Re}_d\text{Pr}}{8}\left(\frac{\mu}{\mu_s}\right)^{0.42} \qquad 0.48 < \text{Pr} < 16{,}700 \qquad 0.0044 < \frac{\mu}{\mu_s} < 9.75$$

The overbar in the Nusselt number indicates that it is formed with the average heat transfer coefficient over the entire length of the tube. Properties of the fluid are evaluated at the arithmetic mean of the inlet and exit bulk temperatures. In Equation (4.2.93) the heat transfer coefficient was determined from

$$q = \bar{h}\pi dL\left(T_s - \frac{T_{bi} + T_{be}}{2}\right) \tag{4.2.94}$$

Therefore, to find the total heat transfer rate with $\bar{h}$ from Equation (4.2.93) employ Equation (4.2.94).

Laminar Flows — Fully Developed Velocity and Temperature Profiles. Evaluate properties at the bulk temperature

$$\text{Uniform Surface Temperature} \qquad \text{Nu}_d = 3.66 \tag{4.2.95}$$

$$\text{Uniform Surface Heat Flux} \qquad \text{Nu}_d = 4.36 \tag{4.2.96}$$

Turbulent Flows. If the flow is turbulent, the difference between the correlations with uniform surface temperature and uniform surface heat flux is not significant and the correlations can be used for both cases. For turbulent flows, Gnielinsky (1976, 1990) recommends:

Evaluate properties at the bulk temperature.

$0.6 < \text{Pr} < 2000 \qquad 2300 < \text{Re}_d < 10^6 \qquad 0 < d/L < 1$

$$\text{Nu}_d = \frac{(f/2)(\text{Re}_d - 1000)\text{Pr}}{1 + 12.7(f/2)^{1/2}\left(\text{Pr}^{2/3} - 1\right)}\left[1 + \left(\frac{d}{L}\right)^{2/3}\right] \tag{4.2.97}$$

$$f = \left[1.58\ln(\text{Re}_d) - 3.28\right]^{-2} \tag{4.2.98}$$

f = friction factor = $2\tau_w/\rho v^2$.

To reflect the effect of variation of fluid properties with temperature, multiply the Nusselt numbers in Equation (4.2.97) by $(T_b/T_s)^{0.45}$ for gases and $(\text{Pr}/\text{Pr}_s)^{0.11}$ for liquids where the temperatures are absolute, and T and Pr with a subscript s are to be evaluated at the surface temperature. The equations can be used to evaluate the heat transfer coefficient in the developing profile region. To determine the heat transfer coefficient in the fully developed region set $d/L = 0$. A simpler correlation (fully developed region) is the Dittus–Boelter (1930) equation. Evaluate properties at T_b.

$0.7 \le \text{Pr} \le 160 \qquad \text{Re}_d > 10{,}000 \qquad d/L > 10$

$$\text{Nu}_d = 0.023\text{Re}_d^{4/5}\text{Pr}^n \tag{4.2.99}$$

where $n = 0.4$ for heating ($T_s > T_b$) and $n = 0.3$ for cooling ($T_s < T_b$).

For liquid metals with $\text{Pr} \ll 1$ the correlations due to Sleicher and Rouse (1976) are

Uniform surface temperature:

$$\text{Nu}_{d,b} = 4.8 + 0.0156\text{Re}_{d,f}^{0.85}\text{Pr}_s^{0.93} \tag{4.2.100}$$

Uniform heat flux:

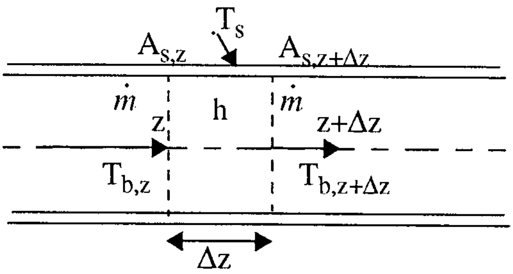

FIGURE 4.2.22 Elemental length of a tube for determining heat transfer rate.

$$\mathrm{Nu}_{d,b} = 6.3 + 0.0167\mathrm{Re}_{d,f}^{0.85}\mathrm{Pr}_s^{0.93} \tag{4.2.101}$$

Subscripts *b*, *f*, and *s* indicate that the variables are to be evaluated at the bulk temperature, film temperature (arithmetic mean of the bulk and surface temperatures), and surface temperature, respectively.

In the computations of the Nusselt number the properties (evaluated at the bulk temperature) vary in the direction of flow and hence give different values of *h* at different locations. In many cases a representative average value of the convective heat transfer coefficient is needed. Such an average value can be obtained either by taking the arithmetic average of the convective heat transfer coefficients evaluated at the inlet and exit bulk temperatures or the convective heat transfer coefficient evaluated at the arithmetic mean of the inlet and exit bulk temperatures. If the variation of the convective heat transfer coefficient is large, it may be appropriate to divide the tube into shorter lengths with smaller variation in the bulk temperatures and evaluating the average heat transfer coefficient in each section.

Uniform Surface Temperature — Relation between the Convective Heat Transfer Coefficient and the Total Heat Transfer Rate: With a uniform surface temperature, employing an average value of the convective heat transfer coefficient the local convective heat flux varies in the direction of flow. To relate the convective heat transfer coefficient to the temperatures and the surface area, we have, for the elemental length Δ*z* (Figure 4.2.22).

$$\dot{m}C_p \frac{dT_b}{dz} = h\frac{dA_s}{dz}\left(T_s - T_b\right) \tag{4.2.102}$$

Assuming a suitable average convective heat transfer coefficient over the entire length of the tube, separating the variables, and integrating the equation from $z = 0$ to $z = L$, we obtain

$$\ln\frac{T_s - T_{be}}{T_s - T_{bi}} = -\frac{hA_s}{\dot{m}C_p} \tag{4.2.103}$$

Equation (4.2.103) gives the exit temperature. For a constant-density fluid or an ideal gas, the heat transfer rate is determined from

$$q = \dot{m}C_p\left(T_{be} - T_{bi}\right) \tag{4.2.104}$$

Equation (4.2.103) was derived on the basis of uniform convective heat transfer coefficient. However, if the functional relationship between *h* and T_b is known, Equation (4.2.102) can be integrated by substituting the relationship. The convective heat transfer coefficient variation with T_b for water in two tubes of different diameters for two different flow rates is shown in Figure 4.2.23. From the figure it is clear that *h* can be very well approximated as a linear function of *T*. By substituting such a linear function relationship into Equation (4.2.102), it can be shown that

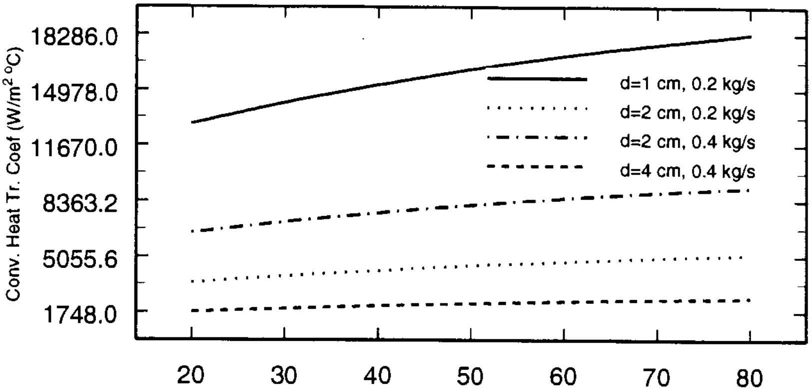

FIGURE 4.2.23 Variation of h with T_b in 1-, 2-, and 4-cm-diameter tubes with water flow rates of 0.2 kg/sec and 0.4 kg/sec with uniform surface temperature.

$$\ln \frac{h_i}{h_e} \frac{T_s - T_{be}}{T_s - T_{bi}} = -\frac{h_s A_s}{\dot{m} C_p} \tag{4.2.105}$$

where h_i, h_e, and h_s are the values of the convective heat transfer coefficient evaluated at bulk temperatures of T_{bi}, T_{be}, and T_s, respectively. Although it has been demonstrated that h varies approximately linearly with the bulk temperature with water as the fluid, the variation of h with air and oil as the fluid is much smaller and is very well approximated by a linear relationship. For other fluids it is suggested that the relationship be verified before employing Equation (4.2.105). [**Note:** It is tempting to determine the heat transfer rate from the relation

$$q = hA_s \frac{(T_s - T_{be}) + (T_s - T_{bi})}{2}$$

Replacing q by Equation (4.2.104) and solving for T_{be} for defined values of the mass flow rate and tube surface area, the second law of thermodynamics will be violated if $hA_s / \dot{m}C_p > 2$. Use of Equation (4.2.103) or (4.2.105) ensures that no violation of the second law occurs however large A_s is.]

Uniform Surface Heat Flux: If the imposed heat flux is known, the total heat transfer rate for a defined length of the tube is also known. From Equation (4.2.104) the exit temperature of the fluid is determined. The fluid temperature at any location in the pipe is known from the heat transfer rate up to that location ($q = q''A_s$) and Equation (4.2.104). The convective heat transfer coefficient is used to find the surface temperature of the tube.

Temperature Variation of the Fluid with Uniform Surface Temperature and Uniform Heat Flux: The fluid temperature variations in the two cases are different. With the assumption of uniform heat transfer coefficient, with a uniform surface temperature the heat flux decreases in the direction of flow leading to a progressively decreasing rate of temperature change in the fluid with axial distance. With uniform heat flux, the surface and fluid temperatures vary linearly except in the entrance region where the higher heat transfer coefficient leads to a smaller difference between the surface and fluid temperatures. The variation of the fluid temperature in the two cases is shown in Figure 4.2.24.

Convective Heat Transfer in Noncircular Tubes

Laminar Flows: The Nusselt numbers for laminar flows have been analytically determined for different noncircular ducts. Some of them can be found in Kakac et al. (1987), Kays and Crawford (1993), and Burmeister (1993). A few of the results are given below. The characteristic length for forming the Reynolds number and Nusselt number is the hydraulic mean diameter defined as

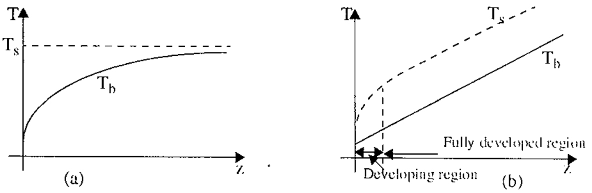

FIGURE 4.2.24 Variation of fluid temperature in a tube with (a) uniform surface temperature and (b) uniform heat flux.

$$d_h = \frac{4 \text{ cross-sectional area}}{\text{wetted perimeter}}$$

Infinite parallel plates: a = spacing between plates, $d_h = 2a$

Both plates maintained at uniform and equal temperatures: Nu = 7.54
Both plates with imposed uniform and equal heat fluxes: Nu = 8.24

Rectangular ducts: a = longer side, b = shorter side, $d_h = 2ab/(a + b)$

b/a	1	0.7	0.5	0.25	0.125
Uniform surface temperature	2.98	3.08	3.39	4.44	5.6
Uniform heat flux*	3.61	3.73	4.12	5.33	6.49

Equilateral triangle: $d_h = a/3^{1/2}$, a = length of each side

Uniform surface temperature: Nu = 2.35
Uniform surface heat flux:* Nu = 3.0

Coaxial tubes: With coaxial tubes many different cases arise — each tube maintained at uniform but different temperatures, each tube subjected to uniform but different heat fluxes (an insulated surface is a special case of imposed heat flux being zero), or a combinations of uniform surface temperature of one tube and heat flux on the other. The manner in which the heat transfer coefficient is determined for uniform but different heat fluxes on the two tubes is described below. Define:

$$d_h = 2(r_o - r_i) \qquad r^* = r_i/r_o$$

$$q_i'' = h_i(T_i - T_b) \qquad \mathrm{Nu}_i = \frac{h_i d_h}{k} \qquad q_o'' = h_o(T_o - T_b) \qquad \mathrm{Nu}_o = \frac{h_o d_h}{k}$$

$$q_o'' = 0 \qquad \mathrm{Nu}_{ii} = \frac{h_i d_h}{k} \quad \text{and} \quad q_i'' = 0 \qquad \mathrm{Nu}_{oo} = \frac{h_o d_h}{k}$$

Then

$$\mathrm{Nu}_i = \frac{\mathrm{Nu}_{ii}}{1 - \dfrac{q_o''}{q_i''}\theta_i^*} \quad \text{and} \quad \mathrm{Nu}_o = \frac{\mathrm{Nu}_{oo}}{1 - \dfrac{q_i''}{q_o''}\theta_o^*} \tag{4.2.106}$$

Some of the values needed for the computations of Nu_i and Nu_o (taken from Kays and Crawford, 1993) are given in the Table 4.2.6.

---

* Uniform axial heat flux but circumferentially uniform surface temperature.

TABLE 4.2.6 Values for Use with Equation (4.2.106)

r^*	Nu_{ii}	Nu_{oo}	θ_i^*	θ_o^*
0.05	17.81	4.792	2.18	0.0294
0.1	11.91	4.834	1.383	0.0562
0.2	8.499	4.883	0.905	0.1041
0.4	6.583	4.979	0.603	0.1823
0.6	5.912	5.099	0.473	0.2455
0.8	5.58	5.24	0.401	0.299
1.0	5.385	5.385	0.346	0.346

For a more detailed information on heat transfer and friction factors for laminar flows in noncircular tubes refer to Kakac et al. (1987).

Turbulent Flows: For noncircular tubes, estimates of the convective heat transfer coefficient can be obtained by employing equations for circular tubes with d_h replacing d in the computations of the Reynolds and Nusselt numbers. To determine the heat transfer coefficients in developing regions and for more-accurate values with turbulent flows in noncircular tubes refer to Kakac et al. (1987) and the references in that book.

Mixed Convection

If the fluid velocity is low, the effect of natural convection becomes significant and the heat transfer rate may be increased or decreased by natural convection. From a review of experimental results, Metais and Eckert (1964) developed maps to delineate the different regimes where one or the other mode is dominant and where both are significant. Figure 4.2.25 and Figure 4.2.26 show the relative significance of natural and forced convection in vertical and horizontal tubes. The maps are applicable for $10^{-2} < \Pr(d/L) < 1$ where d and L are the diameter and the axial length of the tube. The maps show the limits of forced and natural convection regimes. The limits are delineated "in such a way that the actual heat flux under the combined influence of the forces does not deviate by more than 10 percent from the heat flux that would be caused by the external forces alone or by the body forces alone." The Grashof number is based on the diameter of the tube.

For flows in horizontal tubes, correlations were developed for the mixed convection regime in isothermal tubes by Depew and August (1971) and for uniform heat flux by Morcos and Bergles (1975).

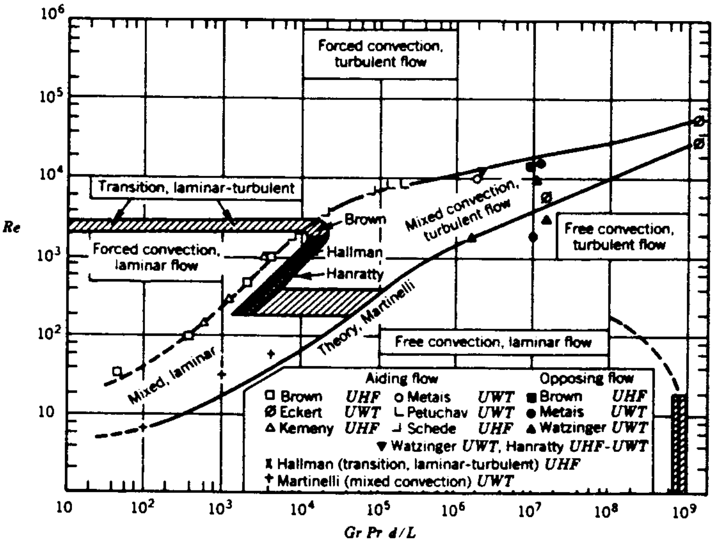

FIGURE 4.2.25 Map delineating forced, mixed, and natural convection — vertical tubes.

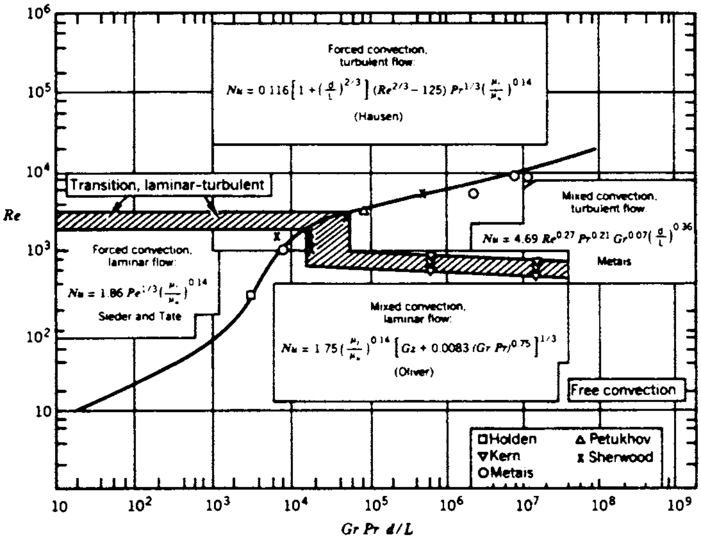

FIGURE 4.2.26 Map delineating forced, mixed, and natural convection — horizontal tubes.

Uniform Surface Temperature. Fully developed velocity profile, developing temperature profile:

$L/d < 28.4$ $\quad$ $25 < \text{Gz} < 712$ $\quad$ $0.7 \times 10^5 < \text{Gr} < 9.9 \times 10^5$
μ_s = dynamic viscosity, evaluated at the wall temperature
All other properties at the average bulk temperature of the fluid

$$\text{Gz} = \frac{\dot{m}C_p}{kL} \qquad \text{Gr} = g\beta\Delta T\, d^3/\nu^2$$

$$\text{Nu}_d = 1.75\left[\text{Gz} + 0.12\left(\text{Gz}\text{Gr}^{1/3}\text{Pr}^{0.36}\right)^{0.88}\right]^{1/3}\left(\mu_b/\mu_s\right)^{0.14} \tag{4.2.107}$$

Uniform Heat Flux. Properties at $(T_s + T_b)/2$: $3 \times 10^4 < \text{Ra} < 10^6$, $4 < \text{Pr} < 175$, $2 < hd^2/(k_w t) < 66$, k_w = tube wall thermal conductivity, t = tube wall thickness.

$$\text{Gr}_d^* = g\beta d^4 q_w''/\left(\nu^2 k\right) \qquad P_w = kd/\left(k_w t\right) \qquad \text{Ra}_d = g\beta\Delta T\, d^3\text{Pr}/\nu^2$$

$$\text{Nu}_d = \left\{4.36^2 + \left[0.145\left(\frac{\text{Gr}_d^*\text{Pr}^{1.35}}{P_w^{0.25}}\right)^{0.265}\right]^2\right\}^{0.5} \tag{4.2.108}$$

In Equation (4.2.107) and (4.2.108) evaluate fluid properties at the arithmetic mean of the bulk and wall temperatures.

Nomenclature

A_s	surface area
d	diameter
d_h	hydraulic mean diameter
f	friction factor

h	convective heat transfer coefficient
k	fluid thermal conductivity
$\mathrm{L_e}$	hydrodynamic entrance length
$\mathrm{L_{e,th}}$	thermal entrance length
Nu_d	Nusselt number
Nu_{ii}	Nusselt number with only inner tube heated
Nu_{oo}	Nusselt number with only outer tube heated
Pr	Prandtl number
q''	heat flux
q_i''	heat flux on the inner tube surface
q_o''	heat flux on the outer tube surface
Re_d	Reynolds number ($\rho vd/\mu$)
$\mathrm{T_b}$	bulk temperature
$\mathrm{T_s}$	surface temperature
v	average fluid velocity
μ	dynamic viscosity
μ_s	dynamic viscosity at surface temperature
ρ	fluid density

4.3 Radiation

Michael F. Modest

Nature of Thermal Radiation

All materials continuously emit and absorb radiative energy by lowering or raising their molecular energy levels. This thermal radiative energy may be viewed as consisting of electromagnetic waves or of massless energy parcels, called **photons**. Electromagnetic waves travel through any medium at the speed of light c, which is $c_0 = 2.998 \times 10^8$ m/sec in vacuum and approximately the same in most gases such as air and combustion products. They are characterized by their wavelength λ (usually measured in $\mu\text{m} = 10^{-6}$ m) or frequency ν (usually measured in cycles/s = Hz), which are related by

$$\nu = c/\lambda \tag{4.3.1}$$

The strength and wavelengths of **emission** and **absorption** depend on the temperature and nature of the material.

The ability of photons to travel unimpeded through vacuum and gases makes thermal radiation the dominant mode of heat transfer in vacuum, low-pressure environments and outer space applications (due to the near absence of conduction and convection). Its temperature dependence (as given by Equation 4.3.3), on the other hand, guarantees that radiative heat transfer is of utmost importance in high-temperature applications (including solar radiation with the sun a high-temperature heat source at an effective temperature of $T_{\text{sun}} = 5777$ K).

When an electromagnetic wave traveling through a gas (or vacuum) strikes the surface of a medium, the wave may be partly or totally reflected, and any nonreflected part will penetrate into the medium. If a wave passes through a medium without any attenuation, the material is called **transparent**. A body with partial attenuation is known as **semitransparent**, and a body through which none of the incoming radiation penetrates is called **opaque**. Most gases are rather transparent to radiation (except for narrow spectral regions, called absorption bands) and most solids tend to be strong absorbers for most wavelengths, making them opaque over a distance of a few nanometers (electrical conductors, i.e., metals) to a few micrometers (ceramics, semiconductors), or more (dielectrics).

Blackbody Radiation

The total amount of radiative energy emitted from a surface into all directions above it is termed emissive power; a distinction is made between spectral (at a given wavelength λ per unit wavelength) and total (encompassing all wavelengths) emissive power. The magnitude of emissive power depends on wavelength λ, temperature T, and a surface property, called emittance ε, that relates the ability of a surface to emit radiative energy to that of an ideal surface, which emits the maximum possible energy (at a given wavelength and temperature). Such an ideal surface is known as a "blackbody" or "black surface" because it absorbs all incoming radiation; i.e., it reflects no radiation and is, therefore, invisible (black) to the human eye. The spectral distribution of the emissive power of a black surface (i.e., its dependence on the spectral variable, for example, λ) is given by Planck's law as

$$E_{b\lambda} = \frac{C_1}{\lambda^5\left[e^{C_2/\lambda T} - 1\right]}, \quad C_1 = 3.7419 \times 10^{-16}\ \mathrm{Wm}^2, \quad C_2 = 14,388\ \mu\mathrm{mK} \tag{4.3.2}$$

where C_1 and C_2 are sometimes called Planck function constants, or the first and second radiation constant, respectively. The total emissive power of a blackbody is given by

$$E_b = \int_0^\infty E_{b\lambda}\, d\lambda = \sigma T^4, \quad \sigma = 5.670 \times 10^{-8}\ \mathrm{W/m^2K^4} \tag{4.3.3}$$

with σ known as the Stefan–Boltzmann constant. Figure 4.3.1 shows the spectral solar irradiation that impinges on Earth, which closely resembles the spectrum of a blackbody at 5777 K. The general behavior of Planck's law is depicted in Figure 4.3.2, together with the fractional emissive power, $f(\lambda T)$, defined as

$$f(\lambda T) = \frac{1}{E_b}\int_0^\lambda E_{b\lambda}(\lambda, T)\, d\lambda \tag{4.3.4}$$

Note that 80% of all blackbody emission takes place between the wavelengths of $\lambda T > 2200\ \mu$mK and $\lambda T < 9400\ \mu$mK. This implies that, for typical high-temperature heat transfer applications in the range between 1000 and 2000 K, infrared wavelengths in the range 1 μm < λ < 10 μm govern the heat transfer

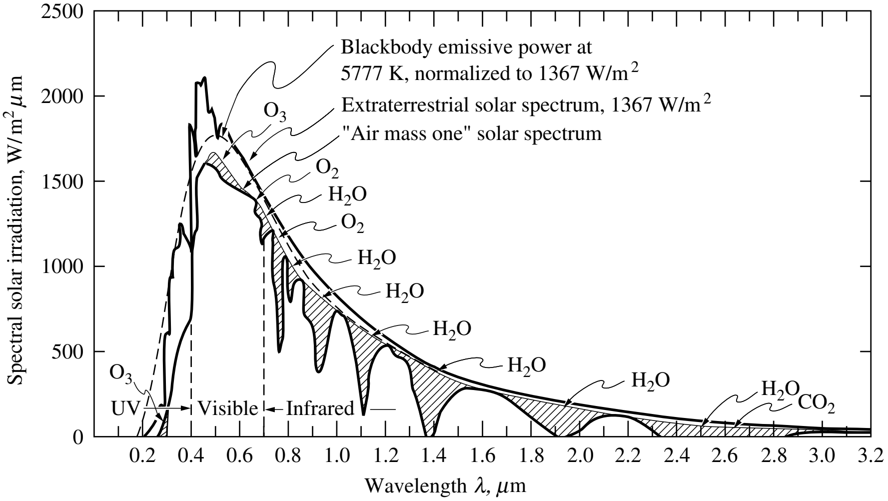

FIGURE 4.3.1 Solar irradiation onto Earth.

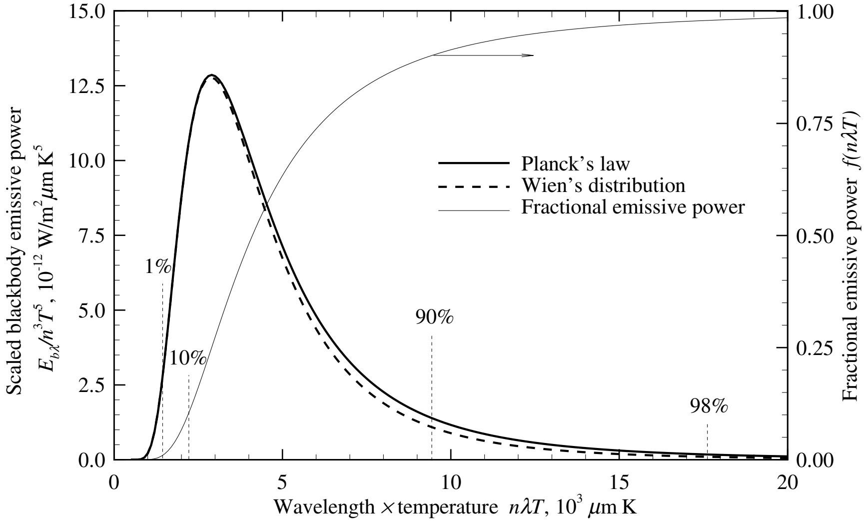

FIGURE 4.3.2 Normalized blackbody emissive power spectrum.

rates. For solar applications, shorter wavelengths, down to λ ≅ 0.4 μm, are also important. Also shown in Figure 4.3.2 is Wien's law:

$$E_{b\lambda} = \frac{C_1}{\lambda^5} e^{-C_2/\lambda T} \tag{4.3.5}$$

which approximates Planck's law accurately over the part of the spectrum that is important to heat transfer and easier to manipulate mathematically.

Example 4.3.1

What fraction of total solar emission falls into the visible spectrum (0.4 to 0.7 μm)?

Solution. With a solar temperature of 5777 K, it follows that for

$$\lambda_1 = 0.4\ \mu\text{m}, \qquad \lambda_1 T_{\text{sun}} = 0.4 \times 5777 = 2311\ \mu\text{mK}$$

and for

$$\lambda_2 = 0.7\ \mu\text{m}, \qquad \lambda_2 T_{\text{sun}} = 0.7 \times 5777 = 4044\ \mu\text{mK}$$

From Figure 4.3.2, one can estimate $f(\lambda_1 T_{\text{sun}}) \cong 12\%$ and $f(\lambda_2 T_{\text{sun}}) \cong 49\%$. Thus, the visible fraction of sunlight is 49 – 12 ≅ 37%: with a bandwidth of only 0.3 μm, the human eye responds to approximately 37% of all emitted sunlight.

Radiative Exchange between Opaque Surfaces

Radiative Properties of Surfaces

Strictly speaking, the surface of an enclosure wall can only reflect radiative energy and allow a part of it to penetrate into the substrate. A surface cannot absorb or emit photons; attenuation takes place inside the solid, as does emission of radiative energy (with some of the emitted energy escaping through the surface into the enclosure). In practical systems, the thickness of the surface layer over which absorption of **irradiation** from inside the enclosure occurs is very small compared with the overall dimension of an enclosure — usually a few nanometers for metals and a few micrometers for most nonmetals. The same may be said about emission from within the walls that escapes into the enclosure. Thus, in the case of opaque walls, it is customary to speak of absorption by and emission from a "surface," although a thin surface layer is implied.

Four fundamental radiative properties are defined:

Reflectance, $$\rho \equiv \frac{\text{reflected part of incoming radiation}}{\text{total incoming radiation}} \tag{4.3.6a}$$

Absorptance, $$\alpha \equiv \frac{\text{absorbed part of incoming radiation}}{\text{total incoming radiation}} \tag{4.3.6b}$$

Transmittance, $$\tau \equiv \frac{\text{transmitted part of incoming radiation}}{\text{total incoming radiation}} \tag{4.3.6c}$$

Emittance, $$\varepsilon \equiv \frac{\text{energy emitted from a surface}}{\text{energy emitted by a black surface at same temperature}} \tag{4.3.6d}$$

Because all incoming radiation must be reflected, absorbed, or transmitted, it follows that

$$\rho + \alpha + \tau = 1 \tag{4.37}$$

In most practical applications, surface layers are thick enough to be opaque ($\tau = 0$, leading to $\rho + \alpha = 1$. All four properties may be functions of wavelength, temperature, incoming direction (except emittance), and outgoing direction (except absorptance).

Directional Behavior. For heat transfer applications, the dependence on incoming direction for absorptance (as well as ρ and τ) and outgoing direction for emittance is generally weak and is commonly neglected; i.e., it is assumed that the surface absorbs and emits **diffusely**. Then, for an opaque surface, at any given wavelength

$$\varepsilon_\lambda = \alpha_\lambda = 1 - \rho_\lambda \tag{4.38}$$

Published values of emittance are generally "normal emittance" (the directional value of ε_λ in the direction perpendicular to the surface) or "hemispherical emittance" (an average value over all outgoing directions). The difference between these two values is often smaller than experimental accuracy and/or repeatability.

Reflected energy (due to a single, distinct incoming direction) may leave the surface in a single direction ("specular" reflection, similar to reflection from a mirror for visible light), or the reflection may spread out over all possible outgoing directions. In the extreme case of equal amounts going into all directions, "diffuse" reflection takes place. Smooth surfaces (as compared with the wavelength of radiation) tend to be specular reflectors, while rough surfaces tend to be more or less diffusely reflecting. Analysis is vastly simplified if diffuse reflections are assumed. Research has shown that — except for some extreme geometries and irradiation conditions susceptible to beam channeling (irradiated open cavities, channels with large aspect ratios) — radiative heat transfer rates are only weakly affected by the directional distribution of reflections. Therefore, it is common practice to carry out radiative heat transfer calculations assuming only diffuse reflections.

Spectral Dependence. The emittance of a surface generally varies strongly and in complex ways with wavelength, depending on the material, surface layer composition, and surface structure (roughness).

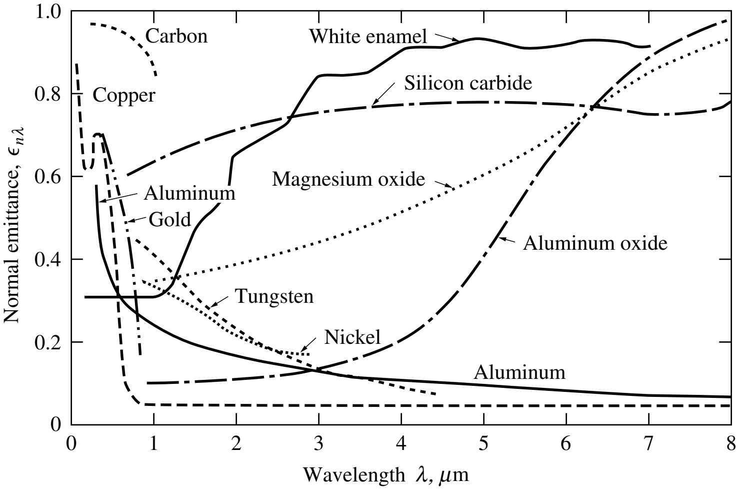

FIGURE 4.3.3 Normal, spectral emittances for selected materials.

Therefore, unlike bulk material properties (such as thermal conductivity), the surface emittance may display significant differences between two ostensibly identical samples, and even for the same sample measured at different times (due to surface roughness and contamination). Despite these difficulties, surfaces may be loosely grouped into two categories — metals and nonconductors (dielectrics) — and some generalizations can be made.

Polished Metals. Smooth, purely metallic surfaces (i.e., without any nonmetallic surface contamination, such as metal oxides) tend to have very low emittances in the infrared. For many clean metals, $\varepsilon_\lambda < 0.1$ for $\lambda > 2$ µm, and spectral as well as temperature dependence is generally well approximated by the proportionality $\varepsilon_\lambda \propto \sqrt{T/\lambda}$ in the infrared. However, for shorter wavelengths ($\lambda < 1$ µm), emittance values may become quite substantial, and temperature dependence is usually reversed (decreasing, rather than increasing, with temperature). Typical room temperature behavior of several metals is shown in Figure 4.3.3. Caution needs to be exercised when choosing an emittance value for a metal surface; unless extraordinary care is taken to keep a polished metal clean (i.e., free from oxidation and/or surface contamination), its emittance may soon become several times the value of the original, polished specimen (for example, consider the formation of aluminum oxide on top of aluminum, Figure 4.3.3).

Ceramics and Refractories. Smooth ceramics tend to have fairly constant and intermediate emittance over the near- to mid-infrared, followed by a sharp increase somewhere between 4 and 10 µm. At short wavelengths, these materials display strong decreases in emittance, so a number of them may appear white to the human eye even though they are fairly black in the infrared. The temperature dependence of the emittance of ceramics is rather weak; generally, a slight increase with temperature is observed in the infrared. The spectral emittance of a few ceramics is also shown in Figure 4.3.3.

Other Nonconductors. The behavior of most electrically nonconducting materials is governed by surface structure, nonhomogeneity, dopants, porosity, flaws, surface films, etc. The emittance may vary irregularly across the spectrum because of various emission bands, influence of flaws, etc., thus making any generalization impossible. This irregularity may be exploited to obtain surfaces of desired spectral behavior, so-called selective surfaces. Some selective surfaces (as compared with a common steel) are depicted in Figure 4.3.4. For a solar collector, it is desirable to have a high spectral emittance for short wavelengths $\lambda < 2.5$ µm (strong absorption of solar irradiation) and a low value for $\lambda > 2.5$ µm (to minimize re-emission from the collector). The opposite is true for a spacecraft radiator panel used to reject heat into space.

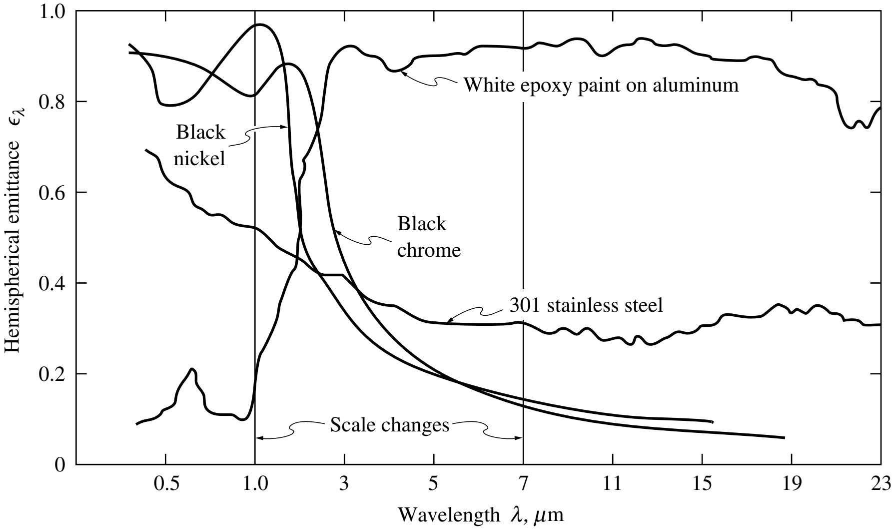

FIGURE 4.3.4 Spectral, hemispherical emittance of several spectrally selective surfaces.

It is clear that (1) values of spectral surface emittance are subject to great uncertainty; and (2) only a relatively small range of infrared wavelengths are important. Therefore, it is often assumed that the surfaces are "**gray**," i.e., the emittance is constant across (the important fraction of) the spectrum, $\varepsilon_\lambda \neq \varepsilon_\lambda(\lambda)$, because this assumption also vastly simplifies analysis. Table 4.3.1 gives a fairly detailed listing of total emittances of various materials, defined as

$$\varepsilon(T) = \frac{1}{E_b(T)} \int_0^\infty \varepsilon_\lambda(\lambda, T) E_{b\lambda}(T)\, d\lambda \tag{4.3.9}$$

which may be enlisted for a gray analysis.

View Factors

In many engineering applications, the exchange of radiative energy between surfaces is virtually unaffected by the medium that separates them. Such (radiatively) *nonparticipating media* include vacuum as well as monatomic and most diatomic gases (including air) at low to moderate temperature levels (i.e., before ionization and dissociation occurs). Examples include spacecraft heat rejection systems, solar collector systems, radiative space heaters, illumination problems, and so on.

It is common practice to simplify the analysis by making the assumption of an *idealized enclosure* and/or *ideal surface properties*. The greatest simplification arises if all surfaces are black: for such a situation, no reflected radiation needs to be accounted for, and all emitted radiation is diffuse (i.e., the radiative energy leaving a surface does not depend on direction). The next level of difficulty arises if surfaces are assumed to be gray diffuse emitters (and thus absorbers) as well as gray diffuse reflectors. The vast majority of engineering calculations are limited to such ideal surfaces, particularly because the effects of nondiffuse reflections are usually weak (see discussion in previous section).

Thermal radiation is generally a long-range phenomenon. This is always the case in the absence of a participating medium because photons will travel unimpeded from surface to surface. Therefore, performing a thermal radiation analysis for one surface implies that all surfaces, no matter how far removed, that can exchange radiative energy with one another must be considered simultaneously. How much energy any two surfaces exchange depends in part on their size, separation, distance, and orientation; this leads to geometric functions known as **view factors**, which are defined as

TABLE 4.3.1 Total Emittance and Solar Absorptance of Selected Surfaces

	Temperature (°C)	Total Normal Emittance	Extraterrestrial Solar Absorptance

$$F_{i-j} = \frac{\text{diffuse energy leaving } A_i \text{ directly toward and intercepted by } A_j}{\text{total diffuse energy leaving } A_i} \tag{4.3.10}$$

In order to make a radiative energy balance, it is always necessary to consider an entire *enclosure* rather than an infinitesimal control volume (as is normally done for other modes of heat transfer, i.e., conduction or convection). The enclosure must be closed so that irradiation from all possible directions can be accounted for, and the enclosure surfaces must be *opaque* so that all irradiation is accounted for, for each direction. In practice, an incomplete enclosure may be closed by introducing artificial surfaces.

An enclosure may be idealized in two ways, as indicated in Figure 4.3.5: by replacing a complex geometric shape with a few simple surfaces and by assuming surfaces to be isothermal with constant (i.e., average) heat flux values across them. Obviously, the idealized enclosure approaches the real enclosure for sufficiently small isothermal subsurfaces.

Mathematically, the view factor needs to be determined from a double surface integral, i.e.,

$$F_{i-j} = \frac{1}{A_i} \int_{A_i} \int_{A_j} \frac{\cos\theta_i \cos\theta_j}{\pi S_{ij}^{\;2}} dA_j dA_i \tag{4.3.11}$$

where θ_i and θ_j are the angles between the surface normals on A_i and A_j, respectively, and the line (of length S_{ij}) connecting two points on the two surfaces.

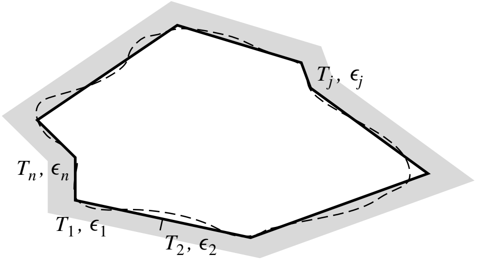

FIGURE 4.3.5 Real and ideal enclosures for radiative transfer calculations.

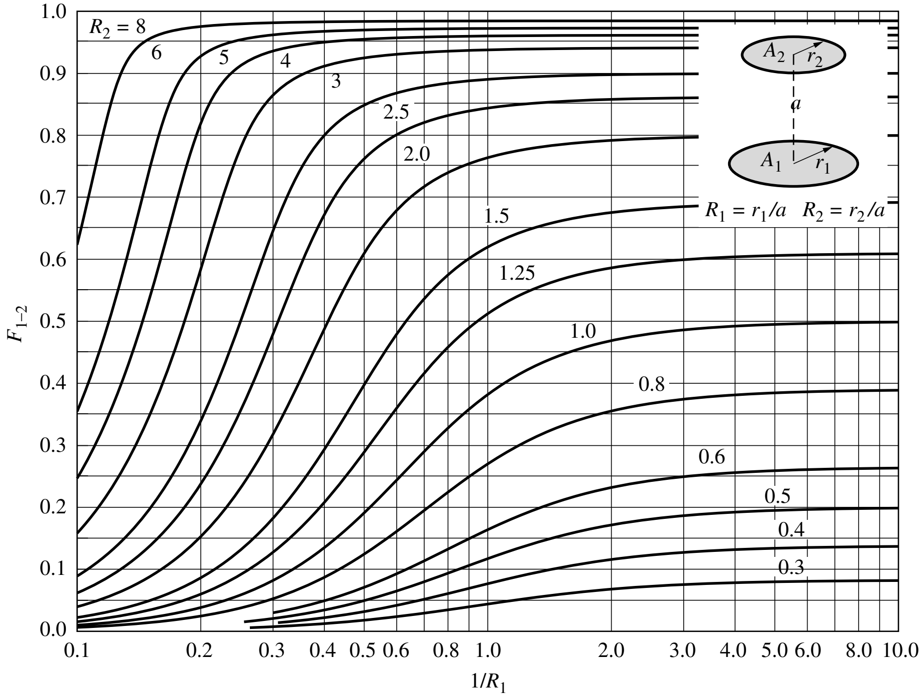

FIGURE 4.3.6 View factor between parallel, coaxial disks of unequal radius.

Analytical solutions to Equation (4.3.11) may be found for relatively simple geometries. A few graphical results for important geometries are shown in Figure 4.3.6 to Figure 4.3.8. More extensive tabulations, as well as analytical expressions, may be found in textbooks on the subject area (Modest, 2003; Siegel and Howell, 2002) as well as view factor catalogs (Howell, 1982). For nontrivial geometries, view factors must be calculated numerically, by (1) numerical quadrature of the double surface integral in Equation (4.3.11); or (2) converting Equation (4.3.11) into a double-line integral, followed by numerical quadrature; or (3) a Monte Carlo method (statistical sampling and tracing of selected light rays).

View Factor Algebra. For simple geometries, analytical values can often be found by expressing the desired view factor in terms of other, known ones. This method is known as view factor algebra, by manipulating the two relations,

Reciprocity rule:

$$A_i F_{i-j} = A_j F_{j-i} \tag{4.3.12}$$

Summation rule:

$$\sum_{j=1}^{N} F_{i-j} = 1, \quad i = 1, N \qquad (4.3.13$$

assuming that the (closed) configuration consists of N surfaces. The reciprocity rule follows immediately from Equation (4.3.11), while the summation rule simply states that the fractional energies leaving surface A_i must add up to a whole.

Example 4.3.2

Assuming the view factor for a finite corner as shown in Figure 4.3.8 is known, determine the view factor F_{3-4}, between the two perpendicular strips as shown in Figure 4.3.9.

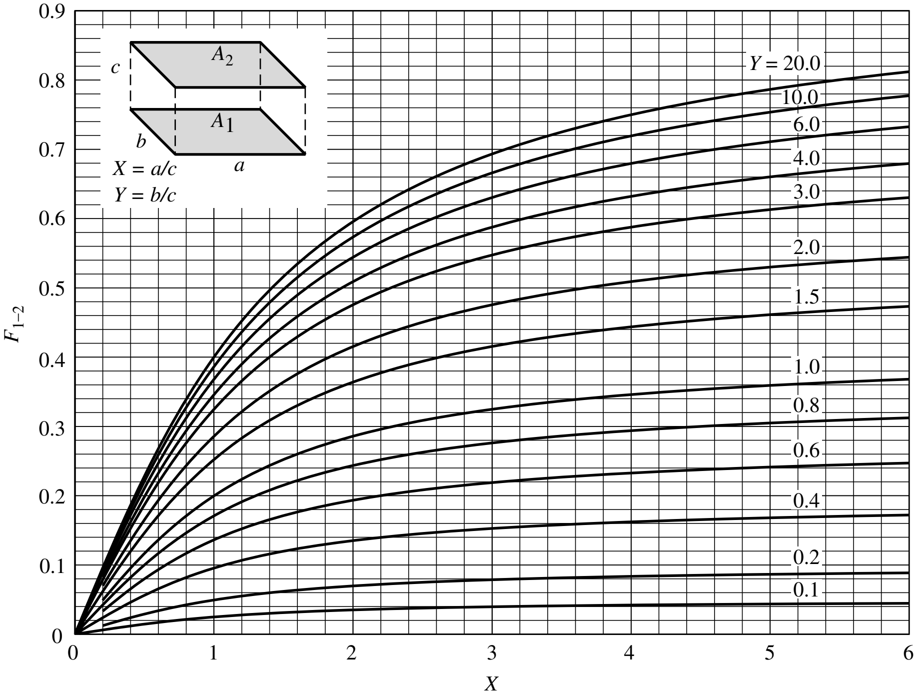

FIGURE 4.3.7 View factor between identical, parallel, directly opposed rectangles.

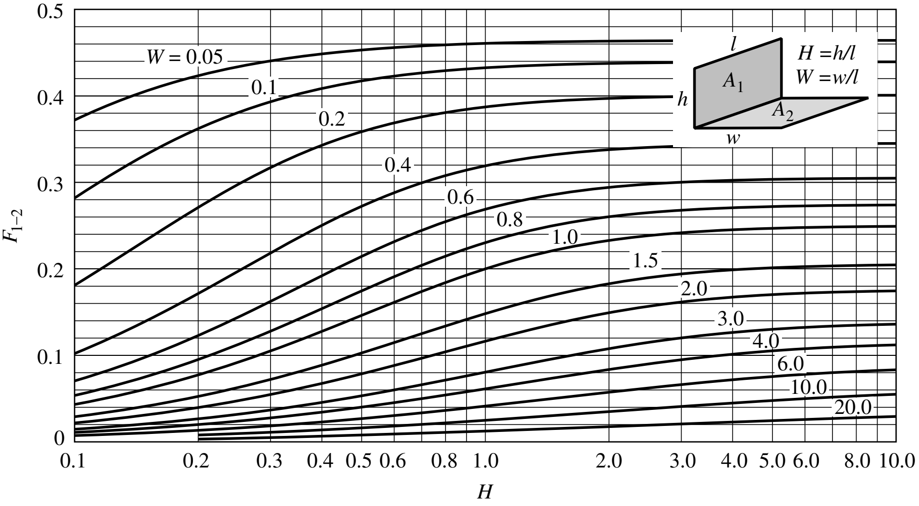

FIGURE 4.3.8 View factor between perpendicular rectangles with common edge.

Solution. From the definition of the view factor, and because the energy traveling to A_4 is the energy going to A_2 and A_4 minus the one going to A_2, it follows that

$$F_{3-4} = F_{3-(2+4)} - F_{3-2}$$

and, using reciprocity,

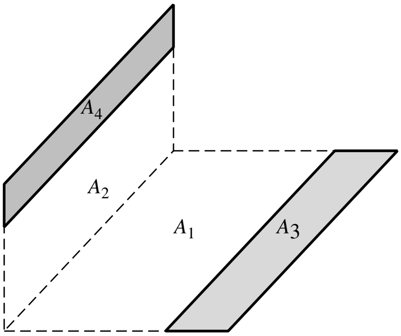

FIGURE 4.3.9 Configuration for Example 4.3.2 (strips on a corner piece).

$$F_{3-4} = \frac{1}{A_3}\left[\left(A_2 + A_4\right)F_{(2+4)-3} - A_2 F_{2-3}\right]$$

Similarly,

$$F_{3-4} = \frac{A_2 + A_4}{A_3}\left(F_{(2+4)-(1+3)} - F_{(2+4)-1}\right) - \frac{A_2}{A_3}\left(F_{2-(1+3)} - F_{2-1}\right)$$

All view factors on the right-hand side are corner pieces and thus are known from Figure 4.3.8.

Crossed-Strings Method. A special type of view factor algebra may be used to determine all the view factors in long enclosures with constant cross section. The method is called the crossed-strings method because the view factors can be determined experimentally with four pins, a roll of string, and a yardstick. Consider the configuration in Figure 4.3.10, which shows the cross section of an infinitely long enclosure, continuing into and out of the plane of the figure. Repeatedly applying reciprocity and summation rules allows the evaluation of F_{1-2} as

$$F_{1-2} = \frac{\left(A_{bc} + A_{ad}\right) - \left(A_{ac} + A_{bd}\right)}{2A_1} \tag{4.3.14}$$

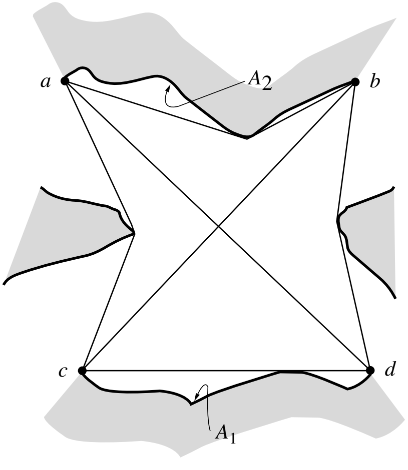

FIGURE 4.3.10 The crossed-strings method for arbitrary two-dimensional configurations.

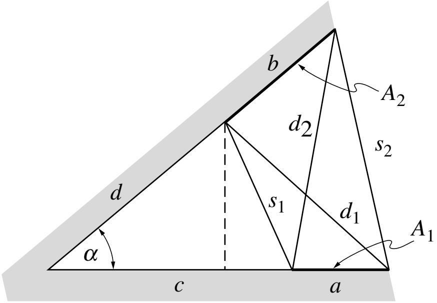

FIGURE 4.3.11 Infinitely long wedge-shaped groove for Example 4.3.3.

where A_{ab} is the area (per unit depth) defined by the length of the string between points *a* and *b*, etc. This formula is easily memorized by looking at the configuration between any two surfaces as a generalized "rectangle," consisting of A_1, A_2, and the two sides A_{ac} and A_{bd}. Then

$$F_{1-2} = \frac{\text{diagonals} - \text{sides}}{2 \times \text{originating area}} \tag{4.3.15}$$

Example 4.3.3

Calculate F_{1-2} for the configuration shown in Figure 4.3.11.

Solution. From the figure, it is obvious that

$$s_1^2 = (c - d\cos\alpha)^2 + d^2\sin^2\alpha = c^2 + d^2 - 2cd\cos\alpha$$

Similarly,

$$s_2^2 = (a+c)^2 + (b+d)^2 - 2(a+c)(b+d)\cos\alpha$$

$$d_1^2 = (a+c)^2 + d^2 - 2(a+c)d\cos\alpha$$

$$d_2^2 = c^2 + (b+d)^2 - 2c(b+d)\cos\alpha$$

and

$$F_{1-2} = \frac{d_1 + d_2 - (s_1 + s_2)}{2a}$$

Radiative Exchange between Opaque Surfaces (Net Radiation Method)

Consider an enclosure consisting of *N* opaque surfaces. The enclosure is closed or, if not, no surface external to the surface reflects or emits radiation into the enclosure (i.e., the open configuration may be artificially closed by replacing openings with cold black surfaces); any external radiation entering the enclosure is dealt with individually for each surface (see Equation 4.3.17). All surfaces are assumed to be gray and emit and reflect diffusely. Traditionally, the **radiosity** *J* of the surfaces is determined, defined as the total diffuse radiative energy leaving a surface (by emission and reflection),

$$J_i = \varepsilon_i E_{bi} + \rho_i H_i, \qquad i = 1, N \tag{4.3.16}$$

where H_i is the incoming radiative flux per unit area (irradiation) onto surface A_i. This leads to *N* simultaneous equations for the unknown radiosities, specifically,

$$J_i = \varepsilon_i E_{bi} + (1-\varepsilon_i)\left[\sum_{j=1}^{N} J_j F_{i-j} + H_{oi}\right] \tag{4.3.17a}$$

or

$$J_i = q_i + \sum_{j=1}^{N} J_j F_{i-j} + H_{oi} \tag{4.3.17b}$$

depending on whether surface temperature or surface flux is known on surface A_i. In Equation (4.3.17), H_{oi} is irradiation onto surface A_i from outside the enclosure, if any; H_{oi} is always zero for closed configurations, but is useful in the presence of external light sources (such as solar energy, lasers, etc.). The radiosity is not a useful quantity to determine, nor is there a need to determine it. Eliminating the radiosities from Equation (4.3.17a) and Equation (4.3.17b) leads to N simultaneous equations in temperature (E_{bi}) and heat flux (q_i):

$$\frac{q_i}{\varepsilon_i} - \sum_{j=1}^{N}\left(\frac{1}{\varepsilon_j} - 1\right) F_{i-j} q_j + H_{oi} = E_{bi} - \sum_{j=1}^{N} F_{i-j} E_{bj} \tag{4.3.18}$$

Note that no artificial closing surfaces ($j > N$) appear in Equation (4.3.18) because, for these surfaces, $\varepsilon_j = 1$ and $E_{bj} = 0$. Thus, such closing surfaces may simply be ignored in the analysis.

Because Equation (4.3.18) is a set of N equations, this requires that N values of emissive power E_{bi} and/or flux q_i must be given as boundary conditions, in order to solve for the remaining N unknowns. For computer calculations, Equation (4.3.18) may be recast in matrix form

$$\mathbf{C} \cdot \mathbf{q} = \mathbf{A} \cdot \mathbf{e_b} - \mathbf{h_o} \tag{4.3.19a}$$

where

$$C_{ij} = \frac{\delta_{ij}}{\varepsilon_j} - \left(\frac{1}{\varepsilon_j} - 1\right) F_{i-j} \tag{4.3.19b}$$

$$A_{ij} = \delta_{ij} - F_{i-j} \tag{4.3.19c}$$

δ_{ij} is Kronecker's delta, i.e.,

$$\delta_{ij} = \begin{cases} 1 \text{ if } i = j \\ 0 \text{ if } i \neq j \end{cases} \tag{4.3.20}$$

and $\mathbf{q}$, $\mathbf{e_b}$, and $\mathbf{h_o}$ are vectors of the surface heat fluxes q_i, emissive powers E_{bi}, and external irradiations H_{oi} (if any). For example, if the temperatures are given for all the surfaces and the heat fluxes are to be determined, Equation (4.3.19) is solved by matrix inversion, and

$$\mathbf{q} = \left(\mathbf{C}^{-1} \cdot \mathbf{A}\right) \cdot \mathbf{e_b} - \left(\mathbf{C}^{-1} \cdot \mathbf{h_o}\right) \tag{4.3.21}$$

Example 4.3.4

A right-angled groove, consisting of two long black surfaces of width a, is exposed to solar radiation q_{sol} (Figure 4.3.12). The entire groove surface is kept isothermal at temperature T. Determine the net radiative heat transfer rate from the groove.

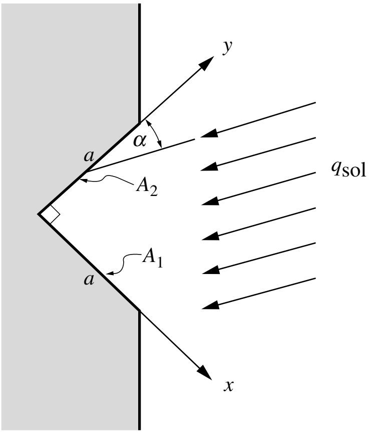

FIGURE 4.3.12 Right-angled groove exposed to solar irradiation, Example 4.3.4.

Solution. Equation (4.3.19) may be used. However, the enclosure is not closed and thus must be closed artificially. Note that any radiation leaving the cavity will not come back (barring any reflection from other surfaces nearby). Thus, the artificial surface should be black. It is also assumed that, with the exception of the (parallel) solar irradiation, no external radiation enters the cavity. Because the solar irradiation is best treated separately through the external irradiation term H_o, the artificial surface is nonemitting. Both criteria are satisfied by covering the groove with a black surface at 0 K (A_3). Even though one now has three surfaces, the last one does not really appear in Equation (4.3.18) (because $E_{b3} = 0$ and $1/\varepsilon_3 - 1 = 0$):

$$q_1 = E_{b1} - F_{1-2}E_{b2} - H_{o1} = \sigma T^4 (1 - F_{1-2}) - q_{\text{sol}} \cos\alpha$$

$$q_2 = E_{b2} - F_{2-1}E_{b1} - H_{o2} = \sigma T^4 (1 - F_{2-1}) - q_{\text{sol}} \sin\alpha$$

From the crossed-strings method, Equation (4.3.15),

$$F_{1-2} = \frac{a + a - \left(\sqrt{2}a + 0\right)}{2a} = \frac{1}{2}\left(2 - \sqrt{2}\right) = 0.293 = F_{2-1}$$

and

$$Q' = a(q_1 + q_2) = a\left[\sqrt{2}\sigma T^4 - q_{\text{sol}}(\cos\alpha + \sin\alpha)\right]$$

Example 4.3.5

Consider a very long duct as shown in Figure 4.3.13. The duct is 30 × 40 cm in cross section, and all surfaces are covered with a gray, diffuse surface material. Top and bottom walls are at $T_1 = T_3 = 1000$ K with $\varepsilon_1 = \varepsilon_3 = 0.3$, while the side walls are at $T_2 = T_4 = 600$ K with $\varepsilon_2 = \varepsilon_4 = 0.8$ as shown. Determine the net radiative heat transfer rates for each surface.

Solution. Using Equation (4.3.18) for $i = 1$ and $i = 2$ and noting that $F_{1-2} = F_{1-4}$ and $F_{2-1} = F_{2-3}$, as well as $q_1 = q_3$ and $q_2 = q_4$,

$$i = 1: \quad \frac{q_1}{\varepsilon_1} - 2\left(\frac{1}{\varepsilon_2} - 1\right)F_{1-2}q_2 - \left(\frac{1}{\varepsilon_1} - 1\right)F_{1-3}q_1 = 2F_{1-2}\left(E_{b1} - E_{b2}\right)$$

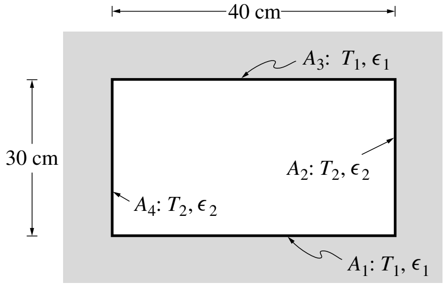

FIGURE 4.3.13 Two-dimensional gray, diffuse duct for Example 4.3.5.

$$i=2:\quad \frac{q_2}{\varepsilon_2}-2\left(\frac{1}{\varepsilon_1}-1\right)F_{2-1}q_1-\left(\frac{1}{\varepsilon_2}-1\right)F_{2-4}q_2=2F_{2-1}\left(E_{b1}-E_{b2}\right)$$

The view factors are readily evaluated from the crossed-strings method as $F_{1-2} = 1/4$, $F_{1-3} = 1 - 2F_{1-2} = 1/2$, $F_{2-1} = 4/3F_{1-2} = 1/3$, and $F_{2-4} = 1 - 2F_{2-1} = 1/3$. Substituting these as well as emissivity values into the relations reduces them to the simpler form of

$$\left[\frac{1}{0.3}-\left(\frac{1}{0.3}-1\right)\frac{1}{2}\right]q_1-2\left(\frac{1}{0.8}-1\right)\frac{1}{4}q_2=2\times\frac{1}{4}\left(E_{b1}-E_{b2}\right)$$

$$-2\left(\frac{1}{0.3}-1\right)\frac{1}{3}q_1+\left[\frac{1}{0.8}-\left(\frac{1}{0.8}-1\right)\frac{1}{3}\right]q_2=2\times\frac{1}{3}\left(E_{b1}-E_{b2}\right)$$

or

$$\frac{13}{6}q_1-\frac{1}{8}q_2=\frac{1}{2}\left(E_{b1}-E_{b2}\right)$$

$$-\frac{14}{9}q_1+\frac{7}{6}q_2=-\frac{2}{3}\left(E_{b1}-E_{b2}\right)$$

Thus,

$$\left(\frac{13}{6}\times\frac{7}{6}-\frac{14}{9}\times\frac{1}{8}\right)q_1=\left(\frac{1}{2}\times\frac{7}{6}-\frac{2}{3}\times\frac{1}{8}\right)\left(E_{b1}-E_{b2}\right)$$

$$q_1=\frac{3}{7}\times\frac{1}{2}\left(E_{b1}-E_{b2}\right)=\frac{3}{14}\sigma\left(T_1^4-T_2^4\right)$$

and

$$\left(-\frac{1}{8}\times\frac{14}{9}+\frac{7}{6}\times\frac{13}{6}\right)q_2=\left(\frac{1}{2}\times\frac{14}{9}-\frac{2}{3}\times\frac{13}{6}\right)\left(E_{b1}-E_{b2}\right)$$

$$q_2=-\frac{3}{7}\times\frac{2}{3}\left(E_{b1}-E_{b2}\right)=-\frac{2}{7}\sigma\left(T_1^4-T_2^4\right)$$

Finally, substituting values for temperatures,

$$Q_1' = 0.4\ \text{m} \times \frac{3}{14} \times 5.670 \times 10^{-8}\ \frac{\text{W}}{\text{m}^2\text{K}^4}\left(1000^4 - 600^4\right)\text{K}^4 = 4230\ \ \text{W/m}$$

$$Q_2' = -0.3\ \text{m} \times \frac{2}{7} \times 5.670 \times 10^{-8}\ \frac{\text{W}}{\text{m}^2\text{K}^4}\left(1000^4 - 600^4\right)\text{K}^4 = -4230\ \ \text{W/m}$$

Note that, for conservation of energy, both heat transfer rates must add up to zero.

Small Body Inside Isothermal Enclosure. An especially simple — but important — case occurs if a small, convex body A_1 (i.e., a surface that cannot "see" itself, or $F_{1-1} = 0$) is totally enclosed by an isothermal enclosure A_2. Then, with $N = 2$ and $F_{1-2} = 1$, Equation (4.3.18) reduces to

$$q_1 = \frac{E_{b1} - E_{b2}}{\dfrac{1}{\varepsilon_1} + \dfrac{A_1}{A_2}\left(\dfrac{1}{\varepsilon_2} - 1\right)} = \frac{\sigma\left(T_1^{\,4} - T_2^{\,4}\right)}{\dfrac{1}{\varepsilon_1} + \dfrac{A_1}{A_2}\left(\dfrac{1}{\varepsilon_2} - 1\right)} \tag{4.3.22}$$

If the enclosure is large, i.e., $A_1 \ll A_2$, then Equation (4.3.22) simplifies further to

$$q_1 = \varepsilon_1 \sigma\left(T_1^{\,4} - T_2^{\,4}\right) \tag{4.3.23}$$

Radiation Shields. If it is desired to minimize radiative heat transfer between two surfaces, it is common practice to place one or more radiation shields between them (usually thin metallic sheets of low emittance). If two surfaces A_i and A_j are close together, so that $A_i \cong A_j$ and $F_{i-j} \cong 1$, then the radiative exchange between them is, from Equation (4.3.22),

$$q = \frac{E_{bi} - E_{bj}}{R_{ij}}, \qquad R_{ij} = \frac{1}{\varepsilon_i} + \frac{1}{\varepsilon_j} - 1 \tag{4.3.24}$$

where R_{ij} is termed the *radiative resistance*. Equation (4.3.24) is seen to be analogous to an electrical circuit with "current" q and "voltage potential" $E_{bi} - E_{bj}$. Therefore, expressing radiative fluxes in terms of radiative resistances is commonly known as **network analogy**.

The network analogy is a very powerful method of solving one-dimensional problems (i.e., whenever only two isothermal surfaces see each other, such as infinite parallel plates, or when one surface totally encloses another). Consider, for example, two large parallel plates, A_1 and A_N, separated by $N - 2$ radiation shields, as shown in Figure 4.3.14. Let each shield have an emittance ε_S on both sides. Then, by applying Equation (4.3.24) to any two consecutive surfaces and using the fact that q remains constant throughout the gap,

$$q = \frac{E_{b1} - E_{b2}}{R_{12}} = \ldots = \frac{E_{bk-1} - E_{bk}}{R_{k-1,k}} = \ldots = \frac{E_{bN-1} - E_{bN}}{R_{N-1,N}} = \frac{E_{b1} - E_{bN}}{\sum_{j-2}^{N} R_{j-1,j}} \tag{4.3.25}$$

where

$$R_{j-1,j} = \frac{1}{\varepsilon_{j-1}} + \frac{1}{\varepsilon_j} - 1 \tag{4.3.26}$$

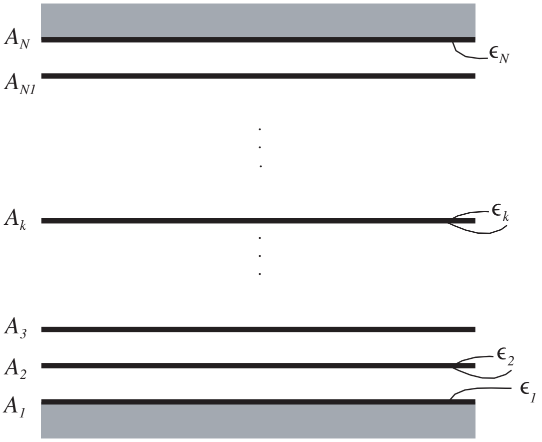

FIGURE 4.3.14 Placement of radiation shields between two large, parallel plates.

and, if $\varepsilon_2 = \varepsilon_3 \ldots = \varepsilon_{N-1} = \varepsilon_S$,

$$\sum_{j=2}^{N} R_{j-1,j} = \frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_N} - 1 + (N-2)\left(\frac{2}{\varepsilon_S} - 1\right) \tag{4.3.27}$$

Equation (4.3.24) to Equation (4.3.27) are also valid for concentric cylinders, concentric spheres, and similar configurations, as long as $r_N - r_1 \ll r_1$. Also, the relations are readily extended to shields with nonidentical emittance.

Although the network analogy can be (and has been) applied to configurations with more than two surfaces seeing each other, this leads to very complicated circuits (because there is one resistance between any two surfaces). For such problems, the network analogy is not recommended, and the net radiation method, Equation (4.3.18), should be employed.

Radiative Exchange within Participating Media

In many high-temperature applications, when radiative heat transfer is important, the medium between surfaces is not transparent, but is "participating" — i.e., it absorbs, emits, and (possibly) scatters radiation. In a typical combustion process, this interaction results in (1) continuum radiation due to tiny, burning soot particles (of dimension < 1 μm) and also due to larger suspended particles, such as coal particles, oil droplets, and fly ash; (2) banded radiation in the infrared due to emission and absorption by molecular gaseous combustion products, mostly water vapor and carbon dioxide; and (3) chemiluminescence due to the combustion reaction. Chemiluminescence may normally be neglected; however, particulates as well as gas radiation generally must be accounted for.

Radiative Properties of Molecular Gases

When a photon (or an electromagnetic wave) interacts with a gas molecule, it may be absorbed, raising the energy level of the molecule. Conversely, a gas molecule may spontaneously lower its energy level by the emission of an appropriate photon. This leads to large numbers of narrow spectral lines, which partially overlap and together form so-called vibration–rotation bands. As such, gases tend to be transparent over most of the spectrum, but may be almost opaque over the spectral range of a band. The **absorption coefficient** κ_λ is defined as a measure of how strongly radiation is absorbed or emitted along a path of length L, leading to the spectral absorptivity and emissivity for this path, or

$$\alpha_\lambda = \varepsilon_\lambda = 1 - e^{-\kappa_\lambda L} \tag{4.3.28}$$

This exponential decay of incident radiation is often called *Beer's law*. Although gases are distinctly nongray, for simple heat transfer calculations it is often sufficient to determine the total emissivity for an isothermal path (compare Equation 4.3.9)

$$\varepsilon = \frac{1}{E_b} \int_0^{\infty} \left(1 - e^{-\kappa_\lambda L}\right) E_{b\lambda}\left(T_g\right) d\lambda \tag{4.3.29}$$

For a mixture of gases, the total emissivity is a function of path length L; gas temperature T_g; partial pressure(s) of the absorbing gas(es) p_a; and total pressure p. For the mixture of nitrogen with water vapor and/or carbon dioxide (in combustion applications most important), the total emissivity may be calculated from Leckner (1972). First, the individual emissivities for water vapor and carbon dioxide, respectively, are calculated separately from

$$\varepsilon\left(p_a L, p, T_g\right) = \varepsilon_0\left(p_a L, T_g\right)\left(\frac{\varepsilon}{\varepsilon_0}\right)\left(p_a L, p, T_g\right) \tag{4.3.30a}$$

$$\left(\frac{\varepsilon}{\varepsilon_0}\right)\left(p_a L, p, T_g\right) = \left[1 - \frac{(a-1)(1-P_E)}{a+b-1+P_E} \exp\left(-c\left[\log_{10}\frac{(p_a L)_m}{p_a L}\right]^2\right)\right] \tag{4.3.30b}$$

$$\varepsilon_0\left(p_a L, T_g\right) = \exp\left[\sum_{i=0}^{N} \sum_{j=0}^{N} c_{ji}\left(\frac{T_g}{T_0}\right)^j \left(\log_{10}\frac{p_a L}{(p_a L)_0}\right)^i\right] \tag{4.3.30c}$$

Here ε_0 is the total emissivity of a reference state, i.e., for the case of $p = 1$ bar and $p_a \to 0$ (but $p_a L > 0$); the correlation constants a, b, c, c_{ji}, P_E, $(p_a L)_0$, $(p_a L)_m$, and $(p_a L)_m$ are given in Table 4.3.2 for water vapor and carbon dioxide. (For convenience, plots of ε_0 are given in Figure 4.3.15 for CO_2 and Figure 4.3.16

TABLE 4.3.2 Correlation Constants for Determination of Total Emissivity for Water Vapor and Carbon Dioxide

Gas	Water Vapor			Carbon Dioxide			
M, N	2,2			2,3			
$\begin{matrix} c_{00} & \cdots & c_{N0} \\ \vdots & \ddots & \vdots \\ c_{0M} & \cdots & c_{NM} \end{matrix}$	−2.2118 0.85667 −0.10838	−1.1987 0.93048 −0.17156	0.035596 −0.14391 0.045915	−3.9893 1.2710 −0.23678	2.7669 1.1090 0.19731	−2.1081 1.0195 −0.19544	0.39163 −0.21897 0.044644

Note: $T_0 = 1000$ K, $p_0 = 1$ bar, $t = T/T_0$, $(p_a L)_0 = 1$ bar cm.

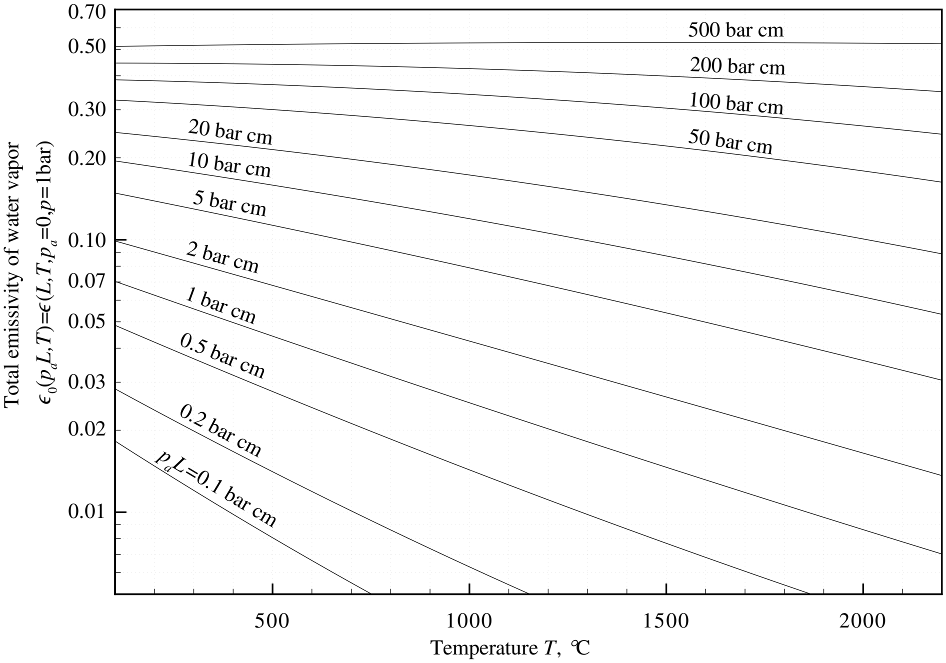

FIGURE 4.3.15 Total emissivity of water vapor at reference state (total gas pressure $p = 1$ bar, partial pressure of $H_2O p_a \rightarrow 0$).

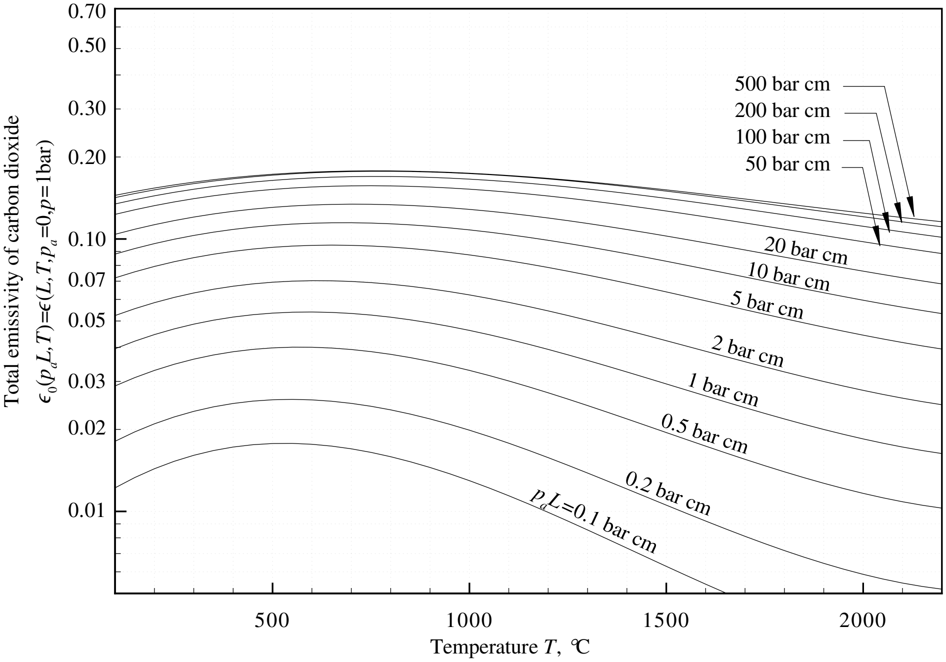

FIGURE 4.3.16 Total emissivity of carbon dioxide at reference state (total gas pressure $p = 1$ bar, partial pressure of $CO_2 p_a \rightarrow 0$).

for H_2O.) The total emissivity of a mixture of nitrogen with water vapor and carbon dioxide is calculated from

$$\varepsilon_{CO_2+H_2O} = \varepsilon_{CO_2} + \varepsilon_{H_2O} - \Delta\varepsilon \tag{4.3.31}$$

$$\Delta\varepsilon = \left(\frac{\zeta}{10.7+101\zeta} - 0.0089\zeta^{10.4}\right)\left(\log_{10}\frac{\left(p_{H_2O}+p_{CO_2}\right)L}{\left(p_a L\right)_0}\right)^{2.76} \tag{4.3.32a}$$

$$\zeta = \frac{p_{H_2O}}{p_{H_2O}+p_{CO_2}} \tag{4.3.32b}$$

where the $\Delta\varepsilon$ compensates for overlap effects between H_2O and CO_2 bands, and the ε_{CO_2} and ε_{H_2O} are calculated from Equation (4.3.30).

If radiation emitted externally to the gas (for example, by emission from an adjacent wall at temperature T_s) travels through the gas, the total amount absorbed by the gas is of interest. This leads to the absorptivity of a gas path at T_g with a source at T_s:

$$\alpha\left(p_a L, p, T_g, T_s\right) = \frac{1}{E_b(T_s)}\int_0^\infty \left(1-e^{-\kappa_\lambda(T_g)L}\right)E_{b\lambda}(T_s)\,d\lambda \tag{4.3.33}$$

which, for water vapor or carbon dioxide, may be estimated from

$$\alpha\left(p_a L, p, T_g, T_s\right) = \left(\frac{T_g}{T_s}\right)^{1/2} \varepsilon\left(p_a L\frac{T_s}{T_g}, p, T_s\right) \tag{4.3.34}$$

where ε is the emissivity calculated from Equation (4.3.30) evaluated at the temperature of the surface T_s, and using an adjusted pressure path length, $p_a L T_s/T_g$. For mixtures of water vapor and carbon dioxide, band overlap is again accounted for by taking

$$\alpha_{CO_2+H_2O} = \alpha_{CO_2} + \alpha_{H_2O} - \Delta\varepsilon \tag{4.3.35}$$

with $\Delta\varepsilon$ evaluated for a pressure path length of $p_a L T_s/T_g$.

Example 4.3.6

Consider a layer of a gas mixture at 1000 K and 5 bar that consists of 10% carbon dioxide and 70% nitrogen. What is its emissivity for a path length of 1.76 m, and its absorptivity (for the same path) if the layer is irradiated by a source at 1500 K?

Solution. First calculate the total emissivity of the CO_2 at the reference state (p = 1 bar, $p_a \to 0$) for a length of 1.76 m from Equation (4.3.30c) or Figure 4.3.15. With

$$T_g = 1000\text{ K} = 727°\text{C} \quad \text{and} \quad p_a L = 0.1\times 5\text{ bar}\times 1.76\text{m} = 88\text{ bar cm}$$

one gets, interpolating Figure 4.3.15, $\varepsilon_0 \cong 0.15$. The correction factor in Equation (4.3.30b) is calculated from Table 4.3.2 with $P_E = 5 + 0.28 \times 0.5 = 5.14$, $a = 1.1$, $b = 0.23$, $c = 1.47$, and $(p_a L)_m = 0.225$ bar cm. Thus,

$$\frac{\varepsilon}{\varepsilon_0} = 1 - \frac{0.1\times(-4.14)}{0.33+5.14}\exp\left(-1.47\left(\log_{10}\frac{0.225}{88}\right)^2\right) \cong 1$$

and

$$\varepsilon \cong 0.15$$

To calculate the absorptivity, ε_0 must be found for a temperature of

$$T_s = 1500\ \text{K} = 1227°\text{C} \quad \text{and} \quad p_a L \frac{T_s}{T_g} = 88 \times 1500/1000 = 132\ \text{bar cm}$$

From Figure 4.3.15, it follows that $\varepsilon_0 \cong 0.15$ again and, with $\varepsilon/\varepsilon_0$ relatively unchanged, from Equation (4.3.34),

$$\alpha \cong \left(\frac{1000}{1500}\right)^{1/2} \times 0.15 \times 1.00 = 0.122$$

Radiative Properties of Particle Clouds

Nearly all flames are visible to the human eye and are therefore called *luminous* (sending out light). Apparently, some radiative emission from within the flame takes place at wavelengths where no vibration–rotation bands for any combustion gases exist. This luminous emission is known today to come from tiny char (almost pure carbon) particles, called soot, which are generated during the combustion process. The "dirtier" the flame is (i.e., the higher the soot content), the more luminous it is.

Radiative Properties of Soot. Soot particles are produced in fuel-rich flames, or fuel-rich parts of flames, as a result of incomplete combustion of hydrocarbon fuels. As shown by electron microscopy, soot particles are generally small and spherical, ranging in size between approximately 50 and 800 Å (0.005 to 0.08 μm), and up to about 3000 Å in extreme cases. Although mostly spherical in shape, soot particles may also appear in agglomerated chunks and even as long agglomerated filaments. It has been determined experimentally in typical diffusion flames of hydrocarbon fuels that the volume percentage of soot generally lies in the range between 10^{-4} to 10^{-6}%.

Because soot particles are very small, they are generally at the same temperature as the flame and strongly emit thermal radiation in a continuous spectrum over the infrared region. Experiments have shown that soot emission often is considerably stronger than the emission from the combustion gases.

For a simplified heat transfer analysis it is desirable to use suitably defined mean absorption coefficients and emissivities. If the soot volume fraction, f_v, is known as well as an appropriate spectral average of the complex index of refraction of the soot, $m = n - ik$, one may approximate the spectral absorption coefficient by (Felske and Tien, 1977):

$$\kappa_\lambda = C_0 \frac{f_v}{\lambda} \qquad C_0 = \frac{36\pi nk}{\left(n^2 - k^2 + 2\right)^2 + 4n^2k^2} \tag{4.3.36}$$

and a total, or spectral-average value may be taken as

$$\kappa_m = 3.72 f_v C_0 T/C_2 \tag{4.3.37}$$

where C_2 = 1.4388 mK is the second Planck function constant. Substituting Equation (4.3.37) into Equation (4.3.29) gives a total soot cloud emissivity of

$$\varepsilon\left(f_v TL\right) = 1 - e^{-\kappa_m L} = 1 - e^{-3.72 C_0 f_v TL/C_2} \tag{4.3.38}$$

Pulverized Coal and Fly Ash Dispersions. To calculate the radiative properties of arbitrary size distributions of coal and ash particles, one must have knowledge of their complex index of refraction as a function of wavelength and temperature. Data for carbon and different types of coal indicate that its real part, n, varies little over the infrared and is relatively insensitive to the type of coal (e.g., anthracite, lignite, bituminous), while the absorptive index, k, may vary strongly over the spectrum and from coal to coal.

If the number and sizes of particles are known and if a suitable average value for the complex index of refraction can be found, then the spectral absorption coefficient of the dispersion may be estimated by a correlation given by Buckius and Hwang (1980). Substitution into Equation (4.3.29) can then provide an estimate of the total emissivity. If soot as well as larger particles are present in the dispersion, the absorption coefficients of all constituents must be added before applying Equation (4.3.29).

Mixtures of Molecular Gases and Particulates. To determine the total emissivity of a mixture, it is generally necessary to find the spectral absorption coefficient κ_λ of the mixture (i.e., the sum of the absorption coefficient of all contributors), followed by numerical integration of Equation (4.3.29). However, because the molecular gases tend to absorb only over a small part of the spectrum, to some degree of accuracy

$$\varepsilon_{\text{mix}} \cong \varepsilon_{\text{gas}} + \varepsilon_{\text{particulates}} \tag{4.3.39}$$

Equation (4.3.39) gives an upper estimate because overlap effects result in lower emissivity (compare Equation 4.3.31 for gas mixtures).

Heat Exchange in the Presence of a Participating Medium

The calculation of radiative heat transfer rates through an enclosure filled with a participating medium is a challenging task, to say the least. High-accuracy calculations are rare and a topic of ongoing research. However, several simple models are available that allow the estimation of radiative heat transfer rates and relatively accurate calculations for some simple cases.

Diffusion Approximation. A medium through which a photon can only travel a short distance without being absorbed is known as *optically thick*. Mathematically, this implies that $\kappa_\lambda L \gg 1$ for a characteristic dimension L, across which the temperature does not vary substantially. For such an optically thick nonscattering medium, the spectral radiative flux may be calculated from

$$\mathbf{q} = -\frac{4}{3\kappa_\lambda}\nabla E_{b\lambda} \tag{4.3.40}$$

similar to Fourier's diffusion law for heat conduction. Note that a medium may be optically thick at some wavelengths, but thin ($\kappa_\lambda L \ll 1$) at others (e.g., molecular gases). For a medium that is optically thick for all wavelengths, Equation (4.3.40) may be integrated over the spectrum, yielding the total radiative flux

$$\mathbf{q} = -\frac{4}{3\kappa_R}\nabla E_b = -\frac{4}{3\kappa_R}\nabla(\sigma T^4) = -\frac{16\sigma T^3}{3\kappa_R}\nabla T \tag{4.3.41}$$

where κ_R is the suitably averaged absorption coefficient, termed the *Rosseland-mean absorption coefficient*. For a cloud of soot particles, $\kappa_R \cong \kappa_m$ from Equation (4.3.37) is a reasonable approximation. Equation (4.3.41) may be rewritten by defining a "radiative conductivity" k_R,

$$\mathbf{q} = -k_R\nabla T \qquad k_R = \frac{16\sigma T^3}{3\kappa_R} \tag{4.3.42}$$

This form shows that the diffusion approximation is mathematically equivalent to conductive heat transfer with a (strongly) temperature-dependent conductivity.

More accurate calculations show that, in the absence of other modes of heat transfer (conduction, convection), there is generally a temperature discontinuity near the boundaries ($T_{\text{surface}} \neq T_{\text{adjacent medium}}$) and, unless boundary conditions that allow such temperature discontinuities are chosen, the diffusion approximation will do very poorly in the vicinity of bounding surfaces.

Example 4.3.7

A soot cloud is contained between two walls at T_1 = 1000 K and T_2 = 2000 K, spaced 1 m apart. The effective absorption coefficient of the medium is $\kappa_R = 10\ \text{m}^{-1}$ and the effective thermal conductivity is k_c = 0.1 W/mK. Estimate the total heat flux between the plates (ignoring convection effects).

Solution. For simplicity, one may want to assume a constant total conductivity $k = k_c + k_R$, leading to

$$q = -k\frac{dT}{dx} = k\frac{T_2 - T_1}{L}$$

where k_R must be evaluated at some effective temperature. Choosing, based on its temperature dependence,

$$k_R \cong \frac{8\sigma}{3\kappa_R}\left(T_1^3 + T_2^3\right) = \frac{8\times 5.670\times 10^{-8}\ \text{W/m}^2\text{K}^4}{3\times 10/\text{m}}\left(1000^3 + 2000^3\right)\text{K}^3 = 136\frac{\text{W}}{\text{mK}}$$

gives

$$q = (0.1 + 136)\frac{2000 - 1000}{1}\frac{\text{W}}{\text{m}^2} = 136\frac{\text{kW}}{\text{m}^2\text{K}}$$

Note that (1) conduction is negligible in this example; and (2) the surface emittances do not enter the diffusion approximation. Although a more accurate answer can be obtained by taking the temperature dependence of k_R into account, the method should be understood as a relatively crude approximation.

Mean Beam Length Method. Relatively accurate, yet simple, heat transfer calculations can be carried out if an isothermal absorbing–emitting, but not scattering, medium is contained in an isothermal black-walled enclosure. Although these conditions are, of course, very restrictive, they are met to some degree by conditions inside furnaces. For such cases, the local irradiation onto a point of the surface may be calculated from

$$H = \left[1 - \alpha(L_m)\right]E_{bw} - \varepsilon(L_m)E_{bg},\quad q_{\text{net}} = E_{bw} - H \tag{4.3.43}$$

where E_{bw} and E_{bg} are blackbody emissive powers for the walls and medium (gas and/or particulates), respectively, and $\alpha(L_m)$ and $\varepsilon(L_m)$ are the total absorptivity and emissivity of the medium for a path length L_m through the medium. The length L_m, known as the average mean beam length, is a directional average of the thickness of the medium as seen from the point on the surface.

On a spectral basis, Equation (4.3.43) is exact if the preceding conditions are met and an accurate value of the (spectral) mean beam length is known. It has been shown that spectral dependence of the mean beam length is weak (generally less than ±5% from the mean). Consequently, total radiative heat flux at the surface may be calculated very accurately from Equation (4.3.43) if the emissivity and absorptivity of the medium are also known accurately. The mean beam lengths for many important geometries have been calculated and are collected in Table 4.3.3. In this table, L_0 is known as the geometric mean beam length, which is the mean beam length for the optically thin limit ($\kappa_\lambda \to 0$), and L_m is a spectral average of the mean beam length. For geometries not listed in Table 4.3.3, the mean beam length may be estimated from

$$L_0 \cong 4\frac{V}{A} \qquad L_m \cong 0.9L_0 \cong 3.6\frac{V}{A} \tag{4.3.44}$$

where V is the volume of the participating medium and A is its entire bounding surface area.

TABLE 4.3.3 Mean Beam Lengths for Radiation from a Gas Volume to a Surface on Its Boundary

Geometry of Gas Volume	Characterizing Dimension, L	Geometric Mean Beam Length, L_0/L	Average Mean Beam Length, L_m/L	L_m/L_0
Sphere radiating to its surface	Diameter, $L = D$	0.67	0.65	0.97
Infinite circular cylinder to bounding surface	Diameter, $L = D$	1.00	0.94	0.94
Semi-infinite circular cylinder to:	Diameter, $L = D$			
Element at center of base		1.00	0.90	0.90
Entire base		0.81	0.65	0.80
Circular cylinder (height/diameter = 1) to:	Diameter, $L = D$			
Element at center of base		0.76	0.71	0.92
Entire surface		0.67	0.60	0.90
Circular cylinder (height/diameter = 2) to:	Diameter, $L = D$			
Plane base		0.73	0.60	0.82
Concave surface		0.82	0.76	0.93
Entire surface		0.80	0.73	0.91
Circular cylinder (height/diameter = 0.5) to:	Diameter, $L = D$			
Plane base		0.48	0.43	0.90
Concave surface		0.53	0.46	0.88
Entire surface		0.50	0.45	0.90
Infinite semicircular cylinder to center of plane rectangular face	Radius, $L = R$	—	1.26	—
Infinite slab to its surface	Slab thickness, L	2.00	1.76	0.88
Cube to a face	Edge L	0.67	0.6	0.90
Rectangular 1 × 1 × 4 parallelepipeds:	Shortest edge, L			
To 1 × 4 face		0.90	0.82	0.91
To 1 × 1 face		0.86	0.71	0.83
To all faces		0.89	0.81	0.91

Example 4.3.8

An isothermal mixture of 10% CO_2 and 90% nitrogen at 1000 K and 5 bar is contained between two large, parallel black plates, which are isothermal at 1500 K. Estimate the net radiative heat loss from the surfaces.

Solution. The heat loss may be calculated from Equation (4.3.43), after determining the mean beam length, followed by evaluation of $\varepsilon(L_m)$ and $\alpha(L_m)$. From Table 4.3.3, it is clear that $L_m = 1.76 \times$ thickness of slab = 1.76 m. It turns out that the necessary $\varepsilon(L_m) = 0.15$ and $\alpha(L_m) = 0.122$ have already been calculated in Example 4.3.6. Thus, the heat flux is immediately calculated from Equation (4.3.43) as

$$H = (1 - 0.122) 5.670 \times 10^{-8} \times 1500^4 - 0.15 \times 5.670 \times 10^{-8} \times 1000^4$$

$$= 2.44 \times 10^5 \frac{\mathrm{W}}{\mathrm{m}^2} = 244 \ \mathrm{kW/m^2}$$

$$q_{\mathrm{net}} = 5.670 \times 10^{-8} \times 1500^4 - 2.44 \times 10^5 = 43 \ \mathrm{kW/m^2}$$

Advanced Concepts

Radiative transfer in a participating medium is governed by the so-called *radiative transfer equation* (RTE), an energy balance for spectral radiative intensity I_λ traveling in a specific direction $\hat{s}$,

$$\frac{dI_\lambda}{ds} = \kappa_\lambda I_{b\lambda} - \beta_\lambda I_\lambda(\hat{s}) + \frac{\sigma_{s\lambda}}{4\pi} \int_{4\pi} I_\lambda(\hat{s}) \Phi_\lambda(\hat{s}, \hat{s}') d\Omega', \tag{4.3.45}$$

in which $I_{b\lambda} = E_{b\lambda}/\pi$ is the blackbody intensity; κ_λ is the *absorption coefficient* (the ability of a medium to absorb and emit radiation, as given in Equation 4.3.28); $\sigma_{s\lambda}$ is the *scattering coefficient* (the ability of a medium to scatter radiation); $\beta_\lambda = \kappa_\lambda + \sigma_{s\lambda}$ is called the *extinction coefficient*; and $\Phi_\lambda(\hat{s}, \hat{s}')$ is the scattering phase function (the probability that radiation traveling in the direction of $\hat{s}$ is scattered, i.e., redirected, into the direction of $\hat{s}'$).

The RTE states that the strength of a light beam traveling along a path s is augmented by emission from the medium (first term on the right-hand side), diminished by absorption and outscattering, i.e., scattering *away* from $\hat{s}$ (second term), and increased by inscattering, i.e., scattering from all other directions *into* direction $\hat{s}$ (last term). The RTE is a five-dimensional (three space coordinates, and two direction coordinates with local origins) integrodifferential equation, which is extremely difficult to solve. The problem is compounded by the complicated spectral behavior usually exhibited by the medium's radiation properties (κ_λ, $\sigma_{s\lambda}$, and Φ_λ). Therefore, numerous approximate and/or numerical techniques have been developed to solve the RTE and to deal with the complicated spectral behavior.

RTE Solution Methods. All RTE solution methods attempt to approximate the directional dependence of radiative intensity or express it numerically. The next level of sophistication beyond the diffusion and mean-beam-length approximations are the so-called *flux methods*. Assuming the intensity to have two constant but different values across two hemispheres of directions, the two-flux model has been successfully applied to one-dimensional problems (Modest, 2003); the six-flux method can be applied to more general geometries, but must be tailored toward each individual problem.

The most popular numerical methods are the *spherical harmonics* and the *discrete ordinates* methods. In the former, the directional dependence of intensity is expanded into a series of spherical harmonics, truncated at the *N*th level and resulting in the so-called *P-N* methods. Although higher order *P-N* methods are difficult to implement, its lowest order, the *P-1* approximation, is very popular because of its simplicity and surprising accuracy. Reducing the RTE into a single elliptical partial differential equation, it is easy to implement and has been incorporated into most modern commercial CFD codes. The *P-1* approximation assumes a near-isotropic intensity distribution and is, therefore, accurate in emission-dominated applications (such as combustion of fuels and high-temperature combustion products) and optically thick systems (large κ_λ); the method fails for predicting heat exchange between hot and cold surfaces separated by an optically thin medium (small κ_λ).

The *discrete ordinates* method (DOM) finite differences the directional dependence of intensity, requiring the simultaneous solution of many hyperbolic partial differential equations (Modest, 2003). Because it can be carried to arbitrary levels of accuracy (albeit at a steep computational price), this and its modern finite volume implementation (FVM) (Modest, 2003) are also incorporated into most CFD codes. Some commercial codes also offer the older *discrete transfer* method, which is today known to be less accurate and less efficient (Modest, 2003) and thus not recommended.

Spectral Models. As indicated earlier, the spectral variations of radiation properties of gases and particles are extremely difficult to predict and to deal with. Although particles tend to have a distribution of particle sizes and shapes, thus smoothing out spectral variations and allowing the assumption of gray or near-gray behavior, this is almost never the case for molecular gases (but may result in errors of hundreds, and even thousands, of percent). This has prompted the development of a number of approximate models, which may be loosely grouped into four groups: (1) line-by-line calculations; (2) narrow band models; (3) wide band models; and (4) global models.

In line-by-line calculations (LBL), the spectral variation of the gas absorption coefficient is followed in small steps across the entire spectrum, requiring 1 million RTE evaluations or more, making this method suitable only for benchmarking. Narrow band models take advantage of the fact that the gas absorption coefficient varies much more rapidly across the spectrum than other quantities, such as emissive power or surface emittance. The models predict gas transmissivities averaged across small spectral ranges; the most successful ones are the so-called *statistical narrow band models* (SNB), in particular the Malkmus model (Modest, 2003). Wide band models (WBM) are similar to narrow band models, but average over an entire vibration–rotation band and usually employ correlations of somewhat dated experimental data. Finally, global models look at the entire spectrum; the most successful is the *weighted sum of gray gases* (WSGG) first introduced by Hottel (Hottel and Sarofim, 1967).

The most modern, accurate, and efficient approach is the method of *correlated k-distributions*, in which the absorption coefficient is reordered across a spectral range into a monotonically increasing function. This method also exists in narrow band, wide band, and global forms and can result in (near) exact answers at a tiny fraction of the costs for LBL calculations. For more detailed information on spectral modeling, the reader is referred to Modest (2003). Apparently, as of 2003, none of the better known CFD packages includes a credible nongray spectral model.

Defining Terms

Absorptance: The ability of a solid material to absorb (i.e., trap and convert to other forms of energy) incoming radiation; gives the fraction of incoming radiation that is absorbed by the medium.

Absorptivity: The fraction of incoming radiation absorbed by a column of a radiatively participating medium (e.g., a gas or a particle cloud).

Absorption coefficient: The ability of a medium to absorb (i.e., trap and convert to other forms of energy) radiative energy over a unit path length; the reciprocal of the mean distance a photon travels before being absorbed.

Blackbody: Any material or configuration that absorbs all incoming radiation completely. A blackbody also emits the maximum possible amount of radiation as described by Planck's law.

Diffuse surface: A surface that emits and/or reflects equal amounts of radiative energy (photons) into all directions; a surface that absorbs and/or reflects equal amounts of radiation independent of incoming direction.

Emissive power: The rate of radiative energy leaving a surface through emission. The maximum amount of emissive power is emitted by a blackbody with a spectral strength described by Planck's law.

Emittance: The ability of a solid material to emit (i.e., convert internal energy into electromagnetic waves or photons) thermal radiation; gives the fraction of emission as compared with a blackbody.

Emissivity: The ability of a column of a radiatively participating medium (e.g., a gas or a particle cloud) to emit thermal radiation; gives the fraction of emission as compared with an opaque (i.e., infinitely long) column.

Gray: A medium whose radiative properties (such as absorptance, emittance, reflectance, absorption coefficient) do not vary with wavelength.

Irradiation: incoming radiative flux onto a surface from outside it.

Network analogy: Expressing radiative heat exchange between surfaces in terms of an electrical network, with heat flux as "current," differences in emissive power as "potentials," and defining radiative resistances.

Opaque medium: A medium of sufficient thickness that absorbs all nonreflected irradiation; no radiation is transmitted through the medium.

Photon: A massless particle carrying energy in the amount of $h\nu$; the quantum mechanical alternative view of an electromagnetic wave carrying radiative energy.

Planck's law: The law describing the spectral distribution of the radiative energy emitted (emissive power) of a blackbody.

Radiosity: Total radiative flux leaving a surface (diffusely), consisting of emitted as well as reflected radiation.

Reflectance: The ability of an interface, a medium, or a composite with a number of interfaces to reflect incoming radiation back into the irradiating medium.

Semitransparent: See transparent.

Spectral value: The value of a quantity that varies with wavelength at a given wavelength; for dimensional quantities, the amount per unit wavelength.

Transmittance: The fraction of incoming radiation transmitted through a layer of a solid material.

Transmissivity: The fraction of incoming radiation transmitted by a column of a radiatively participating medium (e.g., a gas or a particle cloud).

Transparent: The ability of a medium to let incoming radiation pass through it. A medium that lets all radiation pass through it is called transparent; a medium that only allows a part to pass through it is called *semitransparent*.

View factor: The fraction of diffuse radiant energy leaving one surface that is intercepted by another surface.

4.4 Phase-Change

Boiling and Condensation

Van P. Carey

Introduction

Liquid-vapor phase-change processes play an important role in many technological applications. The virtually isothermal heat transfer associated with boiling and condensation processes makes their inclusion in power and refrigeration processes highly advantageous from a thermodynamic efficiency standpoint. In addition, the high heat transfer coefficients associated with boiling and condensation have made the use of these processes increasingly attractive in the thermal control of compact devices that have high heat dissipation rates. Applications of this type include the use of boiling heat transfer to cool electronic components in computers and the use of compact evaporators and condensers for thermal control of aircraft avionics and spacecraft environments. Liquid-vapor phase-change processes are also of critical importance to nuclear power plant design, both because they are important in normal operating circumstances and because they dominate many of the accident scenarios that are studied as part of design evaluation.

The heat transfer and fluid flow associated with liquid-vapor phase-change processes are typically among the more complex transport circumstances encountered in engineering applications. These processes have all the complexity of single-phase convective transport, plus additional elements resulting from motion of the interface, nonequilibrium effects, and dynamic interactions between the phases. Due to the highly complex nature of these processes, development of methods to accurately predict the associated heat and mass transfer is often a formidable task.

In this section, commonly used variables not defined in the nomenclature are as follows: q'' = surface heat flux, μ_l = liquid viscosity, μ_v = vapor viscosity, Pr_l = liquid Prandtl number, T_w = wall surface temperature, T_{sat} = saturation temperature, c_{pl} = liquid specific heat, k_v = vapor thermal conductivity, g = gravitational acceleration, and x = mass quality.

Boiling

Three mechanisms that play important roles in boiling processes are (1) surface tension effects, (2) surface wetting characteristics of the liquid, and (3) metastable phase stability.

Anyone who has watched small bubbles rise in a carbonated beverage or a pot of boiling water has undoubtedly noticed that the bubbles are almost perfectly spherical, as if an elastic membrane were present at the interface to pull the vapor into a spherical shape. This apparent interfacial tension or *surface tension* σ is equivalent to an energy stored in the interface region per unit area. The energy excess in this region is due to the slightly larger separation of the liquid phase molecules adjacent to the gas phase.

The magnitude of the surface tension for a substance is directly linked to the strength of intermolecular forces in the material. Nonpolar liquids typically have the lowest surface tension. Water and other **polar molecules** have somewhat higher surface tension, and liquid metals, which exhibit metallic bond attraction, have very high surface tension. The surface tension of water at 20°C is 0.0728 N/m, whereas liquid mercury has a surface tension of 0.484 N/m at the same temperature. The surface tension for any pure liquid varies with temperature. It decreases almost linearly with increasing temperature, vanishing altogether at the critical point where the distinction between the phases disappears.

As a result of the surface tension at the interface, the pressure inside a spherical bubble of radius r must exceed that in the surrounding liquid by $2\sigma/r$:

$$P_v = P_l + \frac{2\sigma}{r} \tag{4.4.1}$$

By using the relation (1) between the pressure in the two phases it can be shown that for the bubble to be in equilibrium with the surrounding liquid, the liquid must actually be superheated above the saturation temperature for the ambient liquid pressure. The amount of required superheating increases as the radius of curvature of the bubble interface decreases.

The wetting characteristics of the liquid are generally quantified in terms of a *contact angle* between the solid surface and the tangent to the interface at the point where it contacts the solid. This angle is measured through the liquid phase, as shown in Figure 4.4.1. In some systems, the wetting angle established at equilibrium may depend on the fluid motion history. For some systems the contact angle established by liquid advancing over a solid surface is larger than that established when a liquid front recedes over the surface. This behavior is referred to as *contact angle hysteresis*. Contact angle hysteresis can have an important effect on boiling and condensation processes, particularly those involving water.

For a bubble with a specified vapor volume, the contact angle will dictate the radius of curvature of the bubble interface. The wetting behavior in combination with the surface tension effect, thus, determines the level of superheat required for the bubble to be in equilibrium with the surrounding liquid. The liquid must be heated above this superheat level for the bubble to grow. A steady boiling process can be sustained only if the liquid is heated above this threshold superheat level.

It can be shown from basic thermodynamic analysis that a necessary and sufficient condition for phase stability is that

$$\left(\frac{\partial P}{\partial v}\right)_T < 0 \tag{4.4.2}$$

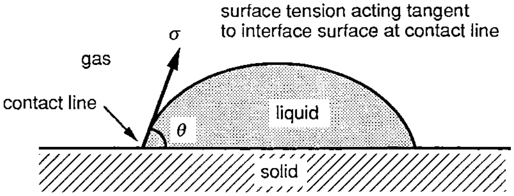

FIGURE 4.4.1 Definition of the contact angle θ.

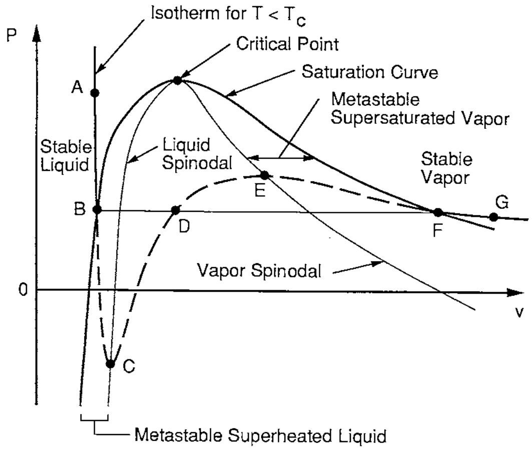

FIGURE 4.4.2 Spinodal lines and metastable regions on a *P*–$\boldsymbol{v}$ diagram.

where v is the specific volume. Below the critical temperature, extrapolation of the isotherms for the liquid and vapor phases consistent with an equation of state like the van de Waals equation results in an isotherm shape similar to that shown in Figure 4.4.2.

The locus of points where $(\partial P/\partial v)_T = 0$ are termed *spinodal curves*. Regions of metastable vapor and liquid exist between the saturation curve and the spinodal curves. The effects of surface tension discussed above require that fluid surrounding a vapor bubble be in the metastable superheated liquid region. Predictions of statistical thermodynamics imply that as $(\partial P/\partial v)_T$ approaches zero, the level of fluctuations in a fluid system increases. This, in turn, increases the probability that an embryonic new phase will form as a result of density fluctuations. Initiation of a phase change in this manner is termed *homogeneous nucleation*. Generally, a pure liquid must be heated to nearly 90% of its absolute critical temperature before homogeneous nucleation of vapor bubbles occurs.

In most physical systems of engineering interest, the bulk phase is in contact with solid walls of the containing structures, or solid particulate contaminants. These solid phases may provide nucleation sites where phase change may occur if the system state is driven into the metastable range. Nucleation of vapor bubbles may preferentially occur at low liquid superheat levels in crevices in the solid surface where gas is trapped. This type of nucleation at the solid surface of a containment wall is categorized as *heterogeneous nucleation*. Because solid containment walls usually contain microscopic crevice-type imperfections, heterogeneous nucleation is more common than homogeneous nucleation in systems where boiling occurs.

Vapor entrapment in crevices of the heated walls of evaporator heat exchangers usually makes it easier to initiate the vaporization process. Vapor bubbles grow from these crevices until buoyancy or drag on the bubbles exceeds the surface tension force holding the droplet to the solid surface. The bubble then releases into the bulk liquid. A small remnant of vapor remains in the crevice after a bubble releases, and this remnant grows in size as further vaporization occurs until the bubble grows out of the crevice again. The result is a cyclic process of bubble growth and release known as the *ebullition cycle*. Crevices at which the ebullition cycle is sustained are said to be active nucleation sites. When the ebullition process occurs at many sites over a heated surface, the overall process is referred to as **nucleate boiling**, which is one possible mode of **pool boiling**.

Pool Boiling

Vaporization of liquid at the surface of a body immersed in an extensive pool of motionless liquid is generally referred to as pool boiling. The nature of the pool boiling process varies considerably depending on the conditions at which boiling occurs. The level of heat flux, the thermophysical properties of the liquid and vapor, the surface material and finish, and the physical size of the heated surface all may have an effect on the boiling process.

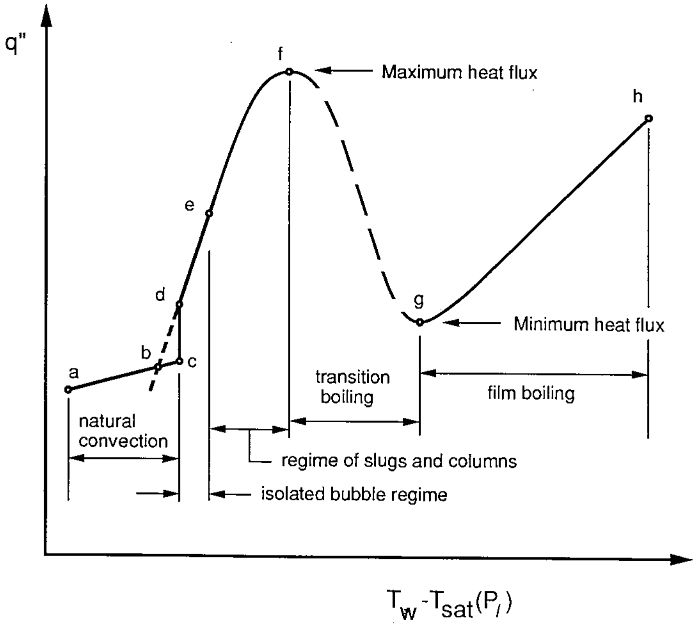

FIGURE 4.4.3 Pool boiling regimes for an independently controlled surface temperature.

The regimes of pool boiling are most easily understood in terms of the so-called boiling curve: a plot of heat flux q'' vs. wall superheat $T_w - T_{sat}$ for the circumstances of interest. Many of the features of the classic pool boiling curve were determined in the early investigations of pool boiling conducted by Nukiyama (1934). Strictly speaking, the classic pool boiling curve defined by the work of this investigator and others applies to well-wetted surfaces for which the characteristic physical dimension L is large compared to the bubble or capillary length scale L_b defined as

$$L_b = \sqrt{\frac{\sigma}{g(\rho_l - \rho_v)}} \tag{4.4.3}$$

The discussion in this section is limited to pool boiling of wetting liquids on surfaces with dimensions large compared with L_b. Additional information on features of the boiling curve when the liquid poorly wets the surface or when L/L_b is small can be found in Carey (1992). To make this discussion concrete, we will assume that the ambient liquid surrounding the immersed body is at the saturation temperature for the ambient pressure. If the surface temperature of the immersed body is controlled and slowly increased, the boiling curve will look similar to that shown in Figure 4.4.3. The axes in this plot are logarithmic scales. The regimes of pool boiling encountered for an upward-facing horizontal flat surface as its temperature is increased are also indicated in Figure 4.4.3. The lateral extent of the surface is presumed to be much larger than L_b. At very low wall superheat levels, no nucleation sites may be active and heat may be transferred from the surface to the ambient liquid by natural convection alone and q'' increases slowly with $T_w - T_{sat}$.

Eventually, the superheat becomes large enough to initiate nucleation at some of the cavities on the surface. This *onset of nucleate boiling* (ONB) condition occurs at point *c* in Figure 4.4.3. Once nucleate boiling is initiated, any further increase in wall temperature causes the system operating point to move upward along section *d-f* of the curve in Figure 4.4.3. This portion of the curve corresponds to the nucleate boiling regime. The active sites are few and widely separated at low wall superheat levels. This range of conditions, corresponding to segment *d-e* of the curve, is sometimes referred to as the *isolated bubble regime.*

With increasing surface superheat, more sites become active, and the bubble frequency at each site generally increases. Eventually, the active sites are spaced so closely that bubbles from adjacent sites merge together during the final stages of growth and release. Vapor is being produced so rapidly that bubbles merging together form columns of vapor slugs that rise upward in the liquid pool toward its free surface. This higher range of wall superheat, corresponding to segment *e-f* of the boiling curve in Figure 4.4.3, is referred to as the *regime of slugs and columns*.

Increasing the wall superheat and heat flux within the regime of slugs and columns produces an increase in the flow rate of vapor away from the surface. Eventually, the resulting vapor drag on the liquid moving toward the surface becomes so severe that liquid is unable to reach the surface fast enough to keep the surface completely wetted with liquid. Vapor patches accumulate at some locations and evaporation of the liquid between the surface and some of these patches dries out portions of the surface.

If the surface temperature is held constant and uniform, dry portions of the surface covered with a vapor film will locally transfer a much lower heat flux than wetted portions of the surface where nucleate boiling is occurring. Because of the reduction in heat flux from intermittently dry portions of the surface, the mean overall heat flux from the surface is reduced. Thus, increasing the wall temperature within the slugs and columns region ultimately results in a peaking and rollover of the heat flux. The peak value of heat flux is called the **critical heat flux** (CHF), designated as point *f* in Figure 4.4.3

If the wall temperature is increased beyond the critical heat flux condition, a regime is encountered in which the mean overall heat flux decreases as the wall superheat increases. This regime, which is usually referred to as the **transition boiling** regime, corresponds to segment *f-g* on the boiling curve shown in Figure 4.4.3. The transition boiling regime is typically characterized by rapid and severe fluctuations in the local surface heat flux and/or temperature values (depending on the imposed boundary condition). These fluctuations occur because the dry regions are generally unstable, existing momentarily at a given location before collapsing and allowing the surface to be rewetted.

The vapor film generated during transition boiling can be sustained for longer intervals at higher wall temperatures. Because the intermittent insulating effect of the vapor blanketing is maintained longer, the time-averaged contributions of the blanketed locations to the overall mean heat flux are reduced. The mean heat flux from the surface thus decreases as the wall superheat is increased in the transition regime. As this trend continues, eventually a point is reached at which the surface is hot enough to sustain a stable vapor film on the surface for an indefinite period of time. The entire surface then becomes blanketed with a vapor film, thus making the transition to the **film boiling** regime. This transition occurs at point *g* in Figure 4.4.3.

Within the film boiling regime, the heat flux monotonically increases as the superheat increases. This trend is a consequence of the increased conduction and/or convection transport due to the increased driving temperature difference across the vapor film. Radiative transport across the vapor layer may also become important at higher wall temperatures.

Once a surface is heated to a superheat level in the film boiling regime, if the surface temperature is slowly decreased, in general the system will progress through each of the regimes described above in reverse order. However, the path of the boiling curve may differ significantly from that observed for increasing wall superheat, depending on whether the surface heat flux or temperature is controlled.

Experimental evidence summarized by Witte and Lienhard (1982) implies that the path of the transition boiling curve is determined, to a large degree, by the wetting characteristics of the liquid on the solid surface. For a given wall superheat level in the transition boiling regime, a higher heat flux is generally obtained if the liquid wets the surface than if it poorly wets the surface. For systems that exhibit contact angle hysteresis, the transition boiling curves obtained for decreasing and increasing wall superheat may therefore be somewhat different. The transition boiling curve for decreasing wall superheat may be significantly below that for increasing superheat for such circumstances, as indicated in Figure 4.4.4.

For an electrically heated surface, the rise in temperature associated with the jump from nucleate to film boiling at the critical heat flux is very often large enough to melt component materials and burn out the component. As a result, the critical heat flux is often referred to as the *burnout heat flux* to

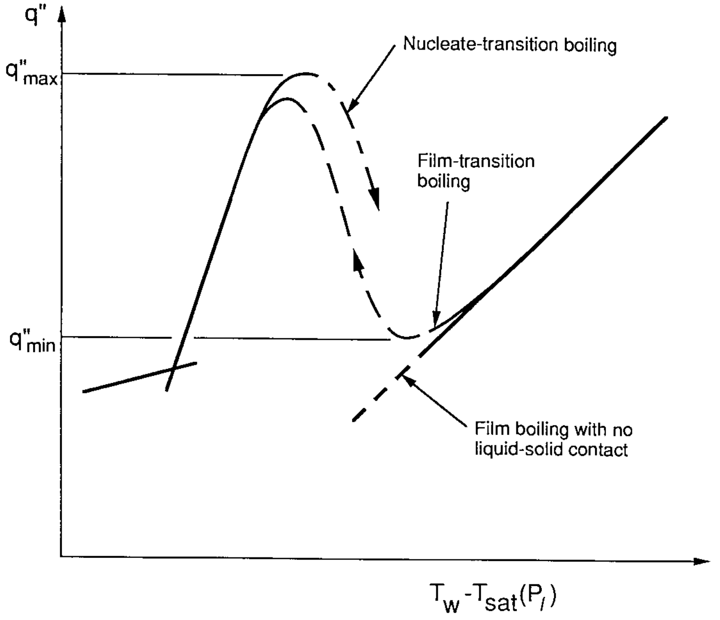

FIGURE 4.4.4 Relative locations of the nucleate transition and film transition portions of the pool boiling curve.

acknowledge the potentially damaging effects of applying this heat flux level to components cooled by nucleate boiling. Once the jump to film boiling has been made, any further increase in applied heat flux increases the wall superheat, and the system follows basically the same film boiling curve as in the temperature-controlled case.

Correlations of nucleate pool boiling heat transfer data have typically been used as tools to predict nucleate boiling heat transfer in engineering systems and heat exchangers. Many investigators have proposed methods of correlating data of this type; so many, in fact, that a complete discussion of them all could easily fill a major portion of this section. In this section, three of the more commonly used correlation methods will be mentioned. However, before proceeding, two aspects of the interpretation of such correlations are worth noting. First, experimental data indicate that the subcooling of the liquid pool has a negligible effect on the nucleate boiling heat transfer rate. Consequently, the pool boiling correlations are generally regarded as being valid for both subcooled and saturated nucleate boiling. Second, it has also been observed that at moderate to high heat flux levels, a pool boiling heat transfer correlation developed for one heated surface geometry in one specific orientation often works reasonably well for other geometries and/or other orientations. Hence, although a correlation was developed for a specific geometry and orientation, it may often be used for other geometries, at least at moderate to high heat flux levels.

Having taken note of the above points, a commonly used correlation for nucleate boiling heat transfer developed by Rohsenow (1962) is

$$\frac{q''}{\mu_l h_{fg}}\left[\frac{\sigma}{g(\rho_l-\rho_v)}\right]^{1/2}=\left(\frac{1}{C_{sf}}\right)^{1/r}\mathrm{Pr}_l^{-s/r}\left[\frac{c_{pl}\left[T_w-T_{sat}(P_l)\right]}{h_{fg}}\right]^{1/r} \tag{4.4.4}$$

Values of $r = 0.33$ and $s = 1.7$ are recommended for this correlation, but for water s should be changed to 1.0. The values of C_{sf} in this correlation vary with the type of solid surface and the type of fluid in the system. This empirically accounts for material property and/or wetting angle effects. Recommended values of C_{sf} for specific liquid–solid combinations are given by Rohsenow (1962), but whenever possible, an experiment should be conducted to determine the appropriate value of C_{sf} for the particular solid–liquid combination of interest. If this is not possible, a value of C_{sf} = 0.013 is recommended as a first approximation.

As noted previously, the pool boiling curve generally exhibits a maximum heat flux or CHF at the transition between nucleate and transition boiling. This peak value is the maximum level of heat flux from the surface which the system can provide in a nonfilm-boiling mode at a given pressure. The mechanism responsible for the CHF has been the subject of considerable investigation and debate over the past five decades. As the heat flux increases, bubbles generated at the surface coalesce to form vapor columns or jets. Perhaps the most widely cited CHF model postulates that the CHF condition occurs when Helmholtz instability of the large vapor jets leaving the surface distorts the jets, blocking liquid flow to portions of the heated surface. Continued vaporization of liquid at locations on the surface which are starved of replacement liquid than leads to formation of a vapor blanket over part or all of the surface. According to Zuber (1959) for a flat horizontal surface, the predicted maximum heat flux $q''_{\max}$ is

$$q''_{\max} = 0.131 \rho_v h_{fg} \left[\frac{\sigma_g (\rho_l - \rho_v)}{\rho_v^2} \right]^{1/4} \tag{4.4.5}$$

but Lienhard and Dhir (1973) recommend that the constant 0.131 in the above relation be replaced with 0.141. Other geometries are treated by Lienhard et al. (1973) and Lienhard and Dhir (1973b). An alternative model has been proposed by Haramura and Katto (1983).

Lienhard and Witte (1985) discuss the development and limitations of hydrodynamic CHF theories.

As shown in the Figure 4.4.3, the boundary between the transition boiling regime and the film boiling regime corresponds to a minimum in the heat flux vs. superheat curve. This condition is referred to as the **minimum heat flux** condition, referred to as the *Leidenfront point*. The minimum heat flux corresponds approximately to the lowest heat flux which will sustain stable film boiling.

For an infinite flat (upward-facing) heated surface, vapor generated at the interface during stable film boiling is released as bubbles at the nodes of a standing two-dimensional Taylor wave pattern. The following relation for the minimum heat flux $q''_{\min}$ derived by Zuber (1959) and Berenson (1961).

$$q''_{\min} = 0.09 \rho_v h_{fg} \left[\frac{\sigma_g (\rho_l - \rho_v)}{(\rho_l + \rho_v)^2} \right]^{1/4} \tag{4.4.6}$$

$q''_{\min}$ correlations have been developed by Lienhard and Wong (1964) for horizontal cylinders and Gunnerson and Cronenberg (1980) for spheres.

In film boiling, transport of heat across the vapor film from the wall to the interface may occur by convection, conduction, and radiation. The radiation contribution depends on the nature of the solid surface, but when the radiation effect is small, the heat transfer for film boiling is independent of the material properties and finish of the surface. For buoyancy-driven laminar film boiling over a vertical flat isothermal surface in a pool of saturated liquid, the local heat transfer coefficient from the surface can be obtained from the following relation:

$$h = \left[\frac{k_v^3 g \rho_v (\rho_l - \rho_v) h_{fg}}{4 \mu_v (T_w - T_{\text{sat}}) x} \right]^{1/4} \tag{4.4.7}$$

At low surface temperatures, radiation effects are negligible and consideration of convective transport alone is sufficient to predict the heat transfer. At higher temperatures radiation effects must also be included. If the vapor in the film absorbs and emits radiation at infrared wavelengths, a detailed treatment of the radiation interaction with the vapor may be necessary to accurately predict the film boiling heat transfer.

Additional information mechanisms such as interfacial waves, turbulence, and variable properties is summarized in Carey (1992).

Transition pool boiling has traditionally been interpreted as a combination of nucleate and film boiling alternately occurring over the heated surface, and a model of transition boiling that accounts for contact angle effects has been proposed by Ramilison and Lienhard (1987).

Internal Convective Boiling

Flow boiling in tubes is perhaps the most complex convective process encountered in applications. In most evaporator and boiler applications, the flow is either horizontal or vertically upward. Figure 4.4.5 schematically depicts a typical low-flux vaporization process in a horizontal round tube. In this example liquid enters as subcooled liquid and leaves as superheated vapor. As indicated in Figure 4.4.5, the flow undergoes transitions in the boiling regime and the two-phase flow regime as it proceeds down the tubes. The regimes encountered depend on the entrance conditions and the thermal boundary conditions at the tube wall. At low quality the vaporization process is dominated by nucleate boiling, with convective effects being relatively weak. As the quality increases, the flow quickly enters the annular film flow regime in which convective evaporation of the annular liquid film is the dominant heat transfer mechanism. Often the conditions are such that liquid droplets are often entrained in the core vapor flow during annular flow evaporation. Eventually, the annular film evaporates away, leaving the wall dry. Mist-flow evaporation of entrained liquid droplets continues in the post-dryout regime until only vapor remains. Similar, sequences of flow and boiling regimes occurring in vertical upward flow, as indicated in Figure 4.4.6.

The boiling regime trends shown in Figure 4.4.5 and Figure 4.4.6 are typical for low heat flux vaporization processes. At high wall superheat levels, transition boiling or film boiling can also occur. The transition from nucleate boiling to one of these regimes is termed a *departure from nucleate boiling* (DNB) or the CHF condition. However, the heat transfer performance of an evaporator under transition or film boiling conditions is so poor that equipment is not usually designed to operate under such conditions.

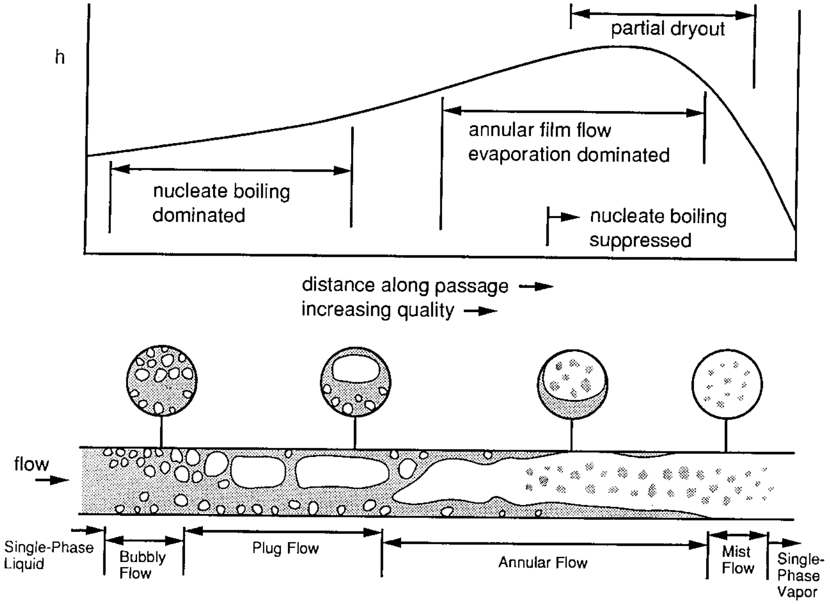

FIGURE 4.4.5 Qualitative variation of the heat transfer coefficient *h* and flow regime with quality for internal convective boiling in a horizontal tube at moderate wall superheat.

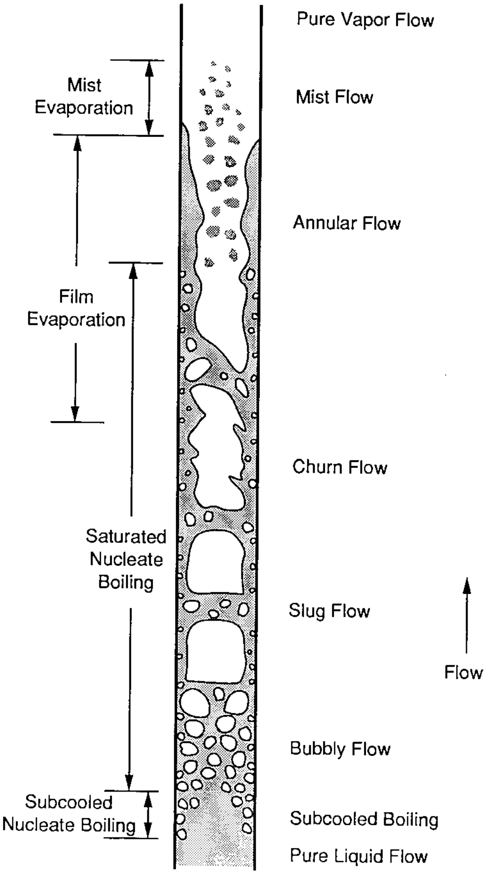

FIGURE 4.4.6 Flow regimes and boiling mechanisms for upflow convective boiling in a vertical tube at moderate wall superheat.

Because low-quality or subcooled flow boiling are nucleate boiling dominated, the heat transfer coefficient in these regimes is often predicted using a nucleate boiling correlation developed as a fit to pool boiling data. The usefulness of such an approach is a consequence of the fact that for most conditions of practical interest, nucleate boiling heat transfer is only weakly affected by liquid subcooling or liquid bulk convection.

For saturated convective boiling prior to dryout, relations to predict the heat transfer coefficient have typically been formulated to impose a gradual suppression of nucleate boiling and gradual increase in liquid film evaporation heat transfer as the quality increases. A number of correlations based on such an approach have been developed. An early correlation of this type developed by Chen (1966) has been widely used. One of the better methods of this type is the recently developed correlation of Kandlikar (1989) which has been fit to a broad spectrum of data for both horizontal and vertical tubes. For this method the heat transfer coefficient for a tube of diameter D is given by

$$h = h_l\left[C_1 Co^{C_2}\left(25\mathrm{Fr}_{le}\right)^{C_5} + C_3 Bo^{C_4} F_K\right] \tag{4.4.8}$$

where

$$Co = \left(\frac{1-x}{x}\right)^{0.8}\left(\frac{\rho_v}{\rho_l}\right)^{0.5} \tag{4.4.9}$$

TABLE 4.4.1 Constants for the Correlation of Kandlikar (1987)

	$Co < 0.65$ (Convective Region)	$Co \geq 0.65$ (Nucleate Boiling Region)
C_1	1.1360	0.6683
C_2	–0.9	–0.2
C_3	667.2	1058.0
C_4	0.7	0.7
C_5[a]	0.3	0.3

[a] $C_5 = 0$ for vertical tubes and horizontal tubes with $\mathrm{Fr}_{le} > 0.04$.

$$Bo = q''/Gh_{fg} \tag{4.4.10}$$

$$Fr_{le} = G^2/\rho_l^2 gD \tag{4.4.11}$$

and h_l is the single-phase heat transfer coefficient for the liquid phase flowing alone in the tube computed as

$$h_l = 0.023\left(\frac{k_l}{D}\right)\left(\frac{G(1-x)D}{\mu_l}\right)^{0.8} \mathrm{Pr}_l^{0.4} \tag{4.4.12}$$

The constants $C_1 - C_5$ are given in Table 4.4.1. The factor F_K is a fluid-dependent parameter. For water, $F_K = 1$. For R-12 and nitrogen, recommended values of F_K are 1.50 and 4.70, respectively. Values of F_K for a variety of other fluids can be obtained from Kandlikar (1989).

Methods for predicting the conditions at which dryout or a DNB transition occurs have typically been empirical in nature. Based on fits to extensive data, Levitan and Lantsman (1975) recommended the following relations for the DNB heat flux and the quality at which dryout occurs during flow boiling of water in a tube with an 8-mm diameter.

$$q''_{\text{crit}} = \left[10.3 - 7.8\left(\frac{P}{98}\right) + 1.6\left(\frac{P}{98}\right)^2\right]\left(\frac{G}{1000}\right)^{1.2\{[0.25(P-98)/98]-x\}} e^{-1.5x} \tag{4.4.13}$$

$$x_{\text{crit}} = \left[0.39 + 1.57\left(\frac{P}{98}\right) - 2.04\left(\frac{P}{98}\right)^2 + 0.68\left(\frac{P}{98}\right)^3\right]\left(\frac{G}{1000}\right)^{-0.5} \tag{4.4.14}$$

In the above relations, q''_{crit} is in MW/m², P is the pressure in bar, and G is in kg/m²sec. To obtain values of q''_{crit} and x_{crit} for diameters other than 8 mm, Levitan and Lantsman (1975) recommended that the 8-mm values from the above relations be corrected as follows:

$$q''_{\text{crit}} = \left(q''_{\text{crit}}\right)_{8\text{mm}}\left(\frac{8}{D}\right)^{1/2} \tag{4.4.15}$$

$$x_{\text{crit}} = \left(x_{\text{crit}}\right)_{8\text{mm}}\left(\frac{8}{D}\right)^{0.15} \tag{4.4.16}$$

where D is the diameter in millimeters. A good generalized empirical correlation for predicting dryout or CHF conditions in vertical uniformly heated tubes is that recently proposed by Katto and Ohno (1984).

In many cases, post-dryout mist flow evaporation is driven primarily by convective transport from the tube wall to the gas and then to the entrained droplets. In some circumstances, impingement of droplets onto the heat surface and radiation interactions may also be important. In cases where convection is dominant, predictions of the heat transfer coefficient have been developed by modifying a single-phase correlation for the entire flow as vapor with a correction factor which accounts for the presence of the entrained droplets. Often this correction factor has been presumed to be a function of property ratios. An example of such an approach is the correlation of Dougall and Rohsenow (1963) for which the heat transfer coefficient h is given by

$$\frac{hD}{k_v} = 0.023\left[\left(\frac{GD}{\mu_v}\right)\left(x + \frac{\rho_v}{\rho_l}(1-x)\right)\right]^{0.8} \mathrm{Pr}_{v,\mathrm{sat}}^{0.4} \tag{4.4.17}$$

For further information on mechanisms of convective boiling, see the texts of Collier (1996), Stephan (1992), and Carey (1992).

Condensation

As in the case of boiling, surface tension effects, surface wetting characteristics, and metastable phase stability also can play important roles in condensation processes. As a result of interfacial tension, the pressure inside a spherical liquid droplet of radius r must exceed that in the surrounding liquid by $2\sigma/r$. A consequence of this and basic thermodynamics is that at equilibrium the surrounding vapor must actually be slightly supersaturated. The amount of supersaturation required at equilibrium increases as the radius of curvature of the bubble interface decreases.

For a liquid droplet on a solid surface with a specified volume, the wetting contact angle dictates the radius of curvature of the droplet interface. Because of the linkage between the interface curvature and the required equilibrium supersaturation, the wetting behavior thus determines the level above which the vapor supersaturation must be raised for the droplet to grow. Steady condensation on the droplet interface can be sustained only if the vapor is driven beyond this supersaturation level by cooling or depressurization. For such conditions, the vapor is in the metastable supersaturated range indicated in Figure 4.4.2.

Condensation on external surfaces of a body immersed in a gas phase generally falls into one or two categories: **dropwise condensation** or **film condensation**. In dropwise condensation, the liquid-phase condensate collects as individual droplets which grow in size with time on the cold surface. This mode of condensation is most likely when the liquid poorly wets the solid surface. When the condensation rate is high or the liquid readily wets the surface, a film of liquid condensate covers the solid surface, and the process is referred to as film condensation.

Dropwise Condensation. Dropwise condensation may occur on a solid surface cooled below the saturation temperature of a surrounding vapor when the surface is poorly wetted except at locations where well-wetted contaminant nuclei exist. The poorly wetted surface condition can result from contamination or coating of the surface with a substance which is poorly wetted by the liquid phase of the surrounding vapor. In practice, this can be achieved for steam condensation by (1) injecting a nonwetting chemical into the vapor which subsequently deposits on the surface, (2) introducing a substance such as a fatty (i.e., oleic) acid or wax onto the solid surface, or (3) by permanently coating the surface with a low-surface-energy polymer or a noble metal. The effects of the first two methods are generally temporary, since the resulting surface films eventually are dissolved or eroded away.

During dropwise condensation, the condensate is usually observed to appear in the form of droplets which grow on the surface and coalesce with adjacent droplets. When droplets become large enough, they are generally removed from the surface by the action of gravity or drag forces resulting from the motion of the surrounding gas. As the drops roll or fall from the surface they merge with droplets in their path, effectively sweeping the surface clean of droplets. Droplets then begin to grow anew on the freshly-exposed solid surface. This sweeping and renewal of the droplet growth process is responsible for the high heat transfer coefficients associated with dropwise condensation. Theoretical aspects of dropwise condensation are described in two publications by Tanaka (1975, 1979). A discussion of correlations for the heat transfer coefficient associated with dropwise condensation is provided in the review article by Merte (1973).

External Film Condensation. If the liquid phase fully wets a cold surface in contact with a vapor near saturation conditions, the conversion of vapor to liquid will take the form of film condensation. As the name implies, the condensation takes place at the interface of a liquid film covering the solid surface. Because the latent heat of vaporization must be removed at the interface to sustain the process, the rate of condensation is directly linked to the rate at which heat is transported across the liquid film from the interface to the surface.

The classic integral analysis of Nusselt (1916) for laminar falling-film condensation on a vertical surface considers the physical circumstances shown in Figure 4.4.7. The surface exposed to a motionless ambient of saturated vapor is taken to be isothermal with a temperature below the saturation temperature. Note that although a vertical surface is considered here, the analysis is identical for an inclined surface, except that the gravitational acceleration g is replaced by $g \sin \Omega$, with Ω being the angle between the surface and the horizontal. Because the liquid film flows down the surface because of gravity, this situation is sometimes referred to as *falling-film condensation*.

In its simplest form, the classic Nusselt analysis incorporates the following idealizations: (1) laminar flow, (2) constant properties, (3) that subcooling of liquid is negligible in the energy balance, (4) that inertia effects are negligible in the momentum balance, (5) that the vapor is stationary and exerts no drag, (6) that the liquid-vapor interface is smooth, and (7) that heat transfer across film is only by conduction (convection is neglected). With these idealizations, the following relation for the local heat transfer coefficient h can be obtained

$$\frac{hz}{k_l} = \left[\frac{\rho_l(\rho_l - \rho_v) g h_{fg} z^3}{4 k_l \mu_\ell (T_{\text{sat}} - T_w)} \right]^{1/4} \tag{4.4.18}$$

Modified versions of this analysis have been subsequently developed which relax many of these assumptions. Laminar film condensation on a vertical surface can also be analyzed with a full boundary layer formulation. An example of this type of approach is the analysis presented by Sparrow and Gregg (1959).

The analyses described above do not include two physical mechanisms which can significantly affect the transport: (1) the effects of waves on the liquid-vapor interface and (2) interfacial vapor shear drag on the interface. The effects of interfacial shear have been studied analytically by numerous investigators. The effects of surface waves on laminar film condensation are more difficult to incorporate into theoretical analyses. In general, interfacial waves are expected to enhance convective heat transport in the film since it intermittently thins the film, increases the interfacial area, and induces mixing. Because of these effects,

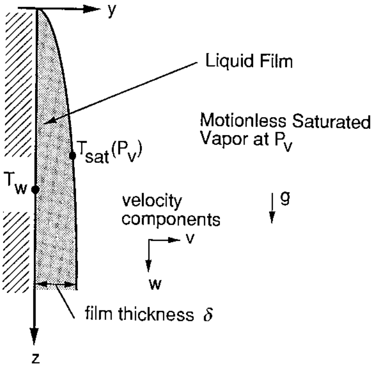

FIGURE 4.4.7 System model for the Nusselt analysis of falling-film condensation.

laminar film condensation heat transfer data are often significantly higher than the values predicted by simple boundary layer models.

As for any boundary layer flow, when the film Reynolds number becomes large enough, it is expected that a transition to turbulent flow will occur. Eddy diffusivity models of the resulting turbulent transport have been developed by Seban (1954), Dukler (1960), and others. This methodology was later extended to evaporation of a falling liquid film (see, for example, Mills and Chung, 1973).

Subsequent studies (see, for example, Mills and Chung, 1973) have suggested that the presence of the interface tends to damp larger turbulent eddies near the interface in the liquid film. This implies that a viscous sublayer exists at the interface as well as at the wall. Recent efforts to model turbulent falling-film evaporation and condensation processes have therefore included a variation of the eddy viscosity in which it goes to zero at both the wall and the interface. The analysis tools and correlations described above work reasonably well for values of liquid Prandtl number above 1. However, deviation of the predictions using these methods from heat transfer data for liquid metals can be quite significant.

Because of its importance to the design of tube-and-shell condensers, condensation on the outside of horizontal tubes has been the subject of numerous studies. The length of the tube perimeter over which the condensate flows is usually small for commonly used tubes. Consequently, the film Reynolds number is usually low and the flow in the liquid film is laminar.

With slight modification, the Nusselt (1916) analysis of laminar falling-film condensation over a flat plate can be adapted to film condensation on an isothermal horizontal cylinder. Doing so yields the following relation for the mean heat transfer coefficient:

$$\frac{\bar{h}D}{k_l} = 0.728\left[\frac{\left(\rho_l - \rho_v\right) g h_{fg} D^3 \mathrm{Pr}_l}{\rho_l \nu_l^2 c_{pl}\left(T_{\mathrm{sat}} - T_w\right)}\right]^{1/4} \tag{4.4.19}$$

Selin (1961) found that better agreement with film condensation data for horizontal tubes was obtained by replacing the constant factor in Equation (4.4.19) by 0.61. Correlations similar to the single-tube relation above have also been developed for the average condensation heat transfer coefficient for banks of round tubes.

Analytical treatment of laminar film condensation on a sphere is virtually the same as that for a horizontal cylinder. The only differences result from the angular variation of the body perimeter because of the spherical geometry. A general analytical prediction of the local heat transfer coefficient for laminar film condensation on arbitrary axisymmetric bodies has been developed by Dhir and Lienhard (1971).

Condensation in the Presence of a Noncondensable Gas. In nature and in a number of technological applications, condensation of one component vapor in a mixture may occur in the presence of other noncondensable components. The most common example is the condensation of water vapor in the air on a cold solid surface. If the component gases are considered to be a mixture of independent substances, condensation of one component vapor will occur if the temperature of the surface is below the saturation temperature of the pure vapor at its partial pressure in the mixture. This temperature threshold is referred to as the *dew point* of the mixture.

Because only the vapor is condensed, the concentration of the noncondensable gas at the interface is higher than its value in the far ambient. This, in turn, decreases the partial pressure of the vapor at the interface below its ambient value. The corresponding saturation temperature at the interface is therefore lower than the bulk temperature. The resulting depression of the interface temperature generally reduces the condensation heat transfer rate below that which would result for pure vapor alone under the same conditions. Space limitations here preclude a detailed discussion of the effects of noncondensable gases. The interested reader may find more-extensive discussions of this topic in the references by Collier (1996) and Carey (1992).

Internal Convective Condensation. In most power and refrigeration systems, the flow in the condenser is either horizontal or vertically downward. Figure 4.4.8 schematically depicts a typical condensation process

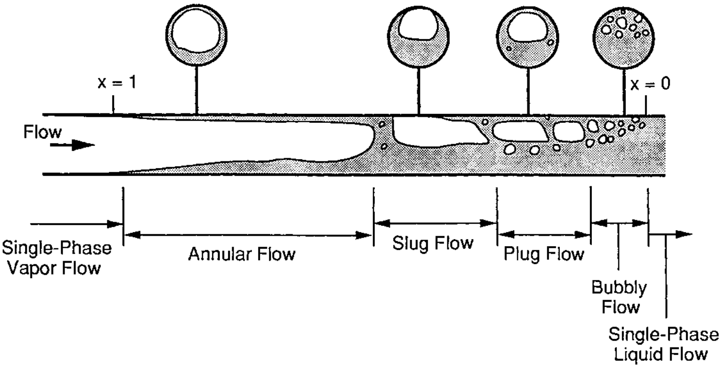

FIGURE 4.4.8 Flow regimes during horizontal cocurrent flow with condensation.

in a horizontal round tube. Superheated vapor enters the tube and at the exit end the liquid is subcooled. At a point some distance downstream of the entrance, vapor begins to condense on the walls of the tube. The location at which this occurs is at or slightly before the bulk flow reaches the equilibrium saturation condition. In most condensers, the liquid readily wets the interior of the tube and at high vapor volume fractions the liquid forms a thin liquid film on the interior wall of the tube.

The vapor velocity is generally high at the inlet end of the condenser tube, and the liquid film is driven along the tube by strong vapor shear on the film. At low vapor flow rates, some stratification may occur and the film may be thicker on the bottom of the horizontal tube. At high vapor flow rates, turbulent stresses acting on the liquid may tend to keep the thickness of the liquid film nominally uniform over the perimeter of the tube.

In most condenser applications, shear-dominated annular flow persists to very low qualities and the overwhelming majority of the heat transfer occurs in this regime. The very last stage of the condensation process, corresponding to qualities less than a few percent, may occur in slug, plug, or bubbly two-phase flow. Generally these regimes represent such a small portion of the overall heat transfer in the condenser that some inaccuracy in estimating the heat transfer coefficient for them is tolerated. As a first estimate, the heat transfer coefficient may be predicted using a correlation for pure single-phase liquid flow in the tube at the same total flow rate, or a correlation for annular flow condensation may simply be extrapolated to zero quality.

Because most of the heat duty occurs in the annular flow regime, accurate prediction of the overall heat transfer performance of the condenser requires a predictive methodology that accurately treats the transport in this regime. For this reason, the form of most correlation methods for predicting local convective condensation heat transfer coefficients are optimized to match data in the annular flow regime. One example of such a correlation is the following relation for the local heat transfer coefficient for annular flow condensation proposed by Traviss et al. (1973):

$$\frac{hD}{k_l} = \frac{0.15 \mathrm{Pr}_l \mathrm{Re}_l^{0.9}}{F_T} \left[\frac{1}{X_{tt}} + \frac{2.85}{X_{tt}^{0.476}} \right] \tag{4.4.20}$$

where

$$\mathrm{Re}_l = \frac{G(1-x)D}{\mu_l}, \qquad X_{tt} = \left(\frac{1-x}{x} \right)^{0.9} \left(\frac{\rho_v}{\rho_l} \right)^{0.5} \left(\frac{\mu_l}{\mu_v} \right)^{0.1}$$

and F_T is given by

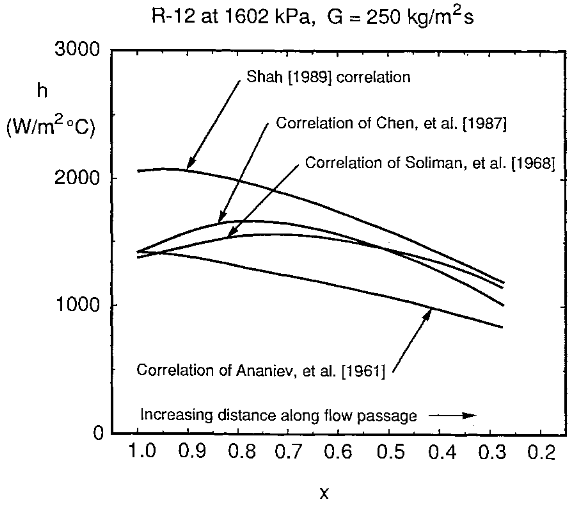

FIGURE 4.4.9 Comparison of the variation of *h* with *x* predicted by four correlation methods for internal convective condensation. References cited in this figure are listed in chapter 11 of Carey (1992).

$$
\begin{aligned}
F_T &= 5\mathrm{Pr}_l + 5\ln\left\{1 + 5\mathrm{Pr}_l\right\} + 2.5\ln\left\{0.0031\mathrm{Re}_l^{0.812}\right\} && \text{for} \quad \mathrm{Re}_l > 1125 \\
&= 5\mathrm{Pr}_l + 5\ln\left\{1 + \mathrm{Pr}_l\left(0.0964\mathrm{Re}_l^{0.585} - 1\right)\right\} && \text{for} \quad 50 < \mathrm{Re}_l < 1125 \\
&= 0.707\mathrm{Pr}_l\mathrm{Re}_l^{0.5} && \text{for} \quad \mathrm{Re}_l < 50
\end{aligned}
$$

Carey (1992) has shown that the generic form of this correlation can be derived from a theoretical model of annular flow condensation in a round tube. Several correlations of this general type have been developed as fits to experimental data; see Carey (1992) for a summary. The predictions of these correlations may vary significantly for a given set of conditions. When possible, a correlation should be selected which has been tested against data for conditions close to those for the application of interest.

A correlation methodology that can be used to predict internal convective condensation heat transfer for slug, plug, or wavy stratified flow has also been proposed by Rossen and Meyers (1965). To predict the overall heat transfer performance of a condenser, methods to predict the local heat transfer coefficient must be combined with a scheme to numerically integrate finite-difference forms of the energy, mass, and momentum balances in the tube. For further information on such schemes see the references by Collier (1996) and Carey (1992) (Figure 4.4.9).

Defining Terms

Critical heat flux (CHF): A maximum heat flux condition that characterizes the transition between nucleate boiling and transition boiling or film boiling.

Dropwise condensation: Condensation of vapor into liquid in discrete droplets, usually attained when a cold surface is poorly wetted by the liquid phase.

Film boiling: Generation of vapor at the interface of a vapor film which entirely covers the hot surface.

Film condensation: Condensation of vapor onto the interface of a liquid film that completely covers a cold surface.

Minimum heat flux: A minimum heat flux condition on the classic boiling curve that characterizes the transition between film boiling and transition boiling. Also, sometimes referred to as the Leidenfrost point, it is a lower bound for heat flux values at which stable film boiling may occur.

Nucleate boiling: Generation of vapor at a hot surface by formation of bubbles at discrete nucleation sites with full liquid wetting of the surface.

Polar molecules: Molecules which have a permanent electric dipole moment. Examples include water and ammonia.

Pool boiling: Generation of vapor at the surface of a hot body immersed in an extensive liquid pool.

Transition boiling: Generation of vapor at a hot surface with intermittent or partial liquid wetting of the surface.

Particle Gas Convection

John C. Chen

Introduction

Heat transfer in two-phase systems involving gas and solid particles are encountered in several types of operations important in chemical, power, and environmental technologies. Chief among these are gas fluidized beds which are widely used to achieve either physical processing or chemical reactions that require interfacial contact between gas and solid particles. Currently, fluidized beds operate in either the *bubbling regime* or the *fast-circulating regime*. In the first case, particles are retained in the fluidized bed while the gas passes upward past the particles, partially as rising bubbles. In the second case, gas velocities exceed terminal velocity for the individual particles and the two phases flow through the fluidized bed in cocurrent upward flow. For those applications which require thermal control, convective heat transfer between the fluidized medium and heat transfer surfaces (either immersed tubes or the vessel walls) is an essential element of the process design.

Bubbling Fluidized Beds

Bubbling fluidization occurs when the superficial gas velocity exceeds a critical value wherein the gravitational body force on the solid particles is balanced by the shear force between particles and flowing gas. The superficial gas velocity at this condition, commonly called the minimum fluidization velocity (U_{mf}), marks the boundary between gas flow through packed beds and gas flow in fluidized beds. Wen and Yu (1966) derived the following general equation to estimate U_{mf} for spherical particles:

$$\mathrm{Re}_{mf} = \left[(33.7)^2 + 0.0408\mathrm{Ar}\right]^{1/2} - 33.7 \qquad (4.4.21)$$

where

$$\mathrm{Re}_{mf} = \text{particle Reynolds number at } U_{\mathrm{mf}} = \frac{U_{\mathrm{mf}} d_p \rho_g}{\mu_g}$$

$$\mathrm{Ar} = \text{Archimedes number} = \frac{d_p^3 \rho_g \left(\rho_s - \rho_g\right) g}{\mu_g^2}$$

Increasing gas velocity beyond minimum fluidization causes the excess gas to collect into discrete bubbles that grow and rise through the fluidized matrix of solid particles. In this bubbling fluidization regime, the total pressure drop over the height of the fluidized bed, H, is equal to the hydrostatic pressure of the solid mass,

$$\Delta P = g\rho_s (1 - \varepsilon) H \qquad (4.4.22)$$

where ε = volume fraction of gas (void fraction).

Tubes carrying cooling or heating fluids are often immersed in bubbling fluidized beds to extract or add thermal energy. The effective heat transfer coefficient at the surface of such tubes has been the objective of numerous experimental and analytical investigations. Data for the circumferentially averaged heat transfer coefficient for horizontal tubes are shown in Figure 4.4.10 for various types of solid particles. Characteristics representative of such systems are

- The heat transfer coefficient increases sharply as the gas velocity exceeds minimum fluidization velocity,
- After the initial increase, the heat transfer coefficient remains fairly constant over a significant range of the gas velocity beyond minimum fluidization velocity,
- The absolute magnitude of the heat transfer coefficient is severalfold greater than single-phase gas convection at the same superficial velocity,
- The heat transfer coefficient increases as particle size decreases.

Kunii and Levenspiel (1991) have shown that increasing gas pressure and density significantly increases the magnitude of the heat transfer coefficient as well as promoting the occurrence of minimum fluidization at a lower value of superficial gas velocity. The effect of bundle spacing is insignificant at 1-atm pressure but becomes increasingly more important as gas pressure and density increase. The data of Jacob and Osberg (1957) indicate that the convective heat transfer coefficient in fluidized beds increases with increasing thermal conductivity of the gas phase, for any given particle size.

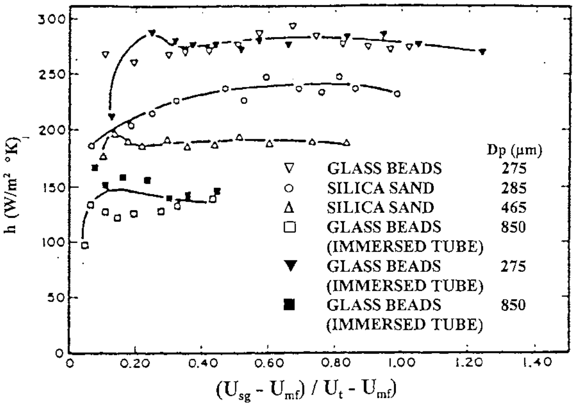

FIGURE 4.4.10 Average heat transfer coefficients for horizontal tubes immersed in bubbling fluidized beds. (From Biyikli, Tuzla and Chen, 1983.)

Several different types of correlations have been suggested for predicting convective heat transfer coefficients at submerged surfaces in bubbling fluidized beds. The first type attributes the enhancement of heat transfer to the scouring action of solid particles on the gas boundary layer, thus decreasing the effective film thickness. These models generally correlate a heat transfer Nusselt number in terms of the fluid Prandtl number and a modified Reynolds number with either the particle diameter or the tube diameter as the characteristic length scale. Examples are

Leva's correlation for vertical surfaces and larger particles (Leva and Gummer, 1952);

$$\mathrm{Nu}_{d_p} = \frac{h_c d_p}{k_g} = 0.525\left(\mathrm{Re}_p\right)^{0.75} \tag{4.4.23}$$

where

$$\mathrm{Re}_p = \frac{d_p \rho_g U}{\mu_g}$$

Vreedenberg's (1958) correlation for horizontal tubes refers to the particle of diameter D_t.

$$\mathrm{Nu}_{Dt} = \frac{h_c D_t}{k_g} = 420\left(\frac{\rho_s}{\rho_g}\mathrm{Re}_t\right)^{0.3}\left(\frac{\mu_g^2}{g\rho_s^2 d_p^3}\right)^{0.3}\left(\mathrm{Pr}_g\right)^{0.3} \tag{4.4.24}$$

for

$$\left(\frac{\rho_s}{\rho_g}\mathrm{Re}_t\right) > 2250$$

where

$$\mathrm{Re}_t = \frac{D_t \rho_g U}{\mu_g}$$

Molerus and Schweinzer (1989) developed an alternative type of correlation based on the supposition that the heat transfer is dominated by gas convection through the matrix of particles in the vicinity of the heat transfer surface. Their correlation takes the form:

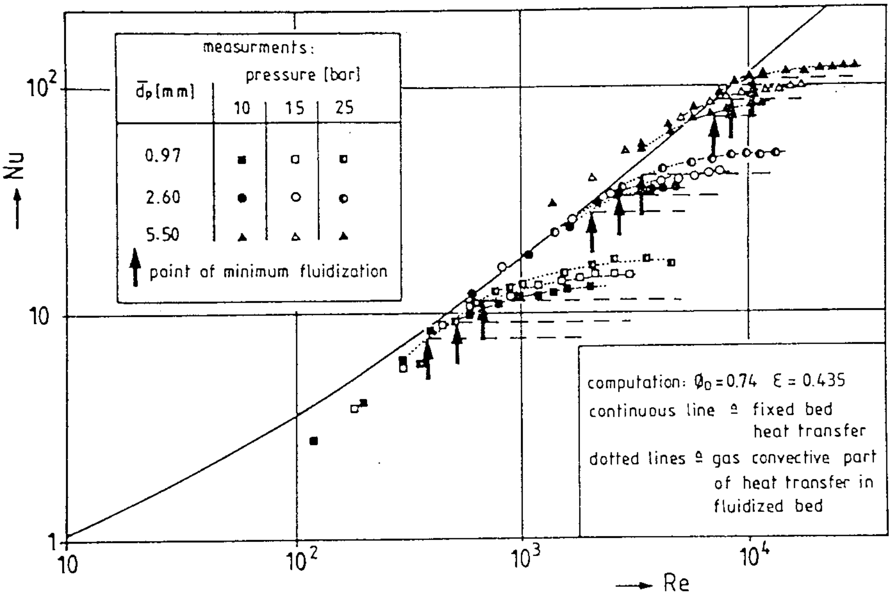

FIGURE 4.4.11 Correlation of Molerus and Schweinzer compared with experimental data (1989).

$$\mathrm{Nu} = \frac{h_c d_p}{k_g} = 0.0247(\mathrm{Ar})^{0.4304}(\mathrm{Pr})^{0.33} \tag{4.4.25}$$

Figure 4.4.11 shows comparison of this model with experimental data obtained at three different pressures. The solid curve represents the relationship for fixed beds, while the dashed lines represent the behavior for fluidized beds (i.e., Equation 4.4.25) upon exceeding minimum fluidization.

A third type of model considers the heat transfer surface to be contacted alternately by gas bubbles and packets of packed particles, leading to a surface renewal process for heat transfer. Mickley and Fairbanks (1955) provided the first analysis of this renewal mechanism. Ozkaynak and Chen (1980) showed that if experimentally measured values of the packet contact time and residence times are used in the packet model analysis, excellent agreement is obtained.

Fast-Circulating Fluidized Beds

Fast fluidization occurs when the superficial gas velocity exceeds the terminal velocity of the solid particles, causing the particles to be suspended in cocurrent upward flow with the gas. This upward flow occurs in “rise reactors” wherein desired physical or chemical reactions occur. In most applications, the two-phase flow exits the top of the riser into a cyclone where the gas phase is separated and exhausted while the solid particles are captured and returned for reinjection at the bottom of the riser. The volumetric concentration of solid particles in these fast fluidized beds (FFBs) tend to be fairly dilute, often with average concentrations of less than 2%. Heat exchange with the particle/gas suspension is usually accomplished through the vertical wall surfaces or through vertical tubes immersed in the duct.

The heat transfer coefficient at vertical surfaces FFBs has been found to increase with increasing solid concentration, aside from other second-order parametric effects. Figure 4.4.12 shows heat transfer coefficients experimentally measured by Dou et al. (1994) for an FFB operating with sand particles of 124 μm mean diameter. Figure 4.4.12b shows that the heat transfer coefficient increased with solid mass flux, for a constant superficial gas velocity. Figure 4.4.12a shows that the heat transfer coefficient decreased parametrically with superficial gas velocity for a constant solid mass flux. Both figures indicate that heat transfer coefficients decrease with increasing elevation in the riser duct. These three parametric trends

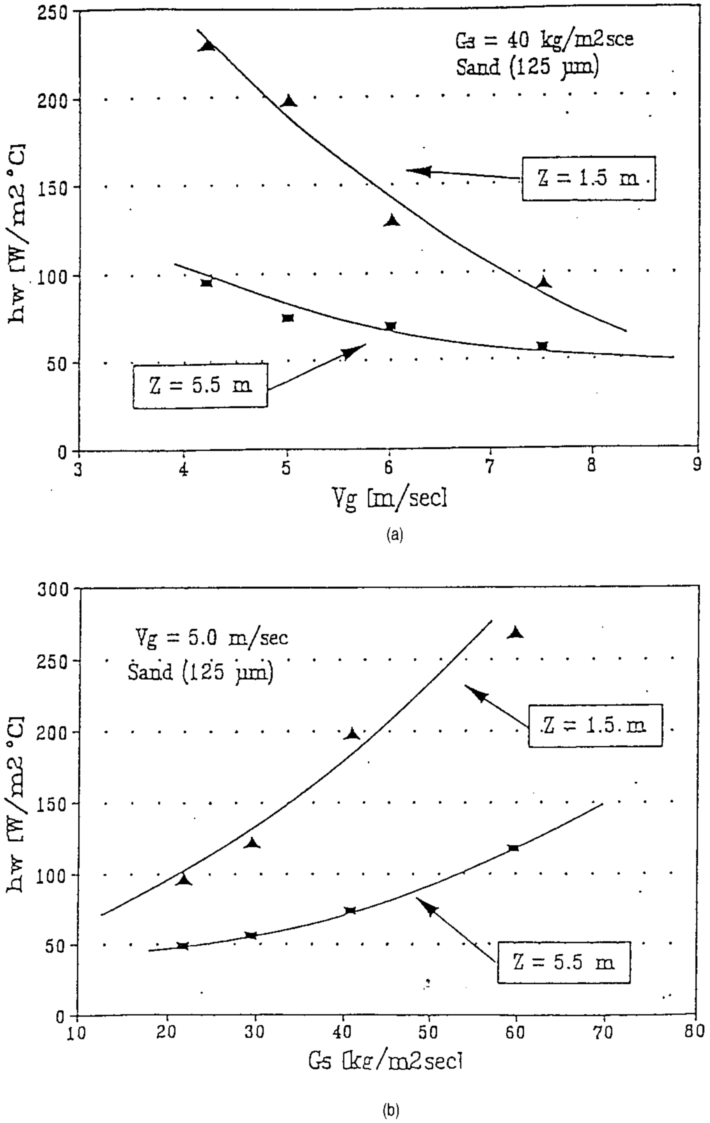

FIGURE 4.4.12 Heat transfer coefficients in fast fluidized beds; Vg is superficial gas velocity, Gs is mass flux of particles, and Z is elevation in FFB. (From Dou, Tuzla and Chen, 1992.)

are all consistent with the hypothesis that heat transfer in FFBs increases with increasing concentration of the solid phase.

It is generally accepted that the effective heat transfer coefficient for surfaces in FFBs have contributions for gas-phase convection, particle-induced convection, and radiation:

$$h = h_g + h_p + h_r \tag{4.4.26}$$

In contrast to the situation in dense-bubbling fluidized beds, the relatively dilute concentration of solid particles in FFBs often results in significant contributions from all three heat transfer mechanisms. The radiation coefficient can be obtained by a gray body model suggested by Grace (1985). The contribution of the gas phase convection (h_g) is commonly estimated based on correlations for gas flow alone at the same superficial gas velocity. Although the presence of particles may alter the turbulence characteristic of this gas flow, any errors caused by this procedure are usually small since h_g is generally smaller than the particle-phase convective coefficient h_p.

For most FFBs, the particle convective contribution to heat transfer is most important and the prediction of h_p is the major concern in thermal design. Unfortunately, mechanistically based models are still lacking and most design methods rely on empirical correlations which often combine the contributions of gas and particle phases into a single convective heat transfer coefficient (h_c). One such correlation proposed by Wen and Miller (1961) is

$$\mathrm{Nu}_{dp} = \frac{h_c d_p}{k_g} = \left(\frac{C_{pp}}{C_{pg}}\right)\left(\frac{\rho_{\mathrm{susp}}}{\rho_p}\right)^{0.3}\left(\frac{V_t}{g d_p}\right)^{0.21} \mathrm{Pr}_g \tag{4.4.27}$$

where V_t = terminal velocity of particle.

Other correlations have been proposed by Fraley (1992) and Martin (1984). These correlations are useful as a starting point but have not yet been verified over wide parametric ranges. Large deviations can occur when compared with measurements obtained outside of the experimental parametric ranges.

Melting and Freezing

Noam Lior

Introduction and Overview

Melting and freezing occur naturally (Lunardini, 1981) as with environmental ice in the atmosphere (hail, icing on aircraft), on water bodies and ground regions at the Earth surface, and in the molten Earth core (Figure 4.4.13). They are also a part of many technological processes, such as preservation of

FIGURE 4.4.13 Melting and freezing in nature. (a) A melting icicle. (b) Frozen lava in Hawaii.

foodstuffs (ASHRAE, 1990, 1993), refrigeration and air-conditioning (ASHRAE, 1990, 1993), snow and ice making for skiing and skating (ASHRAE, 1990), organ preservation and cryosurgery (Rubinsky and Eto, 1990), manufacturing (such as casting, molding of plastics, coating, welding, high-energy beam cutting and forming, crystal growth, electrodischarge machining, electrodeposition) (Flemings, 1974; Cheng and Seki, 1991; Tanasawa and Lior, 1992), and thermal energy storage using solid–liquid phase-changing materials (deWinter, 1991).

In simple thermodynamic systems (i.e., without external fields, surface tension, etc.) of a pure material, melting or freezing occurs at certain combinations of temperature and pressure. Since pressure typically has a relatively smaller influence, only the fusion (freezing or melting) temperature is often used to identify this phase transition. Fusion becomes strongly dependent on the concentration when the material contains more than a single species. Furthermore, melting and freezing are also sensitive to external effects, such as electric and magnetic fields, in more-complex thermodynamic systems.

The equilibrium thermodynamic system parameters during phase transition can be calculated from the knowledge that the partial molar Gibbs free energies or chemical potentials of each component in the two phases must be equal. One important result of using this principle for simple single-component systems is the Clapeyron equation relating the temperature (T) and pressure (P) during the phase transition, such that

$$\frac{dP}{dT} = \frac{h_{s\ell}}{T\Delta v} \tag{4.4.28}$$

where $h_{s\ell}$ is the enthalpy change from phase A to phase B ($=h_B - h_A$, the latent heat of fusion with appropriate sign) and Δv is the specific volume difference between phases A and B ($= v_B - v_A$). Considering for example that phase A is a solid and B a liquid ($h_{s\ell}$ is then positive), examination of Equation (4.4.28) shows that increasing the pressure will result in an increase in the melting temperature if $\Delta v > 0$ (i.e., when the specific volume of the liquid is higher than that of the solid, which is a property of tin, for example), but will result in a decrease of the melting temperature when $\Delta v < 0$ (for water, for example).

In some materials, called glassy, the phase change between the liquid and solid occurs with a gradual transition of the physical properties, from those of one phase to those of the other. When the liquid phase flows during the process, the flow is strongly affected because the viscosity increases greatly as the liquid changes to solid. Other materials, such as pure metals and ice, and eutectic alloys, have a definite line of demarcation between the liquid and the solid, the transition being abrupt. This situation is easier to analyze and is therefore more thoroughly addressed in the literature.

Gradual transition is most distinctly observed in mixtures. Consider the equilibrium phase diagram for a binary mixture (or alloy) composed of species a and b, shown in Figure 4.4.14. χ is the concentration of species b in the mixture, ℓ denotes the liquid, s the solid, s_a a solid with a lattice structure of species a in its solid phase but containing some molecules of species b in that lattice, and s_b a solid with a lattice structure of species b in its solid phase but containing some molecules of species a in that lattice. "Liquidus" denotes the boundary above which the mixture is just liquid, and "solidus" is the boundary separating the final solid mixture of species a and b from the solid–liquid mixture zones and from the other zones of solid s_a and solid s_b.

For illustration, assume that a liquid mixture is at point 1, characterized by concentration χ_1 and temperature T_1 (Figure 4.4.14), and is cooled (descending along the dashed line) while maintaining the concentration constant. When the temperature drops below the liquidus line, solidification starts, creating a mixture of liquid and of solid s_a. Such a two-phase mixture is called the **mushy zone**. At point 2 in that zone, the solid phase (s_a) portion contains a concentration χ_{2,s_a} of component b, and the liquid phase portion contains a concentration $\chi_{2,\ell}$ of component b. The ratio of the mass of the solid s_a to that of the liquid is determined by the lever rule, and is $(\chi_{2,\ell} - \chi_2)/(\chi_2 - \chi_{2,s_a})$ at point 2. Further cooling to below the solidus line, say to point 3, results in a solid mixture (or alloy) of s_a and s_b, containing concentrations χ_{3,s_A} and χ_{3,s_B} of species b, respectively. The ratio of the mass of the solid s_a to that of s_b is again determined by the lever rule, and is $(\chi_{3,s_b} - \chi_3)/(\chi_3 - \chi_{3,s_a})$ at point 3.

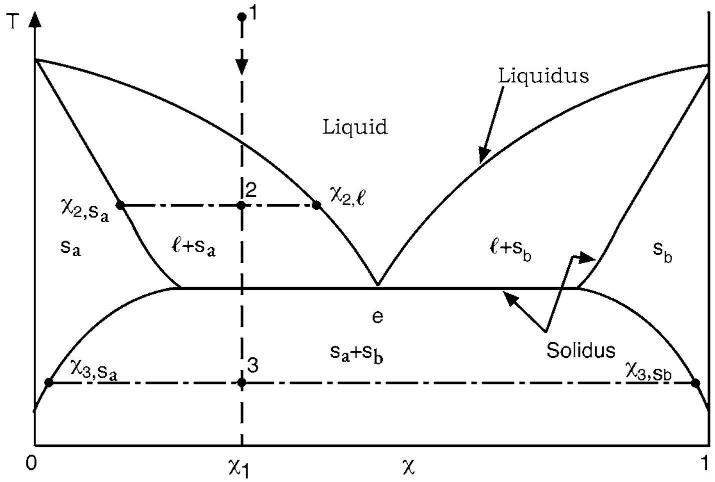

FIGURE 4.4.14 A liquid–solid phase diagram of a binary mixture.

A unique situation occurs if the initial concentration of the liquid is χ_e: upon constant-concentration cooling, the liquid forms the solid mixture $s_a + s_b$ having the same concentration and without the formation of a two-phase zone. χ_e is called the **eutectic concentration**, and the resulting solid mixture (or alloy) is called a *eutectic.*

The presence of a two-phase mixture zone with temperature-dependent concentration and phase proportion obviously complicates heat transfer analysis, and requires the simultaneous solution of both the heat and mass transfer equations. Furthermore, the liquid usually does not solidify on a simple planar surface. Crystals of the solid phase are formed at some preferred locations in the liquid, or on colder solid surfaces immersed in the liquid, and as freezing progesses the crystals grow in the form of intricately shaped fingers, called dendrites. This complicates the geometry significantly and makes mathematical modeling of the process very difficult. An introduction to such problems and further references are available in Hayashi and Kunimine (1992) and Poulikakos (1994).

Flow of the liquid phase often has an important role in the inception of, and during, melting and freezing (see Incropera and Viskanta, 1992). The flow may be forced, such as in the freezing of a liquid flowing through or across a cooled pipe, and/or may be due to natural convection that arises whenever there are density gradients in the liquid, here generated by temperature and possibly concentration gradients. It is noteworthy that the change in phase usually affects the original flow, such as when the liquid flowing in a cooled pipe gradually freezes and the frozen solid thus reduces the flow passage, or when the evolving dendritic structure gradually changes the geometry of the solid surfaces that are in contact with the liquid. Under such circumstances, strong coupling may exist between the heat transfer and fluid mechanics, and also with mass transfer when more than a single species is present. The process must then be modeled by an appropriate set of continuity, momentum, energy, mass conservation, and state equations, which need to be solved simultaneously.

More-detailed information about melting and freezing can be found in the monograph by Alexiades and Solomon (1993) and in the comprehensive reviews by Fukusako and Seki (1987) and Yao and Prusa (1989).

Melting and Freezing of Pure Materials

Thorough mathematical treatment of melting and freezing is beyond the scope of this section, but examination of the simplified one-dimensional case for a pure material and without flow effects provides important insights into the phenomena, identifies the key parameters, and allows analytical solutions and thus qualitative predictive capability for at least this class of problems.

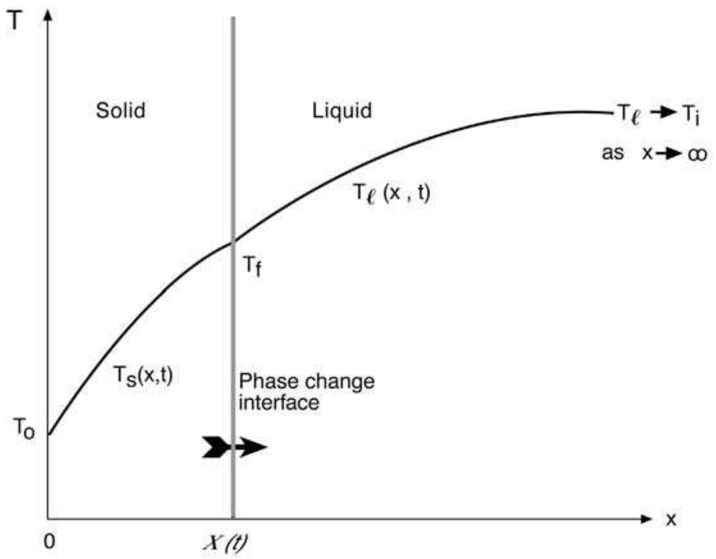

FIGURE 4.4.15 Freezing of semi-inifinite liquid with heat conduction in both phases.

In the freezing model, described in Figure 4.4.15, a liquid of infinite extent is to the right ($x > 0$) of the infinite surface at $x = 0$, initially at a temperature T_i higher than the fusion temperature T_f. At time $t = 0$ the liquid surface temperature at $x = 0$ is suddenly lowered to a temperature $T_0 < T_f$, and maintained at that temperature for $t > 0$. Consequently, the liquid starts to freeze at $x = 0$, and the freezing interface (separating in Figure 4.4.15 the solid to its left from the liquid on its right) located at the position $x = X(t)$ moves gradually to the right (in the positive x direction). We note that in this problem heat is conducted in both phases.

Assuming for simplification that heat transfer is by conduction only — although at least natural convection (Incropera and Viskanta, 1992) and sometimes forced convection and radiation also take place — the governing equations are

In the liquid: The transient heat conduction equation is

$$\frac{\partial T_\ell(x,t)}{\partial t} = \alpha_\ell \frac{\partial^2 T_\ell(x,t)}{\partial x^2} \quad \text{in} \quad X(t) < x < \infty \quad \text{for} \quad t > 0 \tag{4.4.29}$$

$$T_\ell(x,t) = T_i \quad \text{in} \quad x > 0, \quad \text{at} \quad t = 0 \tag{4.4.30}$$

where α_ℓ is the thermal diffusivity of the liquid, with the initial condition and the boundary condition

$$T_\ell(x \to \infty, t) \to T_i \quad \text{for} \quad t > 0 \tag{4.4.31}$$

In the solid: The transient heat conduction equation is

$$\frac{\partial T_s(x,t)}{\partial t} = \alpha_s \frac{\partial^2 T_s(x,t)}{\partial x^2} \quad \text{in} \quad 0 < x < X(t) \quad \text{for} \quad t > 0 \tag{4.4.32}$$

where α_s is the thermal diffusivity of the solid, with the boundary condition

$$T_s(0,t) = T_0 \quad \text{for} \quad t > 0 \tag{4.4.33}$$

The remaining boundary conditions are those of temperature continuity and heat balance at the solid–liquid phase-change interface $X(t)$,

$$T_\ell\left[X(t)\right] = T_s\left[X(t)\right] = T_f \quad \text{for} \quad t > 0 \tag{4.4.34}$$

$$k_s\left(\frac{\partial T_s}{\partial x}\right)_{[X(t)]} - k_\ell\left(\frac{\partial T_\ell}{\partial x}\right)_{[X(t)]} = \rho h_{s\ell}\frac{dX(t)}{dt} \quad \text{for} \quad t > 0 \tag{4.4.35}$$

where k_s and k_ℓ are the thermal conductivities of the solid and liquid, respectively, ρ is the density (here it is assumed for simplicity to be the same for the liquid and solid), and $h_{s\ell}$ is the latent heat of fusion. The two terms on the left-hand side of Equation (4.4.35) thus represent the conductive heat flux away from the phase-change interface, into the solid at left and the liquid at right, respectively. Energy conservation at the interface requires that the sum of these fluxes leaving the interface be equal to the amount of heat generated due to the latent heat released there, represented by the term on the right-hand side of the equation.

The analytical solution of Equation (4.4.29) to Equation (4.4.35) yields the temperature distributions in the liquid and solid phases,

$$T_\ell(x,t) = T_i - \left(T_i - T_f\right)\frac{\operatorname{erfc}\left(\dfrac{x}{2\sqrt{\alpha_\ell t}}\right)}{\operatorname{erfc}\left(\lambda\sqrt{\alpha_s/\alpha_\ell}\right)} \tag{4.4.36}$$

$$T_s(x,t) = T_0 + \left(T_f - T_0\right)\frac{\operatorname{erfc}\left(\dfrac{x}{2\sqrt{\alpha_s t}}\right)}{\operatorname{erfc}\lambda} \tag{4.4.37}$$

where erf and erfc are the *error function* and the *complementary error function*, respectively, and λ is a constant, obtained from the solution of the equation

$$\frac{e^{\lambda^2}}{\operatorname{erf}\lambda} - \frac{k_\ell}{k_s}\sqrt{\frac{\alpha_s}{\alpha_\ell}}\,\frac{T_i - T_f}{T_f - T_0}\,\frac{e^{(\alpha_s/\alpha_\ell)\lambda^2}}{\operatorname{erfc}\left(\lambda\sqrt{\alpha_s/\alpha_\ell}\right)} = \frac{\lambda\sqrt{\pi}}{\mathrm{Ste}_s} \tag{4.4.38}$$

where Ste is the Stefan number (dimensionless), here defined for the solid as

$$\mathrm{Ste}_s \equiv \frac{c_s\left(T_f - T_0\right)}{h_{s\ell}} \tag{4.4.39}$$

and c_s is the specific heat of the solid. Solutions of Equation (4.4.38) are available for some specific cases in several of the references, and can be obtained relatively easily by a variety of commonly used software packages.

The solution of Equation (4.4.29) to Equation (4.4.35) also gives an expression for the transient position of the freezing interface,

$$X(t) = 2\lambda\left(\alpha_s t\right)^{1/2} \tag{4.4.40}$$

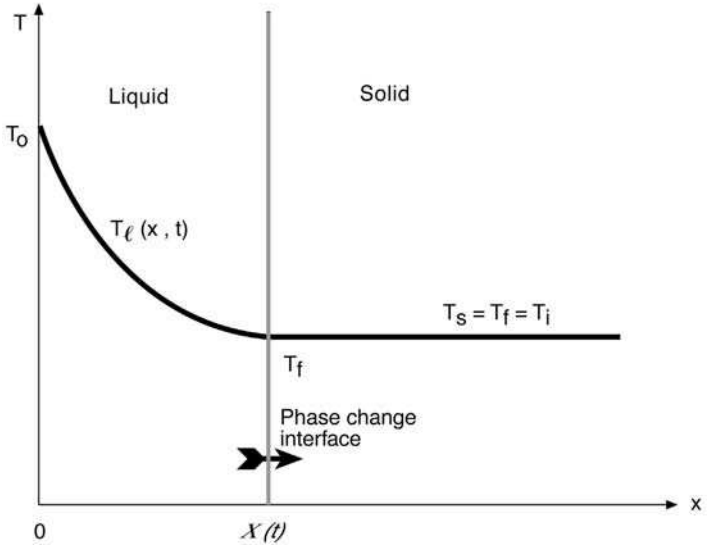

FIGURE 4.4.16 Melting of semi-infinite solid with conduction in the liquid phase only.

where λ is the solution of Equation 4.4.38, and thus the expression for the rate of freezing, i.e., the velocity of the motion of the solid liquid interface, is

$$\frac{dX(t)}{dt} = \lambda \alpha_s^{1/2} t^{1/2} \tag{4.4.41}$$

For a simple one-dimensional melting example of an analytical solution for melting, consider the semi-infinite solid described in Figure 4.4.16, initially at the fusion temperature T_f. For time $t > 0$ the temperature of the surface (at $x = 0$) is raised to $T_0 > T_f$, and the solid consequently starts to melt there. In this case the temperature in the solid remains constant, $T_s = T_f$, so the temperature distribution needs to be calculated only in the liquid phase. It is assumed that the liquid formed by melting remains motionless and in place. Very similarly to the above-described freezing case, the equations describing this problem are the heat conduction equation

$$\frac{\partial T_\ell(x,t)}{\partial t} = \alpha_\ell \frac{\partial^2 T_\ell(x,t)}{\partial x^2} \quad \text{in} \quad 0 < x < X(t) \quad \text{for} \quad t > 0 \tag{4.4.42}$$

with the initial condition

$$T_\ell(x,t) = T_f \quad \text{in} \quad x > 0, \quad \text{at} \quad t = 0 \tag{4.4.43}$$

the boundary condition

$$T_\ell(0,t) = T_0 \quad \text{for} \quad t > 0 \tag{4.4.44}$$

and the liquid–solid interfacial temperature and heat flux continuity conditions

$$T_\ell\left[X(t)\right] = T_f \quad \text{for} \quad t > 0 \tag{4.4.45}$$

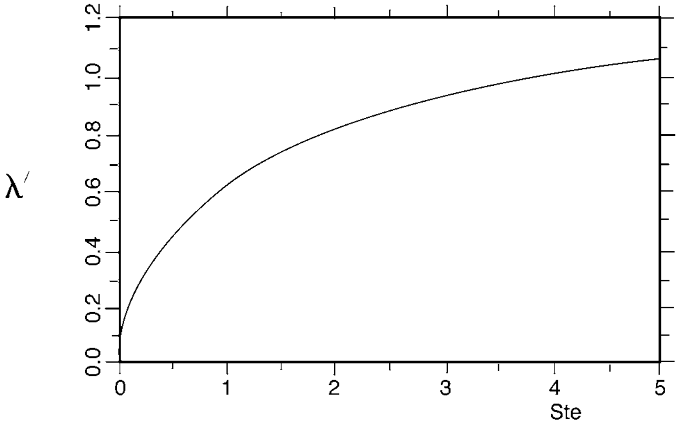

FIGURE 4.4.17 The root λ′ of Equation 4.4.48.

$$-k_\ell \left(\frac{\partial T_\ell}{\partial x}\right)_{[X(t)]} = \rho h_{\ell s} \frac{dX(t)}{dt} \quad \text{for} \quad t > 0 \tag{4.4.46}$$

The analytical solution of this problem yields the temperature distribution in the liquid,

$$T_\ell(x,t) = T_0 - \left(T_0 - T_f\right) \frac{\operatorname{erf}\left(\dfrac{x}{2\sqrt{\alpha_\ell t}}\right)}{\operatorname{erf}\lambda'} \quad \text{for} \quad t > 0 \tag{4.4.47}$$

where λ′ is the solution of the equation

$$\lambda' e^{\lambda'^2} \operatorname{erf}(\lambda') = \frac{\text{Ste}_\ell}{\sqrt{\pi}} \tag{4.4.48}$$

with Ste_ℓ here defined for the liquid as

$$\text{Ste}_\ell \equiv \frac{c_\ell\left(T_0 - T_f\right)}{h_{s\ell}} \tag{4.4.49}$$

λ′ as a function of Ste, for $0 \le \text{Ste} \le 5$, is given in Figure 4.4.17. The interface position is

$$X(t) = 2\lambda'\left(\alpha_\ell t\right)^{1/2} \tag{4.4.50}$$

The solution of the *freezing* problem under similar conditions, i.e., of a semi-infinite liquid initially at temperature T_f where $T(0,t)$ is abruptly reduced to $T_0 < T_f$ for $t > 0$, is identical to the above if every subscript ℓ is replaced by s and the latent heat $h_{s\ell}$ is replaced by $-h_{s\ell}$.

Example: The temperature of the vertical surface of a large volume of solid paraffin wax used for heat storage, initially at the fusion temperature, $T_i = T_f = 28$°C, is suddenly raised to 58°C. Any motion in the melt may be neglected. How long would it take for the paraffin to solidify to a depth of 0.1 m? Given properties: $\alpha_\ell = (1.09)\ 10^{-7}$ m²/sec, $\rho_s = \rho_\ell = 814$ kg/m³, $h_{s\ell} = 241$ kJ/kg, $c_\ell = 2.14$ kJ/kg°C. To find the required time we use Equation (4.4.50), in which the value of λ' needs to be determined. λ' is calculated from Equation (4.4.48), which requires the knowledge of Ste_ℓ. From Equation (4.4.49)

$$\mathrm{Ste}_\ell = \frac{(2.14\ \mathrm{kJ/kg°C})(58°\mathrm{C} - 28°\mathrm{C})}{241.2\ \mathrm{kJ/kg}} = 0.266$$

The solution of Equation (4.4.48) as a function of Ste_ℓ is given in Figure 4.4.17, yielding $\lambda \approx 0.4$. By using Equation (4.4.50), the time of interest is calculated by

$$t = \frac{[X(t)]^2}{4\lambda^2 \alpha_\ell} = \frac{(0.1\ \mathrm{m})^2}{4(0.4)^2\left[(1.09)10^7\ \mathrm{m^2/sec}\right]} = (1.43)10^5\ \mathrm{sec} = 39.8\ \mathrm{hr}$$

The axisymmetric energy equation in *cylindrical coordinates*, applicable to both the solid phase and immobile liquid phase (with appropriate assignment of the properties) is

$$\frac{\partial T(r,t)}{\partial t} = \frac{1}{\rho c}\frac{\partial}{\partial r}\left(\frac{k}{r}\frac{\partial T(r,t)}{\partial r}\right) \quad \text{for} \quad t > 0 \tag{4.4.51}$$

and the temperature and heat balance conditions at the solid–liquid phase-change interface $r = R(t)$ are

$$T_\ell[R(t)] = T_s[R(t)] \quad \text{for} \quad t > 0 \tag{4.4.52}$$

$$k_s\left(\frac{\partial T_s}{\partial r}\right)_{R(t)} - k_\ell\left(\frac{\partial T_\ell}{\partial r}\right)_{R(t)} = h_{s\ell}\frac{dR(t)}{dt} \tag{4.4.53}$$

Because of the nature of the differential equations describing nonplanar and multidimensional geometries, analytical solutions are available for only a few cases, such as line heat sources in cylindrical coordinate systems or point heat sources in spherical ones, which have very limited practical application. Other phase-change problems in nonplanar geometries, and in cases when the melt flows during phase change, are solved by approximate and numerical methods (Yao and Prusa, 1989; Alexiades and Solomon, 1993).

Some Approximate Solutions

Two prominent approximate methods used for the solution of melting and freezing problems are the integral method and the *quasi-static* approximation. The integral method is described in Goodman (1964), and only the quasi-static approximation is described here.

To obtain rough estimates of melting and freezing processes quickly, in cases where heat transfer takes place in only one phase, it is assumed in this approximation that effects of sensible heat are negligible relative to those of latent heat ($\mathrm{Ste} \to 0$), thus eliminating the sensible-heat left-hand side of the energy equations (such as (4.4.29), (4.4.32), and (4.4.51)). This is a significant simplification, since the energy equation then becomes independent of time, and solutions to the steady-state heat conduction problem are much easier to obtain. At the same time, the transient phase-change interface condition (such as Equation (4.4.35) and Equation (4.4.53)) 5 is retained, allowing the estimation of the transient interface position and velocity. This is hence a quasi-static approximation, and its use is shown below.

We emphasize that these are just approximations, without full information on the effect of specific problem conditions on the magnitude of the error incurred when using them. In fact, in some cases, especially with a convective boundary condition, they may produce incorrect results. It is thus necessary to examine the physical viability of the results, such as overall energy balances, when using these approximations.

All of the examples are for melting, but freezing problems have the same solutions when the properties are taken to be those of the solid and $h_{s\ell}$ is replaced everywhere by $-h_{s\ell}$. It is assumed here that the problems are one-dimensional, and that the material is initially at the fusion temperature T_f.

Examples of the Quasi-Static Approximation for Cartesian Coordinate Geometries. Given a semi-infinite solid (Figure 4.4.16), on which a *time-dependent temperature* $T_0(t) > T_f$ *is imposed at* $x = 0$, the above-described quasi-static approximation of Equation (4.4.42) to Equation (4.4.46) easily yields the solution

$$X(t) = \left[2 \frac{k_\ell}{\rho h_{s\ell}} \int_0^t \left[T_0(t) - T_f \right] dt \right]^{1/2} \quad \text{for} \quad t \geq 0 \tag{4.4.54}$$

$$T_\ell(x,t) = T_0(t) - \left[T_0(t) - T_f \right] \frac{x}{X(t)} \quad \text{in} \quad 0 \leq x \leq X(t) \quad \text{for} \quad t \geq 0 \tag{4.4.55}$$

The heat flux needed for melting, $q(x,t)$, can easily be determined from the temperature distribution in the liquid (Equation 4.4.55), which is linear because of the steady-state form of the heat conduction equation in this quasi-static approximation, so that

$$q(x,t) = -k_\ell \frac{dT_\ell(x,t)}{dx} = k_\ell \frac{T_0(t) - T_f}{X(t)} \tag{4.4.56}$$

For comparison of this approximate solution to the exact one (Equation (4.4.47) and Equation (4.4.50)), consider the case where $T_0(t) = T_0$ = constant. Rearranging to use the Stefan number, Equation (4.4.54) and Equation (4.4.55) become

$$X(t) = 2\left(\text{Ste}_\ell/2\right)^{1/2} \left(\alpha_\ell t\right)^{1/2} \quad \text{for} \quad t > 0 \tag{4.4.57}$$

$$T(x,t) = T_0 - \left[T_0 - T_f \right] \frac{x\Big/\left[2\left(\alpha_\ell t\right)^{1/2}\right]}{\left(\text{Ste}_\ell/2\right)^{1/2}} \quad \text{in} \quad 0 \leq x \leq X(t) \quad \text{for} \quad t \geq 0 \tag{4.4.58}$$

It is easy to show that λ' in the exact solution (Equation 4.4.48) approaches the value $(\text{Ste}_\ell/2)^{1/2}$ when $\text{Ste}_\ell \to 0$, and that otherwise $\lambda' < (\text{Ste}_\ell/2)^{1/2}$. The approximate solution is therefore indeed equal to the exact one when $\text{Ste}_\ell \to 0$, and it otherwise overestimates the values of both $X(t)$ and $T(x,t)$. While the errors depend on the specific problem, they are confined to about 10% in the above-described case (Alexiades and Solomon, 1993).

For the same melting problem but with the *boundary condition of an imposed time-dependent heat flux* $q_0(t)$,

$$-k_\ell \left(\frac{dT_\ell}{dx} \right)_{0,t} = q_0(t) \quad \text{for} \quad t > 0 \tag{4.4.59}$$

the quasi-static approximate solution is

$$X(t) \equiv \frac{1}{\rho h_{s\ell}} \int_0^t q_0(t)\, dt \quad \text{for} \quad t > 0 \tag{4.4.60}$$

$$T_\ell(x,t) = T_f + \left[\frac{q_0}{k_\ell} \frac{q_0}{\rho h_{s\ell}} t - x \right] \quad \text{in} \quad 0 \leq x \leq X(t) \quad \text{for} \quad t > 0 \tag{4.4.61}$$

For the same case if the *boundary condition is a convective heat flux* from an ambient fluid at the transient temperature $T_a(t)$, characterized by a heat transfer coefficient $\bar{h}$,

$$-k_\ell\left(\frac{dT_\ell}{dx}\right)_{0,t}=\bar{h}\left[T_a(t)-T_\ell(0,t)\right] \quad \text{for} \quad t\geq 0 \tag{4.4.62}$$

the quasi-static approximate solution is

$$X(t)=-\frac{k_\ell}{\bar{h}}+\left\{\left(\frac{k_\ell}{\bar{h}}\right)^2+2\frac{k_\ell}{\rho h_{s\ell}}\int_0^t\left[T_a(t)-T_f\right]dt\right\}^{1/2} \quad \text{for} \quad t\geq 0 \tag{4.4.63}$$

$$T_\ell(x,t)=T_f(t)\left[T_a(t)-T_f\right]\frac{\bar{h}\left[X(t)-x\right]}{\bar{h}X(t)+k_\ell} \quad \text{in} \quad 0\leq x\leq X(t) \quad \text{for} \quad t>0 \tag{4.4.64}$$

Examples of the Quasi-Static Approximation for Cylindrical Coordinate Geometries. It is assumed in these examples that the cylinders are very long and that the problems are axisymmetric. Just as in the Cartesian coordinate case, the energy equation (4.4.51) is reduced by the approximation to its steady-state form. Here

$$T_\ell\left(r_i,t\right)=T_0(t)>T_f \quad \text{for} \quad t>0 \tag{4.4.65}$$

Consider the *outward-directed melting* of a hollow cylinder due to a temperature imposed at the internal radius r_i. The solution is

$$T_\ell(r,t)=T_f+\left[T_0(t)-T_f\right]\frac{\ln\left[r/R(t)\right]}{\ln\left[r_i/R(t)\right]} \quad \text{in} \quad r_i\leq r\leq R(t) \quad \text{for} \quad t>0 \tag{4.4.66}$$

and the transient position of the phase front, $R(t)$, can be calculated from the transcendental equation

$$2R(t)^2\ln\frac{R(t)}{r_i}=R(t)^2-r_i^2+\frac{4k_\ell}{\rho h_{s\ell}}\int_0^t\left[T_0(t)-T_f\right]dt \tag{4.4.67}$$

If the melting for the same case occurs due to the imposition of a *heat flux* q_0 *at* r_p

$$-k_\ell\left(\frac{dT_\ell}{dx}\right)_{r_i,t}=q_0(t)>0 \quad \text{for} \quad t>0 \tag{4.4.68}$$

the solution is

$$T_\ell(r,t)=T_f-\frac{q_0(t)r_i}{k_\ell}\ln\frac{r}{R(t)} \quad \text{in} \quad r_i\leq r\leq R(t) \quad \text{for} \quad t>0 \tag{4.4.69}$$

$$R(t)=\left(r_i^2+2\frac{r_i}{\rho h_{s\ell}}\int_0^t q_0(t)\,dt\right)^{1/2} \quad \text{for} \quad t>0 \tag{4.4.70}$$

If the melting for the same case occurs due to the imposition of a *convective heat flux from a fluid at the transient temperature* $T_a(t)$, *with a heat transfer coefficient* $\bar{h}$, *at* r_i

$$-k_\ell \left(\frac{dT_\ell}{dr}\right)_{r_i,t} = \bar{h}\left[T_a(t) - T_f(r_i,t)\right] > 0 \quad \text{for} \quad t > 0 \tag{4.4.71}$$

The solution is

$$T_\ell(r,t) = T_f + \left[T_a(t) - T_f\right] \frac{\ln\left[r/R(t)\right]}{\ln\left[r_i/R(t)\right] - k_\ell/\bar{h}r_i} \quad \text{in} \quad r_i \le r \le R(t) \quad \text{at} \quad t > 0 \tag{4.4.72}$$

with $R(t)$ calculated from the transcendental equation

$$2R(t)^2 \ln\frac{R(t)}{r_i} = \left(1 - \frac{2k_\ell}{\bar{h}r_i}\right)\left[R(t)^2 - r_i^2\right] + \frac{4k_\ell}{\rho h_{s\ell}} \int_0^t \left[T_a(t) - T_f\right] dt \tag{4.4.73}$$

The solutions for *inward melting* of a cylinder, where heating is applied at the outer radius r_o, are the same as the above-described ones for the outward-melting cylinder, if the replacements $r_i \rightarrow r_o$, $q_0 \rightarrow -q_0$, and $\bar{h} \rightarrow -\bar{h}$ are made. If such a cylinder is not hollow, then $r_i = 0$ is used.

Estimation of Freezing and Melting Time

There are a number of approximate formulas for estimating the freezing and melting times of different materials having a variety of shapes. The American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) provides a number of such approximations for estimating the freezing and thawing times of foods (ASHRAE, 1993). For example, if it can be assumed that the freezing or thawing occurs at a single temperature, the time to freeze or thaw, t_f, for a body that has shape parameters P and R (described below) and thermal conductivity k, initially at the fusion temperature T_f, and which is exchanging heat via heat transfer coefficient $\bar{h}$ with an ambient at the constant T_a, can be approximated by Planck's equation

$$t_f = \frac{h_{s\ell}\rho}{\left|T_f - T_a\right|}\left(\frac{Pd}{\bar{h}} + \frac{Rd^2}{k}\right) \tag{4.4.74}$$

where d is the diameter of the body if it is a cylinder or a sphere, or the thickness when it is an infinite slab, and where the shape coefficients P and R for a number of body forms are given in Table 4.4.2. Shape coefficients for other body forms are also available. To use Equation 4.4.74 for freezing, k and ρ should be the values for the food in its frozen state. In thawing, they should be for the unfrozen food. Other simple approximations for melting and thawing times can be found in Cleland et al. (1987).

TABLE 4.4.2 Shape Factors for Equation (4.4.74)

Forms	*P*	*R*
Slab	1/2	1/8
Cylinder	1/4	1/16
Sphere	1/6	1/24

From ASHRAE, in *Fundamentals*, ASHRAE, Atlanta, 1993, chap. 29. With permission.

Example of Using Planck's Equation (4.4.74) for Estimating Freezing Time. Estimate the time needed to freeze a fish, the shape of which can be approximated by a cylinder 0.5 m long having a diameter of 0.1 m. The fish is initially at its freezing temperature, and during the freezing process it is surrounded by air at $T_a = -25°C$, with the cooling performed with a convective heat transfer coefficient $\bar{h} = 68$ W/m^2 K. For the fish, $T_f = -1°C$, $h_{s\ell} = 200$ kJ/kg, $\rho_s = 992$ kg/m^3, and $_sk_s = 1.35$ W/m K.

By using Table 4.4.2, the geometric coefficients for the cylindrical shape of the fish are $P = {}^1/_2$ and $R = {}^1/_{16}$, while d is the cylinder diameter, = 0.1 m. Substituting these values into Equation (4.4.74) gives

$$t_f = \frac{200{,}000 \cdot 992}{-1-(-25)}\left(\frac{1/4(0.1)}{68} + \frac{1/16(0.1)^2}{1.35}\right) = 6866 \text{ sec} = 1.9 \text{ hr}$$

In fact, freezing or melting of food typically takes place over a range of temperatures, and approximate Planck-type formulas have been developed for various specific foodstuffs and shapes to represent reality more closely than Equation (4.4.74) (ASHRAE, 1993).

Alexiades and Solomon (1993) provide several easily computable approximate equations for estimating the time needed to melt a simple solid body initially at the fusion temperature T_f. It is assumed that conduction occurs in one phase (the liquid) only, that the problems are axi- and spherically symmetric for cylindrical and spherical bodies, respectively, and that the melting process for differently shaped bodies can be characterized by a single geometric parameter, r, in the body domain $0 \le r \le L$, using a shape factor, ω, defined by

$$\omega = \frac{LA}{V} - 1 \tag{4.4.75}$$

where A is the surface area across which the heat is transferred into the body and V is the body volume, to account for the specific body shape:

$$\omega = \begin{matrix} 0 & \text{for a slab insulated at one end} \\ 1 & \text{for a cylinder} \\ 2 & \text{for a sphere} \end{matrix} \tag{4.4.76}$$

$0 \le \omega \le 2$ always, and ω may be assigned appropriate values for shapes intermediate between the slab, cylinder, and sphere. For example, a football-shaped body, somewhere between a cylinder and sphere, may be assigned $\omega = 1.5$, and a short cylinder with a large diameter-to-height ratio may have $\omega = 0.5$.

For the case where the temperature $T_0 > T_f$ is imposed on the boundary at $t = 0$, the melt time, t_m can be estimated by

$$t_m = \frac{L^2}{2\alpha_\ell(1+\omega)\text{Ste}_\ell}\left[1 + \left(0.25 + 0.17\omega^{0.7}\right)\text{Ste}_\ell\right] \tag{4.4.77}$$

valid for $0 \le \text{Ste}_\ell \le 4$.

If the *heat input is convective*, with a heat transfer coefficient $\bar{h}$ from a fluid at temperature T_a, the approximate melt time is

$$t_m = \frac{L^2}{2\alpha_\ell(1+\omega)\text{Ste}_\ell}\left[1 + \frac{2k_\ell}{\bar{h}L} + \left(0.25 + 0.17\omega^{0.7}\right)\text{Ste}_\ell\right] \tag{4.4.78}$$

valid for $0 \le \text{Ste}_\ell \le 4$ and $\bar{h}L/k_\ell \ge 0.1$, and the temperature, $T(0,t)$, of the surface across which the heat is supplied can be estimated from the implicit time-temperature relationship:

$$t = \frac{\rho c_\ell k_\ell}{2\bar{h}^2 \mathrm{Ste}_\ell}\left[1.18\mathrm{Ste}_\ell \left(\frac{T(0,t) - T_f}{T_a - T(0,t)}\right)^{1.83} + \left(\frac{T_a - T_f}{T_a - T(0,t)}\right)^2 - 1\right] \tag{4.4.79}$$

Both equations (4.4.78) and (4.4.79) are claimed to be accurate within 10%.

The suitability of using several simplified analytical solutions for the estimation of freezing and melting times for more-realistic problems was assessed by Dilley and Lior (1986).

Defining Terms

Eutectic concentration: A concentration of a component of a multicomponent liquid at which the liquid would upon freezing form a solid containing the same concentration, and at which the freezing process is completed at a single temperature.

Mushy zone: The zone composed of both liquid and solid, bounded by the liquidus and solidus curves, in a freezing or melting process.

4.5 Heat Exchangers

Ramesh K. Shah and Kenneth J. Bell

The two major categories of heat exchangers are shell-and-tube exchangers and compact exchangers. Basic constructions of gas-to-gas compact heat exchangers are plate-fin, tube-fin and all prime surface recuperators (including polymer film and laminar flow exchangers), and compact regenerators. Basic constructions of liquid-to-liquid and liquid-to-phase-change compact heat exchangers are gasketed and welded plate-and-frame, welded stacked plate (without frames), spiral plate, printed circuit, and dimple plate heat exchangers.

Shell-and-tube exchangers are custom designed for virtually any capacity and operating condition, from high vacuums to ultrahigh pressures, from cryogenics to high temperatures, and for any temperature and pressure differences between the fluids, limited only by the materials of construction. They can be designed for special operating conditions: vibration, heavy fouling, highly viscous fluids, erosion, corrosion, toxicity, radioactivity, multicomponent mixtures, etc. They are made from a variety of metal and nonmetal materials, and in surface areas from less than 0.1 to 100,000 m^2 (1 to over 1,000,000 ft^2). They have generally an order of magnitude less surface area per unit volume than the compact exchangers, and require considerable space, weight, support structure, and footprint.

Compact heat exchangers have a large heat transfer surface area per unit volume of the exchanger, resulting in reduced space, weight, support structure and footprint, energy requirement and cost, as well as improved process design, plant layout and processing conditions, together with low fluid inventory compared with shell-and-tube exchangers. From the operating condition and maintenance point of view, compact heat exchangers of different constructions are used for specific applications, such as for high-temperature applications (up to about 850°C or 1550°F), high pressure applications (over 200 bars), and moderate fouling applications. However, applications do not involve both high temperature and pressure simultaneously. Plate-fin exchangers are generally brazed, and the largest size currently manufactured is $1.2 \times 1.2 \times 6$ m ($4 \times 4 \times 20$ ft). Fouling is one of the major potential problems in many compact exchangers except for the plate heat exchangers. With a large frontal area exchanger, flow maldistribution could be another problem. Because of short transient times, a careful design of controls is required for startup of some compact heat exchangers compared with shell-and-tube exchangers. Standards are available for compact heat exchangers used in cryogenics applications and process plants (ALPEMA, 2000).

This section is divided into two parts: Compact Heat Exchangers and Shell-and-Tube Exchangers, written by R. K. Shah and K. J. Bell, respectively. In the compact heat exchangers section, the following topics are covered: definition and description of exchangers, heat transfer and pressure drop analyses, heat transfer and flow friction correlations, exchanger design (rating and sizing) methodology, flow maldistribution, and fouling. In the shell-and-tube heat exchangers section, the following topics are covered: construction features, principles of design, and an approximate design method with an example.

Compact Heat Exchangers

Ramesh K. Shah

Introduction

A heat exchanger is a device to provide for transfer of thermal energy (enthalpy) between two or more fluids, between a solid surface and a fluid, or between solid particulates and a fluid, at different temperatures and in thermal contact without external heat and work interactions. The fluids may be single compounds or mixtures. Typical applications involve heating or cooling of a fluid stream of concern, evaporation or condensation of single or multicomponent fluid stream, and heat recovery or heat rejection from a system. In other applications, the objective may be to sterilize, pasteurize, fractionate, distill, concentrate, crystallize, or control process fluid. In some heat exchangers, the fluids transferring heat are in direct contact. In other heat exchangers, heat transfer between fluids takes place through a separating wall or into and out of a wall in a transient manner. In most heat exchangers, the fluids are separated by a heat transfer surface and do not mix. Such exchangers are referred to as *direct transfer type*, or simply *recuperators*. Exchangers in which there is an intermittent flow of heat from the hot to cold fluid (via heat storage and heat rejection through the exchanger surface or matrix) are referred to as *indirect transfer type* or simply *regenerators*.

The heat transfer surface is a surface of the exchanger core which is in direct contact with fluids and through which heat is transferred by conduction in a recuperator. The portion of the surface which also separates the fluids is referred to as a *primary* or *direct surface*. To increase heat transfer area, appendages known as fins may be intimately connected to the primary surface to provide an *extended*, *secondary*, or *indirect surface*. Thus, the addition of fins reduces the thermal resistance on that side and thereby increases the net heat transfer from the surface for the same temperature difference.

Heat exchangers may be classified according to transfer process, construction, flow arrangement, surface compactness, number of fluids, and heat transfer mechanisms as shown in Figure 4.5.1.

A gas-to-fluid heat exchanger is referred to as a compact heat exchanger if it incorporates a heat transfer surface having a surface area density above about 700 m^2/m^3 (213 ft^2/ft^3) on at least one of the fluid sides which usually has gas flow. It is referred to as a laminar flow heat exchanger if the surface area density is above about 3000 m^2/m^3 (914 ft^2/ft^3), and as a micro heat exchanger if the surface area density is above about 15,000 m^2/m^3 (4570 ft^2/ft^3). A liquid/two-phase heat exchanger is referred to as a compact heat exchanger if the surface area density on any one fluid side is above about 400 m^2/m^3 (122 ft^2/ft^3). A typical process industry shell-and-tube exchanger has a surface area density of less than 100 m^2/m^3 on one fluid side with plain tubes, and two to three times that with the high-fin-density low-finned tubing. Plate-fin, tube-fin, and rotary regenerators are examples of compact heat exchangers for gas flows on one or both fluid sides, and gasketed and welded plate heat exchangers are examples of compact heat exchangers for liquid flows and phase-change applications.

Types and Description

Gas-to-Fluid Exchangers.

The important design and operating considerations for compact extended surface exchangers are (1) usually at least one of the fluids is a gas or specific liquid that has low h; (2) fluids must be clean and

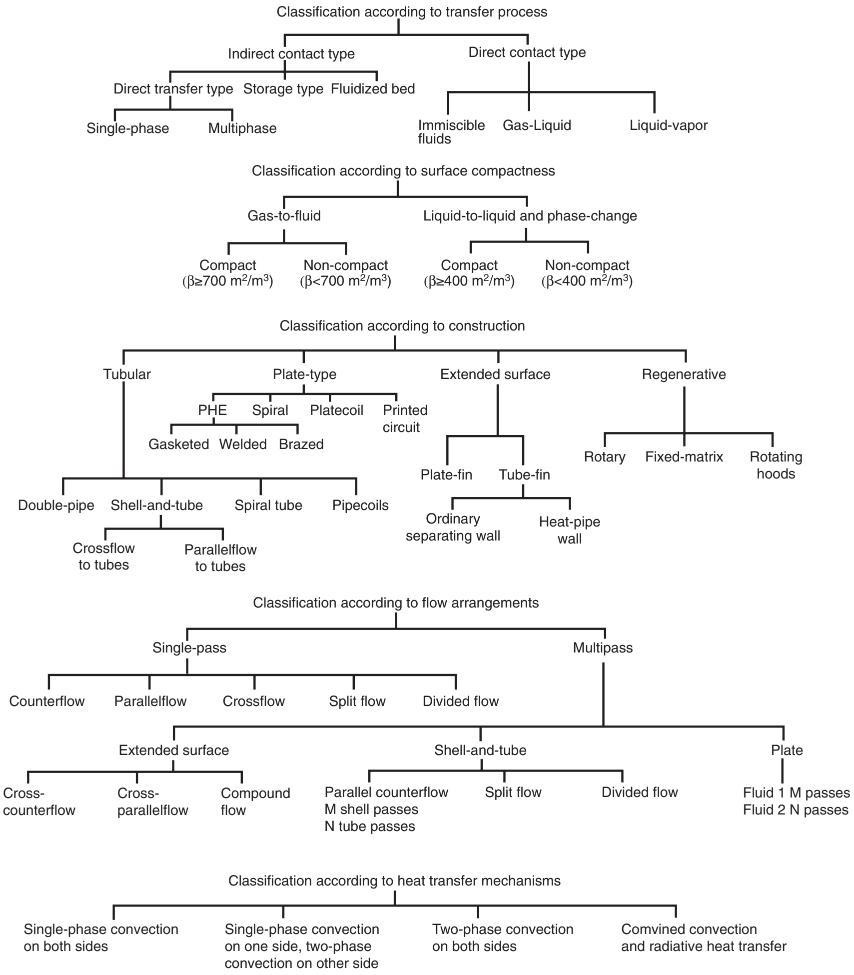

FIGURE 4.5.1 Classification of heat exchangers.

relatively noncorrosive because of small hydraulic diameter (D_h) flow passages and no easy techniques for mechanically cleaning them; (3) the fluid pumping power (i.e., pressure drop) design constraint is often equally as important as the heat transfer rate; (4) operating pressures and temperatures are somewhat limited compared with shell-and-tube exchangers as a result of the joining of the fins to plates or tubes by brazing, mechanical expansion, etc.; (5) with the use of highly compact surfaces, the resultant shape of a gas-to-fluid exchanger is one having a large frontal area and a short flow length (the header design of a compact heat exchanger is thus important for a uniform flow distribution among the very large number of small flow passages); (6) the market potential must be large enough to warrant the sizable manufacturing research and tooling costs for new forms to be developed.

Some advantages of plate-fin exchangers over conventional shell-and-tube exchangers are as follows. Compact heat exchangers, generally fabricated from thin metallic plates, yield large heat transfer surface area per unit volume (β), typically up to ten times greater than the 50 to 100 m^2/m^3 provided by a shell-and-tube exchanger for general process application and from 1000 to 6000 m^2/m^3 for highly compact gas side surfaces. Compact liquid or phase-change side surfaces have a β ratio ranging from 500 to 600 m^2/m^3. A compact exchanger provides a tighter temperature control; thus it is useful for heat-sensitive materials, improves the product (e.g., refining fats from edible oil) and its quality (such as a catalyst bed).

Also, a compact exchanger could provide rapid heating or cooling of a process stream, thus improving the product quality. The plate-fin exchangers can accommodate multiple (up to 12 or more) fluid streams in one exchanger unit with proper manifolding, thus allowing process integration and cost-effective compact solutions.

Fouling is one of the potential major problems in compact heat exchangers (except for plate-and-frame heat exchangers), particularly those having a variety of fin geometries or very fine circular or noncircular flow passages that cannot be cleaned mechanically. Chemical cleaning may be possible; thermal baking and subsequent rinsing is possible for small-size units. Hence, extended surface compact heat exchangers may not be used in heavy fouling applications.

Liquid-to-Liquid Exchangers.

Liquid-to-liquid and phase-change exchangers are plate-and-frame and welded plate heat exchangers (PHE), spiral plate, and printed circuit exchangers; plate-fin exchangers are also used in phase-change applications. Some of them are described next in some detail along with other compact heat exchangers and their applications.

Plate-Fin Heat Exchangers.

This type of exchanger has "corrugated" fins or spacers sandwiched between parallel plates (referred to as plates or parting sheets) as shown in Figure 4.5.2. Sometimes fins are incorporated in a flat tube with rounded corners (referred to as a formed tube), thus eliminating a need for the side bars. If liquid or phase-change fluid flows on the other side, the parting sheet is usually replaced by a flat tube with or without inserts/webs. Other plate-fin constructions include drawn-cup or tube-and-center configurations. Fins are die- or roll-formed and are attached to the plates by brazing, soldering, adhesive bonding, welding, mechanical fit, or extrusion. Fins may be used on both sides in gas-to-gas heat exchangers. In gas-to-liquid applications, fins are usually used only on the gas side; if employed on the liquid side, they are used primarily for structural strength and flow-mixing purposes. Fins are also sometimes used for pressure containment and rigidity.

Plate fins are categorized as (1) plain (i.e., uncut) and straight fins, such as plain triangular and rectangular fins; (2) plain but wavy fins (wavy in the main fluid flow direction); and (3) interrupted fins such as offset strip, louver, and perforated. Examples of commonly used fins are shown in Figure 4.5.3.

Plate-fin exchangers have been built with a surface area density of up to about 5900 m^2/m^3 (1800 ft^2/ft^3). There is a total freedom of selecting fin surface area on each fluid side, as required by the design, by

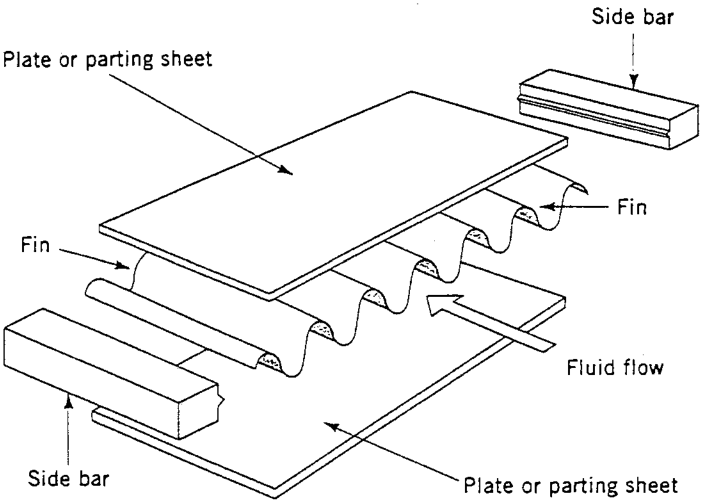

FIGURE 4.5.2 Typical components of a plate-fin exchanger.

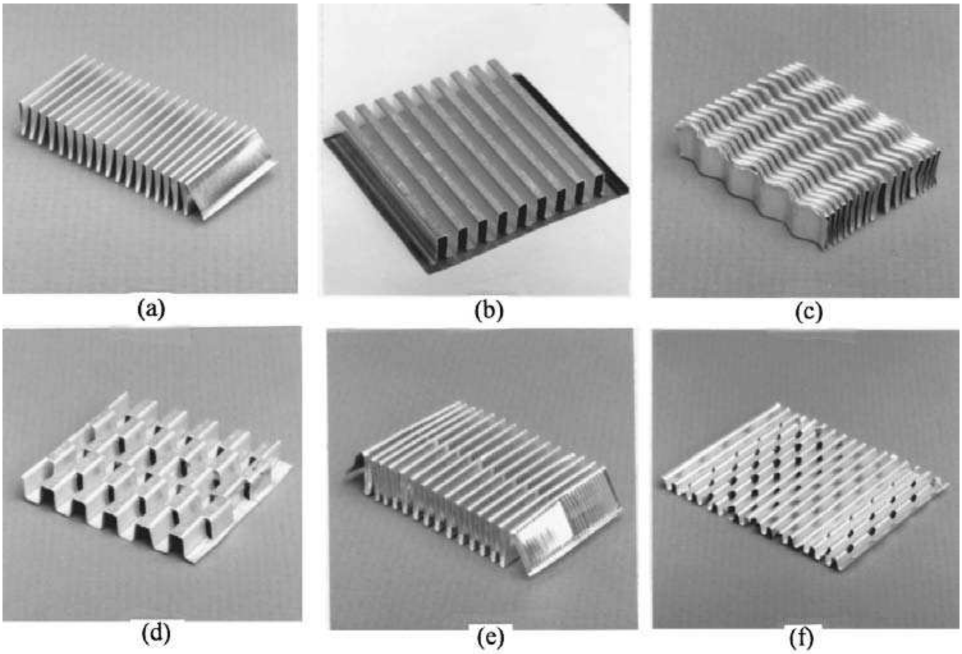

FIGURE 4.5.3 Fin geometries for plate-fin heat exchangers: (a) plain triangular fin, (b) plain rectangular fin, (c) wavy fin, (d) offset strip fin, (e) multilouver fin, and (f) perforated fin.

varying fin height and fin density. Although typical fin densities are 120 to 700 fins/m (3 to 18 fins/in.), applications exist for as many as 2100 fins/m (53 fins/in.). Common fin thicknesses range from 0.05 to 0.25 mm (0.002 to 0.010 in.). Fin heights range from 2 to 25 mm (0.08 to 1.0 in.). A plate-fin exchanger with 600 fins/m (15.2 fins/in.) provides about 1300 m^2 (400 ft^2/ft^3) of heat transfer surface area per cubic meter volume occupied by the fins. Plate-fin exchangers are manufactured in virtually all shapes and sizes, and made from a variety of materials.

Tube-Fin Heat Exchangers.

In this type of exchanger, round and rectangular tubes are the most common, although elliptical tubes are also used. Fins are generally used on the outside, but they may be used on the inside of the tubes in some applications. They are attached to the tubes by a tight mechanical fit, tension winding, adhesive bonding, soldering, brazing, welding, or extrusion. Fins on the outside of the tubes may be categorized as follows: (1) normal fins on individual tubes, referred to as individually finned tubes or simply as *finned tubes*, as shown in Figure 4.5.5 and Figure 4.5.4a; (2) flat or continuous (plain, wavy, or interrupted) external fins on an array of tubes, as shown in Figure 4.5.6 and Figure 4.5.4b; (3) longitudinal fins on individual tubes. The exchanger having flat (continuous) fins on tubes has also been referred to as a *plate-fin and tube* exchanger in the literature. In order to avoid confusion with plate-fin surfaces, we will refer to it as a tube-fin exchanger having flat (plain, wavy, or interrupted) fins. Individually finned tubes are probably more rugged and practical in large tube-fin exchangers. Shell-and-tube exchangers sometimes employ low-finned tubes to increase the surface area on the shell side when the shell-side heat transfer coefficient is low compared with the tube-side coefficient. The exchanger with flat fins is usually less expensive on a unit heat transfer surface area basis because of its simple and mass-production-type construction features. Longitudinal fins are generally used in condensing applications and for viscous fluids in double-pipe heat exchangers.

Tube-fin exchangers can withstand high pressures on the tube side. The highest temperature is again limited by the type of bonding, the materials employed, and the material thickness. Tube-fin exchangers with an area density of about 3300 m^2/m^3 (1000 ft^2/ft^2) are commercially available. On the fin side, the

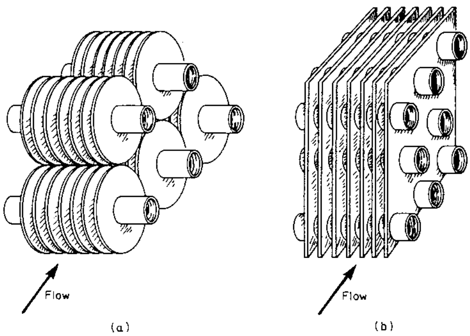

FIGURE 4.5.4 (a) Individually finned tubes, (b) flat or continuous fins on an array of tubes.

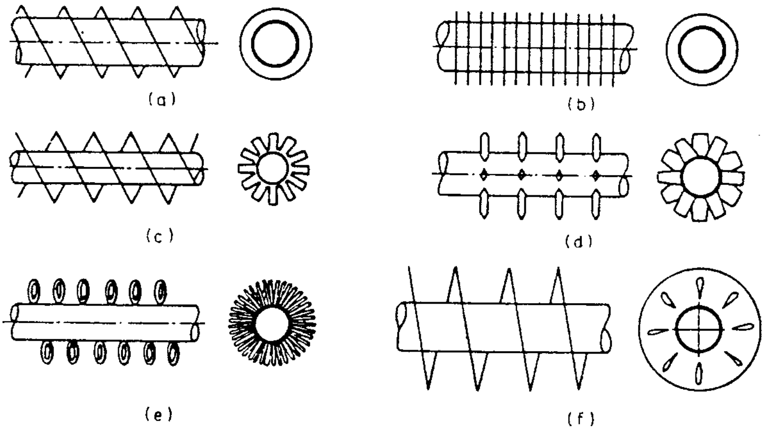

FIGURE 4.5.5 Individually finned tubes: (a) helical, (b) annular disk, (c) segmented, (d) studded, (e) wire loop, and (f) slotted helical.

desired surface area can be employed by using the proper fin density and fin geometry. The typical fin densities for flat fins vary from 250 to 800 fins/m (6 to 20 fins/in.), fin thicknesses vary from 0.08 to 0.25 mm (0.003 to 0.010 in.), and fin flow lengths from 25 to 250 mm (1 to 10 in.). A tube-fin exchanger having flat fins with 400 fins/m (10 fins/in.) has a surface area density of about 720 m^2/m^3(220 ft^2/ft^3). These exchangers are extensively used as condensers and evaporators in air-conditioning and refrigeration applications, as condensers in electric power plants, as oil coolers in propulsive power plants, and as air-cooled exchangers (also referred to as a fin-fan exchanger) in process and power industries.

Regenerators.

The regenerator is a storage-type exchanger. The heat transfer surface or elements are usually referred to as a matrix in the regenerator. In order to have continuous operation, either the matrix must be moved periodically into and out of the fixed streams of gases, as in a *rotary* regenerator (Figure 4.5.7a), or the gas flows must be diverted through valves to and from the fixed matrices as in a *fixed-matrix* regenerator (Figure 4.5.7b). The latter is also sometimes referred to as a *periodic-flow regenerator* or a *reversible heat accumulator*. A third type of regenerator has a fixed matrix (in the disk form) and the fixed stream of gases, but the gases are ducted through rotating hoods (headers) to the matrix as shown in Figure 4.5.7c. This Rothemuhle regenerator is used as an air preheater in some power-generating plants. The thermodynamically superior counterflow arrangement is usually employed in regenerators.

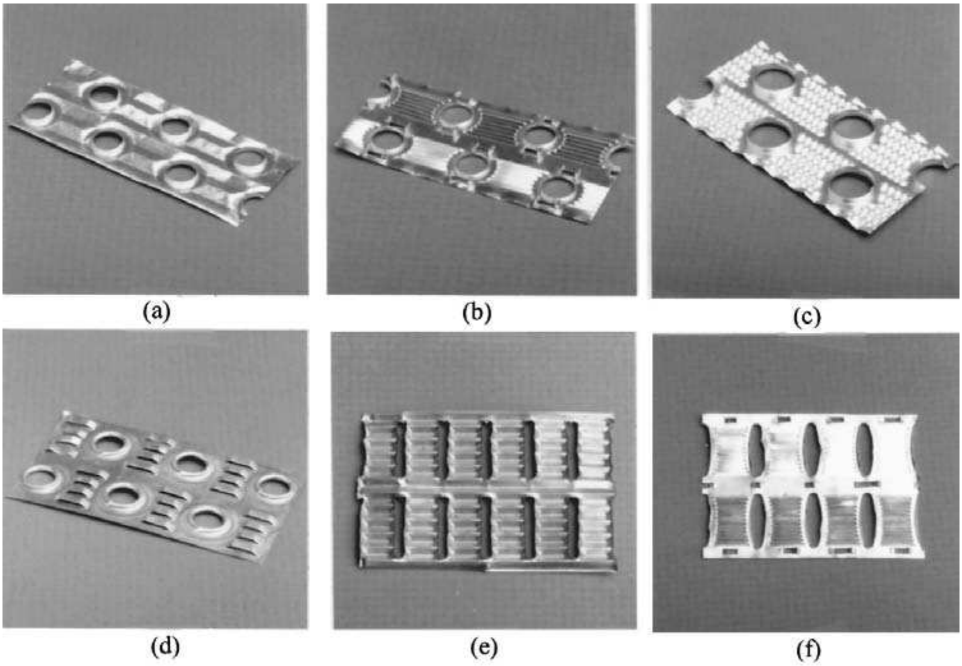

FIGURE 4.5.6 Flat or continuous fins on an array of tubes: On round tubes: (a) wavy fin, (b) multilouver fin, (c) fin with structured surface roughness (dimples), (d) parallel louver fin; (e) louver fin on flat tubes; (f) multilouver fin on elliptical tubes.

The **rotary regenerator** is usually a disk type in which the matrix (heat transfer surface) is in a disk form and fluids flow axially. It is rotated by a hub shaft or a peripheral ring gear drive. For a rotary regenerator, the design of seals to prevent leakage of hot to cold fluids and vice versa becomes a difficult task, especially if the two fluids are at significantly differing pressures. Rotating drives also pose a challenging mechanical design problem.

Major advantages of rotary regenerators are the following. For a highly compact regenerator, the cost of the regenerator surface per unit of heat transfer area is usually substantially lower than that for the equivalent recuperator. A major disadvantage of a regenerator is an unavoidable carryover of a small fraction of the fluid trapped in the passage to the other fluid stream just after the periodic flow switching. Since fluid contamination (small mixing) is prohibited with liquids, the regenerators are used exclusively for gas-to-gas heat or energy recovery applications. Cross contamination can be minimized significantly by providing a purge section in the disk and using double-labyrinth seals.

Rotary regenerators have been designed for a surface area density of up to about 6600 m^2/m^3 (2000 ft^2/ft^3), and exchanger effectivenesses exceeding 85% for a number of applications. They can employ thinner stock material, resulting in the lowest amount of material for a given effectiveness and pressure drop of any heat exchanger known today. The metal rotary regenerators have been designed for continuous inlet temperatures up to about 790°C (1450°F) and ceramic matrices for higher-temperature applications; these regenerators are designed up to 400 kPa or 60 psi pressure differences between hot and cold gases. Plastic, paper, and wool are used for regenerators operating below 65°C (150°F) inlet temperature of the hot gas and 1 atm pressure. Typical regenerator rotor diameters and rotational speeds are as follows: up to 10 m (33 ft) and 0.5 to 3 rpm for power plant regenerators, 0.25 to 3 m (0.8 to 9.8 ft) and up to 10 rpm for air-ventilating regenerators, and up to 0.6 m (24 in.) and up to 18 rpm for vehicular regenerators. Refer to Shah (1994) for the description of **fixed-matrix regenerator**, also referred to as a *periodic-flow*, *fixed bed*, *valved*, or *stationary* regenerator.

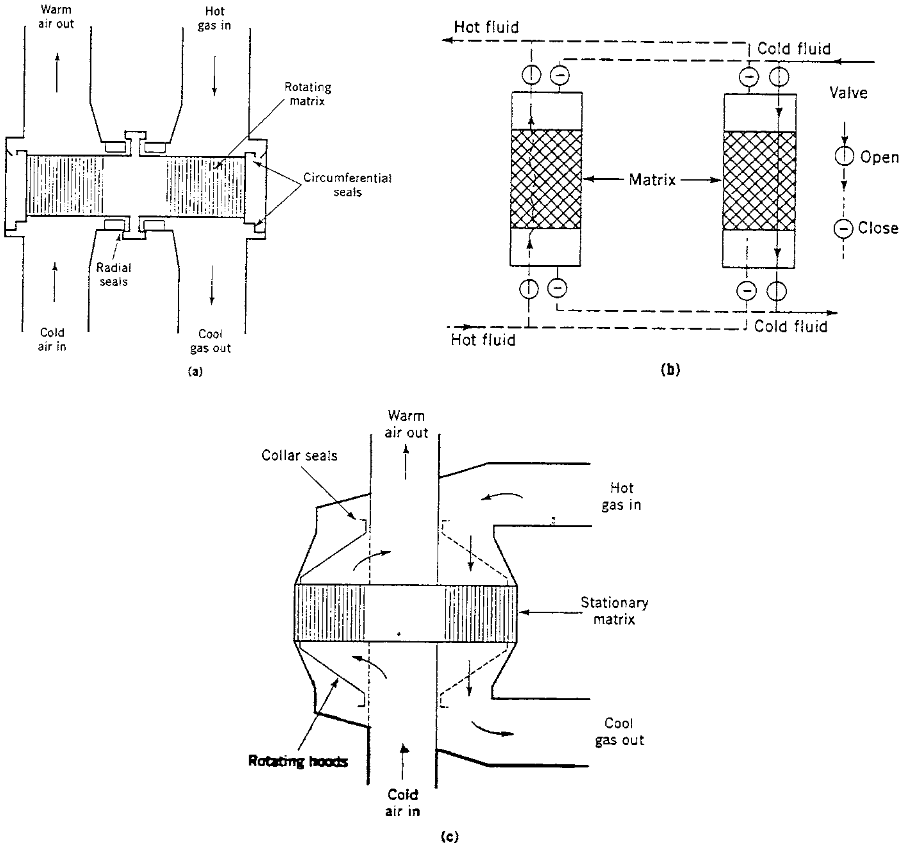

FIGURE 4.5.7 Regenerators: (a) rotary, (b) fixed-matrix, and (c) Rothemuhle.

Plate-Type Heat Exchangers.

These exchangers are usually built of thin plates (all prime surface). The plates are either smooth or have some form of corrugations, and they are either flat or wound in an exchanger. Generally, these exchangers cannot accommodate very high pressures, temperatures, and pressure and temperature differentials. These exchangers may be further classified as plate, spiral plate, lamella, and plate-coil exchangers as classified in Figure 4.5.1. The plate heat exchanger, being the most important of these, is described next.

The **plate-and-frame** or **gasketed PHE** consists of a number of thin rectangular corrugated or embossed metal plates sealed around the edges by gaskets and held together in a frame as shown in Figure 4.5.8. The plate pack with fixed and movable end covers is clamped together by long bolts, thus compressing the gaskets and forming a seal. Sealing between the two fluids is accomplished by elastomeric molded gaskets (typically 5 mm or 0.2 in. thick) that are fitted in peripheral grooves mentioned earlier. The most conventional flow arrangement is 1 pass –1 pass counterflow with all inlet and outlet connections on the fixed end cover. By blocking flow through some ports with proper gasketing, either one or both fluids could have more than one pass. Also more than one exchanger can be accommodated in a single frame with the use of intermediate connector plates such as up to five "exchangers" or sections to heat, cool, and regenerate heat between raw milk and pasteurized milk in a milk pasteurization application.

Typical PHE dimensions and performance parameters are given in Table 4.5.1 (Shah, 1994). Any metal which can be cold-worked is suitable for PHE applications. The most common plate materials are stainless steel (AISI 304 or 316) and titanium. Plates made from Incoloy 825, Inconel 625, Hastelloy C-276 are also available. Nickel, cupronickel, and monel are rarely used. Carbon steel is not used because of low

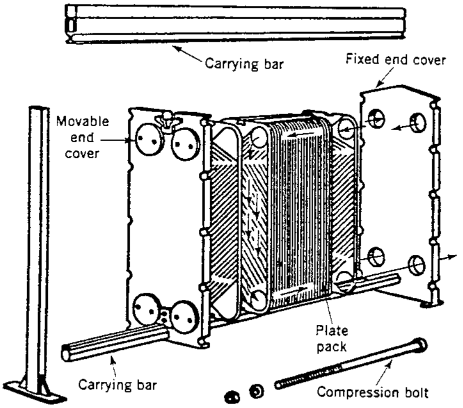

FIGURE 4.5.8 A plate-and-frame or gasketed PHE.

TABLE 4.5.1 Some Geometric and Operating Condition Characteristics of Plate-and-Frame Heat Exchangers

Unit		**Operation**	
Maximum surface area	2500 m^2	Pressure	0.1 to 3.0 MPa
Number of plates	3–700	Temperature	–40 to 260°C
Port size	Up to 400 mm	Maximum port velocity	6 m/sec (for liquids)
Plates		Channel flow rates	0.05 to 12.5 m^3/hr
Thickness	0.5–1.2 mm	Max unit flow rate	2500 m^3/hr
Size	0.03–3.6 m^2	**Performance**	
Spacing	1.5–7 mm	Temperature approach	As low as 1°C
Width	70–1200 mm	Heat exchanger efficiency	Up to 93%
Length	0.4–5 m	Heat transfer coefficients for water-water duties	3000 to 8000 W/m^2 K

corrosion resistance for thin plates. The heat transfer surface area per unit volume for plate exchangers ranges from 120 to 660 m^2/m^3 (37 to 200 ft^2/ft^3).

In PHEs, the high turbulence due to plates reduces fouling from about 10 to 25% of that of a shell-and-tube exchanger. High thermal performance can be achieved in plate exchangers because the high degree of counterflow in PHEs makes temperature approaches of up to 1°C (2°F) possible. The high thermal effectiveness (up to about 93%) makes low-grade heat recovery economical. PHEs are most suitable for liquid-liquid heat transfer duties and high vapor density phase-change applications.

Welded PHEs. One of the limitations of gasketed PHE is the presence of the gaskets which restricts the use to compatible fluids and which limits operating temperatures and pressures. In order to overcome this limitation, a number of welded PHE designs have surfaced with a welded pair of plates for one or both fluid sides. However, the disadvantage of such design is the loss of disassembling flexibility on the fluid side where the welding is done. Essentially, welding is done around the complete circumference where the gasket is normally placed. A *stacked plate heat exchanger* is another welded PHE design from Pacinox in which rectangular plates are stacked and welded at the edges. The physical size limitations of PHEs (1.2 m wide × 4 m long max, 4 × 13 ft) are considerably extended to 1.5 m wide × 20 m long (5 × 66 ft) in this exchanger. A maximum surface area of (10,000 m^2 or over 100,000 ft^2) can be accommodated in one unit. The potential maximum operating temperature is 815°C (1500°F) with an operating pressure of up to 20 MPa (3000 psig) when the stacked plate assembly is placed in a cylindrical pressure vessel. For operating pressures below 2 MPa (300 psig) and operating temperatures below 200°C (400°F), the plate bundle is not contained in a pressure vessel, but is bolted between two heavy plates. Some of the applications of this exchanger are catalytic reforming, hydrosulfurization, crude distillation, synthesis converter feed effluent exchanger for methanol, propane condenser, etc.

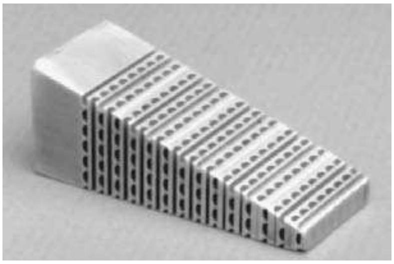

FIGURE 4.5.9 A section of a printed circuit heat exchanger. (Courtesy of Heatric Ltd., Dorset, U.K.)

A number of other PHE constructions have been developed to address some of the limitations of the conventional PHEs. A double-wall PHE is used to avoid mixing of the two fluids. A wide-gap PHE is used for fluids having high fiber content or coarse particles. Graphite and polymer plate PHEs are used for highly corrosive fluids. A flow-flex exchanger has plain fins on one fluid side between plates and the other fluid side has conventional plate channels, and is used to handle asymmetric duties (flow rate ratio of 2 to 1 and higher).

A vacuum **brazed PHE** is a compact PHE for high-temperature and high-pressure duties, and it does not have gaskets, tightening bolts, frame, or carrying and guide bars. It simply consists of stainless steel plates and two end plates. The brazed unit can be mounted directly on piping without brackets and foundations.

Printed Circuit Heat Exchangers. This exchanger, as shown in Figure 4.5.9, has only primary heat transfer surfaces as PHEs. Fine grooves are made in the plate by using the same techniques as those employed for making printed electrical circuits. High surface area densities (650 to 1350 m^2/m^3 or 200 to 400 ft^2/ft^3 for operating pressures of 500 to 20 bar respectively) are achievable. A variety of materials including stainless steel, titanium, copper, nickel, and nicket alloys can be used. It has been successfully used with relatively clean gases, liquids and phase-change fluids in chemical processing, fuel processing, waste heat recovery, and refrigeration industries. Again, this exchanger is a new construction with limited special applications currently.

Exchanger Heat Transfer and Pressure Drop Analysis

In this subsection, starting with the thermal circuit associated with a two-fluid exchanger, ε-NTU, P-NTU, and mean temperature difference (MTD) methods used for an exchanger analysis are presented, followed by the fin efficiency concept and various expressions. Finally, pressure drop expressions are outlined for various single-phase exchangers.

Two energy conservation differential equations for a two-fluid exchanger with any flow arrangement are (see Figure 4.5.10 for counterflow)

$$dq = q'' \, dA = -C_h \, dT_h = \pm C_c \, dT_c \tag{4.5.1}$$

where the ± sign depends upon whether dT_c is increasing or decreasing with increasing dA or dx. The local overall rate equation is

$$dq = q'' \, dA = U\left(T_h - T_c\right)_{\text{local}} \, dA = U \, \Delta T \, dA \tag{4.5.2}$$

Integration of Equation (4.5.1) and Equation (4.5.2) across the exchanger surface area results in

$$q = C_h\left(T_{h,i} - T_{h,o}\right) = C_c\left(T_{c,o} - T_{c,i}\right) \tag{4.5.3}$$

and

$$q = UA \, \Delta T_m = \Delta T_m / R_o$$

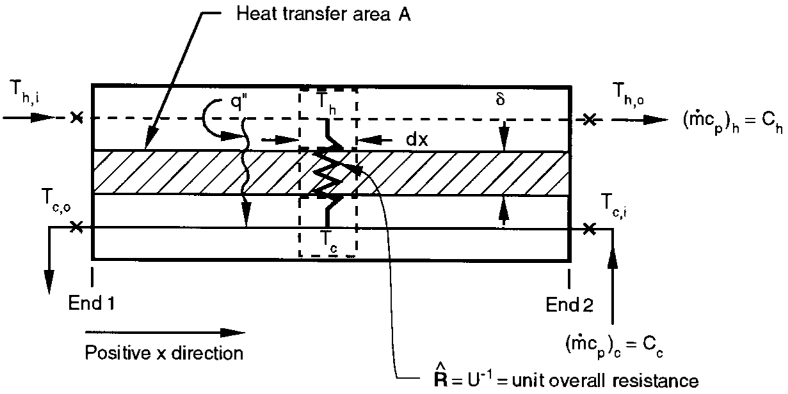

FIGURE 4.5.10 Nomenclature for heat exchanger variables.

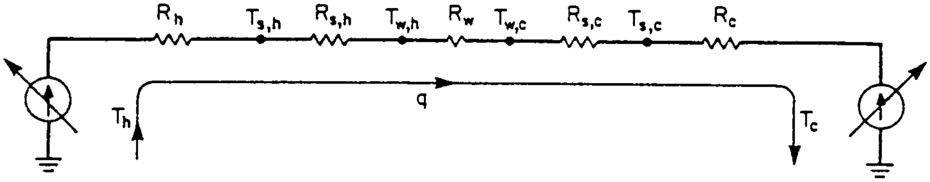

FIGURE 4.5.11 Thermal circuit for heat transfer in an exchanger.

where ΔT_m is the true mean temperature difference (or MTD) that depends upon the exchanger flow arrangement and degree of fluid mixing within each fluid stream. The inverse of the overall thermal conductance *UA* is referred to as the overall thermal resistance R_o as follows (see Figure 4.5.11).

$$R_o = R_h + R_{s,h} + R_w + R_{s,c} + R_c \tag{4.5.4}$$

where the subscripts *h*, *c*, *s*, and *w* denote hot, cold, fouling (or scale), and wall, respectively. In terms of the overall and individual heat transfer coefficients, Equation (4.5.4) is represented as

$$\frac{1}{UA} = \frac{1}{(\eta_o hA)_h} + \frac{1}{(\eta_o h_s A)_h} + R_w + \frac{1}{(\eta_o h_s A)_c} + \frac{1}{(\eta_o hA)_c} \tag{4.5.5}$$

where η_o = the overall extended surface efficiency and is related to the fin efficiency η_f, fin surface area A_f, and the total surface area *A* by Equation (4.5.19).

The wall thermal resistance R_w of Equation (4.5.4) is given by

$$R_w = \begin{cases} \delta / A_w k_w & \text{for a flat wall} \\ \dfrac{\ln(d_o/d_j)}{2\pi k_w L N_t} & \text{for } N_t \text{ circular tubes with a single-layer wall} \\ \dfrac{1}{2\pi L N_t}\left[\displaystyle\sum_j \frac{\ln(d_{j+1}/d_j)}{k_{w,j}}\right] & \text{for } N_t \text{ circular tubes with a multiple-layer wall} \end{cases}$$

TABLE 4.5.2 General Functional Relationships and Dimensionless Groups for ε-NTU, P-NTU, and MTD Methods

ε-NTU Method	P-NTU Method[a]	MTD Method[a]
$q = \varepsilon C_{\min}(T_{h,i} - T_{c,i})$	$q = \mathrm{P}_1 C_1 \lvert T_{1,i} - T_{2,i} \rvert$	$q = UAF\Delta T_{lm}$
$\varepsilon = \phi_1(\mathrm{NTU}, \mathrm{C}^*, \text{flow arrangement})$	$\mathrm{P}_1 = \phi_2(\mathrm{NTU}_1, \mathrm{R}_1, \text{flow arrangement})$	$F = \phi_3(\mathrm{P}, \mathrm{R}, \text{flow arrangement})^{\mathrm{b}}$
$\varepsilon = \dfrac{C_h(T_{h,i} - T_{h,o})}{C_{\min}(T_{h,i} - T_{c,i})} = \dfrac{C_c(T_{c,o} - T_{c,i})}{C_{\min}(T_{h,i} - T_{c,i})}$	$\mathrm{P}_1 = \dfrac{T_{1,o} - T_{1,i}}{T_{2,i} - T_{1,i}}$	$F = \dfrac{\Delta T_m}{\Delta T_{\mathrm{lm}}}$
$\mathrm{NTU} = \dfrac{UA}{C_{\min}} = \dfrac{1}{C_{\min}} \displaystyle\int_A U\, dA$	$\mathrm{NTU}_1 = \dfrac{UA}{C_1} = \dfrac{\lvert T_{1,o} - T_{1,i} \rvert}{\Delta T_m}$	$\mathrm{LMTD} = \Delta T_{\mathrm{lm}} = \dfrac{\Delta T_{\mathrm{I}} - \Delta T_{\mathrm{II}}}{\ln(\Delta T_{\mathrm{I}}/\Delta T_{\mathrm{II}})}$
$C^* = \dfrac{C_{\min}}{C_{\max}} = \dfrac{(\dot{m}c_p)_{\min}}{(\dot{m}c_p)_{\max}}$	$\mathrm{R}_1 = \dfrac{C_1}{C_2} = \dfrac{T_{2,i} - T_{2,o}}{T_{1,o} - T_{1,i}}$	$\Delta T_{\mathrm{I}} = T_{h,i} - T_{c,o} \quad \Delta T_{\mathrm{II}} = T_{h,o} - T_{c,i}$

[a] Although P_1, R_1, and NTU_1 are defined on fluid side 1, it must be emphasized that all the results of the P-NTU and MTD methods are valid if the definitions of P, NTU, and R are consistently based on C_c, C_s, C_h, C_t, *or* C_2.

[b] P and R are defined in the P-NTU method.

If one of the resistances on the right-hand side of Equation (4.5.4) or (4.5.5) is significantly higher than the other resistances, it is referred to as the *controlling thermal resistance*. A reduction in the controlling thermal resistance will have much more impact in reducing the exchanger surface area (A) requirement compared with the reduction in A as a result of the reduction in other thermal resistances.

UA of Equation (4.5.5) may be defined in terms of hot or cold fluid side surface area or wall conduction area as

$$UA = U_h A_h = U_c A_c = U_w A_w \tag{4.5.6}$$

When R_w is negligible, $T_{w,h} = T_{w,c} = T_w$ of Figure 4.5.11 is computed from

$$T_w = \frac{T_h + \left[\left(R_h + R_{s,h}\right)/\left(R_c + R_{s,c}\right)\right]T_c}{1 + \left[\left(R_h + R_{s,h}\right)/\left(R_c + R_{s,c}\right)\right]} \xrightarrow[R_{s,h}=R_{s,c}=0]{} T_w = \frac{T_h/R_h + T_c/R_c}{1/R_h + 1/R_c} = \frac{(\eta_o hA)_h T_h + (\eta_o hA)_c T_c}{(\eta_o hA)_h + (\eta_o hA)_c} \tag{4.5.7}$$

ε-NTU, P-NTU, and MTD Methods. If we consider the fluid outlet temperatures or heat transfer rate as dependent variables, they are related to independent variables/parameters of Figure 4.5.10 as follows.

$$T_{h,o},\ T_{c,o}, \ \text{ or } \ q = \phi\left\{T_{h,i},\ T_{c,i},\ C_c,\ C_h,\ U,\ A,\ \text{flow arrangement}\right\} \tag{4.5.8}$$

Six independent and three dependent variables of Equation (4.5.8) for a given flow arrangement can be transferred into two independent and one dependent dimensionless groups; three different methods are presented in Table 4.5.2 based on the choice of three dimensionless groups. The relationship among three dimensionless groups is derived by integrating Equation (4.5.1) and Equation (4.5.2) across the surface area for a specified exchanger flow arrangement. Such expressions are presented later in Table 4.5.4 for the industrially most important flow arrangements. Now we briefly describe the three methods.

In *the ε-NTU method*, the heat transfer rate from the hot fluid to the cold fluid in the exchanger is

$$q = \varepsilon C_{\min}\left(T_{h,i} - T_{c,i}\right) \tag{4.5.9}$$

Here the exchanger effectiveness ε is an efficiency factor. It is a ratio of the actual heat transfer rate from the hot fluid to the cold fluid in a given heat exchanger of any flow arrangement to the maximum possible heat transfer rate $q_{\max}$ thermodynamically permitted. The $q_{\max}$ is obtained in a *counterflow* heat exchanger (recuperator) of *infinite surface area* operating with the fluid flow rates (heat capacity rates) and fluid inlet temperatures equal to those of an actual exchanger (constant fluid properties are idealized). As noted in Table 4.5.2, the exchanger effectiveness ε is a function of NTU and C^* in this method. The number of transfer units NTU is a ratio of the overall conductance UA to the smaller heat capacity rate $C_{\min}$. NTU designates the dimensionless "heat transfer size" or "thermal size" of the exchanger. Other interpretations of NTU are given by Shah (1983). The heat capacity rate ratio C^* is simply a ratio of the smaller to the larger heat capacity rate for the two fluid streams. Note that $0 \leq \varepsilon \leq 1$, $0 \leq \text{NTU} \leq \infty$ and $0 \leq C^* \leq 1$.

The P-NTU method represents a variant of the ε-NTU method. The ε-NTU relationship is different depending upon whether the shell fluid is the $C_{\min}$ or $C_{\max}$ fluid in the stream asymmetric flow arrangements used for shell-and-tube exchangers. In order to avoid possible errors and to avoid keeping track of the $C_{\min}$ fluid side, an alternative is to present the temperature effectiveness P as a function of NTU and R, where P, NTU, and R are defined consistently either for Fluid 1 side or Fluid 2 side; in Table 4.5.2, they are defined for Fluid 1 side (regardless of whether that side is the hot or cold fluid side), and Fluid 1 side is clearly identified for each flow arrangement in Table 4.5.4; it is the shell side in a shell-and-tube exchanger. Note that

$$q = P_1 C_1 \left| T_{1,i} - T_{2,i} \right| = P_2 C_2 \left| T_{2,i} - T_{1,i} \right| \tag{4.5.10}$$

$$P_1 = P_2 R_2,\ P_2 = P_1 R_1,\ \text{NTU}_1 = \text{NTU}_2 R_2,\ \text{NTU}_2 = \text{NTU}_1 R_1,\ \text{and}\ R_1 = 1/R_2 \tag{4.5.11}$$

In *the MTD method*, the heat transfer rate from the hot fluid to the cold fluid in the exchanger is given by

$$q = UA\,\Delta T_m = UAF\,\Delta T_{\text{lm}} \tag{4.5.12}$$

where ΔT_m the log-mean temperature difference (LMTD), and F the LMTD correction factor, a ratio of true (actual) MTD to the LMTD, where

$$\text{LMTD} = \Delta T_{\text{lm}} = \frac{\Delta T_{\text{I}} - \Delta T_{\text{II}}}{\ln\left(\Delta T_{\text{I}} / \Delta T_{\text{II}}\right)} \tag{4.5.13}$$

Here ΔT_1 and ΔT_2 are defined as

$$\Delta T_{\text{I}} = T_{h,i} - T_{c,o} \quad \Delta T_{\text{II}} = T_{h,o} - T_{c,i} \qquad \text{for all flow arrangements except for parallel flow} \tag{4.5.14}$$

$$\Delta T_{\text{I}} = T_{h,i} - T_{c,i} \quad \Delta T_{\text{II}} = T_{h,o} - T_{c,o} \qquad \text{for parallel flow} \tag{4.4.15}$$

The LMTD represents a true MTD for a counterflow arrangement under the idealizations listed below. Thus, the LMTD correction factor F represents a degree of departure for the MTD from the counterflow LMTD; it does not represent the effectiveness of a heat exchanger. It depends on two dimensionless group P_1 and R_1 or P_2 and R_2 for a given flow arrangement.

The relationship among the dimensionless groups of the ε-NTU, P-NTU, and MTD methods are presented in Table 4.5.3. The closed-form formulas for industrially important exchangers are presented in terms of P_1, NTU_1, and R_1 in Table 4.5.4. These formulas are valid under idealizations which include: (1) steady-state conditions; (2) negligible heat losses to the surrounding; (3) no phase changes in the fluid streams flowing through the exchanger, or phase changes (condensation or boiling) occurring at constant temperature and constant effective specific heat; (4) uniform velocity and temperature at the entrance of the heat exchanger on each fluid side; (5) the overall extended surface efficiency η_o as uniform

TABLE 4.5.3 Relationships between Dimensionless Groups of the P-NTU and LMTD Methods and Those of the ε-NTU Method

$$\mathrm{P}_1 = \frac{C_{\min}}{C_1}\varepsilon = \begin{cases} \varepsilon & \text{for} \quad C_1 = C_{\min} \\ \varepsilon C^* & \text{for} \quad C_1 = C_{\max} \end{cases}$$

$$\mathrm{R}_1 = \frac{C_1}{C_2} = \begin{cases} C^* & \text{for} \quad C_1 = C_{\min} \\ 1/C^* & \text{for} \quad C_1 = C_{\max} \end{cases}$$

$$\mathrm{NTU}_1 = \mathrm{NTU}\frac{C_{\min}}{C_1} = \begin{cases} \mathrm{NTU} & \text{for} \quad C_1 = C_{\min} \\ \mathrm{NTU}\,C^* & \text{for} \quad C_1 = C_{\max} \end{cases}$$

$$F = \frac{\mathrm{NTU}_{\mathrm{cf}}}{\mathrm{NTU}} = \frac{1}{\mathrm{NTU}\left(1 - C^*\right)} \ln\left[\frac{1 - C^*\varepsilon}{1 - \varepsilon}\right] \xrightarrow[C^* = 1]{} \frac{\varepsilon}{\mathrm{NTU}(1 - \varepsilon)}$$

$$F = \frac{1}{\mathrm{NTU}_1\left(1 - \mathrm{R}_1\right)} \ln\left[\frac{1 - \mathrm{R}_1\mathrm{P}_1}{1 - \mathrm{P}_1}\right] \xrightarrow[\mathrm{R}_1 = 1]{} \frac{\mathrm{P}_1}{\mathrm{NTU}_1\left(1\text{-}\mathrm{P}_1\right)}$$

and constant; (6) constant individual and overall heat transfer coefficients; (7) uniformly distributed heat transfer area on each fluid side; (7) a large number of baffles in shell-and-tube exchangers; (8) no flow maldistribution; and (9) negligible longitudinal heat conduction in the fluid and exchanger wall.

The overall heat transfer coefficient can vary as a result of variations in local heat transfer coefficients due to two effects: (1) change in heat transfer coefficients in the exchanger as a result of changes in the fluid properties or radiation due to rise or drop of fluid temperatures and (2) change in heat transfer coefficients in the exchanger due to developing thermal boundary layers; it is referred to as the *length effect*. The first effect due to fluid property variations (or radiation) consists of two components: (1) distortion of velocity and temperature profiles at a given flow cross section due to fluid property variations — this effect is usually taken into account by the so-called property ratio method, with the correction scheme of Equation (4.5.45) and Equation (4.5.46) — and (2) variations in the fluid temperature along the axial and transverse directions in the exchanger depending upon the exchanger flow arrangement — this effect is referred to as the *temperature effect*. The resultant axial changes in the overall mean heat transfer coefficient can be significant; the variations in U_{local} could be nonlinear, dependent upon the type of the fluid. The effect of varying U_{local} can be taken into account by evaluating U_{local} at a few points in the exchanger and subsequently integrating U_{local} values by the Simpson or Gauss method (Shah, 1993). The temperature effect can increase or decrease mean U slightly or significantly, depending upon the fluids and applications. The length effect is important for developing laminar flows for which high heat transfer coefficients are obtained in the thermal entrance region. However, in general it will have less impact on the overall heat transfer coefficient because the other thermal resistances in series in an exchanger may be controlling. The length effect reduces the overall heat transfer coefficient compared with the mean value calculated conventionally (assuming uniform mean heat transfer coefficient on each fluid side). It is shown that this reduction is up to about 11% for the worst case (Shah, 1993).

Shah and Pignotti (1997) have shown that the following are the specific number of baffles beyond which the influence of the finite number of baffles on the exchanger effectiveness is not significantly larger than 2%: $N_b \geq 10$ for 1-1 TEMA E counterflow exchanger; $N_b \geq 6$ for 1-2 TEMA E exchanger for $\mathrm{NTU}_s \leq 2$, $R_s \leq 5$; $N_b \geq 9$ for 1-2 TEMA J exchanger for $\mathrm{NTU}_s \leq 2$, $R_s \leq 5$; $N_b \geq 5$ for 1-2 TEMA G exchanger for $\mathrm{NTU}_s \leq 3$, all R_s; $N_b \geq 11$ for 1-2 TEMA H exchanger for $\mathrm{NTU}_s \leq 3$, all R_s. Various shell-and-tube heat exchangers (such as TEMA E, G, H, J, etc.) are classified by the Tubular Exchanger Manufacturers' Association (TEMA, 1999).

If any of the basic idealizations are not valid for a particular exchanger application, the best solution is to work directly with either Equation 4.5.1 and Equation 4.5.2 or their modified form by including a particular effect, and to integrate them over a small exchanger segment numerically in which all of the idealizations are valid.

TABLE 4.5.4 $P_1 - NTU_1$ Formulas and Limiting Values of P_1 for $R_1 = 1$ and $NTU_1 \to \infty$ for Various Exchanger Flow Arrangements[a]

Flow Arrangement	Eq. no.	General formula	Value for $R_1 = 1$	Value for $NTU_1 \to \infty$
	I.1.1	$P_1 = \dfrac{1-\exp[-NTU_1(1-R_1)]}{1-R_1\exp[-NTU_1(1-R_1)]}$	$P_1 = \dfrac{NTU_1}{1+NTU_1}$	$P_1 \to 1$ for $R_1 \le 1$ $P_1 \to 1/R_1$ for $R_1 \ge 1$
	I.1.2	$NTU_1 = \dfrac{1}{(1-R_1)}\ln\left[\dfrac{1-R_1P_1}{1-P_1}\right]$	$NTU_1 = \dfrac{P_1}{1-P_1}$	$NTU_1 \to \infty$
Counterflow exchanger, stream symmetric.	I.1.3	$F = 1$	$F = 1$	$F = 1$
	I.2.1	$P_1 = \dfrac{1-\exp[-NTU_1(1+R_1)]}{1+R_1}$	$P_1 = \dfrac{1}{2}[1-\exp(-2NTU_1)]$	$P_1 \to \dfrac{1}{1+R_1}$
	I.2.2	$NTU_1 = \dfrac{1}{1+R_1}\ln\left[\dfrac{1}{1-P_1(1+R_1)}\right]$	$NTU_1 = \dfrac{1}{2}\ln\left[\dfrac{1}{1-2P_1}\right]$	$NTU_1 \to \infty$
Parallel flow exchanger, stream symmetric.	I.2.3	$F = \dfrac{(R_1+1)\ln\left[\dfrac{1-R_1P_1}{1-P_1}\right]}{(R_1-1)\ln[1-P_1(1+R_1)]}$	$F = \dfrac{2P_1}{(P_1-1)\ln(1-2P_1)}$	$F \to 0$
	II.1	$P_1 = 1-\exp(NTU_1)$ $-\exp[-(1+R_1)NTU_1]$ $\cdot\sum_{n=1}^{\infty} R_1^n P_n(NTU_1)$	same as Eq. (II.1) with $R_1 = 1$	$P_1 \to 1$ for $R_1 \le 1$ $P_1 \to \dfrac{1}{R_1}$ for $R_1 \ge 1$
Single-pass crossflow exchanger, both fluids unmixed, stream symmetric		$P_n(y) = \dfrac{1}{(n+1)!}\sum_{j=1}^{n}\dfrac{(n+1-j)}{j!}y^{n+j}$	$P_1 \approx 1-\exp\left[\dfrac{NTU_1^{0.22}}{R_1}\left(e^{-P_1NTU_1^{0.78}}-1\right)\right]$ This approximate equation is accurate within ±1% for $1 < NTU_1 < 7$.

---

[a] In this table, all variables, except P_1, R_1, NTU_1 and F, are local or dummy variables not necessarily related to similar ones defined in the nomenclature and the text. Source: Shah, R.K. and Mueller, A.C., 1988. With permission.

Fin Efficiency and Extended Surface Efficiency.

Extended surfaces have fins attached to the primary surface on one or both sides of a two-fluid or a multifluid heat exchanger. Fins can be of a variety of geometries — plain, wavy, or interrupted — and can be attached to the inside, outside, or both sides of circular, flat, or oval tubes, or parting sheets. Fins are primarily used to increase the surface area (when the heat transfer coefficient on that fluid side is relatively low) and consequently to increase the total rate of heat transfer. In addition, enhanced fin geometries also increase the heat transfer coefficient compared to that for a plain fin. Fins may also be used on the high heat transfer coefficient fluid side in a heat exchanger primarily for structural strength purposes (for example, for high-pressure water flow through a flat tube) or to provide a thorough mixing of a highly viscous liquid (such as for laminar oil flow in a flat or a round tube). Fins are attached to the primary surface by brazing, soldering, welding, adhesive bonding, or mechanical expansion, or they are extruded or integrally connected to the tubes. Major categories of extended surface heat exchangers are plate-fin (Figure 4.5.2 to Figure 4.5.4) and tube-fin (Figure 4.5.5 to Figure 4.5.7) exchangers. Note that shell-and-tube exchangers sometimes employ individually finned tubes — low finned tubes (similar to Figure 4.5.5a but with low-height fins) (Shah, 1985).

The concept of fin efficiency accounts for the reduction in temperature potential between the fin and the ambient fluid due to conduction along the fin and convection from or to the fin surface depending upon the fin cooling or heating situation. The fin efficiency is defined as the ratio of the actual heat transfer rate through the fin base divided by the maximum possible heat transfer rate through the fin base which would be obtained if the entire fin were at the base temperature (i.e., its material thermal conductivity were infinite). Since most of the real fins are "thin", they are treated as one-dimensional (1-D) with standard idealizations used for the analysis (Huang and Shah, 1992). This 1-D fin efficiency is a function of the fin geometry, fin material thermal conductivity, heat transfer coefficient at the fin surface, and the fin tip boundary condition; it is not a function of the fin base or fin tip temperature, ambient temperature, and heat flux at the fin base or fin tip in general. Fin efficiency formulas for some common fins are presented in Table 4.5.5 (Shah, 1985). Huang and Shah (1992) also discuss the influence on η_f if any of the basic idealizations used in the fin analysis are violated.

The fin efficiency for flat fins (Figure 4.5.4b) is obtained by a sector method (Shah, 1985). In this method, the rectangular or hexagonal fin around the tube (Figure 4.5.6a and Figure 4.5.6b) or its smallest symmetrical section is divided into n sectors (Figure 4.5.12). Each sector is then considered as a circular

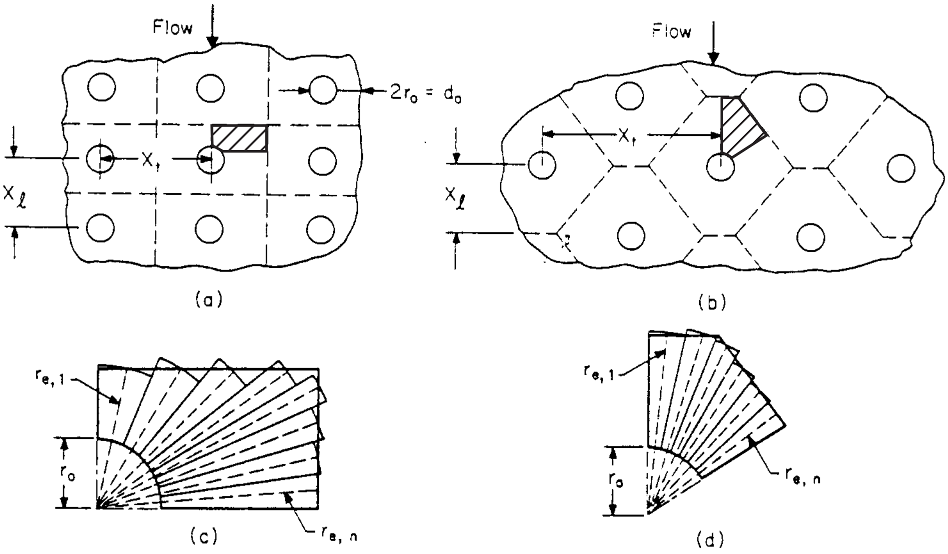

FIGURE 4.5.12 A flat fin over (a) an in-line and (b) staggered tube arrangement; the smallest representative segment of the fin for (c) an in-line and (d) a staggered tube arrangement.

TABLE 4.5.5 Fin Efficiency Expressions for Plate-Fin and Tube-Fin Geometries of Uniform Fin Thickness

Geometry	Fin Efficiency Formula $m_i = \left[\frac{2h}{k_f \delta_{f,i}}\left(1+\frac{\delta_{f,i}}{l_f}\right)\right]^{1/2} \quad E_i = \frac{\tanh(m_i l_i)}{m_i l_i} \quad i = 1, 2, 3$
 Plain, wavy, or offset strip fin of rectangular cross section	$\eta_f = E_1$ $l_1 = \frac{b}{2} - \delta_1 \quad \delta_1 = \delta_f$
 **Triangular fin heated/cooled from one side**	$\eta_f = \dfrac{hA_1(T_0 - T_a)\dfrac{\sinh(m_1 l_1)}{m_1 l_1} + q_e}{\cosh(m_1 l_1)\left[hA_1(T_0 - T_a) + q_e \dfrac{T_0 - T_a}{T_1 - T_a}\right]}$
 Plain, wavy, or louver fin of triangular cross section	$\eta_f = E_1$ $l_1 = \frac{l}{2} \quad \delta_1 = \delta_f$
 Double sandwich fin	$\eta_f = \frac{E_1 l_1 + E_2 l_2}{l_1 + l_2} \frac{1}{1 + m_1^2 E_1 E_2 l_1 l_2}$ $\delta_1 = \delta_f \quad \delta_2 = \delta_3 = \delta_f + \delta_s$ $l_1 = b - \delta_f + \frac{\delta_s}{2} \quad l_2 = l_3 = \frac{p_f}{2}$
 Circular fin	$\eta_j = \begin{cases} a(ml_e)^{-b} & \text{for } \Phi > 0.6 + 2.257(r^*)^{-0.445} \\ \dfrac{\tanh \Phi}{\Phi} & \text{for } \Phi \le 0.6 + 2.257(r^*)^{-0.445} \end{cases}$ $a = (r^*)^{-0.246} \quad \Phi = ml_e(r^*)^{\exp(0.13ml_e - 1.3863)}$ $b = \begin{cases} 0.9107 + 0.0893r^* & \text{for } r^* \le 2 \\ 0.9706 + 0.17125 \ln r^* & \text{for } r^* > 2 \end{cases}$ $m = \left(\frac{2h}{k_f \delta_f}\right)^{1/2} \quad l_e = l_j + \frac{\delta_f}{2} \quad r^* = \frac{d_e}{d_o}$
 Studded fin	$\eta_j = \frac{\tanh(ml_e)}{ml_e}$ $m = \left[\frac{2h}{k_f \delta_f}\left(1+\frac{\delta_f}{w}\right)\right]^{1/2} \quad l_e = l_f + \frac{\delta_f}{2} \quad l_f = \frac{(d_e - d_o)}{2}$

fin with the radius $r_{e,i}$ equal to the length of the centerline of the sector. The fin efficiency of each sector is subsequently computed using the circular fin formula of Table 4.5.5. The fin efficiency η_f for the whole fin is then the surface area weighted average of $\eta_{f,i}$ of each sector.

$$\eta_f = \left(\sum_{i=1}^{n} \eta_{f,i} A_{f,i}\right) \Bigg/ \left(\sum_{i=1}^{n} A_{f,i}\right) \tag{4.5.16}$$

Since the heat flow seeks the path of least thermal resistance, actual η_f will be equal to or higher than that calculated by Equation (4.5.16); hence, Equation (4.5.16) yields a somewhat conservative value of η_f. For a further refinement in η_f of Figure 4.5.12, refer to Shah and Sekulić (2002).

The η_f values of Table 4.5.5 or Equation (4.5.16) are not valid in general when the fin is thick, when it is subject to variable heat transfer coefficients or variable ambient fluid temperature, or when it has a temperature depression at the fin base. See Huang and Shah (1992) for details for these cases. For a thin rectangular fin of constant cross section, the fin efficiency as presented in Table 4.5.5 is given by

$$\eta_f = \frac{\tanh(m\ell)}{m\ell} \tag{4.5.17}$$

where $m = [2h(1 + \delta_f/\ell_f)/k_f\delta_f]^{1/2}$. For a thick rectangular fin of constant cross section, the fin efficiency (a counterpart of Equation (4.5.17) is given by (Huang and Shah, 1992)

$$\eta_f = \frac{\left(\mathrm{Bi}^+\right)^{1/2}}{K\mathrm{Bi}} \tanh\left[K\left(\mathrm{Bi}^+\right)^{1/2}\right] \tag{4.5.18}$$

where $\mathrm{Bi}^+ = \mathrm{Bi}/(1 + \mathrm{Bi}/4)$, $\mathrm{Bi} = h\delta_f/2k_f$, $K = 2\ell/\delta_f$. Equation (4.5.17) is accurate (within 0.3%) for a "thick" rectangular fin having $\eta_f > 80\%$; otherwise, use Equation (4.5.18) for a thick fin.

In an extended-surface heat exchanger, heat transfer takes place from both the fins ($\eta_f < 100\%$) and the primary surface ($\eta_f = 100\%$). In that case, the total heat transfer rate is evaluated through a concept of extended surface efficiency η_o defined as

$$\eta_o = \frac{A_p}{A} + \eta_f \frac{A_f}{A} = 1 - \frac{A_f}{A}\left(1 - \eta_f\right) \tag{4.5.19}$$

where A_f is the fin surface area, A_p is the primary surface area, and $A = A_f + A_p$. In Equation (4.5.19), heat transfer coefficients over the finned and unfinned surfaces are idealized to be equal. Note that $\eta_o \geq \eta_f$ and η_o is always required for the determination of thermal resistances of Equation (4.5.5) in heat exchanger analysis.

Pressure Drop Analysis.

Usually a fan, blower, or pump is used to flow fluid through individual fluid sides of a heat exchanger. Due to potential initial and operating high cost, low fluid pumping power requirement is highly desired for gases and viscous liquids. The fluid pumping power $\wp$ is approximately related to the core pressure drop in the exchanger as (Shah, 1985).

$$\wp = \frac{\dot{m}\Delta p}{\rho\eta_p} = \begin{cases} \dfrac{1}{2g_c\eta_p}\dfrac{\mu}{\rho^2}\dfrac{4L}{D_h}\dfrac{\dot{m}^2}{D_h A_o} f\,\mathrm{Re} & \text{for fully developed laminar flow} \quad (4.5.20) \\[2ex] \dfrac{0.046}{2g_c\eta_p}\dfrac{\mu^{0.2}}{\rho^2}\dfrac{4L}{D_h}\dfrac{\dot{m}^{2.8}}{A_o^{1.8} D_h^{0.2}} & \text{for fully developed turbulent flow} \quad (4.5.21) \end{cases}$$

where η_f is pump/fan efficiency.

It is clear from Equation (4.5.20) and Equation (4.5.21) that the fluid pumping power is strongly dependent upon the fluid density ($\wp \propto 1/\rho^2$) particularly for low-density fluids in laminar and turbulent flows, and upon the viscosity in laminar flow. In addition, the pressure drop itself can be an important consideration when blowers and pumps are used for the fluid flow since they are head limited. Also for condensing and evaporating fluids, the pressure drop affects the heat transfer rate. Hence, the pressure drop determination in the exchanger is important.

The pressure drop associated with a heat exchanger consists of (1) core pressure drop, and (2) the pressure drop associated with the fluid distribution devices such as inlet and outlet manifolds, headers, tanks, nozzles, ducting, and so on, which may include bends, valves, and fittings. This second Δp component is determined from Idelchik (1994) and Miller (1990). The core pressure drop may consist of one or more of the following components depending upon the exchanger construction: (1) friction losses associated with fluid flow over heat transfer surface (this usually consists of skin friction, form (profile) drag, and internal contractions and expansions, if any); (2) the momentum effect (pressure drop or rise due to fluid density changes) in the core; (3) pressure drop associated with sudden contraction and expansion at the core inlet and outlet, and (4) the gravity effect due to the change in elevation between the inlet and outlet of the exchanger. The gravity effect is generally negligible for gases. For vertical flow through the exchanger, the pressure drop or rise ("static head") due to the elevation change is given by

$$\Delta p = \pm \frac{\rho_m g L}{g_c} \tag{4.5.22}$$

Here the "+" sign denotes vertical upflow (i.e., pressure drop), the "–" sign denotes vertical downflow (i.e., pressure rise). The first three components of the core pressure drop are now presented for plate-fin, tube-fin, plate, and regenerative heat exchangers.

Plate-fin heat exchangers. For the plate-fin exchanger (Figure 4.5.2), all three components are considered in the core pressure drop evaluation as follows:

$$\frac{\Delta p}{p_i} = \frac{G^2}{2g_c}\frac{1}{p_i\rho_i}\left[\left(1-\sigma^2+K_c\right)+f\frac{L}{r_h}\rho_i\left(\frac{1}{\rho}\right)_m+2\left(\frac{\rho_i}{\rho_o}-1\right)-\left(1-\sigma^2-K_e\right)\frac{\rho_i}{\rho_o}\right] \tag{4.5.23}$$

where f is the Fanning friction factor, K_c and K_e are flow contraction (entrance) and expansion (exit) pressure loss coefficients (see Figure 4.5.13), and σ is a ratio of minimum free flow area to frontal area. K_c and K_e for four different entrance flow passage geometries are presented by Kays and London (1998). The entrance and exit losses are important at low values of σ and L (short cores), high values of Re, and for gases; they are negligible for liquids. The values of K_c and K_e apply to long tubes for which flow is fully developed at the exit. For partially developed flows, K_c and K_e is higher than that for fully developed flows. For interrupted surfaces, flow is never a fully developed boundary layer type. For highly interrupted fin geometries, the entrance and exit losses are generally small compared to the core pressure drop and the flow is well mixed; hence, K_c and K_e for Re → ∞ should represent a good approximation. The mean specific volume v_m or $(1/\rho)_m$ in Equation (4.5.23) is given as follows. For liquids with any flow arrangement, or for a perfect gas with $C^* = 1$ and any flow arrangement (except for parallel flow),

$$\left(\frac{1}{\rho}\right)_m = v_m = \frac{v_i + v_o}{2} = \frac{1}{2}\left(\frac{1}{\rho_i}+\frac{1}{\rho_o}\right) \tag{4.5.24}$$

where v is the specific volume in m^3/kg. For a perfect gas with $C^* = 0$ and any flow arrangement,

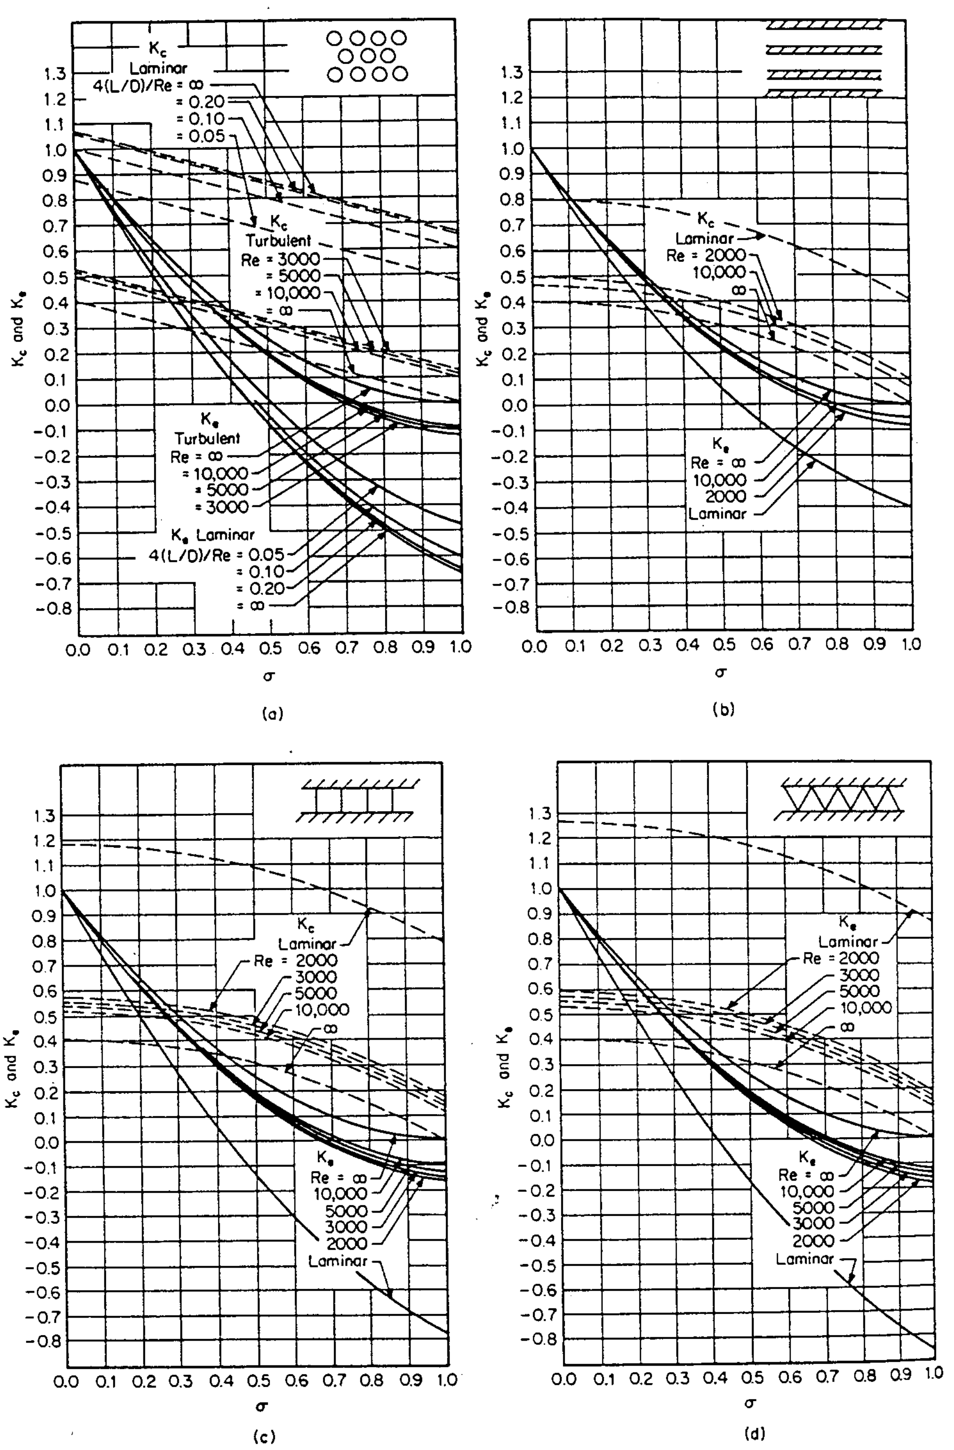

FIGURE 4.5.13 Entrance and exit pressure loss coefficients: (a) circular tubes, (b) parallel plates, (C) square passages, and (d) triangular passages. (From Kays, W.M. and London, A.L., *Compact Heat Exchangers*, 3rd ed., McGraw-Hill, New York, 1984. With permission.) For each of these flow passages, shown in the inset, the fluid flows perpendicular to the plane of the paper into the flow passages.

$$\left(\frac{1}{\rho}\right)_m = \frac{\tilde{R}}{p_{\text{ave}}} T_{\text{lm}} \tag{4.5.25}$$

Here $\tilde{R}$ is the gas constant in J/(kg K), $p_{\text{ave}} = (p_i + p_o)/2$, and $T_{\text{lm}} = T_{\text{const}} \pm \Delta T_{\text{lm}}$ where T_{const} is the mean average temperature of the evaporating (cold) or condensing (hot) fluid on the other side of the exchanger; the LMTD ΔT_{lm} is defined in Table 4.5.2. The core frictional pressure drop in Equation (4.5.23) may be approximated as

$$\Delta p = \frac{4fLG^2}{2g_c D_h}\left(\frac{1}{\rho}\right)_m \approx \frac{4fLG^2}{2g_c \rho_m D_h} \tag{4.5.26}$$

Tube-fin heat exchangers. The pressure drop inside a circular tube is computed using Equation (4.5.23) with proper values of f factors, and K_c and K_e from Figure 4.5.13 for circular tubes.

For flat fins on an array of tubes (see Figure 4.5.4b), the components of the core pressure drop (such as those in Equation 4.5.23) are the same with the following exception: the core friction and momentum effect take place within the core with $G = \dot{m}/A_o$, where A_o is the minimum free-flow area within the core, and the entrance and exit losses occur at the leading and trailing edges of the core with the associated flow area A_o' such that

$$\dot{m} = GA_o = G'A_o' \quad \text{or} \quad G'\sigma' = G\sigma \tag{4.5.27}$$

where σ' is the ratio of free-flow area to frontal area at the fin leading edges. The pressure drop for flow normal to a tube bank with flat fins is then given by

$$\frac{\Delta p}{p_i} = \frac{G^2}{2g_c}\frac{1}{p_i\rho_i}\left[f\frac{L}{r_h}\rho_i\left(\frac{1}{\rho}\right)_m + 2\left(\frac{\rho_i}{\rho_o} - 1\right)\right] + \frac{G'^2}{2g_c}\frac{1}{p_i\rho_i}\left[\left(1-\sigma'^2+K_c\right) - \left(1-\sigma'^2-K_e\right)\frac{\rho_i}{\rho_o}\right] \tag{4.5.28}$$

For individually finned tubes as shown in Figure 4.5.4a, flow expansion and contraction take place along each tube row, and the magnitude is of the same order as that at the entrance and exit. Hence, the entrance and exit losses are generally lumped into the core friction factor. Equation (4.5.23) then reduces for individually finned tubes to

$$\frac{\Delta p}{p_i} = \frac{G^2}{2g_c}\frac{1}{p_i\rho_i}\left[f\frac{L}{r_h}\rho_i\left(\frac{1}{\rho}\right)_m + 2\left(\frac{\rho_i}{\rho_o} - 1\right)\right] \tag{4.5.29}$$

Regenerators. For regenerator matrices having cylindrical passages, the pressure drop is computed using Equation (4.5.23) with appropriate values of f, K_c, and K_e. For regenerator matrices made up of any porous material (such as checkerwork, wire, mesh, spheres, copper wools, etc.), the pressure drop is calculated using Equation (4.5.29) in which the entrance and exit losses are included in the friction factor f.

Plate heat exchangers. Pressure drop in a PHE consists of three components: (1) pressure drop associated with the inlet and outlet manifolds and ports, (2) pressure drop within the core (plate passages), and (3) pressure drop due to the elevation change. The pressure drop in the manifolds and ports should be kept as low as possible (generally < 10%, but it is found as high as 25 to 30% or higher in some designs). Empirically, it is calculated as approximately 1.5 times the inlet velocity head per pass. Since the entrance and exit losses in the core (plate passages) cannot be determined experimentally, they are included in the friction factor for the given plate geometry. The pressure drop (rise) caused by the elevation change for liquids is given by Equation (4.5.22). Hence, the pressure drop on one fluid side in a PHE is given by

$$\Delta p = \frac{1.5 G_p^2 N_p}{2 g_c \rho_i} + \frac{4 f L G^2}{2 g_c D_e}\left(\frac{1}{\rho}\right)_m + \left(\frac{1}{\rho_o} - \frac{1}{\rho_i}\right)\frac{G^2}{g_c} \pm \frac{\rho_m g L}{g_c} \tag{4.5.30}$$

where $G_p = \dot{m}/(\pi/4)D_p^2$ is the fluid mass velocity in the port, N_p is the number of passes on the given fluid side and D_e is the equivalent diameter of flow passages (usually twice the plate spacing). Note that the third term on the right-hand side of the equality sign of Equation (4.5.30) is for the momentum effect which is generally negligible in liquids.

Heat Transfer and Flow Friction Correlations

Accurate and reliable surface heat transfer and flow friction characteristics are a key input to the exchanger heat transfer and pressure drop analyses or to the rating and sizing problems (Shah, 1985). Some important analytical solutions and empirical correlations are presented next for selected exchanger geometries.

The heat transfer rate in laminar duct flow is very sensitive to the thermal boundary condition. Hence, it is essential to identify carefully the thermal boundary condition in laminar flow. The heat transfer rate in turbulent duct flow is insensitive to the thermal boundary condition for most common fluids (Pr > 0.7); the exception is liquid metals (Pr < 0.03). Hence, there is generally no need to identify the thermal boundary condition in turbulent flow for all fluids except liquid metals.

Fully developed laminar flow analytical solutions for some duct shapes of interest in compact heat exchangers are presented in Table 4.5.6 for three important thermal boundary conditions denoted by the subscripts *H*1, *H*2, and *T* (Shah and London, 1978; Shah and Bhatti, 1987). Here, *H*1 denotes constant axial wall heat flux with constant peripheral wall temperature, *H*2 denotes constant axial and peripheral wall heat flux, and *T* denotes constant wall temperature. The entrance effects, flow maldistribution, free convection, property variation, fouling, and surface roughness all affect fully developed analytical solutions. In order to account for these effects in real plate-fin plain fin geometries having fully developed flows, it is best to reduce the magnitude of the analytical Nu by at least 10% and to increase the value of the analytical *f*Re by 10% for design purposes.

The initiation of transition flow, the lower limit of the critical Reynolds number ($\mathrm{Re}_{\mathrm{crit}}$), depends upon the type of entrance (e.g., smooth vs. abrupt configuration at the exchanger flow passage entrance). For a sharp square inlet configuration, $\mathrm{Re}_{\mathrm{crit}}$ is about 10 to 15% lower than that for a rounded inlet configuration. For most exchangers, the entrance configuration would be sharp. Some information on $\mathrm{Re}_{\mathrm{crit}}$ is provided by Ghajar and Tam (1994).

Transition flow and fully developed turbulent flow Fanning friction factors (within ±2% accuracy) are given by Bhatti and Shah (1987) as

$$f = \begin{cases} 0.0054 + 2.3\times10^{-8}\,\mathrm{Re}^{3/2} & \text{for } 2100 \le \mathrm{Re} \le 4000 \\ 0.00128 + 0.1143\,\mathrm{Re}^{0.3111} & \text{for } 4000 < \mathrm{Re} \le 10^7 \end{cases} \tag{4.5.31}$$

The transition flow and fully developed turbulent flow Nusselt number correlation for a circular tube is given by Gnielinski as reported in Bhatti and Shah (1987) as

$$\mathrm{Nu} = \frac{(f/2)(\mathrm{Re} - 1000)\,\mathrm{Pr}}{1 + 12.7(f/2)^{1/2}\left(\mathrm{Pr}^{2/3} - 1\right)} \tag{4.5.32}$$

which is accurate within about ±10% with experimental data for $2300 \le \mathrm{Re} \le 5 \times 10^6$ and $0.5 \le \mathrm{Pr} \le 2000$.

A careful observation of accurate experimental friction factors for all noncircular smooth ducts reveals that ducts with laminar *f*Re < 16 have turbulent *f* factors lower than those for the circular tube; whereas ducts with laminar *f*Re > 16 have turbulent *f* factors higher than those for the circular tube (Shah and

Source: Shah, R.K. and London, A.L., *Laminar Flow Forced Convection in Ducts,* Academic Press, New York, 1978. With permission.

Bhatti, 1988). Similar trends are observed for the Nusselt numbers. Within ±15% accuracy, Equation (4.5.31) and Equation (4.5.32) for f and Nu can be used for noncircular passages with the hydraulic diameter as the characteristic length in f, Nu, and Re; otherwise, refer to Bhatti and Shah (1987) for more accurate results for turbulent flow.

For hydrodynamically and thermally developing flows, the analytical solutions are boundary condition dependent (for laminar flow heat transfer only) and geometry dependent. The hydrodynamic entrance length for developing laminar flow is given by Shah and Bhatti (1987) as $L_{hy}/D_h = 0.0565\ \mathrm{Re}$; it is for developing turbulent flow given by Bhatti and Shah (1987) as $L_{hy}/D_h = 1.359\ \mathrm{Re}^{1/4}$.

Analytical results are useful for well-defined constant-cross-sectional surfaces with essentially unidirectional flows. The flows encountered in heat exchangers are generally very complex having flow separation, reattachment, recirculation, and vortices. Such flows significantly affect Nu and f for the specific exchanger surfaces. Since no analytical or accurate numerical solutions are available, the information is derived experimentally. Kays and London (1998) and Webb (1994) present most of the experimental results reported in the open literature. In the following, empirical correlations for only some important surfaces are summarized due to space limitations. Refer to Section 4.2, subsection "Heat Transfer across Tube Banks" or Shah and Sekulić (2003) for correlations for tube bundles.

Plate-Fin Extended Surfaces.

Offset strip fins. This is one of the most widely used enhanced fin geometries (Figure 4.5.14) in aircraft, cryogenics, and many other industries that do not require mass production. This surface has one of the highest heat transfer performances relative to the friction factor. The most comprehensive correlations for j and f factors for the offset strip fin geometry is provided by Manglik and Bergles (1995) as follows.

$$\begin{aligned} j = {} & 0.6522\mathrm{Re}^{-0.5403}\left(\frac{s}{h'}\right)^{-0.1541}\left(\frac{\delta_f}{l_f}\right)^{0.1499}\left(\frac{\delta_f}{s}\right)^{-0.0678} \\ & \times\left[1+5.269\times10^{-5}\,\mathrm{Re}^{1.340}\left(\frac{s}{h'}\right)^{0.504}\left(\frac{\delta_f}{l_f}\right)^{0.456}\left(\frac{\delta_f}{s}\right)^{-1.055}\right]^{0.1} \end{aligned} \tag{4.5.33}$$

$$\begin{aligned} f = {} & 9.6243\mathrm{Re}^{-0.7422}\left(\frac{s}{h'}\right)^{-0.1856}\left(\frac{\delta_f}{l_f}\right)^{0.3053}\left(\frac{\delta_f}{s}\right)^{-0.2659} \\ & \times\left[1+7.669\times10^{-8}\,\mathrm{Re}^{4.429}\left(\frac{s}{h'}\right)^{0.920}\left(\frac{\delta_f}{l_f}\right)^{3.767}\left(\frac{\delta_f}{s}\right)^{0.236}\right]^{0.1} \end{aligned} \tag{4.5.34}$$

where

$$D_h = 4A_o\Big/\left(A/l_f\right) = 4sh'l_f\Big/\left[2\left(sl_f + h'l_f + \delta_f h'\right) + \delta_f s\right] \tag{4.5.35}$$

Geometric symbols in Equation (4.5.35) are shown in Figure 4.5.14. Note that $h' = b - \delta_f$.

These correlations predict the experimental data of 18 test cores within ±20% for $120 \le \mathrm{Re} \le 10^4$. Although all the experimental data for these correlations are obtained for air, the j factor takes into consideration minor variations in the Prandtl number, and the above correlations should be valid for $0.5 < \mathrm{Pr} < 15$.

Louver fins. Louver or multilouver fins are extensively used in the auto industry because of their mass production manufacturability and hence lower cost. The louver fin has generally higher j and f factors than those for the offset strip fin geometry, and also the increase in the friction factors is in general higher than the increase in the j factors. However, the exchanger can be designed for higher heat transfer and the same pressure drop compared to that with the offset strip fins by a proper selection of exchanger frontal area, core depth, and fin density. Wang (2000) and his co-researchers have correlated experimental data of 91 test cores published in the literature and presented correlations for j and f data that are accurate within ±15% with a mean deviation of 9%.

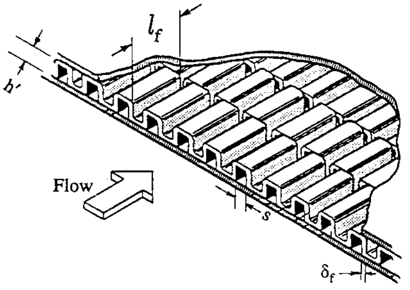

FIGURE 4.5.14 An offset strip fin geometry.

Tube-Fin Extended Surfaces.

Two major types of tube-fin extended surfaces as shown in Figure 4.5.4 are (a) individually finned tubes and (b) flat fins (also sometimes referred to as plate fins) with or without enhancements/interruptions on an array of tubes. An extensive coverage of the published literature and correlations for these extended surfaces are provided by Webb (1994), Kays and London (1984), and Rozenman (1976). Empirical correlations for some important geometries are summarized below.

Individually finned tubes. This fin geometry, helically wrapped (or extruded) circular fins on a circular tube as shown in Figure 4.5.4a, is commonly used in process and waste heat recovery industries. The following correlation for j factors is recommended by Briggs and Young (see Webb, 1994) for individually finned tubes on staggered tube banks.

$$j = 0.134\mathrm{Re}_d^{-0.319}\left(s/l_f\right)^{0.2}\left(s/\delta_f\right)^{0.11} \tag{4.5.36}$$

where l_f is the radial height of the fin, δ_f the fin thickness, $s = p_f - \delta_f$ is the distance between adjacent fins and p_f is the fin pitch. Equation (4.5.36) is valid for the following ranges: $1100 \le \mathrm{Re}_d \le 18{,}000$, $0.13 \le s/l_f \le 0.63$, $1.01 \le s/\delta_f \le 6.62$, $0.09 \le l_f/d_o \le 0.69$, $0.011 \le \delta_f/d_o \le 0.15$, $1.54 \le X_t/d_o \le 8.23$, fin root diameter d_o between 11.1 and 40.9 mm, and fin density N_f $(= 1/p_f)$ between 246 and 768 fin/m. The standard deviation of Equation (4.5.36) with experimental results was 5.1%.

For friction factors, Robinson and Briggs (see Webb, 1994) recommended the following correlation:

$$f_{tb} = 9.465\mathrm{Re}_d^{-0.316}\left(X_t/d_o\right)^{-0.927}\left(X_t/X_d\right)^{0.515} \tag{4.5.37}$$

Here $X_d = (X_t^2 + X_l^2)^{1/2}$ is the diagonal pitch, and X_t and X_l are the transverse and longitudinal tube pitches, respectively. The correlation is valid for the following ranges: $2000 \le \mathrm{Re}_d \le 50{,}000$, $0.15 \le s/l_f \le 0.19$, $3.75 \le s/\delta_f \le 6.03$, $0.35 \le l_f/d_o \le 0.56$, $0.011 \le \delta_f/d_o \le 0.025$, $1.86 \le X_t/d_o \le 4.60$, $18.6 \le d_o \le 40.9$ mm, and $311 \le N_f \le 431$ fin/m. The standard deviation of Equation (4.5.37) with correlated data was 7.8%

For crossflow over low-height finned tubes, a simple but accurate correlation for heat transfer is given by Ganguli and Yilmaz (1987) as

$$j = 0.255\mathrm{Re}_d^{-0.3}\left(d_e/s\right)^{-0.3} \tag{4.5.38}$$

A more accurate correlation for heat transfer is given by Rabas and Taborek (1987). Chai (1988) provides the best correlation for friction factors:

$$f_{tb} = 1.748\mathrm{Re}_d^{-0.233}\left(\frac{l_f}{s}\right)^{0.552}\left(\frac{d_o}{X_t}\right)^{0.599}\left(\frac{d_o}{X_1}\right)^{0.1738} \tag{4.5.39}$$

This correlation is valid for $895 < \mathrm{Re}_d < 713{,}000$, $20 < \theta < 40°$, $X_t/d_o < 4$, $N \ge 4$, and θ is the tube layout angle. It predicts 89 literature data points within a mean absolute error of 6%; the range of actual error is from –16.7 to 19.9%. Refer to Shah and Sekulić (2003) for better correlations.

Plain flat fins on a staggered tubebank. This geometry, as shown in Figure 4.5.4b, is used in air-conditioning/refrigeration industry as well as where the pressure drop on the fin side prohibits the use of enhanced/interrupted flat fins. An inline tubebank is generally not used unless very low fin side pressure drop is the essential requirement. Heat transfer correlation for Figure 4.5.4b plain flat fins on staggered tubebanks is provided by Gray and Webb (see Webb, 1994) as follows for four or more tube rows.

$$j_4 = 0.14\mathrm{Re}_d^{-0.328}\left(X_t/X_l\right)^{-0.502}\left(s/d_o\right)^{0.031} \tag{4.5.40}$$

For the number of tube rows N from 1 to 3, the j factor is lower and is given by

$$\frac{j_N}{j_4} = 0.991\left[2.24\,\mathrm{Re}_d^{-0.092}\left(N/4\right)^{-0.031}\right]^{0.607(4-N)} \tag{4.5.41}$$

Gray and Webb (see Webb, 1994) hypothesized the friction factor consisting of two components: one associated with the fins and the other associated with the tubes as follows.

$$f = \left(0.508\,\mathrm{Re}_d^{-0.521}\left(X_t/d_o\right)^{1.318}\right)\frac{A_f}{A} + f_t\left(1-\frac{A_f}{A}\right)\left(1-\frac{d_f}{p_f}\right) \tag{4.5.42}$$

and f_t (defined the same way as f) is the Fanning friction factor associated with the tube and can be determined from Eu of Figure 19 of Zukaukas (1987) as $f_t = \mathrm{Eu}N(X_t - d_o)/\pi d_o$. Equation (4.5.42) correlated 90% of the data for 19 heat exchangers within ±20%. The range of dimensionless variables of Equation (4.5.42) are $500 \le \mathrm{Re} \le 24{,}700$, $1.97 \le X_t/d_o \le 2.55$, $1.7 \le X_l/d_o \le 2.58$, and $0.08 \le s/d_o \le 0.64$.Wang (2000) and his co-researchers have presented improved correlations for j and f factors for flat fins on a staggered tubebank based on experimental data of 74 test cases. Refer to Shah and Sekulić (2003) for better correlations.

Exchanger Design Methodology

The problem of heat exchanger design is complex and multidisciplinary (Shah, 1991). The major design considerations for a new heat exchanger include process/design specifications, thermal and hydraulic design, mechanical design, manufacturing and cost considerations, and trade-offs and system-based optimization, as shown in Figure 4.5.15 with possible strong interactions among these considerations as indicated by double-sided arrows. The thermal and hydraulic design methods are mainly analytical, and the structural design is analytical to some extent. Most of the other major design considerations involve qualitative and experience-based judgments, trade-offs, and compromises. Therefore, there is no unique solution to designing a heat exchanger for given process specifications. Further details on this design methodology is given by Shah (1991) and Shah and Sekulić (2003).

Two important heat exchanger design problems are the rating and sizing problems. Determination of heat transfer and pressure drop performance of either an existing exchanger or an already sized exchanger is referred to as the rating problem. The objective here is to verify vendor's specifications or to determine the performance at off-design conditions. The rating problem is also sometimes referred to as the performance problem. In contrast, the design of a new or existing type of exchanger is referred to as the sizing problem. In a broad sense, it means the determination of the exchanger construction type, flow arrangement, heat transfer surface geometries and materials, and the physical size of an exchanger to meet the specified heat transfer and pressure drops. However, from the viewpoint of quantitative thermal-hydraulic analysis, we will consider that the selection of the exchanger construction type, flow arrangement, and materials has already been made. Thus, in the sizing problem, we will determine the physical size (length, width, height) and surface areas on each side of the exchanger. The sizing problem is also sometimes referred to as the design problem.

The step-by-step solution procedures for the rating and sizing problems for counterflow and crossflow single-pass plate-fin heat exchangers have been presented with a detailed illustrative example by Shah (1981). Shah (1988a) presented further refinements in these procedures as well as step-by-step procedures for two-pass cross-counterflow plate-fin exchangers, and single-pass crossflow and two-pass cross-counterflow tube-fin exchangers. Also, step-by-step solution procedures for the rating and sizing problems for rotary regenerators (Shah, 1988b), heat pipe heat exchangers (Shah and Giovannelli, 1988) and PHEs (Shah and Wanniarachchi, 1991) are available. As an illustration, the step-by-step solution procedures will be covered here for a single-pass crossflow exchanger.

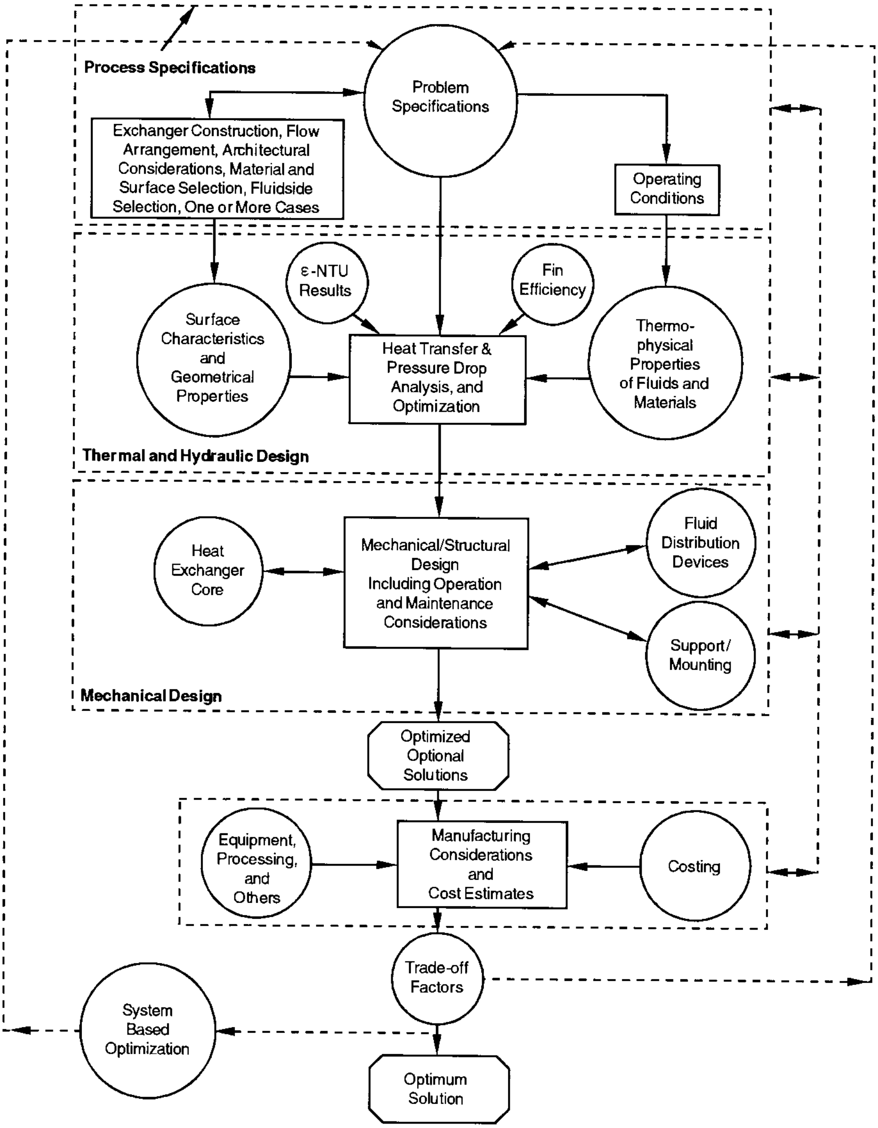

FIGURE 4.5.15 Heat exchanger design methodology.

Rating Problem for a Crossflow Plate-Fin Exchanger.

Following is a step-by-step procedure for rating a crossflow plate-fin exchanger. Inputs to the rating problem for a two-fluid exchanger are the exchanger construction, flow arrangement and overall dimensions, complete details on the materials and surface geometries on both sides including their nondimensional heat transfer and pressure drop characteristics (j and f vs. Re), fluid flow rates, inlet temperatures, and fouling factors. The fluid outlet temperatures, total heat transfer rate, and pressure drops on each side of the exchanger are then determined as the rating problem solution.

1. Determine the surface geometric properties on each fluid side. This includes the minimum free-flow area A_o, heat transfer surface area A (both primary and secondary), flow lengths L, hydraulic diameter D_h, heat transfer surface area density β, the ratio of minimum free-flow area to frontal area σ, fin length l_f, and fin thickness δ_f for fin efficiency determination, and any specialized dimensions used for heat transfer and pressure drop correlations.

2. Compute the fluid bulk mean temperature and fluid thermophysical properties on each fluid side. Since the outlet temperatures are not known for the rating problem, they are estimated initially. Unless it is known from past experience, assume an exchanger effectiveness as 50 to 75% for most single-pass crossflow exchangers, or 75 to 85% for single-pass counterflow exchangers. For the assumed effectiveness, calculate the fluid outlet temperatures.

$$T_{h,o} = T_{h,i} - \varepsilon\left(C_{\min}/C_h\right)\left(T_{h,i} - T_{c,i}\right) \qquad T_{c,o} = T_{c,i} + \varepsilon\left(C_{\min}/C_c\right)\left(T_{h,i} - T_{c,i}\right) \tag{4.5.43}$$

Initially, assume $C_c/C_h = \dot{m}_c/\dot{m}_h$ for a gas-to-gas exchanger, or $C_c/C_h = \dot{m}_c c_{p,c}/\dot{m}_h c_{p,h}$ for a gas-to-liquid exchanger with very approximate values of c_p for the fluids in question.

For exchangers with $C^* < 0.5$ (usually gas-to-gas exchangers), the bulk mean temperatures on each fluid side will be the arithmetic mean of the inlet and outlet temperatures on each fluid side (Shah, 1981). For exchangers with $C^* < 0.5$ (usually gas-to-gas exchangers), the bulk mean temperature on the $C_{\max}$ side will be the arithmetic mean of inlet and outlet temperatures; the bulk mean temperature on the $C_{\min}$ side will be the log-mean average temperature obtained as follows:

$$T_{m,C_{\min}} = T_{m,C_{\max}} \pm \Delta T_{\mathrm{lm}} \tag{4.5.44}$$

where ΔT_{lm} is the LMTD based on the terminal temperatures (see Equation 4.5.13). Use the plus sign if the $C_{\min}$ side is hot; otherwise, use the negative sign.

Once the bulk mean temperature is obtained on each fluid side, obtain the fluid properties from thermophysical property books or from handbooks. The properties needed for the rating problem are μ, c_p, k, Pr, and ρ. With this c_p, one more iteration may be carried out to determine $T_{h,o}$ or $T_{c,o}$ from Equation (4.5.43) on the $C_{\max}$ side, and subsequently T_m on the $C_{\max}$ side, and refine fluid properties accordingly.

3. Calculate the Reynolds number $\mathrm{Re} = GD_h/\mu$ and/or any other pertinent dimensionless groups (from the basic definitions) needed to determine the nondimensional heat transfer and flow friction characteristics (e.g., j or Nu and f) of heat transfer surfaces on each fluid side of the exchanger. Subsequently, compute j or Nu and f factors. Correct Nu (or j) for variable fluid property effects (Shah, 1981) in the second and subsequent iterations from the following equations.

$$\text{For gases:} \qquad \frac{\mathrm{Nu}}{\mathrm{Nu}_{\mathrm{cp}}} = \left[\frac{T_w}{T_m}\right]^{n'} \qquad \frac{f}{f_{\mathrm{cp}}} = \left[\frac{T_w}{T_m}\right]^{m'} \tag{4.5.45}$$

$$\text{For liquids:} \qquad \frac{\mathrm{Nu}}{\mathrm{Nu}_{\mathrm{cp}}} = \left[\frac{\mu_w}{\mu_m}\right]^{n'} \qquad \frac{f}{f_{\mathrm{cp}}} = \left[\frac{\mu_w}{\mu_m}\right]^{m'} \tag{4.5.46}$$

where the subscript cp denotes constant properties, and m' and n' are empirical constants provided in Table 4.5.7. Note that T_w and T_m in Equation (4.5.45) and in Table 4.5.7a and Table 4.5.7b are absolute temperatures, and T_w is computed from Equation (4.5.7).

4. From Nu or j, compute the heat transfer coefficients for both fluid streams.

$$h = \mathrm{Nu}\, k/D_h = jGc_p \mathrm{Pr}^{-2/3} \tag{4.5.47}$$

Subsequently, determine the fin efficiency η_f and the extended surface efficiency η_o

$$\eta_f = \frac{\tanh m\ell}{m\ell} \qquad \text{where} \qquad m^2 = \frac{h\tilde{P}}{k_f A_k} \tag{4.5.48}$$

TABLE 4.5.7a Property Ratio Method Exponents of Equation (4.5.45) and Equation (4.5.46) for Laminar Flow

Fluid	Heating	Cooling
Gases	$n' = 0.00$, $m' = 1.00$ for $1 < T_w/T_m < 3$	$n' = 0.0$, $m' = 0.81$ for $0.5 < T_w/T_m < 1$
Liquids	$n' = -0.14$, $m' = 0.58$ for $\mu_w/\mu_m < 1$	$n' = -0.14$, $m' = 0.54$ for $\mu_w/\mu_m > 1$

Source: Shah, R.K., in *Handbook of Heat Transfer Applications,* 2nd ed., W.M. Rohsenow, J.P. Hartnett, and E.N. Ganić, Eds., McGraw-Hill, New York, Chap. 4, Part 3, 1985.

where $\tilde{P}$ is the wetted perimeter of the fin surface. Refer to Table 4.5.5 for the η_f formulas for some additional fin geometries for a plate-fin exchanger. The extended surface efficiency η_o is then given by Equation (4.5.19). Also calculate the wall thermal resistance $R_w = \delta/A_w k_w$. Finally, compute the overall thermal conductance UA from Equation (4.5.5) knowing the individual convective film resistances, wall thermal resistances, and fouling resistances, if any.

5. From the known heat capacity rates on each fluid side, compute $C^* = C_{\mathrm{min}}/C_{\mathrm{max}}$. From the known UA, determine $\mathrm{NTU} = UA/C_{\mathrm{min}}$. Also calculate the longitudinal conduction parameter λ. With the known NTU, C^*, λ, and the flow arrangement, determine the exchanger effectiveness ε or P from either closed-form equations of Table 4.5.4 or tabular/graphical results from Kays and London (1998).
6. With this ε, finally compute the outlet temperatures from Equation (4.5.43). If these outlet temperatures are significantly different from those assumed in Step 2, use these outlet temperatures in Step 2 and continue iterating Steps 2 to 6, until the assumed and computed outlet temperatures converge within the desired degree of accuracy. For a gas-to-gas exchanger, most probably one or two iterations will be sufficient.
7. Finally, compute the heat duty q from Equation (4.5.9).
8. For the pressure drop calculations, first we need to determine the fluid densities at the exchanger inlet and outlet (ρ_i and ρ_o) for each fluid. The mean specific volume on each fluid side is then computed from Equation (4.5.24).

   Next, the entrance and exit loss coefficients, K_c and K_e, are obtained from Figure 4.5.13 for known σ, Re, and the flow passage entrance geometry.

The friction factor on each fluid side is corrected for variable fluid properties using Equation (4.5.45) or (4.5.46). Here, the wall temperature T_w is computed from

$$T_{w,h} = T_{m,h} - \left(R_h + R_{s,h}\right)q \qquad T_{w,c} = T_{m,c} + \left(R_c + R_{s,c}\right)q \tag{4.5.49}$$

where the various resistance terms are defined by Equation (4.5.5).

The core pressure drops on each fluid side are then calculated from Equation (4.5.23). This then completes the procedure for solving the rating problem.

Sizing Problem for a Crossflow Plate-Fin Exchanger.

As defined earlier, we will concentrate here to determine the physical size (length, width, and height) of a single-pass crossflow exchanger for specified heat duty and pressure drops. More specifically, inputs to the sizing problem are surface geometries (including their nondimensional heat transfer and pressure drop characteristics), fluid flow rates, inlet and outlet fluid temperatures, fouling factors, and pressure drops on each fluid side.

For the solution to this problem, there are four unknowns — two mass velocities or Reynolds numbers (to determine correct heat transfer coefficients and friction factors) and two surface areas — for the two-fluid crossflow exchanger. The following four equations (Equation (4.5.50), Equation (4.5.52), and Equation (4.5.54) are used to solve iteratively the surface areas on each fluid side: UA in Equation (4.5.50) is determined from NTU computed from the known heat duty or ε and C^*; G in Equation (4.5.52) represents two equations, for Fluids 1 and 2 (Shah, 1988a); and the volume of the exchanger in Equation (4.5.54) is the same based on the surface area density of Fluid 1 or Fluid 2.

$$\frac{1}{UA} \approx \frac{1}{\left(\eta_o hA\right)_h} + \frac{1}{\left(\eta_o hA\right)_c} \tag{4.5.50}$$

Here we have neglected the wall and fouling thermal resistances. This equation in nondimensional form is given by

$$\frac{1}{\text{NTU}} = \frac{1}{\text{ntu}_h\left(C_h/C_{\min}\right)} + \frac{1}{\text{ntu}_c\left(C_c/C_{\min}\right)} \tag{4.5.51}$$

$$G_i = \left[\frac{2g_c \Delta p}{\text{Deno}}\right]_i^{1/2} \qquad i = 1,2 \tag{4.5.52}$$

where

$$\text{Deno}_i = \left[\frac{f}{j}\frac{\text{ntu}}{\eta_o}\text{Pr}^{2/3}\left(\frac{1}{\rho}\right)_m + 2\left(\frac{1}{\rho_o} - \frac{1}{\rho_i}\right) + \left(1 - \sigma^2 + K_c\right)\frac{1}{\rho_i} - \left(1 - \sigma^2 - K_e\right)\frac{1}{\rho_o}\right]_i \tag{4.5.53}$$

$$V = \frac{A_1}{\alpha_1} = \frac{A_2}{\alpha_2} \tag{4.5.54}$$

In the iterative solutions, the first time one needs ntu_h and ntu_c to start the iterations. These can be either determined from the past experience or by estimations. If both fluids are gases or both fluids are liquid, one could consider that the design is "balanced," i.e., that the thermal resistances are distributed approximately equally on the hot and cold sides. In that case, $C_h = C_c$, and $\text{nut}_h \approx \text{ntu}_c \approx 2\text{NTU}$. Alternatively, if we have liquid on one side and gas on the other side, consider 10% thermal resistance on the liquid side, i.e., $1/(\eta_o hA)_{\text{liq}} = 0.10(1/UA)$. Then, from Equation (4.5.50) and Equation (4.5.51) with $C_{\text{gas}} = C_{\min}$, we can determine the ntu values on each side as follows: $\text{ntu}_{\text{gas}} = 1.11\text{NTU}$, $\text{ntu}_{\text{liq}} = 10C^*\text{NTU}$.

Also note that initial guesses of η_o and j/f are needed for the first iteration to solve Equation (4.5.53). For a good design, consider $\eta_o = 0.80$ and determine an approximate value of j/f from the plot of j/f vs. Re curve for the known j and f vs. Re characteristics of each fluid side surface. The specific step-by-step design procedure is as follows:

1. In order to compute the fluid mean temperature and fluid thermophysical properties on each fluid side, determine the fluid outlet temperatures from the specified heat duty

$$q = \left(\dot{m}c_p\right)_h \left(T_{h,i} - T_{h,o}\right) = \left(\dot{m}c_p\right)_c \left(T_{c,o} - T_{c,i}\right) \tag{4.5.55}$$

   or from the specified exchanger effectiveness using Equation (4.5.43). For the first time, estimate the values of c_p.

   For exchangers with $C^* \geq 0.5$, the mean temperature on each fluid side will be the arithmetic mean of inlet and outlet temperatures on each fluid side. For exchangers with $C^* < 0.5$, the mean temperature on the $C_{\max}$ side will be the arithmetic mean of the inlet and outlet temperatures on that side and the mean temperature on the $C_{\min}$ side will be the log-mean average as given by Equation (4.5.44). With these mean temperatures, determine c_p and iterate one more time for the outlet temperatures if warranted. Subsequently, determine μ, c_p, k, Pr, and ρ on each fluid side.
2. Calculate C^* and ε (if q is given), and determine NTU from the ε-NTU expression, tables, or graphical results for the selected flow arrangement (in this case, it is unmixed–unmixed crossflow, Table 4.5.4). The influence of longitudinal heat conduction, if any, is ignored in the first iteration since we don't know the exchanger size yet.
3. Determine ntu on each side by the approximations discussed in the paragrapgh after Equation (4.5.54) unless it can be estimated from the past experience.
4. For the selected surfaces on each fluid side, plot j/f vs. Re curve from the given surface characteristics and obtain an approximate value of j/f. If fins are employed, assume $\eta_o = 0.80$ unless a better value can be estimated.
5. Evaluate G from Equation (4.5.52) on each fluid side using the information from Steps 1 to 4 and the input value of Δp.
6. Calculate Reynolds number Re, and determine j and f on each fluid side from the given design data for each surface.
7. Compute h, η_f, and η_o using Equation (4.5.47), Equation (4.5.48), and Equation (4.5.19). For the first iteration, determine U_1 on Fluid 1 side from the following equation derived from Equation (4.5.5) and Equation (4.5.54).

$$\frac{1}{U_1} = \frac{1}{\left(\eta_o h\right)_1} + \frac{1}{\left(\eta_o h_s\right)_1} + \frac{\alpha_1/\alpha_2}{\left(\eta_o h_s\right)_2} + \frac{\alpha_1/\alpha_2}{\left(\eta_o h\right)_2} \tag{4.5.56}$$

   where $\alpha_1/\alpha_2 = A_1/A_2$, $\alpha = A/V$, V is the exchanger total volume, and subscripts 1 and 2 denote Fluid 1 and 2 sides. For a plate-fin exchanger, α terms are given by Shah (1981) and Kays and London (1998):

$$\alpha_1 = \frac{b_1\beta_1}{b_1 + b_2 + 2\delta} \qquad \alpha_2 = \frac{b_2\beta_2}{b_1 + b_2 + 2\delta} \tag{4.5.57}$$

Note that the wall thermal resistance in Equation (4.5.56) is ignored in the first iteration. In second and subsequent iterations, compute U_1 from

$$\frac{1}{U_1} = \frac{1}{(\eta_o h)_1} + \frac{1}{(\eta_o h_s)_1} + \frac{\delta A_1}{k_w A_w} + \frac{A_1/A_2}{(\eta_o h_s)_2} + \frac{A_1/A_2}{(\eta_o h)_2} \tag{4.5.58}$$

where the necessary geometry information A_1/A_2 and A_1/A_w is determined from the geometry calculated in the previous iteration.

8. Now calculate the core dimensions. In the first iteration, use NTU computed in Step 2. For subsequent iterations, calculate longitudinal conduction parameter λ (and other dimensionless groups for a crossflow exchanger). With known ε, C^*, and λ, determine the correct value of NTU using either a closed-form equation or tabular/graphical results (Kays and London, 1998). Determine A_1 from NTU using U_1 from the previous step and known $C_{\min}$.

$$A_1 = \text{NTU}\, C_{\min}/U_1 \tag{4.5.59}$$

and hence

$$A_2 = (A_2/A_1)A_1 = (\alpha_2/\alpha_1)A_1 \tag{4.5.60}$$

A_o from known $\dot{m}$ and G is given by

$$A_{o,1} = (\dot{m}/G)_1 \qquad A_{o,2} = (\dot{m}/G)_2 \tag{4.5.61}$$

so that

$$A_{fr,1} = A_{o,1}/\sigma_1 \qquad A_{fr,2} = A_{o,2}/\sigma_2 \tag{4.5.62}$$

where σ_1 and σ_2 are generally specified for the surface or can be computed for plate-fin surfaces from Shah (1981) and Kays and London (1998):

$$\sigma_1 = \frac{b_1\beta_1 D_{h,1}/4}{b_1 + b_2 + 2\delta} = \frac{\alpha_1 D_{h,1}}{4} \qquad \sigma_2 = \frac{b_2\beta_2 D_{h,2}/4}{b_1 + b_2 + 2\delta} = \frac{\alpha_2 D_{h,2}}{4} \tag{4.5.63}$$

Now compute the fluid flow lengths on each fluid side (see Figure 4.5.16) from the definition of the hydraulic diameter of the surface employed on each fluid side.

$$L_1 = \left(\frac{D_h A}{4A_o}\right)_1 \qquad L_2 = \left(\frac{D_h A}{4A_o}\right)_2 \tag{4.5.64}$$

Since $A_{fr,1} = L_2 L_3$ and $A_{fr,2} = L_1 L_3$, we can obtain

$$L_3 = \frac{A_{fr,1}}{L_2} \quad \text{or} \quad L_3 = \frac{A_{fr,2}}{L_1} \tag{4.5.65}$$

Theoretically, L_3 calculated from both expressions of Equation (4.5.65) should be identical. In reality, they may differ slightly because of the round-off error. In that case, consider an average value for L_3.

9. Finally, compute the pressure drop on each fluid side, after correcting f factors for variable property effects, in a manner similar to Step 8 of the Rating Problem for a Crossflow Plate-Fin Exchanger.

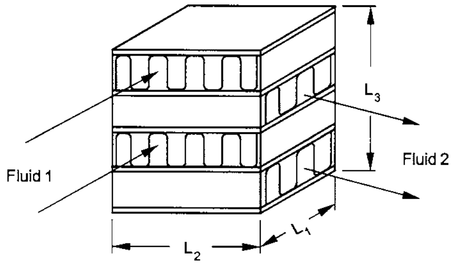

FIGURE 4.5.16 A single-pass crossflow exchanger.

10. If the calculated values of Δp are within and close to input specifications, the solution to the sizing problem is completed. Finer refinements in the core dimensions, such as integer numbers of flow passages, etc., may be carried out at this time. Otherwise, compute the new value of G on each fluid side using Equation (4.5.23) in which Δp is the input-specified value, and f, K_c, K_e, and geometric dimensions are from the previous iteration.
11. Repeat (iterate) Steps 6 to 10 until both transfer and pressure drops are met as specified. It should be emphasized that since we have imposed no constraints on the exchanger dimensions, the above procedure will yield L_1, L_2, and L_3 for the selected surfaces such that the design will meet exactly the heat duty and pressure drops on both fluid sides.

Flow Maldistribution

In the previously presented heat transfer (ε-NTU, MTD, etc. methods) and pressure drop analyses, it is presumed that the fluid is uniformly distributed through the core. In practice, flow maldistribution does occur to some extent and often severely, and may result in a significant reduction in exchanger heat transfer performance and an increase in pressure drop. Hence, it may be necessary for the designer to take into account the effect of flow maldistribution causing undesirable performance deterioration up front while designing a heat exchanger.

Some maldistributions are geometry-induced (i.e., the result of exchanger fabrication conditions, such as header design or manufacturing tolerances, or the duct geometry/structure upstream of the exchanger), and other maldistributions are the result of exchanger operating conditions. Gross, passage-to-passage and manifold-induced flow maldistributions are examples of the former category, while viscosity, natural convection, and density-difference-induced flow maldistributions are of the latter category. Flow maldistributions associated with two-phase and multiphase flow are too complex, with only limited information available in the literature. The analysis methods and results for some of the above flow maldistributions for single-phase flows are given by Shah (1985), Mueller and Chiou (1987), and Putnam and Rohsenow (1985).

Fouling in Heat Exchangers

Fouling, Its Effect, and Mechanisms.

Fouling refers to undesired accumulation of solid material (by-products of the heat transfer processes) on heat exchanger surfaces which results in additional thermal resistance to heat transfer, thus reducing exchanger performance. The fouling layer also blocks the flow passage/area and increases surface roughness, thus either reducing the flow rate in the exchanger or increasing the pressure drop or both. The foulant deposits may be loose such as magnetite particles or hard and tenacious such as calcium carbonate scale; other deposits may be sediment, polymers, coking or corrosion products, inorganic salts, biological growth, etc. Depending upon the fluids, operating conditions, and heat exchanger construction, the maximum fouling layer thickness on the heat transfer surface may result in a few hours to a number of years.

Fouling could be very costly depending upon the nature of fouling and the applications. It increases capital costs: (1) oversurfacing heat exchanger, (2) provisions for cleaning, and (3) use of special materials and constructions/surface features. It increases maintenance costs: (1) cleaning techniques, (2) chemical additives, and (3) troubleshooting. It may cause a loss of production: (1) reduced capacity and (2) shutdown. It increases energy losses: (1) reduced heat transfer, (2) increased pressure drop, and (3) dumping dirty streams. Fouling promotes corrosion, severe plugging, and eventual failure of uncleaned heat exchangers. In a fossil-fired exhaust environment, gas-side fouling produces a potential fire hazard in heat exchangers.

The following are the major fouling mechanisms:

- *Crystallization or precipitation fouling* results from the deposition/formation of crystals of dissolved substances from the liquid onto heat transfer surface due to solubility changes with temperature beyond the saturation point. If the deposited layer is hard and tenacious, it is often referred to as scaling. If it is porous and mushy, it is called sludge.
- *Particulate fouling* results from the accumulation of finely divided substances suspended in the fluid stream onto heat transfer surface. If the settling occurs as a result of gravity, it is referred to as sedimentation fouling.
- *Chemical reaction fouling* is defined as the deposition of material produced by chemical reaction (between reactants contained in the fluid stream) in which the heat transfer surface material does not participate.
- *Corrosion fouling* results from corrosion of the heat transfer surface that produces products fouling the surface and/or roughens the surface, promoting attachment of other foulants.
- *Biological fouling* results from the deposition, attachment, and growth of biological organisms from liquid onto a heat transfer surface. Fouling due to microorganisms refers to microbial fouling and fouling due to macroorganisms refers to macrobial fouling.
- *Freezing fouling* results from the freezing of a single-component liquid or higher-melting-point constituents of a multicomponent liquid onto a subcooled heat transfer surface.

Biological fouling occurs only with liquids since there are no nutrients in gases. Also crystallization fouling is not too common with gases since most gases contain few dissolved salts (mainly in mists) and even fewer inverse-solubility salts. All other types of fouling occur in both liquid and gas. More than one mechanism is usually present in many fouling situations, often with synergetic results. Liquid-side fouling generally occurs on the exchanger side where the liquid is being heated, and gas-side fouling occurs where the gas is being cooled; however, reverse examples can be found.

Importance of Fouling.

Fouling in liquids and two-phase flows has a significant detrimental effect on heat transfer with some increase in fluid pumping power. In contrast, fouling in gases reduces heat transfer somewhat (5 to 10% in general) in compact heat exchangers, but increases fluid pumping power significantly up to several hundred percent. For example, consider U = 1400 W/m^{2}K as in a process plant liquid-to-liquid heat exchanger. Hence, $R = 1/U = 0.00072$ m^{2}K/W. If the fouling factors ($r_{s,h} + r_{s,c}$) together amount to 0.00036 (considering a typical TEMA value of the fouling factor as 0.00018), 50% of the heat transfer area requirement A for given q is chargeable to fouling. However, for gas flows on both sides of an exchanger, $U \approx 280$ W/m^{2}K, and the same fouling factor of 0.00036 would represent only about 10% of the total surface area. Thus, one can see a significant impact on the heat transfer surface area requirement due to fouling in heat exchangers having high U values (such as having liquids or phase-change flows).

Considering the core frictional pressure drop (Equation (4.5.26) as the main pressure drop component, the ratio of pressure drops of fouled and cleaned exchangers is given by

$$\frac{\Delta p_F}{\Delta p_C} = \frac{f_F}{f_C}\left(\frac{D_{h,C}}{D_{h,F}}\right)\left(\frac{u_{m,F}}{u_{m,C}}\right)^2 = \frac{f_F}{f_C}\left(\frac{D_{h,C}}{D_{h,F}}\right)^5 \tag{4.5.68}$$

where the term after the second equality sign is for a circular tube and the mass flow rates under fouled and clean conditions remain the same. Generally, $f_F > f_C$ due to the fouled surface being rough. Thus, although the effect of fouling on the pressure drop is usually neglected, it can be significant, particularly for compact heat exchangers with gas flows. If we consider $f_F = f_C$, and the reduction in the tube inside diameter due to fouling by only 10 and 20%, the resultant pressure drop increase will be 69 and 205%, respectively, according to Equation (4.5.68) regardless of whether the fluid is liquid or gas! However, the resultant fluid pumping power increase will be very small for liquids compared to gases in general since now the density ratio comes into picture (water-to-air density ratio over 800:1 at ambient conditions) as found from the first equality of Equation (4.5.20).

TABLE 4.5.8 Fouling Factors and Design Parameters for Finned Tubes in Fossil Fuel Exhaust Gases

Accounting of Fouling in Heat Exchangers.

Fouling is an extremely complex phenomenon characterized by a combined heat, mass, and momentum transfer under transient condition. Fouling is affected by a large number of variables related to heat exchanger surfaces, operating conditions, and fluids. Fouling is time dependent, zero at $\tau = 0$; after the induction or delay period τ_d, the fouling resistance is either pseudolinear, falling rate, or asymptotic.

Fouling is characterized by all or some of the following sequential events: initiation, transport, attachment, removal, and aging (Epstein, 1983). Research efforts are concentrated on quantifying these events by semitheoretical models (Epstein, 1978) with very limited success on specific fouling situations. Hence, the current heat exchanger design approach is to use a constant (supposedly an asymptotic) value of the *fouling factor* or *fouling resistance* $r_s = 1/h_s$. Equation (4.5.5) presented earlier includes the fouling resistances on the hot and cold fluid sides for a tubular or nontubular extended-surface exchanger. Fouling factors for some common fluids are presented in Table 4.5.8 and Table 4.5.9.

The specification of fouling effects in a process heat exchanger is usually presented in terms of the combined fouling factor $r_{s,t}$, the cleanliness factor CF or percentage oversurface (%OS) as follows:

$$r_{s,t} = \frac{1}{U_C} - \frac{1}{U_F} \tag{4.5.69}$$

$$\mathrm{CF} = U_F / U_C \tag{4.5.70}$$

$$\%\mathrm{OS} = \left(\frac{A_F}{A_C} - 1\right)100 \tag{4.5.71}$$

Here the subscripts F and C denote fouled and clean exchanger values. From Equation (4.5.5) with $A_h = A_c = A$, $\eta_o = 1$, $\Delta T_{m,F} = \Delta T_{m,C}$, it can be shown that

$$\frac{A_F}{A_C} = \frac{U_C}{U_F} = 1 + U_C r_{s,t} \qquad r_{s,t} = \frac{1}{U_F} - \frac{1}{U_C} \tag{4.5.72}$$

In heat exchanger design, constant (supposedly an asymptotoic) values of $r_{s,h}$ and $r_{s,c}$ are used. Accordingly, extra heat transfer surface area is provided to take into account the deleterious effect of fouling. Thus, the heat exchanger will be "oversized" for the initial clean condition, "correctly sized" for asymptotic fouling (if it occurs in practice), and "undersized" just before the cleaning operation for nonasymptotic fouling.

Influence of Operating and Design Variables.

Based on operational experience and research over the last several decades, many variables have been identified that have a significant influence on fouling. The most important variables are summarized next.

Flow velocity. Flow velocity is one of the most important variables affecting fouling. Higher velocities increase fluid shear stress at the fouling deposit–fluid interface and increase the heat transfer coefficient, pressure drop and fluid pumping power. However, at the same time, increased velocity may erode the surface and may accelerate the corrosion of the surface by removing the protective oxide layer. The fouling buildup in general is inversely proportional to $u_m^{1.5}$. For water, the velocity should be kept above 2 m/sec to suppress fouling, and the absolute minimum should be above 1 m/sec to minimize fouling.

Surface temperature. Higher surface temperatures promote chemical reaction, corrosion, crystal formation (with inverse solubility salts), and polymerization, but reduce biofouling for temperatures above the optimum growth, avoid potential freezing fouling, and avoid precipitation of normal-solubility salts. It is highly recommended that the surface temperature be maintained below the reaction temperature; it should be kept below 60°C for cooling tower water.

Tube material. The selection of the tube material is important from the corrosion point of view which in turn could increase crystallization and biological fouling. Copper alloys can reduce certain biofouling, but their use is limited by environmental concerns with river, ocean, and lake waters.

There are many other variables that affect fouling. It is beyond the scope here, but the reader may refer to TEMA (1999).

Fouling Control and Cleaning Techniques.

Control of fouling should be attempted first before any cleaning method is attempted. For gas-side fouling, one should verify that fouling exists, identify the sequential event that dominates the foulant accumulation, and characterize the deposit. For liquid-side fouling, fouling inhibitors/additives should be employed while the exchanger is in operation; for example, use antidispersant polymers to prevent sedimentation fouling, "stabilizing" compounds to prevent polymerization and chemical reaction fouling, corrosion inhibitors to prevent corrosion fouling, biocide/germicide to prevent biofouling, softeners, acids, and polyphosphates to prevent crystallization fouling.

If the foulant control is not effective, the exchanger must be cleaned either on-line or off-line. On-line cleaning includes flow-driven brushes/sponge balls inside tubes, power-driven rotating brushes inside tubes, acoustic horns/mechanical vibrations for tube banks with gases, soot blowers, and shutting off of the cold gas supply, flowing hot gas, or reversing of the fluids. Off-line cleaning methods, without dismantling the exchanger include chemical cleaning (circulate acid/detergent solutions), circulating of particulate slurry (such as sand and water), and thermal melting of frost layers. Off-line cleaning with a heat exchanger opened includes high-pressure steam or water cleaning, and thermal baking of an exchanger and then rinsing for small heat exchanger modules removed from the container of the modular exchangers.

Nomenclature

A	total heat transfer area (primary + fin) on one fluid side of a heat exchanger, A_p: primary surface area, A_f: fin surface area, m^2
A_{fr}	frontal area on one fluid side of an exchanger, m^2
A_k	total wall cross-sectional area for heat conduction in fin or for longitudinal conduction in the exchanger, m^2
A_o	minimum free-flow area on one fluid side of a heat exchanger, m^2
b	plate spacing, $h' + \delta_f$, m
C	flow stream heat capacity rate with a subscript c or h, $\dot{m}c_p$, W/°C
C^*	heat capacity rate ratio, $C_{\min}/C_{\max}$, dimensionless
c_p	specific heat of a fluid at constant pressure, J/kg K
D_h	hydraulic diameter of flow passages, $4A_oL/A$, m
d_e	fin tip diameter of an individually finned tube, m
d_i, d_o	tube inside and outside diameters, respectively, m
Eu	N-row average Euler number, $\Delta p/(\rho\, u_m^2 N/2g_c)$, $\rho\Delta p g_c/(NG^2/2)$, dimensionless
F	log-mean temperature difference correction factor, dimensionless
f	Fanning friction factor, $\rho\Delta p g_c D_h/(2LG^2)$, dimensionless
f_{tb}	Row average Fanning friction factor per tube for crossflow to tubes, $\rho\Delta p g_c/(2NG^2)$, dimensionless
G	mass velocity based on the minimum free flow area, $\dot{m}/A_o$, kg/m²sec
g	gravitational acceleration, m²/sec
g_c	proportionality constant in Newton's second law of motion, $g_c = 1$ and dimensionless in SI units
h	heat transfer coefficient, W/m²K
h'	height of the offset strip fin for the η_f calculation, $b - \delta_f$, m
j	Colburn factor, $\mathrm{NuPr}^{-1/3}/\mathrm{Re}$, $\mathrm{StPr}^{2/3}$, dimensionless
k	fluid thermal conductivity, W/m K
k_f	thermal conductivity of the fin material, W/m K
k_w	thermal conductivity of the matrix (wall) material, W/m K
L	fluid flow (core or tube) length on one fluid side of an exchanger, m
ℓ	fin length for heat conduction from primary surface to the midpoint between plates for symmetric heating, see Table 4.5.5 for other definitions of ℓ, m
l_f	offset trip fin length (see Figure 4.5.14) or fin height for individually finned tubes (see circular fin in Table 4.5.5), l_f represents the fin length in the fluid flow direction for an uninterrupted fin with $l_f = L$ in most cases, m
m	fin parameter, see Table 4.5.5 for specific definitions, 1/m
$\dot{m}$	mass flow rate, kg/sec
N	number of tube rows
N_f	number of fins per meter, 1/m
N_t	total number of tubes in an exchanger
NTU	number of heat transfer units, $UA/C_{\min}$, it represents the total number of transfer units in a multipass unit, $\mathrm{NTU}_s = UA/C_{\mathrm{shell}}$, dimensionless
Nu	Nusselt number, hD_h/k, dimensionless
ntu_c	number of heat transfer units based on the cold fluid side, $(\eta_o hA)_c/C_c$, dimensionless
ntu_h	number of heat transfer units based on the hot fluid side, $(\eta_o hA)_h/C_h$, dimensionless
P	temperature effectiveness of one fluid, dimensionless
$\wp$	fluid pumping power, W
Pr	fluid Prandtl number, $\mu c_p/k$, dimensionless
p	fluid static pressure, Pa
Δp	fluid static pressure drop on one fluid side of heat exchanger core, Pa
p_f	fin pitch, m

q	heat duty, W
q_e	heat transfer rate (leakage) at the fin tip, W
q''	heat flux, W/m^2
R	heat capacity rate ratio used in the P-NTU method, $R_1 = C_1/C_2$, $R_2 = C_2/C_1$, dimensionless
R	thermal resistance based on the surface area A, compare Equation 4.5.4 and Equation 4.5.5 for definitions of specific thermal resistances, K/W
Re	Reynolds number, GD_h/μ, dimensionless
Re$_d$	Reynolds number based on the tube outside diameter, $\rho u_m d_o/\mu$, dimensionless
r_h	hydraulic radius, $D_h/4$, $A_o L/A$, m
r_s	fouling factor or fouling resistance, $1/h_s$, m^{2}K/W
St	Stanton number, h/Gc_p, dimensionless
s	distance between adjacent fins, $p_f - \delta_f$, m
T	fluid static temperature to a specified arbitrary datum, °C
T_a	ambient temperature, °C
T_o	fin base temperature, °C
T_l	fin tip temperature, °C
U	overall heat transfer coefficient, W/m^2 K
u_m	mean axial velocity in the minimum free flow area, m/sec
V	heat exchanger total volume, m^3
X_d	diagonal tube pitch, m
X_l	longitudinal tube pitch, m
X_t	transverse tube pitch, m
α	ratio of total heat transfer area on one fluid side of an exchanger to the total volume of an exchanger, A/V, m^2/m^3
β	heat transfer surface area density, a ratio of total transfer area on one fluid side of a plate-fin heat exchanger to the volume between the plates on that side, m^2/m^3
ε	heat exchanger effectiveness, it represents an overall exchanger effectiveness for a multiplass unit, dimensionless
δ	wall thickness, m
δ_f	fin thickness, m
η_f	fin efficiency, dimensionless
η_o	extended surface efficiency, defined by Equation (4.5.19), dimensionless
λ	longitudinal wall heat conduction parameter based on the total conduction area, $\lambda = k_w A_{k,t}/C_{\min} L$, $\lambda_c = k_w A_{k,c}/C_c L_c$, $\lambda_h = k_w A_{k,h}/C_h L_h$, dimensionless
μ	fluid dynamic viscosity, Pa·s
ρ	fluid density, kg/m^3
σ	ratio of free flow area to frontal area, A_o/A_{fr}, dimensionless

Subscripts

C	clean surface value
c	cold fluid side
F	fouled surface value
f	fin
h	hot fluid side
i	inlet to the exchanger
o	outlet to the exchanger
s	scale or fouling
w	wall or properties at the wall temperature
1	one section (inlet or outlet) of the exchanger
2	other section (outlet or inlet) of the exchanger

Further Information

Heat exchangers play a crucial and dominant role in many developments related to energy conservation, recovery, utilization, economic development of new energy sources, fuel cell technology, and environmental issues such as air and water pollution control, thermal pollution, waste disposal, etc. Many new and innovative heat exchangers have been developed for these and many other applications worldwide. A broad overview is provided for various heat exchangers and basic design theory for single-phase heat exchangers. For further details and study, the reader may refer to the following references: Kakaç et al. (1981; 1983; 1988), Taylor (1987), Shah et al. (1990), Foumeny and Heggs (1991), Kakaç (1991), Roetzel et al. (1991), Shah and Hashemi (1993), Shah et al. (1997), Hesselgreaves (2001), and Shah and Sekulić (2003).

Shell-and-Tube Heat Exchangers

Kenneth J. Bell

Introduction

A shell-and-tube heat exchanger is essentially a bundle of tubes enclosed in a shell and so arranged that one fluid flows through the tubes and another fluid flows across the outside of the tubes, heat being transferred from one fluid to the other through the tube wall. A number of other mechanical components are required to guide the fluids into, through, and out of the exchanger, to prevent the fluids from mixing, and to ensure the mechanical integrity of the heat exchanger. A typical shell-and-tube heat exchanger is shown in Figure 4.5.18 (TEMA, 1988), but the basic design allows many modifications and special features, some of which are described below.

1. Stationary Head-Channel
2. Stationary Head Flange-Channel or Bonnet
3. Channel Cover
4. Stationary Head Nozzle
5. Stationary Tubesheet
6. Tubes
7. Shell
8. Shell Cover
9. Shell Flange-Stationary Head End
10. Shell Flange-Rear Head End
11. Shell Nozzle
12. Shell Cover Flange
13. Floating Tubesheet
14. Floating Head Cover
15. Floating Head Cover Flange
16. Floating Head Backing Device
17. Tierods and Spacers
18. Transverse Baffles or Support Plates
19. Impingement Plates
20. Pass Partition
21. Vent Connection
22. Drain Connection
23. Instrument Connection
24. Support Saddle
25. Lifting Lug

Nomenclature of Heat Exchanger Components

For the purpose of establishing standard terminology, Figure 4.5.17 illustrates various types of heat exchangers. Typical parts and connections, for illustrative purposes only, are numbered for identification:

Shell-and-tube heat exchangers have been constructed with heat transfer areas from less than 0.1 m^2 (1 ft^2) to over 100,000 m^2 (1,000,000 ft^2), for pressures from deep vacuum to over 1000 bar (15,000 psi), for temperatures from near 0 to over 1400 K (2000°F), and for all fluid services including single-phase heating and cooling and multiphase vaporization and condensation. The key to such flexibility is the wide range of materials of construction, forming and joining methods, and design features that can be built into these exchangers (see Schlünder, Vol. 4, 1983; Saunders, 1988; and Yokell, 1990). Most shell-

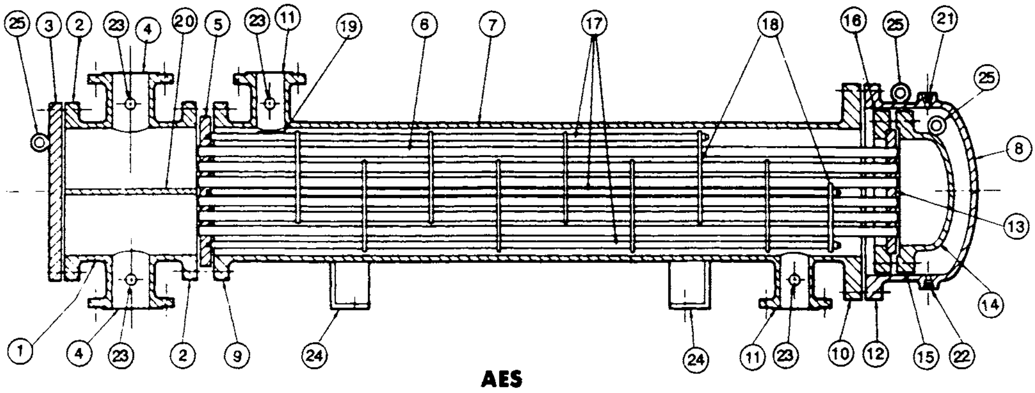

FIGURE 4.5.17 Longitudinal section of a typical shell-and-tube heat exchanger (TEMA AES) with nomenclature. (Modified from TEMA, *Standards* 7th ed., Tubular Exchanger Manufacturers Association, Tarrytown, NY, 1988.)

and-tube heat exchangers are manufactured in conformity with TEMA *Standards* (1988) and the *ASME Boiler and Pressure Vessel Code* (latest edition), but other codes and standards may apply.

Construction Features

In the design process, it is important to consider the mechanical integrity under varying operational conditions and the maintainability (especially cleaning) of the exchanger as equally important with the thermal-hydraulic design.

Tubes. Tubes used in shell-and-tube exchangers range from 6.35 mm ($^1/_4$ in.) to 50.8 mm (2 in.) and above in outside diameter, with the wall thickness usually being specified by the Birmingham wire gauge (BWG). Tubes are generally available in any desired length up to 30 m (100 ft) or more for plain tubes. While plain tubes are widely used, a variety of internally and/or externally enhanced tubes is available to provide special heat transfer characteristics when economically justified (see subsection on enhancement in Section 4.8). Low fin tubes having circumferential fins typically 0.8 to 1.6 mm (0.032 to 0.062 in.) high, spaced 630 to 1260 fins/m (16 to 32 fins/in.) are often employed, especially when the shell-side heat transfer coefficient is substantially smaller than the tube-side coefficient. The outside heat transfer area of a low fin tube is three to six times the inside area, resulting in a smaller heat exchanger shell for the same service, which may offset the higher cost of the tube per unit length.

The tubes are inserted into slightly oversized holes drilled (or, occasionally, punched) through the tubesheets (items 5 and 13, Figure 4.5.17). The tubes are secured by several means, depending upon the mechanical severity of the application and the need to avoid leakage between the streams. In some low-severity applications, the tubes are roller-expanded into smooth holes in the tubesheet. For a stronger joint, two shallow circumferential grooves are cut into the wall of the hole in the tubesheet and the tube roller-expanded into the grooves; to eliminate the possibility of leakage, a seal weld can be run between the outer end of the tube and the tubesheet. Alternatively, the tubes may be strength-welded into the tubesheet.

Tube Supports. It is essential to provide periodic support along the length of the tubes to prevent sagging and destructive vibration caused by the fluid flowing across the tube bank. A secondary role played by the tube supports is to guide the flow back and forth across the tube bank, increasing the velocity and improving the heat transfer on the shell side (but also increasing the pressure drop). The tube support is usually in the form of single segmental baffles (item 18 in Figure 4.5.17) — circular plates with holes drilled to accommodate the tubes and with a segment sheared off to form a “window” or “turnaround” to allow the shell-side fluid to pass from one cross-flow section to the next. The baffles must overlap at least one full row of tubes to give the bundle the necessary rigidity against vibration. When minimizing shell-side pressure drop is not a priority, a baffle cut of 15 to 25% of the shell inside diameter is customary. Baffle spacing is determined first by the necessity to avoid vibration and secondarily to approximately match the free cross-flow area between adjacent baffles to the flow area in the window; i.e., small baffle cuts correspond to closer baffle spacing.

In situations such as low-pressure gas flows on the shell side where pressure drop is severely limited, double segmental and strip baffle arrays can be used. More recently, a helical baffle arrangement has been introduced (Kral et al., 1996) which causes the shell-side fluid to spiral through the exchanger giving improved heat transfer vs. pressure drop characteristics. Where vibration prevention and/or minimum pressure drop are the main concerns, grids of rods or strips can be used (Gentry et al., 1982).

Shells. The shell is the cylinder which confines the shell-side fluid (item 7 in Figure 4.5.17), fitted with nozzles for fluid inlet and exit. Diameters range from less than 50 mm (2 in.) to 3.05 m (10 ft) commonly, and at least twice that value for special applications. In diameters up to 610 mm (24 in.), shells are usually made from standard pipe or tubular goods by cutting to the desired length; in larger sizes, metal plates are rolled to the desired diameter and welded.

A variety of nozzle arrangements are used for special purposes, and TEMA has a standard code to identify the major types, as well as the various front and rear head configurations on the tube side. Figure 4.5.18 shows these configurations with the corresponding code letters.

The E shell (center column, top) has the nozzles on opposite ends of the shell and is the most common configuration. It is used for any of the thermal services (single-phase heating or cooling, vaporization, and condensation). The nozzles may be on opposite sides of the shell as shown, or on the same side; the choice is largely determined by plumbing convenience. The E shell allows countercurrent flow (see below) of the two streams if there is one tube-side pass (i.e., the tube-side fluid flows through all of the tubes in parallel).

The F shell has both nozzles at one end of the shell and uses a longitudinal baffle on the shell side (shown dashed in the drawing) to force the shell-side fluid to flow to the far end of the heat exchanger and then back to the exit nozzle on the other side of the longitudinal baffle. Ideally, this allows countercurrent flow of the two streams if there are two tube-side passes (i.e., the tube-side fluid flows through half of the tubes in one direction, is turned around in the rear head, and returns through the other half of the tubes — see discussion of head types below). However, the longitudinal baffle must be carefully sealed to the shell to prevent leakage of the shell-side fluid across it; this is done by welding the longitudinal baffle to the shell and front tubesheet (which limits some design options) or by using mechanical seals. The F shell is mainly used for sensible heat transfer services.

The G shell has both nozzles at the center of the shell, with a centrally located longitudinal baffle to force the fluid to the ends of the shell before returning. While the G shell is used for all services, its main application is as a shellside vaporizer with either forced or natural (thermosiphon) convection of the boiling fluid; in the latter service, limited leakage across the baffle generally does not greatly degrade the thermal performance and the longitudinal baffle does not need to be perfectly sealed against the shell.

The H shell is effectively a double G shell and is employed in the same services. It is considered when the calculated shell-side pressure drop for a G arrangement is too high and threatens to limit the circulation rate.

The J shell, with one nozzle on top of the shell and two on the bottom, or vice versa, is commonly used in vacuum-condensing applications because of its low pressure drop. Two J shells (one inverted) may be mated in series for long-condensing-range mixtures. The nozzles are usually different diameters, with the large diameter accommodating the inlet vapor. The baffles are vertically cut.

The K shell (or kettle reboiler or flooded chiller) is exclusively intended for vaporization of liquid on the shell side, with a condensing vapor (usually steam) or a hot liquid on the tube side as the heating medium. The tubesheet diameter is large enough to accommodate the tube bundle, but the shell transitions to a larger diameter to allow the vapor to disengage from the liquid pool and exit from the top nozzle. A weir or other level control is used to maintain the liquid level, usually just above the top tubes in the bundle.

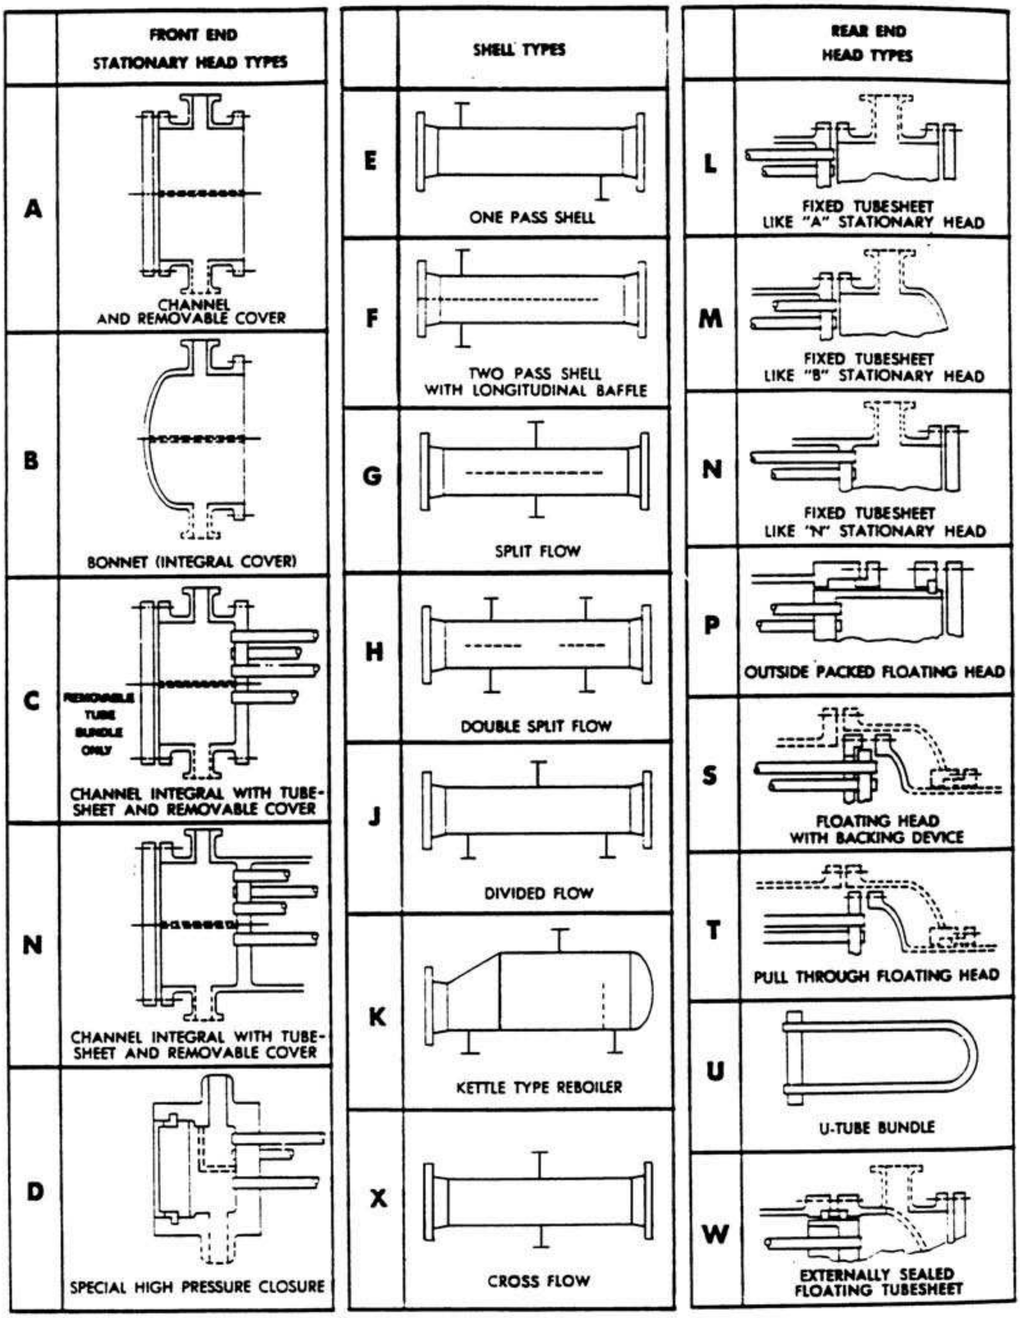

FIGURE 4.5.18 TEMA nomenclature for shell and tube configurations. (From TEMA, *Standards,* 7th ed., Tubular Exchanger Manufacturers Association, Tarrytown, NY, 1988. With permission.)

The X shell is intended to provide a well-distributed cross flow of the shell-side fluid, the fluid usually entering at the top and exiting at the bottom but occasionally used for upflow or horizontal cross flow. To obtain good distribution, multiple nozzles from a properly designed manifold may be required. Alternatively, the upper tubes in the bundle may be omitted to allow internal redistribution, or a large plenum chamber may be welded to the top of the shell ("vapor dome" or "bathtub nozzle"), or a diverging transition section may be placed between the inlet piping and the top of the shell. The tube supports may be complete circles since there is little or no longitudinal shell-side flow. The X shell gives the lowest shell-side pressure drop of any configuration and is often used for low-pressure vapor condensers.

Front Head. TEMA recognizes several front head designs as shown in the first column of Figure 4.5.18. Any of these designs will get the tube-side fluid into the tubes, but each has special features which recommend it to meet special needs. In Figure 4.5.18 the dashed lines indicate optional features depending upon need.

The A head, a channel with removable cover, bolts directly to the shell flange as shown in Figure 4.5.17, the tubesheet in that case being held between them and sealed with gaskets. Alternatively, the tubesheet may be integral with the shell (see the L rear head in Figure 4.5.18). A removable channel cover permits inspection, cleaning, removal, and replacement of tubes without disturbing the piping. The dashed lines at the center and the lower nozzle indicate that a pass partition plate may be welded in the channel (and gasketed against the tubesheet and channel cover) to provide for two tube-side passes (as shown in Figure 4.5.17 and required by the F shell design). Additional pass partitions may be provided to allow four, six, or any even number of tube-side passes. This permits the designer to utilize the available tube-side pressure drop to increase velocity, improve the heat transfer coefficient, and possibly reduce fouling. A second nozzle is required on the channel for multipass designs.

The B, or bonnet, front head reduces the number of gasketed joints and thus the opportunity for leakage, but it does not permit inspection of the tubes without breaking the piping connection. It is generally less expensive than the A head.

C and N heads retain the removable cover feature of the A head but, respectively, replace the channel-to-tubesheet and the tubesheet-to-shell gasketed connections with welds to minimize leakage possibilities. The N head is particularly used in nuclear services.

The D head is mainly used in feed-water heater applications where tube-side pressures are in the 100 to 400 bar range. The internal partition (optional) need only withstand the 1 to 2 bar pressure drop through the tubes so it can be of lightweight construction. The high-pressure closure against the atmosphere uses a shear key ring to lock the main closure in place.

Rear Head. A variety of rear head designs are used in shell-and-tube exchangers, primarily because of the need to accommodate thermally induced stresses. During operation, the tubes and the shell have different temperatures and therefore will expand (or try to) different amounts, even if there were no residual stresses in the exchanger before start-up and even if the entire exchanger is made out of the same material. The thermal stress problem is exacerbated if there are residual stresses, or if the exchanger is made of different materials, or during transient operation (including start-up and shutdown). If the temperature differences are small, the structure may be able to accommodate the thermal stresses safely; usually, however, it is necessary to make specific provision to allow the shell and the tubes to expand or contract independently. Failure to do so can result in buckling, bending, or even rupture of the shell or the tubes, or destruction of the tube-to-tubesheet joint.

A simple solution is to incorporate an expansion joint or a bellows into the shell (or in certain special applications, into the tube-side piping internal to the shell cover). However, this solution cannot cover the entire range of pressures and temperature differences encountered in practice. Further, it is usually possible to incorporate other desirable features, such as removable bundles, with thermal stress relief in the variety of rear head designs available. These are shown in the last column of Figure 4.5.18.

The L and M rear heads correspond to the A and B front heads previously described. As shown, they require a fixed tubesheet design; that is, the tubesheets are rigidly fastened to the shell, and thermal stress relief, if necessary, must be provided by a shell-side expansion joint or bellows. The tube bundle cannot be removed for inspection or mechanical cleaning on the shell side. However, the outer tube limit (OTL) — the diameter of the tube field circumscribing the outermost tubes in the bundle — can be as little as 0.4 in. (10 mm) less than the inside diameter of a pipe shell and 0.5 in. (12.7 mm) for a rolled shell. Therefore, the tube field can be very full, giving more tubes and minimizing bypass flow. Similar comments apply to the N rear head, except that more clearance must be left between the outermost tubes and the shell.

The type P head uses packing between the skirt on the rear tubesheet and the shell extension to seal the shell-side fluid against leakage. The compression on the packing has to be adjusted to prevent excessive leakage on the one hand and to allow limited movement of the tube-side head on the other, so the shell-side fluid must be benign and cheap (not surprisingly, it is often cooling water). On the other hand, leakage between the two fluids can occur only through tube hole leaks. Because of the tubesheet skirt, clearance between the outermost tubes and the shell must increase compared with types L or M; accordingly, fewer tubes are possible in a given shell, and sealing strips to partially block the bundle-to-shell bypass stream are recommended. When the floating head cover and packing gland are removed, the tube bundle can be pulled out of the shell for inspection and cleaning.

The TEMA S split-ring floating head design uses a split backing ring to hold the floating head cover and its gasket to the tubesheet. The split backing ring is bolted to the cover with a bolt circle outside the diameter of the tubesheet. Therefore, when the split ring is removed, the entire tube bundle may be pulled out of the shell. Tube count is similar to type P design and sealing strips are recommended. Usually, the split-ring floating head is used with an even number of tube passes so that a plain bonnet-type shell cover can be used. However, as shown by the dashed lines in Figure 4.5.18, single tube-side pass design (and counter-current flow) can be achieved by use of a packing gland on the exit piping through the bonnet; alternatively, a deep bonnet can be used together with an expansion joint or bellows on the tube-side exit piping.

The pull-through floating head, type T, uses a floating head cover that flanges directly to the tubesheet, reducing the possibility of internal leakage compared with type S, but also eliminating more tubes around the periphery. Sealing strips are a virtual necessity. Single tube-side pass design is similar to type S, but is rarely used.

TEMA type U uses a bundle of U tubes and hence requires no rear head at all. The U-tube bundle effectively eliminates the thermal stress problem between shell and tubes, because each tube is free to expand or contract independently. The U bundle is also the cheapest construction because the cost of a second tubesheet is avoided. However, there are a number of drawbacks: designs must have an even number of tube-side passes, mechanical cleaning of the smaller bend radius tubes in the U bend is impossible, individual tubes cannot be replaced except in the outer row, some tube count is lost because of minimum bend limits, and the U bend must be carefully supported against vibration or kept out of the cross-flow stream by placing the shell nozzle upstream of the bend. The tube side in the U bend is susceptible to erosion, especially with two-phase or particulate-containing fluids.

Type W uses two sets of packing, often with a lantern ring in between. This construction is generally limited to benign fluids and low to very moderate pressures and temperatures.

Other Features. Numerous other components are necessary or optional to construction of shell-and-tube exchangers. Probably the most complete discussion is given by Yokell (1990).

Principles of Design

Design Logic. The design of a shell-and-tube exchanger involves the following steps:

1. Selection of a set of design features which are required for mechanical integrity and ease of maintenance, and which will likely lead to satisfying the thermal requirements within the allowable pressure drops, and at lowest cost.
2. Selection of a set of dimensions for the actual exchanger.
3. For the dimensions selected in (2), calculation of the thermal performance of the heat exchanger and both tube-side and shell-side pressure drops, using available rating procedures.
4. Comparison of the thermal performance calculated in (3) with that required and examination of the pressure drops calculated in (3) to ensure that the allowed pressure drops are reasonably used but not exceeded.
5. Adjustment of the dimensions selected in (2) and repetition of steps (3) and (4) until the criteria are satisfied.
6. Completion of the mechanical design to satisfy code requirements.
7. Cost estimation.

Basic Design Equations. The basic design equation for a shell-and-tube exchanger in steady-state service is

$$A^* = \int_0^{q_T} \frac{dq}{U^*\left(T_h - T_c\right)} \tag{4.5.73}$$

where A^* is the heat transfer area required in the heat exchanger, m^2 (ft^2); q_T is the heat transfer rate of the heat exchanger, W (Btu/hr); U^* is the local overall heat transfer coefficient referenced to area A^*, W/m^2 K (Btu/hr ft^2 °F); and T_h and T_c are the local hot and cold stream temperatures, K (°F). The * superscript on A^* and U^* only means that a consistent reference area must be used in defining these terms. For example, for an exchanger with plain tubes, it is customary to use the total outside heat transfer area of all of the tubes in the exchanger, A_o, as the reference area, and then U_o is the overall heat transfer coefficient referenced to A_o. If the exchanger has low-finned tubes, A^* may refer either to the total outside area including fins or to the inside tube heat transfer area; the choice is optional, but must be spelled out. Since T_h and T_c generally vary with the amount of heat transferred (following the first law of thermodynamics, and excepting isobaric phase transition of a pure component) and U^* may vary with local heat transfer conditions, in principle Equation 4.5.73 must be numerically integrated with T_h, T_c, and U^* calculated along the path of integration, and this process is performed by the most-advanced computer-based design methods.

For many applications, certain reasonable assumptions can be made allowing the analytical integration of Equation 4.5.73 to give (Schlünder, Vol. 1, 1983; Hewitt et al., 1994)

$$A^* = \frac{q_T U^*}{(\mathrm{MTD})} \tag{4.5.74}$$

where MTD is the mean temperature difference for the particular flow conditions and configuration. The key assumptions are that there is no significant bypassing of fluid around the heat transfer surface, that the overall heat transfer coefficient is constant, and that the specific heats of the two streams are constant over their temperature ranges in the exchanger; isothermal phase transitions, such as vaporizing or condensing a pure component at constant pressure, are also allowed.

If the two streams are in countercurrent flow, i.e., if they flow always in the opposite direction to one another,

$$\mathrm{MTD} = (\mathrm{LMTD})_{\text{countercurrent}} = \frac{\left(T_{h,i} - T_{c,o}\right) - \left(T_{h,o} - T_{c,i}\right)}{\ln\left(\dfrac{T_{h,i} - T_{c,o}}{T_{h,o} - T_{c,i}}\right)} \tag{4.5.75}$$

where $(\mathrm{LMTD})_{\text{countercurrent}}$ is the "logarithmic mean temperature difference for countercurrent flow" and the subscripts i and o indicate "inlet" and "outlet," respectively. E shells with a single tube-side pass and F shells with two tube-side passes are almost always designed for countercurrent flow. (While the flow between adjacent baffles is basically cross flow, it can be shown that the total shell-side flow pattern is equivalent to countercurrent flow if there are more than three or four baffles).

Very occasionally, usually when close control of tube wall temperatures is required, cocurrent flow is specified, with the two streams flowing in the same direction through the exchanger. For this case,

$$\mathrm{MTD} = (\mathrm{LMTD})_{\text{cocurrent}} = \frac{\left(T_{h,i} - T_{c,i}\right) - \left(T_{h,o} - T_{c,o}\right)}{\ln\left(\dfrac{T_{h,i} - T_{c,i}}{T_{h,o} - T_{c,o}}\right)} \tag{4.5.76}$$

where the symbols have the same meaning as before. $(\text{LMTD})_{\text{countercurrent}}$ is always equal to or greater than $(\text{LMTD})_{\text{cocurrent}}$, so wherever possible, countercurrent design and operation is preferred.

However, most shell-and-tube exchangers have nozzle and tube pass configurations which lead to mixed countercurrent and cocurrent flow regions (as well as cross flow in the X shell). For these cases,

$$\text{MTD} = F(\text{LMTD})_{\text{countercurrent}} \tag{4.5.77}$$

where $(\text{LMTD})_{\text{countercurrent}}$ is calculated from Equation (4.5.75) and F is the "configuration correction factor" for the flow configuration involved. F has been found as a function of dimensionless temperature ratios for most flow configurations of interest and is given in analytical and/or graphical form in the earlier part of this section by Shah and in many heat transfer references (e.g., Schlünder, Vol. 1, 1983). F is equal to unity for pure countercurrent flow and is less than unity for all other cases; practical considerations limit the range of interest to values above 0.7 at the lowest and more comfortably to values above 0.8. Values of zero or below indicate conditions that violate the second law of thermodynamics.

The Overall Heat Transfer Coefficient. The overall heat transfer coefficient U^*, referenced to the heat transfer area A^*, is related to the individual (film) heat transfer coefficients and the fouling resistances by

$$U^* = \frac{1}{\dfrac{A^*}{h_i A_i} + R_{fi}\dfrac{A^*}{A_i} + \dfrac{A^* \ln\left(d_o/d_i\right)}{2\pi N_t L k_w} + R_{fo}\dfrac{A^*}{A_o} + \dfrac{A^*}{h_o A_o}} \tag{4.5.78}$$

where h_i and h_o are, respectively, the tube-side and shell-side film heat transfer coefficients, W/m^{2}K (Btu/hr ft^2 °F), each referenced to its corresponding heat transfer area; R_{fi} and R_{fo} the corresponding fouling resistances (see below), m^{2}K/W (hr ft^2 °F/Btu); N_t the total number of tubes in the heat exchanger; L the effective tube length between the inside surfaces of the tubesheets, m (ft); d_o and d_i the outside and inside tube diameters, m (ft); and k_w the thermal conductivity of the tube wall material, W/m K (Btu/hr ft°F). For the special but important case of plain tubes

$$A^* = A_o = N_t\left(\pi d_o L\right) \tag{4.5.79}$$

and Equation (4.5.78) reduces to

$$U_o = \frac{1}{\dfrac{d_o}{h_i d_i} + R_{fi}\dfrac{d_o}{d_i} + \dfrac{d_o \ln\left(d_o/d_i\right)}{2k_w} + R_{fo} + \dfrac{1}{h_o}} \tag{4.5.80}$$

If finned tubes are used, the root diameter d_r of the fins replaces d_o in Equation (4.5.78) and A_o includes the surface area of the fins as well as the bare tube surface between the fins; it is also necessary to include a fin efficiency (typically about 0.8 to 0.95) multiplier in the numerators of the last two terms on the right side of Equation (4.5.78) to account for resistance to conduction in the fins. The treatment of fin efficiency is fully developed in Kern and Kraus (1972). Efficiencies of some of the important geometries are given in the earlier half of this section.

Film Heat Transfer Coefficients. Calculation of single-phase tube-side heat transfer coefficients for plain tubes is discussed in Section 4.1; special correlations are required for internally enhanced tubes, see discussion of enhancement in Section 4.8. Intube condensation and vaporization are covered in the subsection on boiling and condensation in Section 4.4.

Shell-side heat transfer calculations are more complex owing to the large number and range of design variables and process conditions that can occur. The most accurate methods are proprietary and computer based. The best known of these methods are those of Heat Transfer Research, Inc. (HTRI), College Station, TX; Heat Transfer and Fluid Flow Services (HTFS), Harwell, U.K.; and B-JAC, Midlothian, VA. For single-phase flow, the Delaware method appears to be the best in the open literature, and it is feasible for both had and computer use; various presentations of the method appear in many references, including Schlünder, Vol. 3 (1983) and Hewitt et al. (1994). These references also give methods for shell-side vaporizing and condensing design. An approximate design procedure is given in the next subsection.

Fouling. Fouling is the formation of any undesired deposit on the heat transfer surface, and it presents an additional resistance to the flow of heat. Several different types of fouling are recognized:

Sedimentation: deposition of suspended material on the surface.
Crystallization: precipitation of solute from supersaturated solutions.
Corrosion: formation of corrosion products on the surface.
Thermal degradation/polymerization: formation of insoluble products by oxidation, charring, and/or polymerization of a process stream.
Biofouling: growth of large organisms (e.g., barnacles) that interfere with flow to or past a heat transfer surface ("macrobiofouling") or small organisms (e.g., algae) that form a fouling layer on the surface ("microbiofouling").

The effect of fouling on design is twofold: Extra surface must be added to the heat exchanger to overcome the additional thermal resistance, and provision must be made to allow cleaning either by chemical or mechanical means. The fouling resistances included in Equation (4.5.78) result in requiring extra surface by reducing U^* (though they do not properly account for the time-dependent nature of fouling) and should be chosen with care. Ranges of typical values for major classes of service are included in Table 4.5.9.

Other things being equal, a fouling stream that requires mechanical cleaning should be put in the tubes because it is easier to clean the tube side. If this is not possible or desirable, then a removable bundle with a rotated square tube layout should be chosen to facilitate cleaning.

Pressure Drop. Tube-side pressure drop in plain tubes is discussed in Section 3.4. These calculations are straightforward and quite accurate as long as the tubes are smooth and clean; however, even a small amount of roughening due to corrosion or fouling (sometimes with a significant reduction of flow area) can double or triple tube-side pressure drop. Special correlations are required for internally enhanced tubes.

Calculation of shell-side pressure drop is implicit in the design methods mentioned above for heat transfer. Roughness has less effect on shell-side pressure drop than on tube side, but fouling still may have a very substantial effect if the deposits fill up the clearances between the baffles and the shell and between the tubes and the baffles, or if the deposits are thick enough to narrow the clearances between adjacent tubes. Existing design methods can predict these effects if the thickness of the fouling layer can be estimated.

Limitations of Design. It should be recognized that even under the best of conditions — new, clean exchangers with conventional construction features — heat exchanger design is not highly accurate. The best methods, when compared with carefully taken test data, show deviations of ±20% on overall heat transfer and ±40% on shell-side pressure drop (Palen and Taborek, 1969). These ranges are considerably worsened in fouling services. In these cases, the thermal *system* should be designed for operational flexibility, including carefully chosen redundancy of key components, and easy maintenance.

Approximate Design Method

Because of the complexity of rigorous design methods, it is useful to have an estimation procedure that can quickly give approximate dimensions of a heat exchanger for a specified service. Such a method is given here for purposes of preliminary cost estimation, plant layout, or checking the results of computer

TABLE 4.5.9 Typical Film Heat Transfer Coefficients for Shell-and-Tube Heat Exchangers

Fluid Conditions		h, W/m^{2}K[a,b]	Fouling resistance, m^2 K/W[a]
Sensible heat transfer			
Water[c]	Liquid	5000–7500	1–2.5 × 10^{-4}
Ammonia	Liquid	6000–8000	0–1 × 10^{-4}
Light organics[d]	Liquid	1500–2000	0–2 × 10^{-4}
Medium organics[e]	Liquid	750–1500	1–4 × 10^{-4}
Heavy organics[f]	Liquid		
	Heating	250–750	2–10 × 10^{-4}
	Cooling	150–400	2–10 × 10^{-4}
Very heavy organics[g]	Liquid		
	Heating	100–300	4–30 × 10^{-3}
	Cooling	60–150	4–30 × 10^{-3}
Gas[h]	Pressure 100–200 kN/m^2 abs	80–125	0–1 × 10^{-4}
Gas[h]	Pressure 1 MN/m^2 abs	250–400	0–1 × 10^{-4}
Gas[h]	Pressure 10 MN/m^2 abs	500–800	0–1 × 10^{-4}
Condensing heat transfer			
Steam, ammonia	Pressure 10 kN/m^2 abs, no noncondensables[i,j]	8000–12000	0–1 × 10^{-4}
Steam, ammonia	Pressure 10 kN/m^2 abs, 1% noncondensables[k]	4000–6000	0–1 × 10^{-4}
Steam, ammonia	Pressure 10 kN/m^2 abs, 4% noncondensables[k]	2000–3000	0–1 × 10^{-4}
Steam, ammonia	Pressure 100 kN/m^2 abs, no noncondensables[i,j,k,l]	10000–15000	0–1 × 10^{-4}
Steam, ammonia	Pressure 1 MN/m^2 abs, no noncondensables[i,j,k,l]	15000–25,000	0–1 × 10^{-4}
Light organics[d]	Pure component, pressure 10 kN/m^2 abs, no noncondensables[i]	1500–2000	0–1 × 10^{-4}
Light organics[d]	Pressure 10 kN/m^2 abs, 4% noncondensables[k]	750–1000	0–1 × 10^{-4}
Light organics[d]	Pure component, pressure 100 kN/m^2 abs, no noncondensables	2000–4000	0–1 × 10^{-4}
Light organics[d]	Pure component, pressure 1 MN/m^2 abs	3000–4000	0–1 × 10^{-4}
Medium organics[e]	Pure component or narrow condensing range, pressure 100 kN/m^2 abs[m,n]	1500–4000	1–3 × 10^{-4}
Heavy organics	Narrow condensing range pressure 100 kN/m^2 abs[m,n]	600–2000	2–5 × 10^{-4}
Light multicomponent mixtures, all condensable[d]	Medium condensing range, pressure 100 kN/m^2 abs[k,m,o]	1000–2500	0–2 × 10^{-4}
Medium multicomponent mixtures, all condensable[e]	Medium condensing range, pressure 100 kN/m^2 abs[k,m,o]	600–1500	1–4 × 10^{-4}
Heavy multicomponent mixtures, all condensable[f]	Medium condensing range, pressure 100 kN/m^2 abs[k,m,o]	300–600	2–8 × 10^{-4}
Vaporizing heat transfer[p,q]			
Water[r]	Pressure < 0.5 MN/m^2 abs, $\Delta T_{SH,max}$ = 25 K	3000–10000	1–2 × 10^{-4}
Water[r]	Pressure < 0.5 MN/m^2 abs, pressure < 10 MN/m^2 abs, $\Delta T_{SH,max}$ = 20 K	4000–15000	1–2 × 10^{-4}

TABLE 4.5.9 (continued) Typical Film Heat Transfer Coefficients for Shell-and-Tube Heat Exchangers

Fluid Conditions		h, W/m^{2}K[a,b]	Fouling resistance, m^2 K/W[a]
Ammonia	Pressure < 3 MN/m^2 abs, $\Delta T_{SH,max} = 20$ K	3000–5000	0–2 × 10^{-4}
Light organics[d]	Pure component, pressure < 2 MN/m^2 abs, $\Delta T_{SH,max} = 20$ K	1000–4000	1–2 × 10^{-4}
Light organics[d]	Narrow boiling range,[s] pressure < 2 MN/m^2 abs, $\Delta T_{SH,max} = 15$ K	750–3000	0–2 × 10^{-4}
Medium organics[e]	Pure component, pressure < 2 MN/m^2 abs, $\Delta T_{SH,max} = 20$ K	1000–3500	1–3 × 10^{-4}
Medium organics[e]	Narrow boiling range,[s] pressure < 2 MN/m^2 abs, $\Delta T_{SH,max} = 15$ K	600–2500	1–3 × 10^{-4}
Heavy organics[f]	Pure component, pressure < 2 MN/m^2 abs, $\Delta T_{SH,max} = 20$ K	750–2500	2–5 × 10^{-4}
Heavy organics[g]	Narrow boiling range,[s] pressure < 2 MN/m^2 abs, $\Delta T_{SH,max} = 15$ K	400–1500	2–8 × 10^{-4}
Very heavy organics[h]	Narrow boiling range,[s] pressure < 2 MN/m^2 abs, $\Delta T_{SH,max} = 15$ K	300–1000	2–10 × 10^{-4}

Source: Schlünder, E.U., Ed., *Heat Exchanger Design Handbook*, Begell House, New York, 1983. With permision.

[a] Heat transfer coefficients and fouling resistances are based on area in contact with fluid. Ranges shown are typical, not all encompassing. Temperatures are assumed to be in normal processing range; allowances should be made for very high or low temperatures.

[b] Allowable pressure drops on each side are assumed to be about 50–100 kN/m^2 except for (1) low-pressure gas and two-phase flows, where the pressure drop is assumed to be about 5% of the absolute pressure; and (2) very viscous organics, where the allowable pressure drop is assumed to be about 150–250 kN/m^2.

[c] Aqueous solutions give approximately the same coefficients as water.

[d] Light organics include fluids with liquid viscosities less than about 0.5×10^{-3} Nsec/m^2, such as hydrocarbons through C_8, gasoline, light alcohols and ketones, etc.

[e] Medium organics include fluids with liquid viscosities between about 0.5×10^{-3} and 2.5×10^{-3} Nsec/m^2, such as kerosene, straw oil, hot gas oil, and light crudes.

[f] Heavy organics include fluids with liquid viscosities greater than 2.5×10^{-3} Nsec/m^2, but not more than 50×10^{-3} Nsec/m^2, such as cold gas oil, lube oils, fuel oils, and heavy and reduced crudes.

[g] Very heavy organics include tars, asphalts, polymer melts, greases, etc., having liquid viscosities greater than about 50×10^{-3} Nsec/m^2. Estimation of coefficients for these materials is very uncertain and depends strongly on the temperature difference, because natural convection is often a significant contribution to heat transfer in heating, whereas congelation on the surface and particularly between fins can occur in cooling. Since many of these materials are thermally unstable, high surface temperatures can lead to extremely severe fouling.

[h] Values given for gases apply to such substances as air, nitrogen, carbon dioxide, light hydrocarbon mixtures (no condensation), etc. Because of the very high thermal conductivities and specific heats of hydrogen and helium, gas mixtures containing appreciable fractions of these components will generally have substantially higher heat transfer coefficients.

[i] Superheat of a pure vapor is removed at the same coefficient as for condensation of the saturated vapor if the exit coolant temperature is less than the saturation temperature (at the pressure existing in the vapor phase) and if the (constant) saturation temperature is used in calculating the MTD. But see note k for vapor mixtures with or without noncondensable gas.

[j] Steam is not usually condensed on conventional low-finned tubes; its high surface tension causes bridging and retention of the condensate and a severe reduction of the coefficient below that of the plain tube.

[k] The coefficients cited for condensation in the presence of noncondensable gases or for multicomponent mixtures are only for very rough estimation purposes because of the presence of mass transfer resistances in the vapor (and to some extent, in the liquid) phase. Also, for these cases, the vapor-phase temperature is not constant, and the coefficient given is to be used with the MTD estimated using vapor-phase inlet and exit temperatures, together with the coolant temperatures.

[l] As a rough approximation, the same relative reduction in low-pressure condensing coefficients due to noncondensable gases can also be applied to higher pressures.

[m] Absolute pressure and noncondensables have about the same effect on condensing coefficients for medium and heavy organics as for light organics. For large fractions of noncondensable gas, interpolate between pure component condensation and gas cooling coefficients.

[n] Narrow condensing range implies that the temperature difference between dew point and bubble point is less than the smallest temperature difference between vapor and coolant at any place in the condenser.

[o] Medium condensing range implies that the temperature difference between dew point and bubble point is greater than the smallest temperature difference between vapor and coolant, but less than the temperature difference between inlet vapor and outlet coolant.

[p] Boiling and vaporizing heat transfer coefficients depend very strongly on the nature of the surface and the structure of the two-phase flow past the surface in addition to all of the other variables that are significant for convective heat transfer in other modes. The flow velocity and structure are very much governed by the geometry of the equipment and its connecting piping. Also, there is a maximum heat flux from the surface that can be achieved with reasonable temperature differences between surface and saturation temperatures of the boiling fluid; any attempt to exceed this maximum heat flux by increasing the surface temperature leads to partial or total coverage of the surface by a film of vapor and a sharp decrease in the heat flux.

Therefore, the vaporizing heat transfer coefficients given in this table are only for very rough estimating purposes and assume the use of plain or low-finned tubes without special nucleation enhancement.

$\Delta T_{\text{SH,max}}$ is the maximum allowable temperature difference between surface and saturation temperature of the boiling liquid. No attempt is made in this table to distinguish among the various types of vapor-generation equipment, since the major heat transfer distinction to be made is the propensity of the process stream to foul. Severely fouling streams will usually call for a vertical thermosiphon or a forced-convection (tube-side) reboiler for ease of cleaning.

[q] Subcooling heat load is transferred at the same coefficient as latent heat load in kettle reboilers, using the saturation temperature in the MTD. For horizontal and vertical thermosiphons and forced-circulation reboilers, a separate calculation is required for the sensible heat transfer area, using appropriate sensible heat transfer coefficients and the liquid temperature profile for the MTD.

[r] Aqueous solutions vaporize with nearly the same coefficient as pure water if attention is given to boiling-point elevation, if the solution does not become saturated, and if care is taken to avoid dry wall conditions.

[s] For boiling of mixtures, the saturation temperature (bubble point) of the final liquid phase (after the desired vaporization has taken place) is to be used to calculate the MTD. A narrow-boiling-range mixture is defined as one for which the difference between the bubble point of the incoming liquid and the bubble point of the exit liquid is less than the temperature difference between the exit hot stream and the bubble point of the exit boiling liquid. Wide-boiling-range mixtures require a case-by-case analysis and cannot be reliably estimated by these simple procedures.

output. This method is based upon Equation (4.5.74) with $A^* = A_o$ and $U^* = U_o$ and depends upon rapidly estimating values for q_T, MTD, and U_o. The procedure is as follows:

Estimation of q_T. For sensible heat transfer,

$$q_T = \dot{m}_h c_{p,h}\left(T_{h,i} - T_{h,o}\right) = \dot{m}_c c_{p,c}\left(T_{c,o} - T_{c,i}\right) \tag{4.5.83}$$

where $\dot{m}$ is the mass flow rate, c_p the specific heat, and T the stream temperature, with subscripts h and c denoting the hot and cold streams, respectively, and i and o inlet and outlet, respectively.

For isothermal phase change,

$$q_T = \dot{m} h_{fg} \tag{4.5.84}$$

where $\dot{m}$ is the mass rate of condensation or vaporization and h_{fg} is the latent heat of phase transformation.

For more complex cases, such as partial or multicomponent condensation, more elaborate analyses are required, although this method can still be used with care to give rough estimates.

Estimation of MTD. The first step is to calculate or estimate $\text{LMTD}_{\text{countercurrent}}$ from Equation (4.5.75) and then estimate F as follows:

1. If the two streams are in countercurrent flow, $F = 1$.
2. If the two streams are in a combination of countercurrent and cocurrent flows (i.e., multiple tube passes) and the outlet temperatures of the two streams are equal, $F = 0.8$.

3. If the exchanger has multiple passes and $T_{h,o} > T_{c,o}$, then $0.8 < F < 1.0$, with the actual value depending upon the temperature ranges of the two streams and $(T_{h,o} - T_{c,o})$. It is usually sufficiently accurate to take $F = 0.9$ in this case, but a more accurate value can be obtained from the earlier half of this section by Shah.
4. Design of a multiple tube pass exchanger with $T_{h,o} < T_{c,o}$ (i.e., a temperature cross) leads to $F < 0.8$, which is inefficient, of uncertain inaccuracy, and perhaps even thermodynamically impossible. The problem can be handled with multiple shells in series. Consult Shah's discussion.
5. Then, $\text{MTD} = F(\text{LMTD})_{\text{countercurrent}}$, (Equation 4.5.77).

Estimation of U_o. The best way to estimate U_o is to use Equation (4.5.80), together with values of h_o, h_i, $R_{f,o}$, and $R_{f,i}$, chosen from Table 4.5.9. This table includes ranges of values that are typical of the fluids and services indicated assuming normally allowable pressure drops, exchanger construction, and fouling. However, care should be taken in selecting values to consider possible unusual conditions, e.g., especially high or low velocities (implying correspondingly high or low allowable pressure drops), and especially fouling. In selecting values from the table, the user should carefully read the footnotes for each entry.

Calculation of A_o. The total outside tube heat transfer area required in the heat exchanger is now found from Equation (4.5.74).

Estimation of Exchanger Dimensions. Figure 4.5.19 shows the relationship among A_o, effective tube length L, and inside shell diameter for a fully tubed, fixed tubesheet heat exchanger with one tube-side pass, with $^3/_4$ in. (19.05 mm) plain tubes on a $^{15}/_{16}$ in. (23.8 mm) pitch equilateral triangular tube layout. These curves are constructed using tube count tables (e.g., Saunders, 1988). The dashed lines marked 3:1, 6:1,

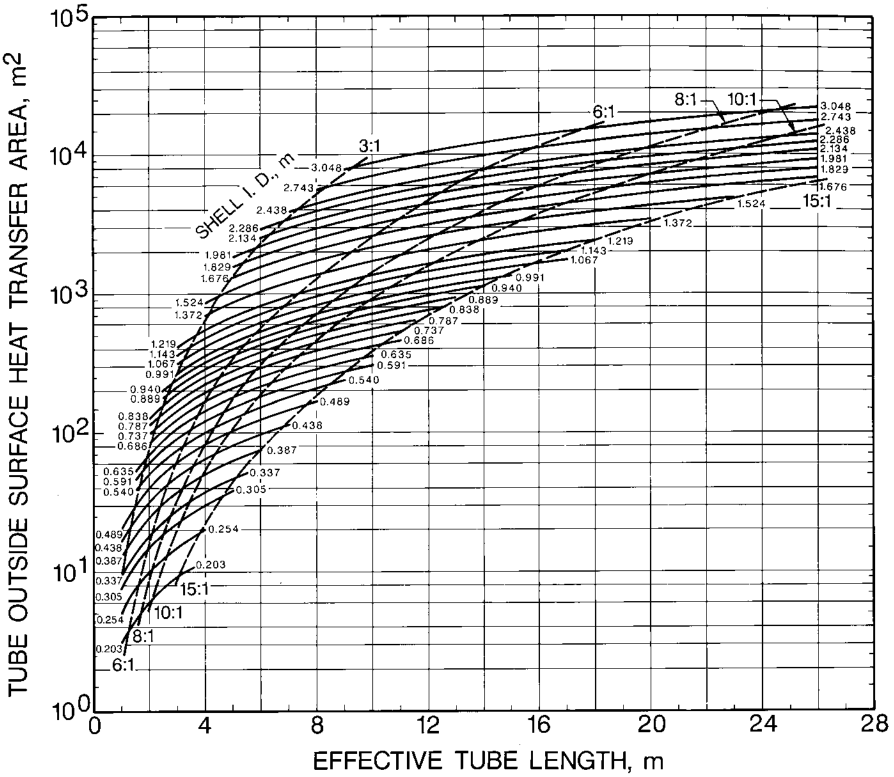

FIGURE 4.5.19 Heat transfer area as a function of shell inside diameter and effective tube length for 19.05 mm ($^3/_4$ in.) tubes on a 23.8 mm ($^{15}/_{16}$ in.) equilateral triangular tube layout, fixed tubesheet, one tube-side pass, fully tubed shell. (From Schlünder, E. U., Ed. *Heat Exchanger Design Handbook*, Begell House, New York, 1983. With permission.)

8:1, 10:1, and 15:1 indicate ratios of tube length to shell inside diameter for guidance in selection. Exchangers of less than 3:1 ratio are expensive because of the large-diameter shell and tubesheet, with more holes to be drilled and tubes rolled and/or welded, and shell-side flow distribution is likely to be poor and lead to excessive fouling. Exchangers greater than 15:1 ratio are probably beyond the point of saving money by reducing shell diameter and number of tubes and may require excessive clear way for pulling the bundle; the bundles may be springy and difficult to handle during maintenance. Most heat exchangers fall into the 6:1 to 10:1 range.

Figure 4.5.19 is a very specific case which is used as a reference. In order to extend its usefulness to other tube diameters, layouts, bundle constructions, etc., Equation (4.5.83) is used:

$$A'_o = A_o F_1 F_2 F_3 \tag{4.5.83}$$

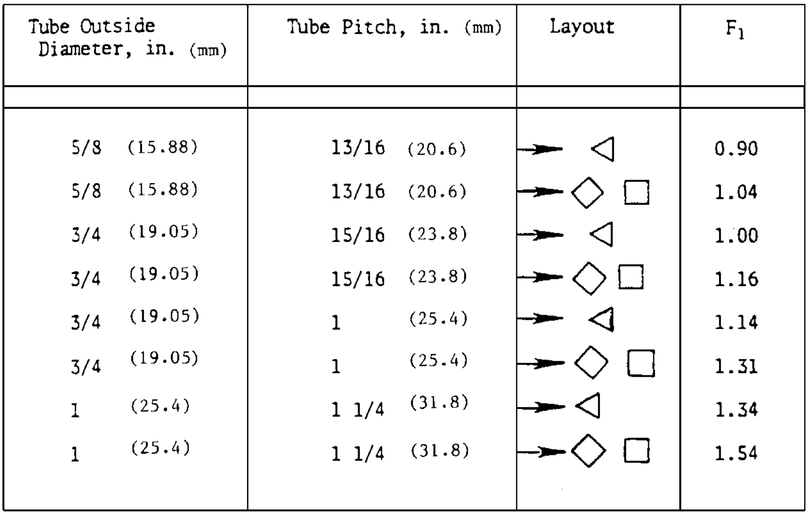
where A'_o is the value to be used with Figure 4.5.19, A_o is the required area calculated from Equation (4.5.74), and

F_1 is the correction factor for the tube layout. F_1 = 1.00 for $^3/_4$ in. (19.05 mm) outside diameter tubes on a $^{15}/_{16}$ in. (23.8 mm) triangular pitch. Values of F_1 for other tube diameters and pitches are given in Table 4.5.10.

F_2 is the correction factor for the number of tube-side passes. F_2 = 1.00 for one tube-side pass, and Table 4.5.11 gives values of F_2 for more passes.

F_3 is the correction factor for shell construction/tube bundle configuration. F_3 = 1.00 for fixed tubesheet, fully tubed shells, and Table 4.5.12 gives values of F_3 for the standard TEMA types.

TABLE 4.5.10 Values of F$_1$ for Various Tube Diameters and Layouts



Tube Outside Diameter, in. (mm)	Tube Pitch, in. (mm)	Layout	F$_1$
5/8 (15.88)	13/16 (20.6)	→ ◁	0.90
5/8 (15.88)	13/16 (20.6)	→ ◇ □	1.04
3/4 (19.05)	15/16 (23.8)	→ ◁	1.00
3/4 (19.05)	15/16 (23.8)	→ ◇ □	1.16
3/4 (19.05)	1 (25.4)	→ ◁	1.14
3/4 (19.05)	1 (25.4)	→ ◇ □	1.31
1 (25.4)	1 1/4 (31.8)	→ ◁	1.34
1 (25.4)	1 1/4 (31.8)	→ ◇ □	1.54

$$F_1 = \frac{(\text{Heat transfer area / cross-sectional area of unit cell})_{\text{Reference}}}{(\text{Heat transfer area / cross-sectional area of unit cell})_{\text{New Case}}}$$

This table may also be used for low-finned tubing in the following way. The value estimated for h_o from Table 4.5.9 should be multiplied by the fin efficiency (usually between 0.75 and 1 for a good application; 0.85 is a good estimate) and used in Equation 4.5.78 with $A^* = A_o$, the total outside heat transfer area including fins. Then this value of A_o is divided by the ratio of the finned tube heat transfer area to the plain tube area (per unit length). The result of this calculation is used as A_o in Equation 4.5.82 to find A'_o to enter Figure 4.5.19.

TABLE 4.5.11 Values of F_2 for Various Numbers of Tube Side Passes[a]

Inside Shell Diameter, in. (mm)	F_2 Number of Tube-Side Passes			
	2	4	6	8
Up to 12 (305)	1.20	1.40	1.80	—
$13^1/_4$ to $17^1/_4$ (337 to 438)	1.06	1.18	1.25	1.50
$19^1/_4$ to $23^1/_4$ (489 to 591)	1.04	1.14	1.19	1.35
25 to 33 (635 to 838)	1.03	1.12	1.16	1.20
35 to 45 (889 to 1143)	1.02	1.08	1.12	1.16
48 to 60 (1219 to 1524)	1.02	1.05	1.08	1.12
Above 60 (above 1524)	1.01	1.03	1.04	1.06

[a] Since U-tube bundles must always have at least two passes, use of this table is essential for U-tube bundle estimation. Most floating head bundles also require an even number of passes.

TABLE 4.5.12 F_3 for Various Tube Bundle Constructions

Type of Tube Bundle Construction	F_3 Inside Shell Diameter, in. (mm)				
	Up to 12 (305)	13–22 (330–559)	23–36 (584–914)	37–48 (940–1219)	Above 48 (1219)
Split backing ring (TEMA S)	1.30	1.15	1.09	1.06	1.04
Outside packed floating heat (TEMA P)	1.30	1.15	1.09	1.06	1.04
U-Tube* (TEMA U)	1.12	1.08	1.03	1.01	1.01
Pull-through floating head (TEMA T)	—	1.40	1.25	1.18	1.15

[a] Since U-tube bundles must always have at least two tube-side passes, it is essential to use Table 4.5.11 also for this configuration.

Source: Schlünder, E.U., Ed., *Heat Exchanger Design Handbook*, Begell House, New York, 1983. With permission.

Once a value of A_o' has been calculated from Equation (4.5.83), enter the ordinate of Figure 4.5.19 at that value and move horizontally, picking off the combinations of shell inside diameter and tube length that meet that requirement. The final choice can then be made from among those possibilities.

Example of the Approximate Design Method

Problem Statement. Estimate the dimensions of a shell-and-tube heat exchanger to cool 100,000 lb_m/hr (12.6 kg/sec) of liquid toluene from 250 to 110°F (121.1 to 43.3°C) using cooling tower water available at 80°F (26.7°C). Use split-ring floating head construction (TEMA S) with $^3/_4$ in. (19.05 mm) outside diameter × 14 BWG (0.083 in. = 2.11 mm wall) low-carbon steel tubes on $^{15}/_{16}$ in. (23.8 mm) equilateral triangular pitch. This construction implies one shell-side pass and an even number of tube-side passes — assume two for the present. Choose cooling water exit temperature of 100°F (37.8°C). Specific heat of toluene is 0.52 Btu/lb_m°F (2177 J/kgK) and viscosity at 180°F (82.2°C) is 0.82 lb/$_\text{m}$/ft hr (0.34×10^{-3} Nsec/m^2 or 0.34 cP).

Solution.

$$q_T = \left(100{,}000\ \text{lb}_\text{m}/\text{hr}\right)\left(0.52\ \text{Btu}/\text{lb}_\text{m}{}^\circ\text{F}\right)(250-110)^\circ\text{F}$$

$$= 7.28\times10^6\ \text{Btu/hr} = 2.14\times10^6\ \text{W}$$

$$\text{LMTD}_{\text{countercurrent}} = \frac{(250-100)-(110-80)}{\ln\dfrac{250-100}{110-80}} = 74.6^\circ\text{F} = 41.4^\circ\text{C}$$

Since there are at least two tube-side passes, flow is not countercurrent, and $T_{h_o} > T_{c_o}$, estimate $F \approx 0.9$. Therefore, MTD = 0.9 (74.6°F) = 67.1°F = 37.3°C.

Estimation of U_o. Light organic liquid cooled by liquid water. (Note that 1 Btu/hr ft² °F = 5.678 W/m²K).

Water (in tubes) h_i	1000 Btu/hr ft² °F	5700 W/m²K
Toluene (in shell) h_o	300 Btu/hr ft² °F	1700 W/m²K
Tube-side fouling R_{f_i}	0.001 hr ft² °F/Btu	1.8×10^{-4} m²K/W
Shell-side fouling R_{f_o}	0.0005 hr ft² °F/Btu	8.8×10^{-5} m²K/W

Tube wall resistance (for estimation purposes, this term can be approximated by x_w/k_w, where x_w is the wall thickness):

$$\frac{x_w}{k_w} = \frac{0.083 \text{ in.}}{(12 \text{ in./ft})(26 \text{ Btu/hr ft °F})} = 2.7 \times 10^{-4} \frac{\text{hr ft}^2 \text{ °F}}{\text{Btu}} = 4.6 \times 10^{-5} \frac{\text{m}^2\text{K}}{\text{W}}$$

Then,

$$U_o = \frac{1}{\dfrac{0.750}{1000(0.584)} + \dfrac{0.001(0.750)}{0.584} + 2.7 \times 10^{-4} + 0.0005 + \dfrac{1}{300}}$$

$$= 150 \text{ Btu/hr ft °F} = 848 \text{ W/m}^2\text{K}$$

$$A_o = \frac{7.28 \times 10^6 \text{ Btu/hr}}{(150 \text{ Btu/hr ft}^2 \text{ °F})(67.1\text{°F})} = 723 \text{ ft}^2 = 67.7 \text{ m}^2$$

Correct for changes in construction features (preliminary examination of Figure 4.5.19 indicates shell inside diameter will be in the range of 500 mm, or 20 in.):

F_1: F_1 = 1.00 since the same tube size and layout is used;
F_2: F_2 = 1.04, assuming two passes;
F_3: F_3 = 1.15, TEMA S construction;
A_o' = (723 ft²) (1.00)(1.04)(1.15) = 865 ft² = 81 m².

From Figure 4.5.19, entering at A_o', pick off the following combinations of shell inside diameter and tube length:

Shell Inside Diameter		Effective Tube Length		L/D_s
in.	mm	ft	m	
27	686	6.6	2.0	2.9
25	635	7.5	2.3	3.6
23 1/4	591	9.2	2.8	4.7
21 1/4	540	10.8	3.3	6.1
19 1/4	489	13.1	4.0	8.2
17 1/4	438	16.7	5.1	11.6

Any of these combinations would supply the desired area; the 21 1/4 in. (540 mm) and 19 1/4 in. (489 mm) would appear to be likely choices.

4.6 Temperature and Heat Transfer Measurements

Robert J. Moffat and Jungho Kim

There are two different kinds of material to consider with respect to experimental methods: the unit operations of measurement (transducers and their environmental errors) and the strategy of experimentation. This section deals only with the unit operations: transducers, their calibrations, and corrections for environmental errors.

Temperature Measurement

An International Practical Temperature Scale (IPTS) has been defined in terms of a set of fixed points (melting points of pure substances) along with a method for interpolating between the fixed points. The IPTS agrees with the thermodynamic temperature scale within a few degrees Kelvin over most of its range. The IPTS is the basis for all commerce and science, and all calibrations are made with respect to the IPTS temperature. The scale is revised periodically.

Accurate calibrations are not enough to ensure accurate data, however. If a sensor has been installed to measure a gas temperature or a surface temperature, any difference between the sensor temperature and the measurement objective due to heat transfer with the environment of the sensor is an “error.” In most temperature-measuring applications, the environmental errors are far larger than the calibration tolerance on the sensor and must be dealt with just as carefully as the calibration.

Thermocouples

Any pair of thermoelectrically dissimilar materials can be used as a thermocouple. The pair need only be joined together at one end and connected to a voltage-measuring instrument at the other to form a usable system. A thermocouple develops its signal in response to the temperature difference from one end of the pair to the other. The temperature at one end, known as the *reference junction* end, must be known accurately before the temperature at the other end can be deduced from the voltage.

Thermocouples are the most commonly used electrical output sensors for temperature measurement. With different materials for different ranges, thermocouples have been used from cryogenic temperatures (a few Kelvin) to over 3000 K. In the moderate temperature range, ambient to 1200°C, manufacturer’s quoted calibration accuracy can be as good as ±3/8% of reading (referred to 0°C) for precision-grade base metal thermocouples. Broader tolerances apply at very high temperature and very low temperatures. Thermocouple signals are DC voltages in the range from a few microvolts to a few tens of microvolts per degree C. Because of their low signal levels, thermocouple circuits must be protected from ground loops, galvanic effects, and from pickup due to electrostatic or electromagnetic interactions with their surroundings. Thermocouples are low-impedance devices. Multiple channels of thermocouples can be fed to a single voltage reader using low-noise-level scanners or preamplifiers and electronic multiplexers.

The alloys most frequently used for temperature measurement are listed in Table 4.6.1. These alloys have been developed, over the years, for the linearity, stability, and reproducibility of their EMF vs. temperature characteristics and for their high-temperature capability.

Calibration data for thermocouples are periodically reviewed by the National Institutes of Science and Technology based on the then-current IPTS. Values in Table 4.6.1 illustrate the approximate levels which can be expected, and are from the National Bureau of Standards Monograph 125. Maximum temperatures listed in this table are estimates consistent with a reasonable service lifetime. Allowable atmosphere refers to the composition in contact with the thermoelements themselves. Accuracy estimates are provided for two levels of precision: standard grade and precision grade where these data are available.

Noble metal and refractory metal thermocouples are often used with substitute lead wires, as a cost-saving measure. These lead wires, described in Table 4.6.2 are cheaper and easier to handle than the high temperature thermocouples. They have the same temperature–EMF characteristics as their primary thermoelements, but only over the range of temperatures the lead wires will usually encounter (up to a few hundred degrees C). Except for the substitute alloys, thermocouple extension wires have the same composition as thermocouple wires, differing only in the type of insulation and the accuracy of calibration, which is not held as closely for extension wire as for thermocouple-grade wire.

Any instrument capable of reading low DC voltages (on the order of millivolts) with 5 to 10 μV resolution will suffice for temperature measurements. *Galvanometric measuring instruments* can be used, but, since they draw current, the voltage available at the terminals of the instrument depends not only on the voltage output of the thermocouple loop but also on the resistance of the instrument and the loop together. Such instruments are normally marked to indicate the external resistance for which they have been calibrated. *Potentiometric instruments*, either manually balanced or automatically balanced, draw no current when in balance, hence can be used with thermocouple loops of any arbitrary resistance without error. High-input impedance *voltmeters* draw very low currents and, except for very high resistance circuits, are not affected by the loop resistance.

Thermocouple Theory. Equation (4.6.1) is the general form describing the EMF generated in a two-wire thermocouple (Moffat, 1962). The same form can be derived from either the free-electron theory of metals or from thermodynamic arguments alone: the output of a thermocouple can be described as the sum of a set of terms, one arising in each wire in the circuit.

The junctions do not generate the EMF: they are merely electrical connections between the wires. For a two-wire circuit,

$$\text{EMF} = \int_0^L \varepsilon_1 \frac{dT}{dx} dx + \int_L^0 \varepsilon_2 \frac{dT}{dx} dx \tag{4.6.1}$$

where

ε_1 and ε_2 = the total thermoelectric power of materials 1 and 2, respectively, mV/C. The value of ε is equal to the sum of the Thomson coefficient and the temperature derivative of the Peltier coefficient for the material.

T = temperature, C

x = distance along the wire, m

L = length of the wire, m

This form for expressing the output of a two-wire circuit applies regardless of whether the wires are uniform in composition or not. If a circuit contained four wires (two thermocouple wires and two extension wires), then Equation (4.6.1) would be written with four terms, one for each length of wire.

When the wire is uniform in composition and both wires begin at (T_o) and both end at (T_L) the two terms can be collected into one integral:

$$\text{EMF} = \int_{T_0}^{T_L} \left(\varepsilon_1 - \varepsilon_2\right) dT \tag{4.6.2}$$

The EMF–temperature (E–T) tables produced by NIST and others are "solutions" to Equation (4.6.2) and can be used only when the following three conditions are met:

1. The thermoelectric power, ε, is not a function of position; i.e., the wires are homogeneous;
2. There are only two wires in the circuit;
3. Each wire begins at T_o and ends at T_L

When the circuit consists entirely of pairs of materials, Equation 4.6.2 can be used directly as the basis for understanding the source of the EMF. As an example, consider the three-pair system shown in Figure 4.6.1. For that circuit, Equation (4.6.2) would have three terms: one for each pair. The total EMF generated by the circuit would be the sum of the EMFs generated in the thermocouple pair and in the extension wire pair. The pair of copper wires would not contribute to the net EMF, assuming the two copper wires were perfectly matched. The EMF contributed by each pair would be proportional to the temperature difference from end to end of that pair, as shown in Equation (4.6.3) and (4.6.4).

$$\text{EMF} = \int_{T_1}^{T_2} \left(\varepsilon_{\text{cu}} - \varepsilon_{\text{cu}}\right) dT + \int_{T_2}^{T_3} \left(\varepsilon_+ - \varepsilon_-\right)_{\text{LEADS}} dT + \int_{T_3}^{T_4} \left(\varepsilon_+ - \varepsilon_-\right)_{\text{TC}} dT \tag{4.6.3}$$

$$\text{EMF} = 0 + (T3 - T2)\left(\varepsilon_+ - \varepsilon_-\right)_{\text{LEADS}} + (T4 - T3)\left(\varepsilon_+ - \varepsilon_-\right)_{\text{TC}} \tag{4.6.4}$$

Most thermocouple circuits consist only of pairs of wires and can be understood in terms of these two equations, but some require a more detailed treatment. A graphical method of analysis is available, based on Equation (4.6.1).

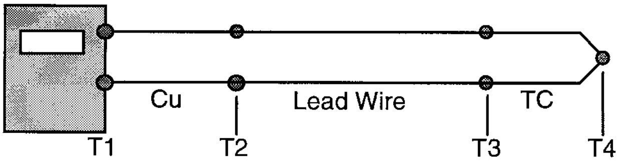

FIGURE 4.6.1 A three-pair circuit.

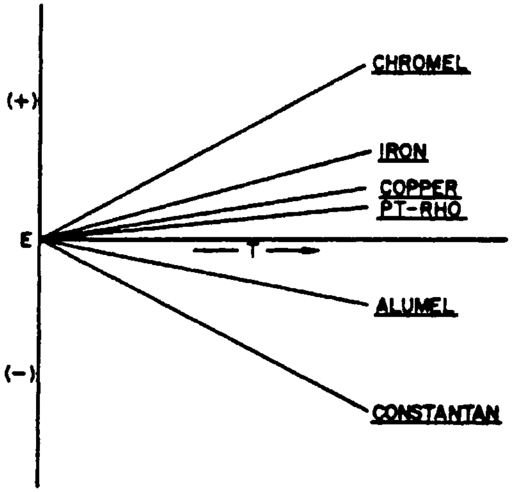

FIGURE 4.6.2 E–T calibrations for several common thermocouple materials.

The temperature–EMF calibrations of the more common materials are shown in Figure 4.6.2 derived from NBS Monograph 125 and other sources. This figure provides the input data for a simple graphical technique for describing the EMF generation in a circuit. Each curve in Figure 4.6.2 represents the output which would be derived from a thermocouple made of material X used with platinum when the cold end is held at 0°C and the hot end is held at *T*.

Those elements commonly used as "first names" for thermocouple pairs, i.e., Chromel (Chromel-Alumel), iron (-constantan), copper (-constantan), have positive slopes in Figure 4.6.2.

The simplest thermocouple circuit for temperature measurement consists of two wires joined together at one end (forming the "measuring junction") with their other ends connected directly to a measuring instrument, as shown in the upper portion of Figure 4.6.3. The EMF generation in this circuit is graphically represented in the lower portion, an E–T diagram, using the data in Figure 4.6.2. The E–T diagram is used for examining the EMF generated in the circuit, to be certain that it arises only from the desired thermocouple materials, and that all segments of the circuit are properly connected. The E–T diagram is not used for evaluating the output — that is done using the tables after the circuit has been shown to be correctly wired.

To construct an E–T diagram, first sketch the physical system considered and assign a number to each "point of interest" on that sketch and a temperature. On E–T coordinates, locate point 1 at 0/mV and at its assigned temperature. Then start a line from point 1, moving toward the temperature of point 2, and copying the shape of the calibration curve of the iron wire (see Figure 4.6.2). From 2 to 3, use the constantan calibration curve. The difference in elevation of points 1 and 3 describes the net EMF generated in the circuit between points 1 and 3, and describes the polarity. When point 3 lies physically above point 1 in the E–T diagram, it is, by convention, electrically negative with respect to point 1.

The simple triangular shape shown in Figure 4.6.3 identifies a proper circuit. Any thermocouple circuit whose E–T diagram is equivalent to that is appropriate for temperature measurement and its EMF may be interpreted using the conventional tables. Any circuit whose E–T diagram is not equivalent to the pattern circuit should be rewired.

Thermocouples generate their signal in response to the temperature difference between the two ends of the loop. For accurate measurements, the temperature of the "reference junction" must be known. Laboratory users often use an ice bath made from a good-quality Dewar flask or vacuum-insulated bottle of at least 1 pt capacity, as shown in Figure 4.6.4. The flask should be filled with finely crushed ice and then flooded with water to fill the interstices between the ice particles. The reference thermocouple is inserted into a thin-walled glass tube containing a small amount of silicone oil and submerged six or eight diameters into the ice pack. The oil assures good thermal contact between the thermocouple junction

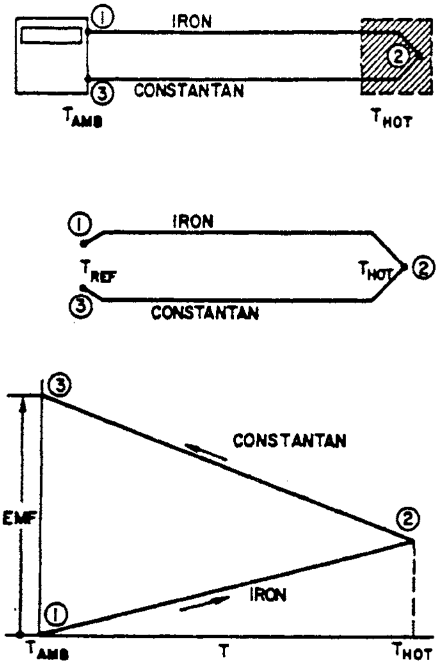

FIGURE 4.6.3 E–T diagram of a thermocouple using an ambient reference.

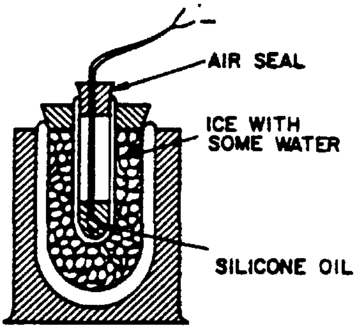

FIGURE 4.6.4 Characteristics of a good ice bath

and the ice/water mixture. The tube should be sealed at the top to prevent atmospheric moisture from condensing inside it, which would cause corrosion when using iron-constantan thermocouples. Figure 4.6.5 shows in iron-constantan thermocouple circuit with an ice bath. The individual thermocouple wires are connected to copper wires in the ice bath, and the two copper wires taken to the voltmeter. The lower portion of this figure shows the E–T diagram for this circuit, and proves that the output of this circuit is entirely due to the temperature difference from end to end of the iron-constantan loop: the two copper wires do not contribute to the output.

Calibration. Thermocouple calibrations are provided by the wire manufacturers to tolerances agreed upon industry-wide, as summarized in Table 4.6.1. These tolerances include two components: the uncertainty in the average slope of the calibration curve of the wire, and the effects of local inhomogeneities in the wire. It is difficult to improve the accuracy of a thermocouple by calibrating it. For a truly significant calibration, the thermocouple would have to be exposed to the same temperature during calibration, at every point along it, that it would encounter in service. In an oven calibration, most of the signal is generated in the material at the mouth of the oven, as could be recognized by considering the temperature gradient distribution along the wire. The material inside the oven contributes little or nothing to the signal.

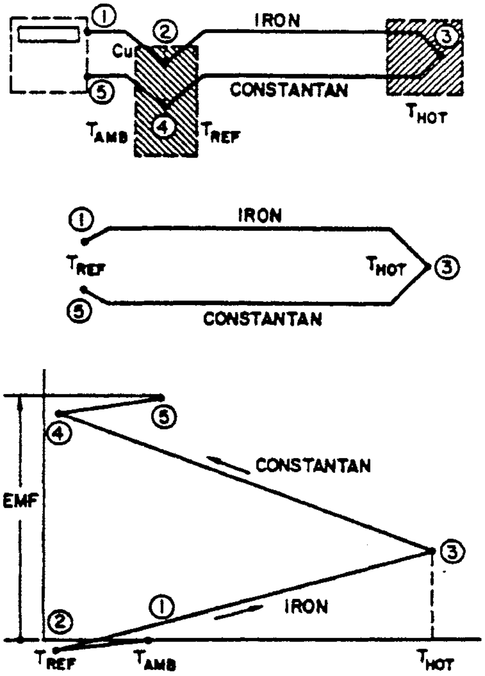

FIGURE 4.6.5 A thermocouple circuit using an ice bath reference, and its E–T diagram.

Thermistors

Thermistors are electrical resistance temperature transducers whose resistance varies inversely, and exponentially, with temperature. The resistance of a 5000 Ω thermistor may go down by 200 Ω for each degree C increase in temperature in the vicinity of the initial temperature. Interrogated by a 1.0 mA current source, this yields a signal of 200 mV/°C. As a consequence of this large signal, thermistors are frequently used in systems where high sensitivity is required. It is not uncommon to find thermistor data logged to the nearest 0.001°C. This does not mean that the data are accurate to 0.001°C, simply that the data are readable to that precision. A thermistor probe is sensitive to the same environmental errors which afflict any immersion sensor: its accuracy depends on its environment.

Thermistor probes can be used between –183°C (the oxygen point) and +327°C (the lead point) but most applications are between –80 and +150°C. The sensitivity of a thermistor (i.e., the percent change in resistance per degree C change in thermistor temperature) varies markedly with temperature, being highest at cryogenic temperatures.

Thermistor probes range in size from 0.25-mm spherical beads (glass covered) to 6-mm-diameter steel-jacketed cylinders. Lead wires are proportionately sized. Disks and pad-mounted sensors are available in a wide range of shapes, usually representing a custom design "gone commercial." Aside from the unmounted spherical probes and the cylindrical probes, there is nothing standard about the probe shapes.

Calibration. Thermistor probes vary in resistance from a few hundred ohms to megohms. Probe resistance is frequently quoted at 25°C, with no power dissipation in the thermistor. The commercial range is from about 2000 to 30,000 Ω. Representative values of the sensitivity coefficient (% change in resistance per degree C) is given in Table 4.6.3 and resistance values themselves, in Table 4.6.4.

Proprietary probes are available which "linearize" thermistors by placing them in combination with other resistors to form a circuit whose overall resistance varies linearly with temperature over some range. These compound probes can be summed, differenced, and averaged as can any linear sensor. Modern manufacturing practices allow matched sets to be made, interchangeable within +/–0.1°C.

TABLE 4.6.3 Thermistor Temperature Coefficient Variations with Temperature

Temp. °C	Condition	ΔR/R, %
–183	Liquid oxygen	–61.8
–80	Dry ice	–13.4
–40	Frozen mercury	–9.2
0	Ice point	–6.7
25	Room temperature	–5.2
100	Boiling water	–3.6
327	Melting lead	–1.4

TABLE 4.6.4 Thermistor Resistance Variation with Temperature

Temp., °C	Res., Ω	Temp., °C	Res., Ω
–80	1.66 M	0	7355
–40	75.79 K	25	2252
–30	39.86 K	100	152.8
–20	21.87 K	120	87.7
–10	12.46 K	150	41.9

TABLE 4.6.5 Representative Thermal Dissipation Constants for Two Thermistor Probe Designs

Environment	1.0-cm Disk	5.0-cm Cylinder
Still air	8 mW/C	1 mW/C
Still oil	55	—
Still water	—	3.5
Oil at 1 m/sec	250	—

Thermal Characteristics. Thermistor probes are generally interrogated using a low current, either AC or DC. A level of about 10 μA would be typical. With a probe resistance of 10 K Ω, 0.01 W must be dissipated into its surrounding material. This current results in the probe running slightly above the temperature of the medium into which it is installed: the "self-heating" effect. Since thermistors are often used where very small changes in temperature are important, even small amounts of self-heating may be important.

The self-heating response is discussed in terms of the "dissipation constant" of the probe, in milliwatts per degree C. The dissipation constant depends on the thermal resistance between the thermistor and its surroundings. For fluid-sensing probes, the self-heating varies with velocity and thermal conductivity, while for solid immersion probes, it varies with the method of attachment and type of substrate.

Dissipation constants for representative probes are given in Table 4.6.5. The self-heating effect must be considered in calibration as well as in use.

The transient response of a thermistor is more complex than that of a thermocouple and, size for size, they are not as well suited to transient measurements.

Thermistor probes are sold with calibration tables of resistance vs. temperature at some specified accuracy, on the order of +/–0.1 or 0.2 K, depending on the grade of probe purchased. These tables are typically in increments of 1 K. For computer interpretation, they should be fit to the Steinhart-Hart form[2] and the coefficients determined for least error.

$$\frac{1}{T} = A_0 + A_1 \ln(R) + A_3 \ln\left(R^3\right) \qquad (4.6.5)$$

Resistance Temperature Detectors

The terms *resistance temperature detector* (RTD) and *resistance thermometer* are used interchangeably to describe temperature sensors containing either a fine wire or a thin film metallic element whose resistance increases with temperature. In use, a small current (AC or DC) is passed through the element, and its resistance measured. The temperature of the element is then deduced from the measured resistance using a calibration equation or table lookup.

RTDs are used both for standards and calibration laboratories and for field service. Field-service probes are generally encased in stainless steel protective tubes with either wire or film elements bonded to sturdy support structures. They are made to take considerable physical abuse. Laboratory standard-grade probes are often enclosed in quartz tubes, with the resistance wire mounted in a strain-free manner on a delicate mandrel.

High-quality resistance thermometers have been used as defining instruments over part of the range of the IPTS. Because of this association with high-precision thermometry, resistance thermometers in general have acquired a reputation for high precision and stability. Commercial probes, however, are far different in design from the standards-grade probes, and their stability and precision depend on their design and manufacture.

RTDs are often recommended for single-point measurements in steady-state service at temperatures below 1000°C where longtime stability and traceable accuracy are required and where reasonably good heat transfer conditions exist between the probe and its environment.

They are not recommended for use in still air, or in low-conductivity environments. RTDs self-heat, which causes an error when the probes are used in a situation with poor heat transfer. They are not recommended for transient service or dynamic temperature measurements unless specifically designed for such service. The probes tend to have complex transient characteristics and are not amenable to simple time-constant compensation.

Physical Characteristics. The physical characteristics of any given resistance thermometer represent a compromise between two opposing sets of requirements. For accuracy, repeatability, and speed of response, a delicate, low-mass sensing element is desired, supported in a strain-free manner in good thermal contact with its surroundings. For durability, a rugged sensor is indicated, mounted firmly to a sturdy structure inside a robust, sealed protection tube.

Both the short-term calibration (resistance vs. specimen temperature) and the long-term stability (drift) are directly affected by the mechanical configuration of the probe. The electrical resistance of the sensing element is a function of its temperature and state of mechanical strain (Figure 4.6.6).

The sensing elements used in field-service RTD probes range from thin metallic films deposited on rectangular ceramic wafers (0.5 × 1.0 × 2.0 mm) with pigtail leads (0.25 mm diameter and 2.5 cm long) to glass-encapsulated, wire-wound mandrels (4 mm in diameter and 2.0 cm long), again with pigtail leads.

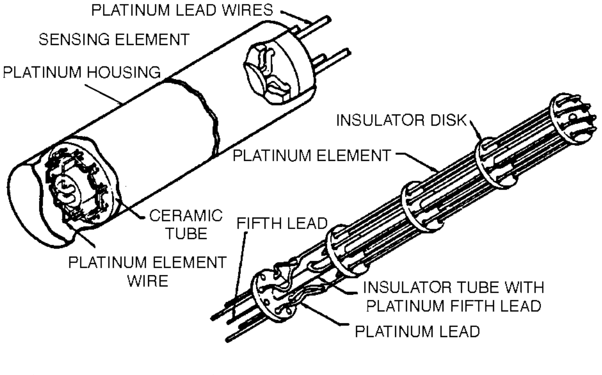

FIGURE 4.6.6 Slack-wire platinum resistance thermometer.

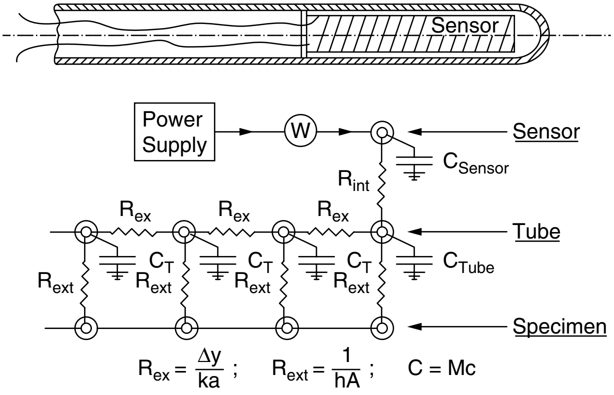

FIGURE 4.6.7 Thermal circuit representation of a typical resistance thermometer.

Bonding the sensor to its support provides good mechanical protection to the element, but subjects the element to strain due to thermal expansion. As long as this process is repeatable, the calibration is stable.

Electrical Characteristics. RTDs are available commercially with resistances from 20 to 20,000 Ω with 100 Ω being common. Bifilar windings are frequently used in wire-wound elements, to reduce the electrical noise pickup. This is more important in the quartz-jacketed probes than in those with stainless steel protection tubes. Twisted pair lead wires are recommended.

Thermal Characteristics. Figure 4.6.7 shows a simplified cross section of a typical resistance thermometer and a thermal circuit which can be used to discuss its behavior. In forming such a thermal circuit model, each element of the probe is described by its resistive and capacitive attributes following conventional heat transfer practice. The principal components are

- The external thermal resistance per unit length;
- The thermal capacitance of the protective tube per unit length, C_T;
- The radial internal thermal resistance between the sensor and the protective tube, R_{int};
- The capacitance of the sensor element and its support, C_{sensor};
- The axial internal thermal resistance of the stem, per unit length, R_T.

This circuit can be used to predict the temperature distribution within the probe both at steady state and during transients and can be refined, if needed, by subdividing the resistance and capacitance entities.

Steady-State Self-Heating. Interrogating an RTD by passing a current through it dissipates power in the element, shown in Figure 4.6.7 as W, which goes off as heat transfer through the internal and external resistances. This self-heating causes the sensing element to stabilize at a temperature higher than its surroundings and constitutes an "error" if the intent is to measure the surrounding temperature. The amount of the self-heating error depends on three factors:

- The amount of power dissipated in the element,
- The internal thermal resistance of the probe, as a consequence of its design, and
- The external thermal resistance between the surface of the probe and the surrounding material.

The self-heating temperature rise is given by Equation (4.6.6):

$$T_{\text{sens}} - T_{\text{surr}} = W\left(R_{\text{int}} + R_{\text{ext}}\right) \tag{4.6.6}$$

The internal thermal resistance of a probe, R_{int}, measured in degree C per watt, describes the temperature rise of the sensing element above the surface temperature of the probe, per unit of power dissipated. The internal thermal resistance can be deduced from measurements of the sensor temperature at several different current levels when the probe is maintained in a well-stirred ice bath, where the external thermal resistance is very low. The slope of the apparent temperature vs. power dissipated line, °C/W, is the internal thermal resistance. When an RTD is used in a gas or liquid, the external resistance between the probe and its surroundings must be estimated from standard heat transfer data. The external resistance is 1/(hA), °C/W.

A typical cylindrical probe exposed to still air will display self-heating errors on the order of 0.1 to 1.0°C per mW (commercial probes of 1.5 to 5 mm in diameter). At 1 m/sec air velocity, the self-heating error is reduced to between 0.03 and 0.3°C. In water at 1 m/sec velocity, the self-heating effect would be reduced by a factor of four or five compared to the values in moving air, depending on the relative importance of the internal and the external thermal resistances.

Calibration and Drift. The relationship between resistance and temperature must be determined for each probe or acquired from the manufacturer. Generally speaking, the reported values will require interpolation.

The resistance–temperature characteristic of a probe may drift (i.e., change with time) while the probe is in service. Manufacturers of laboratory-grade probes will specify the expected drift rate, usually in terms of the expected error in temperature over an interval of time. Two sample specifications are "0.01 C per 100 hours" for a low-resistance, high-temperature probe (0.22 Ω at 0°C, 1100°C maximum service temperature) and "0.01 C per year" for a moderate-resistance, moderate-temperature probe (25.5 Ω at 0°C, 250°C maximum service temperature). Drift of the resistance-temperature relationship takes place more rapidly at high temperatures.

Radiation Devices

Surface temperatures and gas temperatures can be deduced from radiation measurements. Surface-temperature measurements are based on the emitted infrared energy, while gas-temperature measurements use specific emission lines from the gas itself or from a tracer inserted into the gas.

Commercial surface-temperature measurement systems (single-point) are available, at low cost, which can measure temperature to +/–1% of reading, above 38°C, if the emissivity of the surface is known. The device referenced requires a spot size of 1.25 cm diameter, viewed from 75 cm. Spectroscopic gas-temperature measurements can be accurate to +/–3 or 4% of reading, but require a significant investment in effort as well as equipment (on the order of 1 to 2 years and $100,000 to $200,000). Several techniques based on Raman scattering have been used in combustion systems. Planar-lasar-induced fluorescence has shown considerable promise as one of the newer methods.

Infrared emission from a surface is described by two laws: the Stefan Boltzmann law describing the total emitted radiation as a function of temperature, and Planck's law describing its distribution as a function of temperature. These laws form the basis for all radiation-based surface-temperature detectors.

Early radiometers focused the total infrared energy on a thermopile bolometer and used the temperature rise across its calibrated heat loss path to measure the incident energy flux. Solid-state photon detectors have replaced thermopile bolometers as the detector of choice. Such a detector will respond to any photon having energy above a certain level (specific to the detector). Since the energy of a photon is inversely proportional to its wavelength, detectors respond to all wavelengths below some value. Modern detectors use band-pass filters to limit the wavelength band of photons admitted to the detector and rely on Planck's law to infer the temperature from the energy flux:

$$E_{b,\lambda} = \frac{C_1 \lambda^{-5}}{e^{C_2/\lambda T} - 1} \tag{4.6.7}$$

Commercial radiation temperature detectors use different wave bands for different temperature ranges, with different detectors for each band. The emissivity of the surface must be known, as a function of temperature, in the wavelength band used by the detector.

Many IR thermometers have an emissivity compensator that is used to correct for non-blackbody behavior. This compensator amplifies the detector output to compensate for emissivities less than 1, but can also be used to correct for transmission losses due to smoke, dust, or windows. If the emissivity of the material is less than 1, then the emissivity multiplied by the transmissivity must be entered into the instrument. Some ways of determining emissivity are as follows.

1. Heat a sample of the material to a known temperature, and dial in the emissivity required to get that temperature reading on the instrument.
2. Cover the material with a *thin* layer of another material that does not affect the surface temperature but is of known emissivity, and measure the temperature. Remove the thin layer or go to another section, and dial in the emissivity to get that temperature again.
3. Drill a hole in the surface (depth should be at least six times the diameter) and measure the temperature of the hole. The hole simulates a blackbody since much of the energy is absorbed after multiple reflections. Measure the temperature of another area on the surface, and dial in the emissivity to get the hole temperature.

Radiation detectors are vulnerable to interference from many sources. if it is desired to measure the temperature of materials that can transmit radiation, then a wavelength must be chosen so that the material appears opaque. One could use a wavelength that is semi-opaque, but care must be taken so that radiation that is transmitted *throught* the material does not bias the readings. Often, it is desired to measure the temperature behind a glass or quartz window. In this case, an appropriate wavelength must be chosen so that the radiation readily travels through the window (shorter wavelengths). For reflective surfaces, it is important that the surface not see sources of heat that can be reflected into the instrument. Reflective sources can usually be removed using shields.

Because the atmosphere contains components that absorb infrared radiation (CO_2, water vapor, methane) at certain wavelengths, care must be taken to operate outside of these wavelengths or to compensate for them. If one does operate at the absorption wavelengths, then the measurement will be distance dependent, or may be affected by changes in humidity. There are “windows” in the IR spectrum which allow these absorption bands to be avoided, however. A good choice for many low temperature applications is 8 to 14 microns. Higher temperatures require that one use narrowband filters at shorter wavelengths.

Filters are used to determine the portion of the spectrum that is used for the measurement. For low temperatures (less than 500°C), the most popular band is 8 to 14 microns. This is a wide range (resulting in much energy emitted from the surface), is free of atmospheric absorption, and can even be used at temperatures below ambient. For temperatures between 100°C and 800°C, wavelengths around 3.8 microns are preferred. This allows for no atmospheric absorption, and allows for penetraiton of flames. At high temperatures (above 300°C), 2.2 microns is popular. Again, this allows for no atmospheric absorption. These are more expensive, however, since relatively little energy is available at this wavelength and a high-gain amplifier is required to amplify the weak signal.

Since IR thermometers determine the average temperature of everything in their field of view (FOV), then a temperature between the object temperature and the surroundings will be indicated if the desired object does not fill the filed of view. One must either decrease the distance between the thermometer and the object, or use the emissivity compensator to correct for the loss in energy.

Two color interferometers determine the temperature by measuring the ratio of the energies at two wavelengths. If the change in the emissivity is the same (which occurs if the body is gray), then the unit does not depend on the absolute value of emissivity. Another advantage of this instrument is that it is often not affected by dust or smoke obscuring the target since it usually results in the same decrease in energy at both wavelengths. In reality, however, one must be sure that the emissivity at both wavelenghts change equally. These units are much more expensive, and they may not provide superior performance under certain circumstances.

A fiber-optic blackbody temperature detector system is offered by the Luxtron Corporation for standards room and field service above 300°C. The unit consists of a blackbody capsule fiber-optically coupled to a filtered, band-limited photon detector. Accuracy of 0.01 to 0.1°C is claimed, depending on temperature level.

A fluoroptic temperature-measuring system is also offered by the same company, for use only at lower temperatures (–200 to +450°C). This system uses an ultraviolet-stimulated phosphor on the end of an optical fiber as its sensor. The fluorescent signal from the phosphor decays with time, and its "time constant" is a function of temperature. Accuracy of +/–0.5°C is claimed for measurements within +/–50°C of a calibration point, or +/–1°C within 100°C.

Temperature-Sensitive Paints, Crayons, and Badges

Temperature-sensitive paints, crayons, and badges are available from several suppliers (Omega Engineering, Inc., Stamford, CT, and others in Germany and Japan). Each undergoes an irreversible change (e.g., a change in color or a change from solid to liquid) at one specified temperature. With a range of paints, temperatures from ambient to about 1500°C can be covered. The accuracy generally quoted is about +/–1% of level, although melting standards are available to +/–0.5°C.

The phase-change materials melt at well-defined temperatures, yielding easily discernible evidence that their event temperature has been exceeded. When more than one phase-change paint is applied to the same specimen, there can be interference if the melt from the low-melting paint touches the high-melting material. Color change materials do not interfere, but are more difficult to interpret. The calibration of high-temperature paints (both phase change and color change) may shift when they are used on heavily oxidized materials, due to alloying of the oxide with the paint. Recommended practice is to calibrate the paints on specimens of the application material. The event temperature which will cause transformation depends on the time at temperature: short exposure to a high temperature often has the same effect as long exposure to a lower temperature.

The paints and crayons are nonmetallic and, therefore, tend to have higher emissivities for thermal radiation than metals. They should be used only over small areas of metallic surfaces, compared with the metal thickness, or else their different emissivities may lead to a shift in the operating temperature of the parts.

The principal disadvantages of the paints and crayons are that they require visual interpretation, which can be highly subjective, and they are one-shot, irreversible indicators which respond to the highest temperature encountered during the test cycle. They cannot record whether the peak was reached during normal operation or during soak-back.

Liquid crystals can be divided into three groups, depending on their molecular arrangements: (1) smectic, (2) nematic, and (3) cholesteric. Most of the temperature-sensitive liquid crystals now in use are cholesteric: made from esters of cholesterol. Their molecules are arranged in planar layers of molecules with their long axes parallel and in the plane of the layer. The molecules in each layer are rotated with respect to those in its neighboring layers by about 15 min of arc in a continuous, helical pattern along an axis normal to the layers.

The colors reflected from cholesteric liquid crystals are thought to be due to Bragg diffraction from the aligned layers. The "wrap angle" between adjacent layers increases with temperature; hence, the color of the liquid crystal shifts toward short wavelengths (toward blue) as the temperature is raised. The color can also be affected by electric fields, magnetic fields, pressure, shear stress, and some chemical vapors.

Warm cholesterics are colorless liquids and they pass through a series of bright colors as they are heated through their "color-play" temperature band. The first color to appear is a deep red, followed by yellow, green, blue, and violet. Further heating yields a colorless liquid again. This cycle is reversible and repeatable, and the color–temperature relationship can be calibrated.

Liquid crystals selectively reflect only a small fraction of the incident light; hence, to enhance the brightness of the color image, they must be backed up with black paint or a nonreflecting surface.

A typical calibration is shown in Figure 4.6.8 for liquid crystals painted over black paint on an aluminum calibration strip. The upper part of Figure 4.6.8 describes the color variation, while the lower part shows the imposed linear temperature distribution. The hot end is blue, the cold end is red. Color-play intervals range from 0.5 to 10.0°C. Liquid crystals whose color-play interval is on the order of 0.5 to 2.0°C are often referred to as *narrow-band* materials, while those whose interval extends to 5.0 to 10°C are called *wide band*. Narrow-band images are easy to interpret by eye. Wide-band images show only

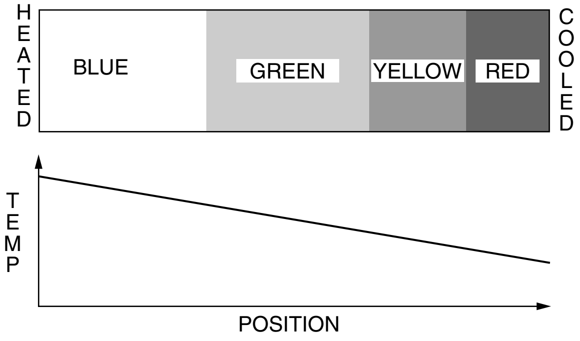

FIGURE 4.6.8 Schematic representation of a calibration strip.

subtle variations of color for small changes in temperature, and accurate work requires digital image handling or multiple images taken with different filters.

Several different narrow-band liquid crystals can be mixed together to make a single, multi-event paint covering a wide range of temperatures, provided their color-play intervals do not overlap. Such a mixture yields a set of color-play bands, one for each component.

Calibration. Liquid crystals are sold by event temperature and color-play bandwidth, with a nominal accuracy of +/–1°C on the event temperature. In many applications, especially if the image is to be visually interpreted, no further calibration is needed.

The accuracy attainable with a liquid crystal is related to the width of the color-play interval. With narrow-band material (a color-play interval of about 1.0°C), visual interpretation can be done with an uncertainty of 0.25 to 0.5°C. With digital image interpretation, spectrally controlled lighting and appropriate corrections for reflected light interference, the uncertainty can be held below 0.25°C.

Early users reported that the perceived color of a liquid crystal depended on both the lighting angle and the viewing angle. This dependence can be eliminated by using a light source along the line of sight (coaxial viewing and illumination).

Multiple-Event Paints. Several narrow-band paints can be mixed together to make a single paint with all the characteristics of each component, if their color-play intervals do not overlap. Each component retains its original calibration and acts independently of the other components.

Figure 4.6.9 shows the image from a five-event paint used to map the adiabatic wall temperature isotherms around a heated block in mixed convection. The outermost isotherm is 30°C, and the events are spaced apart at 5°C intervals. Determination of the temperatures from a multiple-event image requires that the temperature be known at one point in the image.

Liquid Crystals in Water. Liquid crystals can be used to mark the temperature distribution in water and some other liquids by adding a small quantity of encapsulated liquid crystal material to the liquid and photographing the color distribution using planar lighting. Velocity and temperature distributions can be determined by photographing the liquid crystal particles using a known exposure time. The temperature is deduced from the particle color, and the velocity by the length of the streak its image forms. Figure 4.6.10 shows the velocity and temperature distributions in a shear-driven, water-filled cavity 30 sec after the impulsive start of belt motion. In this view, the belt is at the top of the image, and moved from left to right. The water was stably stratified initially, with the top being 4°C hotter than the bottom. This technique was demonstrated by Rhee et al. (1984) and has been used by several workers.

Image Processing. Several schemes have been proposed to remove the subjectivity from interpretation of liquid crystal images. Akino et al. (1989), and others, have processed RGB video images of narrow-band images using multiple filters to extract images of specified isochromes, related to temperatures through a calibration. Hollingsworth et al. (1989) processed RGB images of wide-band images using chromaticity

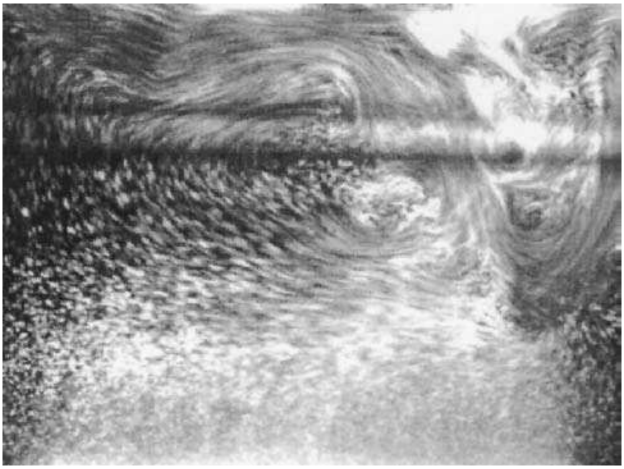

FIGURE 4.6.10 Liquid crystal visualization of the velocity and temperature distribution in a water-filled tank.

coordinates (hue, saturation, and intensity) and extracted temperature at each pixel, rather than along isochromes.

Heat Flux

Heat flux to or from a surface can be measured directly, using heat flux meters, or inferred from an overall energy balance, or inferred from temperature–time measurements at the surface or within the body. There are no primary standards for heat flux measurement.

Three general classes of heat flux meters are in common use: slug calorimeters, planar heat flux gauges (sometimes called Schmidt–Boelter gauges), and circular foil gauges (sometimes called Gardon gauges).

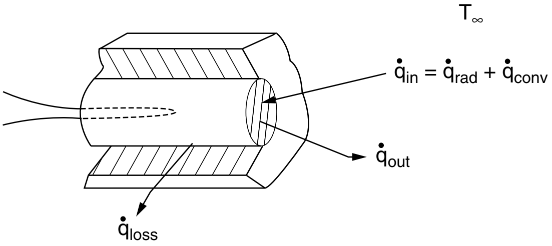

FIGURE 4.6.11 A simple slug calorimeter.

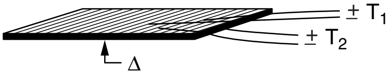

FIGURE 4.6.12 A typical planar heat flux gauge.

Sensitivities range from microvolts per kW/m² to millivolts per W/m². Planar gauges can be used for radiant or convective heat loads. Circular foil gauges should be used only for radiant loads.

Slug Calorimeter

The slug calorimeter is an energy balance transducer consisting of a known mass of material instrumented so that its temperature can be measured. A simple version is shown in Figure 4.6.11. If losses are negligibly small and the mass and the specific heat are constant, the instantaneous heat flux is deduced from

$$\dot{q}''_{\text{in}} A = Mc \frac{\partial T}{\partial t} \tag{4.6.8}$$

The variation of slug temperature with time is used to infer net heat transfer rate to the gauge. Slug calorimeters are used mainly when the heat flux, or the heat transfer coefficient, is expected to be relatively constant. They are of less value when the input flux changes arbitrarily because of the inaccuracies inherent in differentiating the signals.

Planar Heat Flux Gauge

Planar heat flux gauges use Fourier's law to deduce the heat flux from a steady-state measurement of the temperature difference across a thin sheet of thermally insulating material. The planar gauge geometry is shown in Figure 4.6.12. The working equation for a planar gauge is

$$\text{EMF} = N\varepsilon \Delta T = \frac{N\varepsilon t}{k} \dot{q}'' \tag{4.6.9}$$

where

N = number of junction pairs,
e = thermoelectric power of the thermoelement, mV/C
t = thickness of the insulator, m
k = conductivity of the insulator, W/m·C
q'' = heat flux through the gauge, W/m²

The figure shows one thermocouple junction on the top and one on the bottom surface of the insulator. Most gauges use multiple junctions. The thermoelements may be wire (down to 0.025 mm diameter) or thin films deposited on the insulator (10 to 20 Å). The assembly is usually sandwiched between two sheets of protective material to form an integral unit. Up to 150°C application temperature, these units are often made of Kapton, and provided with a contact adhesive. They may be as thin as 0.15 mm overall.

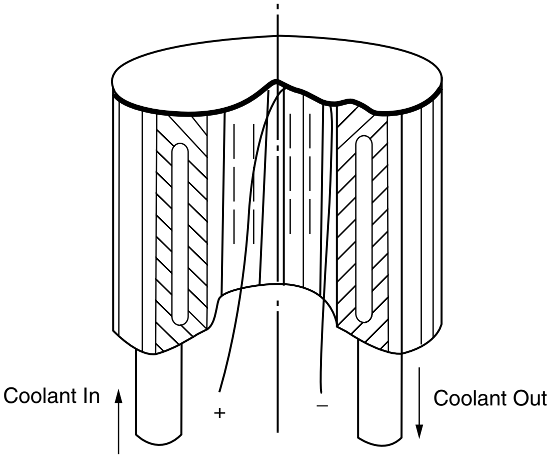

FIGURE 4.6.13 A water-cooled circular foil gauge (Gardon gauge).

Gauges should not be removed and reinstalled without recalibration, as the act of removing them from the surface may delaminate the gauge, changing its thermal resistance, and therefore its calibration.

Circular Foil Gauges

A circular foil gauge consists of a thin circular disk of metal supported by its edge from a structure of constant and uniform temperature. The circular foil gauge is often called a Gardon gauge. A constantan foil is often used, with a copper support structure. Two copper wires complete the circuit: one attached to the center of the foil disk and one to the support structure. The copper–constantan thermocouple thus formed produces an EMF determined by the temperature difference from the center of the foil disk to its rim. That temperature difference is directly proportional to the average heat flux on the disk. A cross-sectional view of a circular foil gauge is shown in Figure 4.6.13.

The working equation for a circular foil gauge is

$$\text{EMF} = \varepsilon \frac{R^2}{4kt}\dot{q}'' \tag{4.6.10}$$

The output signal is thus directly proportional to the heat flux on the disk. Cooling passages are frequently built into the support structure to maintain the edge of the disk (the heat sink for the foil disk) at constant temperature.

Fast Response Heat Flux Gages

The bulk of heat flux measuring devices on the market are for use where the heat flux varies slowly with time. Heat flux gages with frequency response up to 100 kHz are required for applications such as gas turbines, shock tubes, and IC engines.

A heat flux microsensor has been developed at Virginia Polytechnic University and marketed by Vatell Corporation (Diller and Onishi, 1988; Hager et al., 1991; Hager et al., 1993). This device consists of a thermopile manufactured on a substrate using VLSI techniques (see Figure 4.6.14). One set of thermocouple junctions are deposited onto an electrically insulating substrate. A thin layer of insulation (typically an oxide) is then deposited on top of the thermocouple junctions. A second layer of thermocouple junctions is deposited on the previous layers such that a thermopile is formed. Finally, a protective oxide layer is deposited. Because of the thinness of the insulator, a small temperature difference will result. Many thermocouple junctions are therefore needed to obtain a measurable signal. Between 40 and 90 junctions per device is not uncommon. The device size is on the order of millimeters (typically 3 mm × 3 mm sensing area). A temperature level since the thermopile only outputs temperature differences. The

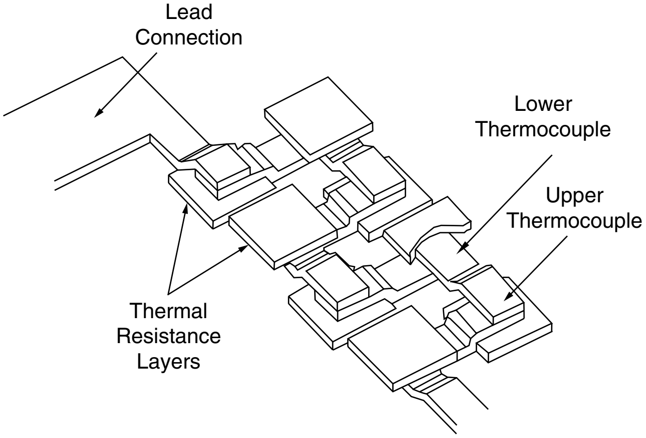

FIGURE 4.6.14 Schematic of heat flux microsensor. (From Hager, J.M., Simmons, S., Smith, D., Onishi, S., Langley, L.W., and Diller, T.E., Experimental performance of a heat flux microsensor. *ASME Journal of Engineering for Gas Turbines and Power,* 113, 246–250, 1991.)

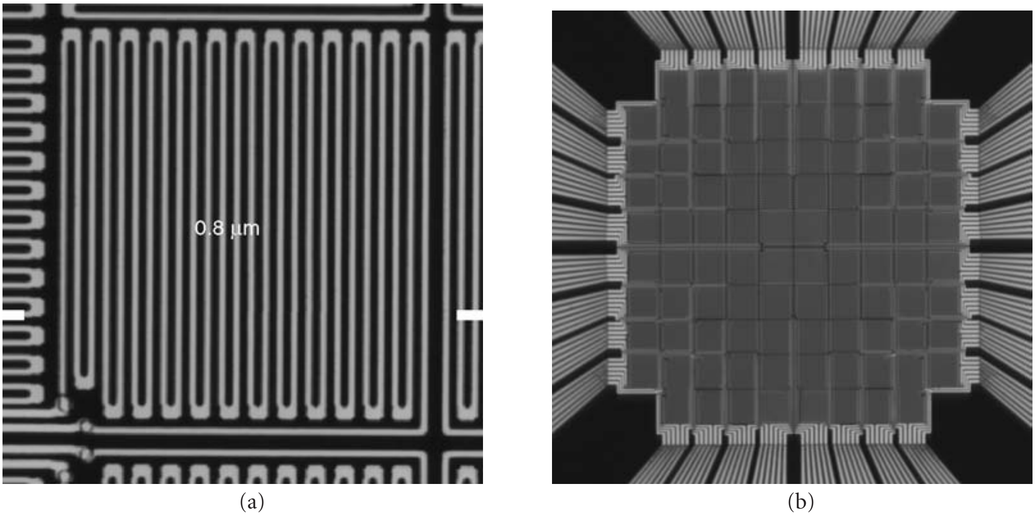
advantage of this device is that the layers are very thin, resulting in frequency responses as high as 100 kHz and minimal thermal and flow disruption to the surface. The device is able to operate at temperature as high as 800°C, depending on the type of thermocouple used, with a precision of up to 0.1 W/cm^2. Because of the high frequency response of the device, calibration can be performed in the steady state.

The second device developed at MIT by Epstein et al. (1986) consists of a polyimide substrate with resistance thermometers deposited on each side. The substrate is relatively thick, about 25 μm (0.001″), which result sin a low inherent frequency response (about 100 Hz). The frequency response can be increased up to 100 kHz through numerical processing as follows. Since the temperature at the boundaries of the substrate are measured using the resistance thermometers, the temperature profile within the substrate as a function of time can be obtained by numerically solving the transient conduction equation. The heat flux is then calculated by taking the derivative of this numerically constructed temperature profile to obtain the slope at the surface at every time step. The density, specific heat, and the substrate thickness are needed to perform this calculation. Because the substrate is quite thick, measurable signals can be obtained easily making the device quite small (about 1 mm × 1 mm sensing area). The flexible substrate allows the gages to be applied to curved surfaces. A disadvantage of the device is the numerical processing associated with the device if high frequency response is desired. Also, an unsteady calibration of the device must be performed to determine the density and specific heat of the substrate. High temperature capabilities are obtainable depending on the substrate material. The device as described by MIT (resistance thermometers of nickel on a polyimide substrate) has a maximum temperature capability of about 300°C.

Button type heat flux gages have been used in shock tubes to measure heat flux transients (Hartunian and Varwig, 1962; Skinner, 1961). This gage consists of an insulating Pyrex substrate about 1 mm in diameter and a few millimeters thick that is mounted within a gas turbine blade. A thin platinum film is hand painted onto this substrate, and is used as a resistance thermometer to measure the surface temperature of the substrate as a function of time. The instantaneous heat flux into the substrate can then be obtained by assuming the substrate acts as a semi-infinite solid and numerically reconstructing the instantaneous temperature profile at the surface (George et al., 1987). The low thermal diffusivity of the Pyrex substrate relative to the surrounding metal is critical to the successful performance of these gages because they "hold the heat at the surface," producing a large increase in temperature and enabling a measurable signal to be obtained.

An active heat transfer measurement technique has recently been developed that can measure heat transfer at many points on the surface at frequencies up to 15 kHz (Rule and Kim, 1999). An array of



(a) (b)

FIGURE 4.6.15 Photograph of (a) a single heater element and (b) an array of 96 heaters.

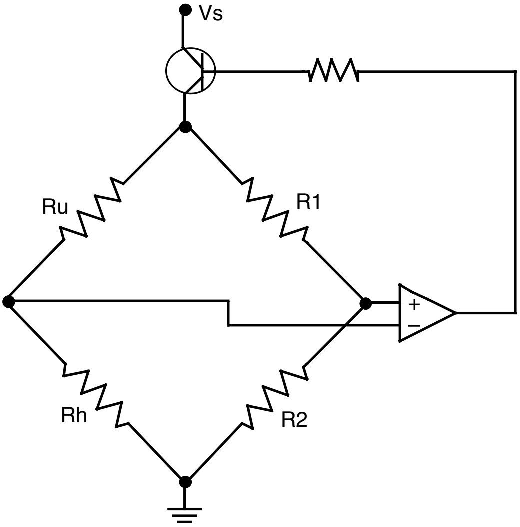


FIGURE 4.6.16 Simplified schematic of control circuit.

platinum resistance heater elements is deposited onto a quartz substrate. Pictures of a single heater element and the array are shown in Figure 4.6.15. Each element is nominally 0.25 mm × 0.25 mm in size. Aluminum lines supply power to the heaters, and are routed between the heaters to the edge of the array. A 1 micron layer of SiO_2 is deposited over the heater array to protect the heaters and to provide the surface with a uniform surface energy. The temperature of each heater in the array is regulated by a series of feedback control circuits similar to those used in constant-temperature hot-wire anemometry. Figure 4.6.16 shows a simplified schematic of the feedback control circuit that is used to maintain each heater at a constant temperature. The voltage difference across a Wheatstone bridge is sensed by an amplifier which provides enough power to the heater to keep the bridge in balance. This condition is satisfied if the ratio of $R_h/R_u = R_2/R_1$. This technique has been used to measure time resolved heat flux distributions beneath growing and departing bubbles during boiling (Yaddanapudi and Kim, 2001) as well as during droplet evaporation (Lee et al., 2001).

Sensor Environmental Errors

Temperature sensors generate signals in response to their own temperatures, but are usually installed to measure the temperature of some fluid or solid. There is heat transfer between the sensor and all of its surroundings, with the result that the sensor usually equilibrates at some temperature different from the fluid or solid it is installed in. This difference is considered an error in the measurement.

Similarly, heat flux gauges are generally installed so one can infer the heat flux which would have been there had the gauge not altered the system behavior. But heat flux gauges do disturb the system, and the heat flux at the gauge location, when the gauge is there, may be significantly different from that which would have been there without the gauge. This system disturbance effect must also be considered an error.

Steady-State Errors in Gas-Temperature Measurement

All immersion-type temperature sensors (thermocouples, resistance detectors, and thermistors) are subject to the same environmental errors, which are frequently larger than the calibration errors of the sensors. Large probes are usually affected more than small ones; hence, RTDs and thermistors (selected by investigators who wish to claim high accuracy for their data) are more vulnerable to environmental errors (due to their larger size and their self-heating errors). This aspect of accuracy is sometimes overlooked.

Sensor installations for gas-temperature measurements should be checked for all three of the usual steady-state environmental errors: velocity error, radiation error, and conduction error. The same equations apply to all sensors, with appropriate dimensions and constants.

$$\text{velocity error:} \qquad E_v = (1-\alpha)\frac{V^2}{2g_c J c_p} \tag{4.6.11}$$

$$\text{radiation error:} \qquad E_r = \frac{\sigma\varepsilon}{h}\left(T_{\text{sens}}^4 - T_{\text{surr}}^4\right) \tag{4.6.12}$$

$$\text{conduction error:} \qquad E_c = \frac{T_{\text{gas}} - T_{\text{mount}}}{\cosh\left[L\sqrt{\dfrac{hA_c}{kA_k}}\right]} \tag{4.6.13}$$

Velocity error depends upon the recovery factor, which varies with the Prandtl number of the fluid. The Prandtl numbers of most liquids are greater than 1; hence, the recovery factor α is greater than 1 and probes tend to read higher than the stagnation temperature in high-speed liquid flows. With thermistors and RTDs in liquids, the self-heating effect and the velocity error both tend to cause high readings. In gases, where the Prandtl number is less than 1, the two effects are of opposite sign and may partly cancel each other.

Radiation and conduction errors vary inversely with the heat transfer coefficient. Both tend to be larger for larger-diameter probes since, all other factors remaining the same, the heat transfer coefficient will be lower for a large-diameter probe. This results in larger radiation and conduction errors. In liquids, radiation error is not a problem, but velocity error and conduction error may both be significant. Conduction error becomes a problem in liquid-temperature measurements when thermowells are used. The depth of immersion of the well is frequently too short to eliminate conduction error.

Steady-State Errors in Solid and Surface-Temperature Measurements

When probes are used to measure solid temperature by inserting them into a hole in the specimen, they are subject to conduction errors proportional to their size and conductivity. A general rule of thumb is to keep the insertion depth at least 20 times the diameter (or wall thickness) of the probe. This assumes a close-fitting hole, backfilled with a material with higher thermal conductivity than air. For more-exact

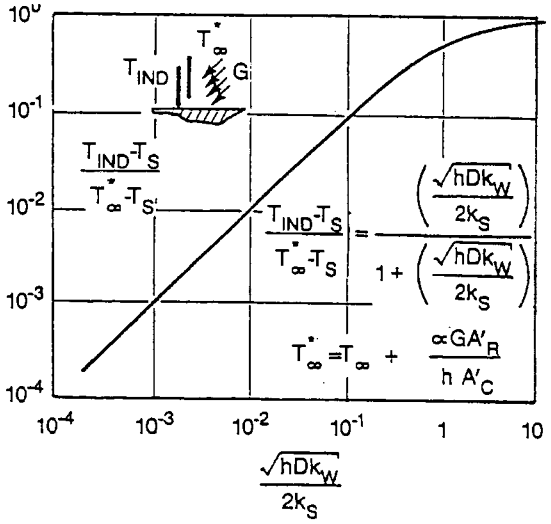

FIGURE 4.6.17 System disturbance errors caused by an attached thermocouple (worst case).

advice regarding a specific installation, a careful thermal circuit analysis of the installation should be developed, and its results used to guide the selection of diametrical clearance, backfill materials, and penetration depth.

A thermocouple attached to a hot surface surrounded by cooler fluid will exchange heat with the fluid by convection and with the surrounding solids by radiation. Heat lost from the thermocouple must be made up from the surface by conduction, which will result in a cold spot at the point of attachment.

Figure 4.6.17 shows the system disturbance error caused by a surface-attached thermocouple, as a fraction of the maximum possible error for the installation. If the surface is irradiated (e.g., by heating lamps), the irradiation will raise the surface temperature, but will also affect the system disturbance error. The effect on the system disturbance error caused by turning on the irradiation is similar to that of raising the temperature of the surrounding fluid to a new value, T_∞°.

The effective gas temperature is defined in terms of the incident irradiation and the heat transfer coefficient as

$$T_\infty^* = T_\infty + \frac{\alpha G A_R}{h A_C} T_\infty^* \tag{4.6.14}$$

Steady-State Errors in Heat Flux Gauges for Convective Heat Transfer

If the gauge is not flush with the surface, it may disturb the flow, and if it is not at the same temperature as the surface, it will disturb the heat transfer. Thus, the gauge may properly report the heat flux which is present when the gauge is present, but that may be significantly different from the heat flux which would have been there if the gauge had not been there.

For planar gauges, both effects are usually small. The thermal resistance of such a gauge is generally small, and they are thin enough to avoid disturbing most flows. Circular foil gauges pose a more serious problem, since they are often cooled significantly below the temperature of the surrounding surface. Dropping the wall temperature at the gauge location can significantly increase the local heat load in two ways: one due to the fact that, for a given value of *h*, a cold spot receives a higher heat load from the gas stream. The second effect arises because the value of the heat transfer coefficient itself depends on the local wall temperature distribution: a local cold spot under a hot gas flow will experience a higher heat transfer coefficient than would have existed had the surface been of uniform temperature.

Evaluating the Heat Transfer Coefficient

The heat transfer coefficient is a defined quantity, given by

$$h = \frac{\dot{q}''_{\text{conv}}}{\left(T_o - T_{\text{ref}}\right)} \tag{4.6.15}$$

Different reference temperatures are conventionally used for different situations:

- T_∞: The free-stream temperature. Used for isolated objects of uniform temperature in a uniform free stream, where an average value of h is desired which describes the overall heat transfer between the object and the flow. Also used in boundary layer heat transfer analyses where local values of h are needed to deal with locally varying conditions.
- T_m: The mixed mean fluid temperature. Used for internal flows where the intent of the calculation is to describe the changes in mixed mean fluid temperature (e.g., heat exchangers).
- $T_{\text{adiabatic}}$: The adiabatic surface temperature. Used for isolated objects or small regions of uniform temperature in either internal or external flows, where the overall thermal boundary conditions are neither uniform heat flux nor uniform temperature.

For a given data set, the value of the heat transfer coefficient will depend on the reference temperature chosen, and h should be subscripted to inform later users which reference was used: e.g., h_∞, h_m, or $h_{\text{adiabatic}}$.

Direct Methods

The two most commonly used methods for measuring the heat transfer coefficient are both derived from the same energy balance equation:

$$hA\left(T_o - T_{\text{ref}}\right) = \dot{e}_{\text{in}} + \dot{q}_{\text{cond,in}} + \dot{q}_{\text{rad,in}} - Mc\frac{dT}{d\tau} \tag{4.6.16}$$

Steady State. In the steady-state method, the transient term is zero (or nearly so), and h is determined by measuring the input power and the operating temperature, and correcting for losses. Equation (4.6.16) can be applied to differentially small elements or to whole specimens. The considered region must be reasonably uniform in temperature, so the energy storage term and the convective heat transfer term use the same value.

For tests of isolated objects, or embedded calorimeter sections, steady-state tests usually use high-conductivity specimens (e.g., copper or aluminum) with embedded electric heaters. The resulting value of h is the average over the area of the specimen. The Biot number, hL/k, for the specimen should be low (on the order of 0.01 or less) if only one temperature sensor is used in the specimen, so the surface temperature can be determined from the embedded sensor.

If a single heated element is used within an array of unheated elements, the resulting heat transfer coefficient is implicitly defined as $h_{\text{adiabatic}}$ and should be identified as such. Heat transfer coefficients measured with single-active-element tests cannot be used with the mixed mean fluid temperature.

When the variation of h over a surface is required, one common steady-state technique is to stretch a thin foil (stainless steel, or carbon impregnated paper, or gold deposited on polycarbonate) over an insulating substrate, and electrically heat the foil surface. Liquid crystals or infrared techniques can be used to map the surface temperature, from which the heat transfer coefficient distribution can be determined. The "heated foil with liquid crystal" approach was used by Cooper et al. in 1975 to measure heat transfer coefficients, and has since been used by many others. Hippensteele et al. (1985) have made extensive use of the foil technique in studies of gas turbine heat transfer. An example of their work on the end wall of a turbine cascade is shown in Figure 4.6.18.

Hollingsworth et al. (1989) used a stainless steel foil heater for a study in air for an electronics cooling application, illustrated in Figure 4.6.19.

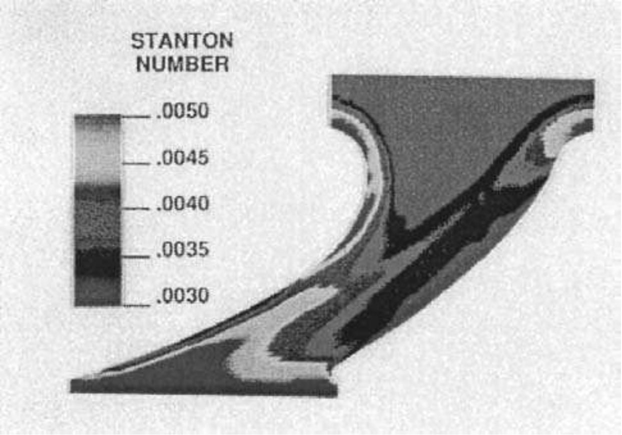

FIGURE 4.6.18 Heat transfer coefficient distribution on the end wall of a turbine cascade. (From Hippensteele, S.A. et al., NASA Technical Memorandum 86900, March, 1985. With permission.)

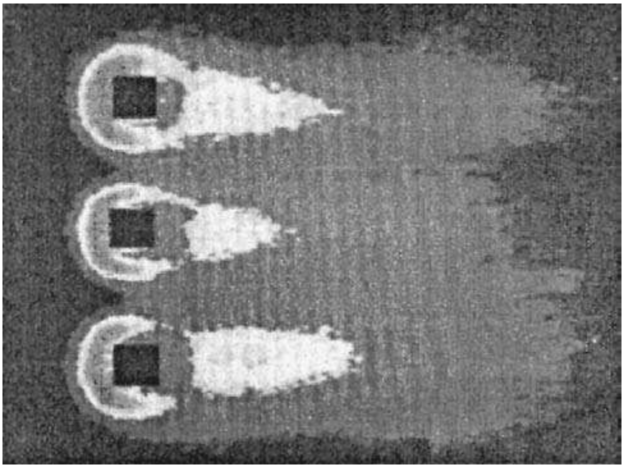

FIGURE 4.6.19 Visualization of the heat transfer coefficient distribution on a heated plate around three unheated cubes.

Another steady-state technique which reveals the distribution of *h* on the surface was introduced by den Ouden and Hoogendoorn (1974) and is currently in use by Meinders (1996). It uses a uniform and constant-temperature substrate (originally, a tank of warm water, now a copper block) covered with a layer of known thermal resistance (originally, a plate of glass, now a thin layer of epoxy). The surface was painted with liquid crystals (now visualized using infrared imaging) and the surface-temperature distribution determined. The inner (uniform) and outer (measured) temperature distributions are then used as boundary conditions to a three-dimensional conduction solver which calculates the total heat flux at each point on the surface. The total heat flux is corrected for radiation to yield the net convective transport at each point, from which *h* can be determined.

This method appears to have an advantage in accuracy over the heated foil technique because of the more accurate handling of substrate conduction.

Transient Lumped Parameter Systems. In the lumped parameter transient method, the specimen is assumed to be uniform in temperature at every instant through the transient. The power, $\dot{e}_{\text{in}}$, in Equation

(4.6.16) is usually zero, although that is not necessary (one could simply change the power level at time zero to initiate the transient). At time zero, a transient is initiated, and the response curve recorded.

The data can be interpreted, and the validity of the first-order assumption tested at the same time by plotting $(T - T_{\text{final}})/(T_{\text{initial}} - T_{\text{final}})$ on the log scale of semilog coordinates, with time on the algebraic scale. If the line is straight, then the system is first order and the characteristic time can be determined from any two points on the line by

$$\tau = \frac{\left(t_2 - t_1\right)}{\ln\left\{\dfrac{T_{\text{fin}} - T_1}{T_{\text{fin}} - T_2}\right\}} \tag{4.6.17}$$

The heat transfer coefficient is extracted from the time-constant definition.

Indirect Methods

An increasingly popular method is the extraction of *h* from surface-temperature variations after a step in flow temperature using an inverse calculation method (see the section on inferential methods of heat flux measurement). The simplest inverse method assumes one-dimensional conduction into an infinitely thick plate of constant material properties. Even highly irregular geometries can be studied with this technique, if the streamwise extent of the specimen is small and the testing time is short. A short time interval is necessary so the penetration of the thermal wave is limited to a thin layer near the surface. The short streamwise extent is necessary so the temperature response of the surface upstream does not alter the thermal step applied to the downstream surface. This technique has been used to determine the heat transfer coefficient distribution on the inside walls of passages of irregular shape, by making the passage in a transparent material.

Naphthalene Sublimination. The equations for mass diffusion are similar to those for heat transfer, except for replacing the Prandtl number in the heat transfer equation by the Schmidt number in the diffusion equation. Thus, one could expect that the distribution of the mass transfer coefficients on a surface would mimic the distribution of the heat transfer coefficients.

The most commonly used analog technique is naphthalene sublimination. As early as 1940, the mass transfer/heat transfer similarity was used to estimate the heat transfer coefficient distribution. Naphthalene is a solid material which sublimes at a reasonable rate in air at ambient temperature. Specimens can be cast in naphthalene with good precision, and the recession of the surface mapped as a function of position and time using automated or semiautomated measuring equipment. The surface recession over a known interval of time is a measure of the mass transfer rate, from which the mass transfer coefficient can be deduced.

Naphthalene experiments are generally done at uniform temperature; hence, a uniform vapor pressure exists at the surface. This corresponds to the heat transfer situation of heat transfer from a uniform temperature surface. No counterpart of the uniform heat flux situation has been produced using naphthalene, nor have there been experiments corresponding to variable wall temperature.

Naphthalene sublimation experiments do not suffer from any counterpart of the conduction heat transfer in the substrate. Conduction makes it difficult to work near discontinuities in wall temperature in a heat transfer experiment. Details of the fine structure of mass transfer near obstructions and discontinuities can be resolved in naphthalene experiments, but those details might not exist in a heat transfer process. The Prandtl number of air is much lower than the Schmidt number of naphthalene diffusing in air; hence, thermal conduction would tend to blur out sharp gradients in the temperature field more than diffusion would blur out gradients in naphthalene concentration.

The Schmidt number of naphthalene in air is about 2.5, far different than the Prandtl number of air (0.71); hence, the mass transfer coefficient deduced from a naphthalene experiment is not numerically equal to the heat transfer coefficient which would have existed at those conditions. The usual recommendation is to adjust for the Prandtl number of Schmidt number using a relation of the form:

$$\mathrm{St}\,\mathrm{Pr}^{2/3} = f\{\mathrm{Re}\} = \mathrm{Sh}_j \mathrm{Sc}_j^{2/3} \qquad (4.6.18)$$

based on laminar results. That recommendation has not been seriously tested by experiments in turbulent and separated flows. By using nominal values of the Schmidt number and Prandtl number, the heat transfer Stanton number would be 2.3 times higher than the measured Sherwood number and an uncertainty of 10% in that ratio would alter the inferred heat transfer coefficient by 23%.

System Performance Matching. Sometimes the "effective average heat transfer coefficient" for a system is inferred from the overall behavior of the system, e.g., estimating h from the effectiveness of a heat exchanger. Values deduced by this means cannot be expected to agree well with direct measurements unless a very sophisticated system description model is used.

4.7 Mass Transfer

Anthony F. Mills

Introduction

Mass transfer may occur in a gas mixture, a liquid solution, or a solid solution. There are several physical mechanisms that can transport a chemical species through a phase and transfer it across phase boundaries. The two most important mechanisms are ordinary diffusion and convection. Mass diffusion is analogous to heat conduction and occurs whenever there is a gradient in the concentration of a species. Mass convection is essentially identical to heat convection: a fluid flow that transports heat may also transport a chemical species. The similarity of mechanisms of heat transfer and mass transfer results in the mathematics often being identical, a fact that can be exploited to advantage. But there are some significant differences between the subjects of heat and mass transfer. One difference is the much greater variety of physical and chemical processes that require mass transfer analysis. Another difference is the extent to which the essential details of a given process may depend on the particular chemical system involved, and on temperature and pressure.

In the next subsection, concentrations, velocities, and fluxes are defined, and special attention is paid to phase interfaces where the concentration of a chemical species is almost always discontinuous. Fick's law of ordinary diffusion is introduced in the third section, where other diffusion phenomena are also discussed. The fourth section presents various forms of the species conservation equation. Results for diffusion in a stationary medium are given in the fifth section, and include steady diffusion across a plane wall, transient diffusion in a semi-infinite solid, and diffusion in a porous catalyst. Results for diffusion in a moving medium are given in the sixth section, and the Stefan flow is introduced for diffusion with one component stationary. Also considered are particle combustion, droplet evaporation, and combustion of a volatile liquid hydrocarbon fuel droplet. The last section deals with mass convection. Low mass transfer rate theory is presented and how to exploit the analogy between convective heat and mass transfer is shown. Particular attention is given to situations involving simultaneous heat and mass transfer associated with evaporation or condensation. The section closes by presenting high mass transfer rate theory for convection, and gives engineering calculation methods for boundary layer flows that account for variable property effects.

Concentrations, Velocities, and Fluxes

Definitions of Concentrations

In a gas mixture, or liquid or solid solution, the local *concentration* of a mass species can be expressed in a number of ways. The *number density* of species *i* in a mixture or solution of *n* species is defined as

$$\begin{aligned}\text{Number density of species } i &\equiv \text{Number of molecules of } i \text{ per unit volume}\\ &\equiv \mathcal{N}_i \text{ molecules/m}^3\end{aligned} \tag{4.7.1}$$

Alternatively, if the total number of molecules of all species per unit volume is denoted as $\mathcal{N}$, then we define the *number fraction* of species *i* as

$$n_i \equiv \frac{\mathcal{N}_i}{\mathcal{N}}; \qquad \mathcal{N} = \sum \mathcal{N}_i \tag{4.7.2}$$

where the summation is over all species present, $i = 1, 2, \ldots, n$. Equation (4.7.1) and Equation (4.7.2) describe *microscopic* concepts and are used, for example, when the kinetic theory of gases is used to describe transfer processes.

Whenever possible, it is more convenient to treat matter as a continuum. Then the smallest volume considered is sufficiently large for macroscopic properties such as pressure and temperature to have their usual meanings. For this purpose we also require *macroscopic* definitions of concentration. First, on a mass basis,

$$\begin{aligned} &\textit{Mass concentration} \text{ of species } i \equiv \text{partial density of species } i \\ &\equiv \rho_i \text{ kg/m}^3 \end{aligned} \tag{4.7.3}$$

The total mass concentration is the total mass per unit volume, that is, the density $\rho = \sum\rho_i$. The *mass fraction* of species i is defined as

$$m_i = \frac{\rho_i}{\rho} \tag{4.7.4}$$

Second, on a molar basis,

$$\begin{aligned} &\textit{Molar concentration} \text{ of species } i \equiv \text{number of moles of } i \text{ per unit volume} \\ &\equiv c_i \text{ kmol/m}^3 \end{aligned} \tag{4.7.5}$$

If M_i (kg/kmol) is the molecular weight of species i, then

$$c_i = \frac{\rho_i}{M_i} \tag{4.7.6}$$

The total molar concentration is the molar density $c = \sum c_i$. The *mole fraction* of species i is defined as

$$x_i \equiv \frac{c_i}{c} \tag{4.7.7}$$

A number of important relations follow directly from these definitions. The mean molecular weight of the mixture of solution is denoted M and may be expressed as

$$M = \frac{\rho}{c} = \sum x_i M_i \tag{4.7.8a}$$

or

$$\frac{1}{M} = \sum \frac{m_i}{M_i} \tag{4.7.8b}$$

There are summation rules

$$\sum m_i = 1 \tag{4.7.9a}$$

$$\sum x_i = 1 \tag{4.7.9b}$$

It is often necessary to have the mass fraction of species *i* expressed explicitly in terms of mole fractions and molecular weights; this relation is

$$m_i = \frac{x_i M_i}{\sum x_j M_j} = x_i \frac{M_i}{M} \tag{4.7.10a}$$

and the corresponding relation for the mole fraction is

$$x_i = \frac{m_i / M_i}{\sum m_j / M_j} = m_i \frac{M}{M_i} \tag{4.7.10b}$$

Dalton's law of partial pressures for an ideal gas mixture states that

$$P = \sum P_i, \qquad \text{where} \quad P_i = \rho_i R_i T \tag{4.7.11}$$

Dividing partial pressure by total pressure and substituting $R_i = \mathcal{R}/M_i$ gives

$$\frac{P_i}{P} = \frac{\rho_i}{M_i}\frac{\mathcal{R}T}{P} = c_i \frac{\mathcal{R}T}{P} = x_i \frac{c\mathcal{R}T}{P} = x_i \tag{4.7.12}$$

Thus, for an ideal gas mixture, the mole fraction and partial pressure are equivalent measures of concentration (as also is the number fraction).

A commonly used specification of the composition of dry air is 78.1% N_2, 20.9% O_2, and 0.9% Ar, by volume. (The next largest component is CO_2, at 0.3%.) Since equal volumes of gases contain the same number of moles, specifying composition on a volume basis is equivalent to specifying mole fractions, namely,

$$x_{N_2} = 0.781; \qquad x_{O_2} = 0.209; \qquad x_{Ar} = 0.009$$

The corresponding mass fractions are calculated to be

$$m_{N_2} = 0.755; \qquad m_{O_2} = 0.231; \qquad m_{Ar} = 0.014$$

Concentrations at Interfaces

Although temperature is continuous across a phase interface, concentrations are usually discontinuous. In order to define clearly concentrations at interfaces, we introduce imaginary surfaces, denoted *u* and *s*, on both sides of the real interface, each indefinitely close to the interface, as shown in Figure 4.7.1 for water evaporating into an airstream. Thus, the liquid-phase quantities at the interface are subscripted *u*, and gas-phase quantities are subscripted *s*. If we ignore the small amount of air dissolved in the water, $x_{H_2O,u} = 1$. Notice that the subscript preceding the comma denotes the chemical species, and the subscript following the comma denotes location. To determine $x_{H_2O,s}$ we make use of the fact that, except in extreme circumstances, the water vapor and air mixture at the *s*-surface must be in thermodynamic equilibrium with water at the *u*-surface. Equilibrium data for this system are found in conventional steam tables: the saturation vapor pressure of steam at the water temperature, T_s, ($T_s = T_u$), is the required partial pressure

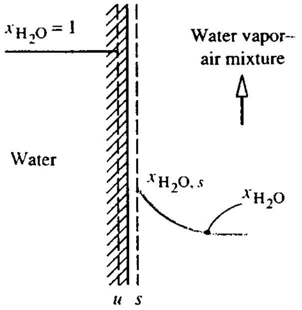

FIGURE 4.7.1 Concentrations at a water-air interface.

$P_{H_2O,s}$. With the total pressure P known, $x_{H_2O,s}$ is calculated as $P_{H_2O,s}/P$. If $m_{H_2O,s}$ is required, Equation (4.7.10a) is used.

For example, at $T_s = 320$ K, the saturation vapor pressure is obtained from steam tables as 0.10535×10^5 Pa. If the total pressure is 1 atm = 1.0133×10^5,

$$x_{H_2O,s} = \frac{0.10535 \times 10^5}{1.0133 \times 10^5} = 0.1040$$

$$m_{H_2O,s} = \frac{(0.1040)(18)}{(0.1040)(18) + (1 - 0.1040)(29)} = 0.06720$$

For a gas or solid dissolving in a liquid, equilibrium data are often referred to simply as solubility data, found in chemistry handbooks. Many gases are only sparingly soluble, and for such dilute solutions solubility data are conveniently represented by *Henry's law*, which states that the mole fraction of the gas at the *s*-surface is proportional to its mole fraction in solution at the *u*-surface, the constant of proportionality being the *Henry number*, He. For species *i*,

$$x_{i,s} = \mathrm{He}_i x_{i,u} \tag{4.7.13}$$

The Henry number is inversely proportional to total pressure and is also a function of temperature. The product of Henry number and total pressure is the *Henry constant*, C_{He}, and for a given species is a function of temperature only:

$$\mathrm{He}_i P = C_{\mathrm{He}_i}(T) \tag{4.7.14}$$

Solubility data are given in Table 4.7.1.

TABLE 4.7.1 Henry Constants C_{He} for Dilute Aqueous Solutions at Moderate Pressures ($P_{i,s}/x_{i,u}$ in atm, or in bar = 10^5 Pa, within the accuracy of the data)

Solute	290 K	300 K	310 K	320 K	330 K	340 K
H_2S	440	560	700	830	980	1,140
CO_2	1,280	1,710	2,170	2,720	3,220	—
O_2	38,000	45,000	52,000	57,000	61,000	65,000
H_2	67,000	72,000	75,000	76,000	77,000	76,000
CO	51,000	60,000	67,000	74,000	80,000	84,000
Air	62,000	74,000	84,000	92,000	99,000	104,000
N_2	16,000	89,000	101,000	110,000	118,000	124,000

For example, consider absorption of carbon dioxide from a stream of pure CO_2 at 2 bar pressure into water at 310 K. From Table 4.7.1, C_{He} = 2170 bar; thus

$$\mathrm{He}_{CO_2} = \frac{2170}{2} = 1085; \qquad x_{CO_{2,u}} = \frac{1}{1085} = 9.22 \times 10^{-4}$$

Dissolution of gases into metals is characterized by varied and rather complex interface conditions. Provided temperatures are sufficiently high, hydrogen dissolution is reversible (similar to CO_2 absorption into water); hence, for example, titanium-hydrogen solutions can exist only in contact with a gaseous hydrogen atmosphere. As a result of hydrogen going into solution in atomic form, there is a characteristic square root relation

$$m_{H_2,u} \alpha P_{H_2,s}^{1/2}$$

The constant of proportionality is strongly dependent on temperature, as well as on the particular titanium alloy: for Ti-6Al-4V alloy it is twice that for pure titanium. In contrast to hydrogen, oxygen dissolution in titanium is irreversible and is complicated by the simultaneous formation of a rutile (TiO_2) scale on the surface. Provided some oxygen is present in the gas phase, the titanium-oxygen *phase diagram* (found in a metallurgy handbook) shows that $m_{O_2,u}$ in alpha-titanium is 0.143, a value essentially independent of temperature and O_2 partial pressure. Dissolution of oxygen in zirconium alloys has similar characteristics to those discussed above for titanium.

All the preceding examples of interface concentrations are situations where thermodynamic equilibrium can be assumed to exist at the interface. Sometimes thermodynamic equilibrium does not exist at an interface: a very common example is when a chemical reaction occurs at the interface, and temperatures are not high enough for equilibrium to be attained. Then the concentrations of the reactants and products at the *s*-surface are dependent both on the rate at which the reaction proceeds — that is, the *chemical kinetics* — as well as on mass transfer considerations.

Definitions of Fluxes and Velocities

The mass (or molar) flux of species *i* is a vector quantity giving the mass (or moles) of species *i* that pass per unit time through a unit area perpendicular to the vector (Figure 4.7.2). We denote the absolute mass and molar fluxes of species *i*, that is, relative to stationary coordinate axes, as $\boldsymbol{n}_i$ (kg/m²sec) and $\boldsymbol{N}_i$ (kmol/m²sec), respectively. The absolute mass flux of the mixture (mass velocity) is

$$\boldsymbol{n} = \sum \boldsymbol{n}_i \tag{4.7.15}$$

and the local mass-average velocity is

$$\boldsymbol{v} = \frac{\boldsymbol{n}}{\rho} \text{ m/sec} \tag{4.7.16}$$

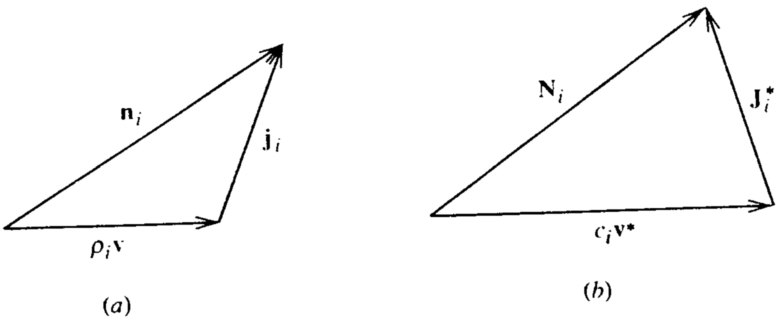

FIGURE 4.7.2 Flux vectors: (a) mass basis, (b) molar basis.

The velocity $\boldsymbol{v}$ is the velocity that would be measure by a Pitot tube and corresponds to the velocity used in considering pure fluids. On a molar basis, the absolute molar flux of the mixture is

$$\boldsymbol{N} = \sum \boldsymbol{N}_i \tag{4.7.17}$$

and the local molar-average velocity is

$$\boldsymbol{v}^* = \frac{\boldsymbol{N}}{c} \text{ m/sec} \tag{4.7.18}$$

The absolute fluxes at species *i* have two components. On a mass basis we write

$$\boldsymbol{n}_i = \rho_i \mathbf{v} + \boldsymbol{j}_i \tag{4.7.19}$$

where $\rho_i \boldsymbol{n}$ is transport of species *i* by bulk motion of the fluid at velocity $\boldsymbol{v}$ and is the *convective* component. Thus, $\boldsymbol{j}_i$ is transport of species *i* relative to the mass average velocity; it is called the *diffusive* component because most commonly it is due to ordinary (concentration) diffusion of the species. On a molar basis the corresponding relation is

$$N_i = c_i \mathbf{v}^* + \boldsymbol{J}_i^* \tag{4.7.20}$$

Some important relations follow from these definitions:

$$\sum \boldsymbol{j}_i = \sum \boldsymbol{J}_i^* = 0 \tag{4.7.21}$$

$$\boldsymbol{N}_i = \frac{\boldsymbol{n}_i}{M_i} \tag{4.7.22}$$

$$\boldsymbol{n}_i = \rho_i \boldsymbol{v} + \boldsymbol{j}_i = m_i \sum \boldsymbol{n}_i + \boldsymbol{j}_i \tag{4.7.23a}$$

$$\boldsymbol{N}_i = c_i \boldsymbol{v}^* + \boldsymbol{J}_i^* = x_i \sum \boldsymbol{N}_i + \boldsymbol{J}_i^* \tag{4.7.23b}$$

Mechanisms of Diffusion

Ordinary Diffusion

Fick's law of ordinary diffusion is a linear relation between the rate of diffusion of a chemical species and the local concentration gradient of that species. It is exact for a binary gas mixture, for which the kinetic theory of gases gives

$$\boldsymbol{j}_1 = -\rho \mathcal{D}_{12} \nabla m_1 \text{ kg/m}^2 \text{ sec} \tag{4.7.24a}$$

on a mass basis, and

$$\boldsymbol{J}_1^* = -c \mathcal{D}_{12} \nabla x_1 \text{ kg/m}^2 \text{ sec} \tag{4.7.24b}$$

on a molar basis; $\mathcal{D}_{12}$ (m^2/sec) is the binary diffusion coefficient (or mass diffusivity), and $\mathcal{D}_{21} = \mathcal{D}_{21}$. Equation (4.7.24a) and Equation (4.7.24b) are mathematically equivalent; however, notice that it is incorrect to write

$$\boldsymbol{j}_i = -\mathcal{D}_{12} \nabla \rho_1 \tag{4.7.25}$$

since $\nabla \rho_1 \neq \rho \nabla m_1$ in general. Fick's law in the form of Equation (4.7.24a) and Equation (4.7.24b) is also valid for dilute liquid and solid solutions, for which it is often possible to assume ρ (or c) constant, and then Equation (4.7.25) or its molar equivalent are good approximations.

Ordinary diffusion in multicomponent systems is described by the Stefan–Maxwell equations (Hirschfelder et al., 1954). These equations are difficult to use for engineering analysis. In gas mixtures containing species that do not have widely varying molecular weights, it is possible to model approximately the diffusion process by using an effective binary diffusion coefficient in Fick's law. This coefficient is a suitable average over the species in the mixture, and may be calculated from

$$\mathcal{D}_{1m} = \frac{\left(1 - x_1\right)}{\sum_{i=2}^{n} \left(x_i / \mathcal{D}_{1i}\right)}; \qquad x_1 \ll 1 \tag{4.7.26}$$

This equation works well for most mixtures of combustion gases (except those containing appreciable concentrations of H or H_2).

Binary diffusion coefficients at 300 K are of the order of 10^{-5} m^2/sec in gases at 1 atm, 10^{-9} m^2/sec in aqueous solutions, and 10^{-10} to 10^{-13} m^2/sec in solids. However, the product $\rho\mathcal{D}$ or $(c\mathcal{D})$ is, at most, one order of magnitude different for gases and liquids. Data for diffusion coefficients may be found in Table 4.7.2 through Table 4.7.5.

Molecules in a gas mixture, and in a liquid or solid solution, can diffuse by mechanisms other than ordinary diffusion governed by Fick's law. *Thermal diffusion* is diffusion due to a temperature gradient and is often called the *Soret effect*. Thermal diffusion is usually negligible compared with ordinary diffusion, unless the temperature gradient is very large. However, there are some important processes that depend on thermal diffusion, the most well known being the large-scale separation of uranium isotopes. *Pressure diffusion* is diffusion due to a pressure gradient and is also usually negligible unless the pressure gradient is very large. Pressure diffusion is the principle underlying the operation of a centrifuge. Centrifuges are used to separate liquid solutions and are increasingly being used to separate gaseous isotopes as well. *Forced diffusion* results from an external force field acting on a molecule. Gravitational force fields do not cause separation since the force per unit mass of a molecule is constant. Forced diffusion occurs when an electrical field is imposed on an electrolyte (for example, in charging an automobile battery), on a semiconductor, or on an ionized gas (for example, in a neon tube or metal-ion laser). Depending on the strength of the electric field, rates of forced diffusion can be very large.

Some interesting diffusion phenomena occur in porous solids. When a gas mixture is in a porous solid, such as a catalyst pellet or silica–gel particle, the pores can be smaller than the mean free path of the molecules. Then, the molecules collide with the wall more often than with other molecules. In the limit of negligible molecule collisions we have *Knudsen diffusion*, also called *free molecule flow* in the fluid mechanics literature. If the pore size approaches the size of a molecule, then Knudsen diffusion becomes negligible and *surface diffusion*, in which adsorbed molecules move along the pore walls, becomes the dominant diffusion mechanism.

Very small particles of 10^{-3} to 10^{-1} μm size — for example, smoke, soot, and mist — behave much like large molecules. Ordinary diffusion of such particles is called *Brownian motion* and is described in most elementary physics texts. Diffusion of particles due to a temperature gradient is called *thermophoresis* and plays an important role for larger particles, typically in the size range 10^{-1} to 1 μm. Diffusion of particles in a gas mixture due to concentration gradients of molecular species is called *diffusiophoresis.*

TABLE 4.7.2 Diffusion Coefficients in Air at 1 atm (1.013×10^5 Pa)[a]

	Binary Diffusion Coefficient (m^2/sec $\times 10^4$)							
T(K)	O_2	CO_2	CO	C_7H_6	H_2	NO	SO_2	He
200	0.095	0.074	0.098	0.036	0.375	0.088	0.058	0.363
300	0.188	0.157	0.202	0.075	0.777	0.180	0.126	0.713
400	0.325	0.263	0.332	0.128	1.25	0.303	0.214	1.14
500	0.475	0.385	0.485	0.194	1.71	0.443	0.326	1.66
600	0.646	0.537	0.659	0.270	2.44	0.603	0.440	2.26

900	1.26	1.05	1.28	0.538	4.77	1.18	0.887	4.42
1000	1.52	1.24	1.54	0.641	5.69	1.41	1.060	5.26
1200	2.06	1.69	2.09	0.881	7.77	1.92	1.440	7.12
1400	2.66	2.17	2.70	1.13	9.90	2.45	1.870	9.20
1600	3.32	2.75	3.37	1.41	12.5	3.04	2.340	11.5
1800	4.03	3.28	4.10	1.72	15.2	3.70	2.850	13.9
2000	4.80	3.94	4.87	2.06	18.0	4.48	3.360	16.6

[a] Owing to the practical importance of water vapor-air mixtures, engineers have used convenient empirical formulas for $\mathcal{D}_{H_2O\,\text{air}}$. A formula that has been widely used for many years is

$$\mathcal{D}_{H_2O\,\text{air}} = 1.97 \times 10^{-5} \left(\frac{P_0}{P}\right)\left(\frac{T}{T_0}\right)^{1.685} \text{m}^2/\text{sec}; \quad 273 \text{ K} < T < 373 \text{ K}$$

where $P_0 = 1$ atm; $T_0 = 256$ K. More recently, the following formula has found increasing use. (Marrero, T.R. and Mason, E.A. 1992. Gaseous diffusion coefficients, *J. Phys. Chem. Ref. Data*, 1, 3–118):

$$\mathcal{D}_{H_2O\,\text{air}} = 1.87 \times 10^{-10} \frac{T^{2.072}}{P}; \quad 280 \text{ K} < T < 450 \text{ K}$$

$$= 2.75 \times 10^{-9} \frac{T^{1.632}}{P}; \quad 450 \text{ K} < T < 1070 \text{ K}$$

for P in atmospheres and T in kelvins. Over the temperature range 290 to 330 K, the discrepancy between the two formulas is less than 2.5%. For small concentrations of water vapor in air, the older formula gives a constant value of $\text{Sc}_{H_2O\,\text{air}} = 0.61$ over the temperature range 273 to 373 K. On the other hand, the Marrero and Mason formula gives values of $\text{Sc}_{H_2O\,\text{air}}$ that vary from 0.63 at 280 K to 0.57 at 373 K.

Forced diffusion of a charged particle in an electrical field is similar to that for an ionized molecular species. Thermal and electrostatic precipitators are used to remove particles from power plant and incinerator stack gases, and depend on thermophoresis and forced diffusion, respectively, for their operation. Diffusion phenomena are unimportant for particles of size greater than about 1 μm in air at 1 atm; the motion of such particles is governed by the laws of Newtonian mechanics. Transport of particles is dealt with in the *aerosol science* literature.

Species Conservation Equation

The principle of conservation of a chemical species is used to derive the *species conservation equation.* On a mass basis this equation is

$$\frac{\partial \rho_i}{\partial t} + \nabla \cdot \boldsymbol{n}_i = \dot{r}_i''' \tag{4.7.27}$$

and on a molar basis

$$\frac{\partial c_i}{\partial t} + \nabla \cdot \boldsymbol{N}_i = \dot{R}_i''' \tag{4.7.28}$$

TABLE 4.7.3 Schmidt Number for Vapors in Dilute Mixture in Air at Normal Temperature, Enthalpy of Vaporization, and Boiling Point at 1 atm[a]

Vapor	Chemical Formula	Sc[b]	h_{fg}, J/kg × 10^{-6}	T_{BP}, K
Acetone	CH_3COCH_3	1.42	0.527	329
Ammonia	NH_3	0.61	1.370	240
Benzene	C_6H_6	1.79	0.395	354

Carbon monoxide	CO	0.77	0.217	81
Chlorine	Cl_2	1.42	0.288	238
Ethanol	CH_3CH_2OH	1.32	0.854	352
Helium	He	0.22	—	4.3
Heptane	C_7H_{16}	2.0	0.340	372
Hydrogen	H_2	0.20	0.454	20.3
Hydrogen sulfide	H_2S	0.94	0.548	213
Methanol	CH_3OH	0.98	1.110	338
Naphthalene	$C_{10}H_8$	2.35[c]	—	491
Nitric oxide	NO	0.87	0.465	121
Octane	C_8H_{18}	2.66	0.303	399
Oxygen	O_2	0.83	0.214	90.6
Pentane	C_5H_{12}	1.49	0.357	309
Sulfur dioxide	SO_2	1.24	0.398	263
Water vapor	H_2O	0.61	2.257	373

[a] With the Clausius-Clapeyron relation, one may estimate vapor pressure as

$$P_{\text{sat}} \simeq \exp\left\{-\frac{Mh_{fg}}{\mathcal{R}}\left(\frac{1}{T}-\frac{1}{T_{BP}}\right)\right\} \text{ atm} \quad \text{for } T \sim T_{BP}$$

[b] The Schmidt number is defined as Sc = $\mu/\rho\mathcal{D} = \nu/\mathcal{D}$. Since the vapors are in small concentrations, values for μ, ρ, and ν can be taken as pure air values.

[c] From a recent study by Cho, C., Irvine, T.F., Jr., and Karni, J. 1992. Measurement of the diffusion coefficient of naphthalene into air, *Int. J. Heat Mass Transfer*, 35, 957–966. Also, $h_{sg} = 0.567 \times 10^6$ J/kg at 300 K.

where $\dot{r}_i'''$ and $\dot{R}_i'''$ are the mass and molar rates of production of species i due to chemical reactions. Summing Equation 4.7.27 over all species gives the mass conservation or continuity equation,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \boldsymbol{v} = 0 \tag{4.7.29}$$

The molar form is

$$\frac{\partial c}{\partial t} + \nabla \cdot c\boldsymbol{v}^* = \sum_i \dot{R}_i''' \tag{4.7.30}$$

since, in general, moles are not conserved in chemical reactions. A useful alternative form to Equation 4.7.27 can be obtained using Equation (4.7.23a) and Equation (4.7.29) and is

$$\rho \frac{Dm_i}{Dt} = \nabla \cdot \boldsymbol{j}_i + \dot{r}_i''' \tag{4.7.31}$$

where D/Dt is the substantial derivative operator.

If we consider a binary system of species 1 and 2 and introduce Fick's law, Equation (4.7.24a) into Equation (4.7.31), then

$$\rho \frac{Dm_i}{Dt} = \nabla \cdot \left(\rho \mathcal{D}_{12} \nabla m_1\right) + \dot{r}_1''' \tag{4.7.32}$$

TABLE 4.7.4 Schmidt Numbers for Dilute Solution in Water at 300 K[a]

From Spalding, D.B. 1963. *Convective Mass Transfer*, McGraw-Hill, New York. With permission.

When working on a mass basis we define a stationary medium as one in which the mass average velocity $\boldsymbol{v}$ is zero everywhere. Substituting in Equation (4.7.32) with no chemical reactions and assuming constant properties,

$$\frac{\partial m_1}{\partial t} = \mathcal{D}_{12}\nabla^2 m_1 \tag{4.7.33}$$

TABLE 4.7.5 Diffusion Coefficients in Solids, $\mathcal{D} = \mathcal{D}_o \exp(-E_a/\mathcal{R}T)$

System	$\mathcal{D}_o$, m^2/sec	E_a, kJ/kmol

Various sources.

which is the *diffusion* equation, and is the mass transfer analog to Fourier's equation for heat conduction. For steady diffusion, Equation (4.7.33) reduces to Laplace's equation

$$\nabla^2 m_1 = 0 \qquad (4.7.34)$$

Notice that since properties have been assumed constant, any measure of concentration can be used in Equation (4.7.33) and Equation (4.7.34), for example ρ_1, c_1, and x_1.

Diffusion in a Stationary Medium

Many problems involving diffusion in a stationary medium are governed by the diffusion equation (Equation 4.7.33). Often solutions may be obtained from their heat conduction analogs. Some important cases follow.

Steady Diffusion through a Plane Wall

The mass flow of species 1 across a plane wall of thickness L and cross-sectional area A is

$$\dot{m}_1 = \frac{\rho \mathcal{D}_{12} A}{L}\left(m_{1,u} - m_{1,u'}\right) \text{ kg/m}^2 \text{ sec} \qquad (4.7.35)$$

where the u- and u'-surfaces are shown in Figure 4.7.3. Solubility data are required to relate the u- and u'-surface concentrations to s- and s'-surface concentrations. Alternatively for systems that obey Henry's law, a solubility $\mathcal{S}$ can be defined as the volume of solute gas (at STP of 0°C and 1 atm) dissolved in unit volume when the gas is at a partial pressure of 1 atm. Then, defining permeability $\mathcal{P}_{12}$ as the product $\mathcal{D}_{12}\mathcal{S}$, the volume flow of species 1 is

$$\dot{V}_1 = \frac{\mathcal{P}_{12} A}{L}\left(P_{1,s} - P_{1,s'}\right) \text{ m}^3 \text{ (STP)/sec} \qquad (4.7.36)$$

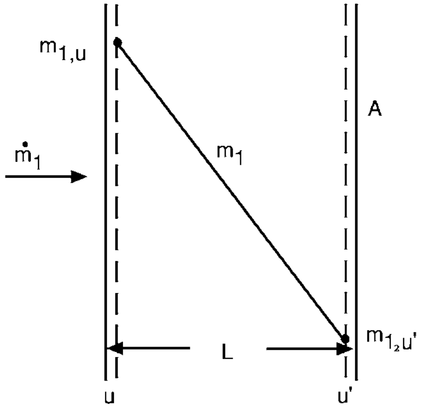

FIGURE 4.7.3 Steady diffusion across a plane wall.

where the partial pressures P_1 are in atmospheres. The SI units for permeability are m^3 (STP)/m^2sec(atm/m). Permeability and solubility data are given in Table 4.7.6. For example, consider helium at 10^5 Pa contained in a 7056-glass vessel with a 1-mm-thick wall at 680 K. For a surface area of 0.01 m^2, the leakage rate into ambient air is

$$\dot{V} = \frac{\left(1.0\times 10^{-12}\right)(0.01)}{(0.001)}\left(10^5 - 0\right) = 1.0\times 10^{-6}\ \text{m}^3\ \text{(STP)/sec}$$

where the value $\mathcal{P}_{12}$ was obtained from Table 4.7.6.

In general, mass fractions are discontinuous across phase interfaces. Hence, Equation (4.7.35) cannot be generalized to a number of walls in series by simply adding diffusion resistances. However, equilibrium partial pressures P_1 are continuous, and for two walls *A* and *B*, Equation 4.7.36 becomes

$$\dot{V}_1 = \frac{P_{1,s} - P_{1,s'}}{\dfrac{L_A}{\mathcal{P}_{1A}A} + \dfrac{L_B}{\mathcal{P}_{1B}A}}\ \text{m}^3\ \text{(STP)/sec} \qquad (4.7.37)$$

Transient Diffusion in a Semi-Infinite Solid

The typically low diffusion coefficients characterizing solids result in many situations where concentration changes are limited to a thin region near the surface (of thickness $\delta_c \sim (\mathcal{D}_{12}t)^{1/2}$). Examples include case-hardening of mild steel and coloring of clear sapphires. Details of the geometry are then unimportant and semi-infinite solid model can be used (Figure 4.7.4). For an initial concentration $m_{1,0}$ and a *u*-surface concentration suddenly changed to $m_{1,u}$ at time $t = 0$, the concentration distribution $m_1(z,t)$ is

$$\frac{m_1 - m_{1,0}}{m_{1,u} - m_{1,0}} = erfc\frac{z}{\left(4\mathcal{D}_{12}t\right)^{1/2}} \qquad (4.7.38)$$

and the dissolution rate is

$$\dot{m}_1 = j_{1,u}A = \rho A\left(\frac{\mathcal{D}_{12}}{\pi t}\right)^{1/2}\left(m_{1,u} - m_{1,0}\right)\ \text{kg/sec} \qquad (4.7.39)$$

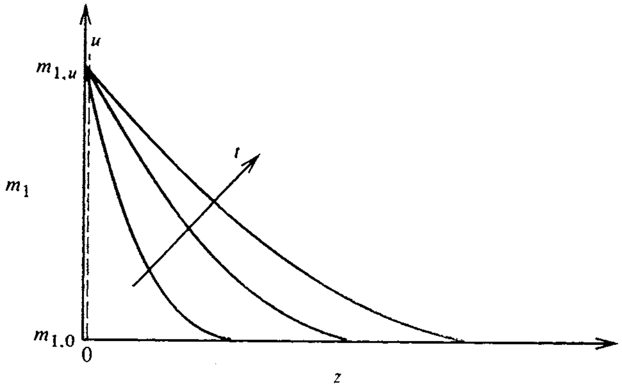

FIGURE 4.7.4 Transient diffusion in a plane slab.

For example, consider a Pyrex glass slab at 800 K suddenly exposed to helium at 10^4 Pa. The molar equivalent to Equation (4.7.39) for an assumed constant solid phase molar concentration c is

$$\frac{\dot{M}_1}{A} = \left(\frac{\mathcal{D}_{12}}{\pi t}\right)^{1/2} \left(c_{1,u} - c_{1,0}\right)$$

From Table 4.7.6, $\mathcal{S}' = c_{1,u}/c_{1,s} \cong 0.024$; hence, $c_{1,u} = (0.024)(10^4)/(8314)(800) = 3.61 \times 10^{-5}$ kmol/m^3. From Table 4.7.4, $\mathcal{D}_{12} = 4.76 \times 10^{-8} \exp[-(2.72 \times 10^4)(10^3)/(8314)(800)] = 7.97 \times 10^{-10}$ m^2/sec. Hence,

$$\frac{\dot{M}_1}{A} = \left(\frac{7.97 \times 10^{-10}}{\pi t}\right)^{1/2} \left(3.61 \times 10^{-5} - 0\right) = 5.75 \times 10^{-10}/t \text{ kmol/sec}$$

Transient Diffusion in Slabs, Cylinders, and Spheres

Transient heat conduction in slates, cylinders, and spheres with surface convection is dealt with in Section 4.1. The analogous mass diffusion problem for the slab $-L < z < L$ is now considered. On a molar basis the governing differential equation is

$$\frac{\partial x_1}{\partial t} = \mathcal{D}_{12} \frac{\partial^2 x_1}{\partial z^2} \tag{4.7.40}$$

with initial condition $x_1 = x_{1,0}$ at $t = 0$. Boundary conditions are $\partial x_1/\partial z = 0$ at $z = 0$, and at the surface $z = L$,

$$-c\mathcal{D}_{12} \left.\frac{\partial x_1}{\partial z}\right|_{z=L} = \mathcal{G}_{m1}\left(y_{1,s} - y_{1,e}\right) \tag{4.7.41}$$

The convective boundary condition is of the same form as Newton's law of cooling, and defines the mole transfer conductance $\mathcal{G}_{m1}$ (kmol/m^{2}sec) (see also the section on mass and mole transfer conductances). Also, we have followed chemical engineering practice and denoted mole fraction x in the solid (or liquid) phase and y in the liquid (or gas) phase, to emphasize that generally mole fraction is not continuous across a phase interface. For example, consider absorption of a sparingly soluble gas into a liquid for which Henry's law, Equation (4.7.13), applies: then $y_{1,s} = \text{He}x_{1,u}$.

In using heat conduction charts for mass diffusion problems, particular care must be taken with the evaluation of the Biot number. For heat conduction Bi = h_cL/k, where k is the solid conductivity. For mass diffusion the Biot number accounts for the discontinuity in concentration across the phase interface.

Using gas absorption into a plane layer of liquid, for example, when Equation (4.7.41) is put into an appropriate dimensionless form, the mass transfer Biot number is seen to be

$$\mathrm{Bi}_m = \frac{\mathcal{G}_{m1}\mathrm{He}L}{c\mathcal{D}_{12}} \tag{4.7.42}$$

For sparingly soluble gases, e.g., O_2 or CO_2 in water, He, and hence Bi_m, are very large, and the absorption process is liquid-side controlled; that is, a uniform gas-phase composition can be assumed. Often interface equilibrium data are in graphical or tabular form; then an effective Biot number at the concentration of concern must be used.

For example, consider a 2-mm-diameter droplet of water at 300 K entrained in an air flow at 1 atm pressure containing 1% by volume CO_2. From Table 4.7.5, He = C_{He}= 1710. The liquid phase molar density can be approximated by the pure water value of $c = \rho/M = 996/18 = 55.3$ kmol/m^3. The liquid phase diffusion coefficient is obtained from Table 4.7.4 as $\mathcal{D}_{12} = \nu_{H_2O}/Sc_{12} = 0.87 \times 10^{-6}/420 = 2.07 \times 10^{-9}$ m^2/sec. For negligible relative motion between the droplet and gas, the Sherwood number (see the section on dimensionless groups) is approximately 2.0, and hence the gas phase mole transfer conductance is $\mathcal{G}_{m1} = 2c\mathcal{D}_{12}/\mathcal{D}$. For the gas phase, the molar density $c = \mathcal{P}/\mathcal{R}T = (1.0133 \times 10^5)/(8314)(300) = 0.0406$ kmol/m^3 and $\mathcal{D}_{12} = 0.157 \times 10^{-4}$ m^2/sec from Table 4.7.2. Thus,

$$\mathcal{G}_{m1} = \frac{(2)(0.0406)\left(0.157\times10^{-4}\right)}{(0.002)} = 6.37\times10^{-4}\ \mathrm{kmol/m^2\,sec}$$

From Equation 4.7.42 with $L = R$ the droplet radius, the mass transfer Biot number is

$$\mathrm{Bi}_m = \frac{\left(6.37\times10^{-4}\right)(1710)(0.001)}{(55.3)\left(2.07\times10^{-9}\right)} = 9520$$

Thus, even for a small droplet with a relatively large gas-side mole transfer conductance, the absorption process is liquid-side controlled.

Diffusion in a Porous Catalyst

Porous catalysts are used to give a large surface area per unit volume of catalyst surface. Current practice for automobile catalytic convertors is to use a ceramic matrix as a support for a thin porous alumina layer that is impregnated with the catalyst (called a *washcoat*). A typical matrix has passages of hydraulic diameter 1 mm, and the washcoat may be about 20 μm thick. Pore sizes are of the order of 1 μm for which ordinary and Knudsen diffusion resistances are important. A simple model for diffusion in a porous catalyst is

$$\mathbf{J}_1 = -c\mathcal{D}_{1,\mathrm{eff}}\nabla x_1\ \mathrm{kmol/m^2\,sec} \tag{4.7.43}$$

where the subscript eff denotes an effective diffusivity that accounts for the presence of the solid material. Assuming additive resistances,

$$\frac{1}{\mathcal{D}_{1,\mathrm{eff}}} = \frac{1}{\mathcal{D}_{12,\mathrm{eff}}} + \frac{1}{\mathcal{D}_{K1,\mathrm{eff}}} \tag{4.7.44}$$

and

$$\mathcal{D}_{12,\mathrm{eff}} = \frac{\varepsilon_v}{\tau}\mathcal{D}_{12}; \qquad \mathcal{D}_{K1,\mathrm{eff}} = \frac{\varepsilon_v}{\tau}\mathcal{D}_{K1,\mathrm{eff}} \tag{4.7.45}$$

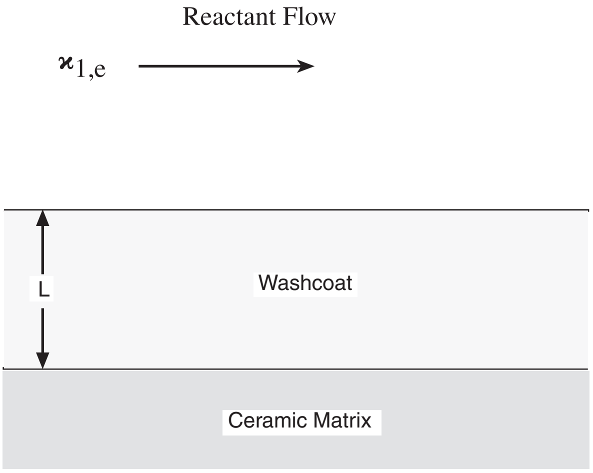

FIGURE 4.7.5 A catalyst layer.

where ε_v is the volume void fraction and τ is the tortuosity factor (usually between 4 and 8). From the kinetic theory of gases the Knudsen diffusion coefficient is

$$\mathcal{D}_{K1} = 97 r_e \left(T/M_1\right)^{1/2} \text{ m}^2/\text{sec} \tag{4.7.46}$$

for effective pore radius r_e in meters and T in kelvins.

When a chemical reaction takes place within a porous layer, a concentration gradient is set up, and surfaces on pores deep within the pellet are exposed to lower reactant concentrations than surfaces near the pore openings. For a first-order reaction it is straightforward to obtain the concentration distribution. The results of such an analysis are conveniently given in the form of an effectiveness η_p, which is defined as the actual consumption rate of the reactant divided by that for an infinite diffusion coefficient. For a layer of thickness L exposed to reactants on one side, as shown in Figure 4.7.5.

$$\eta_p = \frac{\tanh bL}{bL}; \qquad b = \left(\frac{k'' a_P}{\mathcal{D}_{1,\text{eff}}}\right)^{1/2} \tag{4.7.47}$$

where k'' (m/sec) is the rate constant for a first-order reaction and a_p (m^{-1}) is the catalyst area per unit volume. Notice that this effectiveness is analogous to the efficiency of a heat transfer fin.

For example, consider a 30-μm-thick porous alumina washcoat with a volume void fraction $\varepsilon_v = 0.8$, a tortuosity factor $\tau = 4.0$, average pore radius $r_e = 1$ μm, and catalytic surface area per unit volume $a_p = 7.1 \times 10^5$ cm^2/cm^3. For carbon monoxide oxidation by copper oxide at 800 K, 1 atm, the rate constant is approximately 4.2×10^{-4} m^2/sec. To calculate the effectiveness of the washcoat, we first need to calculate the effective diffusion coefficient $\mathcal{D}_{1,\text{eff}}$:

$$\mathcal{D}_{12,\text{eff}} = \frac{\varepsilon_v}{\tau}\mathcal{D}_{12} = \frac{0.8}{4.0}\left(1.06 \times 10^{-4}\right) = 2.12 \times 10^{-5} \text{ m}^2/\text{sec}$$

where $\mathcal{D}_{12}$ is approximated as the CO-air value from Table 4.7.2.

$$\mathcal{D}_{K1,\text{eff}} = \frac{\varepsilon_v}{\tau}\mathcal{D}_{12} = \frac{0.8}{4.0}(97)\left(1 \times 10^{-6}\right)(800/28)^{1/2} = 1.04 \times 10^{-4} \text{ m}^2/\text{sec}$$

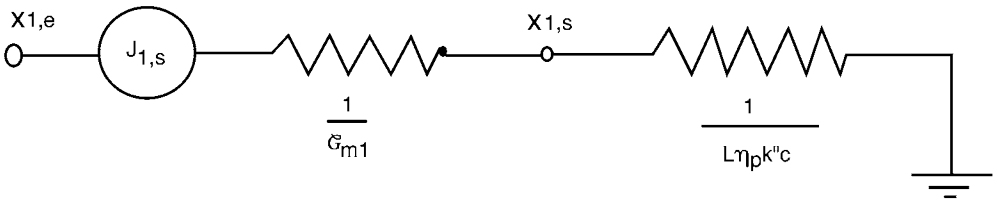

FIGURE 4.7.6 Equivalent circuit for mass transfer in an automobile catalytic convertor.

$$\frac{1}{\mathcal{D}_{1,\mathrm{eff}}} = \frac{1}{2.12\times10^{-5}} + \frac{1}{1.04\times10^{-4}}; \qquad \mathcal{D}_{1,\mathrm{eff}} = 1.76\times10^{-5}\ \mathrm{m^2/sec}$$

$$b = \left[\frac{\left(4.2\times10^{-4}\right)\left(7.1\times10^{5}\right)\left(10^{2}\right)}{1.76\times10^{-5}}\right]^{1/2} = 4.2\times10^{4}\ \mathrm{m^{-1}}; \qquad bL = \left(4.2\times10^{4}\right)\left(30\times10^{-6}\right) = 1.236$$

$$\eta_P = \frac{\tanh 1.236}{1.236} = 68.3\%$$

In an automobile catalytic convertor, Equation 4.7.47 applies to the catalyst washcoat. However, the mass transfer problem also involves a convective process for transport of reactants from the bulk flow. Referring to Figure 4.7.6 there are two mass transfer resistances in series, and the consumption rate of species 1 per unit surface area of the washcoat is

$$J_{1,s} = \frac{-x_{1,e}}{\dfrac{1}{L\eta_p k''c} + \dfrac{1}{\mathcal{G}_{m1}}}\ \mathrm{kmol/m^2\ sec} \tag{4.7.48}$$

where $\mathcal{G}_{m1}$ is the mole transfer conductance describing convective transport to the washcoat surface (see the section on mass and mole transfer conductances). Notice that when $\mathcal{G}_{m1} \lll L\eta_p k''c$ the reaction rate is controlled by mass transfer from the gas stream to the washcoat surface; when $L\eta_p k''c \lll \mathcal{G}_{m1}$, the reaction rate is controlled by diffusion within the washcoat and the kinetics of the reaction.

Diffusion in a Moving Medium

Net mass transfer across a surface results in a velocity component normal to the surface, and an associated convective flux in the direction of mass transfer. This convective flow is called a *Stefan flow*. The solutions of a number of mass transfer problems, involving a Stefan flow induced by the mass transfer process itself, follow. When necessary to obtain an analytical result, properties are assumed constant. Thus, use of these results requires evaluation of properties at a suitable reference state.

Diffusion with One Component Stationary

As an example, consider the simple heat pipe shown in Figure 4.7.7 with the evaporator and condenser located at the ends only (a bad design!). Then, if the working fluid is species 1, and a noncondensable gas is species 2, the concentration distribution is

$$\left(\frac{1-x_1}{1-x_{1,s}}\right) = \left(\frac{1-x_{1,e}}{1-x_{1,s}}\right)^{z/L} \tag{4.7.49}$$

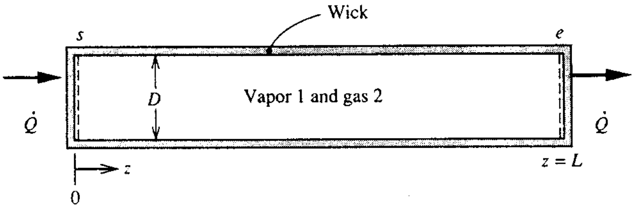

FIGURE 4.7.7 A simple heat pipe with the evaporator and condenser located at its ends.

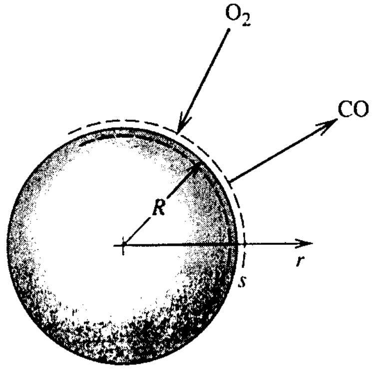

FIGURE 4.7.8 Combustion of a carbon particle in high-temperature air. The surface reaction is 2C + $O_2 \rightarrow$ 2CO.

and the vapor flux along the heat pipe is

$$N_1 = \frac{c\mathcal{D}_{12}}{L} \ln \frac{1 - x_{1,e}}{1 - x_{1,s}} \text{ kmol/m}^2 \text{ sec} \tag{4.7.50}$$

Notice that $N_2 = 0$; that is, the gas is stationary. The rate of heat flow for a heat pipe of cross-sectional area of A_c is $\dot{Q} = N_1 M_1 h_{fg} A_c$. Evaluation of the $c\mathcal{D}$ product at a reference temperature $T_r = (1/2)(T_s + T_e)$ is adequate for most applications. Equation (4.7.50) applies to any situation where a one-dimensional model of mass transport is appropriate.

Heterogeneous Combustion

As an example, consider a small carbon particle entrained in a high-temperature airstream, as shown in Figure 4.7.8. The surface reaction is 2C + $O_2 \rightarrow$ 2CO and there are no reactions in the gas phase. The stoichiometric ratio for the reaction is $r = 4/3$ kg oxygen/kg carbon. The reaction is diffusion controlled at the temperatures under consideration, that is, $m_{O_2,s} \simeq 0$. The mass transfer rate is n_s, which we give the distinctive symbol $\dot{m}''$ since it is usually the desired result of an analysis; in this situation $\dot{m}'' = n_{C,u}$ is the combustion rate of carbon, and for a spherical particle of radius R is given by

$$\dot{m}'' = \frac{\rho\mathcal{D}_{O_2,m}}{R} \ln\left[1 + \frac{m_{O_2,e} - m_{O_2,s}}{m_{O_2,s} + 4/3}\right] = 0.160 \frac{\rho\mathcal{D}_{O_2,m}}{R} \text{ kg/m}^2 \text{ sec} \tag{4.7.51}$$

The carbon particle temperature depends on its radius, and it is required to evaluate the property product $\rho\mathcal{D}$ at an appropriate reference temperature: an energy balance on the particle should be performed by this purpose. The resulting particle lifetime τ is

$$\tau = \frac{\rho_{\text{solid}} D_O^2}{1.28\left(\rho\mathcal{D}_{O_2,m}\right)_r} \text{ sec} \tag{4.7.52}$$

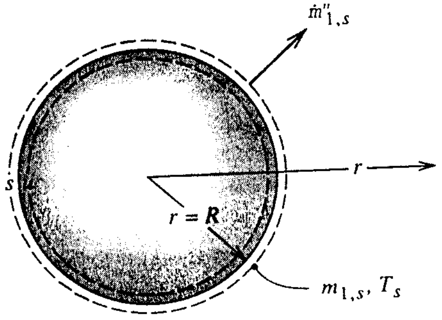

FIGURE 4.7.9 Evaporation of a droplet.

for an initial particle diameter of D_0. Air properties at an average mean film temperature can be used to evaluate $\rho\mathcal{D}_{O_2,m}$.

Consider a 10-μm-diameter carbon particle ignited in an airstream at 1500 K and 1 atm. An energy balance on the particle (including radiation to surroundings at 1500 K) shows that the average temperature of the particle is approximately 2550 K, and, thus, $T_r = (1/2)(1500 + 2550) = 2025$ K or $\rho \simeq \rho_{air} = 0.175$ kg/m^3 and $\mathcal{D}_{O_2,m} \simeq \mathcal{D}_{O_2,air} = 4.89 \times$ m^2/sec (from Table 4.7.1). Then

$$\tau = \frac{(1810)\left(10\times 10^{-6}\right)^2}{(1.28)(0.175)\left(4.89\times 10^{-4}\right)} = 1.65\times 10^{-3} \text{ sec}$$

Droplet Evaporation

Consider a small droplet of species 1 entrained in a gas stream, species 2 (Figure 4.7.9). This is a simultaneous heat and mass transfer problem, and the mass transfer rate can be obtained by solving simultaneously

$$\dot{m}'' = \frac{\rho\mathcal{D}_{12}}{R}\ln\left(1+\frac{m_{1,e}-m_{1,s}}{m_{1,s}-1}\right) = \frac{k/c_{p1}}{R}\ln\left(1+\frac{c_{p1}\left(T_e-T_s\right)}{h_{fg}}\right) \text{kg/m}^2 \text{ sec} \tag{4.7.53a}$$

$$m_{1,s} = m_{1,s}(T,P) \qquad \text{(from vapor−pressure data)} \tag{4.7.53b}$$

Temperature T_s is the adiabatic vaporization temperature and is essentially the psychrometric wet-bulb temperature. Properties can be evaluated at mean film temperature and composition; alternatively, c_{p1} can be set equal to the reference specific heat and all properties evaluated using Hubbard's $^1/_3$ rule, namely,

$$m_{1,r} = m_{1,s} + (1/3)\left(m_{1,e} - m_{1,s}\right) \tag{4.7.54a}$$

$$T_r = T_s + (1/3)\left(T_e - T_s\right) \tag{4.7.54b}$$

Droplet Combustion

Figure 4.7.10 shows a schematic of a volatile liquid hydrocarbon fuel droplet burning in air at zero gravity. The flame diameter is typically four to six times the droplet diameter. Heat is transferred from the flame to the droplet and serves to vaporize the fuel. In the flame the vapor reacts with oxygen to form gaseous products, primarily CO_2 and H_2O. When a fuel droplet ignites, there is a short initial transient during which the droplet heats up, until further conduction into the droplet is negligible and the droplet attains a steady temperature (approximately the wet-bulb temperature, which is very close to the boiling point

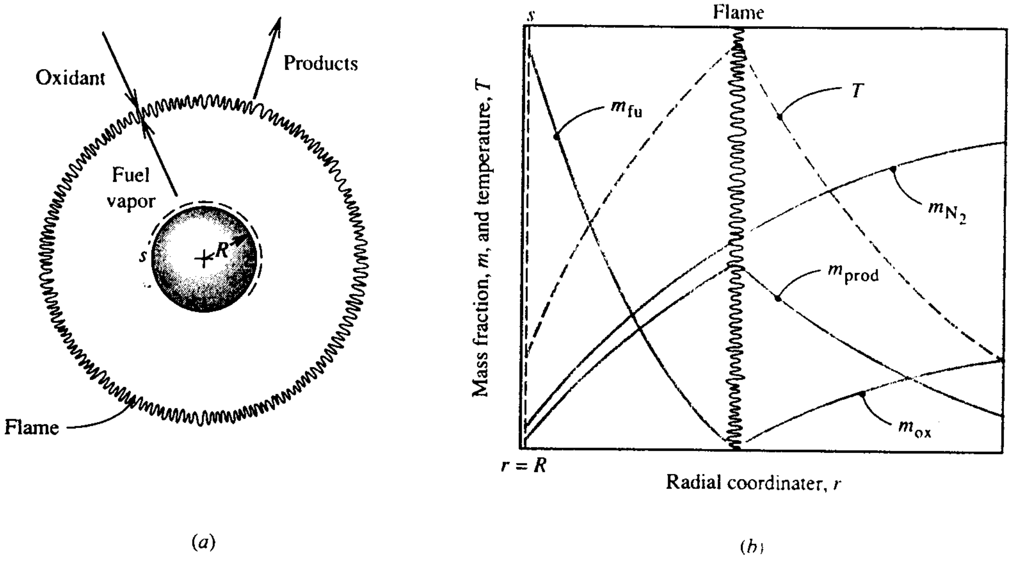

FIGURE 4.7.10 Combustion of a volatile fuel droplet burning in air: (a) schematic showing the flame, (b) concentration and temperature profiles.

for a typical hydrocarbon fuel). The reaction in the flame can be modeled as a single-step reaction with a constant stoichiometric ratio, r, and heat of combustion Δh_c J/kg of fuel.

The burning (mass transfer) rate of the droplet is given by the Godsave–Spalding formula,

$$\dot{m}'' = \frac{k/c_p}{R} \ln[1 + \mathcal{B}] \text{ kg/m}^2 \text{ sec} \tag{4.7.55}$$

where

$$\mathcal{B} = \frac{m_{ox,e}\,\Delta h_c / r + c_p\left(T_e - T_s\right)}{h_{fg}}$$

is the *mass transfer driving force* (or *transfer number*). The droplet lifetime is then

$$\tau = \frac{\rho_l D_O^2}{8\left(k/c_p\right)\ln(1 + \mathcal{B})} \text{ sec} \tag{4.7.56}$$

Based on experimental data for alkane droplets burning in air, Law and Williams (1972) recommend that properties be evaluated at a reference temperature $T_r = (1/2)(T_{BP} + T_{\text{flame}})$ where T_{flame} is the adiabatic flame temperature. The reference specific heat is $c_{pr} = c_{pfu}$, and the reference thermal conductivity is $k_r = 0.4k_{fu} + 0.6k_{\text{air}}$. Radiation has been ignored in the analysis leading to Equation (4.7.55) but is accounted for in using the Law and Williams reference-property scheme.

For example, consider a 1-mm-diameter n-octane droplet burning in air at 1 atm and 300 K, at near zero gravity. For n-octane (n-C_8H_{18}), $\rho_l = 611$ kg/m^3, $h_{fg} = 3.03 \times 10^5$ J/kg, $\Delta h_c = 4.44 \times 10^7$ J/kg, and $T_{BP} = 399$ K. The flame temperature is $T_{\text{flame}} = 2320$ K. At a reference temperature of (1/2) ($T_{\text{flame}} + T_{BP}$) = 1360 K, property values of n-octane vapor include $k = 0.113$ W/m K, $c_p = 4280$ J/kg K. The reaction is

$$C_8H_{18} + 12.5O_2 \rightarrow 8CO_2 + 9H_2O$$

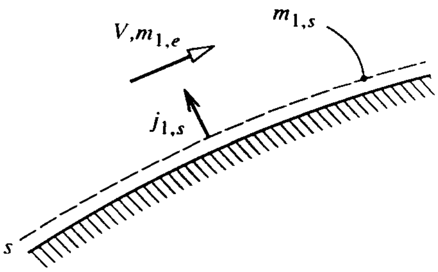

FIGURE 4.7.11 Notation for convective mass transfer into an external flow.

Hence, the stoichiometric ratio $r = 400/114.2 = 3.50$. Also $m_{ox,e} = 0.231$ and $T_s \cong T_{BP} = 399$ K. Thus, the transfer number is

$$\mathcal{B} = \frac{(0.231)\left(4.44\times10^7\right)/(3.50) + 4280(300-399)}{3.03\times10^5} = 8.27$$

At $T_r = 1360$ K, $k_{\text{air}} = 0.085$ W/m K. Hence,

$$k_r = 0.4k_{fu} + 0.6k_{\text{air}} = (0.4)(0.113) + (0.6)(0.085) = 0.096 \text{ W/m K}$$

and the droplet lifetime is

$$\tau = \frac{(611)\left(1\times10^{-3}\right)^2}{(8)(0.096/4280)\ln(1+8.27)} = 1.53 \text{ sec}$$

Mass Convection

The terms *mass convection* or *convective mass transfer* are generally used to describe the process of mass transfer between a surface and a moving fluid, as shown in Figure 4.7.11. The surface may be that of a falling water film in an air humidifier, of a coke particle in a gasifier, or of a silica-phenolic heat shield protecting a reentry vehicle. As is the case for heat convection, the flow can be *forced* or *natural, internal* or *external,* and *laminar* or *turbulent*. In addition, the concept of whether the mass transfer rate is *low* or *high* plays an important role: when mass transfer rates are low, there is a simple analogy between heat transfer and mass transfer that can be efficiently exploited in the solution of engineering problems.

Mass and Mole Transfer Conductances

Analogous to convective heat transfer, the rate of mass transfer by convection is usually a complicated function of surface geometry and *s*-surface composition, the fluid composition and velocity, and fluid physical properties. For simplicity, we will restrict our attention to fluids that are either binary mixtures or solutions, or situations in which, although more than two species are present, diffusion can be adequately described using effective binary diffusion coefficients, as was discussed in the section on ordinary diffusion. Referring to Figure 4.7.11, we define the *mass transfer conductance* of species 1, g_{m1}, by the relation

$$j_{1,s} = g_{m1}\,\Delta m_1; \qquad \Delta m_1 = m_{1,s} - m_{1,e} \tag{4.7.57}$$

and the units of g_{m1} are seen to be the same as for mass flux (kg/m^{2}sec). Equation (4.7.57) is of a similar form to Newton's law of cooling, which defines the heat transfer coefficient h_c. Why we should not use a similar name and notation (e.g., mass transfer coefficient and h_m) will become clear later. On a molar basis, we define the *mole transfer conductance* of species 1, $\mathcal{G}_{m1}$, by a corresponding relation,

$$J_{1,s} = \mathcal{G}_{m1}\,\Delta x_1; \qquad \Delta x_1 = x_{1,s} - x_{1,e} \tag{4.7.58}$$

where $\mathcal{G}_{m1}$ has units (kmol/m^{2}sec).

Low Mass Transfer Rate Theory

Consider, as an example, the evaporation of water into air, as shown in Figure 4.7.12. The water–air interface might be the surface of a water reservoir, or the surface of a falling water film in a cooling tower or humidifier. In such situations the mass fraction of water vapor in the air is relatively small; the highest value is at the s-surface, but even if the water temperature is as high as 50°C, the corresponding value of $m_{H_2O,s}$ at 1 atm total pressure is only 0.077. From Equation 4.7.54 the driving potential for diffusion of water vapor away from the interface is $\Delta m_1 = m_{1,s} - m_{1,e}$, and is small compared to unity, even if the free-stream air is very dry such that $m_{1,e} \simeq 0$. We then say that the mass transfer rate is *low* and the rate of evaporation of the water can be approximated as $j_{1,s}$; for a surface area A,

$$\dot{m}_1 = \left(m_{1,s} n_s + j_{1,s}\right) A \simeq j_{1,s} A \text{ kg/sec} \tag{4.7.59}$$

In contrast, if the water temperature approaches its boiling point, $m_{1,s}$ is no longer small, and of course, in the limit of $T_s = T_{BP}$, $m_{1,s} = 1$. The resulting driving potential for diffusion Δm_1 is then large, and we say that the mass transfer rate is *high*. Then, the evaporation rate cannot be calculated from Equation 4.7.59, as will be explained in the section on high mass transfer rate theory. For water evaporation into air, the error incurred in using low mass transfer rate theory is approximately $(^1/_2)\ \Delta m_1$, and a suitable criterion for application of the theory to engineering problems is $\Delta m_1 < 0.1$ or 0.2.

A large range of engineering problems can be adequately analyzed assuming low mass transfer rates. These problems include cooling towers and humidifiers as mentioned above, gas absorbers for sparingly soluble gases, and catalysis. In the case of catalysis, the *net* mass transfer rate is actually zero. Reactants diffuse toward the catalyst surface and the products diffuse away, but the catalyst only promotes the reaction and is not consumed. On the other hand, problems that are characterized by high mass transfer rates include condensation of steam containing a small amount of noncondensable gas, as occurs in most power plant condensers; combustion of volatile liquid hydrocarbon fuel droplets in diesel engines and oil-fired power plants, and ablation of phenolic-based heat shields on reentry vehicles.

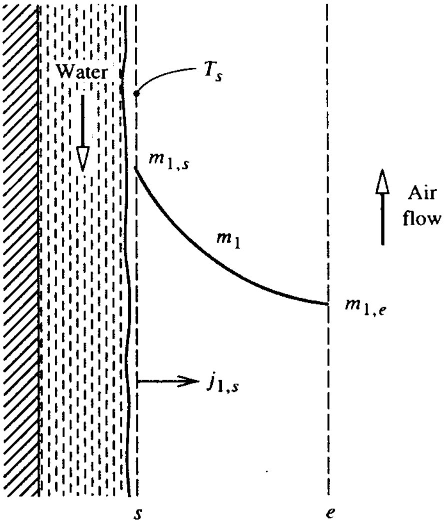

FIGURE 4.7.12 Evaporation of water into an air flow.

Dimensionless Groups

Dimensional analysis of convective mass transfer yields a number of pertinent dimensionless groups that are, in general, analogous to dimensionless groups for convective heat transfer. The most important groups are as follows.

1. The Schmidt number, $\mathrm{Sc}_{12} = \mu/\rho\mathcal{D}_{12}$, which is a properties group analogous to the Prandtl number. For gas mixtures, $\mathrm{Sc}_{12} = O(1)$, and for liquid solutions, $\mathrm{Sc}_{12} = O(100)$ to $O(1000)$. There are not fluids for which $\mathrm{Sc}_{12} \ll 1$, as is the case of Prandtl number for liquid metals.
2. The Sherwood number (or mass transfer Nusselt number). $\mathrm{Sh} = g_{m1}L/\rho\mathcal{D}_{12}$ $(= \mathcal{G}_{m1}L/c\mathcal{D}_{12})$ is a dimensionless conductance.
3. The mass transfer Stanton number $\mathrm{St}_m = g_{\mathrm{m1}}/\rho V$ $(= \mathcal{G}_{m1}/cV)$ is an alternative dimensionless conductance.

As for convective heat transfer, forced convection flows are characterized by a Reynolds number, and natural convection flows are characterized by a Grashof or Rayleigh number. In the case of Gr or Ra it is not possible to replace $\Delta\rho$ by $\beta\Delta T$ since density differences can result from concentration differences (and both concentration and temperature differences for simultaneous heat and mass transfer problems).

Analogy between Convective Heat and Mass Transfer

A close analogy exists between convective heat and convective mass transfer owing to the fact that conduction and diffusion in a fluid are governed by physical laws of identical form, that is, Fourier's and Fick's laws, respectively. As a result, in many circumstances the Sherwood or mass transfer Stanton number can be obtained in a simple manner from the Nusselt number or heat transfer Stanton number for the same flow conditions. Indeed, in most gas mixtures Sh and St_m are nearly equal to their heat transfer counterparts. For dilute mixtures and solutions and low mass transfer rates, the rule for exploiting the analogy is simple: The *Sherwood or Stanton number is obtained by replacing the Prandtl number by the Schmidt number in the appropriate heat transfer correlation*. For example, in the case of fully developed turbulent flow in a smooth pipe

$$\mathrm{Nu}_D = 0.023\mathrm{Re}_D^{0.8}\mathrm{Pr}^{0.4}; \qquad \mathrm{Pr} > 0.5 \tag{4.7.60a}$$

which for mass transfer becomes

$$\mathrm{Sh}_D = 0.023\mathrm{Re}_D^{0.8}\mathrm{Sc}^{0.4}; \qquad \mathrm{Sc} > 0.5 \tag{4.7.60b}$$

Also, for natural convection from a heated horizontal surface facing upward,

$$\overline{\mathrm{Nu}} = 0.54\left(\mathrm{Gr}_L\mathrm{Pr}\right)^{1/4}; \qquad 10^5 < \mathrm{Gr}_L\mathrm{Pr} < 2\times10^7 \quad \text{(laminar)} \tag{4.7.61a}$$

$$\overline{\mathrm{Nu}} = 0.14\left(\mathrm{Gr}_L\mathrm{Pr}\right)^{1/3}; \qquad 2\times10^7 < \mathrm{Gr}_L\mathrm{Pr} < 3\times10^{10} \quad \text{(turbulent)} \tag{4.7.61b}$$

which for isothermal mass transfer with $\rho_s < \rho_e$ become

$$\overline{\mathrm{Sh}} = 0.54\left(\mathrm{Gr}_L\mathrm{Sc}\right)^{1/4}; \qquad 10^5 < \mathrm{Gr}_L\mathrm{Sc} < 2\times10^7 \quad \text{(laminar)} \tag{4.7.62a}$$

$$\overline{\mathrm{Sh}} = 0.14\left(\mathrm{Gr}_L\mathrm{Sc}\right)^{1/3}; \qquad 2\times10^7 < \mathrm{Gr}_L\mathrm{Sc} < 3\times10^{10} \quad \text{(turbulent)} \tag{4.7.62b}$$

With evaporation, the condition, $\rho_s < \rho_e$ will be met when the evaporating species has a smaller molecular weight than the ambient species, for example, water evaporating into air. Mass transfer correlations can be written down in a similar manner for almost all the heat transfer correlations given in Section 4.2. There are some exceptions: for example, there are no fluids with a Schmidt number much less than unity, and thus there are no mass transfer correlations corresponding to those given for heat transfer to liquid metals with $\mathrm{Pr} \ll 1$. In most cases it is important for the wall boundary conditions to be of analogous form, for example, laminar flow in ducts. A uniform wall temperature corresponds to a uniform concentration $m_{1,s}$ along the *s*-surface, whereas a uniform heat flux corresponds to a uniform diffusive flux $j_{1,s}$. In chemical engineering practice, the analogy between convective heat and mass transfer is widely used in a form recommended by Chilton and Colburn in 1934, namely, $\mathrm{St}_m/\mathrm{St} = (\mathrm{Sc}/\mathrm{Pr})^{-2/3}$. The Chilton-Colburn form is of adequate accuracy for most external forced flows but is inappropriate for fully developed laminar duct flows.

For example, air at 1 atm and 300 K flows inside a 3-cm-inside-diameter tube at 10 m/sec. Using pure-air properties the Reynolds number is $VD/\nu = (10)(0.03)/15.7 \times 10^{-6} = 1.911 \times 10^4$. The flow is turbulent. Using Equation (4.7.60b) with $\mathrm{Sc}_{12} = 0.61$ for small concentrations of H_2O in air,

$$\mathrm{Sh}_D = (0.023)\left(1.911\times 10^4\right)^{0.8}(0.61)^{0.4} = 50.2$$

$$g_{m1} = \rho\mathcal{D}_{12}\mathrm{Sh}/D = \rho\nu\mathrm{Sh}/\mathrm{Sc}_{12}D = \frac{(1.177)\left(15.7\times 10^{-6}\right)(50.2)}{(0.61)(0.03)} = 5.07\times 10^{-2}\ \mathrm{kg/m^2\ sec}$$

Further insight into this analogy between convective heat and mass transfer can be seen by writing out Equation (4.7.60a) and Equation (4.7.60b) as, respectively,

$$\frac{\left(h_c/c_p\right)D}{k/c_p} = 0.023\mathrm{Re}_D^{0.8}\left(\frac{\mu}{k/c_p}\right)^{0.4} \tag{4.7.63a}$$

$$\frac{g_m D}{\rho\mathcal{D}_{12}} = 0.023\mathrm{Re}_D^{0.8}\left(\frac{\mu}{\rho\mathcal{D}_{12}}\right)^{0.4} \tag{4.7.63b}$$

When cast in this form, the correlations show that the property combinations k/c_p and $\rho\mathcal{D}_{12}$ play analogous roles; these are *exchange coefficients* for heat and mass, respectively, both having units kg/m sec, which are the same as those for dynamic viscosity μ. Also, it is seen that the ratio of heat transfer coefficient to specific heat plays an analogous role to the mass transfer conductance, and has the same units (kg/m^2 sec). Thus, it is appropriate to refer to the ratio h_c/c_p as the *heat transfer conductance*, g_h, and for this reason we should not refer to g_m as the mass transfer *coefficient*.

Simultaneous Heat and Mass Transfer

Often problems involve simultaneous convective heat and mass transfer, for which the surface energy balance must be carefully formulated. Consider, for example, evaporation of water into air, as shown in Figure 4.7.13. With H_2O denoted as species 1, the steady-flow energy equation applied to a control volume located between the *u*- and *s*-surfaces requires that

$$\dot{m}\left(h_{1,s} - h_{1,u}\right) = A\left(q''_{\mathrm{cond}} - q''_{\mathrm{conv}} - q''_{\mathrm{rad}}\right)\ \mathrm{W} \tag{4.7.64}$$

where it has been recognized that only species 1 crosses the *u*- and *s*-surfaces. Also, the water has been assumed to be perfectly opaque so that all radiation is emitted or absorbed between the *u*-surface and the interface.

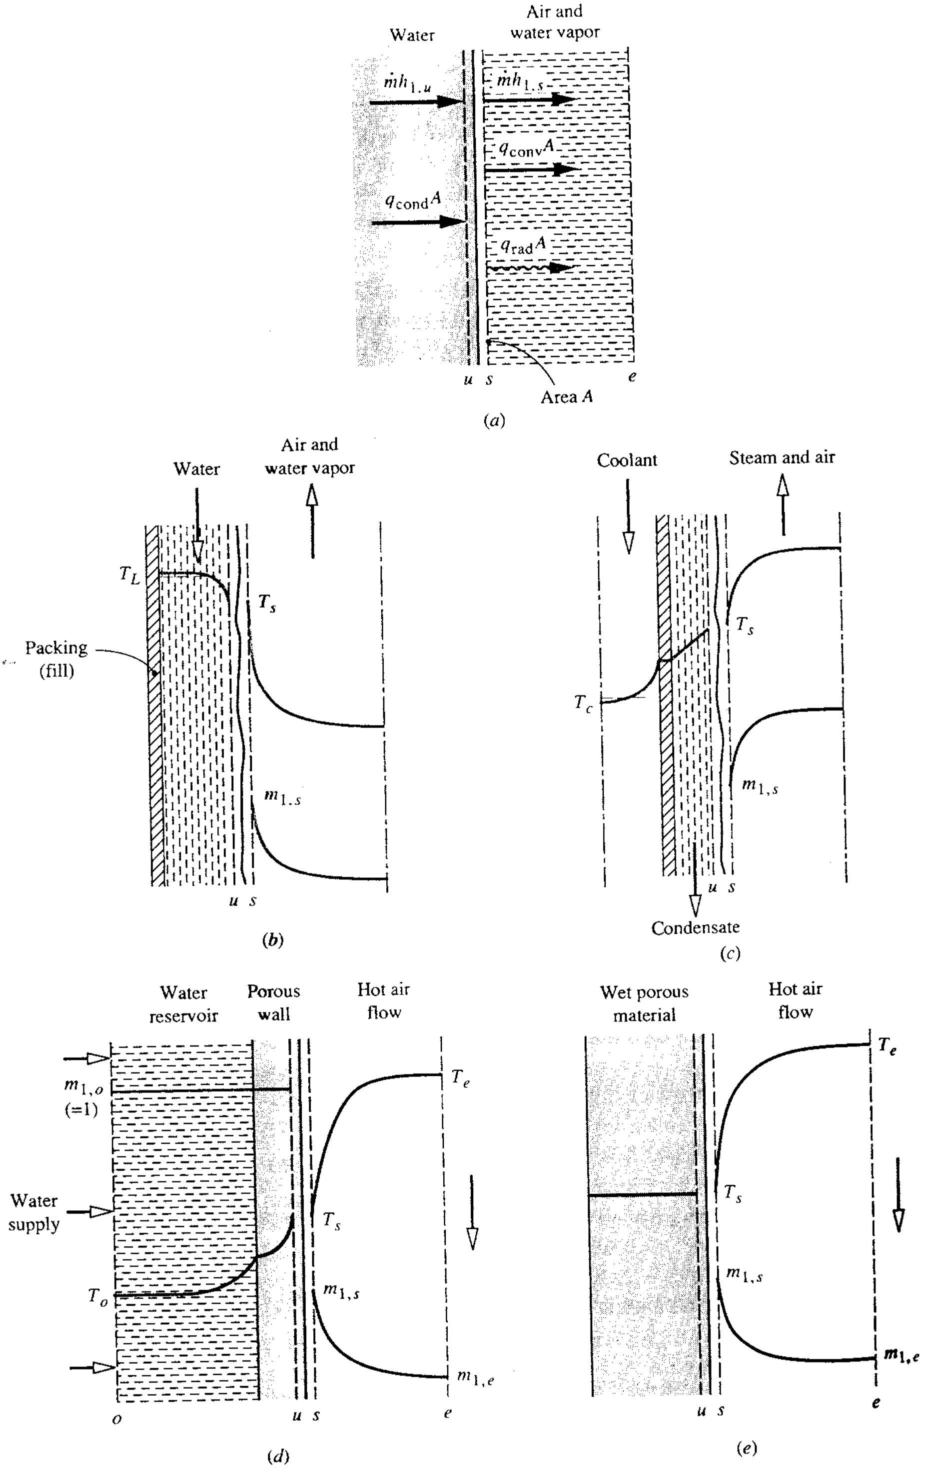

FIGURE 4.7.13 The surface energy balance for evaporation of water into an air stream.

If we restrict our attention to conditions for which low mass transfer rate theory is valid, we can write $\dot{m}/A \simeq j_{1,s} = g_{m1}\,(m_{1,s} - m_{1,e})$. Also, we can then calculate the convective heat transfer as if there were no mass transfer, and write $q_{\text{conv}} = h_c(T_s - T_e)$. Substituting in Equation (4.7.64) with $q_{\text{conv}} = -k\partial T/\partial y|_u$, $h_{1,s} - h_{1,u} = h_{fg}$, and rearranging, gives

$$-k\frac{\partial T}{\partial y}\bigg|_u = h_c\left(T_s - T_e\right) + g_{m1}\left(m_{1,s} - m_{1,e}\right)h_{fg} + q''_{\text{rad}} \text{ W/m}^2 \tag{4.7.65}$$

It is common practice to refer to the convective heat flux $h_c(T_s - T_e)$ as the *sensible* heat flux, whereas the term $g_{m1}\,(m_{1,s} - m_{1,e})\,h_{fg}$ is called the *evaporative* or *latent* heat flux. Each of the terms in Equation 4.7.65 can be positive or negative, depending on the particular situation. Also, the evaluation of the conduction heat flux at the u-surface, $-k\partial T/\partial y|_u$, depends on the particular situation. Four examples are shown in Figure 4.7.13. For a water film flowing down a packing in a cooling tower (Figure 4.7.13b), this heat flux can be expressed in terms of convective heat transfer from the bulk water at temperature T_L to the surface of the film, $-k\partial T/\partial y|_u = h_{cL}\,(T_L - T_s)$. If the liquid-side heat transfer coefficient h_{cL} is large enough, we can simply set $T_s \simeq T_L$, which eliminates the need to estimate h_{cL}. The evaporation process is then *gas-side controlled*. Figure 4.7.13c shows film condensation from a steam-air mixture on the outside of a vertical tube. In this case we can write $k\partial T/\partial y|_u = U(T_s - T_c)$, where T_c is the coolant bulk temperature. The overall heat transfer coefficient U includes the resistances of the condensate film, the tube wall, and the coolant. Sweat cooling is shown in Figure 4.7.13d, with water from a reservoir (or *plenum chamber*) injected through a porous wall at a rate just sufficient to keep the wall surface wet. In this case, the conduction across the u-surface can be related to the reservoir conditions by application of the steady-flow energy equation to a control volume located between the o- and u-surfaces. Finally, Figure 4.7.13e shows drying of a wet porous material (e.g., a textile or wood). During the constant-rate period of the process, evaporation takes place from the surface with negligible heat conduction into the solid; then $-k\partial T/\partial y|_u \simeq 0$. The term *adiabatic vaporization* is used to describe evaporation when $q_{\text{cond}} = 0$; constant-rate drying is one example, and the wet-bulb psychrometer is another.

Consider a 1-m-square wet towel on a washline on a day when there is a low overcast and no wind. The ambient air is at 21°C, 1 atm, and 50.5% RH. In the constant-rate drying period the towel temperature is constant, and $q_{\text{cond}} = 0$. An iterative calculation is required to obtain the towel temperature using correlations for natural convection on a vertical surface to obtain h_c and g_{m1}; q_{rad} is obtained as $q_{\text{rad}} = \sigma\varepsilon(T_s^4 - T_e^4)$ with $\varepsilon = 0.90$. The results are $T_s = 17.8$°C, $h_c = 1.69$ W/m²K, $g_{m1} = 1.82 \times 10^{-3}$ kg/m²sec, and the energy balance is

$$q_{\text{cond}} = h_c\left(T_s - T_e\right) + g_{m1}\left(m_{1,s} - m_{1,e}\right)h_{fg} + q_{\text{rad}}$$

$$0 = -5.4 + 21.7 - 16.3 \text{ W/m}^2$$

Evaluation of composition-dependent properties, in particular the mixture specific heat and Prandtl number, poses a problem. In general, low mass transfer rates imply small composition variations across a boundary layer, and properties can be evaluated for a mixture of the free-stream composition at the mean film temperature. In fact, when dealing with evaporation of water into air, use of the properties of dry air at the mean film temperature gives results of adequate engineering accuracy. If there are large composition variations across the boundary layer, as can occur in some catalysis problems, properties should be evaluated at the mean film composition and temperature.

The Wet- and Dry-Bulb Psychrometer

The wet- and dry-bulb psychrometer is used to measure the moisture content of air. In its simplest form, the air is made to flow over a pair of thermometers, one of which has its bulb covered by a wick whose

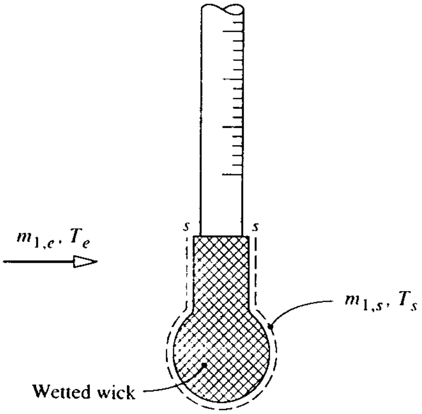

FIGURE 4.7.14 Wet bulb of a wet- and dry-bulb psychrometer.

other end is immersed in a small water reservoir. Evaporation of water from the wick causes the wet bulb to cool and its steady-state temperature is a function of the air temperature measured by the dry bulb and the air humidity. The wet bulb is shown in Figure 4.7.14. In order to determine the water vapor mass fraction $m_{1,e}$, the surface energy balance Equation (4.7.66) is used with conduction into the wick and q''_{rad} set equal to zero. The result is

$$m_{1,e} = m_{1,s} - \frac{c_p}{h_{fg}}\left(\frac{\text{Pr}}{\text{Sc}_{12}}\right)^{-2/3}\left(T_e - T_s\right) \qquad (4.7.66)$$

Usually $m_{1,e}$ is small and we can approximate $c_p = c_{p\text{ air}}$ and $(\text{Pr}/\text{Sc}_{12})^{-2/3} = 1/1.08$. Temperatures T_s and T_e are the known measured wet- and dry-bulb temperatures. With T_s known, $m_{1,s}$ can be obtained using steam tables in the usual way. For example, consider an air flow at 1000 mbar with measured wet- and dry-bulb temperatures of 305.0 and 310.0 K, respectively. Then $P_{1,s} = P_{\text{sat}}(T_s) = P_{\text{sat}}(305.0\text{ K}) = 4714$ Pa from steam tables. Hence, $x_{1,s} = P_{1,s}/P = 4714/10^5 = 0.04714$, and

$$m_{1,s} = \frac{0.04714}{0.04714 + (29/18)(1 - 0.04714)} = 0.02979$$

Also, h_{fg} (305 K) = 2.425×10^6 J/kg, and $c_{p\text{ air}} = 1005$ J/kg K; thus

$$m_{1,e} = 0.02979 - \frac{1005}{(1.08)\left(2.425 \times 10^6\right)}(310 - 305) = 0.02787$$

$$x_{1,e} = \frac{0.02787}{0.02787 + (18/29)(1 - 0.02787)} = 0.04415$$

$$P_{1,e} = x_{1,e}P = (0.04415)\left(10^5\right) = 4412\text{ Pa}$$

By definition, the relative humidity is RH = $P_{1,e}/P_{\text{sat}}(T_e)$; RH = 4415/6224 = 70.9%.

In the case of other adiabatic vaporization processes, such as constant-rate drying or evaporation of a water droplet, $m_{1,e}$ and T_e are usually known and Equation (4.7.66) must be solved for T_s. However, the thermodynamic wet-bulb temperature obtained from psychrometric charts or software is accurate enough for engineering purposes.

High Mass Transfer Rate Theory

When there is net mass transfer across a phase interface, there is a convective component of the absolute flux of a species across the *s*-surface. From Equation (4.7.23a) for species 1,

$$n_{1,s} = \rho_{1,s} \mathrm{v}_s + j_{1,s} \text{ kg/m}^2 \text{ sec} \tag{4.7.67}$$

During evaporation the convection is directed in the gas phase, with a velocity normal to the surface v_s. When the convective component cannot be neglected, we say that the mass transfer rate is *high*. There are two issues to consider when mass transfer rates are high. First, the rate at which species 1 is transferred across the *s*-surface is not simply the diffusive component $j_{1,s}$ as assumed in low mass transfer rate theory, but is the sum of the convective and diffusive components shown in Equation 4.7.67. Second, the normal velocity component v_s has a *blowing* effect on the concentration profiles, and hence on the Sherwood number. The Sherwood number is no longer analogous to the Nusselt number of conventional heat transfer correlations, because those Nusselt numbers are for situations involving impermeable surfaces, e.g., a metal wall, for which $v_s = 0$.

Substituting for $j_{1,s}$ from Equation (4.7.57) into Equation (4.7.67) gives

$$\dot{m}'' = \mathcal{g}_{m1} \frac{m_{1,e} - m_{1,s}}{m_{1,s} - n_{1,s}/\dot{m}''} = \mathcal{g}_{m1} \mathcal{B}_{m1} \tag{4.7.68}$$

where $\dot{m}'' = n_s$ is the mass transfer rate introduced in the section on heterogeneous combustion and $\mathcal{B}_{m1}$ is the *mass transfer driving force*. In the special case where only species 1 is transferred, $n_{1,s}/\dot{m}'' = 1$, for example, when water evaporates into air, and dissolution of air in the water is neglected. It is convenient to rewrite Equation (4.7.68) as

$$\dot{m}'' = \mathcal{g}^*_{m1} \left(\mathcal{g}_{m1} / \mathcal{g}^*_{m1} \right) \mathcal{B}_{m1} \text{ kg/m}^2 \text{ sec} \tag{4.7.69a}$$

where

$$\mathcal{g}^*_{m1} = \lim_{\mathcal{B}_m \to 0} \mathcal{g}_{m1} \tag{4.7.69b}$$

Now $\mathcal{g}^*_{m1}$ is the limit value of $\mathcal{g}_{m1}$ for zero mass transfer (i.e., $v_s = 0$), and Sh^* can be obtained from conventional heat transfer Nusselt number correlations for impermeable surfaces. The ratio $(\mathcal{g}_{m1}/\mathcal{g}^*_{m1})$ is termed a *blowing factor* and accounts for the effect of v_s on the concentration profiles. Use of Equation (4.7.69) requires appropriate data for the blowing factor. For the constant-property laminar boundary layer on a flat plate, Figure 4.7.15 shows the effect of the Schmidt number on the blowing factor. The abscissa is a *blowing parameter* $B_m = \dot{m}''/\mathcal{g}^*_m$.

The blowing velocity also affects the velocity and temperature profiles, and hence the wall shear stress and heat transfer. The curve for $\mathrm{Sc} = 1$ in Figure 4.7.15 also gives the effect of blowing on shear stress as τ_s/τ^*_s, and the curve for $\mathrm{Sc} = 0.7$ gives the effect of blowing on heat transfer for air injection into air as h_c/h^*_c (since $\mathrm{Pr} = 0.7$ for air).

Variable Property Effects of High Mass Transfer Rates

High mass transfer rate situations are usually characterized by large property variations across the flow, and hence property evaluation for calculating $\mathcal{g}_m$ and h_c is not straightforward. An often-encountered situation is transfer of a single species into an inert laminar or turbulent boundary layer flow. The effect

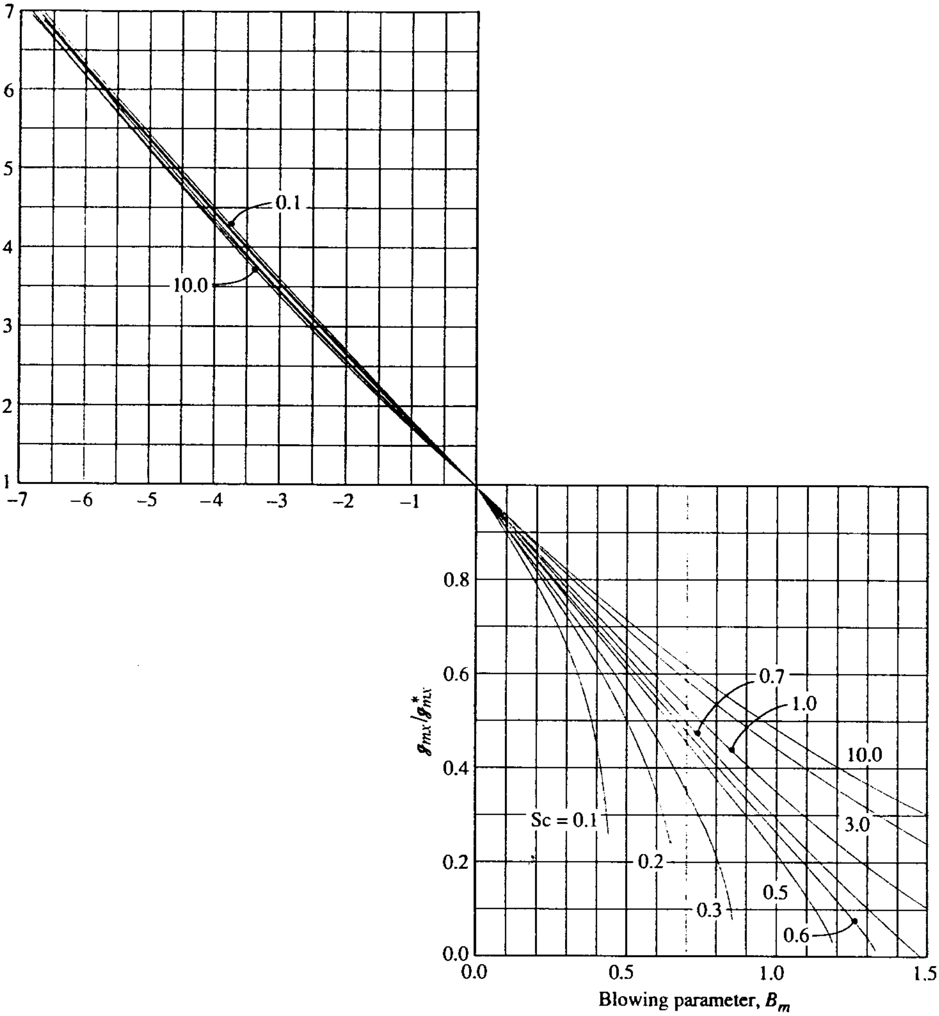

FIGURE 4.7.15 Effect of mass transfer on the mass transfer conductance for a laminar boundary layer on a flat plate: g_m / g^*_m vs. blowing parameter $B_m = \dot{m}'' / g^*_m$.

of variable properties can be very large as shown in Figure 4.7.16 for laminar boundary layers, and Figure 4.7.17 for turbulent boundary layers.

A simple procedure for correlating the effects of flow type and variable properties is to use weighting factors in the exponential functions suggested by a constant-property Couette-flow model (Mills, 1995). Denoting the injected species as species i, we have

$$\frac{g_{m1}}{g^*_{m1}} = \frac{a_{mi} B_{mi}}{\exp(a_{mi} B_{mi}) - 1}; \qquad B_{mi} = \frac{\dot{m}''}{g^*_{mi}} \tag{4.7.70a}$$

or

$$\frac{g_{m1}}{g^*_{mi}} = \frac{\ln(1 + a_{mi} \mathcal{B}_{mi})}{a_{mi} \mathcal{B}_{mi}}; \qquad \mathcal{B}_{mi} = \frac{\dot{m}''}{g_{mi}} = \frac{m_{i,e} - m_{i,e}}{m_{i,s} - 1}$$

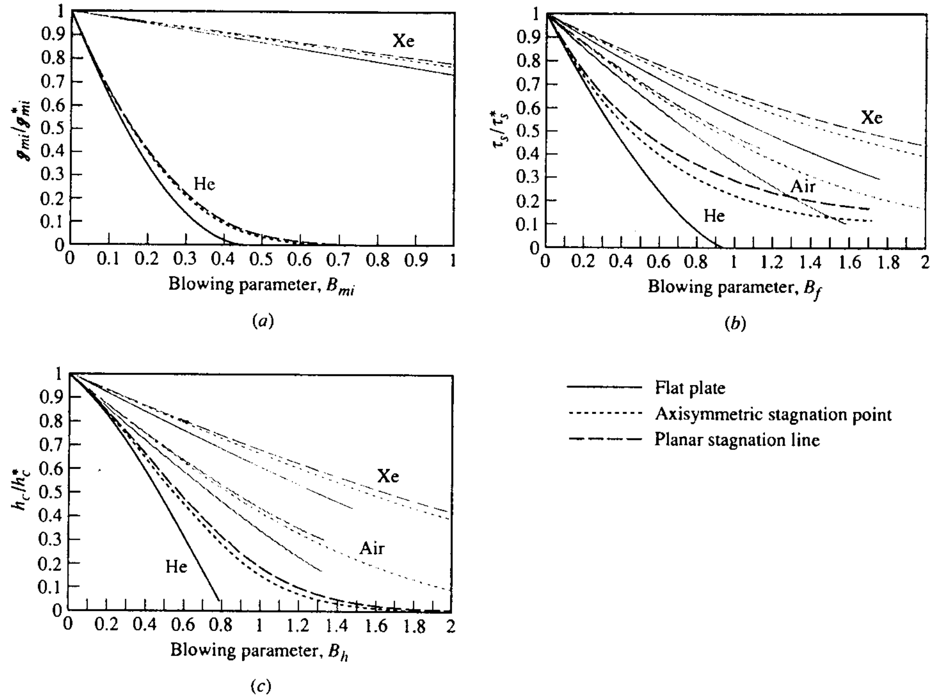

FIGURE 4.7.16 Numerical results for the effect of pressure gradient and variable properties on blowing factors for laminar boundary layers: low-speed air flow over a cold wall ($T_s/T_e = 0.1$) with foreign gas injection: (a) mass transfer conductance, (b) wall shear stress, (c) heat transfer coefficient. (From Wortman, A., Ph.D. dissertation, University of California, Los Angeles, 1969. With permission.)

$$\frac{\tau_s}{\tau_s^*} = \frac{a_{fi} B_f}{\exp\left(a_{fi} B_f\right) - 1}; \qquad B_f = \frac{\dot{m}'' u_e}{\tau_s^*} \tag{4.7.70b}$$

$$\frac{h_c}{h_c^*} = \frac{a_{hi} B_h}{\exp\left(a_{hi} B_h\right) - 1}; \qquad B_h = \frac{\dot{m}'' c_{pe}}{h_c^*} \tag{4.7.70c}$$

Notice that g^*_{mi}, τ^*_s, h^*_c, and c_{pe} are evaluated using properties of the free-stream gas at the mean film temperature. The weighting factor a may be found from exact numerical solutions of boundary layer equations or from experimental data. Some results for laminar and turbulent boundary layers follow.

1. *Laminar Boundary Layers.* We will restrict our attention to low-speed air flows, for which viscous dissipation and compressibility effects are negligible, and use exact numerical solutions of the self-similar laminar boundary layer equations (Wortman, 1969). Least-squares curve fits of the numerical data were obtained using Equation (4.7.70a) to Equation (4.7.70c). Then, the weighting factors for axisymmetric stagnation-point flow with a cold wall ($T_s/T_e = 0.1$) were correlated as

$$a_{mi} = 1.65\left(M_{\text{air}}/M_i\right)^{10/12} \tag{4.7.71a}$$

$$a_{fi} = 1.38\left(M_{\text{air}}/M_i\right)^{5/12} \tag{4.7.71b}$$

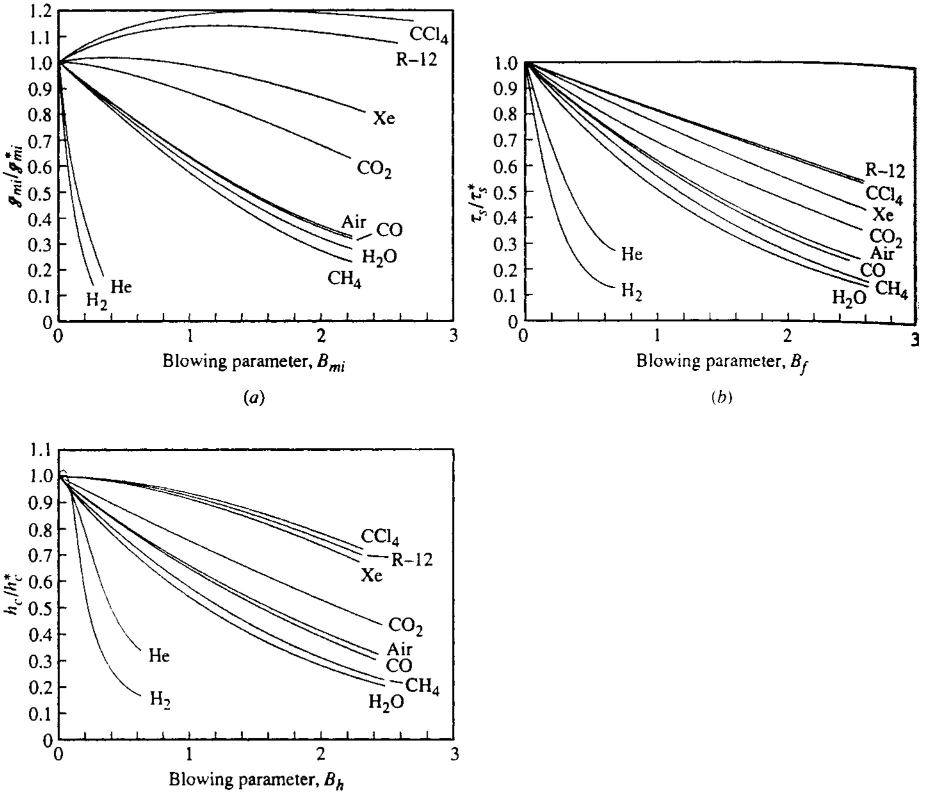

FIGURE 4.7.17 Numerical results for the effect of variable properties on blowing factors for a low-speed turbulent air boundary layer on a cold flat plate ($T_s/T_e = 0.2$) with foreign gas injection: (a) mass transfer conductance, (b) wall shear stress, (c) heat transfer coefficient. (From Landis, R.B., Ph.D. dissertation, University of California, Los Angeles, 1971. With permission.)

$$a_{hi} = 1.30\left(M_{\text{air}}/M_i\right)^{3/12}\left[c_{pi}/\left(2.5\mathcal{R}/M_i\right)\right] \tag{4.7.71c}$$

Notice that $c_{pi}/2.5\mathcal{R}/M_i)$ is unity for a monatomic species. For the planar stagnation line and the flat plate, and other values of the temperature ratio T_s/T_e, the values of the species weighting factors are divided by the values given by Equations (4.7.71a,b,c) to give correction factors G_{mi}, G_{fi}, and G_{hi}, respectively. The correction factors are listed in Table 4.7.7.

The exponential relation blowing factors cannot accurately represent some of the more anomalous effects of blowing. For example, when a light gas such as H_2 is injected, Equation (4.7.70c) indicates that the effect of blowing is always to reduce heat transfer, due to both the low density and high specific heat of hydrogen. However, at very low injection rates, the heat transfer is actually increased, as a result of the high thermal conductivity of H_2. For a mixture, $k \approx \sum x_i k_i$ whereas $c_p = \sum m_i c_{pi}$. At low rates of injection, the mole fraction of H_2 near the wall is much larger than its mass fraction; thus, there is a substantial increase in the mixture conductivity near the wall, but only a small change in the mixture specific heat. An increase in heat transfer results. At higher injection rates, the mass fraction of H_2 is also large, and the effect of high mixture specific heat dominates to cause a decrease in heat transfer.

TABLE 4.7.7 Correction Factors for Foreign Gas Injection into Laminar Air Boundary Layers

		G_{mi} T_s/T_e			G_{fi} T_s/T_e			G_{hi} T_s/T_e

Based on numerical data of Wortman (1969). Correlations developed by Dr. D.W. Hatfield.

2. *Turbulent Boundary Layers.* Here we restrict our attention to air flow along a flat plate for Mach numbers up to 6, and use numerical solutions of boundary layer equations with a mixing length turbulence model (Landis, 1971). Appropriate species weighting factors for $0.2 < T_s/T_e < 2$ are

$$a_{mi} = 0.79\left(M_{\text{air}}/M_i\right)^{1.33} \tag{4.7.72a}$$

$$a_{fi} = 0.91\left(M_{\text{air}}/M_i\right)^{0.76} \tag{4.7.72b}$$

$$a_{hi} = 0.86\left(M_{\text{air}}/M_i\right)^{0.73} \tag{4.7.72c}$$

In using Equation (4.7.70), the limit values for $\dot{m}'' = 0$ are elevated at the same location along the plate. Whether the injection rate is constant along the plate or varies as $x^{-0.2}$ to give a self-similar boundary layer has little effect on the blowing factors. Thus, Equation (4.7.72) has quite general applicability. Notice that the effects of injectant molecular weight are greater for turbulent boundary layers than for laminar ones, which is due to the effect of fluid density on turbulent transport. Also, the injectant specific heat does not appear in a_{hi} as it did for laminar flows. In general, c_{pi} decreases with increasing M_i and is adequately accounted for in the molecular weight ratio.

Reference State Schemes. The reference state approach, in which constant-property data are used with properties evaluated at some reference state, is an alternative method for handling variable-property effects. In principle, the reference state is independent of the precise property data used and of the combination of injectant and free-stream species. A reference state for a boundary layer on a flat plate that can be used in conjunction with Figure 4.7.14 is (Knuth, 1963)

$$m_{1,r} = 1 - \frac{M_2}{M_2 - M_1} \frac{\ln\left(M_e / M_s\right)}{\ln\left(m_{2,e} M_e / m_{2,s} M_s\right)} \tag{4.7.73}$$

$$T_r = 0.5\left(T_e + T_s\right) + 0.2 r^* \left(u_e^2 / 2c_{pr}\right) + 0.1\left[B_{hr} + \left(B_{hr} + B_{mr}\right) \frac{c_{p1} - c_{pr}}{c_{pr}}\right]\left(T_s - T_e\right) \tag{4.7.74}$$

where species 1 is injected into species 2 and r^* is the recovery factor for an impermeable wall. Use of the reference state method is impractical for hand calculations: a computer program should be used to evaluate the required mixture properties.

4.8 Applications

Enhancement

Arthur E. Bergles

Introduction

Energy- and materials-saving considerations, as well as economic incentives, have led to efforts to produce more efficient heat exchange equipment. Common thermal-hydraulic goals are to reduce the size of a

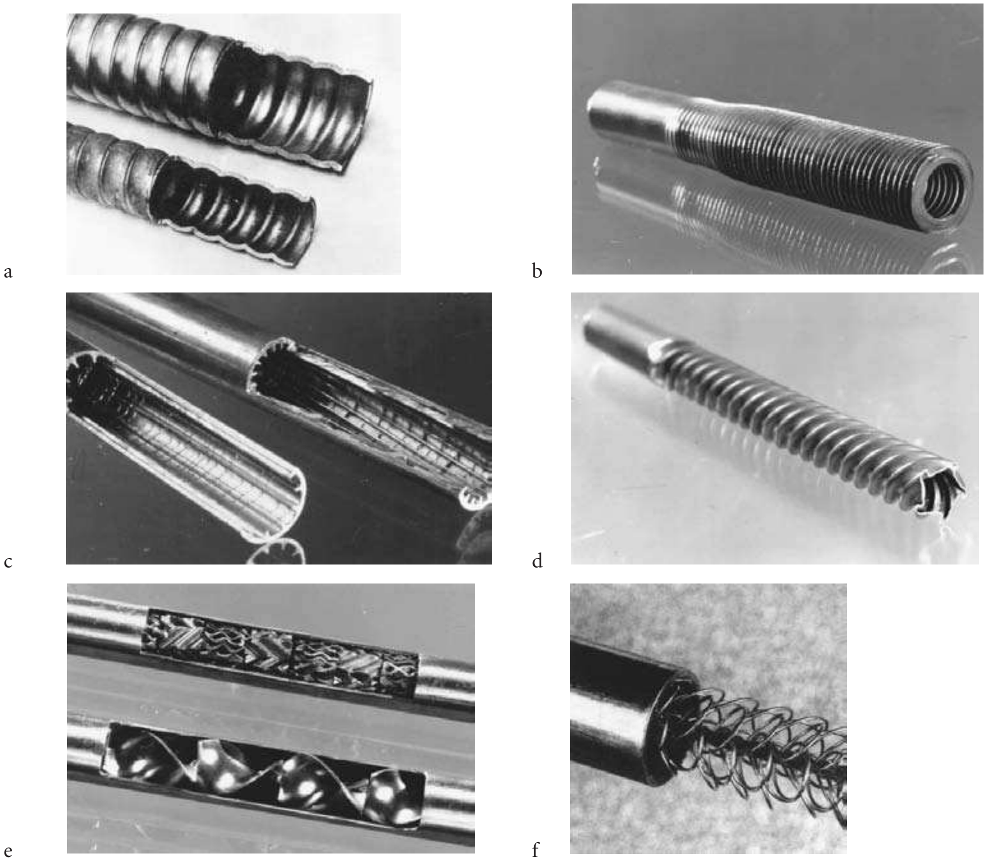

FIGURE 4.8.1 Enhanced tubes for augmentation of single-phase heat transfer. (a) Corrugated or spirally indented tube with internal protuberances. (b) Integral external fins. (c) Integral internal fins. (d) Deep spirally fluted tube. (e) Static mixer inserts. (f) Wire-wound insert.

heat exchanger required for a specified heat duty, to upgrade the capacity of an existing heat exchanger, to reduce the approach temperature difference for the process streams, or to reduce the pumping power.

The study of improved heat transfer performance is referred to as heat transfer *enhancement*, *augmentation*, or *intensification*. In general, this means an increase in heat transfer coefficient. Attempts to increase "normal" heat transfer coefficients have been recorded for more than a century, and there is a large store of information. A bibliographic survey (Bergles et al., 1995) lists 5676 technical publications, excluding patents and manufacturers' literature. An update for 2001 by Manglik and Bergles (2004) indicates that new literature is being added to this field at the rate of about 400 references per year.

Enhancement techniques can be classified either as passive methods, which require no direct application of external power (Figure 4.8.1), or as active methods, which require external power. The effectiveness of both types of techniques is strongly dependent on the mode of heat transfer, which may range from single-phase free convection to dispersed-flow film boiling. Brief descriptions of these methods follow.

Treated surfaces involve fine-scale alternation of the surface finish or coating (continuous or discontinuous). They are used for boiling and condensing; the roughness height is below that which affects single-phase heat transfer.

Rough surfaces are produced in many configurations ranging from random sand-grain-type roughness to discrete protuberances. See Figure 4.8.1a. The configuration is generally chosen to disturb the viscous sublayer rather than to increase the heat transfer surface area. Application of rough surfaces is directed primarily toward single-phase flow.

Extended surfaces are routinely employed in many heat exchangers. See Figure 4.8.1a to d. Work of special interest to enhancement is directed toward improvement of heat transfer coefficients on extended surfaces by shaping or perforating the surfaces.

Displaced enhancement devices are inserted into the flow channel so as indirectly to improve energy transport at the heated surface. They are used with forced flow. See Figure 4.8.1e and f.

Swirl-flow devices include a number of geometric arrangements or tube inserts for forced flow that create rotating and/or secondary flow: coiled tubes, inlet vortex generators, twisted-tape inserts, and axial-core inserts with a screw-type winding.

Surface-tension devices consist of wicking or grooved surfaces to direct the flow of liquid in boiling and condensing.

Additives for liquids include solid particles and gas bubbles in single-phase flows and liquid trace additives for boiling systems.

Additives for gases are liquid droplets or solid particles, either dilute-phase (gas-solid suspensions) or dense-phase (fluidized beds).

Mechanical aids involve stirring the fluid by mechanical means or by rotating the surface. Surface "scraping," widely used for batch processing of viscous liquids in the chemical process industry, is applied to the flow of such diverse fluids as high-viscosity plastics and air. Equipment with rotating heat exchanger ducts is found in commercial practice.

Surface vibration at either low or high frequency has been used primarily to improve single-phase heat transfer.

Fluid vibration is the practical type of vibration enhancement because of the mass of most heat exchangers. The vibrations range from pulsations of about 1 Hz to ultrasound. Single-phase fluids are of primary concern.

Electrostatic fields (DC or AC) are applied in many different ways to dielectric fluids. Generally speaking, electrostatic fields can be directed to cause greater bulk mixing or fluid or disruption of fluid flow in the vicinity of the heat transfer surface, which enhances heat transfer.

Injection is utilized by supplying gas to a stagnant or flowing liquid through a porous heat transfer surface or by injecting similar fluid upstream of the heat transfer section. Surface degassing of liquids can produce enhancement similar to gas injection. Only single-phase flow is of interest.

Suction involves vapor removal, in nucleate or film boiling, or fluid withdrawal, in single-phase flow, through a porous heated surface.

Two or more of the above techniques may be utilized simultaneously to produce an enhancement that is larger than either of the techniques operating separately. This is termed *compound enhancement*.

It should be emphasized that one of the motivations for studying enhanced heat transfer is to assess the effect of an inherent condition on heat transfer. Some practical examples include roughness produced by standard manufacturing, degassing of liquids with high gas content, surface vibration resulting from rotating machinery or flow oscillations, fluid vibration resulting from pumping pulsation, and electrical fields present in electrical equipment.

The surfaces in Figure 4.8.1 have been used for both single-phase and two-phase heat transfer enhancement. The emphasis is on effective and cost-competitive (proved or potential) techniques that have made the transition from the laboratory to commercial heat exchangers.

Single-Phase Free Convection

With the exception of the familiar technique of providing extended surfaces, the passive techniques have little to offer in the way of enhanced heat transfer for free convection. This is because the velocities are usually too low to cause flow separation or secondary flow.

The restarting of thermal boundary layers in interrupted extended surfaces increases heat transfer so as to more than compensate for the lost area.

Mechanically aided heat transfer is a standard technique in the chemical and food industries when viscous liquids are involved. The predominant geometry for surface vibration has been the horizontal cylinder, vibrated either horizontally or vertically. Heat transfer coefficients can be increased tenfold for both low-frequency/high-amplitude and high-frequency/low-amplitude situations. It is, of course, equally effective and more practical to provide steady forced flow. Furthermore, the mechanical designer is concerned that such intense vibrations could result in equipment failures.

Since it is usually difficult to apply surface vibrations to practical equipment, an alternative technique is utilized whereby vibrations are applied to the fluid and focused toward the heated surface. With proper transducer design, it is also possible to improve heat transfer to simple heaters immersed in gases or liquids by several hundred percent.

Electric fields are particularly effective in increasing heat transfer coefficients in free convection. Dielectrophoretic or electrophoretic (especially with ionization of gases) forces cause greater bulk mixing in the vicinity of the heat transfer surface. Heat transfer coefficients may be improved by as much as a factor of 40 with electrostatic fields up to 100,000 V. Again, the equivalent effect could be produced at lower capital cost and without the voltage hazard by simply providing forced convection with a blower or fan.

Single-Phase Forced Convection

The present discussion emphasizes enhancement of heat transfer *inside* ducts that are primarily of circular cross section. Typical data for turbulence promoters inserted inside tubes are shown in Figure 4.8.2. As shown in Figure 4.8.2a, the promoters produce a sizable elevation in the Nusselt number, or heat transfer coefficient, at constant Reynolds number, or velocity. However, as shown in Figure 4.8.2b, there is an accompanying large increase in the friction factor.

Surface roughness has been used extensively to enhance forced convection heat transfer. Integral roughness may be produced by the traditional manufacturing processes of machining, forming, casting, or welding. Various inserts can also provide surface protuberances. In view of the infinite number of possible geometric variations, it is not surprising that, even after more than 300 studies, no completely satisfactory unified treatment is available.

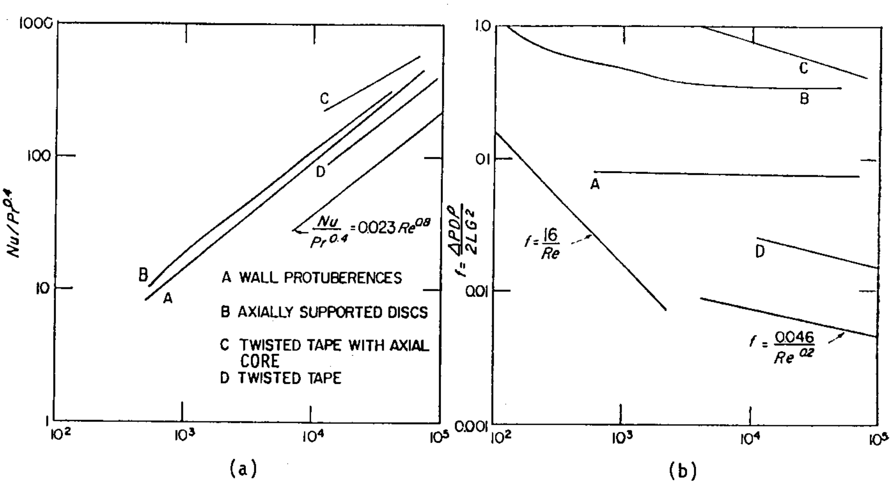

FIGURE 4.8.2 Typical data for turbulence promoters inserted inside tubes: (a) heat transfer data, (b) friction data. (From Bergles, 1969. With permission.)

In general, the maximum enhancement of laminar flow with many of the techniques is the same order of magnitude, and seems to be independent of the wall boundary condition. The enhancement with some rough tubes, corrugated tubes, inner-fin tubes, various static mixers, and twisted-type inserts is about 200%. The improvements in heat transfer coefficient with turbulent flow in rough tubes (based on nominal surface area) are as much as 250%. Analogy solutions for sand-grain-type roughness and for square-repeated-rib roughness have been proposed. A statistical correlation is also available for heat transfer coefficient and friction factor.

The following correlations are recommended for tubes with transverse or helical repeated ribs (Figure 4.8.1a) with turbulent flow (Ravigururajan and Bergles, 1996):

$$\mathrm{Nu}_{D_i,a}/\mathrm{Nu}_{D_i,s} = \left\{1+\left[2.64\mathrm{Re}^{0.036}\left(e/D_i\right)^{0.212}\left(\left(p/D_i\right)^{-0.21}\right)\left(\alpha/90\right)^{0.29}(\mathrm{Pr})^{-0.024}\right]^7\right\}^{1/7} \tag{4.8.1}$$

$$f_a/f_s = \left\{1+\left[29.1\mathrm{Re}_{D_i}^{\left(0.67-0.06\,p/D_i-0.49\,a/90\right)}\times\left(e/D_i\right)^{\left(1.37-0.157\,p/D_i\right)}\times\left(p/D_i\right)^{\left(-1.66\times10^{-6}\,\mathrm{Re}_{D_i}-0.33\,\alpha/90\right)}\left(\alpha/90\right)^{\left(4.59+4.11\times10^{-6}\,\mathrm{Re}_{D_i}-0.15\,p/D_i\right)}\times\left(1+\frac{2.94}{n}\right)\sin\beta\right]^{15/16}\right\}^{16/15} \tag{4.8.2}$$

where the subscript a refers to the enhanced tube and the subscript s refers to the smooth tube. The special symbols are given as follows: e = protuberance height; p = repeated-rib pitch; α = spiral angle for helical ribs, °; n = number of sharp corners facing the flow; and β = contact angle of rib profile, °.

Also,

$$\mathrm{Nu}_s = 0.125 f\,\mathrm{Re}_{D_i}\mathrm{Pr}\Big/\left(1+12.7(0.125f)^{0.5}\,\mathrm{Pr}^{0.667}-1\right)$$

and

$$f_s = \left(1.58\ln\,\mathrm{Re}_{D_i}-3.28\right)^{-2}\,{}^{*}$$

Much work has been done to obtain the enhanced heat transfer of parallel angled ribs in short rectangular channels, simulating the interior of gas turbine blades. Jets are frequently used for heating, cooling, and drying in a variety of industrial applications. A number of studies have reported that roughness elements of the transverse-repeated-rib type mitigate the deterioration in heat transfer downstream of stagnation.

In the case of rough surfaces, Champagne and Bergles (2001) have proposed and tested a novel variable roughness that can provide enhancement "on demand" for single-phase flows. This is based on a shape-memory coil. At low wall temperature (efficient heat transfer), the roughness coil is closely pitched. An excessive tube-wall temperature (low heat transfer coefficient) results in extension of the coil, which has been shown to provide considerable heat transfer enhancement. Current limitations in material processing and training techniques of shape-memory alloys impose a manual resetting of the coil once it is extended; thus, this should perhaps be considered an active enhancement technique rather than a passive one.

---

[*] The Fanning friction factor is used in all equations in this section, but the Darcy friction factor appears in Figure 4.8.2(b).

Extended surfaces can be considered "old technology" as far as most applications are concerned. The real interest now is in increasing heat transfer coefficients on the extended surface. Compact heat exchangers of the plate-fin or tube-and-center variety use several enhancement techniques: offset strip fins, louvered fins, perforated fins, or corrugated fins. Coefficients are several hundred percent above the smooth-tube values; however, the pressure drop is also substantially increased, and there may be vibration and noise problems.

For the case of offset strip fins the following correlations are recommended for calculating the *j* and *f* characteristics (Manglik and Bergles, 1990)

$$j_h = 0.6522\mathrm{Re}_h^{-0.5403}\,\alpha^{-0.1541}\,\delta^{0.1499}\,\gamma^{-0.0678}\times\left[1+5.269\times10^{-5}\,\mathrm{Re}_h^{1.340}\,\alpha^{0.504}\,\delta^{0.456}\,\gamma^{-1.055}\right]^{0.1} \quad (4.8.3)$$

$$f_h = 9.6243\mathrm{Re}_h^{-0.7422}\,\alpha^{-0.1856}\,\delta^{0.3053}\,\gamma^{-0.2659}\times\left[1+7.669\times10^{-8}\,\mathrm{Re}_h^{4.429}\,\alpha^{0.920}\,\delta^{3.767}\,\gamma^{0.236}\right]^{0.1} \quad (4.8.4)$$

where j_H (the heat transfer *j*-factor $\mathrm{Nu}_H/\mathrm{Re}_H\mathrm{Pr}^{1/3}$), and f_h, and Re_h are based on the hydraulic diameter given by

$$D_h = 4shl\big/\left[2(sl+hl+th)+ts\right] \quad (4.8.5)$$

Special symbols are α = aspect ratio s/h, δ = ratio t/l, γ = ratio t/s, s = lateral spacing of strip fin, h = strip fin height, l = length of one offset module of strip fins, and t = fin thickness.

These equations are based on experimental data for 18 different offset strip-fin geometries, and they represent the data continuously in the laminar, transition, and turbulent flow regions.

Internally finned circular tubes are available in aluminum and copper (or copper alloys). Correlations (for heat transfer coefficient and friction factor) are available for laminar flow, for both straight and spiral continuous fins.

Turbulent flow in tubes with straight or helical fins (Figure 4.8.1c) was correlated by (Carnavos, 1979)

$$\mathrm{Nu}_h = 0.023\mathrm{Pr}^{0.4}\mathrm{Re}_h^{0.8}\left[\frac{A_c}{A_{ci}}\right]^{0.1}\left[\frac{A_{s,i}}{A_s}\right]^{0.5}(\sec\alpha)^3 \quad (4.8.6)$$

$$f_h = 0.046\mathrm{Re}_h^{-0.2}\left[\frac{A_c}{A_{c,i}}\right]^{0.5}(\sec\alpha)^{0.75} \quad (4.8.7)$$

where $A_{c,i}$ is based on the maximum inside (envelope) flow area, $A_{s,i}$ is based on the maximum inside (envelope) surface area, and α the spiral angle for helical fins, °.

A numerical analysis of turbulent flow in tubes with idealized straight fins was reported. The necessary constant for the turbulence model was obtained from experimental data for air. Further improvements in numerical techniques are expected, so that a wider range of geometries and fluids can be handled without resort to extensive experimental programs.

Many proprietary surface configurations have been produced by deforming the basic tube. The "convoluted," "corrugated," "spiral," or "spirally fluted" tubes (Figure 4.8.1a) have multiple-start spiral corrugations, which add area, along the tube length. A systematic survey of the single-tube performance of condenser tubes indicates up to 400% increase in the nominal inside heat transfer coefficient (based on diameter of a smooth tube of the same maximum inside diameter); however, pressure drops on the water side are about 20 times higher.

Displaced enhancement devices are typically in the form of inserts, within elements arranged to promote transverse mixing (static mixers, Figure 4.8.1e). They are used primarily for viscous liquids, to promote either heat transfer or mass transfer. Displaced promoters are also used to enhance the radiant heat transfer in high-temperature applications. In the flue-tube of a hot-gas-fired hot water heater, there is a trade-off between radiation and convection. Another type of displaced insert generates vortices, which enhance the downstream flow. Delta-wing and rectangular wing promoters, both co-rotating and counterrotating, have been studied. Wire-loop inserts (Figure 4.8.1f) have also been used for enhancement of laminar and turbulent flow.

Twisted-tape inserts have been widely used to improve heat transfer in both laminar and turbulent flow. Correlations are available for laminar flow, for both uniform heat flux and uniform wall temperature conditions. Turbulent flow in tubes with twisted-tape inserts has also been correlated. Several studies have considered the heat transfer enhancement of a decaying swirl flow, generated, say, by a short twisted-tape insert.

Performance Evaluation Criteria for Single-Phase Forced Convection in Tubes

Numerous, and sometimes conflicting, factors enter into the ultimate decision to use an enhancement technique: heat duty increase or area reduction that can be obtained, initial cost, pumping power or operating cost, maintenance cost (especially cleaning), safety, and reliability, among others. These factors are difficult to quantitize, and a generally acceptable selection criterion may not exist. It is possible, however, to suggest some performance criteria for preliminary design guidance. As an example, consider the basic geometry and the pumping power fixed, with the objective of increasing the heat transfer. The following ratio is then of interest

$$R_3 = \left(\frac{h_a}{h_s}\right)_{D_i,L,N,P,T_{\text{in}},\Delta T} = \frac{\left(\text{Nu}/\text{Pr}^{0.4}\right)_a}{\left(\text{Nu}/\text{Pr}^{0.4}\right)_s} = \frac{q_a}{q_s} \tag{4.8.8}$$

where P = pumping power, T_{in} = inlet bulk temperature of fluid, and ΔT = average wall-fluid temperature difference.

With the pumping power (neglecting entrance and exit losses) given as

$$P = NVA_c 4f(L/D)\rho V^2/2 \tag{4.8.9}$$

and

$$f_s = 0.046/\text{Re}_s^{0.2} \tag{4.8.10}$$

$$A_{c,a} f_a \text{Re}_a^3 = 0.046\, A_{c,s} \text{Re}_s^{2.8} \tag{4.8.11}$$

The calculation best proceeds by picking $\text{Re}_{D_i,a}$, and reading $\text{Nu}_{D_i,a}/\text{Pr}^{0.4}$ and f_a. $\text{Re}_{D_i,s}$ is then obtained from Equation (4.8.11) and $\text{Nu}_{D_i,s}/\text{Pr}^{0.4}$ obtained from a conventional, empty-tube correlation. The desired ratio of Equation (4.8.8) is then obtained. Typical results are presented in Figure 4.8.3 for a repeated-rib roughness (Bergles et al., 1974).

Active and Compound Techniques for Single-Phase Forced Convection

Under active techniques, mechanically aided heat transfer in the form of surface scraping can increase forced convection heat transfer. Surface vibration has been demonstrated to improve heat transfer to both laminar and turbulent duct flow of liquids. Fluid vibration has been extensively studied for both air (loudspeakers and sirens) and liquids (flow interrupters, pulsators, and ultrasonic transducers). Pulsations are relatively simple to apply to low-velocity liquid flows, and improvements of several hundred percent can be realized.

Some very impressive enhancements have been recorded with electrical fields, particularly in the laminar-flow region. Improvements of at least 100% were obtained when voltages in the 10-kV range were applied to transformer oil. It is found that even with intense electrostatic fields, the heat transfer enhancement disappears as turbulent flow is approached in a circular tube with a concentric inner electrode.

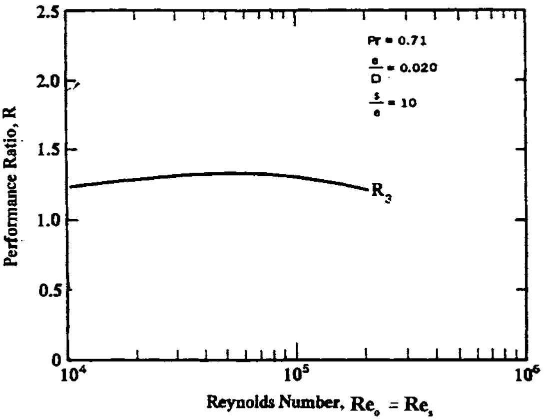

FIGURE 4.8.3 Constant pumping power performance criterion applied to repeated rib roughness.

Compound techniques are a slowly emerging area of enhancement that holds promise for practical applications, since heat transfer coefficients can usually be increased above each of the several techniques acting along. Some examples that have been studied are as follows: rough tube wall with twisted-tape inserts, rough cylinder with acoustic vibrations, internally finned tube with twisted-tape inserts, finned tubes in fluidized beds, externally finned tubes subjected to vibrations, rib-roughened passage being rotated, gas-solid suspension with an electrical field, fluidized bed with pulsations of air, and a rib-roughened channel with longitudinal vortex generation.

Pool Boiling

Selected passive and active enhancement techniques have been shown to be effective for pool boiling and flow boiling/evaporation. Most techniques apply to nucleate boiling; however, some techniques are applicable to transition and film boiling.

It should be noted that phase-change heat transfer coefficients are relatively high. The main thermal resistance in a two-fluid heat exchanger often lies on the non-phase-change side. (Fouling of either side can, of course, represent the dominant thermal resistance.) For this reason, the emphasis is often on enhancement of single-phase flow. On the other hand, the overall thermal resistance may then be reduced to the point where significant improvement in the overall performance can be achieved by enhancing the two-phase flow. Two-phase enhancement would also be important in double-phase-change (boiling/condensing) heat exchangers.

As discussed elsewhere, surface material and finish have a strong effect on nucleate and transition pool boiling. However, reliable control of nucleation on plain surfaces is not easily accomplished. Accordingly, since the earliest days of boiling research, there have been attempts to relocate the boiling curve through use of relatively gross modification of the surface. For many years, this was accomplished simply by area increase in the form of low helical fins. The subsequent tendency was to structure surfaces to improve the nucleate boiling characteristics by a fundamental change in the boiling process. Many of these advanced surfaces are being used in commercial shell-and-tube boilers.

Several manufacturing processes have been employed: machining, forming, layering, and coating. In Figure 4.8.4a standard low-fin tubing is shown. Figure 4.8.4c depicts a tunnel-and-pore arrangement produced by rolling, upsetting, and brushing. An alternative modification of the low fins is shown in Figure 4.8.4d, where the rolled fins have been split and rolled to a T shape. Further modification of the internal, Figure 4.8.4e, or external, Figure 4.8.4f, surface is possible. Knurling and rolling are involved in producing the surface shown in Figure 4.4.8g. The earliest example of a commercial structured surface, shown in Figure 4.8.4b is the porous metallic matrix produced by sintering or brazing small particles. Wall superheat reductions of up to a factor of ten are common with these surfaces. The advantage is not

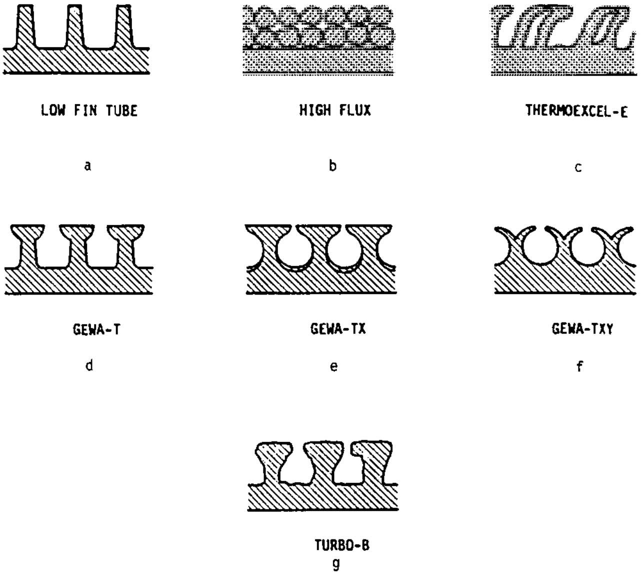

FIGURE 4.8.4 Examples of commercial structured boiling surfaces. (From Pate, M.B. et al., in *Compact Heat Exchangers*, Hemisphere Publishing, New York, 1990. With permission.)

only a high nucleate boiling heat transfer coefficient, but the fact that boiling can take place at very low temperature differences.

These structured boiling surfaces, developed for refrigeration and process applications, have been used as "heat sinks" for immersion-cooled microelectronic chips.

The behavior of tube bundles is often different with structured-surface tubes. The enhanced nucleate boiling dominates, and the convective boiling enhancement, found in plain tube bundles, does not occur.

Active enhancement techniques include heated surface rotation, surface wiping, surface vibration, fluid vibration, electrostatic fields, and suction at the heated surface. Although active techniques are effective in reducing the wall superheat and/or increasing the critical heat flux, the practical applications are very limited, largely because of the difficulty of reliably providing the mechanical or electrical effect.

Compound enhancement, which involves two or more techniques applied simultaneously, has also been studied. Electrohydrodynamic enhancement was applied to a finned tube bundle, resulting in nearly a 200% increase in the average boiling heat transfer coefficient of the bundle, with a small power consumption for the field.

Convective Boiling/Evaporation

The structured surfaces described in the previous section are generally not used for in-tube vaporization, because of the difficulty of manufacture. One notable exception is the high-flux surface in a vertical thermosiphon reboiler. The considerable increase in the low-quality, nucleate boiling coefficient is desirable, but it is also important that more vapor is generated to promote circulation.

Helical repeated ribs and helically coiled wire inserts have been used to increase vaporization coefficients and the dry-out heat flux in once-through boilers.

Numerous tubes with internal fins, either integral or attached, are available for refrigerant evaporators. Original configurations were tightly packed, copper, offset strip fin inserts soldered to the copper tube or aluminum, star-shaped inserts secured by drawing the tube over the insert. Examples are shown in Figure 4.8.5. Average heat transfer coefficients (based on surface area of smooth tube of the same diameter) for typical evaporator conditions are increased by as much as 200%. A cross-sectional view of a typical "microfin" tube is included in Figure 4.8.5. The average evaporation boiling coefficient is increased 30

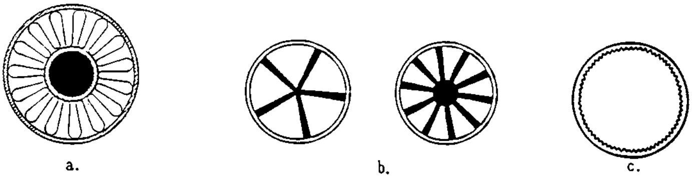

FIGURE 4.8.5 Inner-fin tubes for refrigerant evaporators: (a) Strip-fin inserts, (b) Star-shaped inserts, (c) Microfin.

to 80%. The pressure drop penalties are less; that is, lower percentage increases in pressure drop are frequently observed.

Twisted-tape inserts are generally used to increase the burnout heat flux for subcooled boiling at high imposed heat fluxes $10^7 - 10^8$ W/m^2, as might be encountered in the cooling of fusion reactor components. Increases in burnout heat flux of up to 200% were obtained at near atmospheric pressure.

Vapor-Space Condensation

As discussed elsewhere, condensation can be either filmwise or dropwise. In a sense, dropwise condensation is enhancement of the normally occurring film condensation by surface treatment. The only real application is for steam condensers, because nonwetting coatings are not available for most other working fluids. Even after much study, little progress has been made in developing permanently hydrophobic coatings for practical steam condensers. The enhancement of dropwise condensation is pointless, because the heat transfer coefficients are already so high.

Surface extensions are widely employed for enhancement of condensation. The integral low fin tubing (Figure 4.8.4a), used for kettle boilers, is also used for horizontal tube condensers. With proper spacing of the fins to provide adequate condensate drainage, the average coefficients can be several times those of a plain tube with the same base diameter. These fins are normally used with refrigerants and other organic fluids that have low condensing coefficients, but which drain effectively, because of low surface tension.

The fin profile can be altered according to mathematical analysis to take full advantage of the Gregorig effect, whereby condensation occurs mainly at the tops of convex ridges. Surface tension forces then pull the condensate into concave grooves, where it runs off. The average heat transfer coefficient is greater than that for an axially uniform film thickness. The initial application was for condensation of steam on vertical tubes used for reboilers and in desalination. According to numerical solutions, the optimum geometry is characterized by a sharp fin tip, gradually changing curvature of the fin surface from tip to root, wide grooves between fins to collect condensate, and periodic condensate strippers. Figure 4.8.6 schematically presents the configuration.

Recent interest has centered on three-dimensional surfaces for horizontal-tube condensers. The considerable improvement relative to low fins or other two-dimensional profiles is apparently due to multidimensional drainage at the fin tips. Other three-dimensional shapes include circular pin fins, square pins, and small metal particles that are bonded randomly to the surface.

Convective Condensation

This final section on enhancement of the various modes of heat transfer focuses on in-tube condensation. The applications include horizontal kettle-type reboilers, moisture separator reheaters for nuclear power plants, and air-conditioner condensers.

Internally grooved or knurled tubes, deep spirally fluted tubes, random roughness, conventional inner-fin tubes have been shown to be effective for condensation of steam and other fluids.

The microfin tubes mentioned earlier have also been applied successfully to in-tube condensing. As in the case of evaporation, the substantial heat transfer improvement is achieved at the expense of a lesser percentage increase in pressure drop. By testing a wide variety of tubes, it has been possible to suggest some guidelines for the geometry, e.g., more fins, longer fins, and sharper tips; however, general correlations are not yet available. Fortunately for heat-pump operation, the tube that performs best for evaporation also performs best for condensation.

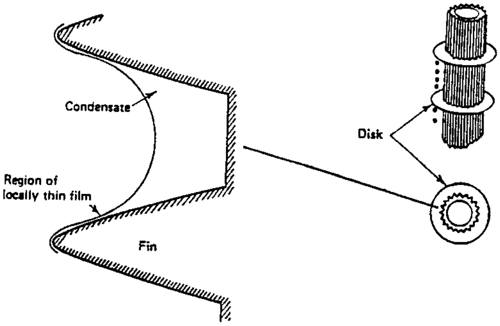

FIGURE 4.8.6 Recommended flute profile and schematic of condensate strippers.

Twisted-tape inserts result in rather modest increases in heat transfer coefficient for complete condensation of either steam or refrigerant. The pressure drop increases are large because of the large wetted surface. Coiled tubular condensers provide a modest improvement in average heat transfer coefficient.

Further Information

This section gives some indication as to why heat transfer enhancement is one of the fastest growing areas of heat transfer. Many techniques are available for improvement of the various modes of heat transfer. Fundamental understanding of the transport mechanism is growing, but, more importantly, design correlations are being established. Many effective and cost-competitive enhancement techniques have made the transition from the laboratory to commercial heat exchangers.

Broad reviews of developments in enhanced heat transfer are available (Bergles, 1988, 1997, 1998, 2002; Thome, 1990; Webb, 1994; Manglik, 2003). Also, several journals, especially *Heat Transfer Engineering, Enhanced Heat Transfer,* and *International Journal of Heating, Ventilating, Air-Conditioning and Refrigerating Research*, feature this technology.

Cooling Towers

Anthony F. Mills

Introduction

In a wet cooling tower, water is evaporated into air with the objective of cooling the water stream. Both natural- and mechanical-draft towers are popular, and examples are shown in Figure 4.8.7. Large natural-draft cooling towers are used in power plants for cooling the water supply to the condenser. Smaller mechanical-draft towers are preferred for oil refineries and other process industries, as well as for central air-conditioning systems and refrigeration plant. Figure 4.8.7a shows a natural draft *counterflow* unit in which the water flows as thin films down over a suitable packing, and air flows upward. In a natural-draft tower the air flows upward due to the buoyancy of the warm, moist air leaving the top of the packing. In a mechanical-draft tower, the flow is forced or induced by a fan. Since the air inlet temperature is usually lower than the water inlet temperature, the water is cooled both by evaporation and by sensible heat loss. For usual operating conditions the evaporative heat loss is considerably larger than the sensible heat loss. Figure 4.8.7b shows a mechanical draft cross-flow unit. Figure 4.8.8 shows a natural-draft cross-flow tower for a power plant.

Packing Thermal Performance

Counterflow units. Merkel's method (Merkel, 1925) for calculating the number of transfer units required to cool the water stream, for specified inlet and outlet water temperatures and inlet air condition is (Mills, 1995)

$$N_{tu} = \frac{g_m S}{\dot{m}_L} = \int_{h_{L,\text{in}}}^{h_{L,\text{out}}} \frac{dh_L}{h_s - h_G} \tag{4.8.12}$$

$$h_G = h_{G,\text{in}} + \left(\dot{m}_L/\dot{m}_G\right)\left(h_L - h_{L,\text{out}}\right) \tag{4.8.13}$$

$$h_s\left(P, T_s\right) = h_s\left(P, T_L\right) \tag{4.8.14}$$

It is imperative that the usual enthalpy datum states be used, namely, zero enthalpy for dry air and liquid water at 0°C. Table 4.8.1 gives enthalpy data for 1 atm pressure. The important assumptions required to obtain this result include

1. A Lewis number of unity;
2. Low mass transfer rate theory is valid;
3. The liquid-side heat transfer resistance is negligible, that is, $T_s \simeq T_L$;
4. The amount of water evaporated is small compared with the water and air flow rates.

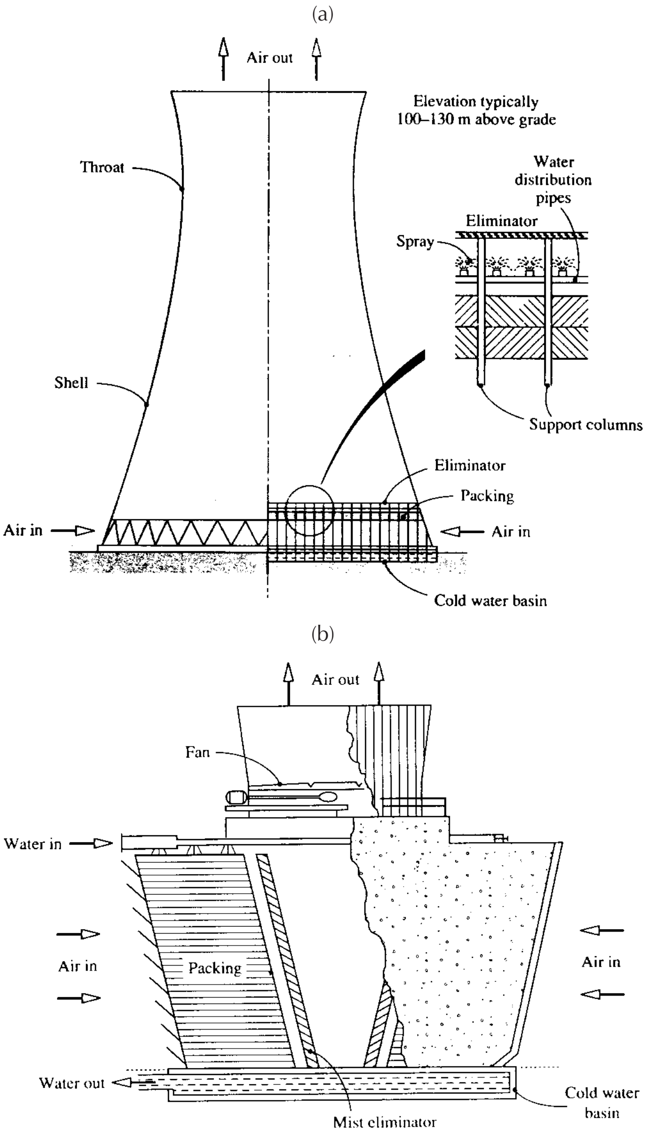

FIGURE 4.8.7 (a) A natural-draft counterflow cooling tower for a power plant. (b) A cross-flow cooling tower for an air-conditioning system.

The method is accurate up to temperatures of about 60°C; comparisons with more exact results are usually within 3 to 5%, and seldom show errors greater than 10%. Notice that the method does not give the outlet state of the air; however, in situations encountered in practice, the outlet air can be assumed to be saturated for the purposes of calculating its density. It is possible to extend Merkel's method to include a finite liquid-side heat transfer resistance, but such refinement is seldom warranted. For typical operating conditions the bulk liquid temperature is seldom more than 0.3 K above the interface temperature.

Cross-flow units. Figure 4.8.9 shows a schematic of a cross-flow packing. If we assume that both the liquid and gas streams are unidirectional, and that there is no mixing in either stream, then use of Merkel's assumptions leads to the following pair of differential equations (Mills, 2001):

FIGURE 4.8.8 A natural-draft cross-flow cooling tower for a power plant.

$$\frac{\partial h_G}{\partial x} = \frac{g_m a}{G}\left(h_s - h_G\right) \tag{4.8.15}$$

$$\frac{\partial h_L}{\partial y} = -\frac{g_m a}{L}\left(h_s - h_G\right) \tag{4.8.16}$$

Also $h_s = h_s(h_L)$ for a negligible liquid-side heat transfer resistance and the required boundary conditions are the inlet enthalpies of both streams. Equation (4.8.15) and Equation (4.8.16) are solved numerically and the solution used to evaluate the average enthalpy of the outlet liquid,

$$\bar{h}_{L,\text{out}} = \frac{1}{X}\int_0^X h_{L,\text{out}}\; dx \tag{4.8.17}$$

Substituting in an exchanger energy balance on the liquid stream gives the heat transfer as

$$q = \dot{m}_L\left(h_{L,\text{in}} - h_{L,\text{out}}\right) \tag{4.8.18}$$

[a] The enthalpies of dry air and liquid water are set equal to zero at a datum temperature of 0°C.

[b] The enthalpy of an unsaturated water vapor-air mixture can be calculated as $h = h_{\text{dry air}} + (m_1/m_{1,\text{sat}})(h_{\text{sat}} - h_{\text{dry air}})$.

Sample calculation. Consider a counterflow unit that is required to cool water from 40 to 26°C when the inlet air is at 10°C, 1 atm, and saturated. We will calculate the number of transfer units required for balanced flow, that is, $\dot{m}_G/\dot{m}_L = 1$. Equation (4.8.12) is to be integrated numerically, with h_G obtained from Equation 4.8.13. The required thermodynamic properties can be obtained from Table 4.8.1. Using Table 4.8.1, $h_{G,\text{in}} = h_{\text{sat}}$ (10°C) = 29.15 kJ/kg, $h_{L,\text{out}} = h_L(26°\text{C}) = 109.07$ kJ/kg. Substituting in Equation (4.8.13),

$$h_G = 29.15 + \left(h_L - 109.07\right)$$

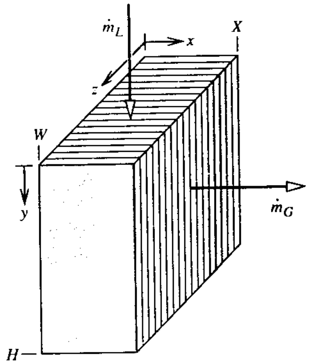

FIGURE 4.8.9 Schematic of a cross-flow cooling tower packing showing the coordinate system.

T_L, °C	h_L, kJ/kg	h_G, kJ/kg	h_s, kJ/kg	$h_s - h_g$, kJ/kg	$\dfrac{1}{h_s - h_g}$
26	109.07	29.15	79.12	49.97	0.02001
28	117.43	37.51	87.86	50.35	0.01986
30	125.79	45.87	97.36	51.49	0.01942
32	134.15	54.23	107.67	53.44	0.01871
34	142.50	62.58	118.89	56.31	0.01776
36	150.86	70.94	131.10	60.16	0.01662
38	159.22	79.30	144.39	65.09	0.01536
40	167.58	87.66	158.86	71.20	0.01404

Choosing 2°C intervals for convenient numerical integration, the above table is constructed, with h_L and $h_s = h_s(T_L)$ also obtained from Table 4.8.1.
Using the trapezoidal rule,

$$\begin{aligned}\int_{h_{L,\text{out}}}^{h_{L,\text{in}}} \frac{dh_L}{h_s - h_G} &= \frac{8.36}{2}\Big[0.02001 + 2(0.01986 + 0.01942 + 0.01871 + 0.01776 \\ &\quad + 0.01662 + 0.01536) + 0.01404\Big] \\ &= 1.043\end{aligned}$$

From Equation (4.8.12), $N_{tu} = 1.043$. Also, by using Table 4.8.1, $T_{G,\text{out}} = 27.9°$ for saturated outlet air.

Thermal-Hydraulic Design of Cooling Towers

The thermal-hydraulic design of a mechanical-draft cooling tower is relatively straightforward. The flow rate ratio $\dot{m}_L / \dot{m}_G$ can be specified and varied parametrically to obtain an optimal design, for which the size and cost of the packing is balanced against fan power requirements and operating cost. Data are required for mass transfer conductances and friction for candidate packings. Table 4.8.2a and Table 4.8.2b give correlations for a selection of packings. In Table 4.8.2b, the mass transfer conductance is correlated as $g_m a/L$, where a is the transfer area per unit volume and $L = \dot{m}_L / A_{fr}$ is the superficial mass velocity of the water flow (also called the *water loading* on the packing). Similarly, we define $G = \dot{m}_G / A_{fr}$. Typical water loadings are 1.8 to 2.7 kg/m^2 sec, and superficial air velocities fall in the range 1.5 to 4 m/sec. No attempt is made to correlate g_m and a separately. The number of transfer units of a packing of height H is then

$$N_{tu} = \frac{g_m S}{\dot{m}_L} = \frac{g_m a H}{L} \tag{4.8.19}$$

TABLE 4.8.2a Packings for Counterflow and Cross-Flow Cooling Towers: Designations and Descriptions

Counterflow Packings

1. Flat asbestos sheets, pitch 4.45 cm
2. Flat asbestos sheets, pitch 3.81 cm
3. Flat asbestos sheets, pitch 3.18 cm
4. Flat asbestos sheets, pitch 2.54 cm
5. 60° angle corrugated plastic, Munters M12060, pitch 1.17 in.
6. 60° angle corrugated plastic, Munters M19060, pitch 1.8 in.
7. Vertical corrugated plastic, American Tower Plastics Coolfilm, pitch 1.63 in.
8. Horizontal plastic screen, American Tower Plastics Cooldrop, pitch 8 in. 2 in. grid
9. Horizontal plastic grid, Ecodyne shape 10, pitch 12 in.
10. Angled corrugated plastic, Marley MC67, pitch 1.88 in.
11. Dimpled sheets, Toschi Asbestos-Free Cement, pitch 0.72 in.
12. Vertical plastic honeycomb, Brentwood Industries Accu-Pack, pitch 1.75 in.

Cross-Flow Packings

1. Doron V-bar, 4 × 8 in. spacing
2. Doron V-bar, 8 × 8 in. spacing
3. Ecodyne T-bar, 4 × 8 in. spacing
4. Ecodyne T-bar, 8 × 8 in. spacing
5. Wood lath, parallel to air flow, 4 × 4 in. spacing
6. Wood lath, perpendicular to air flow, 4 × 4 in. spacing
7. Marley α-bar, parallel to air flow, 16 × 4 in. spacing
8. Marley ladder, parallel to air flow, 8 × 2 in. spacing

The correlations are in terms of dimensionless mass velocities L^+ and G^+, and a *hot water correction* T^+_{HW}. The hot water correction accounts for a number of factors, such as errors associated with Merkel's method, deviations from low mass transfer rate theory at higher values of T_s, and fluid property dependence on temperature. Frictional resistance to air flow through the packings is correlated as a *loss coefficient* $N = \Delta P/(\rho V^2/2)$ per unit height or depth of packing, as a function of L^+ and G^+. The velocity V is superficial gas velocity. No hot water correction is required.

In a natural-draft tower, the thermal and hydraulic performance of the tower are coupled, and the flow rate ratio $\dot{m}_L/\dot{m}_G$ cannot be specified *a priori*. The buoyancy force producing the air flow depends on the state of the air leaving the packing which in turn depends on $\dot{m}_L/\dot{m}_G$ and the inlet air and water states. An iterative solution is required to find the operating point of the tower. The buoyancy force available to overcome the shell and packing pressure drops is

$$\Delta P^B = g\left(\rho_a - \rho_{G,\mathrm{out}}\right)H \qquad (4.8.20)$$

where ρ_a is the ambient air density and H is usually taken as the distance from the bottom of the packing to the top of the shell. The various pressure drops are conveniently expressed as

$$\Delta P_i = N_i \frac{\rho_{Gi} V_i^2}{2} \qquad (4.8.21)$$

Where N_i is the loss coefficient and V_i is the air velocity at the corresponding location. The pressure drops are associated with the shell, the packing, the mist eliminators, supports and pipes, and the water spray below the packing. Some sample correlations are given in Table 4.8.3.

Water loadings in counterflow natural-draft towers typically range from 0.8 to 2.4 kg/m^2 sec, and superficial air velocities range from 1 to 2 m/sec. The ratio of base diameter to height may be 0.75 to 0.85, and the ratio of throat to base diameter 0.55 to 0.65. The height of the air inlet is usually 0.10 to

With permission.

0.12 times the base diameter to facilitate air flow into the tower. In practice the air flow distribution in natural-draft towers is not very uniform. However, the assumption of uniform air and water flows in our model of counterflow packing is adequate for most design purposes.

Cost-optimal design of cooling towers requires consideration of the complete power or refrigeration system. For refrigeration, the economics are determined mainly by the operating cost of the chiller (Kintner-Meyer and Emery, 1955).

Cooling Tower Behavior

There are a number of computer programs available that use variations of Merkel's method to calculate the cooling tower performance, for example, TEFRI (Bourillot, 1983), VERA2D-84 (Mujamdar et al., 1985), CTOWER (Mills, 2001). These programs can be used to perform parametric studies to obtain the response of cooling towers to environmental, duty, and design changes. However, before using such programs, some thought should be given to the important characteristics of cooling tower behavior. For this purpose, it is useful to consider a graphical representation of Merkel's theory for a counterflow tower. Figure 4.8.10 shows a chart with moist air enthalpy plotted vs. water enthalpy (or, equivalently, water

TABLE 4.8.3 Pressure Drop Correlations for Cooling Tower Shells, Sprays, Supports, and Mist Eliminators

1. Shell (natural draft counterflow):

   $$N = 0.167\left(\frac{D_B}{b}\right)^2$$

   where D_B *is* the diameter of the shell base and b is the height of the air inlet.
2. Spray (natural-draft counterflow):

   $$N = 0.526(Z_p[\mathrm{m}] + 1.22)\ (\dot{m}_L/\dot{m}_G)^{1.32}$$
3. Mist eliminators:
   $N = 2–4$
4. Support columns, pipes, etc. (natural-draft counterflow):
   $N = 2–6$
5. Fan exit losses for mechanical-draft towers (velocity based on fan exit area):

   $$N = 1.0,\ \text{forced draft}$$
   $$\simeq 0.5,\ \text{induced draft, depending on diffuser design}$$
6. Miscellaneous losses for mechanical-draft towers (velocity based on packing crosssectional area):
   $N \simeq 3$

Note: N is the loss coefficient defined by Equation 4.8.21, with velocity based on cross-sectional area for air flow underneath the packing in items 1 through 4.

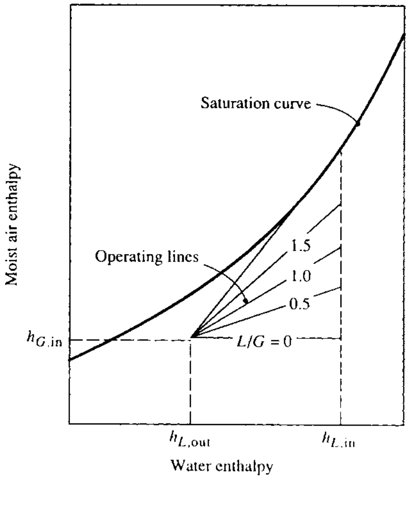

FIGURE 4.8.10 Counterflow cooling tower operating lines for various water-to-air flow-rate ratios shown on an enthalpy chart.

temperature) at 1 atm pressure. The *saturation curve* $h_s(T_s)$ is the enthalpy of saturated air. The *operating lines* $h_G(h_L)$ are given by Equation (4.8.13) and relate the air enthalpy to the water enthalpy at each location in the packing. The slope of an operating line is L/G. Since the assumption $T_s = T_L$ is made in Merkel's method, vertical lines on the chart connect h_s and h_G at each location in the packing. The driving force for enthalpy transfer, $(h_s - h_G)$, is the vertical distance between the saturation curve and the operating line. The integral in Equation (4.8.12) averages the reciprocal of this distance. By using this chart, a number of observations about cooling tower behavior can be made.

1. Figure 4.8.10 shows the effect of L/G for fixed water inlet and outlet temperatures, and fixed inlet air temperature and humidity. If we imagine L to be fixed as well, we see that as G decreases, the driving forces decrease, and so a larger NTU is required.
2. The minimum NTU required corresponds to $L/G = 0$, that is, an infinite air flow rate, for which the operating line is horizontal.
3. Due to the curvature of the operating line, it is possible for the operating line to be tangent to the saturation curve. The indicated NTU is then infinite, which tells us that the air flow rate must be increased in order to achieve the desired water cooling range.
4. For a mechanical-draft tower, the optimal value of L/G lies between the two limits described in items 2 and 3 above. If L/G is large, the required height of packing is large, and the capital cost will be excessive. If L/G is small, the fan power will be excessive (since fan power is proportional to air volume flow rate times pressure drop).

Range and Approach

Cooling tower designers and utility engineers have traditionally used two temperature differences to characterize cooling tower operation. The *range* is the difference between the water inlet and outlet temperatures (also called simply the hot and cold water temperatures). The *approach* is the difference between the outlet water temperature and the wet-bulb temperature of the entering (ambient) air. The approach characterizes cooling tower performance; for a given inlet condition, a larger packing will produce a smaller approach to the ambient wet-bulb temperature, and hence a lower water outlet temperature. (The water cannot be cooled below the ambient wet-bulb temperature.) The approach concept is useful because the ambient dry-bulb temperature has little effect on performance at usual operating conditions (for a specified wet-bulb temperature).

Cooling Demand Curves

Electrical utility engineers have found it convenient to use charts of *cooling demand curves* to evaluate packing specifications. Figure 4.8.11 is an example of such a chart, on which the required NTU, for a given inlet air wet-bulb temperature and range, is plotted vs. L/G with the approach as a parameter. Such a plot is possible since the inlet air dry-bulb temperature has only a small effect under usual operating conditions. Now, if it is possible to correlate the mass transfer conductance as

$$\frac{g_m a}{L} = C\left(\frac{L}{G}\right)^{-n} \tag{4.8.22}$$

the NTU of a packing of height H is

$$\frac{g_m S}{\dot{m}_L} = \frac{g_m a H}{L} = C\left(\frac{L}{G}\right)^{-n} H \tag{4.8.23}$$

Equation (4.8.23) can also be plotted on the chart to give the *packing capability line*. For a required approach, the *operating point* of the tower is the intersection of the cooling demand curve and packing capability line. Charts of cooling demand curves are available (Cooling Tower Institute, 1967; Kelly, 1976). Correlations of the form of Equation (4.8.22) do not necessarily fit experimental data well. A dependence $g_m a \; \alpha L^{1-n} G^n$ is implied and, in the past, experimental data were often forced to fit such a relation. If the $g_m a$ correlation does not have the form of Equation (4.8.22), the NTU cannot be plotted as a line on a cooling demand chart.

With the almost universal use of computers and the availability of suitable computer programs, one can expect less use of cooling demand charts in the future. The major sources of error in the predictions made by these programs are related to nonuniform air and water flow, and the correlations of packing mass transfer and pressure drop experimental data. The experimental data are obtained in small-scale test rigs, in which it is impossible to simulate many features of full-size towers — for example, nonuniform

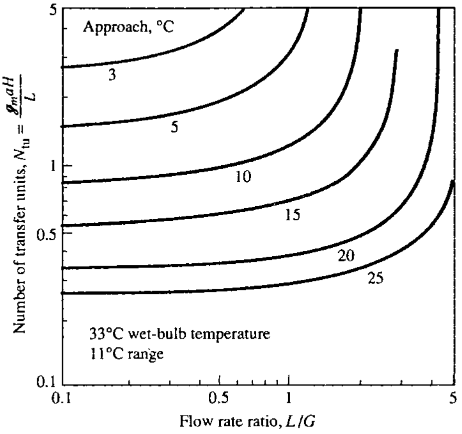

FIGURE 4.8.11 Example of cooling demand curves for a specified wet-bulb temperature and range: NTU vs. flow rate ratio for a fixed approach.

flow due to entrance configuration, nonuniform wetting of the packing, and, in the case of counterflow towers, the effect of spray above the packing and rain below the packing. Furthermore, since testing of packings in small-scale test rigs is itself not easy, considerable scatter is seen in such test data. Correlations of the data typically have root mean square errors of 10 to 20%.

Legionnaires' Disease

Legionnaires' disease is a form of pneumonia caused by a strain of legionnella bacteria (sero group I). Smokers and sick people are particularly vulnerable to the disease. Major outbreaks have occurred at conventions and in hospitals, for which the source of the bacteria has been traced to cooling towers of air-conditioning systems. The bacteria require nutrients such as algae or dead bacteria in sludge, and thrive if iron oxides are present. However, properly designed, installed, and maintained cooling towers have never been implicated in an outbreak of the disease. Key requirements to be met include the following:

1. Mist (drift) eliminators should be effective.
2. The tower should be located so as to minimize the possibility of mist entering a ventilation system.
3. Corrosion in the tower and water lines should be minimized by use of glass fiber, stainless steel, and coated steel.
4. The design should facilitate inspection and cleaning, to allow early detection and remedy of sludge buildup.
5. Water treatment and filtration procedures should meet recommended standards.

Heat Pipes

Larry W. Swanson

Introduction

The heat pipe is a vapor-liquid phase-change device that transfers heat from a hot reservoir to a cold reservoir using **capillary forces** generated by a **wick** or porous material and a working fluid. Originally conceived by Gaugler in 1944, the operational characteristics of heat pipes were not widely publicized until 1963 when Grover and his colleagues at Los Alamos Scientific Laboratory independently reinvented the concept. Since then many types of heat pipes have been developed and used by a wide variety of industries.

Figure 4.8.12 shows a schematic of a heat pipe aligned at angle ψ relative to the vertical axis (gravity vector). The heat pipe is composed of a container lined with a wick that is filled with liquid near its saturation temperature. The vapor-liquid interface, usually found near the inner edge of the wick, separates the liquid in the wick from an open vapor core. Heat flowing into the evaporator is transferred through the container to the liquid-filled wicking material, causing the liquid to evaporate and vapor to flow into the open core portion of the evaporator. The capillary forces generated by the evaporating interface increase the pressure difference between the vapor and liquid. The vapor in the open core flows out of the evaporator through the adiabatic region (insulated region) and into the condenser. The vapor then condenses, generating capillary forces similar, although much less in magnitude, to those in the evaporator. The heat released in the condenser passes through the wet wicking material and container out into the cold reservoir. The condensed liquid is then pumped, by the liquid pressure difference due to the net capillary force between the evaporator and condenser, out of the condenser back into the evaporator. Proper selection and design of the pipe container, working fluid, and wick structure are essential to the successful operation of a heat pipe. The **heat transfer limitations, effective thermal conductivity**, and axial temperature difference define the operational characteristics of the heat pipe.

Heat Pipe Container, Working Fluid, and Wick Structures

The container, working fluid, and wick structure of a heat pipe determine its operational characteristics. One of the most important considerations in choosing the material for the heat pipe container and wick is its compatibility with the working fluid. Degradation of the container or wick and contamination of the working fluid due to chemical reaction can seriously impair heat pipe performance. For example, noncondensable gas created during a chemical reaction eventually can accumulate near the end of the condenser, decreasing the condensation surface area. This reduces the ability of the heat pipe to transfer heat to the external heat sink. The material and geometry of the heat pipe container also must have a high burst strength, low weight, high thermal conductivity, and low porosity.

Using the proper working fluid for a given application is another critical element of proper heat pipe operation. The working fluid must have good thermal stability properties at the specified operational temperature and pressure. The operational temperature range of the working fluid has to lie between its triple point and its critical point for liquid to exist in the wicking material. The **wettability** of the working

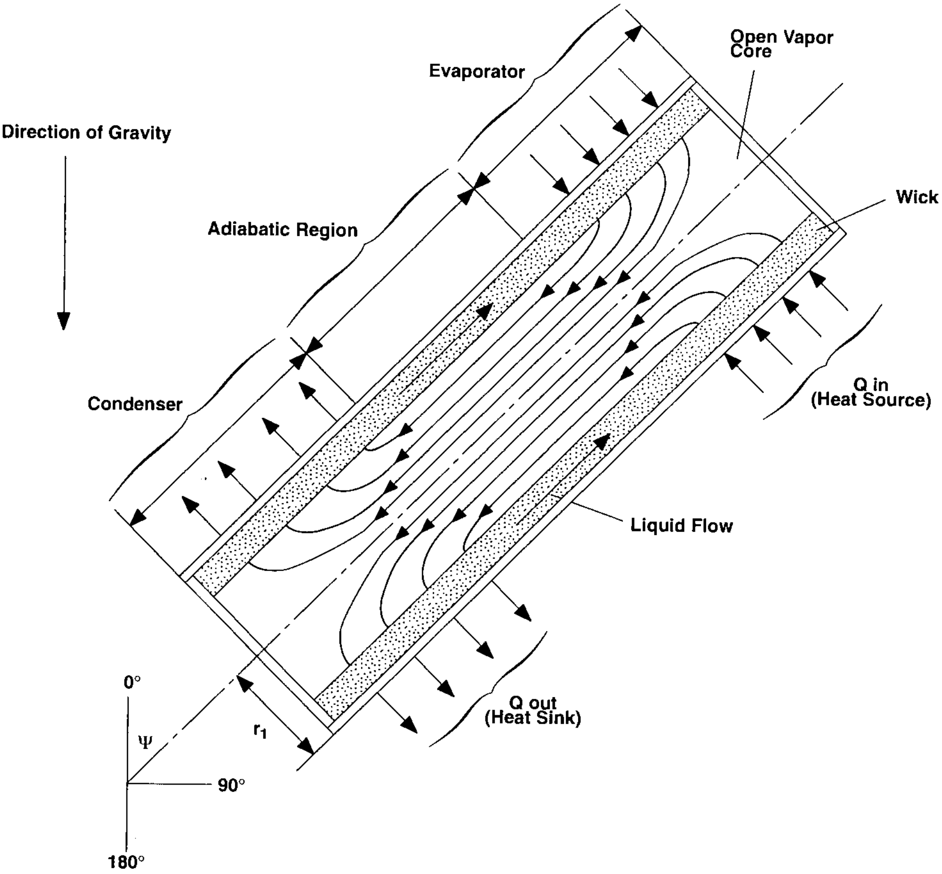

FIGURE 4.8.12 Schematic of a typical heat pipe.

fluid contributes to its capillary pumping and priming capability. High-surface-tension fluids are commonly used in heat pipes because they provide the capillary pumping and wetting characteristics necessary for proper operation. Other desirable thermophysical properties include a high liquid thermal conductivity, high latent heat of vaporization, low liquid viscosity, and a low vapor viscosity. Table 4.8.4 gives the thermophysical properties for three typical heat pipe working fluids that span a fairly wide operating temperature range. The thermophysical properties for other heat pipe working fluids can be obtained from Dunn and Reay (1982) and Peterson (1994).

The wick structure and working fluid generate the capillary forces required to (1) pump liquid from the condenser to the evaporator and (2) keep liquid evenly distributed in the wicking material. Heat pipe wicks can be classified as either homogeneous wicks or composite wicks. Homogeneous wicks are composed of a single material and configuration. The most common types of homogeneous wicks include wrapped screen, sintered metal, axial groove, annular, crescent, and arterial. Composite wicks are composed of two or more materials and configurations. The most common types of composite wicks include variable screen mesh, screen-covered groove, screen slab with grooves, and screen tunnel with grooves. Regardless of the wick configuration, the desired material properties and structural characteristics of heat pipe wick structures are a high thermal conductivity, high wick porosity, small capillary radius, and high wick permeability. Table 4.8.2 gives the geometric properties of some commonly used homogeneous wicks. The properties of other wick structures, including nonhomogenous types, can be obtained from Peterson (1994). The container, wick structure, and working fluid are used to determine the heat transfer limitations of heat pipes.

Heat Transfer Limitations

Heat pipes undergo various heat transfer limitations depending on the working fluid, the wick structure, the dimensions of the heat pipe, and the heat pipe operational temperature. Figure 4.8.13 gives a qualitative description of the various heat transfer limitations, which include vapor-pressure, sonic, entrainment, capillary, and boiling limitations. The composite curve enclosing the shaded region in Figure 4.8.13 gives the maximum heat transfer rate of the heat pipe as a function of the operational temperature. The figure shows that as the operational temperature increases, the maximum heat transfer rate of the heat pipe is limited by different physical phenomena. As long as the operational heat transfer rate falls within the shaded region, the heat pipe will function properly.

The vapor-pressure limitation (or viscous limitation) in heat pipes develops when the pressure drop in the vapor core reaches the same order of magnitude as the vapor pressure in the evaporator. Under

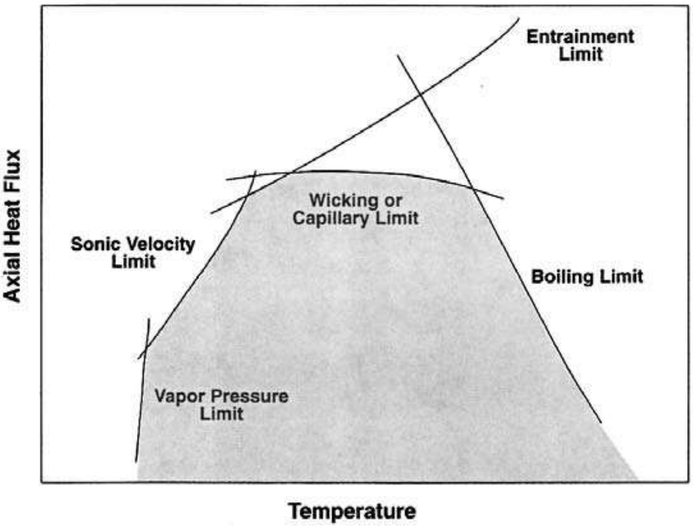

FIGURE 4.8.13 Heat transfer limitations in heat pipes.

these conditions, the pressure drop due to flow through the vapor core creates an extremely low vapor pressure in the condenser preventing vapor from flowing in the condenser. A general expression for the vapor-pressure limitation is (Dunn and Reay, 1982)

$$Q_{\mathrm{v}p,\max} = \frac{\pi r_{\mathrm{v}}^4 h_{fg} \rho_{v,e} P_{\mathrm{v},e}}{12 \mu_{v,e} l_{\mathrm{eff}}} \tag{4.8.24}$$

where r_v is the cross-sectional radius of the vapor core (m), h_{fg} is the latent heat of vaporization (J/kg), $\rho_{v,e}$ is the vapor density in the evaporator (kg/m^3), P_{ve} is the vapor pressure in the evaporator (Pa), and $\mu_{v,e}$ is the vapor viscosity in the evaporator (N sec/m^2). l_{eff} is the effective length of the heat pipe (m) equal to $l_{\mathrm{eff}} = 0.5(l_e + 2l_a + l_c)$. The vapor-pressure limitation can occur during the start-up of heat pipes at the lower end of the working-fluid-temperature range.

The sonic limitation also can occur in heat pipes during start-up at low temperatures. The low temperature produces a low vapor density, thereby reducing the speed of sound in the vapor core. Thus, a sufficiently high mass flow rate in the vapor core can cause sonic flow conditions and generate a shock wave that chokes the flow and restricts the pipes ability to transfer heat to the condenser. Dunn and Reay (1982) give an expression for the sonic limitation that agrees very well with experimental data,

$$Q_{s,\max} = 0.474 A_{\mathrm{v}} h_{fg} \left(\rho_v P_v\right)^{1/2} \tag{4.8.25}$$

where A_v is the cross-sectional area of the vapor core (m^2). The sonic limitation should be avoided because large temperature gradients occur in heat pipes under choked-flow conditions.

The entrainment limitation in heat pipes develops when the vapor mass flow rate is large enough to shear droplets of liquid off the wick surface causing dry-out in the evaporator. A conservative estimate of the maximum heat transfer rate due to entrainment of liquid droplets has been given by Dunn and Reay (1982) as

$$Q_{e,\max} = A_{\mathrm{v}} h_{fg} \left[\frac{\rho_v \sigma_l}{2 r_{c,\mathrm{ave}}}\right]^{1/2} \tag{4.8.26}$$

where σ_l is the surface tension (N/m) and $r_{c,\mathrm{ave}}$ is the average capillary radius of the wick. Note that for many applications $r_{c,\mathrm{ave}}$ is often approximated by $r_{c,e}$.

The capillary limitation in heat pipes occurs when the net capillary forces generated by the vapor-liquid interfaces in the evaporator and condenser are not large enough to overcome the frictional pressure losses due to fluid motion. This causes the heat pipe evaporator to dry out and shuts down the transfer of heat from the evaporator to the condenser. For most heat pipes, the maximum heat transfer rate due to the capillary limitation can be expressed as (Chi, 1976).

$$Q_{c,\max} = \left[\frac{\rho_l \sigma_l h_{fg}}{\mu_l}\right]\left[\frac{A_w K}{l_{\mathrm{eff}}}\right]\left(\frac{2}{r_{c,e}} - \left[\frac{\rho_l}{\sigma_l}\right] g L_t \cos\Psi\right) \tag{4.8.27}$$

where K is the wick permeability (m^2), A_w is the wick cross-sectional area (m^2), ρ_l is the liquid density (m^3), μ_l is the liquid viscosity (N sec/m^2), $r_{c,e}$ is the wick capillary radius in the evaporator (m), g is the acceleration due to gravity (9.8 m/sec^2), and L_t is the total length of the pipe (m). For most practical operating conditions, this limitation can be used to determine maximum heat transfer rate in heat pipes.

The boiling limitation in heat pipes occurs when the degree of liquid superheat in the evaporator is large enough to cause the nucleation of vapor bubbles on the surface of the wick or the container. Boiling is usually undesirable in heat pipes because local hot spots can develop in the wick, obstructing the flow of liquid in the evaporator. An expression for the boiling limitation is (Chi, 1976)

$$Q_{b,\max} = \frac{4\pi l_{\mathrm{eff}} k_{\mathrm{eff}} T_v \sigma_v}{h_{fg} \rho_l \ln\left(r_i / r_v\right)}\left(\frac{1}{r_n} - \frac{1}{r_{c,e}}\right) \tag{4.8.28}$$

where k_{eff} is the effective thermal conductivity of the composite wick and working fluid (W/m K), T_v is the vapor saturation temperature (K), r_i is the inner container radius (m), r_n is the nucleation radius (equal to 2.00×10^{-6} m in the absence of noncondensable gas).

Effective Thermal Conductivity and Heat Pipe Temperature Difference

One key attribute of the heat pipe is that it can transfer a large amount of heat while maintaining nearly isothermal conditions. The temperature difference between the external surfaces of the evaporator and the condenser can be determined from the following expression

$$\Delta T = R_t Q \tag{4.8.29}$$

where R_t is the total thermal resistance (K/W) and Q is the heat transfer rate (W). Figure 4.8.14 shows the thermal resistance network for a typical heat pipe and the associated thermal resistances. In most cases, the total thermal resistance can be approximated by

$$R_t = R_1 + R_2 + R_3 + R_5 + R_7 + R_8 + R_9 \tag{4.8.30}$$

The reader is referred to Peterson (1994) for the specific mathematical relationships used to calculate each thermal resistance. The effective thermal conductivity of the heat pipe is defined as the heat transfer rate divided by the temperature difference between the heat source and heat sink,

$$k_{\mathrm{eff}} = \frac{L_t}{R_t A_t} \tag{4.8.31}$$

where A_t is the overall cross-sectional area of the pipe (m^2). Under normal operating conditions, the total thermal resistance is relatively small, making the external surface temperature in the evaporator approx-

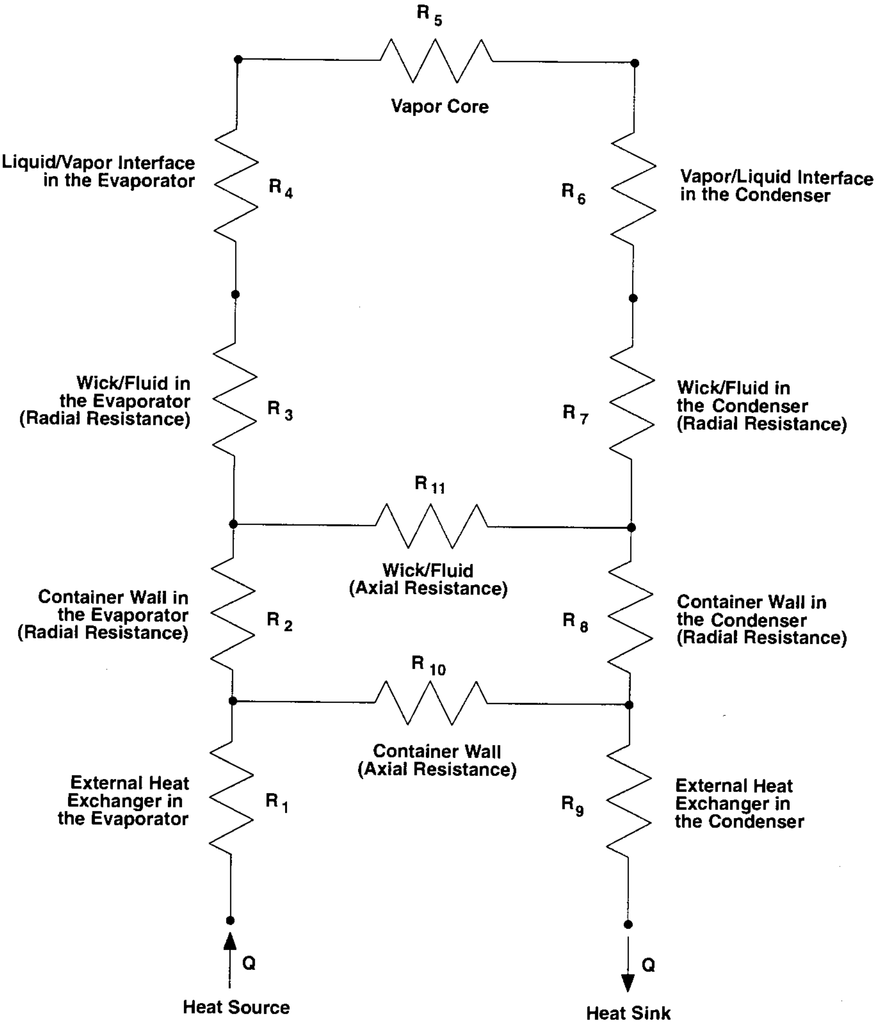

FIGURE 4.8.14 Thermal resistance network in a heat pipe.

imately equal to that in the condenser. Thus, the effective thermal conductivity in a heat pipe can be very large (at least an order of magnitude larger than that of aluminum).

Design Example

Design a water heat pipe to transport 80 W of waste heat from an electronics package to cooling water. The heat pipe specifications are

1. Axial orientation — complete gravity-assisted operation (condenser above the evaporator; ψ = 180°)
2. Maximum heat transfer rate — 80 W
3. Nominal operating temperature — 40°C
4. Inner pipe diameter — 3 cm
5. Pipe length — 25 cm evaporator length, 50 cm adiabatic section, and 25 cm condenser length

The simplest type of wick structure to use is the single-layer wire mesh screen wick shown in Table 4.8.5. The geometric and thermophysical properties of the wick have been selected as (this takes some forethought)

- $d = 2.0 \times 10^{-5}$ m
- $w = 6.0 \times 10^{-5}$ m
- $\dfrac{1}{2N} = r_c = {}^1/_2(2.0 \times 10^{-5} + 6 \times 10^{-5}) = 4.0 \times 10^{-5}$ m
- $\varepsilon = 1$
- $k_{\text{eff}} = k_1 = 0.630 \ \dfrac{\text{W}}{\text{mK}}$
- $t_w = 1.0 \times 10^{-3}$ m
- $K = \dfrac{t_w^2}{12} = \dfrac{\left(1\times 10^{-3}\right)^2}{12} = 8.33\times 10^{-8}\ \text{m}^2$

The other heat pipe geometric properties are

- $r_v = r_i - t_w = 0.015 - 0.001 = 0.014$ m
- $l_{\text{eff}} = \dfrac{0.25+0.25}{2} + 0.5 = 0.75$ m
- $L_t = 0.25 + 0.50 + 0.25 + 1.0$ m
- $A_w = \pi(r_i^2 - r_v^2) = \pi[(0.015)^2 - (0.014)^2] = 9.11 \times 10^{-5}\ \text{m}^2$
- $A_v = \pi r_v^2 = \pi(0.014)^2 = 6.16 \times 10^{-4}\ \text{m}^2$

The thermophysical properties of water at 40°C are (see Table 4.8.4):

- $\rho_l = 992.1\ \text{kg/m}^3$
- $\rho_v = 0.05\ \text{kg/m}^3$
- $\sigma_l = 2.402 \times 10^6$ J/kg
- $\mu_l = 6.5 \times 10^{-3}$ kg/m sec
- $\mu_v = 1.04 \times 10^{-4}$ kg/m sec
- $P_v = 7000$ Pa

The various heat transfer limitations can now be determined to ensure the heat pipe meets the 80 W heat transfer rate specification. The vapor-pressure limitation is

$$Q_{vp,\max} = \frac{\pi(0.014)^4\left(2.402\times 10^6\right)(0.05)(7000)}{12\left(1.04\times 10^{-4}\right)(0.75)} = 1.08\times 10^5\ \text{W} \tag{4.8.32}$$

The sonic limitation is

$$\begin{aligned} Q_{s,\max} &= 0.474\left(6.16\times 10^{-4}\right)\left(2.402\times 10^6\right)\left[(0.05)(7000)\right]^{1/2} \\ &= 1.31\times 10^4\ \text{W} \end{aligned} \tag{4.8.33}$$

The entrainment limitation is

$$\begin{aligned} Q_{e,\max} &= \left(6.16\times 10^{-4}\right)\left(2.402\times 10^6\right)\left[\frac{(0.05)(0.07)}{2\left(4.0\times 10^{-5}\right)}\right]^{1/2} \\ &= 9.79\times 10^3\ \text{W} \end{aligned} \tag{4.8.34}$$

Noting that cos ψ = −1, the capillary limitation is

$$Q_{c,\max} = \left[\frac{(992.1)(0.07)\left(2.402\times10^{6}\right)}{6.5\times10^{-3}}\right]\left[\frac{\left(9.11\times10^{-5}\right)\left(8.33\times10^{-8}\right)}{0.75}\right]\left[\frac{2}{4.0\times10^{-5}}+\frac{992.1}{0.07}9.8(1.0)\right] \tag{4.8.35}$$

$$= 4.90\times10^{4}\ \text{W}$$

Finally, the boiling limitation is

$$Q_{b,\max} = \frac{4\pi(0.75)(0.63)(313)(0.07)}{\left(2.402\times10^{6}\right)(992.1)\ln\left(\dfrac{0.015}{0.014}\right)}\left[\frac{1}{2.0\times10^{-6}}-\frac{1}{4.0\times10^{-5}}\right] \tag{4.8.36}$$

$$= 0.376\ \text{W}$$

All of the heat transfer limitations, with the exception of the boiling limitation, exceed the specified heat transfer rate of 80 W. The low value of 0.376 W for the boiling limitation strongly suggests that the liquid will boil in the evaporator and possibly cause local dry spots to develop. The reason the liquid boils is because the effective thermal conductivity of the wick is equal to the conductivity of the liquid, which is very low in this case. Because the liquid is saturated at the vapor-liquid interface, a low effective thermal conductivity requires a large amount of wall superheat which, in turn, causes the liquid to boil. This problem can be circumvented by using a high conductivity wire mesh or sintered metal wick, which greatly increases the effective conductivity. It should be noted, however, that because porous wicks have lower permeabilities, the capillary limitation should be lower as well. Let's try a sintered particle wick made of copper with the following properties (see Table 4.8.5):

- $d = 1.91 \times 10^{-4}$ m
- $r_{c,3} = 0.21d = 4.0 \times 10^{-5}$ m (same as before)
- $\varepsilon = 0.48$
- $K = \dfrac{\left(1.91\times10^{-4}\right)^{2}(0.48)}{150(1-0.48)^{2}} = 2.07\times10^{-10}\ \text{m}^{2}$
- $k_s = 400\ \dfrac{\text{W}}{\text{mK}}$ (copper)
- $k_1 = 0.630\ \dfrac{\text{W}}{\text{mK}}$ (water)
- $k_{\text{eff}} = \dfrac{400\left[2(400)+0.63-2(0.48)(400-0.63)\right]}{2(400)+0.63+0.48(400-0.63)} = 168\ \text{W/mK}$

All other geometric and thermophysical properties are the same. The heat transfer limitations affected by the change in wick structure are the capillary and boiling limitations. The sintered metal wick produces a capillary limitation of

$$Q_{c,\max} = \left[\frac{(992.1)(0.07)\left(2.402\times10^{6}\right)}{6.5\times10^{-3}}\right]\left[\frac{\left(9.11\times10^{-5}\right)\left(2.07\times10^{-10}\right)}{0.75}\right]\left[\frac{2}{4.0\times10^{-5}}+\frac{992.1}{0.07}9.8(1.0)\right] \tag{4.8.37}$$

$$= 122\ \text{W}$$

The boiling limitation for the sintered wick is

TABLE 4.8.5 Physical Properties of Wick Structures

	Wick Type[a]	Thermal Conductivity	Porosity	Minimum Capillary Radius	Permeability
Single-layer wire mesh screens (heat-pipe axis in the plane of the paper in this sketch)  $1/N = d + w$ N = number of aperatures per unit length		$k_{\text{eff}} = k_e$	$\varepsilon = 1$	$r_c = {}^1/_{(2N)}$	$K = t_w^2/12$
	Multiple wire mesh screens,[b] plain or sintered (screen dimensions as for single layers illustrated above)	$k_{\text{eff}} = \dfrac{k_e\left[k_e + k_s - (1-\varepsilon)(k_e - k_s)\right]}{k_e + k_s + (1-\varepsilon)(k_e - k_s)}$	Estimated from $\varepsilon = 1 - (\pi N d)/4$	$r_c = {}^1/_{(2N)}$	$k = \dfrac{d^2\varepsilon^2}{122(1-\varepsilon)^2}$

TABLE 4.8.5 Physical Properties of Wick Structures (continued)

	Wick Type[a]		Thermal Conductivity	Porosity	Minimum Capillary Radius	Permeability
	Unconsolidated packed spherical particles (d = average particle diameter)	Plain	$k_{\text{eff}} = \dfrac{k_e\left[2k_e + k_s - 2(1-\varepsilon)(k_e - k_s)\right]}{2k_e + k_s + (1-\varepsilon)(k_e - k_s)}$	Estimated from (assuming cubic packing) ε = 0.48	$r_c = 0.21d$	$k = \dfrac{d^2\varepsilon^2}{150(1-\varepsilon)^2}$
		Sintered	$k_{\text{eff}} = \dfrac{k_e\left[2k_s + k_e - 2\varepsilon(k_s - k_e)\right]}{2k_s + k_e + \varepsilon(k_s - k_e)}$			
	Sintered metal fibers (d = fiber diameter)		$k_{\text{eff}} = \varepsilon^2 k_e (1-\varepsilon)^2 k_s + \dfrac{4\varepsilon(1-\varepsilon)k_e k_s}{k_e + k_s}$	Use manufacturers data	$r_c = \dfrac{d}{2(1-\varepsilon)}$	$k = C_1 \dfrac{y^2 - 1}{y^2 - 1}$ where $y = 1 + \dfrac{C_2 d^2 \varepsilon^3}{(1-\varepsilon)^2}$ $C_1 = 6.0 \times 10^{-10}\ \text{m}^2$ $C_2 = 3.3 \times 10^7\ \text{l/m}^2$

[a] The axis of the pipe and direction of fluid flow are normal to the paper.

[b] These wicks are positioned so that the layers follow the contours of the iner surface of the pipe wall.

Revised from Peterson, G.P., *An Introduction to Heat Pipes Modeling, Testing, and Applications*, John Wiley & Sons, New York, 1994.

$$Q_{b,\max} = \frac{4\pi(0.75)(168)(313)(0.07)}{\left(2.402\times10^{6}\right)(992.1)\ln\left(\dfrac{0.015}{0.014}\right)}\left[\frac{1}{2.0\times10^{-6}}-\frac{1}{4.0\times10^{-5}}\right] \tag{4.8.38}$$

$$= 100 \text{ W}$$

This design now meets all the specifications defined in the problem statement.

Application of Heat Pipes

Heat pipes have been applied to a wide variety of thermal processes and technologies. It would be an impossible task to list all the applications of heat pipes; therefore, only a few important industrial applications are given in this section. In the aerospace industry, heat pipes have been used successfully in controlling the temperature of vehicles, instruments, and space suits. Cryogenic heat pipes have been applied in (1) the electronics industry for cooling various devices (e.g., infrared sensors, parametric amplifiers) and (2) the medical field for cryogenic eye and tumor surgery. Heat pipes have been employed to keep the Alaskan tundra frozen below the Alaskan pipeline. Other cooling applications include (1) turbine blades, generators, and motors; (2) nuclear and isotope reactors; and (3) heat collection from exhaust gases, solar and geothermal energy.

In general, heat pipes have advantages over many traditional heat-exchange devices when (1) heat has to be transferred isothermally over relatively short distances, (2) low weight is essential (the heat pipe is a passive pumping device and therefore does not require a pump), (3) fast thermal-response times are required, and (4) low maintenance is mandatory.

Defining Terms

Capillary force: The force caused by a curved vapor-liquid interface. The interfacial curvature is dependent on the surface tension of the liquid, the contact angle between the liquid wick structure, the vapor pressure, and the liquid pressure.

Effective thermal conductivity: The heat transfer rate divided by the temperature difference between the evaporator and condenser outer surfaces.

Heat transfer limitations: Limitations on the axial heat transfer capacity imposed by different physical phenomena (i.e., vapor pressure, sonic, entrainment, capillary, and boiling limitations).

Wettability: The ability of a liquid to spread itself over a surface. A wetting liquid spreads over a surface whereas a nonwetting liquid forms droplets on a surface.

Wick: A porous material used to generate the capillary forces that circulate fluid in a heat pipe.

Cooling Electronic Equipment

Vincent W. Antonetti

Introduction

In electronic packages, the thermal resistances to heat transfer from heat source to heat sink are often grouped into an internal resistance and an external resistance. The **internal thermal resistance** R_{int} is conductive and exists between the chip and the module case:

$$R_{\text{int}} = \frac{T_{\text{chip}} - T_{\text{case}}}{P_{\text{chip}}} \tag{4.8.39}$$

where P_{chip} is the chip power.

The **external thermal resistance** R_{ext} is primarily convective and exists between the surface of the case of the module and some reference point, typically the temperature of the cooling fluid near the module. In a multichip module, the module power P_m is the sum of the individual chip powers, and the external resistance is

$$R_{\text{ext}} = \frac{T_{\text{case}} - T_{\text{coolant}}}{P_m} \tag{4.8.40}$$

The internal and external resistances are related to the chip junction temperature T_j through the following expression:

$$T_j = \Delta T_{j-\text{chip}} + P_{\text{chip}} R_{\text{int}} + P_m R_{\text{ext}} + \Delta T_{\text{coolant}} + T_{\text{coolant in}} \tag{4.8.41}$$

Many factors are involved in determining the appropriate cooling mode to be used. If the component junction temperature is constrained to approximately 85°C, Table 4.8.6 may be used to make a preliminary selection of the cooling mode. Extended surfaces can often be used to increase the allowable heat fluxes.

Free Convection Air Cooling of Vertical Printed Circuit Boards

Data have been collected from rack-mounted simulated printed circuit boards (PCBs) (see Figure 4.8.15) and from several actual electronic systems at AT&T Bell Laboratories. Results indicated that existing parallel plate correlations for symmetric isoflux plates (separated by distance "b") could be adapted to

TABLE 4.8.6 Maximum Component Heat Flux for Various Cooling Modes

Cooling Mode	W/cm^2
Free convection air	0.05
Forced convection air	0.5
Impingement air	1.0
Free convection immersion	1.0
Forced convection immersion	50
Pool boiling	20
Forced convection boiling	100
Jet immersion (single phase)	40
Boiling jet immersion	90

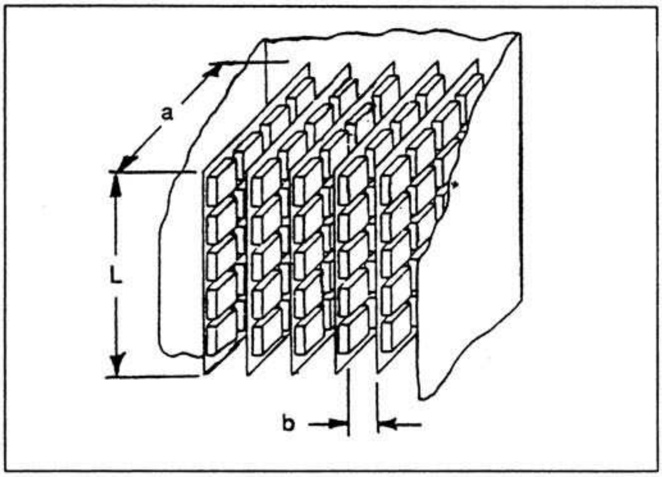

FIGURE 4.8.15 Typical PCB array. (From Antonetti, V.W., in *Heat Transfer and Fluid Flow Data Books*, F. Kreith, Ed., Genium Publishing, Schenectady, NY, 1993. With permission.)

PCB conditions. Specifically, for $\mathrm{Ra}_b < 10$ use the equation corresponding to the fully developed laminar boundary layer condition:

$$\mathrm{Nu}_b = 0.144\mathrm{Ra}_b^{0.5} \tag{4.8.42}$$

For $10 < \mathrm{Ra}_b < 1000$, use

$$\mathrm{Nu}_b = \left[\frac{48}{\mathrm{Ra}_b} + \frac{2.5}{\mathrm{Ra}_b^{0.4}}\right]^{-0.5} \tag{4.8.43}$$

where

$$\mathrm{Ra}_b = \frac{g\beta c_p \rho^2 b^5 q''}{\mu k L}$$

For Ra > 1000, the expression for an isolated plate in infinite media is recommended:

$$\mathrm{Nu}_b = 0.524\mathrm{Ra}_b^{0.2} \tag{4.8.44}$$

In the previous three expressions air properties are evaluated at the average of the module case and ambient temperatures.

The PCB spacing $b_{\max}$ for a given power dissipation which yields the lowest PCB component case temperatures (or which maximizes the rate of heat transfer while maintaining PCB temperatures below the maximum allowable) occurs when the developing boundary layers from adjacent PCBs do not interfere, i.e., so the isolated plate condition is approached as follows: If heat is transferred from both sides of the PCB, let $\mathrm{Ra}_{ab} = 17{,}000$ and the recommended PCB spacing is $b_{\max} = 7.02\xi^{-0.2}$. If heat is transferred from only one side of the PCB, let $\mathrm{Ra}_{ab} = 5400$ and the recommended PCB spacing is $b_{\max} = 5.58\xi^{-0.2}$. In both cases

$$\xi = \frac{g\beta\rho^2 \mathrm{Pr} q''}{\mu^2 k L} \tag{4.8.45}$$

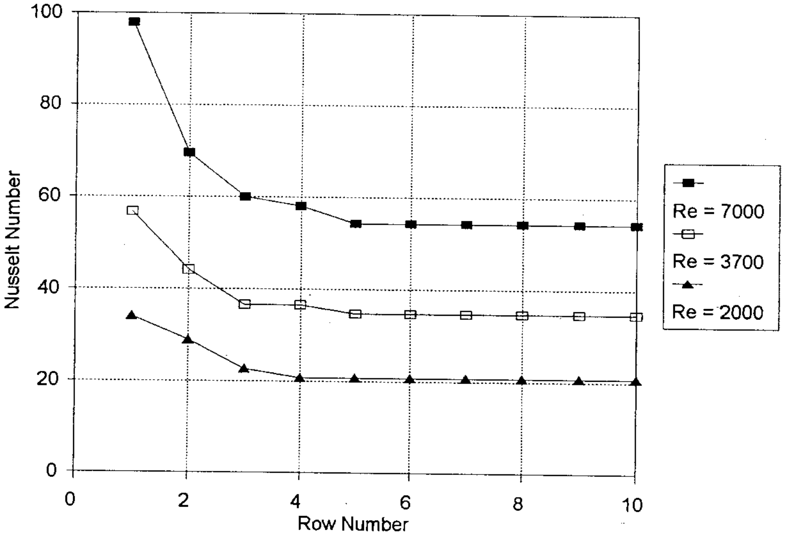

FIGURE 4.8.16 Nusselt number for fully populated array of modules. (From Sparrow, E.M. et al., *Int. J. Heat Mass Transfer*, 25, 961–973, 1982. With permission.)

Forced Convection Air Cooling of Vertical PCBs

Sparrow et al. (1982, 1984) studied vertical arrays with simulated modules of uniform size, which was 4 modules wide by 17 module rows deep in the flow direction; the modules were 26.7 mm square and 10 mm high; the space between modules was 6.67 mm, and the distance from the top of the module to the adjoining card Hc = 16.7 mm. The Nusselt number as a function of module row position for a fully populated array may be determined from Figure 4.8.16. Correction factors to the fully developed Nusselt numbers for the effect of missing modules and the presence of modules whose height differs from others in the array are presented in the cited references.

In actual electronic packages, conditions differ from the relatively ideal setups in laboratories because in real packages the flow is disturbed by the PCB supporting hardware and may extend the entry region effect.

Data from actual computer hardware with PCBs containing a 6 × 4 array of 28 mm modules (4 in the flow direction) were used to develop the following expressions:

$$\mathrm{Nu}_x = C\left\{\mathrm{Re}_{D_h}\left[1 + x/\left(D_h\right)^{-0.836}\right]\right\}^m \tag{4.8.46}$$

For Re < 2000, $C = 0.072$ and $m = 0.70$, and for 2000 < Re < 10,000, $C = 0.056$ and $m = 1.02$, where x is the distance in the flow direction. Because the array was only 4 modules deep, all the modules on the PCB were in the entry region.

Tests have been conducted on a 9 × 7 array of 25-mm-square by 6.4-mm-high blocks cooled by a 3 × 3 array of air jets directed normal to the face of each block. The spent flow exited along the channel formed by the orifice plate and the heat transfer surfaces. Test results were correlated by the relation:

$$N_d = 0.213(z/d)^{-0.376}\,\mathrm{Re}_d^{0.743} \tag{4.8.47}$$

where d is the jet orifice diameter, s is the orifice-to-orifice spacing, and z is the distance from the orifice outlet to the face of the module.

Immersion Cooling

The highly inert perfluorinated liquids, called FC coolants by the 3M Company, are frequently used in **immersion cooling** applications. FC coolants are available with boiling points from 30 to 172°C at atmospheric pressure. FC-75 are FC-77 with boiling points of 100°C are often used in single-phase applications, while FC-72 and FC-87, with boiling points of 56 and 30°C, respectively, are used in systems involving phase change.

Data exist for free convection immersion cooling of a 3 × 3 array of simulated chips mounted on a vertical wall in an enclosure filled with FC-75. Each heat source was 8 mm high by 24 mm wide by 6 mm thick. With the Nusselt and modified Rayleigh numbers based on the heater height, L, the best fit to the data is

$$\mathrm{Nu}_L = 0.279\mathrm{Ra}_b^{0.224} \tag{4.8.48}$$

Air cooling expressions have been modified to make them applicable to free convection immersion cooling of vertical PCB arrays with FC coolants. The Nusselt number (based on PCB spacing "b") at the top of the PCB is

$$\mathrm{Nu}_L = \left[\frac{C}{\mathrm{Ra}_b} + \frac{2.78}{\mathrm{Ra}_b^{0.4}}\right]^{-0.5} \tag{4.8.49}$$

$C = 24$ when heat transfer is from one side of the PCB, and $C = 48$ when from both sides.

Nucleate Pool Boiling

A number of investigators have tested small flush heat sources boiling in a pool of dielectric liquid. The heaters ranged from 4 × 4 mm to 12.7 × 12.7 mm. Typical saturated pool boiling data for FC-72 and FC-87 are shown in Figure 4.8.17. Note that a temperature overshoot up to 25°C has been regularly observed for silicon chips in dielectric liquid pools. To estimate the temperature excursion at boiling incipience (q_i''), the following approximation is recommended

$$\Delta T_{\mathrm{ex}} = T_{\mathrm{sat}}\left(p - \frac{2\sigma}{r_b} - p_g\right) - T_{\mathrm{sat}} - C\left(q_i''\right)^n \tag{4.8.50}$$

where

$$C = \mu h_{fg}\left[\frac{c_p}{h_{fg}\mathrm{Pr}^b C_{sf}}\right]^{1/a}\left[\frac{\alpha}{g\left(\rho - \rho_g\right)}\right]^{0.5} \tag{4.8.51}$$

with $r_b = 0.25$ µm, $C_{sf} = 0.003$, $a = 0.33$, and $b = 1.7$. (Note that $n = 1/a = 3$.)

Park and Bergles (1988) determined the critical heat flux (CHF) as a function of size for flush heaters operating in a saturated pool of R-113. For a 5-mm-wide heater, and for heater heights from 5 to 80 mm, use

$$\frac{q''_{c_{\mathrm{sat}}}}{q''_{c_z}} = 0.86\left[1 + \frac{152}{L^{*3.29}}\right]^{0.14} \tag{4.8.52}$$

where the CHF prediction of Zuber, $q''_{c_z} = \rho_g^{0.5} h_{fg}[\sigma g(\rho_f - \rho_g)]^{0.5}$, and $L^* = L[g(\rho_f - \rho_g)/\sigma]^{0.5}$.

For a 5-mm-high heater, and for heater widths from 2.5 to 70 mm, use

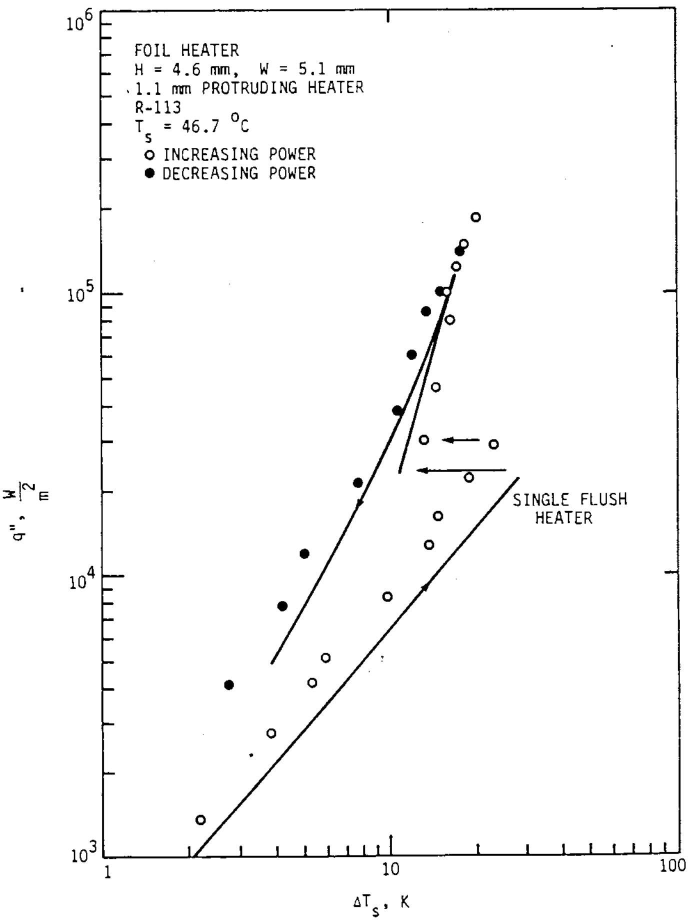

FIGURE 4.8.17 Typical pool boiling curve for small heater. (From Park, K.A. and Bergles, A.E. *J. Heat Transfer*, 110, 728–734, 1988. With permission.)

$$\frac{q''_{c_{\text{sat}}}}{q''_{c_z}} = 0.93\left[1 + \frac{52}{I^{1.02}}\right]^{0.14} \tag{4.8.53}$$

where the induced convection parameter is $I = (\rho_f W\sigma/\mu^2)^{0.5}$.

For flush 12.7 × 12.7 mm heaters in FC-72, test data yield $q''_{c_{\text{sat}}}/q''_{c_z} \approx 1.45$. These subcooling data were correlated by

$$\frac{q''_{c_{\text{sub}}}}{q''_{c_{\text{sat}}}} = 1 + \frac{0.0643\rho_f c_{p,f}}{\rho_g h_{fg}}\left[\frac{\rho_g}{\rho_f}\right]^{1/4} \Delta T_{\text{sub}} \tag{4.8.54}$$

Single-Phase and Boiling Forced Convection in Channel Flow

The average Nusselt numbers for 12 flush 12.7 × 12.7 mm heaters (4 rows of 3 sources per row) operating in FC-77 has been correlated by the following expression:

$$\overline{\text{Nu}_L} = C\left(\text{Re}_{D_h}\right)^m \text{Pr}^{0.11} \tag{4.8.55}$$

For row 1: $C = 0.194$ and $m = 0.60$; for row 2: $C = 0.069$ and $m = 0.69$; for row 3: $C = 0.041$ and $m = 0.74$; and for row 4: $C = 0.029$ and $m = 0.78$. All properties are determined at the inlet temperature except for μ_h, which is evaluated at the heater temperature. Note that when heat sinks are employed, forced convection immersion cooling can support a heat flux of approximately 50 W/cm^2.

Test data have been obtained for a vertical column of ten 6.4 mm × 6.4 mm heaters, with subcooled R-113 flowing in the upward direction. In general, CHF occurred first at the last downstream element in the array, and that CHF values of 100 W/cm^2 were easily attained. The CHF data yielded the following equation:

$$q_c'' = C_5 \mathrm{We}^n V \rho_f h_{fg} \left(\frac{\rho_f}{\rho_g}\right)^{15/23} \left(\frac{L}{D_h}\right)^{1/23} \left[1 + \frac{c_{pf}\Delta T_{\mathrm{sub}}}{h_{fg}}\right]^{7/23} \left[1 + \frac{0.021\rho_f c_{pf}\Delta T_{\mathrm{sub}}}{\rho_g h_{fg}}\right] \tag{4.8.56}$$

where the Weber number, $\mathrm{We} = \rho_f V^2 L/\sigma$. Note that for $\mathrm{We} > 100$, $C_5 = 0.125$ and $n = -8/23$, and for $\mathrm{We} < 10$, $C_5 = 0.254$ and $n = -^1/_2$.

Immersion Cooling Using Jets

Two modes have been studied. In the first, a dielectric liquid jet discharges into a miscible liquid and is said to be submerged; in the second, a liquid jet discharges into an immiscible gas (air) and is said to be free. In general, the average Nusselt number can be expressed as

$$\overline{\mathrm{Nu}} = f\left(\mathrm{Re}^m, \mathrm{Pr}^n, L/d, z/d\right) \tag{4.8.57}$$

where L/d is the ratio of the chip length to orifice diameter, and z/d is the ratio of the jet to heat source distance to the orifice diameter. A free jet is virtually unaffected by the orifice-to-chip distance, and as a consequence the (z/d) term drops out.

Data for single-phase forced convection cooling with free jets are available for 2 × 2 and 3 × 3 heat source arrays. The heat sources were 12.7 × 12.7 mm and the cooling fluid was FC-77. Each heat source was cooled either by a single jet or by a 2 × 2 or 3 × 3 array of jets per source. For all the configurations tested, the average Nusselt number was correlated by a single expression:

$$\overline{\mathrm{Nu}_L} = 3.84\left(0.008\frac{L}{d}n + 1\right)\mathrm{Re}^{1/2}\mathrm{Pr}^{1/3} \tag{4.8.58}$$

where fluid properties are to be evaluated at an average of the heat source and jet inlet temperatures.

Data for single-phase forced convection using submerged jets are available for a 5 × 5 mm vertical heat source cooled by a 1.0-mm-diameter submerged jet of R-113. The Nusselt number at the stagnation point was correlated by

$$\mathrm{Nu}_d = 1.29\mathrm{Re}_d^{1/2}\mathrm{Pr}^{0.4} \tag{4.8.59}$$

Also note that the performance of a submerged liquid jet should be approximately equivalent to gas jet impingement.

Data for two-phase forced convection using free jets have been collected for a single 12.7 × 12.7 mm heat source cooled by either a single jet or a 2 × 2 or 3 × 3 array of jets. The jet diameter, velocity, and jet-to-source distance were varied. The CHF data was correlated by

$$q_c'' = 0.0742\mathrm{We}^{-0.365} V \rho_f h_{fg} \left(\frac{\rho_g}{\rho_f}\right)^{0.239} \left[1 + 0.952\left(\frac{\rho_f}{\rho_g}\right)^{0.118} \left(\frac{c_{pf}\Delta T_{\mathrm{sub}}}{h_{fg}}\right)\right]^{1.414} \tag{4.8.60}$$

Experimental evidence in two-phase forced convection using submerged jets indicates that (1) the temperature overshoot at incipient boiling was very small compared with pool or forced boiling; (2) the boiling curves at various velocities merge to a single curve and that this curve coincides approximately with an upward extrapolation of the pool boiling curve; (3) the CHF varies as the cube of the jet velocity; (4) the CHF is greatly improved by increasing the subcooling; and (5) powers in excess of 20 W (5×5-mm chip) could be accommodated within a 85°C chip temperature.

Defining Terms

External thermal resistance: The thermal resistance from a convenient reference point on the outside of the electronic package to the local ambient.

Internal thermal resistance: The thermal resistance from the device junction inside an electronic package to a convenient reference point on the outside surface of the package.

Immersion cooling: Concerns applications where the coolant is in direct physical contact with the electronic components.

4.9 Non-Newtonian Fluids — Heat Transfer

Thomas F. Irvine, Jr., and Massimo Capobianchi

Introduction

The general characteristics of non-Newtonian fluids are described in Section 3.9 and will not be repeated here. Topics to be included in this section are laminar and turbulent heat transfer in fully developed duct flow, and laminar free convection heat transfer in vertical channels and plates and several other common geometries.

For non-Newtonian flows, except for certain classes of fluids which exhibit a slip phenomenon at solid boundaries, the boundary condition is taken as no-slip or zero velocity at all solid surfaces. For heat transfer analyses, however, the situation is more complicated because there are many different ways to heat a wall, which in turn affects the type of thermal boundary conditions.

In general, the rate of heat transfer from a surface, or the temperature difference between the wall and the fluid, is calculated using the equation $q_c = h_c A_q \Delta T$. Since the heat transfer coefficient can vary

TABLE 4.9.1 Thermal Boundary Conditions for Duct Heat Transfer

1.	Constant wall temperature in both the flow and circumferential direction	Nu_T
2.	Constant heat flux in the flow direction and constant temperature in the circumferential direction	Nu_{H1}
3.	Constant heat flux in the flow and circumferential directions	Nu_{H2}
4.	Constant heat flux per unit volume in the wall with circumferential wall heat conduction	Nu_{H4}

considerably for different thermal boundary conditions, it is important that the boundary conditions be specified correctly. Although the number of thermal boundary conditions is in principle infinite, several classical types have been identified and are in common use. They are usually identified in terms of the Nusselt number, $\mathrm{Nu} = h_c L/k$, with a particular subscript. For example, for duct flow, the symbol Nu_T is used to specify the Nusselt number when the wall temperature is constant in both the flow and peripheral directions. Other thermal boundary conditions are described in Table 4.9.1 for duct heat transfer and will be used throughout this section.

It should be noted that because of the symmetry in circular and parallel plate ducts, Nu_{H1} and Nu_{H2} are identical and are referred to simply as Nu_H. Nu_{H4} with wall conduction is a more-complicated problem where the energy equations must be solved simultaneously in both the wall and the fluid. Such problems are called conjugated. In the Nu_{H4} situation, the designer has the flexibility of affecting the heat transfer by varying either or both the characteristics of the duct wall or the convective fluid. In the heat transfer relations to be considered later, care will be taken to identify the proper thermal boundary conditions using the nomenclature in Table 4.9.1.

Laminar Duct Heat Transfer — Purely Viscous, Time-Independent Non-Newtonian Fluids

As discussed in Section 3.9, a convenient and comprehensive constitutive equation for pseudoplastic fluids (flow index, $n < 1$) is the modified power law equation:

$$\mu_a = \frac{\mu_o}{1 + \frac{\mu_o}{K}(\dot{\gamma})^{1-n}} \tag{4.9.1}$$

Equation (4.9.1) has the characteristic that at low shear rates, the equation approaches that for a Newtonian fluid while at large shear rates it describes a power law fluid. In addition, solutions using Equation (4.9.1) generate a shear rate parameter, β, which describes whether any particular system is in the Newtonian, transitional, or power law region. For duct flow, β is given by

$$\beta = \frac{\mu_o}{K}\left(\frac{\bar{u}}{D_H}\right)^{1-n} \tag{4.9.2}$$

If $\log_{10} \beta > 2$: Power law region
If $\log_{10} \beta < -2$: Newtonian region
If $-2 \le \log_{10} \beta \le 2$: Transition region

For fully developed flow, the characteristic length is the hydraulic diameter, D_H, and the fluid temperature is the “bulk” temperature defined as

$$T_b = \frac{1}{A_c \bar{u}} \int_{A_c} uT dA_c \tag{4.9.3}$$

Figure 4.9.1 illustrates the values of Nu_T vs. β for a circular duct with the flow index, n, as a parameter. It is seen from the figure that the effect of β on Nu_T is only moderate, but for some applications it may

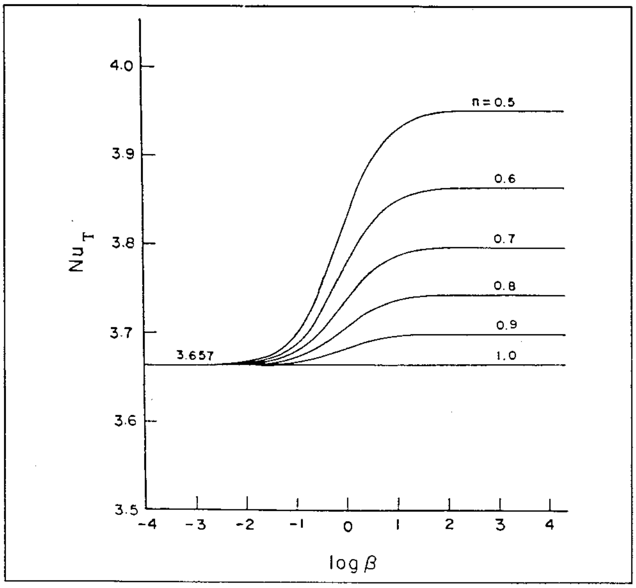

FIGURE 4.9.1 Variation of the fully developed circular duct Nusselt numbers, Nu_T, with the shear rate parameter β and *n*. (From Irvine, T.F., Jr. et al., in *ASME Symposium on Fundamentals of Forced Convection Heat Transfer*, ASME publ. HTD 101, 1988, 123–127. With permission.)

be important to know at what value of β the system is operating. The situation is similar for boundary condition Nu_H.

Although Figure 4.9.1 shows the Nusselt number relation graphically, it is convenient to have simple correlation equations to represent the solutions for both boundary conditions. For fully developed Nusselt numbers with values of $0.5 \le n \le 1.0$ and $10^{-4} \le \beta \le 10^4$, Irvine et al. (1988) present the following equation which represents both solutions with a maximum difference of 1.5%:

$$Nu = \frac{Nu_N (1+\beta)}{1 + \dfrac{Nu_N \beta}{Nu_P}} \tag{4.9.4}$$

The Newtonian Nusselt numbers are $Nu_N = 3.6568$ for Nu_T, and $Nu_N = 4.3638$ for Nu_H. In addition, Table 4.9.2 lists the power law Nusselt numbers, Nu_{TP} and Nu_{HP}, for $\log_{10} \beta = 4$.

Graetz solutions for the thermal entrance lengths are also available. They assume that the velocity profile is fully developed at the duct entrance and present the duct lengths required for the Nusselt

TABLE 4.9.2 Power Law Nu_T and Nu_H Solutions for a Circular Duct ($\log_{10} \beta = 4$)

n	Nu_{TP}	Nu_{HP}

numbers to reach within 1% of the fully developed values. Figure 4.9.2 shows these thermal entrance lengths for Nu_T thermal boundary condition. The situation is similar for boundary condition Nu_H.

A correlation equation for the thermal entrance lengths for both the Nu_T and Nu_H boundary conditions by Irvine et al. (1988) represents the numerical solutions within 0.5% for $0.5 \le n \le 1.0$ and $-4 \le \log_{10} \beta \le 4$. Table 4.9.3 lists the power law thermal entrance lengths which are needed to evaluate the following correlation equation:

$$x^+_{\mathrm{ent},\beta,n} = \frac{x^+_{\mathrm{ent},N}(1+\beta)}{1+\dfrac{x^+_{\mathrm{ent},N}(\beta)}{x^+_{\mathrm{ent},P}}} \tag{4.9.5}$$

where $x^+_{\mathrm{ent},\beta,n}$ is the modified power law dimensionless entrance length defined as $x^+_{\mathrm{ent},\beta,n} = (x_{\mathrm{ent},\beta,n}/D_H)/Pe$, and $x^+_{\mathrm{ent},N}$ and $x^+_{\mathrm{ent},P}$ are the Newtonian and power law values, respectively. The Newtonian dimensionless entrance lengths are $x^+_{\mathrm{ent},N} = 0.03347$ for Nu_T and $x^+_{\mathrm{ent},N} = 0.04309$ for Nu_H.

Only one noncircular geometry using the modified power law equation has been published in the archival literature for laminar fully developed heat transfer (Capobianchi and Irvine, 1992). A correlation equation for Nu_{H1} for annuli with constant heat flux at the inner wall and the outer wall insulated is

$$n<1 \qquad \mathrm{Nu}_{H1}=\frac{1+\beta}{\dfrac{1}{\mathrm{Nu}_{H1,N}}+\dfrac{\beta}{\mathrm{Nu}_{H1,P}}} \tag{4.9.6}$$

Nusselt numbers for square ducts and power law fluids can be found in Chandrupatla and Sastri (1977) and, for isosceles triangular ducts, in Cheng (1984). Thermally developing and thermally developed laminar heat transfer in rectangular channels has been studied by Hartnett and Kostic (1989).

For other cross-sectional shapes, a power law approximate correlation has been proposed by Cheng (1984):

$$\mathrm{Nu}_P=\mathrm{Nu}_N\left[\frac{(a+bn)}{(a+b)n}\right]^{1/3} \tag{4.9.7}$$

where a and b are the Kozicki geometric constants listed in Table 3.9.3 in the section on non-Newtonian flows. Equation (4.9.7) applies to any thermal boundary condition. For circular ducts, Equation 4.9.7 predicts the correct solution for both Nu_T and Nu_H.

Turbulent Duct Flow for Purely Viscous Time-Independent Non-Newtonian Fluids

It is known that in turbulent flow, the type of thermal boundary conditions has much less effect than in laminar flow. Therefore, turbulent flow heat transfer investigations are often reported without specifying the thermal boundary conditions. Yoo (1974) has presented an empirical correlation for turbulent heat transfer in circular ducts for purely viscous time-independent power law fluids.

$$\mathrm{St}\,\mathrm{Pr}_a^{2/3}=0.0152\,\mathrm{Re}_a^{-0.155} \tag{4.9.8}$$

Equation (4.9.8) describes all of the experimental data available in the literature at the time with a mean deviation of 2.3%. Equation (4.9.8) is recommended in order to predict the turbulent fully developed heat transfer in the ranges $0.2 \le n \le 0.9$ and $3000 \le \mathrm{Re}_a \le 90{,}000$. The Reynolds number and Prandtl numbers in Equation (4.9.8) are based on the apparent viscosity at the wall, μ_a, i.e.,

$$\mathrm{Re}_a=\frac{\rho\bar{u}D_H}{\mu_a} \tag{4.9.9}$$

$$\mathrm{Pr}_a=\frac{\mu_a c_p}{k} \tag{4.9.10}$$

In order to evaluate Equation (4.9.9) and Equation (4.9.10) in terms of the rheological properties and operating parameters, an expression must be obtained for μ_a in terms of these quantities. The value of μ_a is evaluated by considering that μ_a is determined from fully developed laminar circular tube power law fluid flow for which it can be shown that (Irvine and Karni, 1987)

$$\mu_a=K\left(\frac{3n+1}{4n}\right)^{n-1}\left(\frac{8\bar{u}}{D_H}\right)^{n-1} \tag{4.9.11}$$

assuming that the quantities K, n, c_p, and k are constant. It is also of interest that the Prandtl number is no longer a thermophysical property for power law fluids but depends upon the average velocity, $\bar{u}$, and the hydraulic diameter, D_H.

Hartnett and Rao (1987) have investigated fully developed turbulent heat transfer for a rectangular duct with a 2:1 aspect ratio and propose the following equation which generally agreed with their experimental data within ±20%:

$$\mathrm{Nu} = (0.0081 + 0.0149n)\mathrm{Re}_a^{0.8}\mathrm{Pr}_a^{0.4} \tag{4.9.12}$$

Viscoelastic Fluids

An important characteristic of viscoelastic fluids is their large hydrodynamic and thermal entrance lengths. Cho and Hartnett (1982) have reported hydrodynamic entrance lengths of up to 100 diameters and thermal entrance lengths up to 200 to 800 diameters depending upon the Reynolds and Prandtl numbers. These can be compared with Newtonian fluids entrance lengths which are of the order of 10 to 15 diameters. Therefore, care must be used in applying fully developed relations to practical situations.

Cho et al. (1980) reported heat transfer measurements in the thermal entrance region and recommend the following empirical equation for saturated aqueous polymer solutions for $6000 \le \mathrm{Re}_a$ and x/D_H values up to 450:

$$J_H = 0.13\left(x/D_H\right)^{-0.24}\mathrm{Re}_a^{-0.45} \tag{4.9.13}$$

where $J_H = \mathrm{St}\,\mathrm{Pr}_a^{2/3}$ and $\mathrm{St} - h_c/\rho c_p\,\bar{u}$.

All of the reported fully developed turbulent flow heat transfer measurements have been plagued by solute and solvent, thermal entrance, and degradation effects, and thus there is considerable scatter in the results. Degradation effects can be reduced or eliminated by using large amounts of polymer (500 to 10,000 wppm) so that the solution becomes saturated. Cho and Hartnett (1982) attempted to eliminate these effects by using a thermal entrance length of 430 diameters and saturated polymer solutions which should yield maximum heat transfer reductions. Their experimental results for fully developed heat transfer were correlated for a Reynolds number range $3500 \le \mathrm{Re}_a \le 40{,}000$ and concentration solutions of 500 to 5000 wppm of polyacrylamide and polyethylene oxide by

$$J_H = 0.03\mathrm{Re}_a^{-0.45} \tag{4.9.14}$$

For viscoelastic fluids in fully developed (hydrodynamically and thermally) *laminar flow in circular ducts* there is no apparent viscoelastic effect. Thus, the heat transfer relations are the same as those for time-independent fluids such as power law or modified power law fluids. The same situation holds for thermal entrance region heat transfer (Graetz problem). Relations for laminar Nusselt numbers in thermal entrance regions are presented by Cho and Hartnett (1982).

Free Convection Flows and Heat Transfer

Free convection information available in the heat transfer literature up to the present time is concentrated on heat transfer to power law fluids for vertical plates and parallel plate channels. For free convection flows, however, the velocities and thus the shear rates are low and care must be taken that the flow for a particular fluid is in the power law shear rate region before using power law solutions or correlations. Comprehensive review articles on free convection with non-Newtonian fluids have been presented by Shenoy and Mashelkar (1982) and Irvine and Karni (1987).

For a single vertical plate with a modified power law fluid and a thermal boundary condition $\overline{Nu}_T$, in laminar flow, the following relation is recommended by Shenoy and Mashelkar (1982):

$$\overline{Nu}_{TL} = T(n)Gr_{TL}^{1/(2n+2)}\mathrm{Pr}_{TL}^{n/(3n+1)} \tag{4.9.15}$$

where $\overline{Nu}_{TL}$ is the average Nusselt number and

$$\mathrm{Gr}_{TL} = \frac{\rho^2 L^{n+2}}{K^2}\left[g\alpha\left(T_s - T_\infty\right)\right]^{2-n} \tag{4.9.16}$$

$$\mathrm{Pr}_{TL} = \frac{\rho c_p}{k}\left(\frac{K}{\rho}\right)^{2/(n+1)} L^{(n-1)/(2n+2)}\left[g\alpha\left(T_s - T_\infty\right)\right]^{(3n-3)/(2n+2)} \tag{4.9.17}$$

where α is the isobaric thermal expansion coefficient.

In the range $0.5 \le n \le 1$, $T(n)$ can be approximated by

$$T(n) = 0.1636n + 0.5139 \tag{4.9.18}$$

The characteristic dimension in the Nusselt and Grashof numbers is the plate height, L.

For thermal boundary conditions Nu_H, the following relation is also recommended by Shenoy and Mashelkar (1982). Since the heat flux, q_w is specified in this case, the local plate temperature at any x (measured from the bottom of the plate) can be obtained from the local Nusselt number Nu_{Hx}. The heat transfer coefficient is defined in terms of the difference between the wall and free-stream temperatures.

$$\mathrm{Nu}_{Hx} = 0.619\left[\mathrm{Gr}_{Hx}^{(3n+2)/(n+4)}\mathrm{Pr}_{Hx}^{n}\right]^{0.213} \tag{4.9.19}$$

where

$$\mathrm{Gr}_{Hx} = \frac{\rho^2 x^4}{k^2}\left(\frac{g\alpha q_w}{k}\right)^{2-n} \tag{4.9.20}$$

$$\mathrm{Pr}_{Hx} = \frac{\rho c_p}{K}\left(\frac{K}{\rho}\right)^{5/(n+4)} x^{(2n-2)/(n+4)}\left(\frac{g\alpha q_w}{k}\right)^{(3n-3)/(n+4)} \tag{4.9.21}$$

Vertical Parallel Plates

For *power law fluids* and laminar flow, Figure 4.9.3 presents the graphical results of a numerical solution. Of interest are the average Nusselt number $\overline{Nu}_{Tb}$ and the dimensionless average flow velocity between the plates, U_o^+. These are shown on the left and right ordinates respectively in Figure 4.9.3 (Irvine et al., 1982). The characteristic dimension in the Nusselt and Grashof numbers is the plate spacing, b. The dimensionless quantities used in Figure 4.9.3 are defined as follows:

$$\overline{Nu}_{Tb} = \frac{\bar{h}_c b}{k} \qquad U_o^+ = \frac{b u_o}{L u^*}$$

$$\mathrm{Pr}_g = \frac{\rho c_p}{k}\left[\frac{\nu_k^{1/(2-n)}}{\left(\frac{L}{b}\right)^{(1-n)/(2-n)} b^{(2n-2)/(2-n)}}\right] \qquad \nu_K = \frac{K}{\rho}$$

$$\mathrm{Gr}_g = \frac{g\alpha\left(T_s - T_\infty\right) b^{(n+2)/(2-n)}}{\nu_K^{2/(2-n)}\left(\frac{L}{b}\right)^{n/(2-n)}} \qquad u^* = \frac{\nu_K^{1/(2-n)}\, b^{(1-2n)/(2-n)}}{L^{(1-n)/(2-n)}}$$

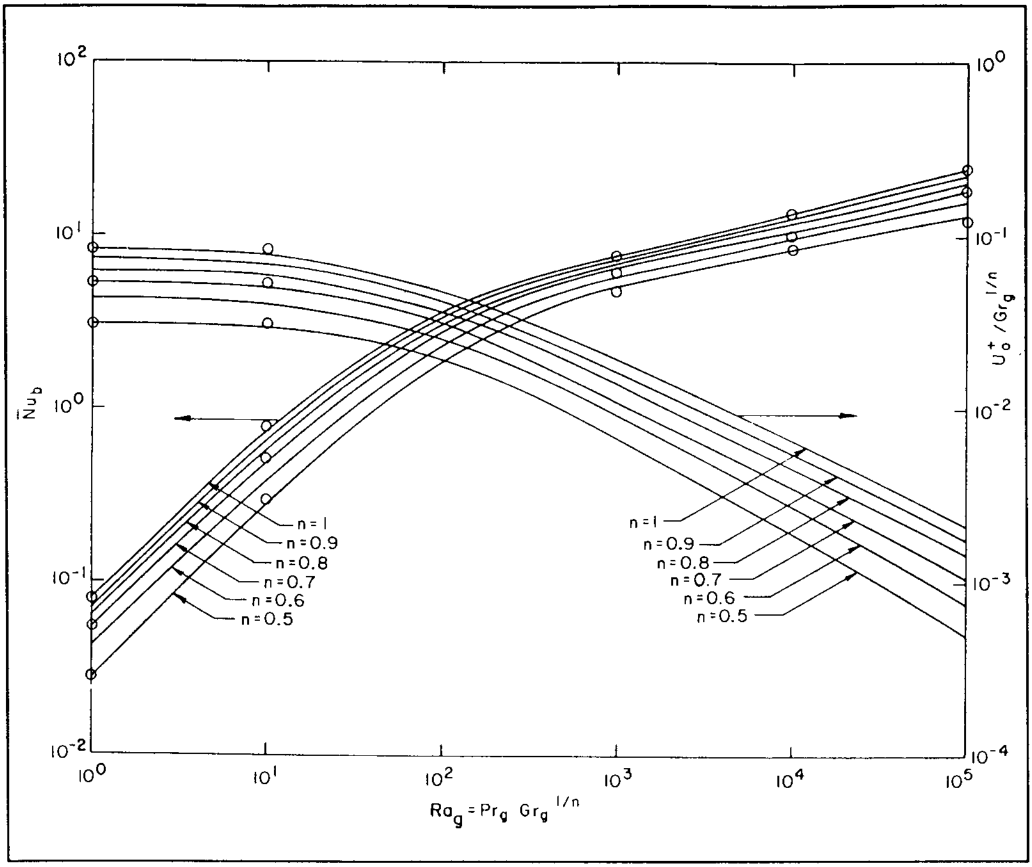

FIGURE 4.9.3 Free convection average Nusselt number, $\overline{Nu}_b$ and dimensionless average velocity U_o^+ between vertical plates for a power law fluid vs. generalized Raleigh number for the Nu_T boundary condition. (From Irvine, T.F., Jr. et al., ASME Paper 82-WA/HT-69, 1982. With permission.)

For vertical parallel plates for the average Nusselt number, $\overline{Nu}_{Hb}$, and the between plate average velocity, Schneider and Irvine (1984) have presented graphical results similar to Figure 4.9.3.

Lee (1992) has presented a numerical solution for laminar flow of a *modified power law fluid* between vertical plates. Lee has also calculated thermal entrance regions and shown that if a parallel plate system is actually operating in the transition region and if the power law solution is used, both the total heat transfer and the velocity between plates can differ by over an order of magnitude. It is important to consider the shear rate parameter in order to determine which free convection solution to use.

Sphere and Horizontal Cylinder — Power Law Fluids

For flow over a sphere, the correlation for power law fluids by Amato and Tien (1976) is

$$\overline{Nu}_{Tr} = CZ^D \tag{4.9.22}$$

where

$$Z = \mathrm{Gr}_{Tr}^{1/(2n+2)}\,\mathrm{Pr}_{Tr}^{n/(3n+1)} \tag{4.9.23}$$

and

$$C = 0.996 \pm 0.120, \quad D = 0.682 \qquad \text{for } Z < 10$$

$$C = 0.489 \pm 0.005, \quad D = 1.10 \qquad \text{for } 10 \le Z \le 40$$

where the characteristic dimension in all dimensionless variables is the sphere radius, r, and Gr_{Tr} and Pr_{Tr} are defined in Equation (4.9.16) and Equation (4.9.17).

For pseudoplastic fluids flowing over a cylinder, an experimental correlation proposed by Gentry and Worllersheim (1974) for the average Nusselt number, $\overline{Nu}_{TD}$, is

$$\overline{Nu}_{TD} = \frac{\bar{h}_c D}{k} = 1.19\left(\mathrm{Gr}_{TD}\,\mathrm{Pr}_{TD}\right)^{0.2} \tag{4.9.24}$$

where Gr_{TD} and Pr_{TD} are defined as in Equation (4.9.16) and Equation (4.9.17) with the cylinder diameter, D, being used instead of L.

4.10 Bioheat Transfer

Kenneth R. Diller, Jonathan W. Valvano, and John A. Pearce

Introduction

Analysis and control of heat transfer processes in living systems involves phenomena not encountered in systems that are not alive. For example, there is a continuous flow of blood through tissues and organs via a complex network of branching vessels. Heat exchange processes are influenced by vascular geometry, which consists of arteries and veins with countercurrent flow over large portions of the network of pairs. For some physiological conditions, arterial and venous blood temperatures are different — neither is equal to the local tissue temperature — and these temperature differences may vary as a function of many transient physiological and physical parameters. Mechanisms of regulation for the thermal state in tissue are quite nonlinear and have presented a major challenge to understand and model. Nonetheless, thermoregulatory processes are critical to the maintenance of life and must be accounted for in the design of many types of systems that interface with humans and animals.

Although considerable progress has been made in defining and modeling thermal processes in living systems, especially so over the past 15 years, many important problems remain. This chapter provides a brief discussion of the present state of knowledge of some of the more active areas of bioheat transfer. Greater detail and additional areas of application of bioheat transfer may be found among the references cited.

Coupling Temperature History to Rate Processes

Although the processes of life are observed at the system (macroscopic) and microscopic levels of resolution, the true essence of life lies in the multitudinous biochemical phenomena that occur continuously throughout all organisms. Over the past 50 years the science of biochemistry has elucidated many of the governing life processes at the molecular level. Today, the major frontier of knowledge in the life sciences is associated with molecular biology. Increasingly, bioengineers are collaborating with molecular biologists to understand and manipulate the molecules and biochemical processes that constitute the basis of life.

Temperature is a primary controlling parameter in the regulation of these rate processes. The study of thermal biology has identified that the rates of nearly all physiological functions are altered by 6 to 10% per degree Celsius over a wide a range of thermal states produced in response to environment conditions [1]. Likewise, temperature is often altered during therapeutic or diagnostic procedures to produce or measure a targeted effect, based on the fact that a change in local temperature will have a large effect on biochemical process rates. Thus, knowledge of how temperature can be monitored and/or controlled in living tissues is of great value in the assessment of normal physiological function and treatment of pathological states.

In assessing the effects of temperature alterations on biochemical rate processes, two broad categories of state changes can be considered: temperatures above and below the normal physiological thermal state. An extensive review of these thermal domains has been published recently, to which the reader is referred for further details and bibliography [2]. A summary of some of the most important and recent advances in bioheat transfer will be discussed in this chapter.

Tissue Thermal Transport Properties

The transport of thermal energy in living tissue is a complex process involving multiple phenomenological mechanisms including conduction; convection; radiation; metabolism; evaporation; and phase change. The equilibrium thermal properties presented in this chapter were measured after temperature stability had been achieved.

Thermal probe techniques are used frequently to determine the thermal conductivity and the thermal diffusivity of biomaterials [3–6]. Common to these techniques is the use of a thermistor bead as a heat source or a temperature sensor. Various thermal diffusion probe techniques [7] have been developed from Chato's first practical use of the thermal probe [3]. Physically, for all of these techniques, heat is introduced to the tissue at a specific location and is dissipated by conduction through the tissue and by convection with blood perfusion.

Thermal probes are constructed by placing a miniature thermistor at the tip of a plastic catheter. The volume of tissue over which the measurement occurs depends on the surface area of the thermistor. Electrical power is delivered simultaneously to a spherical thermistor positioned invasively within the tissue of interest. The tissue is assumed to be homogeneous within the milliliter surrounding the probe. The electrical power and the resulting temperature rise are measured by a microcomputer-based instrument. When the initial tissue temperature is just below the freezing point, the thermistor heat is removed by conduction and by latent heat. In this situation, the instrument measures effective thermal properties that are the combination of conduction and latent heat.

By taking measurements over a range of temperatures, the processes of conduction and latent heat can be separated. When the tissue is perfused by blood, the thermistor heat is removed by conduction and by heat transfer due to blood flow near the probe. *In vivo*, the instrument measures effective thermal properties that are the combination of conductive and convective heat transfer. Thermal properties are derived from temperature and power measurements using equations that describe heat transfer in the integrated probe/tissue system.

The following five complexities make the determination of thermal properties a technically challenging task:

- Tissue heat transfer includes conduction, convection, radiation, metabolism, evaporation, and phase change. It is difficult but necessary to decouple these different heat transfer mechanisms.
- Mechanical and thermal interactions between the probe and tissue are complex and must be properly modeled to achieve accurate measurements. When the probe is inserted into living tissue, a fluid pool may form around the probe because of the mechanical trauma. Because the probe is most sensitive to the tissue closest to it, the presence of a pool of blood and other fluids will significantly alter the results. Tissue damage due to probe insertion may also occur *in vitro*.
- Tissue structure is quite heterogeneous within each sample. Thus, the probe (which returns a single measurement value) measures a spatial average of the tissue properties surrounding the active elements. Unfortunately, the spatial average is very nonuniform [8]; the probe is most sensitive to the tissue immediately adjacent to it. It is important to control this effective measurement volume. If the effective volume is too small, the measurement is highly sensitive to the mechanical/thermal contact between the probe and tissue. If the effective volume is too large, then the measurement is sensitive to the boundary conditions at the surface of the tissue sample.
- Significant sample-to-sample and species-to-species variabilities exist. One must be careful when extrapolating results obtained in one situation to different situations.
- Tissue handling is critical. Thermal properties are dependent on temperature and water content [9–12]. Blood flow, extracellular water, and local metabolism are factors that strongly affect heat transfer in living tissue, but are difficult to determine or control experimentally. Once a tissue dies, if handled improperly significant water fluxes that will affect tissue thermal properties will occur. Tissues should be stored in a slightly hypertonic saline buffer or on a saline-moistened surgical gauzepad and wrapped in aluminum foil and kept at 4°C to minimize tissue mass transfer.

Currently, no method can simultaneously quantify the major three parameters: intrinsic tissue thermal conductivity, k_m; the tissue thermal diffusivity, α_m; and perfusion, w. The knowledge of k_m is required prior to the perfusion measurement or, even when k_m is measured in the presence of perfusion, the thermal diffusivity cannot be measured [6, 13].

Background

There are many good reviews of techniques to measure thermal properties [10, 14–16]. *Thermophysical Properties of Matter* is a 10-volume set that catalogs thermal properties. Volumes 1 and 3 contain thermal conductivity data, and volume 10 contains thermal diffusivity data. Extensive reviews of measurement techniques exist as prefaces to each volume of the set. Additional thermal property data can be found in Kreith and Bohn [17]. Chato has written an excellent chapter in *Heat Transfer in Medicine and Biology*, which reviews techniques to measure thermal properties of biologic materials [10]. Valvano has documented the temperature dependence of tissue thermal properties [11, 12] and Duck has written an excellent review chapter on this subject [18].

The thermal diffusion probe was conceived by Chato [3, 10]. Significant developments were obtained by Balasubramaniam, Bowman, Chen, Holmes, and Valvano [4,19–27]. Patel and Walsh have applied the self-heated thermistor technique to nondestructive surface measurements [8, 24–26]. Unfortunately, surface probes are unreliable due to poor probe–tissue contact and uncertain boundary conditions at the tissue surface [8, 24].

Self-heated thermistors have been used to measure perfusion [4, 9, 19, 20, 22–24]. Effective thermal conductivity, k_{eff}, is the total ability of perfused tissue to transfer heat in the steady state. k_{eff} is the combination of conduction (due to intrinsic thermal conductivity, k_m) and convection (due to perfusion.) Measurements of k_{eff} are very sensitive to perfusion. The limitation of most techniques is that the intrinsic tissue thermal conductivity must be known in order to measure perfusion accurately. Holmes and Chen use a combination of steady state and transient heating modes to determine perfusion without requiring a no-flow calibration measurement [13, 19, 20]. The uncertainty of k_m significantly limits the perfusion accuracy [9].

Measurement of Thermal Conductivity and Diffusivity

Methods

In the constant temperature heating technique, the instrument first measures the baseline tissue temperature, T_0. Then, an electronic feedback circuit applies a variable voltage, $V(t)$, in order to maintain the average thermistor temperature at a predefined constant, T_h. The electrical circuit used to implement the constant temperature heating technique is shown in Figure 4.10.1. Three high-quality, gold-plated, electromagnetic relays are used to switch the thermistor (R_s) between "heat" and "sense" mode. The figure shows the position of the three relays in "heat" mode.

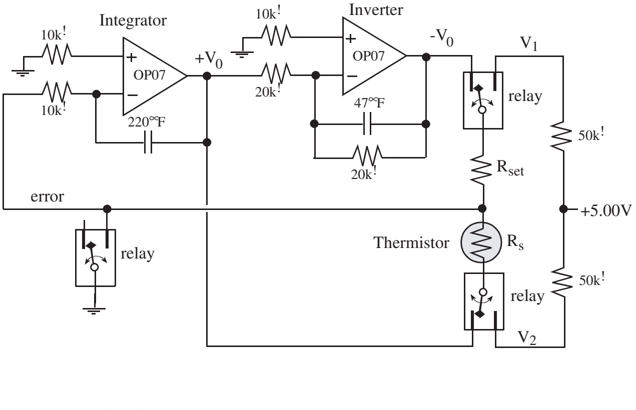

FIGURE 4.10.1 Electrical circuit for the constant temperature heating technique.

Initially, the instrument places the circuit in "sense" mode with the three relays in the opposite position as shown in Figure 4.10.1. A precision +5.00 V reference (PMI REF02) supplies voltage to the four-resistor bridge, formed by the two 50-kΩ, R_{set} and R_s resistors. The voltage difference $V_2 - V_1$ is fed to a differential amplifier, passed through a low-pass filter, then fed to a 12-bit ADC. Resistance calibration is performed to determine the relationship between the ADC sample and the unknown R_s. Next, temperature calibration is performed by placing the thermistor adjacent to an accurate temperature monitor and placing the combination in a temperature-controlled water bath. The thermistor resistance varies nonlinearly with its temperature. For small temperature ranges, Equation (4.10.1) can be used for temperature calibration:

$$R_s = R_o e^{\beta/(T_s+273.15)} \tag{4.10.1}$$

where T_s is the temperature in °C, and R_s is the thermistor resistance in ohms. Equation (4.10.2) yields an accurate fit over a wide range of temperatures:

$$T = \frac{1}{H_0 + H_1 \ln(R) + H_3\left[\ln(R)\right]^3} - 273.15 \tag{4.10.2}$$

In "heat" mode, the integrator/inverter circuit varies the voltage across the thermistor until the thermistor resistance, R_s, matches the fixed resistor, R_{set}. It takes just a few milliseconds for the electrical control circuit to stabilize. Once stable, R_s is equal to R_{set}, meaning the volume average thermistor temperature is equal to a constant. The instrument uses the calibration temperature vs. resistance curve, Equation (4.10.2), to determine the heated temperature T_h from the fixed resistor R_{set}. The power applied to the thermistor is calculated from $(V_0)^2/R_{set}$.

The applied thermistor power includes a steady state and a transient term:

$$P(t) = A + Bt^{-1/2} \tag{4.10.3}$$

where A and B are system constants that depend on the characteristics of the probe and the thermal interaction with the tissue in which it is embedded.

In order to measure thermal conductivity, thermal diffusivity, and tissue perfusion, the relationship between applied thermistor power, P, and resulting thermistor temperature rise, $T(t)=T_h - T_0$, must be known. In the constant temperature method, T is constant. The thermistor bead is treated as a sphere of radius "a" embedded in a homogeneous medium. Because all media are considered to have constant parameters with respect to time and space, the initial temperature will be uniform when no power is supplied to the probe:

$$T_b = T_m = T_0 = T_a + \frac{Q_{met}}{wc_{bl}} \text{ at } t = 0 \tag{4.10.4}$$

where w is the rate of perfusion of blood through the local tissue (ml blood/ml tissue–s) and c_{bl} is the specific heat of blood (kJ/kg.K).

Let V be the temperature rise above baseline, $V = T - T_s$. The thermistor bead temperature rise (V_b) and the tissue temperature rise (V_m) are initially zero.

$$V_b = V_m = 0 \text{ at } t = 0 \tag{5}$$

Assuming the venous blood temperature equilibrates with the tissue temperature and that the metabolic heat is uniform in time and space, the Pennes' bioheat transfer equation in spherical coordinates is given by [28]:

$$\rho_b c_b \frac{\partial V_b}{\partial t} = k_b \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 \frac{\partial V_b}{\partial r}\right) + \frac{A + Bt^{-1/2}}{\frac{4}{3}\pi a^3} \quad r < a \tag{4.10.6}$$

$$\rho_m c_m \frac{\partial V_m}{\partial t} = k_m \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 \frac{\partial V_m}{\partial r}\right) - wc_{bl} V_m \quad r > a \tag{4.10.7}$$

Perfect thermal contact is assumed between the finite-sized spherical thermistor and the infinite homogeneous perfused tissue. At the interface between the bead and the tissue, continuity of thermal flux and temperature leads to the following boundary conditions:

$$V_b = V_m \text{ at } r = a \tag{4.10.8}$$

$$k_b \frac{\partial V_b}{\partial r} = k_m \frac{\partial V_m}{\partial r} \text{ at } r = a \tag{4.10.9}$$

The other boundary conditions are necessary at positions $r \rightarrow 0$ and $r \rightarrow \infty$. Because no heat is gained or lost at the center of the thermistor:

$$V_b = \text{finite (or } k_b \frac{\partial V_b}{\partial r} = 0) \text{ as } r \rightarrow 0 \tag{4.10.10}$$

Because thermistor power is finite and tissue is infinite, the tissue temperature rise at infinity goes to zero:

$$V_m \rightarrow 0 \text{ as } r \rightarrow \infty \tag{4.10.11}$$

It is this last initial condition that allows the Laplace transform to be used to solve the coupled partial differential equations. The Laplace transform converts the partial differential equations into ordinary differential equations that are independent of time *t*. The steady state solution allows for the determination of thermal conductivity and perfusion [20]:

$$V_b(r) = \frac{A}{4\pi a k_b}\left\{\frac{k_b}{k_m\left(1+\sqrt{z}\right)}\right\} + \frac{1}{2}\left[1 - \left(\frac{r}{a}\right)^2\right] \tag{4.10.12}$$

$$V_m(r) = \frac{A}{4\pi r k_m}\left(\frac{e^{\left(1-r/a\right)\sqrt{z}}}{1+\sqrt{z}}\right) \tag{4.10.13}$$

where *z* is a dimensionless Pennes' model perfusion term ($wc_{bl}a^2/k_m$). The measured thermistor response, ΔT, is assumed be the simple volume average of the thermistor temperature:

$$\Delta T = \frac{\int_0^a V_b\left(r\right) 4\pi r^2 \, dr}{\frac{4}{3}\pi a^3} \tag{4.10.14}$$

Inserting Equation (4.10.12) into Equation (4.10.14) yields the relationship used to measure thermal conductivity, assuming no perfusion [4]:

$$k_m = \frac{1}{\frac{4\pi a\Delta T}{A} - \frac{0.2}{k_b}} \tag{4.10.15}$$

A similar equation allows the measurement of thermal diffusivity from the transient response, again assuming no perfusion [22]:

$$\alpha_m = \left[\frac{a}{\sqrt{\pi}\, B/A\left(1+0.2\frac{k_m}{k_b}\right)}\right]^2 \tag{4.10.16}$$

Rather than using the actual probe radius (a) and probe thermal conductivity (k_b), the following empirical equations are used to calculate thermal properties:

$$k_m = \frac{1}{\frac{c_1\ T}{A} + c_2} \tag{4.10.17}$$

$$\alpha_m = \left[\frac{c_3}{\sqrt{\pi}\, B/A\left(1+0.2\frac{k_m}{c_4}\right)}\right]^2 \tag{4.10.18}$$

The coefficients c_1, c_2, c_3, and c_4 are determined by operating the probe in two materials of known thermal properties. Typically, agar-gelled water and glycerol are used as thermal standards. This empirical calibration is performed at the same temperatures at which the thermal property measurements will be performed.

It is assumed that the baseline tissue temperature, T_0, is constant during the 30-sec transient. Patel has shown that if the temperature drift, dT_0/dt, is larger than 0.1°C/min, then significant errors will occur [8]. The electronic feedback circuit forces T_h to a constant. Thus, if T_0 is constant, ΔT does not vary during the 30-sec transient perod.

The applied power, $P(t)$, varies during the 30-sec transient. Linear regression is used to calculate the steady state and transient terms in Equation (4.10.3). Figure 4.10.2 shows some typical responses. The steady state response (time equals infinity) is a measure of the thermal conductivity. The transient response (slope) indicates the thermal diffusivity.

The time of heating can vary from 10 to 60 s. Shorter heating times are better for small tissue samples and for situations in which baseline tissue temperature drift is present. Another advantage of shorter heating times is the reduction in the total time required to make one measurement. Longer heating times increase the measurement volume and reduce the effect of imperfect thermistor–tissue coupling. Typically, shorter heating times are used *in vivo* because more measurements may be taken over the same time period. On the other hand, longer heating times are used *in vitro* because accuracy is more important than measurement speed.

Probe Design

Thermal probes must be specially constructed in order to measure thermal properties. The two important factors for the thermal probe are thermal contact and transducer sensitivity. The shape of the probe should be chosen in order to minimize trauma during insertion. Any boundary layer between the

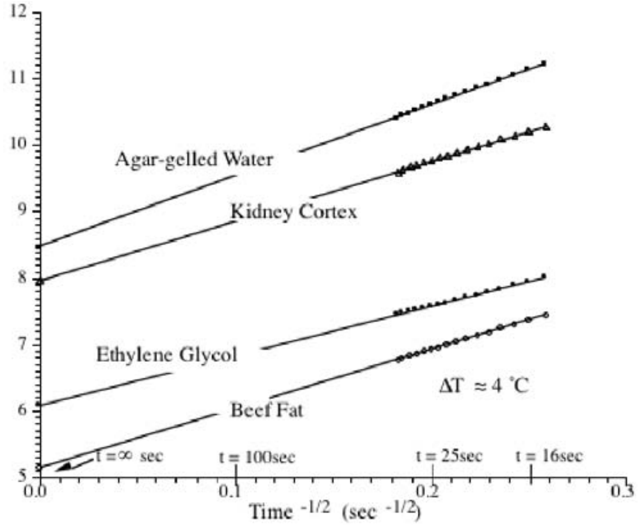

FIGURE 4.10.2 Typical P/T vs. time$^{-1/2}$ data for the constant temperature heating technique.

thermistor and the tissue of interest will cause a significant measurement error. The second factor is transducer sensitivity that is the slope of the thermistor voltage vs. tissue thermal conductivity. Equation (4.10.15) shows for a fixed ΔT, k_m and k_b, the thermistor power (A) increases linearly with probe size (a). Therefore, larger probes are more sensitive to thermal conductivity.

Thermometrics P60DA102M and Fenwal 121-102EAJ-Q01 are glass probe thermistors that make excellent transducers. The glass-coated spherical probes provide a large bead size and a rugged, stable transducer. The Thermometrics BR55KA102M and Fenwal 112-102EAJ-B01 bead thermistors also provide excellent results. For large tissue samples, multiple thermistors can be wired in parallel so that they act electrically and thermally as one large device.

Using multiple thermistors has two advantages. The effective radius, $a = c_1/4\pi$, is increased from about 0.1 cm for a typical single P60DA102M probe to about 0.5 cm for a configuration of three P60DA102M thermistors. The second advantage is that the three thermistors are close enough to each other that the tissue between the probes will be heated by all three thermistors. This cooperative heating tends to increase the effective measurement volume and reduce the probe–tissue contact error. Good mechanical/thermal contact is critical. The probes are calibrated after they are constructed so that the thermistor geometry is incorporated into the coefficients c_1, c_2, c_3, and c_4. The same water bath and probe configuration should be used during the calibration and during the tissue measurements.

Calibration

Calibration is a critical factor when using an empirical technique. For temperatures below 0°C, ice and ethylene glycol are used as thermal standards. For temperatures between 0 and 15°C, agar-gelled water and ethylene glycol can be used as thermal standards. For temperatures between 15 and 75°C, agar-gelled water and glycerol were used. One gram of agar per 100 mL of water should be added to prevent convection. The instrument has been used to measure k_m and α_m of various concentrations of agar-gelled water at 37°C.

A mixture of water and glycerol can be used to estimate the accuracy of the technique. The mass fraction, m, can be used to determine the true thermal properties of the mixture [29]:

$$k_m = m\, k_g + (1 - m)k_w + 1.4\, m\,(m - 1)(k_w - \mathrm{k_g} - 2) - 0.014\, m\,(m - 1)(T - 20°\mathrm{C}) \quad (4.10.19)$$

$$\alpha_m = m\, \alpha_g + (1 - m)\, \alpha_w \quad (4.10.20)$$

Estimation of Heat Transfer Coefficient

Introduction

Heat-flux transducers measure net heat transfer rate at the transducer surface. These sensors can be classified according to their principle of operation [30] as follows:

- Time rate change of thermal energy at the surface
- Temperature difference across a known thermal resistance
- Electric power dissipated in a heater at steady-state

The first type of gauge is too slow to measure unsteady heat transfer flux [30] as found in the body. Moreover, it requires that the surrounding temperature be constant. Unfortunately, the temperature *in vivo* can vary during an experiment. The second type requires a heater and at least two temperature sensors to measure the difference of temperature across a known thermal resistance. This would make the sensor apparatus difficult to realize due to uncertainties in the placement of the sensors and in the thermal resistance. The third has some advantages over the others. First, only one sensor is necessary in order to measure h. Second, the sensor can be a conventional thermistor found in regular Swan–Ganz catheters. Third, the frequency response of the sensor placed in a feedback circuit is typically 10 to 100 Hz, which is high enough to measure the instantaneous h in the ventricles.

Several researchers have addressed the use of the heat flux gauges of the third type for measurements of the heat flux:

- Van Heiningen and colleagues [31] acknowledged that it is possible to use thin-film gauges with constant-temperature anemometer control for heat flux measurements without guard heater. In this case, the sensor overheat ratio must be kept small in order to be calibrated correctly.
- Kraabel et al. [32] used a self-heated thermistor embedded in a conical shape sensor to measure heat flux. In this study, they did not use guard heaters, but rather used their probe for measurements in air. Consequently, they did not cover the sensor with a protective layer.
- Campbell and Diller [33] used a thin film gauge placed in a constant-temperature anemometer to keep the sensor at constant temperature under fluctuating condition. In one of their steady-state calibrations, they calibrate the gauge against the predictable value of Nusselt numbers for cylinders in crossflow.
- Fitzgerald et al. [34] used a small gauge with small overheat ratio (above 2°C) to measure instantaneous heat transfer coefficient in immersed tubes in fluidized beds.
- Wu and colleagues [35] developed an instantaneous heat transfer probe to measure local heat convection coefficients. They used a platinum film as a heater element as well as a temperature sensor. To minimize heat loss due to conduction, they used a guard heater. Despite the fact that they used their probe in the air, they coated the sensor with a plastic film. During their experiments, the average probe temperature was set to be 3°C above the surrounding temperature for the purpose of keeping the stability of the instrumentation.
- Pflum and coworkers [36] used a resistance wire to measure heat convection coefficient in fluidized beds. They pointed out two systematic errors inherent to heated-wire technique: temperature gradients between wires and heat conduction through the sensor substrate and proposed a finite-difference model to correct these errors.
- Beasley and Figliola [37] found that the probe effective area differs from that of the actual film sensor surface area. However, it keeps nearly constant for a wide range of heat convection coefficient for large values of k_c/k_s, where k_c is the thermal conductivity of the coating and k_s is the thermal conductivity of the substrate.
- Figliola and Swaminathan [38] analyzed the influence of thermal boundary conditions around the sensor perimeter during steady state conditions. They found that boundary conditions alter the static calibration of the probe and that this influence is linear. Moreover, they concluded that, for high-convection conditions, the results tend toward those of perfect boundary conditions.

- Griffth et al. [39] measured heat convection coefficients using a small platinum coil. To account for conduction losses, they used a one-dimensional model.
- Holmberg and Womeldorf [40] compared the calibration of three types of sensors in the NIST (National Institute of Standards and Technology — U.S.) convective heat flux calibration facility. Because the sensor disturbs the thermal and velocity boundary layer, they calibrated the sensor output as a function of the heat flux through the surrounding surface. In other words, they did not assume that the heat fluxes through the sensor and through the surroundings are the same. This opened the possibility of calibrating a sensor against predicted values of h.
