These works suggest that, in order to measure the heat convection coefficient correctly, one should be aware of the sensor behavior. In addition, they also suggest that: (1) guard heaters are not necessary to correctly evaluate h; (2) a one-dimensional model can correctly account for probe behavior; (3) it is possible to calibrate the sensor output against the environment predicted or known values of h; and (4) a calibration is more useful when it is performed in conditions similar to the conditions to be found in the actual measurement site.

The topologies of the inner surfaces of the heart and blood vessels are very complex. Consequently, it is very difficult to model the heat transfer at the wall analytically. Any attempt to estimate the heat transfer coefficient analytically will be inaccurate because of the complex contours of structures like the endocardium. Thus, the experimental method presented in this section to estimate the heat transfer coefficient is very appropriate. In order to measure the h, a thermoresistive sensor is employed as heating element and temperature sensor. The probe is placed in close contact with the endocardium and self-heated by electric power above the temperature of the circulating blood pool. The power lost by convection can then be used to measure h on the endocardial surface. This method can also be applied to blood vessels.

In this configuration, the instrumentation has two modes of operation: the sensing and the heating modes. The probe can be switched from one mode to another anytime using a circuit similar to that in Figure 4.10.1 [41, 42]. In the sensing mode, the probe measures the surrounding temperature, T_s. In the heating mode, the electrical resistance of the probe and thus its volume-averaged temperature, T_h, is kept constant by a feedback circuit like the one described in dos Santos et al. [41]. In order to measure h, in principle one could use the so-called Newton's law of cooling, Equation (4.10.21):

$$P = hA(T_h - T_s) \tag{4.10.21}$$

where P is the power dissipated by the probe, which can be calculated from the voltage across its terminal and its resistance; T_h is the temperature at the surface of the sensor that is ideally kept constant by the anemometer circuitry in the heating mode; T_s is the fluid temperature measured in the sensing mode; and A is the surface area in contact with the fluid. Because the probe is meant to be used inside the heart, a Swan–Ganz catheter, which has a thermistor embedded close to its tip that can be used to measure h, was chosen as a suitable instrument to make the measurements. However, one should be aware that using this instrument to measure h is complicated by the following factors:

- A portion of the heat is conducted through the back of the sensor.
- The catheter surface temperature depends on h.
- The catheter surface temperature is not the temperature measured by the instrument.
- The sensor area is not easy to measure because the sensor is mounted in the catheter.

Consequently, an empirical calibration technique is used [41].

Calibration

The calibration method consists of using empirical equations to predict h on the wall in circular tubes. The predicted value is then used to calibrate the instrument. Besides the fact that the calibration environment closely matches the environment where the measurement will be performed, turbulent flow was chosen for three reasons. First, it facilitates calibration because the values of h can be easily controlled under this condition by simply changing the flow rate. Second, the fully developed velocity profile is attained for small tube lengths. Third, long-time and widely used empirical equations are available to evaluate h under this condition. Thus, knowing the tube diameter and shape and the mean flow velocity and thermal properties of the water, the evaluation of the heat transfer coefficient from the wall to the circulating flow inside the tube is possible. This means that the sensor output can be calibrated vs. the evaluated average heat convection coefficient (h).

The following empirical equation [41–43] was proposed by dos Santos. Let ΔT be the temperature difference, $T_h - T_s$, between the heated thermistor and the circulating blood.

$$h - c_1\left(\frac{P}{\Delta T}\right)^3 + c_2\left(\frac{P}{\Delta T}\right)^2 + c_3\left(\frac{P}{\Delta T}\right) + c_4 \tag{4.10.22}$$

where c_1, c_2, c_3, and c_4 are calibration constants; dos Santos [42] showed the accuracy of this curve to be 7.4%. The key to accurate measurements lies in how close the calibration configuration matches the actual experimental conditions.

A second calibration equation can be derived analytically, assuming a spherical thermistor of radius a and having a uniform convective boundary condition around its entire surface area [43]. The voltage average temperature rise is ΔT and P is the total steady state power, which is uniformly applied throughout the entire thermistor volume:

$$\frac{\Delta T}{P} = \left(\frac{1}{8\pi a k_i} - \frac{3}{40\pi a k_i}\right) + \left(\frac{1}{4\pi a^2}\right)\frac{1}{h} \tag{4.10.23}$$

This analytic solution suggests the following empirical equation:

$$h = \frac{1}{c_1\dfrac{\Delta T}{P} + c_2} \tag{4.10.24}$$

where c_1 and c_2 are calibration constants.

For a smooth tube of cylindrical cross section, the relation among Nu, Re, and Pr, for turbulent flow conditions, is given by

$$\mathrm{Nu}_D = \frac{(f/8)(\mathrm{Re}_D - 1000)\mathrm{Pr}}{1 + 12.7(f/8)^{1/2}\left(\mathrm{Pr}^{2/3} - 1\right)} \tag{4.10.25}$$

where the friction factor, f, is

$$f = (0.79 \ln \mathrm{Re}_D - 1.64)^{-2} \tag{4.10.26}$$

This correlation is valid for $0.5 < \mathrm{Pr} < 2000$ and $2300 < \mathrm{Re}_D < 5 \times 10^6$. The setup was calibrated with a tube of 1.46 cm diameter and then tested with a tube of 1.27 cm. The flow rates were selected to give a range of h values from 800 to 4000 W/m^{2}K. The average accuracy is about 10%.

In Vivo *Measurements*

The heat convection coefficient was measured in several locations in the right atrium and right ventricle of two pigs [42]. Figure 4.10.3 illustrates that the cylindrical shape of catheter matches the contour of the endocardial surface of the ventricle. For each location, three sets of measurements were taken and the standard deviation of the average values was calculated. For a short period of time (up to 15 heart

Source: dos Santos, I., Will, J.A., da Rocha, A.F., de O. Nascimento, F.A., Webster, J.G., and Valvano, J.W., *Physiol. Meas.*, 24, 793–804, 2003.42

beats), no changes occurred in h because the temperature, heart rate, cardiac output, and ejection fraction are unlikely to change in such a short period of time. This means that the standard deviation of the average values can be used as an assessment of the performance of the instrument.

Positions A1 and B1 are on the anterior surface of the right atrium located midway between superior vena cava inlet and the tricuspid valve. Position A2 is on the anterolateral surface of the right atrium, just above the tricuspid valve. Position B5 is on the anterior surface of the right ventricle just below the pulmonary valve. Positions A3 and B3 are at the midpoint of the anterolateral surface of the right ventricle. Position A4 and B4 are on the intraventricular septal surface of the right ventricle. Table 4.10.1 gives the measured convective coefficient values.

Temperature-Dependent Thermal Properties

Temperature Dependence of Organ Tissue

When modeling heat transfer in situations in which the temperature range exceeds 10°C, it is important to consider the temperature dependence of the tissue thermal properties. Valvano and colleagues [11] and Valvano and Chitsabesan [12] measured tissue thermal properties as a function of temperature using the constant ΔT thermistor heating technique. The results shown in Table 4.10.2 were derived from *in vitro* measurements taken at 3, 10 17, 23, 30, 37, and 45°C.

The animal tissues were measured from freshly sacrificed dogs, rabbits, and pigs. The normal human tissues were obtained from autopsy. The human cancers were freshly excised. The k_0, k_1, α_0, and α_1 values are the linear fit of the thermal properties as a function of temperature.

$$k = k_0 + k_1\ T \tag{4.10.27}$$

where conductivity is in mW/cm°C; diffusivity is in cm^2/sec and temperature is in °C.

Temperature Dependence of Human Arterial Tissue

Aortic tissue was obtained from a local pathology lab. The thermal probes were placed on the endothelial surface of the aortic wall, and the tissue–probe combination was wrapped in plastic. The tissue surface was kept wet to improve the thermal contact and to prevent drying. The samples were placed in a breaker of saline and the breaker was put into a temperature-controlled water bath. Thermal conductivity and thermal diffusivity were measured 10 times at each temperature 35, 55, 75, and 90°C. The measurement order was varied among 35, 55, 75, and 90°C; 95, 75, 55, and 35°C; 75, 90, 55, and 35°C; and 55, 35, 90, and 75°C. Measurements were obtained from normal and diseased tissue and the plaques were categorized by gross visual observation. The calcified plaques were hard and bony; the fibrous plaques were firm but pliable and the fatty plaques were loose and buttery. The results from 54 tissues are presented in Table 4.10.3 and Table 4.10.4. The column *n* refers to the number of tissue samples. The standard deviation is given in parentheses.

The two-sample *t*-test with $p = 0.05$ was used to determine significant differences. Tissue thermal properties increased with temperature and were significantly less than those of water. The measurement order did

not affect the measured thermal properties and no difference was found among the thermal conductivity of normal aorta, fatty plaque, and fibrous plaque. The thermal conductivity and thermal diffusivity of calcified plaque were slightly higher than normal aorta, fatty plaque, and fibrous plaque.

Temperature Dependence of Canine Arterial Tissue

Carotid and femoral arteries were harvested immediately *post mortem*. The thermal probes were placed on the endothelial surface of the arterial wall. Thermal conductivity and thermal diffusivity were measured 10 times at each temperature: 25, 35, 45, 55, 65, 75, 85, and 95°C. Measurements were obtained only from normal tissue. The results from 18 tissues are summarized in Equation (4.1031) through Equation (4.10.35).

Canine femoral artery:

$$k\ (\text{mW/cm–°C}) = 3.688 + 0.0062014\ T\ (°\text{C}) \tag{4.10.31}$$

$$\alpha\ (\text{cm}^2/\text{sec}) = 0.001003 + 0.000001381\ \text{T}\ (°\text{C}) \tag{4.10.32}$$

Canine carotid artery:

$$k\ (\text{mW/cm–°C}) = 4.480 + 0.0000164\ T\ (°\text{C}) \tag{4.10.33}$$

$$\alpha\ (\text{cm}^2/\text{sec}) = 0.001159 + 0.000003896\ T\ (°\text{C}) \tag{4.10.34}$$

The two-sample t-test with $p = 0.01$ shows that thermal conductivity and thermal diffusivity are larger in carotid vs. femoral artery. These results could be explained from the fact that the carotid artery contains more collagen than femoral artery does. A tissue with a higher percentage of collagen would have lower thermal properties because collagen is a thermal insulator.

Temperature Dependence of Swine Left Ventricle

Swine myocardial samples were harvested immediately *post mortem*. The thermal probes were placed on the left ventricular muscle. Thermal conductivity and thermal diffusivity were measured 10 times at each temperature: 25, 37. 50, 62, and 76°C. Measurements were obtained only from normal tissue. The results are summarized in Table 4.10.5 andTable 4.10.6.

Thermal Properties of Frozen Tissue

The thermal properties of frozen tissue are significantly different from those of normal tissue. Valvano measured frozen tissue thermal properties using the constant ΔT thermistor heating technique [44]. The results shown in Table 4.10.7 were derived from *in vitro* measurements taken at –18, –5, and +0.1°C.

Thermal Properties as a Function of Water and Fat Content

In a global sense, the thermal properties of tissue are determined by the relative concentrations of its constituate parts. Spells found a linear relationship between tissue thermal conductivity and water content [45]:

$$k\ (\text{mW/cm–°C}) = 0.54 + 5.73\ m_{water} \text{ for } m_{water} > 0.2 \tag{4.10.35}$$

where m_{water} is the mass fraction of water in the tissue. Cooper and Trezek found an empirical relationship between thermal conductivity and mass fractions of water, protein, and fat [46]:

$$k\ (\text{mW/cm–°C}) = \rho \sum_n \frac{k_n m_n}{\rho_n} = \rho\left(6.28 m_{water} + 1.17 m_{protein} + 2.31 m_{fat}\right) \tag{4.10.36}$$

Cooper and Trezek [46] found similar relationships for specific heat and density:

$$c\ (\text{J/g-°C}) = \sum_n c_n m_n = 4.2\ m_{water} + 1.09\ m_{protein} + 2.3\ m_{fat} \tag{4.10.37}$$

$$\rho\ (\text{g/cm}^3) = \frac{1}{\sum_n \frac{m_n}{\rho_n}} = \frac{1}{m_{water} + 0.649 m_{protein} + 1.227 m_{fat}} \tag{4.10.38}$$

Effect of Blood Flow on Temperature

Introduction

Bioheat transfer processes in living tissues are often affected by the influence of blood perfusion through the vascular network on the local temperature distribution. When the difference between the temperature of blood and the tissue through which it flows is significant, convective heat transport will occur, altering the temperatures of blood and tissue. Perfusion-based heat transfer interaction is critical to a number of physiological processes such as thermoregulation and inflammation.

The blood–tissue thermal interaction is a function of several parameters, including the rate of perfusion and the vascular anatomy, which vary widely among the different tissues, organs of the body, and pathology. Appendix B contains an extensive compilation of perfusion rate data for many tissues and organs and for many species. The literature on mathematical modeling of the influence of blood perfusion on bioheat transfer phenomena has been reviewed recently by Charney [47]; his paper is highly recommended for readers desiring an in-depth presentation of the topic.

The rate of perfusion of blood through different tissues and organs varies over the time course of a normal day's activities, depending on factors such as physical activity, physiological stimulus, and environmental conditions. Furthermore, many disease processes are characterized by alterations in blood perfusion, and some therapeutic interventions result in an increase or decrease in blood flow in a target tissue. For these reasons, it is very useful in a clinical context to know the absolute level of blood perfusion within a given tissue. Numerous techniques have been developed for this purpose over the past several decades. In some of these techniques, the coupling between vascular perfusion and local tissue temperature is applied to advantage to assess the flow through local vessels via inverse solution of equations that model the thermal interaction between perfused blood and the surrounding tissue.

Pennes [28] published the seminal work on developing a quantitative basis for describing the thermal interaction between tissue and perfused blood. His work consisted of a series of experiments to measure temperature distribution as a function of radial position in the forearms of nine human subjects. A butt-junction thermocouple was passed completely through the arm via a needle inserted as a temporary guideway, with the two leads exiting on opposite sides of the arm. The subjects were unanesthetized so as to avoid the effects of anesthesia on blood perfusion. Following a period of normalization, the thermocouple was scanned transversely across the mediolateral axis to measure the temperature as a function of radial position within the interior of the arm. The environment in the experimental suite was kept thermally neutral during experiments. Pennes' data showed a temperature differential of 3 to 4° between the skin and the interior of the arm; he attributed this to the effects of metabolic heat generation and heat transfer with arterial blood perfused through the microvasculature.

Pennes proposed a model to describe the effects of metabolism and blood perfusion on the energy balance within tissue. These two effects were incorporated into the standard thermal diffusion equation, which is written in its simplified form as:

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot k \nabla T + (\rho c)_b \omega_b (T_a - T) + q_{met} \tag{4.10.39}$$

Metabolic heat generation, q_{met}, is assumed to be homogeneously distributed throughout the tissue of interest as rate of energy deposition per unit volume. It is assumed that the blood perfusion effect is homogeneous and isotropic and that thermal equilibration occurs in the microcirculatory capillary bed. In this scenario, blood enters capillaries at the temperature of arterial blood, T_a, where heat exchange occurs to bring the temperature to that of the surrounding tissue, T. There is assumed to be no energy transfer before or after the blood passes through the capillaries, so that the temperature at which it enters the venous circulation is that of the local tissue. The total energy exchange between blood and tissue is directly proportional to the density, ρ_b, specific heat, c_b, and perfusion rate, ω_b, of blood through the tissue, and is described in terms of the change in sensible energy of the blood. This thermal transport model is analogous to the process of mass transport between blood and tissue, which is confined primarily to the capillary bed.

A major advantage of the Pennes' model is that the added term to account for perfusion heat transfer is linear in temperature, which facilitates the solution of Equation (4.10.39). Since the publication of this work, the Pennes' model has been adapted by many researchers for the analysis of a variety of bioheat transfer phenomena. These applications vary in physiological complexity from a simple homogeneous volume of tissue to thermal regulation of the entire human body [48, 49]. As more scientists have evaluated the Pennes' model for application in specific physiological systems, it has become increasingly clear that many of the assumptions foundational to the model are not valid.

For example, Chato [50], Chen and Holmes [51], and Weinbaum et al. [52–64] have demonstrated very convincingly that thermal equilibration between perfused blood and local tissue occurs in the precapillary arterioles and that, by the time blood flows into vessels 60 μm in diameter and smaller, the equilibration process is complete. Therefore, no significant heat transfer occurs in the capillary bed; the exchange of heat occurs in the larger components of the vascular tree. The vascular morphology varies considerably among the various organs of the body, which contributes to the need for specific models for the thermal effects of blood flow (as compared to the Pennes' model that incorporates no information concerning vascular geometry). As a consequence of these physiological realities, it would appear that the validity of the Pennes' model is questionable.

Many investigators have developed alternative models for the exchange of heat between blood and tissue. These models have accounted for the effects of vessel size [50, 51, 65]; countercurrent heat exchange [65–69]; and a combination of partial countercurrent exchange and bleed-off perfusion [52–64]. All of these models provided a larger degree of rigor in the analysis, but at the compromise of greater complexity and reduced generality. Some of these models have been the subject of considerable debate concerning their validity and range of appropriate application [70–73]. These studies also led to an increased appreciation of the necessity for a more explicit understanding of the local vascular morphology as it governs bioheat transfer, which has given rise to experimental studies to measure and characterize the three-dimensional architecture of the vasculature in tissues and organs of interest.

It is quite interesting that, in the context of the preceding studies to improve on the widely applied but questioned Pennes' model, the 50th anniversary of the publication of Pennes' paper was recognized recently [74]. For this occasion Wissler [73] returned to Pennes' original data and analysis and reevaluated his work. Given the hindsight of five decades of advances in bioheat transfer plus greatly improved computational tools and better constitutive property data, Wissler's analysis pointed out further flaws in Pennes' work that had not been appreciated previously. However, he also showed that much of the criticism directed toward the Pennes' model is not justified, in that his improved computations with the model demonstrated a good standard of agreement with the experimental data. Thus, Wissler's conclusion is that "those who base their theoretical calculations on the Pennes' model can be somewhat more confident that their starting equations are valid." The quantitative analysis of the effects of blood perfusion on the internal temperature distribution in living tissue remains a topic of active research after a half century of study.

Limitations of Pennes' Model

Pennes' model was the first major effort in quantifying the heat transfer contribution of perfusion. It was developed for describing the transverse temperature profile in the human forearm. The model is unique in that the perfusion term is very simple. The "bioheat equation" was previously shown as Equation (4.10.39).

The limitations of this model arise from the erroneous view of the heat transfer process and its anatomical location. Chen and Holmes' analysis of blood vessel thermal equilibration lengths showed that Pennes' concept is incorrect [51]. The thermal equilibration length is defined as the length at which the difference between the blood and tissue temperature decreases to $1/e$ of the initial value. They indicated that thermal equilibration occurs predominantly within the terminal arterioles and venules, and that blood is essentially equilibrated prior to the capillaries. In considering the contribution of perfusion as a nondirectional term, the directional convective mechanism is neglected. The model also does not account for specific vascular architecture such as countercurrent arteries and veins. The limitations of Pennes' model have motivated subsequent investigators to develop their own models.

Despite its erroneous concept, the perfusion term of Pennes' model has been widely used and found to be valid for situations other than the forearm. Its wide usage has been mainly due to its simplicity of implementation, especially in analyses in which a closed form analytical solution is sought [22, 75]. Investigators have obtained good temperature predictions for the following circumstances:

- Porcine kidney cortex in the absence of large vessels (diameter > 300 μm) [76]
- Rat liver [5, 22]
- Capillary bleed-off from large vessels [56]

In the last case, Charny compared Weinbaum–Jiji's countercurrent model and Pennes' model against the experimental results of Pennes. The simulations found that Pennes' model is valid in the initial branchings of the largest microvessels from the countercurrent vessels (diameter > 500 μm) in deep tissue. In this case, the microvessel blood temperature is close to arterial temperature. Arkin et al. [77] provide an explanation of the inconsistencies between the two anatomical sites. They suggest that because blood typically travels down successive generations of the vascular branches before equilibrating with the tissue temperature, Charny's claim actually refers to the collective contribution of numerous smaller thermally significant vessels in a region dominated by the large microvessels. The distinction of being thermally significant is based upon the ratio of thermal equilibration length to actual vessel length (ε):

$$\varepsilon = \frac{L_e}{L} \tag{4.10.40}$$

Along with Xu's observations on porcine kidney [76], Pennes' model appears to be applicable to regions in which the vasculature comprises numerous small thermally significant vessels ($\varepsilon \approx 1$).

Continuum Models

Among the continuum formulations of bioheat transfer, the Chen–Holmes model is the most developed. Prior to Chen–Holmes, continuum formulations by Wulff [78] and Klinger [79] addressed the isotropicity of Pennes' perfusion term. However, they did not challenge Pennes' concept of the site of heat exchange. Chen and Holmes [51] formulated their model after analyzing the significance of blood vessel thermal equilibration length. Through this analysis, they quantitatively showed that the major heat transfer processes occur in the 50- to 500-μm diameter vessels and refuted Pennes' paradigm.

In their model, they proposed that larger vessels be modeled separately from smaller vessels and tissue. Larger vessels were distinguished using the ratio of equilibration length to actual vessel length of about one ($\varepsilon \approx 1$) as the criteria. The smaller vessels and tissue were then modeled as a continuum. In a differential control volume of this continuum, they further separated solid tissue from the blood within the vascular space (Figure 4.10.4).

Subsequently, the heat transfer mechanisms can be divided into the contributions from (1) nonequilibrated blood in the thermally significant vessels; (2) blood that has equilibrated with the surrounding tissue; and (3) nearly equilibrated blood. The perfusion term of Pennes is then replaced with three terms:

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot k \nabla T + (\rho c)_b \, \omega^* \left(T_a^* - T\right) - (\rho c)_b \, \vec{u} \cdot \nabla T + \nabla \cdot k_p \nabla T + q_m \tag{4.10.41}$$

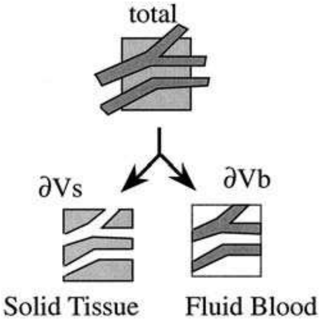

FIGURE 4.10.4 Schematic representation of tissue control volume as used by Chen–Holmes. (From Chen, M.M. and Holmes, K.R., *Ann. NY Acad. Sci.*, 335, 137–150, 1980.)

The second through the fourth terms on the right-hand side arise from each of the three categories described earlier. The second term, $(\rho c)_b \omega^*(T_a^* - T)$, is similar to Pennes except the perfusion and the arterial temperature are specific to the volume being considered. The $\nabla\ (\rho c)_b\ \vec{u} \cdot \nabla T$ term is a directional convective term due to the net flux of equilibrated blood. Finally, the $\nabla \cdot k_p \nabla T$ term is to account for the contribution of the nearly equilibrated blood in a tissue temperature gradient. The nearly equilibrated blood contributes to small temperature fluctuations within the tissue and the effect is modeled as a tensor "perfusion conductivity":

$$k_p = n(\rho c)_b \pi r_b^2\ \vec{V} \cos^2 \gamma \sum_{i=1}^{\infty} \frac{L_e}{L_e^2 \beta_i^2 + 1} \tag{4.10.42}$$

which is a function of local average blood flow velocity vector within the vessel ($\vec{V}$); relative angle (γ) between blood vessel direction and the tissue temperature gradient; the number of vessels (n); and vessel radius (r_b). The Fourier integral spectral wave number (β) can be approximated as the inverse of vessel length. The contribution of this conductivity is minimal except when vessels with large equilibration lengths are considered. However, for this situation, Chen and Holmes recommend that these vessels be treated separately. The assumptions made for their model include: (1) neglecting the mass transfer between vessel and tissue space; and (2) treating the thermal conductivity and temperature within the tissue–blood continuum as that of the solid tissue because the vascular volume is much smaller than that of the solid tissue.

The limitation of this model is that, given the detail required, the model is not easy to implement. Also, the perfusion conductivity term is difficult to evaluate, and distinction within the continuum model is not well defined. Furthermore, the model does not explicitly address the effect of closely spaced countercurrent artery–vein pairs. This model has been applied to the porcine kidney and found to predict temperatures similar to Pennes' model; thus, given the simplicity of the latter, Xu et al. [76] recommended that Pennes be used. Arkin et al. [77] claim that the Chen–Holmes model can be essentially applied to the same tissue region as that for Pennes.

Vasculature-Based Models

Weinbaum–Jiji–Lemons [52–64]

The modeling of countercurrent vasculature, which was not explicitly addressed by the Chen–Holmes model, developed separately from that of the continuum models. Bazett et al. [80] initially presented the countercurrent structure from observations of large arteries and veins in human limbs. The first major quantitative analysis was presented by Mitchell and Myers [69]. It was then followed by the work of Keller and Seiler [68], which became the predecessor to the Weinbaum–Jiji models. In 1979, Weinbaum and Jiji [57] proposed the initial model of the artery–vein pair as two parallel cylinders of equal diameters with collateral bleedoff in the plane normal to the cylinders. The anatomical configuration is a schematic of an artery and vein pair with branches to the peripheral skin layer (Figure 4.10.5).

The contribution of perfusion to heat transfer in tissue was treated as heat transfer in a porous medium and was considered a unidirectional convective term normal to the artery–vein pair. Knowledge of vessel density, diameter, and blood velocity was required at the different blood vessel generations.

In 1984, Weinbaum and Jiji presented a more thorough model based upon anatomical observations with Lemons [52, 53]. This model analyzed three tissue layers of a limb: (1) deep; (2) intermediate; and (3) superficial or cutaneous. For the countercurrent structure of the deep tissue layer, they proposed a system of three coupled equations:

$$(\rho c)_b \pi r_b^2\ \overline{V} \cdot \frac{dT_a}{ds} = -q_a \tag{4.10.43}$$

$$(\rho c)_b \pi r_b^2\ \overline{V} \cdot \frac{dT_v}{ds} = -q_v \tag{4.10.44}$$

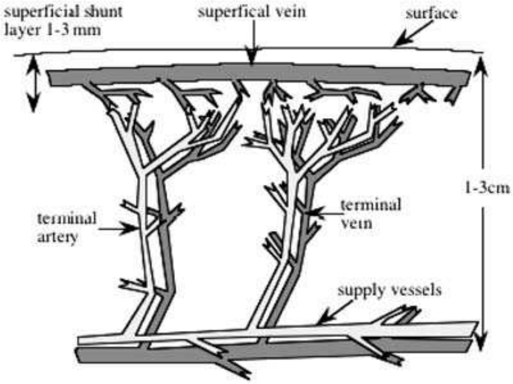

FIGURE 4.10.5 Schematic of artery and vein pair in peripheral skin layer. (From Weinbaum, S. and Jiji, L.M., *Advan. Bioeng.*, ASME WA/HT-72: 179–182, 1979.)

$$\rho c\frac{\partial T}{\partial t} = \nabla \cdot k\nabla T + n\, g\left(\rho c\right)_b \cdot \left(T_a - T_v\right) - n\,\pi\, r_b^2\left(\rho c\right)_b \overline{V} \cdot \frac{d\left(T_a - T_v\right)}{ds} + q_m \tag{4.10.45}$$

The first two equations describe the heat transfer of the thermally significant artery and vein, respectively. The third equation refers to the tissue surrounding the artery–vein pair. For this equation, the middle two right-hand side terms represent the capillary bleed-off energy exchange and the net heat exchange between the tissue and artery–vein pair, respectively. The capillary bleed-off term is similar to Pennes' perfusion term except the bleed-off mass flow (g) is used. Their analysis showed that the major heat transfer is due to the imperfect countercurrent heat exchange between artery–vein pairs. They quantified the effect of perfusion bleedoff associated with this vascular structure and showed that Pennes' perfusion formulation is negligible due to the temperature differential.

Assumptions include the following:

- Neglecting the lymphatic fluid loss so that the mass flow rate in the artery is equal to that of the vein
- Spatially uniform bleed-off perfusion
- Heat transfer in the plane normal to the artery–vein pair greater than that along the vessels (in order to apply the approximation of superposition of a line sink and source in a pure conduction field)
- Linear relationship for the temperature along the radial direction in the plane normal to the artery and vein
- Artery–vein border temperature equal to the mean of the artery and vein temperature
- Blood exiting the bleed-off capillaries and entering the veins at the venous blood temperature

The last assumption has drawn criticism based on studies that indicate the temperature is closer to tissue [72, 77]. Limitations of this model include the difficulty of implementation and identical artery and vein diameters. These two issues have lead to the development of the models described in subsequent sections. Studies using this model have been applied to the peripheral muscle tissue of a limb [68–70], and the model is accepted as valid for vasculature with diameters < 300 μm and $\varepsilon < 0.3$ [77].

Simplified Weinbaum–Jiji (W–J) [54]

In response to the criticism that their previous model is difficult and complex to apply, Weinbaum and Jiji simplified the three-equation model to a single equation:

$$\rho c\frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(k_{eff}\frac{\partial T}{\partial x}\right) + q_{met} \tag{4.10.46}$$

In their simplification, they derived an equation based on the temperature of tissue only. The imperfect countercurrent heat exchange is embodied in an effective conductivity tensor term:

$$k_{eff} = k\left\{1 + \frac{n\left[(\rho c)_b \pi r_b^2 \overline{V} \cos\gamma\right]^2}{\sigma_\Delta \cdot k^2}\right\} + q_{met} \tag{4.10.47}$$

The k_{eff} term has similar parameters to the tissue and artery–vein pair heat exchange term in Equation (4.10.47), and a shape factor term (σ_Δ). In order to eliminate the blood temperature from their previous formulation, two major assumptions (the closure conditions) were used:

- Mean tissue temperature = $(T_a + T_v)/2$
- Heat from paired artery is mostly conducted to the corresponding vein:

$$q_a \approx q_v \approx \sigma_\Delta k\,(T_a - T_v). \tag{4.10.48}$$

Both these assumptions were based upon studies in rabbit thigh muscle from their previous formulation. However, to respond to criticism of these assumptions, Weinbaum and Jiji performed further mathematical analysis on ε and provided insights into the limits for applying these assumptions [61]. An obvious limitation of this model is that the local temperatures along the countercurrent artery and vein cannot be calculated. Another limitation is that the model is applicable only in situations in which $L_e/L \ll 1$.

In the example of analyzing the peripheral tissue in the arm, L is equal to the characteristic radius of the arm [62]. Weinbaum and Lemons [62] admit that this assumption breaks down under the following conditions: (1) if blood flow rates significantly increased in the larger vessel pairs of the peripheral tissue layer; and (2) if deeper muscle tissue, where the diameters of the countercurrent pair vessels are less than 300 μm, are included. This model has been tested in the porcine [76] and canine kidney [81] and continues to be verified by the Weinbaum group [55, 64] and other investigators [82].

Small Artery Model [83, 84]

The small artery model was developed by Anderson in studies of the canine kidney cortex [83, 84]. The model considers the energy balance in a control volume (i, j, k) that contains an arterial (Q_a) or venous (Q_v) vessel. For a volume with an artery parallel to the z coordinate axis, the equation is

$$Q_a = N(VA)_a(\rho c)_b(1+\lambda-2\lambda\xi)\left(\frac{T_z - T_{z-\Delta z}}{\Delta z}\right) \tag{4.10.49}$$

For a volume with a vein:

$$Q_v = M(VA)_v(\rho c)_b(1+\lambda-2\lambda\xi)\left(\frac{T_{z+\Delta z} - T_z}{\Delta z}\right) \tag{4.10.50}$$

where N and M are the density of the interlobular arteries and veins in the kidney cortex, respectively. Zeta refers to the fraction of the total interlobular artery flow within the control volume; in the kidney cortex, $\xi = 1$ at the corticomedullary junction and decreases to $\xi = 0$ at the outer capsule. The total flow within this region accounts for bleedoff from the interlobular arteries through the λ term, where $\lambda = 1$ represents complete bleedoff. The discrete representation provides for straightforward numerical implementation when the vessel density within the tissue region of interest is known. Model assumptions include:

- Thermal equilibration length within the volume is much less than vessel length.
- There is a linear relation between the effect of bleedoff on arterial flow and location along the length of the vessel.
- Bleedoff is modeled as change in the arterial flow.
- Bleed-off heat transfer is negligible.
- No major thermally significant vessels (i.e., $\varepsilon \ll 1$) are in the region of interest.

In its initial formulation, arbitrarily oriented vessels that would cause more than one vessel to occupy a control volume were not considered. Branching vessels are also not addressed. Even though this is not an inherent limitation of the model, implementation would be more difficult. Due to its discrete representation, the model cannot solve the inverse problem. The model has been shown to be valid in the canine kidney cortex in which there is uniformly oriented countercurrent artery vein architecture of 70 μm diameters.

Hybrid Models

The lack of an encompassing model that can account for the various tissue structures has lead researchers to propose and apply hybrid models. The substantial amount of effort related to the application and investigation of the major models discussed has shown that no one model applies to all the different vascular structures in tissue [72, 77]. Wissler [72, 73] points to the unlikelihood of a single equation providing a complete description of the heat transfer process in tissue and thus suggests using a combination of equations. The realization of this suggestion is found in Charny's work [56] in which W–J's and Pennes' models are used to describe peripheral and deep muscle tissue, respectively. When the applicability of each of the major models has been conclusively defined, an algorithm that would enable users to arrive at the appropriate choice of equations, given the tissue vasculature of interest, would be beneficial.

The applicability of the models discussed requires an understanding of the validity and development of each model. A comparison of the models discussed has been summarized by Charney [47].

Thermal Measurements of Perfusion

Introduction

Perfusion, the transmission of blood in the microcirculation, is an important factor in surgery, tissue transplants, heart disease, and cancer therapy. Despite its importance, no clinical method of measuring perfusion is currently available for a majority of applications. One technique that shows considerable promise involves the use of self-heated thermistors [6–13]. In this method, a miniature thermistor (0.5 to 2.5 mm diameter) is placed invasively in the tissue of interest and heated with a predetermined applied power. Because tissue conduction and perfusion act to carry heat away from the thermistor, the resulting volumetric-average temperature rise in the thermistor bead, ΔT, is related to the tissue thermal conductivity and perfusion. When the intrinsic tissue conductivity and the apparent conductivity of the tissue (due to blood flow and conduction) are known, the perfusion rate can be calculated.

At least two difficulties exist with this technique. The first is that the intrinsic tissue conductivity of perfused tissue must be known in order to calculate the perfusion rate. Although one could stop the blood flow to a tissue and measure its conductivity, this is clearly not desirable and is not always practical. In order to overcome this problem, Holmes and Chen have proposed techniques that measure perfusion without interrupting blood flow [13, 20].

Perfusion Resolution

The perfusion resolution, δw, is defined as the smallest change in perfusion that can be detected by the instrument. It can be determined theoretically:

$$\delta w = \delta k \bullet \frac{\partial w}{\partial k} = \delta k \bullet c_{15} \tag{4.10.51}$$

For the constant temperature heating technique using a P60 thermistor, δk is about 0.02 mW/cm-°C, and the sensitivity is about 100 (mL/100 g-min)/(mW/cm-°C). Using Equation (4.10.51) gives a perfusion resolution of about 2 mL/100 g-min. Due to fluctuations in the baseline tissue temperature, the practical resolution is about 10 mL/100 g-min. Because so many experimental and tissue variables exist, it is extremely important to test these techniques in preparations in which the perfusion is known.

Measurement Volume

The measurement volume of a thermistor is a complex function of many factors, including the perfusion rate and vascular anatomy of the tissue of interest. One problem with small thermistors is their small measurement volume. A boundary layer (decoupler) between the thermistor and the tissue causes a significant measurement error. This unwanted boundary layer is often caused by the probe during insertion. The larger probes exhibit a smaller error, but are likely to cause a larger decoupler because of the increased trauma during insertion.

Temperature Dependence of Perfusion

Perfusion depends on a wide variety of factors: some are local to the tissue (pH, temperature, O_2); some are external but directly control local flow (parasympathetic, hormones); and some indirectly affect local flow (heart rate, blood pressure, skin temperature, needs of other organs). A simple experiment studied the effect of local tissue temperature on muscle perfusion. The constant ΔT method was used to measure perfusion in an anesthetized rat. The muscle temperature was manipulated by placing the hind limb into a water bath. Insulation was carefully placed so as to minimize changes to the body temperature. The rectal and neck temperatures were constant while the muscle in the hind limb was heated.

Figure 4.10.6 shows the perfusion as a function of tissue temperature for a typical experiment. The dip in perfusion as a function of temperature as shown in Figure 4.10.6 consistently occurred, but did not always occur at the same temperature. This dip may be due to an anastomotic shunt attempting to regulate the core body temperature.

Figure 4.10.7 presents the averaged results for 10 rats. Because the dip occurred at different temperatures for the various rats, it does not appear in the average. The large standard deviations are due to perfusion differences from one rat to the next. A linear fit to this averaged data gives the following approximation:

$$w = 1.9720\,(1 + 0.059\,T) \tag{4.10.52}$$

where w has units of mL/100 g-min and T has units of °C.

Yuan et al. [85] measured perfusion and temperatures at various locations within each of four canine prostates subjected to a transurethral microwave thermal source. The total number of the perfusion sampling points coupled with temperature is 15. Colored microspheres were used to measure perfusion due to its simplicity compared with radioactively labeled microspheres and because the microsphere trapping method is regarded as a standard. Temperatures were measured using miniature thermistors. The prostate temperatures were raised to 40 ~ 45°C by 5-W step increments of the microwave power at

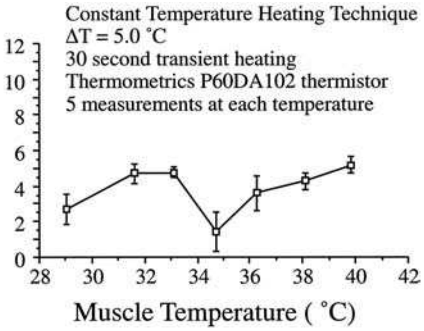

FIGURE 4.10.6 Perfusion vs. muscle temperature during a typical experiment.

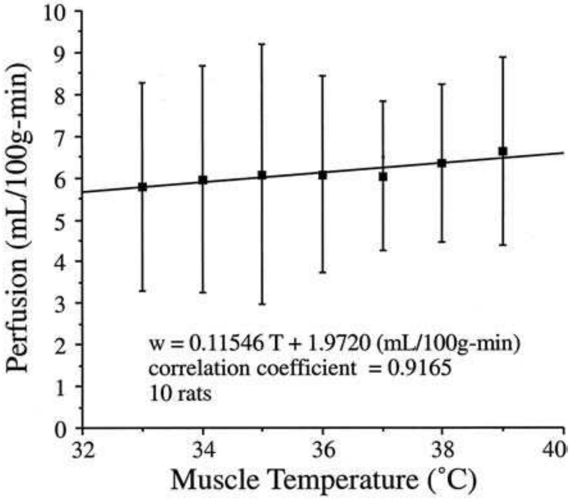

FIGURE 4.10.7 Perfusion vs. muscle temperature averaged over 10 experiments.

hourly intervals to 15 W. Temperatures and perfusion were measured at baseline and at the beginning and end of each heating interval. Thus, the periods between perfusion samples were approximately 5 or 60 minutes. Under baseline conditions, the temperature fluctuations within the prostate were approximately ±0.3°C. A relative dispersion estimate of 15% was derived from one dog for the fluctuations in baseline perfusion. Thus, changes in absolute perfusion and temperature greater than 15% and 0.3°C, respectively, were considered to be substantial changes.

As heating progressed, a variety of substantial changes were observed, but no uniform pattern emerged. However, the measurements included changes typically expected for hyperthermia: (1) an initial perfusion increase associated with elevating the baseline temperature; (2) a perfusion return toward baseline after this initial increase; and (3) a dramatic increase in perfusion at elevated temperatures. The initial perfusion increases were observed in three dogs when the temperatures exceeded 38 ± 3°C (mean ± 1 s.d., $N = 8$). The perfusion increased 34% from a baseline value of 0.59 ± 0.26 ml/g-min over a temperature rise of 1.7 ± 1.3°C. Half of the measurements in the three dogs subsequently showed a decrease in perfusion ranging from 16 to 25%. In two dogs, dramatic perfusion increases as high as 364% were observed with a corresponding decrease in tissue temperature.

The mean perfusion and temperature measured from all dogs at similar instances during the experimental protocol were calculated. Figure 4.10.8 shows the changes as the experiment progressed from

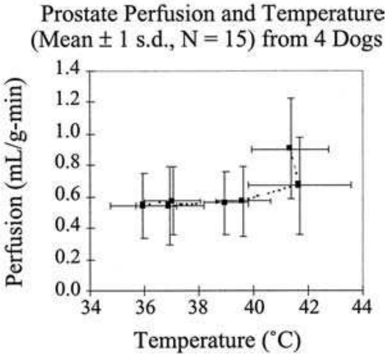

FIGURE 4.10.8 Perfusion vs. prostate temperature. (From Yuan, D.Y., Xu, L.X., Zhu, L., Holmes, K.R., and Valvano, J.W., *17th S. Biomed. Engr. Conf.*, 85, 1998.)

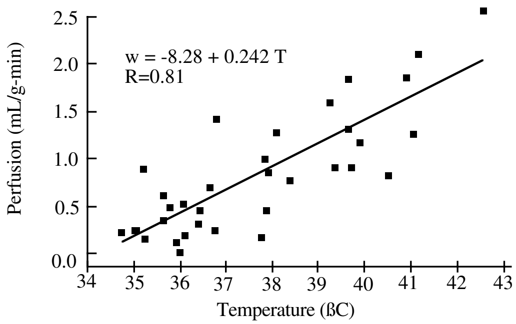

FIGURE 4.10.9 Perfusion vs. prostate temperature. (From Xu, L.X., Zhu, L., and Holmes, K.R., *Int. J. Hyperthermia.* 14, 65–73, 1998.)

baseline conditions. The mean behavior indicates no substantial change in perfusion until the tissue temperature exceeded 39.6°C, after which the perfusion increased 17%. This occurred over a 5-min period as the nominal microwave power was stepped from 10 to 15 W. The perfusion increased another 35% when the tissue temperature exceeded 41.7°C and appeared to affect a slight lowering of tissue temperature.

Xu et al. [86] measured perfusion using the pulse-decay self-heated thermistor technique [13, 20] in these dog prostates during the same transurethral microwave hyperthermia treatments. Interestingly, the perfusion response to temperature measured with the thermal technique was roughly linear with temperature in the same dogs at roughly the same locations, as shown in Figure 4.10.9.

The interdependence between perfusion and temperature was observed in these studies. Most notably, a decrease in tissue temperature was associated with a dramatic increase of perfusion. Such changes have been modeled previously with Pennes' bioheat equation using assumed perfusion values and changes for the prostate. The data from this study will provide more realistic estimates of perfusion values and thermoregulation models in hyperthermic canine prostates. Two hypotheses explain the differences between the perfusion responses to hyperthermia as measured by microspheres and the thermal decay probe. The first possibility is that one or both methods have significant measurement errors. A second possibility is that perfusion as measured by spheres trapped in the capillaries is a different parameter than perfusion as measured by enhanced heat transfer within the 70- to 200-μm diameter vessels.

Human Thermoregulation

Humans possess an elaborate thermal control (thermoregulation) system that ensures maintenance of internal body temperatures near a physiological set point under a large spectrum of environmental conditions and metabolic rate activities. After many years of research, much has been learned of the operation of the human thermoregulatory system, although it remains a topic of active investigation. A number of reviews on specific aspects of the physiological basis of thermoregulation are recommended for further background detail [87–92].

Internal and boundary heat transfer processes are key to thermoregulation. As the operational mechanisms have been understood, it has been possible to model these functions in an attempt to simulate and predict thermoregulatory behavior and to be able to design systems to interact thermally with the human body (e.g., an environmental protective garment or a space suit) without compromising the health and safety of the subject.

Physiological Processes of Thermoregulation

The prevailing thermal physiology theory is that the human thermoregulation system operates to maintain the body core temperature at a constant value consistent with that required for regular body function, regardless of the environmental temperature and energy loading. Alternatively, it has been suggested that thermoregulation serves the purpose of maintaining the body's energy balance, with body temperatures a *result*, not a cause, of the regulation process [87, 93, 94].

Many general observations of the thermal characteristics of human thermoregulation are consistent, even if alternative explanations of the underlying operative mechanisms are preferred. For example, temperature and internal energy storage of the human body vary with time of day, metabolic activity, and individuality of the human [95]. The body incorporates a number of energy production and dissipation mechanisms to preserve thermal homeostasis, many of which are controlled by feedback signals based on specific physiological states. Examples of thermoregulatory processes governed by feedback are sweating, shivering, and variable localized blood flow.

According to the theory of thermoregulation by control of the body core temperature, the main control center is located in the hypothalamus of the brain, from which multiple reflex responses operate to maintain the body temperature within a narrow range [96]. The signals that activate the hypothalamic temperature-regulating centers come largely from two sources: temperature-sensitive cells in the anterior hypothalamus and cutaneous temperature receptors. The cells in the anterior hypothalamus sense the temperature of the body core or, specifically, the temperature of arterial blood that passes through the head.

Webb has presented a theory of thermoregulation to maintain an energy balance within the body, as demonstrated by the existence of temperature sensors at several levels in the skin enabling the sensing of heat flow within and from the body [94]. Evidence also supports neurological sensing of thermal gradients that direct thermoregulation behavior. The hypothesis in support of the theory of energy content regulation based on Webb's experimental observations is [94]:

> Heat (energy) regulation achieves heat (energy) balance over a wide range of heat (energy) loads. Heat flow to or from the body is sensed, and physiological responses defend the body heat (energy) content. Heat (energy) content varies over a range that is related to heat (energy) load. Changes in body heat (energy) content drive deep body temperatures.

The proposed mechanism of energy-driven thermoregulation balances constantly changing metabolic energy production and the adjustment of heat losses to maintain the body as a system in equilibrium. In contrast, the proposed mechanism of temperature-driven thermoregulation effects a coordination of physiological processes to maintain the body core temperature at a set point.

Thermoregulatory Processes

Conservation of energy for the human body must account for internal metabolic energy production plus multiple mechanisms of environmental heat and work exchange:

$$\Delta E = M - (W + Q_{conv} + Q_{cond} + Q_{rad} + Q_{evap} + Q_{resp}) \tag{4.10.53}$$

where

ΔE = rate of energy storage in the body (W)
M = metabolic energy production (W)
W = external work (W)
Q_{conv} = surface heat loss by convection (W)
Q_{cond} = surface heat loss by conduction (W)
Q_{rad} = surface heat loss by radiation (W)
Q_{evap} = surface heat loss by evaporation (W)
Q_{resp} = respiratory heat loss (W)

The human body produces energy, exchanges heat with the environment, and loses heat by evaporation of body fluids. Energy is produced in the body by basal, or resting, metabolism, defined as the minimal metabolism measured at a temperature of thermal neutrality in a resting homeotherm with normal body temperature several hours after a meal and not immediately after hypothermia. It is also produced at an increased rate due to muscle activity, including physical exercise and shivering, and by food intake. Therefore, the total energy production in the body is determined by the energy needed for basic body processes plus any external work.

Because the body operates with less than 100% efficiency, only a fraction of the metabolic rate is applied to work, with the remainder dissipated as heat [95, 96]. The mechanical efficiency, η, associated with metabolic energy utilization is zero for most activities except when the person is performing external mechanical work such as walking upstairs, lifting something to a higher level, or cycling on an ergometer [97]. When work transferred from the environment is dissipated as heat in the human body, η is negative. An example of this case is walking downstairs.

Convection, radiation, conduction, and evaporation of sweat at the skin surface facilitate heat transfer from the body. Heat transfer also occurs via the respiratory tract and lungs, although to a minor extent in human beings compared with many mammals and reptiles. Storage of energy takes place whenever production and dissipation mechanisms are not in balance. In many instances, such as astronauts in space suits or military personnel in chemical defense garments, energy storage is forced due to the lack of appropriate heat exchange with the environment [98].

The human thermoregulatory system is quite complex and behaves mathematically in a highly nonlinear manner. It contains multiple sensors, multiple feedback loops, and multiple outputs [99]. The primary mechanisms by which the body responds to control the storage of energy (positive or negative) include the evaporation of sweat, shivering of the muscles, and vasoconstriction and vasodilatation of the blood vessels.

Heat transfer internal to the body is due to the conductance that governs the flow of energy between the core, through the tissue, and the surface. This transport process is governed significantly by peripheral blood flow, the core–skin temperature gradient, and the conductivity of the various body tissues. Transient blood perfusion provides an effective variable path of peripheral energy transport via convection between blood and tissue and countercurrent heat exchange between the arteries and the veins. Blood flow distribution is controlled according to metabolic needs of the body, local tissue temperature, and the need to maintain the appropriate core temperature.

When the core becomes too hot, the blood vessels in the skin dilate to allow increased perfusion to the body surface. The blood is cooled by the environment, and the cooler blood is returned to the core. Increased blood flow to the skin surface also enables greater sweat production, adding to the cooling process. In contrast, when the core becomes too cold, blood flow to the skin is constricted to conserve the body's internal energy. Sweating occurs when the arterial blood is elevated in temperature, causing the hypothalamus to increase nerve impulses to the sweat glands. Shivering, on the other hand, is an involuntary response of the skeletal muscles when passive body cooling exceeds metabolic energy production [96].

Human thermoregulation mechanisms can be divided into two main categories: autonomic and behavioral [99]. Autonomic thermoregulation is controlled primarily by the hypothalamus, whereas behavioral thermoregulation is controlled consciously by man and includes active movement and adjustment of clothing. Behavioral thermoregulation is associated with conscious temperature sensation as well as with thermal comfort or discomfort. Some engineered systems are designed to interact with the body to enhance it ability to maintain thermoregulation in harsh or hazardous environments. Examples range from the common HVAC systems encountered in buildings and vehicles to sophisticated garments worn during certain military and space missions.

Wissler Model of Human Thermoregulation

Models that incorporate accurately the transient whole body behavior during thermoregulation for a wide range of states and environmental challenges may be quite useful in describing and predicting this important human physiological function. Moreover, such a model can be used as a design tool in the development of systems with which humans must interact for a variety of work, pathological, and recreational circumstances. The development of models of human thermoregulation has proved to be a daunting task that has been addressed by many researchers. The complexity of the coupling among

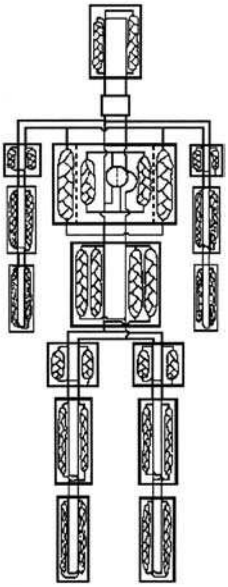

FIGURE 4.10.10 Multi-element model representing the human body in the Wissler model.

physiological processes involved in thermoregulation and of the control algorithms has dictated that models incorporating these multiple effects be solved numerically. Thus, the first realistic thermoregulation models appeared in the 1960s and 1970s from the studies of Wissler [100, 101]; Stolwijk [102]; Nadel et al. [103]; Mitchell et al. [104]; Hayward [105, 106]; and Kuznetz [107]. An important early application of modeling human thermoregulation was the design and development of active thermal control garments to be worn under the space suit during extravehicular activity [95, 98, 108, 109]. Over the intervening years, the Wissler model has been improved and updated on a continuous basis; it is now applied to a very broad spectrum of human thermal control scenarios [107–113].

The Wissler human thermoregulation model is a transient-state mathematical formulation used to describe human physiological responses to various levels and combinations of exercise and thermal stress. The model computes thermal, cardiovascular, ventilatory, and metabolic changes that occur during a specified period of time. The values for the independent physiological and environmental variables, such as metabolic rate, environmental conditions, and liquid cooling garment flow rate, are specified as inputs to the model. A finite-difference scheme is applied to compute tissue and blood temperatures throughout the body numerically as a function of time.

The model represents the human body as 15 cylindrical elements for the head, thorax, abdomen, and proximal, medial, and distal portions of each arm and leg. A schematic representation of the multielement model of the human body is shown in Figure 4.10.10. Each body element is composed of cylindrical shells defined by physical and physiological properties for composite layers of viscera, bone, muscle, fat, and skin. In each of the elements, metabolic energy may be generated as appropriate due to basal metabolism, exercise, and shivering. The generated energy is conducted to adjacent body regions, convected to circulating blood, or stored in the element. Each body element contains an arterial and venous pool and a capillary bed. The pools are interconnected serially between adjacent elements. As venous blood is returned to the heart, it passes through the lungs for exchange of gases before entering the arterial system.

A number of signal feedback loops are used to account for thermoregulation within the body. Feedback data are the differences between skin and central head temperatures and their respective specified set point values. Error signals specified by these differences drive sweat secretion, shivering, and vasomotion responses. The algorithm equations have the general format of a proportional controller that is activated when a defined threshold condition is satisfied. The control equations do not all have the same level of response to error signals. For example, sweating and vasodilation are more responsive to an increase in central head temperature than in cutaneous temperature, while vasoconstriction is more responsive to cutaneous temperature.

Thermoregulation is also affected via heat exchange during the venous return flow of blood. Venous flow occurs through deep or superficial veins, thus influencing the rate of countercurrent heat exchange. Modeling the venous return provides a realistic simulation of the countercurrent heat exchange that takes place in the extremities during exercise in hot environments and immersion in cold water.

Blood flow rates are simulated to satisfy the level of local metabolic need for oxygen in the tissues. Therefore, a lower limit is set for extremity blood perfusion during cold exposure. The model also incorporates material balances for oxygen, carbon dioxide, and lactate as defined for cardiovascular response. In addition to physiological factors, conditions of the environment with which the subject interacts are accounted for. Physical properties of the environmental fluid and characteristics of the flow field in the vicinity of the subject are specified because they determine conductive and convective heat transfer.

The model allows the user to specify layers of clothing described by physical properties of annular shells outside and interacting with the skin layer. The physical properties of the garments may change with accumulation of unevaporated sweat, which may saturate the material.

Transient tissue and blood temperatures are calculated during simulated thermal scenarios by Crank–Nicolson type finite-difference equations. Undated temperatures and other physiological values are computed every 10 s. The model allows a simulation to be broken down into any number of scenario subintervals, with the following factors specified in each interval:

- Basal metabolic rate
- Kind and level of exercise performed
- Environmental conditions (pressure, temperature, dewpoint, etc.)
- Garment properties
- Use of a fluid-conditioned garment (FCG) (flow rates, inlet temperatures, etc.)

The equations needed to describe a liquid or air-cooled garment are derived from material and energy balances for the circulating fluid. Sensible heat transfer is treated the same for liquid- and air-cooling situations. However, the evaporation and condensation associated with latent heat transfer must be treated differently for the two fluids. In the case of the liquid-cooled garment, water from sweat and environmental moisture condenses on the cool surface of the garment. On the other hand, air cooling generally facilitates evaporation of sweat by removing water vapor from the garment.

In its early formulation, the Wissler model required a large main frame computer to perform simulations of thermal regulation. However, owing to advances in computational capabilities in recent years, it is now possible to run extensive simulations on a desktop personal computer in an order of magnitude less than real time. The thermoregulation model provides reliable predictions of changes in the human thermal state for many different types of environmental and metabolic stress, and it has been used for the design of new automated personal garments for application in hazardous environments [114].

Therapeutic Heating

Normal physiologic temperatures range from approximately 30 to 42°C. The average so-called “core” (central abdominal) temperature in mammals varies slightly among species between about 36 and 38°C (37°C for humans, 38°C for most canines). Thermal gradients are inherent in metabolically driven open systems at steady state and measured core temperatures will vary slightly depending on the relative metabolic rate, blood flow, and location of the various organs, as well as from point to point within an organ. Although core temperature is maintained close to a steady-state value, for example, skin surface temperature at rest in a controlled room environment varies between about 30 and 34°C depending on climate and season.

Elevation of body, appendage, or organ temperature to between 40 and 42°C can be used for analgesia (relief of pain) and to provide the most advantageous environment for injury-response (wound healing) processes. Note that no external intervention can be claimed to promote wound healing — one may only provide the best conditions under which the natural processes will heal wounds. Thermal intervention has been used for many years for these two purposes.

Heat Generation Modalities

Therapeutic heating can be obtained by surface heat transfer means (hot or cold packs), but the effectiveness is limited to surface injury. Nevertheless, contact heating is the method of choice for such injuries as sprains, muscle strain, and postoperative swelling. The standard response to elevated temperatures is to increase blood flow and thus perfusion. One applies cold heat sinks to reduce perfusion in the injured area during the first 12 or 24 h; warm hot packs or circulating water (up to 45°C) are then used to promote perfusion and thus increase the supply of neutrophils and other blood components related to the injury response and wound healing.

Deeper injuries require volumetric heating to attain adequate temperatures. The most effective volumetric heating methods to date have been: (1) electromagnetic fields at radio frequencies (RF) or microwave frequencies (MW); and (2) ultrasound (US). Assigned radio frequencies for industrial, medical, and scientific use (ISM) are: 6.78, 13.56, 27.12, and 40.68 MHz. Practical ISM frequencies for medical use in the microwave range are 915 MHz and 2.45 GHz. Typical ultrasound heating devices operate between about 500 kHz and 10 MHz. In all three cases, an engineering tradeoff takes place among local volumetric heat generation, q''', thermal heat generation field dimensions, and depth of penetration. Higher frequencies have shorter wavelengths and are, in general, absorbed more strongly and thus penetrate less deeply. Tissues are inhomogeneous and, with only a few exceptions, anisotropic. The electrical and acoustic properties of tissues can vary over several orders of magnitude. Consequently, electromagnetic and acoustic boundary conditions often determine the volume generation term in spite of efforts to shape the field by clever applicator design.

For electromagnetic heating in tissues, the volume generation term is essentially governed by the electrical conductivity, σ (S/m); the imaginary part of the electric permittivity, ε'' (F/m); and the magnitude of the local electric field, $|E|$ (V/m):

$$q''' = \left(\sigma + \omega\varepsilon''\right)\left|\mathbf{E}\right|^2 \tag{4.10.54}$$

where ω is the angular frequency (r/s). Heating due to direct absorption from a magnetic field, $\omega\mu''|\mathbf{H}|^2$, where μ is the magnetic permeability (H/m), is negligible except in the most unusual circumstances. Yet, RF and MW magnetic fields heat tissue very effectively, too. This is because, by Faraday's law of induction, a time-varying magnetic field will induce an electric field in the tissue, but the electric field actually generates the heat:

Integral form:

$$\oint \mathbf{E}\bullet d\mathbf{L} = -\frac{\partial}{\partial t}\left[\iint \mu\mathbf{H}\bullet d\mathbf{S}\right] \tag{4.10.55}$$

Point form:

$$\nabla\times\mathbf{E} = -\mu\frac{\partial \mathbf{H}}{\partial t} \tag{4.10.56}$$

A comprehensive discussion of these properties and effects in materials may be found in Roussy and Pearce [115]. Values of relevant electrical and acoustical properties of tissues are given in Table 4.10.8 and Table 4.10.9, respectively.

Acoustic waves are highly scattered in many tissues, so simple wave propagation models are inadequate to predict the local acoustic field strength. Nevertheless, a uniform plane wave description of the heating field often suffices to explain the distribution of the heat generation with acceptable accuracy. The volume

TABLE 4.10.8 Representative Electric Properties of Tissues

Tissue	Conductivity (*S*/*m*)	Real Part, ε_r'	Imaginary Part, ε_r''
Fat	0.05–0.09	3.9–7.2	0.67–1.4
Muscle	0.1–1.0	45–48	13–13.9
Bone	0.006–0.05	4.2–5.8 (marrow)	0.7–1.3 (marrow)

Notes: Muscle is highly anisotropic, with higher conductivity parallel to fibers. Electric permittivity is as measured at 3 GHz, and ε (*F*/*m*) = $\varepsilon_0[\varepsilon_r' - j\varepsilon_r'']$ where $j = \sqrt{(-1)}$ and ε_0 = free space permittivity, 8.85×10^{-12} *F*/*m*.

heat generation term is determined by the acoustic absorption coefficient, α (m^{-1}), and the wave power density, E (W/m^2), approximately according to Beer's law:

$$q'''(z) = \alpha E_0 e^{-\alpha z} \tag{4.10.57}$$

where E_0 is the surface intensity (at $z = 0$) and α varies according to frequency, f (Hz) $\alpha \approx f^n$, where $1 < n < 2$. Table 4.10.9 units for α are cm^{-1}. In other references, α may be reported as dB/cm (dB = $10 \log_{10}\{E_{\text{out}}/E_{\text{in}}\}$).

Physiologic Effects of Local Heating

The general physiological effects of local heating comprise a cascade of response [118]. As noted in the previous subsection, systemic response is controlled from the hypothalamus by neuronal and hormonal signals. Appendage- and organ-level response to local heat may be spinal-cord mediated; however, local heating can trigger local release of bradykinins that induce vascular dilation or constriction, thus affecting temperature rise.

The increase in tissue temperature is accompanied by an increase in cellular metabolism. The arterioles (microscopic arteries typically about 40 to 200 μm inner diameter [118]) dilate in response to heating under smooth muscle control. The downstream capillary pressure increases above the homeostatic level of about 25 torr. Two consequences are increased capillary flow and capillary pressure.

First, at higher capillary pressures the gaps between the endothelial cells (thin epithelial cells comprising the vessel wall) tend to widen and, at higher pressures, edema may form (an increase in the fluid in the extracellular compartment) [119, 120]. Second, higher capillary flow results in rapid clearing of cellular metabolites and increases convection heat transfer, delivery of tissue oxygen, cellular nutrients, antibodies, and leukocytes (white blood cells) including the monocytes necessary in the healing response. Neutrophils are white blood cells that initially release proteolytic enzymes to digest dead tissue and, later, phagocytose (eat) the debris [121]. Monocytes are other leukocytes that remove damaged and dead cells by phagocytosis.

Tissue Effects: Elevated Temperatures

Exposure to temperatures above normal physiologic ranges (>42°C) can result in measurable irreversible changes in tissue structure or function. Cell death or tissue alterations may be detrimental — for example, skin burns — or beneficial, as in vessel sealing or tumor destruction. Tissues of the central nervous system are the most thermally sensitive, exhibiting irreversible changes for long-term exposures above about 42°C. The specific pathologic end point may be evaluated histologically, histochemically, and/or physiologically. Most assays of thermal alterations are qualitative in nature; however, several end points that are inherently quantitative lend themselves well to rate process descriptions of their thermal kinetics. Even for qualitative processes, thermal kinetic models often provide useful descriptions and thus provide helpful insights into the underlying principles of tissue thermal damage.

Here, "damage" is used in a generic sense to denote all kinds of irreversible alterations, therapeutic or not. In the Arrhenius models, irreversible thermal damage is exponentially dependent on temperature and linearly dependent on time of exposure. Many damage processes can be modeled as first-order rate processes for which two experimentally derived coefficients are sufficient. Second-order processes require four parameters, again derived from experiment. The first-order rate process models often apply well to the prediction of damage thresholds and less well as the damage becomes complete or severe because several of the fundamental assumptions are violated. In order to be useful in evaluating thermal insult, the kinetic model must be coupled to quantitative pathological analysis. This subsection describes several quantitative markers of thermal damage and experimental methods for estimating relevant kinetic coefficients in constant temperature and in transient thermal history experiments. As expected, transient *in vivo* thermal history data yield a noisy kinetic plot; nevertheless, estimates of the appropriate rate coefficients can be made.

Theory of Rate Process Descriptions

The original work on the application of rate process models to thermal damage was reported by Moritz and Henriques in a series of seminal papers entitled "Studies of Thermal Injury" in 1947 [122–125]. They applied flowing water at elevated temperatures to pig skin and measured exposure times required to create first-, second-, and third-degree burns. In their work, the damage was quantified using a single parameter, Ω, which ranges on the positive real axis and is calculated from an Arrhenius integral:

$$\Omega(\tau) = \int_0^{\tau} A\, e^{\left[\frac{-E}{RT}\right]} dt \qquad (4.10.58)$$

where

A = a frequency factor (s^{-1})
τ = the total heating time (s)
E = an activation energy barrier (J/mol)
R = the universal gas constant (8.32 J–mol^{-1}–K^{-1})
T = the absolute temperature (K).

Over the ensuing 50 years many subsequent investigators have modeled this process [126–129] and made experimental measurements of threshold burn conditions in human [130–132]; animal [133–134]; and cellular and molecular [135–137] systems. Although a considerable body of literature has been accrued, there is by no means a consensus on how to predict the occurrence of thermal injury accurately over the wide range of conditions that cause burns.

One difficulty with this model is that a single damage parameter inherently lumps all damage processes into one global measure. In multiple process cases, such as in the case of a skin burn, the lowest temperature process saturates the damage measure, Ω, early during an exposure. In this discussion, we review the underlying assumptions and origin of the terms in Equation (4.10.58) are reviewed and the traditional thermal damage parameter, Ω, recast into a form suitable for evaluation of multiple-process thermal damage effects.

Kinetic Models of Reaction Product Formation Rates

The basis for rate process models of thermal damage may be obtained from chemical reaction kinetics (see, for example, Maron and Lando [138]). In a typical reaction process, thermally active reactants jump an activation barrier to form products, as illustrated in Figure 4.10.11, in which E is the energy barrier

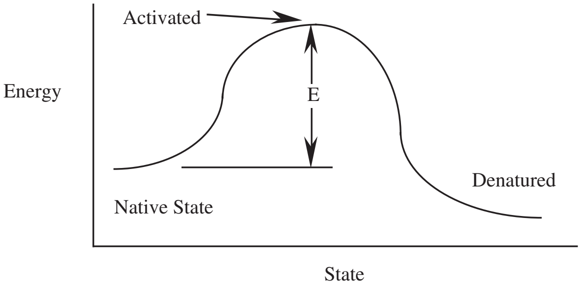

FIGURE 4.10.11 Energy-state diagram of a bimolecular process.

in Equation (4.10.58). The collision theory description of ordinary first-order bimolecular reaction kinetics holds that the reactants are activated by collisions; n^* are activated out of n total molecules, and the probability of activation is:

$$\frac{n^*}{n} = e^{-\left[\frac{E}{RT}\right]} \tag{4.10.59}$$

In such a process, activated reactants are considered to form an activated "complex" that may relax to inactivated single reactants or irreversibly progress to form product molecules. The complex has some of the properties of an ordinary molecule and is at least temporarily stable. For reactant molecules A and B the sequence of formation is:

$$\left[A\right]+\left[B\right] \underset{k_b}{\overset{k_a}{\rightleftarrows}} \left[AB\right]^* \xrightarrow{k} \text{Pr}\mathit{oducts} \tag{4.10.60}$$

The overall reaction velocity, k (s^{-1}), determines the rate of formation of product and is related to the equilibrium constant for formation of activated complex, K^*, by:

$$k = \frac{RT}{Nh} K^* = \frac{RT}{Nh} e^{-\frac{\Delta G^*}{RT}} \tag{4.10.61}$$

where

N = Avogadro's number (6.023×10^{23})
h = Planck's constant (6.627×10^{-34} J-s)
ΔG^* = the Gibb's free energy of formation of activated complex

In turn, the free energy of formation is given by:

$$\Delta G^* = \Delta H^* - T\Delta S^* \tag{4.10.62}$$

where ΔH^* is the enthalpy of activation (J/mol) and ΔS^* is the entropy of activation (J/mol–K).

The activation entropy is not calculable except for the simplest possible reactions in the gas phase and is therefore usually determined from experimental measurements of the reaction velocity and activation enthalpy. The activation enthalpy, ΔH^*, is determined from the observed activation energy, E by:

$$\Delta H^* = E - iRT \tag{4.10.63}$$

where i is 1 for first-order reactions in solution and gases; 2 for second order; and 3 for third-order reactions.

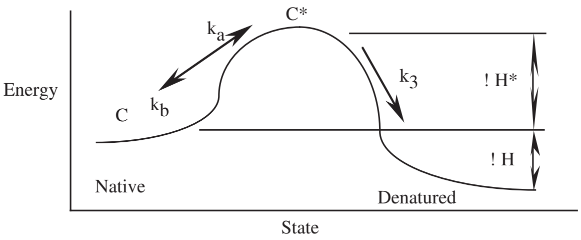

FIGURE 4.10.12 Unimolecular process activation and denaturization.

Unimolecular Process Descriptions

Thermal damage in tissue is a unimolecular process — tissue constituents transition from the native state to the damaged state (Figure 4.10.12). Absolute reaction rate theory can also be used to explain the rate of formation for this process if one assumes that a time lag exists between molecular activation and denaturization [138]. During this time lag, the molecules may denature or relax back to the native state, as illustrated in Figure 4.10.10. Here, ΔH is the enthalpy (internal thermal energy) difference between native state and denatured molecules. The relative barriers are such that, in the thermal damage of tissue, ΔH^* is almost always smaller than ΔH.

Thus, the activation process may be regarded as reasonably likely, and the probability of denatured tissue relaxing back to native state tissue is near enough to zero that it may be regarded as an impossible event in the absence of an energy-consuming healing process. The rate of damage formation is then proportional to only molecules that remain activated. For a unimolecular process in the native state C, with an activated state, C^*, and velocity constants k_a, and k_b:

$$[C] \underset{k_b}{\overset{k_a}{\rightleftarrows}} [C]+[C^*] \tag{4.10.64}$$

The activated complex, $[C^*]$ progresses to the damaged state at k_c:

$$[C^*] \xrightarrow{k_c} \text{Damaged state} \tag{4.10.65}$$

so that the rate of disappearance of native state molecules, $[C]$, is given by:

$$-\frac{d[C]}{dt} = k_c[C^*] \tag{4.10.66}$$

Generally $[C^*]$ is neither known nor calculable; however, at sufficiently low concentrations of C^*, the steady-state principle asserts that for short-lived activated states, the rate of formation can be considered equal to the rate of disappearance. The activated state, $[C^*]$, forms at a rate $k_a\,[C]^2$, relaxes back to inactivated at rate $k_b\,[C][C^*]$; and denatures at the rate $k_c\,[C^*]$. Consequently:

$$k_a[C]^2 = k_b[C][C^*] + k_c[C^*] \tag{4.10.67}$$

and so:

$$[C^*] = \frac{k_a[C]^2}{k_c + k_b[C]} \tag{4.10.68}$$

An overall reaction velocity, k, which relates $[C]$ to its rate of disappearance, is needed:

$$-\frac{d[C]}{ct}=k[C] \tag{4.10.69}$$

There are two limiting cases for Equation (4.10.68):

- The concentration of remaining undamaged material, $[C]$, may be large enough that deactivation at k_b dominates the k_c pathway, so $[C^*] \cong [C]\ k_a/k_b$ for which the overall formation rate, $k = k_c\ k_a/k_b$ and a first-order process result.
- If the remaining undamaged material concentration, $[C]$, is small, $k_c \gg k_b\ [C]$ and the process is second-order because, from Equation (4.10.68), $k = k_a\ [C]$.

In liquid-phase systems with appreciable concentrations of native state molecules, the first condition should apply, so the first-order approximation applies. After a long time of exposure at damaging temperatures so that $[C]$ is very small, $k_c \gg k_b\ C$ and a second-order process results:

$$-\frac{d[C]}{dt}=k[C]^2 \tag{4.10.70}$$

where for simplicity the $[C]$ dependence has been removed from k.

First-Order Solution

Equation (4.10.69), then, is a Bernoulli differential equation with the solution:

$$C(\tau)=C(0)e^{\{\int k dt\}} \tag{4.10.71}$$

Equation (4.10.61) and Equation (4.10.62) may be used to relate k to $\Delta H*$ and $\Delta S*$. It should be noted at this point that the energy barrier, E, (Figure 4.10.8) is in fact $\Delta H* + \mathrm{RT}$; however, in practice $\{\Delta H^* \cong 5 \times 10^5\} \gg \{\mathrm{RT} \cong 3 \times 10^3\}$, so it may be assumed that $E \cong \Delta H^*$.

The pre-exponential term in Equation (4.10.61) suggests that it is temperature dependent; however, the linear dependence of A on $1/T$ is extremely weak compared to the exponential dependence in the final term.

Second-Order Solution

The second-order process of Equation (4.10.69) can be solved by dividing both sides by C^2 and using the substitution that $y = 1/C$. With that substitution:

$$\frac{dy}{dt}=\frac{dy}{dC}\frac{dC}{dt}= \quad \frac{1}{C^2}\frac{dC}{dt}=k \tag{4.10.72}$$

and the solution is straightforward:

$$y(\tau)=\int_0^\tau k\,dt+y(0) \tag{4.10.73}$$

or:

$$\frac{1}{C(\tau)}-\frac{1}{C(0)}=\int_0^\tau k\,dt \tag{4.10.74}$$

Application of Kinetic Formulations in Thermal Damage Studies

When a quantitative thermal damage phenomenon has been identified, it can be studied as a first-order or combined first- and second-order process. This subsection inspects the more common first-order analysis in some detail and introduces one form of combined process analysis to extend the usefulness of the method. The specific example of Henriques and Moritz original data is also studied. When the damage end point is a qualitative measure, application of these kinetic models is closer to a curve-fitting exercise than to a fundamental study of the underlying phenomena. Therefore, precise identification and strict definition of quantifiable damage end points are required for meaningful analysis.

First-Order Process Analysis

A more useful form of Equation (4.10.58) may obtained by recasting the result into a volume fraction model. In this formulation, C signifies the remaining concentration of native state (undamaged) tissue constituent. Therefore, the physical significance of the traditional damage measure, Ω, is the logarithm of the ratio of the original concentration of native tissue to the remaining native state tissue:

$$\Omega(\tau) = \ln\left\{\frac{C(0)}{C(\tau)}\right\} = \int_0^\tau A\, e^{-\left[\frac{E}{RT}\right]} dt \qquad (4.10.75)$$

This form of the damage integral has the advantage that it is easily compared to quantitative pathologic endpoints such as collagen and muscle birefringence loss; collagen hyaline damage; leakage of fluorescent dyes; or cell survival in culture. Using this description, direct comparisons can be made between computer models of $T(x, y, z, \tau)$ and measured histologic damage. A set of coefficients, A and E, is required for each damage process considered in the computer model. For tissue damage processes studied to date, A varies from about 10^{40} to 10^{105} s^{-1} while E usually ranges from about 10^5 to 10^6 J/mol.

Each damage process is then allowed to progress in parallel, driven by the calculated thermal field. This formulation assumes that the individual processes are thermodynamically independent, a reasonable description for identifiable thermal damage processes. The concentration of each of the damage markers, $C(\tau)_i$, is accumulated; a distributed field description of the predicted histologic endpoint may be generated.

Functional Behavior of the First-Order Model — The characteristic behavior of the kinetic damage model is that, below a threshold temperature, the rate of damage accumulation is negligible and it increases precipitously when this value is exceeded. For purposes of discussion, it is useful to define the critical temperature as the temperature at which the damage accumulation rate, $d\Omega/dt$, is 1.0:

$$T_{crit} = \frac{E}{R\ln\{A\}} \qquad (4.10.76)$$

A damage process with representative coefficients of $A = 1.0 \times 10^{75}$ and $\Delta E = 5 \times 10^5$ has a critical temperature of 74.8°C. Figure 4.10.13 illustrates the damage accumulation rate dependence on temperature for the example process.

Constant temperature exposures of the example process will result in a decrease in concentration of native state material depending on the time of exposure. Figure 4.10.14 shows the remaining concentration for this process for constant temperature exposures of $\tau = 0.1$, 1.0, and 10 s; the concentration is seen to decrease gradually with increasing temperature for fixed exposure times, as expected. The strong exponential nature of the process is evident as well. Applying this model framework relies heavily on identifying independent damage processes that can be quantitatively measured.

From plots of the form of Figure 4.10.14, estimates of A and E may be made. Each curve will give one point on an Arrhenius plot (see above), where $\Omega = 1$. Note the necessity of using exposure times that span several orders of magnitude in order to separate the curves sufficiently to give acceptable accuracy in determination of the kinetic coefficients.

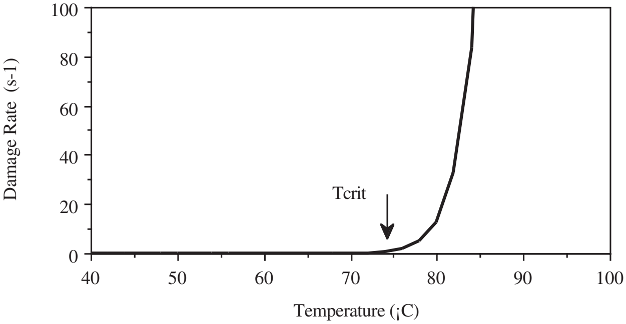

FIGURE 4.10.13 Hypothetical example damage accumulation process has $A = 1.0 \times 10^{75}$ and $\Delta E = 5 \times 10^5$, which gives the damage rate, $d\Omega/dt$, and a critical temperature of 74.8°C.

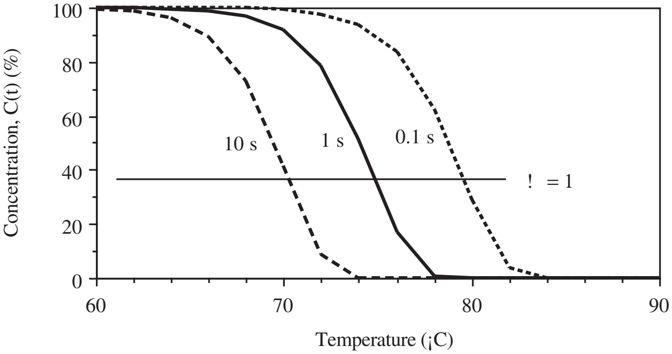

FIGURE 4.10.14 Concentration vs. temperature at various durations of exposure for the hypothetical example process.

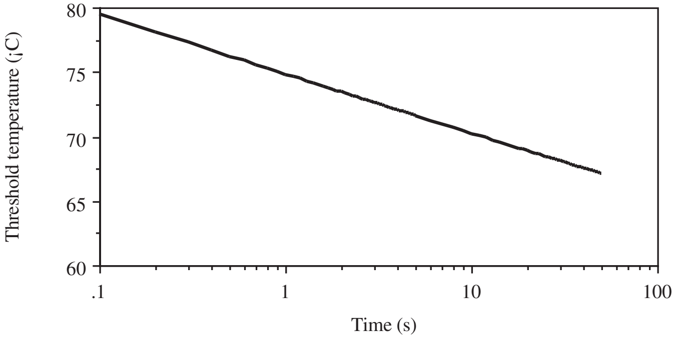

FIGURE 4.10.15 Threshold temperature, T_{TH}, (where $\Omega = 1$) as a function of duration, τ, for constant temperature exposures for the hypothetical example damage process.

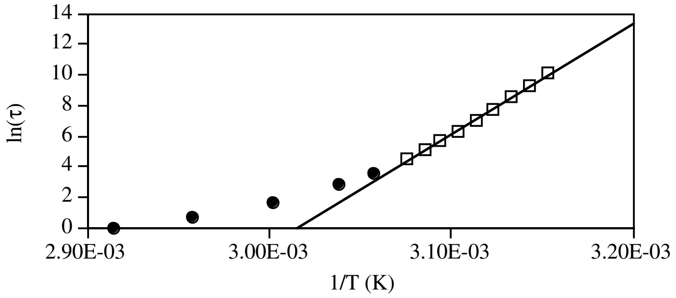
Though the damage parameter, Ω, cannot be measured directly in histologic section, often a clearer picture of the functional behavior can be obtained from it. The exponential dependence of damage on the inverse of absolute temperature means that the temperature required to obtain comparable damage levels is quite sensitive to time of exposure. For example, a threshold temperature, T_{TH}, may be defined as the temperature at which the damage parameter, Ω, is 1 for a given duration, τ. Assuming a constant temperature exposure, the integral of Equation (4.10.74) reduces to a simple multiplication and the threshold temperature is



$$\ln(\tau) = 72504\ (1/T) - 218.610; \quad r^2 = 0.997$$

FIGURE 4.10.16 Plot of Henriques and Moritz data on Arrhenius axes with curve fit line for data at 52°C and lower (open diamonds). For the fit E/R = 72,504 and $\ln\{A\}$ = 218.61.

$$T_{TH} = \frac{E}{R\left[\ln\{\tau\} - \ln\left\{{}^{1}\!/\!_{A}\right\}\right]} \tag{4.10.77}$$

Figure 4.10.15 is a plot of the threshold temperature as a function of duration for the example damage process of Figure 4.10.13 and Figure 4.10.14. Note that threshold temperature is approximately exponentially dependent on duration, as expected, with (in this case) a slope of about –4.65°C/decade. Thus, although 79.5°C is sufficient to result in $\Omega = 1$ at 0.1 s, 102.3°C would be required for a 1-µs exposure for the example process.

Application to Henriques and Moritz Data — A study of the original skin burn data reported by Henriques and Moritz [125] (Figure 4.10.16 and Table 4.10.10) shows that the fit to a first-order process is weak for the higher temperature–shorter exposure time experiments [139], and that the original values of $A = 3.1 \times 10^{98}$ and $E = 6.27 \times 10^5$ (J/mol) [125] do not fit the data as well as their values of $A = 1.3 \times 10^{95}$ and $E = 6.04 \times 10^5$ (for temperatures less than 52°C). In Figure 4.10.17, the skin burn data are fit well with $A = 87.3 \times 10^{93}$ and $E = 6.03 \times 10^5$ when the last reasonable datum is included (at 52°C).

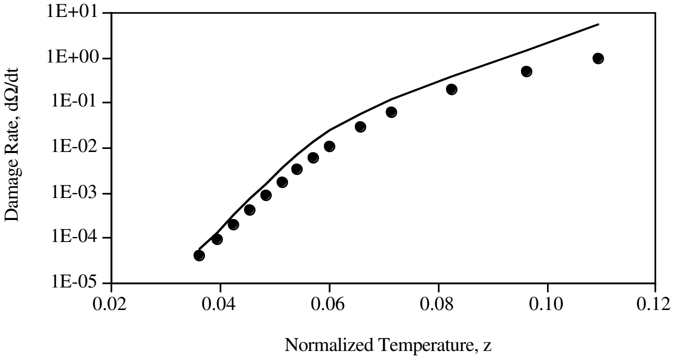

FIGURE 4.10.17 Plot of damage rate for the original Henriques and Moritz data (solid circles) and the enzyme deactivation model of Xu and Qian vs. normalized temperature. (From Henriques, F.C., and Moritz, A.R., *Am. J. Pathol.,* 23, 531–549, 1947, and Xu, Y. and Qian, R., *Trans. ASME J. Biomech. Eng.*, 117, 462–465, 1995.)

Enzyme Deactivation Model

Xu and Qian [140] presented an enzyme deactivation model for skin burn data that combines some of the first- and second-order aspects in a single calculation. The method is based on a general simple enzyme catalyzed reaction sequence from substrates, *S*, to products, *P*:

$$E_a + S \underset{k^-}{\overset{k^+}{\rightleftarrows}} E_aS \xrightarrow{k} E_a + P \tag{4.10.78}$$

and:

$$E_a \xrightarrow{k_d} E_i \tag{4.10.79}$$

where E_a is activated enzyme; E_i is inactivated denatured enzyme (at velocity k_d); and E_aS is the enzyme–substrate complex. The analysis is completed by assuming that the enzyme inactivation process is slow compared to the main reaction sequence. Nondimensional temperature, *z*, is used in the analysis, where:

$$z = 1 - \frac{T_0}{T} \tag{4.10.80}$$

The reference temperature, T_0, as used by Xu and Qian, was representative of the average resting skin temperature: $T_0 = 32.49°\text{C} = 305.65\text{K}$.

$$\Omega(\tau) = \ln\left\{\frac{C(0)}{C(\tau)}\right\} = \ln\left\{\frac{E_a(0)}{E_a(\tau)}\right\} = \int_0^\tau \frac{Ae^{-\alpha z}}{1 + Be^{-\beta z}}\,dt \tag{4.10.81}$$

This combined formulation fits the Henriques and Moritz data (Table 4.10.10) quite well over its entire range if $A = 1.0 \times 10^{-4}$; $\alpha = 100$, $B = 8.0 \times 10^4$; and $\beta = 195$ [123] (see Figure 4.10.17).

Histologic Markers of Thermal Damage*

Tissue and cell heating produce several pathologic alterations that can be directly attributed to thermal damage mechanisms. Many of these are measurable using quantitative pathologic techniques and thus

---

* The authors acknowledge contributions to this section by Sharon Thomsen, M.D.

are amenable to description by kinetic rate process models. As discussed earlier, it is important to recognize that several independent damage processes can occur at the same time. Therefore, it is imperative to describe precisely which particular end point will be measured for kinetic analysis. Depending on the tissue, some end points are more easily identified and measured than others. From the pragmatic biological standpoint, cellular and tissue thermal damage end points are divided into two general categories: lethal and nonlethal thermal injury.

Nonlethal Low-Temperature Tissue Effects

Most living cells and tissues can tolerate and survive modest temperature elevations for limited time periods depending on the species and the metabolic status of the individual. Recovery after heating is marked by restoration of normal functions. Most nonlethal thermal injuries of individual cells are secondary to: (1) heat-induced acceleration of metabolism; (2) thermal inactivation of particular enzymes; and/or (3) rupture of cellular membranes. These alterations lead to disruption of several physiologic reactions of which the most critical are respiration and energy-generating metabolic functions [140, 141]. The best indicators of reversible, nonlethal thermal injury in the living cell or organism are physiological tests that monitor heat-sensitive biochemical and metabolic changes rather than morphologic alterations.

Immediate Effects — Routine light microscopic techniques applied immediately after heating are not useful for the detection of histologic markers of nonlethal thermal injury. However, enzyme histochemistry, a laborious, somewhat capricious methodology, can be used to reveal inactivation of a few heat-labile enzymes [142]. Additionally, transmission electron microscopy (TEM) provides sufficient magnification and resolution to show ruptured cellular membranes and distorted organelles; however, if the ruptures and distortions are frequently seen, the damage is not likely to be lethal. Over time, recovery occurs with synthesis of replacement enzyme proteins and new membranes to patch the holes and reconstitute the normal functions of the organelle and cell.

On the other hand, tissues and organs are composed of a diverse population of cells that have: (1) varying levels of heat sensitivity; (2) different types of metabolic functions and repair capabilities; and (3) various contributions to the function of the tissue or organ. Unlike single cells, reversible thermal damage of tissues can and usually does involve some cell death; however, it occurs at a level that does not impair the function of the organ or tissues. Similarly to the situation in single cells, histologic assessment of reversible tissue thermal injury immediately after heating requires enzyme histochemistry and TEM to determine the degree and distribution of thermal damage because this damage is not detectable with routine light microscopic techniques.

Delayed Effects — Depending on the tissue, intracellular edema, tissue edema, and hyperemia occur within seconds to hours. These are easily identified, delayed organismal responses to nonlethal thermal damage in single cells as well as living tissues. Intracellular edema is due to abnormal accumulation of fluids secondary to thermally induced metabolic dysfunction; resolution of the edema upon repair is a marker of healing. Heat-induced tissue edema and transient hyperemia (increased blood flow and blood vessel dilatation) are mediated by release of vasoactive polypeptides from local inflammatory cells within several seconds of injury. The action of the polypeptides causes blood fluids (primarily plasma) to escape through gaps between the endothelial cells lining the vessel. On the other hand, prolonged hyperemia like that associated with sunburn is a delayed response associated with direct endothelial damage. In this case, the histologic indicators of the more severe vascular damage are dilated blood vessels stuffed with red blood cells and, not infrequently, microscopic leakage of the red blood cells through the damaged vessel wall into the adjacent tissue spaces. Recovery, which is secondary to endothelial regeneration and repair, is seen in a few days [143].

Lethal Low-Temperature Thermal Effects

Cell and Tissue Death and Necrosis — Cell death and subsequent necrosis result when the damage is so severe that the usual repair mechanisms cannot cope and/or the mediators of the repair mechanisms (DNA and RNA transcription enzymes) are thermally destroyed. Again, routine light microscopic techniques cannot be used to identify dead cells immediately after heating except in the case of severe damage. However, within minutes of lethal thermal damage, TEM reveals accumulation of chromatin (the DNA containing chromosomes) at the margins of the nuclei (a recognized TEM marker of cell death) plus more extensive disruption of cellular organelles and limiting cell membranes that are incompatible with survival [144]. Enzyme histochemistry demonstrates enzyme inactivation but, as discussed previously, enzyme inactivation by itself cannot be used as a hallmark of cell death.

After death, cells and tissues undergo necrosis, which is a natural process of disintegration that follows a predictable course over time. Tissue necrosis, the "gold standard" marker of death, is easily recognized in light microscopic sections of lesions 24 to 72 h after the lethal event and, for most tissues, histologic evaluation of the maximal extent of tissue necrosis is seen at about 3 to 5 days for most tissues [145–147]. After 5 days, the boundaries of necrosis and other markers of thermal coagulation are obscured by the healing processes and precise measurement of the extent of lethal heating can no longer be done.

In Vivo *Red Zone Thermal Damage* — When localized electromagnetic, acoustic, or optical heating results in deep zones of necrosis, as when laser light is delivered through an optical fiber or ultrasound or electromagnetic waves are focused, concentric zones of thermal damage form around the source during heating and immediately thereafter. The boundaries between these zones are often distinct and measurable. Depending on the power density and duration of exposure, the three major zones in the lesion that can be seen by the naked eye are: (1) a central ablation hole (at high-power densities); (2) a whitish zone of coagulation; and (3) when the blood supply is intact, a surrounding peripheral red zone. The red zone is formed as a result of hemostasis, hemorrhage, and hyperemia (increased blood flow). The vascular responses are intermixed; however, hemostasis — due to direct damage to blood cells and vessels — tends to occur at the inner boundary between the surrounding red zone and the more central white coagulation zone. Studies performed in rat liver and goat breast show that the outer boundary of the red zone corresponds to the maximum extent of lethal thermal damage as determined by tissue necrosis evaluated in surviving animals 3 days after treatment [145, 146].

Microscopically, additional distinct zones of thermal damage can be detected in the white coagulum. Advancing radially inward from the boundary between the red and white zones, the following quantitative histopathological markers of thermal damage can be observed:

- Lethal cellular injury manifested by cell shrinkage, spindling, and hyperchromasia
- Collagen hyalinization
- Collagen birefringence changes
- Muscle birefringence changes
- Water-dominated effects

The changes intensify as the hotter center of the lesion is approached. Additionally, a mass defect created by ablation of the tissue is observed in cases of intense heating, but is not considered in this chapter.

Thermal Coagulation

As temperatures rise and/or heating times are prolonged, cellular and tissue structural proteins, which are thermally more stable than the vital, energy-producing enzymes, undergo denaturization and conformational changes, a process defined as thermal coagulation. Coagulation is immediately apparent and always indicates lethal thermal effect. For most tissues, coagulation can be seen with the naked eye as whitening of the tissue associated with increased turgor and opacity. The changes of the egg white while the egg is fried is an obvious example of thermal coagulation. On the other hand, coagulation of collagen-rich tissues such as tendon and skin can be signaled by increasing transparency, apparently due to decreased optical scattering by the denatured collagen fibrils.

Microscopically, thermal coagulation of cellular and extracellular structural proteins includes an array of morphological alterations that mark a large range of temperatures and exposure times. As tissue temperatures and/or exposure times increase, the coagulative changes become more obvious and light microscopic analysis becomes the investigative tool of choice.

The most useful histologic markers of coagulative thermal damage in tissues are structural alterations of cells and collagens. Thermally coagulated cells and intracellular organelles shrink and undergo characteristic conformational changes. Collagens are a widely dispersed biochemical class of extracellular fibrous proteins that form the supporting scaffolding of nearly all soft tissues and the organic strut system of bone, cartilage, and teeth. These fibrillar proteins swell and form amorphous masses as a unique response to heat.

Cellular Shrinkage and Conformational Changes — Thermally coagulated cells shrink due to denaturation of the elongate cytoplasmic and nuclear proteins that form the three-dimensional scaffolding system of these structures [147, 148]. Coagulated surface epithelial cells — such as those that line the gut, bladder, and numerous glands of the body — tend to become elongate (spindle shaped). The boundary between this change and the normal epithelium can be quite distinct and thus potentially useful for kinetic analysis.

In contrast, the epithelial cells of the solid organs — such as the liver, pancreas, and kidney — just shrink and do not undergo noticeable conformational change at the light microscopic level. The cellular shrinkage is also due to loss of intracellular water. The coagulated proteins of the desiccated cells become more densely packed, as reflected by dark cytoplasmic and nuclear staining (hyperchromasia) in routinely prepared histologic sections. Unfortunately, these histologic changes are very subtle and, frequently, cannot be distinguished from technical artifacts due to poor fixation. Therefore, they are not reliable markers of thermal damage, especially in the hands of an inexperienced observer.

Collagen Coagulation — Thermal denaturization of extracellular fibrous structural proteins, the collagens, is marked histologically by swelling and an amorphous, glassy transformation of the fibers (hyalinization) [145, 146, 149, 150]. This transformation is easily seen in tissues composed of loose networks of collagen fibers, such as the cornea, skin, submucosa of the stomach, intestines, and urinary bladder. However, some collagen fibers, such as those found in arterial media and liver sinusoids, are very thin ("reticulin fibers"); thus, detection of hyalinization is beyond the resolution of the light microscope. Additionally, at the other end of the fiber size spectrum, mild hyalinization and fiber swelling are equally difficult to see in tissues composed of thick, densely packed collagen fibers, such as those found in blood vessel adventitia and dermis. Changes of birefringence of thermally coagulated collagen (described later) are sometimes easier to detect than hyalinization in these circumstances.

Thermally Induced Loss of Birefringence

Birefringence is an optical property of some tissues that rotates incident polarized light. Thermal coagulation is associated with partial and total loss of the native birefringence of muscle tissues and certain fibrillar collagens as revealed by transmission polarizing microscopy (TPM) [146, 150]. The birefringence of muscle is due to the very regular arrangement of the fibrillar contractile protein macromolecules, actin and myosin, that form the contractile unit of the muscle. Collagen birefringence is the result of the molecular structure and regimentation of the tropocollagen molecules from which collagen fibrils are built.

Tissue birefringence has two components: intrinsic and form birefringence. Intrinsic birefringence is secondary to the α-helical conformation of the polypeptides that form the individual contractile proteins of muscle and tropocollagen molecules; it accounts for 12 to 30% of the total birefringence of these tissues. The remaining birefringence, form birefringence, is related to the crystalline-like array of the actin and myosin molecules in the sarcomere and the regimented longitudinal array of tropocollagens within the collagen fibrils [148, 150–163].

Thermally induced changes of muscle birefringence are associated with dissociation and disruption of the molecules, as revealed by TEM. Partial loss of birefringence in skeletal and cardiac muscle has been identified with the breakdown of the relationships of actin and myosin in the sarcomere (loss of form birefringence). The source of the birefringence of striated muscle is the central portion of the sarcomere, the A or anisotropic band, in which the actin and myosin are arranged in parallel crystalline-like array. The I, or isotropic, band of the sarcomere includes portions of adjacent sarcomeres that contain actin molecules attached to the Z band, an attachment zone for the actin molecules. Total loss of birefringence is associated with increased temperature–time histories and is probably related to reduction of the individual fibrillar contractile proteins to thermally denatured granular profiles (loss of intrinsic birefringence) as shown in TEM of heated myocardium [164, 165].

Thermally induced birefringence changes in collagen involve decreasing intensity of the birefringent image until it is totally lost at higher temperatures. TEM of heated collagens shows a gradual unraveling of the fibers with disappearance of the characteristic periodicity of collagen reflecting the dissolution of the regimented organization of native collagen as it is heated [146, 163].

The onset of the birefringence changes of collagens varies depending on the experimental conditions, anatomic site, and the age of the organism. Native tissue collagens reside in complex environments of different proteins, glycoproteins, and cells that are greatly influenced by the local and systemic physiology of the living organism. The intimate relationships of the collagens with these tissue constituents are regulated by water and salt concentrations; ionic and covalent bonds; and hormonal and metabolic effects. Collagens extracted from tissues are not in their natural environment; therefore, *in vitro* experiments testing molecular relationships including measurements of birefringence will not predict the native behavior of collagen *in situ* or *in vivo* [159–161]. In addition, as the organism ages, the collagens, especially the Type I collagen found in most tissues, form more molecular cross links that alter the temperature–time thresholds of fiber dissociation [160].

Polarizing microscopy can be performed on paraffin sections prepared for routine light microscopy; thus, the birefringent images can be correlated directly to morphologic structure. The intensity of the birefringent images is governed by the thickness of the section, the types of dyes used, and, in the case of collagens, the collagen fiber thickness [145, 166].

Water-Dominated Effects

The role of water vaporization becomes dominant as tissue temperatures approach 100°C. The tissue effects depend on: (1) the rate of water vapor formation; (2) the temperature of the water vapor; (3) the rate of diffusion (escape) of the vapor from the tissue; and (4) the tissue mechanical properties [167–176]. All tissues exposed to air will lose water vapor to the atmosphere because of the differences between the partial pressure of water vapor across the tissue–air boundary. Below 100°C, water vaporization is a surface phenomenon. As tissues are heated, water vapor will be generated and the vapor will diffuse toward the surface to escape. The water vapor is in thermodynamic equilibrium with liquid water; in tissues deep beneath the surface, the relatively low partial pressure gradients favor the liquid over the vapor phase. Meanwhile, at the surface, the tissues dry out as the water vapor escapes leaving the hard, not infrequently brittle, solid tissue components behind.

At or just above 100°C, water vapor is generated volumetrically, equilibrium is pushed toward the vapor phase, and, for sufficiently high-volume generation rates, q''', more vapor is produced than can escape by simple diffusion. The excess vapor is trapped within the cell and in the extracellular tissue layers forming vacuoles or dissections along planes of mechanical weakness [176–178]. The surface desiccates rapidly because diffusion lengths are short. The temperatures of the tissues that still contain liquid water will remain close to 100°C or the pressure will rise.

The vapor in the vacuoles will expand quickly, compressing the surrounding, rapidly drying tissues that form the vacuolar walls. As the vacuoles expand, the walls separating the vapor pockets from each other or the tissue surface become thin. The walls rupture as the force of the increasing pressures of expanding vapor overcomes the mechanical strength of the tissue. The vacuoles coalesce to become larger holes within the tissues or form irregular defects on the surface. When this process takes place over relatively long heating times, the tissue defects are formed as the result of tissue compression, desiccation, and shrinkage but *not* to loss of dry mass. On the other hand, rapid heating times result in explosive rupture, which causes tissue fragments to be ejected from the surface, thus creating irregular craters formed secondary to dry tissue mass loss. These water-dominated events are the same as those when popcorn is made; thus, the tissue changes have been called the “popcorn” effect [168–171, 177–179].

The kinetics of water vaporization will not be treated here; see the chapter on nucleate boiling for a kinetic discussion of this phenomenon. Histologically, the zone of water vapor formation manifests as a distinct region populated by vacuoles adjacent to ablation craters formed from volume heat sources. In some experiments — for example, electrosurgical cutting and laser ablation at water-absorbed wavelengths — the vacuolized zone usually has a distinct and measurable border.

Damage Rate Process Coefficients

Thermal damage kinetic coefficients are usually determined from constant temperature exposures of relatively long duration. Threshold damage results are selected out of a set of damaged tissue samples for analysis from which estimates of A and E are obtained.

Constant Temperature Exposures

Because of the sensitivity of the damage integral to small changes in temperature, the typical approach in obtaining A and ΔE is to expose the tissue to a constant temperature; identify experiments in which the damage is threshold — i.e., for which $\Omega = 1$ or $C(t) = 36.8\%$ of $C(0)$ — and obtain A from the intercept and E from the slope of an Arrhenius plot of $\ln(t)$ vs. $1/T$ for the threshold experiments. If the temperature is held constant, the integral reduces to a simple multiplication, and $C(t) = 0.368\ C(0)$; then Equation (4.10.71) becomes:

$$\ln\{\tau\} = \frac{E}{R}\frac{1}{T} - \ln\{A\} \tag{4.10.82}$$

The usual experimental method is to expose thin slices of tissue to constant temperature in a water bath, by surface application of heated water [122–125] or on a heated metallic plate for desired time intervals. Table 4.10.11 lists rate coefficients obtained in various experiments and the relative damage rates ($d\Omega/dt$) are compared for several of them in Figure 4.10.18.

When using the kinetic models and measured coefficients, it is imperative that an adequate description of the particular end point be given. This is because different end points in the same tissue will have widely varying critical temperatures and damage accumulation rates. For example, in addition to the variation in tissue, the end points in the various studies listed in Table 4.10.11 differ markedly.

Retina — The measurements of Welch and Polhamus [180] used the diameter of the edge of the visible lesion formed in bovine retina under argon laser irradiation as the end point. The temperatures were not measured directly, but were determined in separate experiments on retinas in which a correlation between temperature and radius was established using microthermocouples (about 5 μm in diameter) advanced from the posterior surface of the eye to a point just below the retina. The correlates were used to estimate the retinal temperature, given laser beam power and duration. The critical temperature for these coefficients is 56.0°C.

Takata et al. [181] used a similar decision criterion for retinal damage for shorter exposure times. They fit the data with three sets of coefficients because a single first-order model was not sufficient. It would appear that because several parallel damage processes were at work in their study, a set of coefficients was required. The critical temperature for the high-temperature set of coefficients is 59.9°C. Birngruber et al. [182, 183] estimated a frequency factor and activation energy from consideration of the thermodynamics of protein and enzyme denaturization processes. Their estimates have a critical temperature of 74.5°C.

Skin — The end point for $\Omega = 1$ in the original studies of Henriques and Moritz [122–125] corresponded to a continuum of cascaded effects. In their study, the skin of pigs was exposed, *in vivo*, to flowing water at a controlled temperature for exposure times varying over several orders of magnitude. They calibrated their coefficients so that $\Omega = 0.53$ corresponded to the onset of erythema (characterized as first degree in their paper). Then, $\Omega = 1.0$ corresponded to a second-degree, or partial-thickness, burn and $\Omega = 10^4$ to a full-thickness, or third-degree, burn. Their coefficients, $A = 3.1 \times 10^{98}$ and $E = 6.27 \times 10^5$, have a critical temperature of 59.7°C. Weaver and Stoll [128] used similar criteria to those of Henriques and Moritz and applied two sets of coefficients (the upper values applicable above 50°C, as in the Takata et al.

TABLE 4.10.11 Experimentally Determined Rate Coefficients

A (s^{-1})	E (J/mol)	Conditions	Ref.

study) to match the experimental data. The critical temperature for their highest temperature coefficient set is 59.4°C.

Egg White and Egg Yolk — Egg white and yolk were exposed to constant temperature (±0.2°C) in a water bath for varying exposure times [184]. Coagulation was defined as the onset of whiteness (coagulum formation apparently due to increased scattering in the clear liquid egg white) observed by the naked eye. Water bath temperatures ranged from 60 to 90°C in 4°C increments. At each temperature, the time to threshold was measured and plotted in accordance with Equation (4.10.24) and rate coefficients determined from linear regression, as described. Approximately 3 to 5 s were required to obtain whitening in the egg white at 70°C; in the egg yolk, 82°C was required for the same exposure time. The table values have critical temperatures of 76.0°C for egg white and 86.6°C for egg yolk.

Aorta — Coefficients for collagen damage have been measured in excised human aorta wherein the specific damage end point was a measurable and repeatable weakening of the connection between collagen and elastin in the medial layers [185]. The experiments consisted of variable exposure time (15 to 1500 s) contact of the intimal surface with a heated copper block controlled to ±1°C; the adventitial surface was insulated. The weakening was reflected as a tearing between these fibers in histologic section. Of course, tearing in a histologic section can be due to a number of processing variables. In order for an experiment to be acceptable as a damage measure, the tearing region had to be specifically associated with the region of heated block application in multiple adjacent sections. Ten thresholds were obtained in 90 experiments, from which the damage coefficients were estimated to be: $A = 5.6 \times 10^{63}$ (s^{-1}) and $E = 4.3 \times 10^5$ (J/mol). The critical temperature for these coefficients is 78.9°C.

The kinetic nature of thermal damage means that the time of exposure is critically important when discussing threshold temperatures. For example, it is commonly stated that thermal damage occurs above 45°C — and, in fact, 45°C was identified by Moritz and Henriques as the long-term exposure asymptote for threshold damage. However, at that temperature, it would require 9.7 h of exposure to get a burn ($\Omega = 1$). To get a skin burn in 1 s, a temperature of 59°C would be required; over the 0.1 s typical of the laser activations, 63°C is required. Similarly, using the coefficients for collagen, at 45°C, it would require about 73 days of exposure to get $\Omega = 1$; for damage in 1 s, 79°C is necessary; and in 0.1 s a constant temperature of 84.5°C is required.

Thus, when comparing the higher temperatures required to obtain collagen denaturization in laser experiments (above about 80°C), for example, to published values of collagen temperature thresholds (which range from 50 to 60°C), it is important to note that: (1) the times of exposure used in published collagen damage reports are usually in terms of hours; and (2) it is entirely likely that collagen in dilute solution has a different set of kinetic coefficients than collagen *in situ* because of complex structural interrelationships inherent in the tissue.

Calcein Leakage — Bhowmick and Bischof [137] measured calcein leakage rates from type AT-1 prostate tumor cells exposed to elevated temperatures. Calcein is a fluorescent dye that leaks out of cell membranes at varying rates depending on membrane integrity. The coefficients in Table 4.10.11 correspond to 50% decrease in intracellular calcein fluorescence intensity. These researchers also reported cell survival rates (again, for 50% survival). These data are reasonably close to $\Omega = 1$ point (36.8% survival or remaining fluorescence intensity). Many other cell survival studies have been reported in the literature (see, for example, Mixter et al. [186] and Padanilam et al. [187]).

Transient Thermal History Experiments

Problems with the standard constant temperature approach to determining A and ΔE are that

- With only a very few exceptions, the tissue must be excised to perform the experiments, thus disrupting its blood perfusion and activating autolytic (*postmortem* degeneration and necrosis) processes.
- No exposure is truly constant temperature and rise time segments must necessarily be short compared to total exposure time in order to be negligible (restricting one to the study of very slow processes).
- It is difficult to obtain trustworthy estimates of A because the temperature axis is hyperbolic ($1/T$) and, even if the exposure times vary over several orders of magnitude, small uncertainties in the slope ($\Delta E/R$) create very large uncertainties in A.
- The methods are difficult to use in laser damage studies because constant temperature exposures are not possible to obtain.

Working with transient thermal data adds a high level of uncertainty to the damage coefficients because the time of exposure is problematic. Nevertheless, estimates of rate coefficients can be made upon which treatment protocols can be evaluated. An approximate method has been applied with some limited success [188, 189], and is described here.

As can be seen from Table 4.10.11, most of the damage processes have activation enthalpies on the order of 10^5 J/mol. For the hypothetical example damage process, with $E = 5.0 \times 10^5$ J/mol, at 60°C the rate of damage formation would double if the temperature increased to 61.3°C (about 0.4% temperature increase on the absolute scale). The rate of rise of laser spot heating experiments is usually many degrees per second; therefore, the exposure time is assigned as the time during which the tissue temperature is within 2°C of the maximum value. Of course, noise in the determination of temperature creates significant uncertainty in the determination of exposure time, τ, for a calculation; however, technically acceptable experiments can be extracted by inspection of the temperature history.

Note that the temperature history at the location of threshold damage is required, so the surface location of threshold damage in the histologic section is determined, using the methods previously outlined, and then the thermographic record of temperature at that location is analyzed. This method has been used to make preliminary estimates of damage coefficients for birefringence loss in rabbit myocardium and purpura formation in pig skin irradiated with an argon laser. By referring directly to the recorded thermographic image data, the uncertainty associated with optical models and properties of the tissue can be avoided.

Purpura Formation — When using lasers for the clinical treatment of dermatologic anomalies such as port wine stain, a variable of major importance in dosimetry planning is the purpura threshold. The purpura threshold is determined by optical and thermal properties of the skin because purpura generation is of photothermal rather than photochemical origin. In controlling the dose, thermal feedback can be used to limit the laser irradiance if the damage process is known. Direct use of thermal feedback has the additional advantage that variations in the tissue optical properties are not important to the control algorithm. Therefore, useful thermodynamic models of purpura formation could provide additional information to be used in treatment planning and will likely facilitate thermal feedback approaches to dosimetry control.

An argon laser was used to conduct 20 experiments on porcine skin *in vivo* [188]. The spot size was nominally 2 mm and activation times and beam powers ranged from 0.2 to 20 s and 1 to 11 W, respectively. Skin surface temperature was recorded thermographically and transient thermal histories for the radius of purpura formation were determined *a posteriori* at locations determined from gross and histologic observation. The 2°C criterion was used to estimate the exposure time at the threshold radius. The time and temperature were plotted on an Arrhenius plot and A and ΔE determined by linear regression.

It should be noted that the purpura coefficients were derived by measuring surface temperature and the active thermal damage process is occurring subsurface at the capillary level. Also, the Argon laser wavelength is significantly scattered in dermis and epidermis, so one would expect that the deep temperatures were higher than the skin surface temperatures. Consequently, the coefficients apply to measured surface temperature, not the capillary damage process per se. Of course, when feedback control based on surface temperature is desired, this is the variable of choice. For these data, $A = 4.11 \times 10^{53}\ \mathrm{s}^{-1}$ and $\Delta E = 3.39 \times 10^5$ J/mol and the critical temperature is 56.9°C. Not unexpectedly, the data are quite noisy, as can be seen in Figure 4.10.19.

Birefringence Loss in Myocardium — A similar series of experiments was conducted on freshly excised rabbit myocardium less than 10 min after sacrifice [189]. The epicardial surface of the excised left ventricle was exposed to argon laser light. Again, the spot size was 2 mm with durations and beam powers from 0.2 to 20 s and 1 to 12 W, respectively. After exposure, the visible lesion was measured and marked across the diameter to guide the histologic sections. Stained sections (Mallory's trichrome and H&E) were analyzed to determine the depth and surface diameter of the zones of partial and total birefringence loss. The temperature histories of the radii of the threshold of birefringence loss were calculated from the recorded thermal imagery.

Figure 4.10.20 is an Arrhenius plot of the resulting data. Damage coefficients for this process were estimated to be: $A = 3.12 \times 10^{20}$ (s^{-1}) and $\Delta E = 1.28 \times 10^5$ (J/mol) with a critical temperature of 52.9°C.

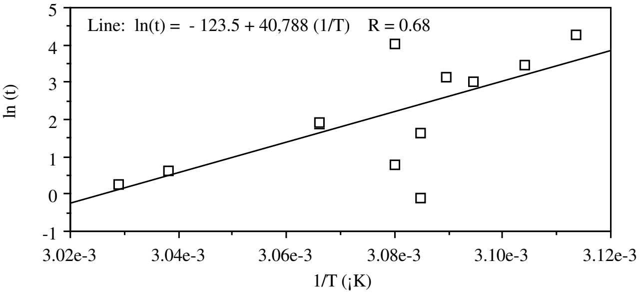

FIGURE 4.10.19 Arrhenius plot for purpura formation *in vivo* in porcine skin. Data derived from surface measurement of temperature resulting from coagulation of deeper blood vessels.

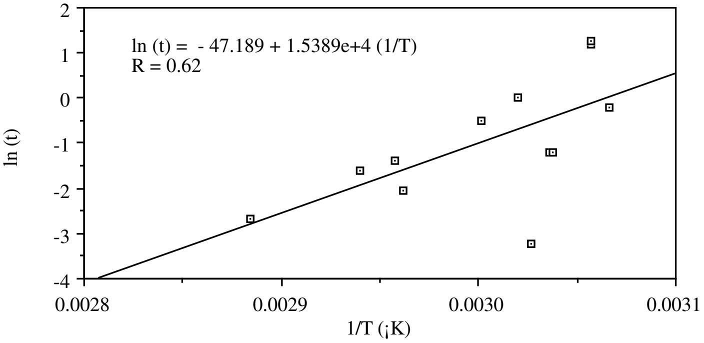

FIGURE 4.10.20 Arrhenius plot for birefringence loss in rabbit myocardium *in vitro.*

Interestingly, in this data set the diameters of the visible lesions equaled those of the birefringence loss zones within the accuracy of the measurements.

Summary

First-order kinetic models for tissue damage are useful for predicting trends in damage experiments. Unfortunately, the frequency factor and energy have been determined *in situ* for only a few damage processes; critical temperatures for known processes range from about 50 to 90°C. Nevertheless, these models can be used to make direct comparisons between numerical predictions of damage and histologic results — something that cannot, as yet, be achieved any other way.

A very careful definition of the particular histologic end point is necessary. To avoid the arbitrariness that characterizes much of the early damage studies, the end point should: (1) be clearly recognizable and defined; (2) be reproducible under varying experimental conditions; (3) be easily measured; and (4) involve relatively homogeneous and readily available test tissues. For example, thermally induced birefringence image intensity decrease in skeletal and cardiac muscle is easily seen and measured using polarizing microscopy and optical detectors. Beef and pork loin cuts, chicken breasts, and canine or beef hearts can provide the numerous tissue slices required to accumulate adequate data.

In part because of the effects of biologic inhomogeneities and random fluctuations in tissue characteristics, and in part due to the difficulty of resolving small temperature differences, thermal damage data are inherently noisy. Consequently, the prediction of observed damage boundaries in very long exposure experiments (on the order of minutes to hours) in the presence of substantial spatial thermal gradients may be frustrating. However, in small spot size exposures of relatively short duration (up to fractions of seconds), the predicted boundaries compare favorably to those observed. This is probably due to the very steep thermal gradients typical of small spot experiments — that is, a rather large error in actual critical temperature may be swamped out by the very steep thermal gradient so that the location of the predicted damage contour may, in fact, agree fairly well with experimental histologic observation.

Certainly, even though the results of a particular experiment may eventually prove impossible to duplicate in numerical models, a rather careful analysis of the trends, which could be obtained from changing power, contact temperature, spot size, and duration, can be studied in detail in the numerical model and on a spatial scale similar to microscopic observation. Also, the numerical model allows dissection of the transient development of thermal damage — something that cannot be achieved in any other way. Thus, although many uncertainties are associated with kinetic models of thermal damage, they can be extremely illuminating and helpful in dosimetry planning.

Tissue Effects: Subzero Temperatures

An important area of bioheat transfer application is in the domain of subzero temperatures. As was noted previously, biochemical rate processes are governed by the local system temperature. Lowering the temperature has the effect of reducing reaction rates and, at sufficiently low temperatures, a state of suspended animation can be achieved. Owing to the major aqueous component of physiological fluids, temperatures low enough to effect suspended animation normally result in freezing. The freezing of native biomaterials is nearly always lethal to the affected tissue upon thawing. The effected injury can be used to benefit in cryosurgery for the purpose of destroying a target tissue such as cancer.

Alternatively, the tissue can be modified prior to freezing by the introduction of a chemical cryoprotective agent (CPA) to afford protection from freeze–thaw injury. Techniques have been developed for the successful long-term cryopreservation of many biomaterials for subsequent applications, including human transplantation. The response of living biomaterials to freezing and thawing is intimately tied to thermal history during processing, especially at subzero temperatures. Thus, bioheat transfer analysis has played a key role in the design and development of low-temperature bioprocessing protocols.

Cryopreservation

Living tissues may be frozen to deep subzero temperatures to create a state of suspended animation for indefinite periods and recovered with very minimal loss of viability and function. It is necessary to store tissues at below approximately –120°C so that the kinetics of chemical reactions and ice nucleation become infinitesimally small. Successful cryopreservation protocols require that subject tissue be modified prior to cooling to subzero (°C) temperatures by addition of a CPA to protect against the injurious effects of ice formation or to block the formation of ice so that a glassy state results (vitrification).

Widespread interest has developed in exploiting cryopreservation as a means for reversibly banking a broad spectrum of tissues for transplantation. The seminal paper that first reported this work described the use of glycerol to freeze fowl sperm 50 years ago [190]. Successes were then reported for other types of tissues having rather simple cell structures, such as erythrocytes, gametes, and various cells obtained from primary cultures [191–193]. Most of these cryopreservation techniques were derived via largely empirical methods. Starting in the 1970s, it was realized that cryopreservation of more complex systems such as multicellular tissues and whole organs required a more rigorous scientific understanding of the mechanisms of the governing biophysical processes and cellular response to freezing and thawing. Since that time, engineers have made significant contributions to the developing science of cryobiology — not the least of which has been to identify some of the key biophysical problems to be solved [194].

Biophysical Basis of Freezing Processes in Cells

Analysis of cryopreservation by freeze–thaw processes is based on addressing phenomena associated with the solidification of aqueous solutions and their resulting effects on embedded living cells surrounded by semipermeable membranes. When an aqueous solution freezes, water is sequestered into the solid ice phase, resulting in concentration of solutes in the residual liquid phase solution. If equilibrium is maintained between the liquid and solid phases, the coupling between temperature and solute concentration is described by the phase diagram for the solution. As shown in Figure 4.10.21, as the temperature is depressed below 0°C, the amount of solute in the liquid increases according to a function

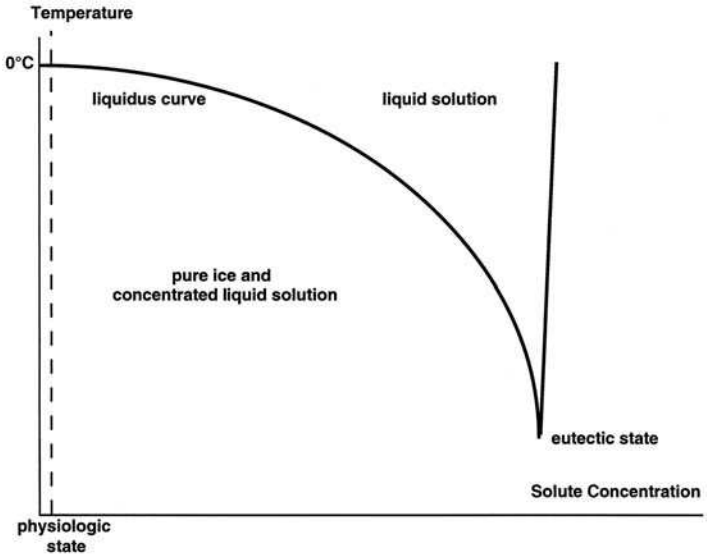

FIGURE 4.10.21 Simplified representation of an aqueous equilibrium phase diagram. Physiological solutions have solute concentrations that are quite small (about 300 mOsm) in comparison with the eutectic state. As freezing progresses, the liquid phase concentration may increase by more than 20-fold, subjecting cells to intense osmotic stress

defined by the liquidus curve until the eutectic state is reached. Thus, cooling a biological tissue until ice is nucleated imposes osmotic as well as thermal stress.

A consequence of the osmotic stress is that the individual cells in a tissue will lose intracellular water to the solute-enriched environment. (It is assumed that, at subzero temperatures, the time scales for transport of other molecular species will be negligible in comparison to that for water.) The rate at which this mass transport occurs across the cell membrane is governed by the membrane's permeability to water. This process was modeled initially by Mazur as a simple transport phenomenon [195]:

$$\frac{\partial \Psi}{\partial T} = -\frac{L_p S B \Re T}{v} \ln\left(\frac{p_{in}}{p_{ex}}\right) \tag{4.10.83}$$

The Mazur equation predicts the change in the volume, Ψ, of a cell with temperature during freezing at a cooling rate of B in conjunction with the transport of water from within the cell in response to the osmotic differential developed across the membrane as solutes are concentrated during the solidification process. The rate of transport is dependent on the surface area, S, of the cell; the membrane permeability to water, L_p; the molar volume of water, v; and the ratio of intracellular to extracellular vapor pressures of water. Although the latter term is not a rigorous description of the driving potential for the transport process, it is easily replaced by the transmembrane differential in chemical potential or solution concentration.

Dehydration is not the only process by which equilibrium can be achieved between intracellular and extracellular water during freezing. Ice crystals may nucleate within the cell, forming intracellular ice (IIF) [196]. The occurrence of IIF is nearly always lethal to cells, with certain explicit exceptions [197] and is therefore to be avoided during cryopreservation. The balance between equilibration of water across the cell membrane by osmotic dehydration and by IIF is governed primarily by the magnitude of the cooling rate [198]. As depicted in Figure 4.10.22, at rapid cooling rates, water has little opportunity to escape from the interior of the cell as the extracellular solute concentration increases with progressive freezing.

Eventually, the conditions are satisfied for intracellular nucleation of ice crystals. At slow cooling rates, the cells are able to dehydrate as the extracellular solute concentration increases, and the intracellular

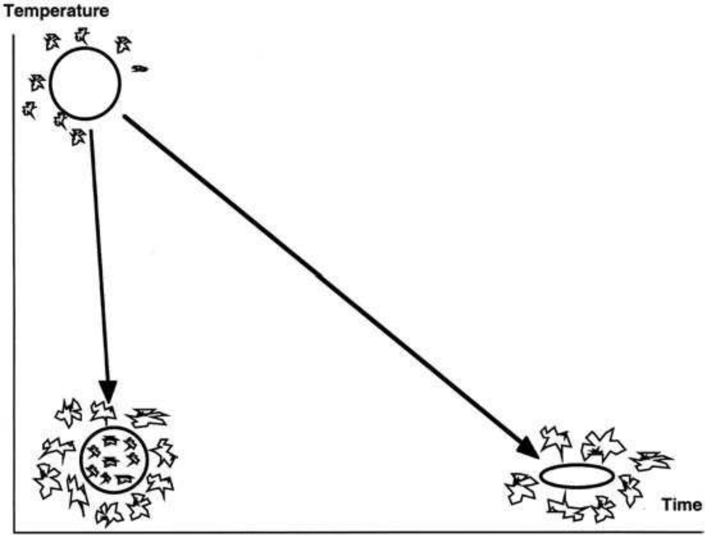

FIGURE 4.10.22 Schematic of the reaction of individual cells to extreme variations in the cooling rate during freezing. At rapid cooling rates dehydration of the cell is minimal, and intracellular ice forms. At slow cooling rate, dehydration is extensive, resulting in loss of intracellular water and morphological distortion.

water becomes frozen in the extracellular space. The resulting shrinkage of the cell can give rise to injurious chemical and mechanical stresses. In general, optimal survival from cryopreservation is achieved at intermediate cooling rates, the magnitude of which are dictated by the membrane's permeability at subzero temperatures [199].

Cryoprotective Additives (CPA)

The sensitivity of cells and tissues to IIF and osmotic stress and dehydration can be modified substantially by the prefreezing additions of a CPA. As a consequence, virtually all practical cryopreservation procedures are based on the use of a CPA to which the cell membrane is permeable. Interestingly, recent research has demonstrated that some cell species damaged by typical freezing and thawing processes can be cryopreserved successfully via microinjection of small amounts of sugars into the intracellular volume [200, 201] and by addition of sugars into the extracellular solution along with common permeating CPAs [202].

During the CPA addition and removal procedures and the freezing and thawing processes, the applied osmotic stress results in coupled transport between the CPA and water. This coupled process is typically described in terms of irreversible thermodynamics using a format defined by Kedem and Katchalsky in which the phenomenological coefficients are related directly to physically measurable properties of a cell membrane [203, 204]. These equations are written as

$$J_V = L_p \Delta p - \sum_{i=1}^{n} \sigma_i \Delta \pi_i \tag{4.10.84}$$

$$J_S = C_S (1 - \sigma) J_V + \omega_S \Delta \pi \tag{4.10.85}$$

L_p is the membrane permeability to water; ω is the permeability to solute (CPA for applications in cryopreservation); and σ is the coupling between the two flows (reflection coefficient). The average concentration of permeable solute between the extracellular and intracellular solutions is given by C_S, and the total volume flux and solute fluxes by J_V and J_S, respectively. Equation (4.10.84) shows a provision for volume flow occurring under the action of multiple solutes. Evidence is growing that in at least some cell systems the movements of water and CPA across the plasma membrane are uncoupled [205, 206], thus obviating the need for an irreversible thermodynamic formulation of the process [207].

An alternative, more generalized formulation of this type of phenomenon was also posed by Katchalsky in terms of network thermodynamics [208]. The network thermodynamic model has been applied successfully to the analysis of the cellular response to freezing processes [209, 211]. It can readily be applied for inverse solution to quantify the transport coefficients from freezing data or CPA addition data [210, 212].

Cryoprotective additives may also have a significant effect on IIF and the general mechanical properties of ice growing in biological systems. In particular, various antifreeze proteins (AFP) isolated from cold weather organisms have been demonstrated to influence damage processes to living cells during freezing and thawing [213, 214]. Long-standing evidence indicates that one mechanism of cryoinjury derives from a mechanical interaction between cells and the growing extracellular ice phase in which they are enmeshed [215–217].

The presence of a CPA can strongly modify the structure of ice growth through a cell suspension, as observed and measured by cryomicroscopy [218]. Decoupling the cooling rate into the product of the temperature gradient and interface velocity and then controlling these parameters independently on a directional solidification cryomicroscope allows demonstration that identical cooling rates can produce very different ice crystal morphologies and concomitant cell damage, thereby implicating ice–cell interaction as a damage mechanism [219, 220]. Further studies have shown the ability of AFP to alter ice crystal structure [221, 222] dramatically; these results are being applied to design cryopreservation protocols, including the use of synthetic polymers for specific applications [223].

Multicellular Systems, Tissues, and Organs

The preceding models hold for the analysis of individual cells. However, many important biological systems of interest for cryopreservation consist of organized tissues that have a two- or three-dimensional geometry that may exert a significant effect on the system osmotic behavior and on processes sensitive to cell–cell interactions. For these systems, transport not only occurs across the individual cell membranes, but the interstitial volume is also involved in the transport and storage of water and CPA. In this case, the model must be expanded to include parallel and serial transport and storage for all mobile chemical species. Network thermodynamics provides an effective modeling format for describing these processes [211].

The cryopreservation of whole organs, which is still in the research stage, will demand even more complex coupled thermal and chemical transport analyses. CPAs are added and removed via perfusion through the vascular network; this hydrodynamic flow is coupled to the osmotic, diffusional, and viscoelastic energy domains of the organ. The network thermodynamic approach to modeling is very well suited to analysis of these coupled multidomain processes and has been applied successfully to the design of CPA perfusion protocols [224].

Cell–cell contact has been shown to affect IIF in a number of different experimental systems, generally by enhancing the ability of ice crystals to nucleate on the cell interior [225–227]. This rate of propagation of intracellular ice is greater in a cell culture grown to confluence and is dimished when a gap junction blocker is introduced [228]. The phenomenon is explained by modification of an IIF nucleation model [229].

The Influence of Cell Membrane Permeability

It is well documented that the permeability of cell membranes to water and to CPA is a strong function of the cell species, and that for all species it is a function of temperature [204]. For example, the water permeability among various species may vary by a factor of 10^3 or greater. In general, membranes are significantly more permeable to water than to common CPAs, although the opposite case may also occur under unusual conditions [206]. As the temperature is reduced, the permeability is depressed dramatically. For most practical purposes, at temperatures below the range of about –20 to –30°C, the impedance to membrane transport becomes so high that very little molecular exchange can take place between the intracellular and extracellular compartments.

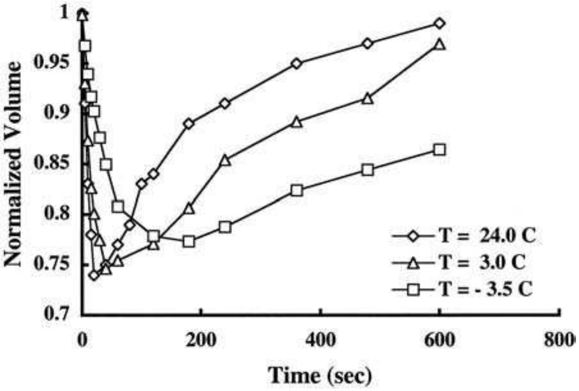

FIGURE 4.10.23 Osmotic response of human pancreas islets to exposure to a 2-*M* solution of dimethylsulfoxide at the indicated temperatures. (From Acker, J.P., Larese, A., Yang, H., Petrenko, A., and McGann, L.E., *Cryobiology*, 38, 363–371, 1999.)

One of the major challenges in applying models for cell membrane transport during freezing has been to develop instrumentation to measure the permeability to water and CPAs at subzero temperatures, in the presence as well as in the absence of ice. The most successful approach is to follow visually on a light microscope the transient size of individual cells or tissues when they are subjected to controlled osmotic stress created by freezing the specimen [230–232] or by changing the chemical environment [233, 234]. An effective step change in the concentration of the extracellular solution is produced when ice is nucleated in the extracellular medium and the temperature is subsequently held constant for the duration of the experiment, or when a new bathing medium is perfused rapidly through the specimen chamber on the stage while the cells or tissues are physically immobilized. Both procedures cause the concentration of the environmental solution to be altered from an initial value to a final well-defined state, and the change in cell volume with time can be measured by direct microscopic observation.

The two-dimensional cross-sectional areas of the cells in the micrographs are quantified via digital image analysis and extrapolated to three-dimensional volumes based on an assumption of a consistent geometric morphology throughout the process. These experiments are repeated serially at different temperatures to generate a series of transient volume curves as shown in Figure 4.10.23 for pancreas islets [235], a multicellular mammalian tissue.

A 2-*M* solution of the CPA dimethyl sulfoxide (Me_2SO) was introduced stepwise into the perfusion cryostage to control the osmotic environment of the islets. An initial shrinkage is measured because water leaves the cells more rapidly than the Me_2SO can enter. As time progresses, the islet reaches a minimum volume and then begins to swell as Me_2SO and water enter the cell. The design of protocols for addition and removal of CPAs to tissues is an important and challenging step in developing effective cryopreservation methods. A rational design process is dependent on the ability to measure the constitutive transport properties of the tissue of interest and have a model that can be applied to optimize the osmotic process, minimizing stresses (which are potentially lethal) on the cells.

Thus, the utility of the transient volume data is to provide a database from which Equation (4.10.81) through Equation (4.10.83) can be applied to determine the constitutive transport properties for a cell or tissue of interest by inverse solution techniques. Property values are identified at each temperature for which experimental data exist, and the data for each property are used to fit an Arrhenius type function to characterize the temperature coefficient [204]. Equation (4.10.86) shows a typical formulation used for this purpose:

$$L_p(T) = L_{p,g}(T_g)\exp\left[\frac{\Delta E}{\Re}\left(\frac{1}{T} - \frac{1}{T_g}\right)\right] \tag{4.10.86}$$

Experiments for many different cell types have shown that the Arrhenius expression provides a model that describes the temperature dependence of the tissue transport properties well [204].

In order to fully interpret the transient osmotic data described earlier, it is necessary to determine the fraction of the cell contents unable to cross the cell membrane under the types of osmotic stress encountered during cryopreservation. This component of the cytoplasm is often referred to as the osmotically inactive volume. It can be measured by conducting a series of experiments in which cells are exposed to increasing concentrations of impermeable solute and measuring the equilibrium volume at each state. These volumes are then plotted as a function of reciprocal solute concentration and extrapolated to the intercept of the ordinate, which indicates the volume that the cell would assume without injury when exposed to an infinitely large solute concentration. The complementary normalized fraction is a measure of the initial amount of intracellular water that can participate in the response to extracellular osmotic stress. The data are displayed on a Boyle–van't Hoff plot [236].

A fundamental issue in the analysis of cryopreservation processes that has only recently begun to be addressed via rigorous quantitative modeling is the osmotic behavior of frozen cells during the thawing process. It has now been demonstrated by application of a model based on Equation (4.10.83) that, for some combinations of freeze–thaw protocols, the warming rate may be the governing component of the thermal history in determining the mechanism and extent of injury [237]. The design of optimal cryoprocessing protocols may therefore require an analysis of the effect on a tissue of interest of the complete thermal history, including cooling and warming.

Cryopreservation by Vitrification

Ice nucleation can be avoided by doping the biological specimen with a high concentration of chemicals to induce a vitreous state [238]. The chemicals act to raise the glass transition temperature to a high value, which can be reached at cooling rates consistent with standard refrigeration systems. By vitrifying the system injury, mechanisms associated with freeze-concentration of solutes and with IIF are avoided. Major problems involving transport processes remain to be solved before vitrification can be applied to the cryopreservation of whole organs.

In order to achieve a vitrified state, a 4- to 5-*M* solution must be equilibrated with the entire volume of an organ, including all the constituent cells. Because this high concentration of CPA can be toxic to cells, the addition process is preferably effected at a low temperature such as 4°C to reduce the rates of injurious chemical reactions. In addition, the duration of exposure to the CPA prior to further cooling should be minimized to limit the accrued reaction time. However, the tradeoff to lowering the temperature is caused by the thermal coefficient of viscosity, which makes it much more difficult to effect the perfusion of CPA solution through the vascular systems of an organ and the diffusion from the vascular lumen through the interstitial tissue and into the individual cells. Optimal design is dependent upon balancing the coupled hydrodynamic, osmotic and viscoelastic reaction of the organ to the perfusion process with the biochemical toxic reactions [239].

Although increasing numbers of biological systems are being identified that are compatible with cryopreservation by vitrification, widespread application will require that the technique become easier to use in practical clinical and biological environments. To this end, there is an ongoing search for CPAs that render the vitrification process less sensitive to accurate control of thermal history; to toxic injury to the biological specimen; and to devitrification (crystal nucleation) during rewarming. This process involves gaining a better understanding of the phase change and vitrification kinetics of various CPA solutions [240, 241] and of identifying new and more effective CPAs [223].

Optimization of Heat Transfer during Cryopreservation

The foregoing discussion indicates the importance of the combined osmotic and thermal history at the local cellular level in determining the response to cryopreservation, including the type and extent of injury that may occur. For a given combination of cell type and CPA composition and concentration, the post-thaw viability achieved is governed by the thermal history of the process. The cooling rate determines the frozen state for storage, and the warming rate determines the manifestation of the frozen state on the final level of viability.

In general, there are two extremes of behavior during freezing [242]. For relatively slow cooling rates the rate at which the extracellular solute concentration increases will have a time scale comparable with that for the osmotic dehydration of the cell at high subzero temperatures. Therefore, the cell will lose a considerable fraction of its water and experience extensive dehydration as indicated in Figure 4.10.22. This large loss of volume is known to damage cells by one or more molecular level mechanisms, which have not been fully identified [199]. Increasing the concentration of CPA will provide an osmotic buffer against this type of dehydration-induced injury, as well as possibly providing other means of protection.

Alternatively, when the cooling rate is rapid, the temperature is reduced much more rapidly than the cell can respond osmotically (because the membrane permeability becomes greatly reduced at low temperatures as will be explained subsequently). Therefore, no opportunity exists for intracellular water to osmotically equilibrate with the extracellular water being progressively diminished in concentration. When the transmembrane water disequilibrium (as manifested in terms of liquid phase supercooling) reaches a critical value, the conditions will be satisfied for nucleation of ice in the intracellular volume. It is important to note that the cell membrane acts as a barrier to the growth of a continuous ice phase between the intracellular and extracellular compartments. The crystalline structure of intracellular ice will be considerably smaller than that of extracellular ice because of the greater extent of supercooling prior to nucleation. Consequently, the propensity for recrystallization will be relatively large in the intracellular volume, and this process has been demonstrated to be nearly universally lethal to cells.

The combination of different injury mechanisms associated with rapid and slow cooling rates during freezing gives rise to a two-factor theory of cryoinjury [242, 243]. Between the extremes of rapid and slow cooling will be a range of intermediate rates at which survival will be maximized. The magnitude and breadth of this range are defined uniquely for each cell type as a function of its membrane permeability and sensitivity to injury. Cryopreservation protocols are targeted to produce a cooling process lying within the optimal range of this survival signature that will produce the highest possible biological function following thawing. The design of a cryopreservation protocol for a given cell type must take into account the combined effects of the CPA composition and concentration plus the cooling and warming rates [244, 245]. A true optimal process design can be conducted based on the availability of relevant constitutive properties of cell species of interest and models for the behavior of cells during the ice nucleation, freezing, and thawing events [246].

The preceding analysis of the freezing process is presented from the perspective of the local thermal history for an individual cell. However, practical cryopreservation procedures are conducted on tissues and organs of finite macroscopic dimensions or on containers of solutions of cells or microscopic tissue suspensions. The consequence is that, although the governing mass transport processes occur across microscopic scale dimensions (a single membrane and the associated boundary layers may be less than 0.1 μm), the governing heat transport occurs on a scale measured in millimeters or centimeters. It is this macroscopic heat transfer that drives all components of the cryopreservation process. Because of the macroscopic dimensions and the restriction that the refrigeration source be applied only at the external boundary of the systems during cooling, significant spatial gradients in cooling rate can be manifested within the system.

Also, in general the cooling rate will not be constant over the entire cooling process; it should be defined over the range of temperatures most important to determining the frozen state of a cell. The critical temperature range is defined as that for which transport occurs across the cell membrane and for which intracellular ice formation (IIF) is most probable. Analysis of this process involves solution of the classic Stefan moving boundary problem. For the freezing of biological systems, it is most important to determine the cooling at high subzero temperatures accurately within the mushy zone [247] during which the primary membrane transport processes occur.

It is precisely this range of temperatures for which simplifying assumptions concerning the pattern of latent heat release are frequently made in order to render the mathematical solution more tractable. Therefore, it is important to match as well as possible the coupling between temperature and changing solute concentration as defined by the phase diagram. Only when the actual process physics are matched can the cooling rate for the critical temperature range be described accurately. The combination of a nonlinear pattern of latent heat release with temperature and the often complex system geometry dictates that the governing heat transport equations be solved via numerical methods. The thermal histories calculated may then be correlated with the cooling rates on the survival signature and with the membrane mass transport equations, such as Equation (4.10.83), to predict the biological response of a given tissue to a defined boundary cooling protocol [248].

Thermal Stress Effects

Another analysis problem to be addressed in cryopreservation is that of thermal stresses in a frozen or vitrified organ. The paucity of constitutive property data for the thermal expansion of biological tissues and solutions in the subzero temperature range has been long standing. Recently, intial experiments have been conducted to make these measurements [249, 250]. It is apparent that a biological tissue with dimensions on the order of several centimeters will be subject to fracture at even moderate cooling rates below –120°C after a glass phase has formed [251]. A mechanical fracture of a whole organ will render it useless for subsequent transplantation. It is important to measure the viscoelastic properties of biological materials loaded with high concentrations of CPA over the temperature range between the glass transition and storage temperatures (usually at or near liquid nitrogen temperature at –196°C).

Complementary to the property measurements is a need for a thermal stress analysis that can be applied with versatility of geometric details. Rubinsky et al. [252] have developed a model for how mechanical stresses may develop in the interior of an organ during solidification and the subsequent cooling process. Different organs have widely divergent shapes and sizes, and constitutive property data for frozen and vitrified tissues are practically nonexistent. In addition, an organ is likely to be preserved in a container of fluid with which it will be coupled thermally and mechanically. Factors to be considered in a process design are: manipulation of the boundary thermal protocol; shape of the overall container into which an organ is placed; and coordination of the pattern of distributed internal deposition with cooling at the boundary.

Recent Developments and Innovations

Recent innovative experiments by Fowler and Toner [253] have demonstrated that it is possible at the micro (cellular) scale to melt and recool cells containing intracellular ice at a rate that can produce a vitrified state without the introduction of the CPA to block the initial ice nucleation event. The frozen specimen is irradiated with a laser wavelength that is absorbed preferentially by the cell cytoplasm over the extracellular solution. For a solution of individual cells having characteristic diameters of about 6 μm, warming rates on the order of 10^{11}°C/s can be achieved within the cells, while the extracellular matrix remains frozen.

When the heating process is terminated in an approximate step-wise manner after 7 ns, heat transfer from the extracellular matrix to the cells produces an intracellular cooling rate of about 10^{6}°C/s, which is adequate to produce a glass state in an aqueous solution. The vitrified cells may then be warmed rapidly to suprafreezing temperatures (>0°C) without nucleation and with no measured injury. If this process is to realize broad clinical or commercial application, considerable engineering work must be accomplished in scale-up from these microscopic level processes to applications in larger tissue and organ systems.

Since the initial achievements in the cryopreservation of cells, many applications have been developed in the biological and medical fields. Numerous for-profit concerns have now developed successful techniques for preserving human tissues for subsequent transplantation. Many of these corporations use proprietary processing protocols to preserve specific tissues; the number of commercial participants in this field has been growing steadily over the past 10 years. In like manner, many for-profit and not-for-profit groups are marketing the cryopreservation of a very broad spectrum of nonhuman tissues. Some of the more prominent applications involve mammalian and amphibian gametes, tissue culture collections, and plant germplasm.

A potentially important new area of application will be the cryopreservation of living materials manufactured by tissue engineering techniques being developed [254]. Bioartificial systems such as skin and organs that contain living cells will require a technology for maintaining them in a viable but latent state between the time of manufacture and implementation in a clinical setting. Cryopreservation provides a tool of suitable potential for meeting this unique need, but the processing protocols will need to be designed to ensure successful storage and recovery for each type of manufactured tissue.

Studies are progressing on the cryopreservation of numerous types of engineered cells and tissues [255–258]. Realization of the potential for cryopreservation in these new application arenas will be facilitated by parallel developments in instrumentation and analaysis techniques that enable more accurate and subtle measurements of the processes and properties that govern cellular and tissue response to freezing and thawing. An example is the identification and measurement of the energy associated with the subzero transport of water across cell membranes [259–262].

Cryosurgery

All of the foregoing discussion has been devoted to cryopreservation, for which the objective is to maximize the survival of cells from the frozen state to ensure their living function after thawing. The antithesis of this work is cryosurgery, for which the objective is to maximize destruction of a target tissue *in situ* [263]. Cryosurgery has long been practiced as an effective means for killing surface lesions; recently, it has been adopted more widely as a tool for treating internal tumors that are difficult to resect mechanically [264].

Many of the recent gains in the successful application of cryosurgery are due to the development of new imaging methods that enable the surgeon to follow the growth of the solid–liquid interface, to which the zone of cellular destruction is coupled, in real time during the freezing process. The initial imaging methodology adapted for this purpose was ultrasonography [265]. Subsequently, other imaging modalities that can be coupled to the transient temperature field are being developed, including NMR [266–268]; spectroscopy [269]; and electrical impedance [270]. Advances in cryosurgical probes that provide more effective removal of heat from tissues via enhanced thermal transport mechanisms have also contributed to the recent growth in cryosurgery [271]. Finally, over the past decade there has been a steady advance in understanding the mechanisms by which freezing and thawing act to cause tissue death as a function of the thermal parameters of the solidification process and tissue properties. Many of these fundamental advances have resulted from the application of bioengineering analysis of the tissue freezing process [272–276], which portends the potential for engineering to contribute further to the field of cryosurgery.

A new approach to improving the efficacy of cryosurgery is derived from techniques long applied to enhance cryopreservation processes. Namely, the tissue is modified by adding a chemical agent prior to the initiation of freezing. However, for applications in cryosurgery, the desired result is an increased level of cell killing. Antifreeze proteins (AFP) are proving to be effective for this purpose [277–279]. AFPs are chemical compounds synthesized by many differing types of plants and animals to provide protection against freezing injury at high subzero temperatures [280, 281]. It has also been demonstrated that AFPs modify ice crystals to needle-like shapes that can destroy cells during freezing to deeper subzero temperatures [282].

In summary, clearly there continue to be many opportunities for contributions in low-temperature biological heat transfer with the potential for substantial positive impact on health care delivery.

Acknowledgments

This paper was prepared with the support of National Science Foundation grants no. CTS-9632378 to KRD and no. DBI-9512746 to KRD; NIH grant #1 R01 HL56143-01 to JWV, and the Joe J. King Professorship in Engineering at the University of Texas at Austin. The perfusion measurements were supported in part by a grant to JWV from Urologix Inc. The sections on convective heat transfer and thermal properties of swine myocardium were derived from N.C. Bhavaraju's [283] and I. dos Santos' Ph.D. dissertations [43]. In a similar fashion, the sections on thermal models and microsphere perfusion measurements in the canine prostate were derived from D. Yuan's Ph.D. dissertation [284]. Collaborations with colleagues in writing prior reviews in bioheat transfer are acknowledged. In particular, we note

Dr. Sharon Thomsen's contribution to the subsection on histologic markers of thermal damage and Dr. Thomas Ryan's broad review [285].

Nomenclature

σ (S/m)	electrical conductivity
ε'' (F/m)	electric permittivity
$\lvert E \rvert$ (V/m)	magnitude of local electric field
ω	angular frequency (r/s)
μ	magnetic permeability (H/m)
α (m^{-1})	acoustic absorption coefficient
E (W/m^2)	wave power density
f (Hz)	frequency
A	a frequency factor (s^{-1})
τ	the total heating time (s)(s^{-1}) frequency factor
E	activation energy barrier (J/mol)

The following physiological properties were compiled by Kenneth R. Holmes <krholmes@ux1.cso.uiuc.edu> and were published in part previously [286]. The tabulation includes values for the native thermal conductivity of biomaterials (Appendix A) and the blood perfusion rates for specific tissues and organs (Appendix B). Original sources are documented in the dedicated list of references at the end of each appendix. Knowledge of the perfusion behavior of tissues is important in that the flow of blood can have a direct quantitative effect on the temperature distribution within living tissue.

Appendix A

Thermal Conductivity Data for Specific Tissues and Organs for Humans and Other Mammalian Species

Tissue	k (W/mK)	%H_2O	Ref.
Kidney			
Whole (rabbit)	.502	81	6
Whole (rabbit)	.495		16
Whole (human)	.543	84	4
Cortex (rabbit)	.465–.490 ($n = 7$)	76.6–79.81	
Cortex (dog)	.491		16
Cortex (human)	.499		16
Medulla (rabbit)	.502–.544 ($n = 7$)	82.0–86.0	1
Medulla (dog)	.507		16
Medulla (human)	.499		16
Aorta			
Human	.476 ± .041 (SD) ($n = 12$)		2

Tissue	k (W/mK)	%H_2O	Ref.
Arterial plaque			
Fatty	.484 ± .044 (SD) (n = 13)		2
Fibrous	.485 ± .022 (SD) (n = 12)		2
Calcified	.502 ± .059 (SD) (n = 17)		2
Artery			
Femoral (dog)	.391		2
Carotid (dog)	.448		2
Blood			
Whole	.505		10
Whole (human)	.492 ± .009 (SD) (n = 10)		5
Plasma	.582		10
Plasma (human)	.570 ± .010 (SD) (n = 10)		5
Spleen			
Human	.543	80	4
Liver			
Rabbit	.493	72	6
Rat	.498–.528 (n = 4)		3
Sheep	.495 ± .017 (SD) (n = 9)		5
Dog	.550 ± .010 (SD) (n = 7)		5
Dog	.574		11
Pig	.498		16
Human	.469		16
Human	.564	77	4
Heart			
Rat	.521–.531 (n = 2)		3
Dog	.527		11
Dog	.487		16
Pig	.484		
Human	.493		16
Human	.585	81	4
Muscle			
Rat	.505–.530 (n = 7)		3
Cow	.410–.426		7
Pig	.518–.618		7
Pig	.460		17
Sheep	.478 ± .019 (SD) (n = 10)		5
Fat			
Cow	.185–.233		7
Cow	.222		17
Pig	.317–.402		
Pig	.159		
Blubber (Minke whale)	.200–.280	3–30	
Blubber (Harp seal)	.190 ± .010		8
Human	.201–.217		17
Brain			
Whole	.527	78	4
Cerebral cortex	.564	83	4
Cerebral cortex	.504		16
White matter	.502	71	4
Tumor			
Periphery	.511		11
Core	.561		
Colon cancer (human)	.545		
Bone	.410–.630		15
Skin	.210–.410		
Crocodile, middle of back	.432		12
Crocodile, tail, ventral	.334		12

Tissue	k (W/mK)	%H_2O	13
Epidermis (elephant; freeze/thaw)	.475	62.5	14
Epidermis (rhinoceros; freeze/thaw)	.452	60.1	14
Giraffe (formalin fixed)	.442	60.0	14
Epidermis (human)	.209		17
Epidermis (pig)	.209		17
Dermis (human)	.293–.322		17
Pure water	.627		17

Notes: $c = [\%H_2O + 0.4 * (100 - \%H_2O)] * 41.9$ J/kg K; $\rho = 1.05(10^3)$ kg/m^3. (From Balasubramaniam, T.A. and Bowman, H.F., Biomech. Eng., 99, 148–154, 1977.

Electrical Engineering

Giorgio Rizzoni
Ohio State University

5.1 Introduction

The role played by electrical and electronic engineering in mechanical systems has dramatically increased in importance in the past two decades, thanks to advances in integrated circuit electronics and in materials that have permitted the integration of sensing, computing, and actuation technology into industrial systems and consumer products. Examples of this integration revolution, which has been referred to as a new field called *Mechatronics*, can be found in consumer electronics (auto-focus cameras, printers, microprocessor-controlled appliances), in industrial automation, and in transportation systems, most notably in passenger vehicles. The aim of this chapter is to review and summarize the foundations of electrical engineering for the purpose of providing the practicing mechanical engineer a quick and useful reference to the different fields of electrical engineering. Special emphasis has been placed on those topics that are likely to be relevant to product design.

5.2 Fundamentals of Electric Circuits

This section presents the fundamental laws of circuit analysis and serves as the foundation for the study of electrical circuits. The fundamental concepts developed in these first pages will be called on through the chapter.

The fundamental electric quantity is **charge**, and the smallest amount of charge that exists is the charge carried by an electron, equal to

$$q_e = -1.602 \times 10^{-19} \text{ coulomb} \tag{5.2.1}$$

As you can see, the amount of charge associated with an electron is rather small. This, of course, has to do with the size of the unit we use to measure charge, the **Coulomb** (C), named after Charles Coulomb. However, the definition of the coulomb leads to an appropriate unit when we define electric current, since current consists of the flow of very large numbers of charge particles. The other charge-carrying particle in an atom, the proton, is assigned a positive sign and the same magnitude. The charge of a proton is

$$q_p = +1.602 \times 10^{-19} \text{ coulomb} \tag{5.2.2}$$

Electrons and protons are often referred to as **elementary charges**.

Electric current is defined as the time rate of change of charge passing through a predetermined area. If we consider the effect of the enormous number of elementary charges actually flowing, we can write this relationship in differential form:

$$i = \frac{dq}{dt} \frac{\text{C}}{\text{s}} \tag{5.2.3}$$

The units of current are called **amperes** (A), where 1 A = 1 C/sec. The electrical engineering convention states that the positive direction of current flow is that of positive charges. In metallic conductors, however, current is carried by negative charges; these charges are the free electrons in the conduction band, which

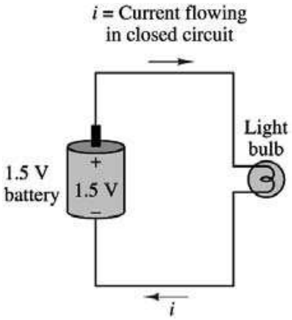

FIGURE 5.2.1 A simple electrical circuit.

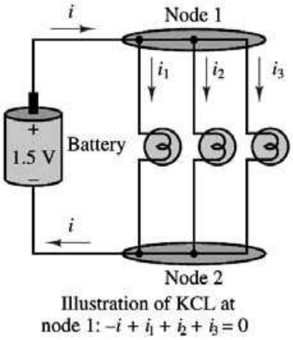

FIGURE 5.2.2 Illustration of Kirchhoff's current law.

are only weakly attracted to the atomic structure in metallic elements and are therefore easily displaced in the presence of electric fields.

In order for current to flow there must exist a closed circuit, Figure 5.2.1 depicts a simple circuit, composed of a battery (e.g., a dry-cell or alkaline 1.5-V battery) and a light bulb.

Note that in the circuit of Figure 5.2.1, the current, *i*, flowing from the battery to the resistor is equal to the current flowing from the light bulb to the battery. In other words, no current (and therefore no charge) is "lost" around the closed circuit. This principle was observed by the German scientist G.R. Kirchhoff and is now known as **Kirchhoff's current law** (KCL). KCL states that because charge cannot be created but must be conserved, *the sum of the currents at a node must equal zero* (in an electrical circuit, a **node** is the junction of two or more conductors). Formally:

$$\sum_{n=1}^{N} i_n = 0 \qquad \text{Kirchhoff' s current law} \tag{5.2.4}$$

The significance of KCL is illustrated in Figure 5.2.2, where the simple circuit of Figure 5 has been augmented by the addition of two light bulbs (note how the two nodes that exist in this circuit have been emphasized by the shaded areas). In applying KCL, one usually defines currents entering a node as being negative and currents exiting the node as being positive. Thus, the resulting expression for the circuit of Figure 5.2.2 is

$$-i + i_1 + i_2 + i_3 = 0$$

Charge moving in an electric circuit gives rise to a current, as stated in the preceding section. Naturally, it must take some work, or energy, for the charge to move between two points in a circuit, say, from point *a* to point *b*. The total *work per unit charge* associated with the motion of charge between two points is called **voltage**. Thus, the units of voltage are those of energy per unit charge:

$$1 \text{ volt} = \frac{1 \text{ joule}}{\text{coulomb}} \tag{5.2.5}$$

- The voltage, or **potential difference,** between two points in a circuit indicates the energy required to move charge from one point to the other. As will be presently shown, the direction, or polarity, of the voltage is closely tied to whether energy is being dissipated or generated in the process. The seemingly abstract concept of work being done in moving charges can be directly applied to the analysis of electrical circuits; consider again the simple circuit consisting of a battery and a light bulb. The circuit is drawn again for convenience in Figure 5.2.3, and nodes are defined by the letters *a* and *b*. A series of carefully conducted experimental observations regarding the nature of voltages in an electric circuit led Kirchhoff to the formulation of the second of his laws, **Kirchhoff's voltage law,** or KVL. The principle underlying KVL is that no energy is lost or created in an electric circuit; in circuit terms, the sum of all voltages associated with sources must equal the sum of the load voltages, so that *the net voltage around a closed circuit is zero.* If this were not the case, we would need to find a physical explanation for the excess (or missing) energy not accounted for in the voltages around a circuit. KVL may be stated in a form similar to that used for KCL:

$$\sum_{n=1}^{N} v_n = 0 \quad \text{Kirchhoff's voltage law} \tag{5.2.6}$$

where the v_n are the individual voltages around the closed circuit. Making reference to Figure 5.2.3, we can see that it must follow from KVL that the work generated by the battery is equal to the energy dissipated in the light bulb to sustain the current flow and to convert the electric energy to heat and light:

$$v_{ab} = -v_{ba}$$

or

$$v_1 = v_2$$

One may think of the work done in moving a charge from point *a* to point *b* and the work done moving it back from *b* to *a* as corresponding directly to the *voltages across individual circuit elements.* Let *Q* be the total charge that moves around the circuit per unit time, giving rise to the current *i.* Then the work done in moving *Q* from *b* to *a* (i.e., across the battery) is

$$W_{ba} = Q \times 1.5 \text{ V} \tag{5.2.7}$$

Similarly, work is done in moving *Q* from *a* to *b*, that is, across the light bulb. Note that the word *potential* is quite appropriate as a synonym of voltage, in that voltage represents the potential energy between two points in a circuit: if we remove the light bulb from its connections to the battery, there still exists a voltage across the (now disconnected) terminals *b* and *a*.

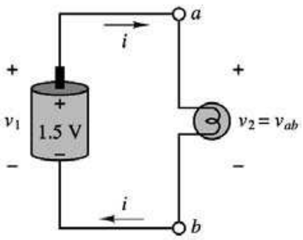

Illustration of Kirchhoff's voltage law: $v_1 = v_2$

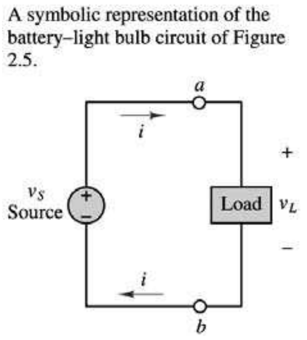
FIGURE 5.2.3 Voltages around a circuit.



A symbolic representation of the battery–light bulb circuit of Figure 2.5.

FIGURE 5.2.4 Sources and loads in an electrical circuit.

A moment's reflection upon the significance of voltage should suggest that it must be necessary to specify a sign for this quantity. Consider, again, the same dry-cell or alkaline battery, where, by virtue of an electrochemically induced separation of charge, a 1.5-V potential difference is generated. The potential generated by the battery may be used to move charge in a circuit. The rate at which charge is moved once a closed circuit is established (i.e., the current drawn by the circuit connected to the battery) depends now on the circuit element we choose to connect to the battery. Thus, while the voltage across the battery represents the potential for *providing energy* to a circuit, the voltage across the light bulb indicates the amount of work done in *dissipating energy*. In the first case, energy is generated; in the second, it is consumed (note that energy may also be stored, by suitable circuit elements yet to be introduced). This fundamental distinction required attention in defining the sign (or polarity) of voltages.

We shall, in general, refer to elements that provide energy as **sources**, and to elements that dissipate energy as **loads**. Standard symbols for a generalized source-and-load circuit are shown in Figure 5.2.4. Formal definitions will be given in a later section.

Electric Power and Sign Convention

The definition of voltage as work per unit charge lends itself very conveniently to the introduction of power. Recall that power is defined as the work done per unit time. Thus, the power, *P*, either generated or dissipated by a circuit element can be represented by the following relationship:

$$\text{Power} = \frac{\text{Work}}{\text{Time}} = \frac{\text{Work}}{\text{Unit charge}}\frac{\text{Charge}}{\text{Time}} = \text{Voltage} \times \text{Current} \tag{5.2.8}$$

Thus, the electrical power generated by an active element, or that dissipated or stored by a passive element, is equal to the product of the voltage across the element and the current flowing through it.

$$P = VI \tag{5.2.9}$$

It is easy to verify that the units of voltage (joules/coulomb) times current (coulombs/second) are indeed those of power (joules/second, or watts).

It is important to realize that, just like voltage, power is a signed quantity, and that it is necessary to make a distinction between *positive* and *negative power*. This distinction can be understood with reference to Figure 5.2.5, in which a source and a load are shown side by side. The polarity of the voltage across the source and the direction of the current through it indicate that the voltage source *is doing work in moving charge from a lower potential to a higher potential*. On the other hand, the load is dissipating energy, because the direction of the current indicates that *charge is being displaced from a higher potential to a lower potential*. To avoid confusion with regard to the sign of power, the electrical engineering community uniformly adopts the **passive sign convention**, which simply states that *the power dissipated by a load is a positive quantity* (or, conversely, that the power generated by a source is a positive quantity). Another way of phrasing the same concept is to state that if current flows from a higher to a lower voltage (+ to –), the power dissipated will be a positive quantity.

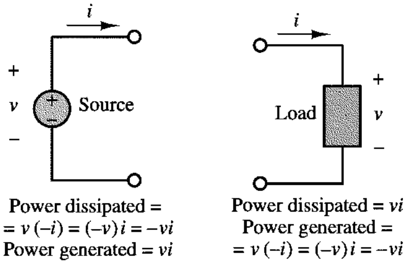


FIGURE 5.2.5 The passive sign convention.

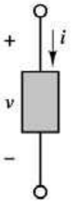

FIGURE 5.2.6 Generalized representation of circuit elements.

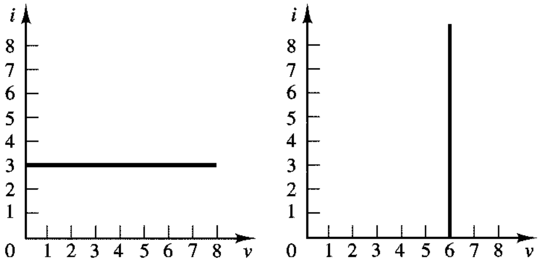
Circuit Elements and Their *i-v* Characteristics

The relationship between current and voltage at the terminals of a circuit element defines the behavior of that element within the circuit. In this section, we shall introduce a graphical means of representing the terminal characteristics of circuit elements. Figure 5.2.6 depicts the representation that will be employed throughout the chapter to denote a generalized circuit element: the variable i represents the current flowing through the element, while v is the potential difference, or voltage, across the element.

Suppose now that a known voltage were imposed across a circuit element. The current that would flow as a consequence of this voltage, and the voltage itself, form a unique pair of values. If the voltage applied to the element were varied and the resulting current measured, it would be possible to construct a functional relationship between voltage and current known as the ***i-v* characteristic** (or **volt-ampere characteristic**). Such a relationship defines the circuit element, in the sense that if we impose any prescribed voltage (or current), the resulting current (or voltage) is directly obtainable from the *i-v* characteristic. A direct consequence is that the power dissipated (or generated) by the element may also be determined from the *i-v* curve.

The *i-v* characteristics of ideal current and voltage sources can also be useful in visually representing their behavior. An ideal voltage source generates a prescribed voltage independent of the current drawn from the load; thus, its *i-v* characteristic is a straight vertical line with a voltage axis intercept corresponding to the source voltage. Similarly, the *i-v* characteristic of an ideal current source is a horizontal line with a current axis intercept corresponding to the source current. Figure 5.2.7 depicts this behavior.



i-v characteristic of a 3 A current source

i-v characteristic of a 6 V voltage source

Physical resistors with resistance *R*. Typical materials are carbon, metal film.

Circuit symbol

i-*v* characteristic

FIGURE 5.2.8 The resistance element.

Resistance and Ohm's Law

When electric current flows through a metal wire or through other circuit elements, it encounters a certain amount of **resistance,** the magnitude of which depends on the electrical properties of the material. Resistance to the flow of current may be undesired — for example, in the case of lead wires and connection cable — or it may be exploited in an electrical circuit in a useful way. Nevertheless, practically all circuit elements exhibit some resistance; as a consequence, current flowing through an element will cause energy to be dissipated in the form of heat. An ideal **resistor** is a device that exhibits linear resistance properties according to **Ohm's law,** which states that

$$V = IR \tag{5.2.10}$$

that is, that the voltage across an element is directly proportional to the current flow through it. *R* is the value of the resistance in units of **ohms** (Ω), where

$$1\,\Omega = 1\ \text{V/A} \tag{5.2.11}$$

The resistance of a material depends on a property called **resistivity,** denoted by the symbol ρ; the inverse of resistivity is called **conductivity** and is denoted by the symbol σ. For a cylindrical resistance element (shown in Figure 5.2.8), the resistance is proportional to the length of the sample, *l*, and inversely proportional to its cross-sectional area, A, and conductivity, σ.

$$v = \frac{l}{\sigma A} i \tag{5.2.12}$$

It is often convenient to define the **conductance** of a circuit element as the inverse of its resistance. The symbol used to denote the conductance of an element is *G*, where

$$G = \frac{1}{R}\ \text{siemens (S)} \quad \text{where} \quad 1\ \text{S} = 1\ \text{A/V} \tag{5.2.13}$$

Thus, Ohm's law can be rested in terms of conductance, as

$$I = GV \tag{5.2.14}$$

Ohm's law is an empirical relationship that finds widespread application in electrical engineering because of its simplicity. It is, however, only an approximation of the physics of electrically conducting materials. Typically, the linear relationship between voltage and current in electrical conductors does not

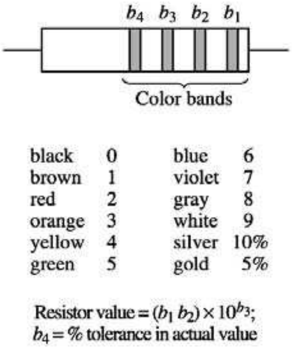

FIGURE 5.2.9 Resistor color code.

apply at very high voltages and currents. Further, not all electrically conducting materials exhibit linear behavior even for small voltages and currents. It is usually true, however, that for some range of voltages and currents, most elements display a linear *i-v characteristic.*

The typical construction and the circuit symbol of the resistor are shown in Figure 5.2.8. Resistors made of cylindrical sections of carbon (with resistivity $\rho = 3.5 \times 10^{-5}$ Ω-m) are very common and are commercially available in a wide range of values for several power ratings (as will be explained shortly). Another commonly employed construction technique for resistors employs metal film. A common power rating for resistors used in electronic circuits (e.g., in most consumer electronic appliances such as radios and television sets) is $^1/_4$ W. Table 5.2.1 lists the standard values for commonly used resistors and the color code associated with these values (i.e., the common combinations of the digits $b_1 b_2 b_3$ as defined in Figure 5.2.9. For example, if the first three color bands on a resistor show the colors red ($b_1 = 2$), violet ($b_2 = 7$), and yellow ($b_3 = 4$), the resistance value can be interpreted as follows:

$$R = 27 \times 10^4 = 270{,}000\ \Omega = 270\ \text{k}\Omega$$

In Table 5.2.1, the leftmost column represents the complete color code; columns to the right of it only show the third color, since this is the only one that changes. For example, a 10-Ω resistor has the code brown-black-*black*, while a 100-Ω resistor has brown-black-*brown.*

In addition to the resistance in ohms, the maximum allowable power dissipation (or **power rating**) is typically specified for commercial resistors. Exceeding this power rating leads to overheating and can cause the resistor to literally start on fire. For a resistor R, the power dissipated is given by

$$P = VI = I^2 R = \frac{V^2}{R} \tag{5.2.15}$$

That is, the power dissipated by a resistor is proportional to the square of the current flowing through it, as well as the square of the voltage across it. The following example illustrates how one can make use of the power rating to determine whether a given resistor will be suitable for a certain application.

Example 5.2.1 Resistance Strain Gauges

A common application of the resistance concept to engineering measurements is the resistance **strain gauge**. Strain gauges are devices that are bonded to the surface of an object, and whose resistance varies as a function of the surface strain experienced by the object. Strain gauges may be used to perform measurements of strain, stress, force, torque, and pressure. Recall that the resistance of a cylindrical conductor of cross-sectional area A, length L, and conductivity σ is given by the expression

$$R = \frac{L}{\sigma A}$$

If the conductor is compressed or elongated as a consequence of an external force, its dimensions will change, and with them its resistance. In particular, if the conductor is stretched, its cross-sectional area will decrease and the resistance will increase. If the conductor is compressed, its resistance decreases, since the length, L, will decrease. The relationship between change in resistance and change in length is given by the gauge factor, G, defined by

$$\mathrm{G} = \frac{\Delta R/R}{\Delta L/L}$$

and since the strain ε is defined as the fractional change in length of an object by the formula

$$\varepsilon = \frac{\Delta L}{L}$$

the change in resistance due to an applied strain ε is given by the expression

$$\Delta R = R_0 G\varepsilon$$

where R_0 is the resistance of the strain gauge under no strain and is called the zero strain resistance. The value of G for resistance strain gauges made of metal foil is usually about 2.

Figure 5.2.10 depicts a typical foil strain gauge. The maximum strain that can be measured by a foil gauge is about 0.4 to 0.5%; that is , $\Delta L/L = 0.004$ to 0.005. For a 120-Ω gauge, this corresponds to a change in resistance of the order of 0.96 to 1.2 Ω. Although this change is resistance is very small, it can be detected by means of suitable circuitry. Resistance strain gauges are usually connected in a circuit called the Wheatstone bridge, which we analyze later in this section.

Open and Short Circuits

Two convenient idealizations of the resistance element are provided by the limiting cases of Ohm's law as the resistance of a circuit element approaches zero or infinity. A circuit element with resistance approaching zero is called a **short circuit**. Intuitively, one would expect a short circuit to allow for unimpeded flow of current. In fact, metallic conductors (e.g., short wires of large diameter) approximate the behavior of a short circuit. Formally, a short circuit is defined as a circuit element across which the voltage is zero, regardless of the current flowing through it. Figure 5.2.11 depicts the circuit symbol for an ideal short circuit.

Physically, any wire or other metallic conductor will exhibit some resistance, though small. For practical purposes, however, many elements approximate a short circuit quite accurately under certain conditions.

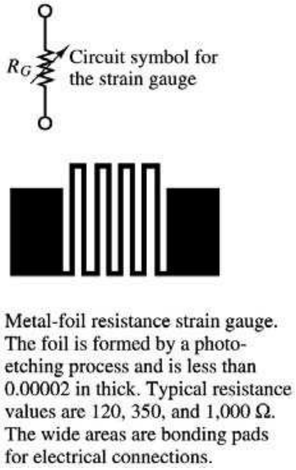

FIGURE 5.2.10 The resistance strain gauge.

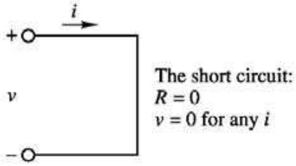

FIGURE 5.2.11 The short circuit.

TABLE 5.2.2 Resistance of Copper Wire

AWG Size	Number of Strands	Diameter per Strand	Resistance per 1000 ft (Ω)
24	Solid	0.0201	28.4
24	7	0.0080	28.4
22	Solid	0.0254	18.0
22	7	0.0100	19.0
20	Solid	0.0320	11.3
20	7	0.0126	11.9
18	Solid	0.0403	7.2
18	7	0.0159	7.5
16	Solid	0.0508	4.5
16	19	0.0113	4.7

For example, a large-diameter copper pipe is effectively a short circuit in the context of a residential electrical power supply, while in a low-power microelectronic circuit (e.g., an FM radio) a short length of 24 gauge wire (refer to Table 5.2.2 for the resistance of 24 gauge wire) is a more than adequate short circuit.

A circuit element whose resistance approaches infinity is called an **open circuit**. Intuitively, one would expect no current to flow through an open circuit, since it offers infinite resistance to any current. In an open circuit, we would expect to see zero current regardless of the externally applied voltage. Figure 5.2.12 illustrates this idea.

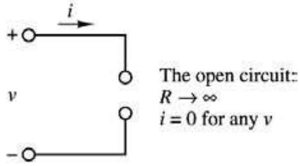

FIGURE 5.2.12 The open circuit.

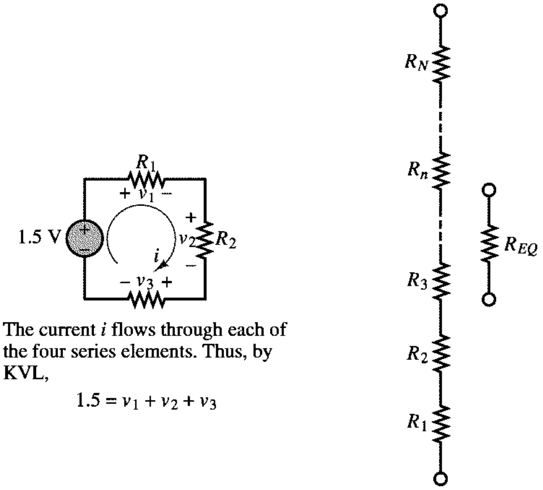


The current i flows through each of the four series elements. Thus, by KVL,

$$1.5 = v_1 + v_2 + v_3$$

N series resistors are equivalent to a single resistor equal to the sum of the individual resistances.

FIGURE 5.2.13 Voltage divider rule.

In practice, it is not too difficult to approximate an open circuit; any break in continuity in a conducting path amounts to an open circuit. The idealization of the open circuit, as defined in Figure 5.2.12 does not hold, however, for very high voltages. The insulating material between two insulated terminals will break down at a sufficiently high voltage. If the insulator is air, ionized particles in the neighborhood of the two conducting elements may lead to the phenomenon of arcing; in other words, a pulse of current may be generated that momentarily jumps a gap between conductors (thanks to this principle, we are able to ignite the air-fuel mixture in a spark-ignition internal combustion engine by means of spark plugs). The ideal open and short circuits are useful concepts and find extensive use in circuit analysis.

Series Resistors and the Voltage Divider Rule

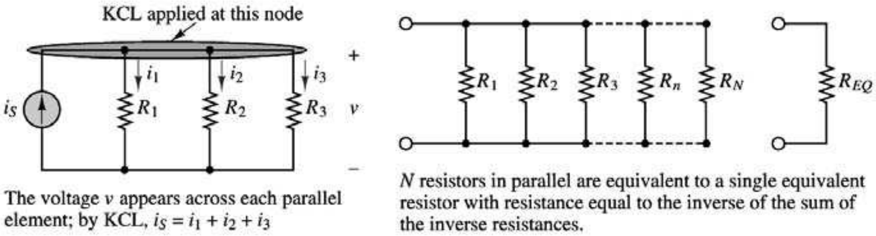
Although electrical circuits can take rather complicated forms, even the most involved circuits can be reduced to combinations of circuit elements *in parallel* and *in series*. Thus, it is important that you become acquainted with parallel and series circuits as early as possible, even before formally approaching the topic of network analysis. Parallel and series circuits have a direct relationship with Kirchhoff's laws. The objective of this section and the next is to illustrate two common circuits based on series and parallel combinations of resistors: the voltage and current dividers. These circuits form the basis of all network analysis; it is therefore important to master these topics as early as possible.

For an example of a series circuit, refer to the circuit of Figure 5.2.13, where a battery has been connected to resistors R_1, R_2, and R_3. The following definition applies.

Definition. Two or more circuit elements are said to be in series if the same current flows through each of the elements.

The three resistors could thus be replaced by a single resistor of value R_{EQ} without changing the amount of current required of the battery. From this result we may extrapolate to the more general relationship defining the equivalent resistance of N series resistors:

$$R_{EQ} = \sum_{n=1}^{N} R_n \tag{5.2.16}$$



The voltage v appears across each parallel element; by KCL, $i_S = i_1 + i_2 + i_3$

N resistors in parallel are equivalent to a single equivalent resistor with resistance equal to the inverse of the sum of the inverse resistances.

FIGURE 5.2.14 Parallel circuits.

which is also illustrated in Figure 5.2.13. A concept very closely tied to series resistors is that of the **voltage divider**.

The general form of the voltage divider rule for a circuit with N series resistors and a voltage source is

$$v_n = \frac{R_n}{R_1 + R_2 + \ldots + R_n + \ldots + R_N} v_S \tag{5.2.17}$$

Parallel Resistors and the Current Divider Rule

A concept analogous to that of the voltage may be developed by applying Kirchhoff's current law to a circuit containing only parallel resistances.

Definition. Two or more circuit elements are said to be in parallel if the same voltage appears across each of the elements. (See Figure 5.2.14.)

N resistors in parallel act as a single equivalent resistance, R_{EQ}, given by the expression

$$\frac{1}{R_{EQ}} = \frac{1}{R_1} + \frac{1}{R_2} + \ldots + \frac{1}{R_N} \tag{5.2.18}$$

or

$$R_{EQ} = \frac{1}{1/R_1 + 1/R_2 + \ldots + 1/R_N} \tag{5.2.19}$$

Very often in the remainder of this book we shall refer to the parallel combination of two or more resistors with the following notation:

$$R_1 \parallel R_2 \parallel \cdots$$

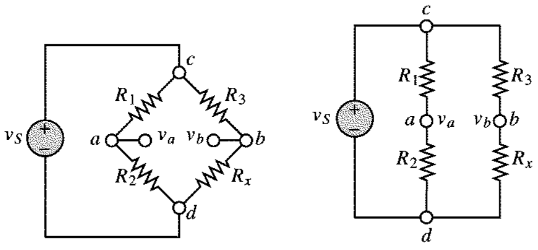
where the symbol $\parallel$ signifies "in parallel with."

The general expression for the current divider for a circuit with N parallel resistors is the following:

$$i_n = \frac{1/R_n}{1/R_1 + 1/R_2 + \ldots + 1/R_n + \ldots + 1/R_N} i_S \quad \text{Current divider} \tag{5.2.20}$$

Example 5.2.2 The Wheatstone Bridge

The **Wheatstone bridge** is a resistive circuit that is frequently encountered in a variety of measurement circuits. The general form of the bridge is shown in Figure 5.2.15(a), where R_1, R_2, and R_3 are known, while R_x is an unknown resistance, to be determined. The circuit may also be redrawn as shown in Figure 5.2.15(b). The latter circuit will be used to demonstrate the use of the voltage divider rule in a mixed series-parallel circuit. The objective is to determine the unknown resistance R_x.



(a) (b)

FIGURE 5.2.15 Wheatstone bridge circuits.

1. Find the value of the voltage $v_{ad} = v_{ad} - v_{bd}$ in terms of the four resistances and the source voltage, v_s. Note that since the reference point d is the same for both voltages, we can also write $v_{ab} = v_a - v_b$.
2. If $R_1 = R_2 = R_3 = 1\ \text{k}\Omega$, $v_s = 12$ V, and $v_{ab} = 12$ mV, what is the value of R_x?

Solution.

1. First, we observe that the circuit consists of the parallel combination of three subcircuits: the voltage source, the series combination of R_1 and R_2, and the series combination of R_3 and R_x. Since these three subcircuits are in parallel, the same voltage will appear across each of them, namely, the source voltage, v_s.

   Thus, the source voltage divides between each resistor pair, R_1-R_2 and R_3-R_x, according to the voltage divider rule: v_a is the fraction of the source voltage appearing across R_2, while v_b is the voltage appearing across R_x:

$$v_a = v_S \frac{R_2}{R_1 + R_2} \quad \text{and} \quad v_b = v_S \frac{R_x}{R_3 + R_x}$$

   Finally, the voltage difference between points a and b is given by:

$$v_{ab} = v_a - v_b = v_S \left(\frac{R_2}{R_1 + R_2} - \frac{R_x}{R_3 + R_x} \right)$$

   This result is very useful and quite general, and it finds application in numerous practical circuits.
2. In order to solve for the unknown resistance, we substitute the numerical values in the preceding equation to obtain

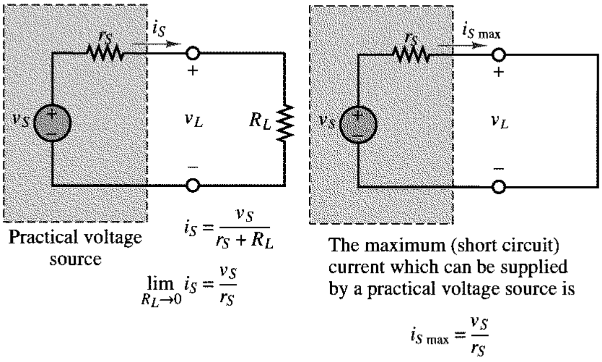
$$0.012 = 12 \left(\frac{1{,}000}{2{,}000} - \frac{R_x}{1{,}000 + R_x} \right)$$

   which may be solved for R_x to yield

$$R_x = 996\ \Omega$$

Practical Voltage and Current Sources

Idealized models of voltage and current sources fail to take into consideration the finite-energy nature of practical voltage and current sources. The objective of this section is to extend the ideal models to



Practical voltage source

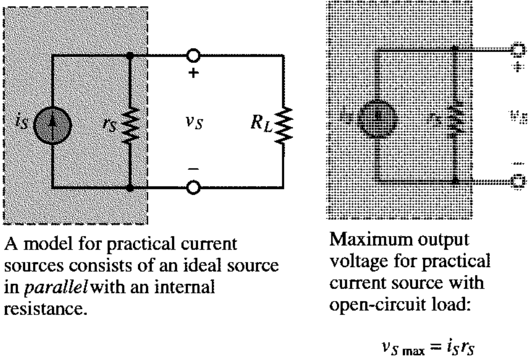
$i_S = \frac{v_S}{r_S + R_L}$

$\lim_{R_L \to 0} i_S = \frac{v_S}{r_S}$

The maximum (short circuit) current which can be supplied by a practical voltage source is

$i_{S\,\max} = \frac{v_S}{r_S}$

FIGURE 5.2.16 Practical voltage source.



A model for practical current sources consists of an ideal source in *parallel* with an internal resistance.

Maximum output voltage for practical current source with open-circuit load:

$v_{S\,\max} = i_S r_S$

FIGURE 5.2.17 Practical current source.

models that are capable of describing the physical limitations of the voltage and current sources used in practice. Consider, for example, the model of an ideal voltage source. As the load resistance (R) decreases, the source is required to provide increasing amounts of current to maintain the voltage $v_s(t)$ across its terminal:

$$i(t) = \frac{v_S(t)}{R} \tag{5.2.21}$$

This circuit suggests that the ideal voltage source is required to provide an infinite amount of current to the load, in the limit as the load resistance approaches zero.

Figure 5.2.16 depicts a model for a practical voltage source; this is composed of an ideal voltage source, v_s, in series with a resistance, r_s. The resistance r_s in effect poses a limit to the maximum current the voltage source can provide:

$$i_{S\,\max} = \frac{v_S}{r_S} \tag{5.2.22}$$

It should be apparent that a desirable feature of an ideal voltage source is a very small internal resistance, so that the current requirements of an arbitrary load may be satisfied.

A similar modification of the ideal current source model is useful to describe the behavior of a practical current source. The circuit illustrated in Figure 5.2.17 depicts a simple representation of a practical current source, consisting of an ideal source in parallel with a resistor. Note that as the load resistance approaches infinity (i.e., an open circuit), the output voltage of the current source approaches its limit,

$$v_{S\max} = i_S r_S \tag{5.2.23}$$

A good current source should be able to approximate the behavior of an ideal current source. Therefore, a desirable characteristic for the internal resistance of a current source is that it be as large as possible.

Measuring Devices

The Ammeter

The **ammeter** is a device that, when connected in series with a circuit element, can measure the current flowing through the element. Figure 5.2.18 illustrates this idea. From Figure 5.2.18, two requirements are evident for obtaining a correct measurement of current:

1. The ammeter must be placed in series with the element whose current is to be measured (e.g., resistor R_2).
2. The ammeter should not resist the flow of current (i.e., cause a voltage drop), or else it will not be measuring the true current flowing the circuit. *An ideal ammeter has zero internal resistance.*

The Voltmeter

The **voltmeter** is a device that can measure the voltage across a circuit element. Since voltage is the difference in potential between two points in a circuit, the voltmeter needs to be connected across the element whose voltage we wish to measure. A voltmeter must also fulfill two requirements:

1. The voltmeter must be placed in parallel with the element whose voltage it is measuring.
2. The voltmeter should draw no current away from the element whose voltage it is measuring, or else it will not be measuring the true voltage across that element. Thus, *an ideal voltmeter has infinite internal resistance.*

Figure 5.2.19 illustrates these two points.

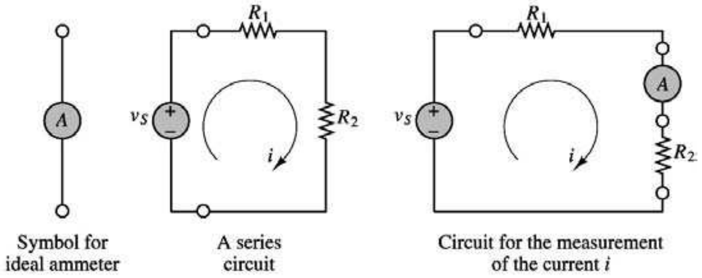


FIGURE 5.2.18 Measurement of current.

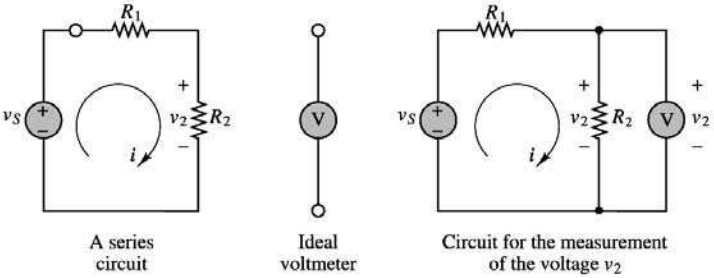

FIGURE 5.2.19 Measurement of voltage.

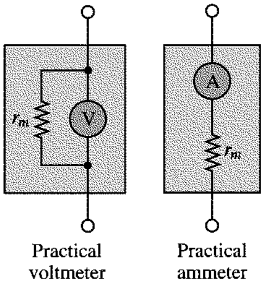

FIGURE 5.2.20 Models for practical ammeter and voltmeter.

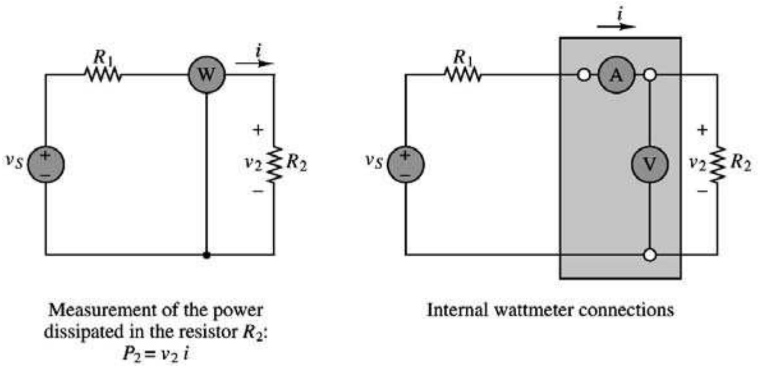

FIGURE 5.2.21 Measurement of power.

Once again, the definitions just stated for the ideal voltmeter and ammeter need to be augmented by considering the practical limitations of the devices. A practical ammeter will contribute some series resistance to the circuit in which it is measuring current; a practical voltmeter will not act as an ideal open circuit but will always draw some current from the measured circuit. Figure 5.2.20 depicts the circuit models for the practical ammeter and voltmeter.

All of the considerations that pertain to practical ammeters and voltmeters can be applied to the operation of a **wattmeter**, a measuring instrument that provides a measurement of the power dissipated by a circuit element, since the wattmeter is in effect made up of a combination of a voltmeter and an ammeter.

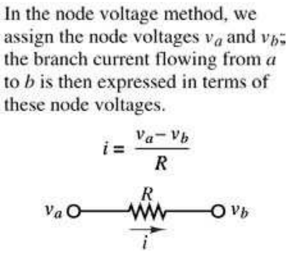
Figure 5.2.21 depicts the typical connection of a wattmeter in the same series circuit used in the preceding paragraphs. In effect, the wattmeter measures the current flowing through the load and, simultaneously, the voltage across it and multiplies the two to provide a reading of the power dissipated by the load.

5.3 Resistive Network Analysis

This section will illustrate the fundamental techniques for the analysis of resistive circuits. The methods introduced are based on Kirchhoff's and Ohm's laws. The main thrust of the section is to introduce and illustrate various methods of circuit analysis that will be applied throughout the book.

The Node Voltage Method

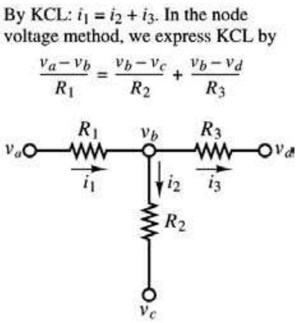
Node voltage analysis is the most general method for the analysis of electrical circuits. In this section, its application to linear resistive circuits will be illustrated. The **node voltage method** is based on defining the voltage at each node as an independent variable. One of the nodes is selected as a **reference node**



In the node voltage method, we assign the node voltages v_a and v_b; the branch current flowing from a to b is then expressed in terms of these node voltages.

$$i = \frac{v_a - v_b}{R}$$

FIGURE 5.3.1 Branch current formulation in nodal analysis.



By KCL: $i_1 = i_2 + i_3$. In the node voltage method, we express KCL by

$$\frac{v_a - v_b}{R_1} = \frac{v_b - v_c}{R_2} + \frac{v_b - v_d}{R_3}$$

FIGURE 5.3.2 Use of KCL in nodal analysis.

(usually — but not necessarily — ground), and each of the other node voltages is referenced to this node. Once each node voltage is defined, Ohm's law may be applied between any two adjacent nodes in order to determine the current flowing in each branch. In the node voltage method, *each branch current is expressed in terms of one or more node voltages;* thus, currents do not explicitly enter into the equations. Figure 5.3.1 illustrates how one defines branch currents in this method.

Once each branch current is defined in terms of the node voltages, Kirchhoff's current law is applied at each node. The particular form of KCL employed in the nodal analysis equates the sum of the currents into the node to the sum of the currents leaving the node:

$$\sum i_{\text{in}} = \sum i_{\text{out}} \tag{5.3.1}$$

Figure 5.3.2 illustrates this procedure.

The systematic application of this method to a circuit with n nodes would lead to writing n linear equations. However, one of the node voltages is the reference voltage and is therefore already known, since it is usually assumed to be zero. Thus, we can write $n - 1$ *independent linear equations* in the $n - 1$ independent variables (the node voltages). Nodal analysis provides the minimum number of equations required to solve the circuit, since any branch voltage or current may be determined from knowledge of nodal voltages.

The nodal analysis method may also be defined as a sequence of steps, as outlined below.

Node Voltage Analysis Method

1. Select a reference node (usually ground). All other node voltages will be referenced to this node.
2. Define the remaining $n - 1$ node voltages as the independent variables.
3. Apply KCL at each of the $n - 1$ nodes, expressing each current in terms of the adjacent node voltages.
4. Solve the linear system of $n - 1$ equations in $n - 1$ unknowns.

In a circuit containing n nodes we can write at most $n - 1$ independent equations.

The current i, defined as flowing from left to right, establishes the polarity of the voltage across R.

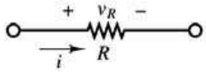


FIGURE 5.3.3 Basic principle of mesh analysis.

Once the direction of current flow has been selected, KVL requires that $v_1 = v_2 + v_3$.

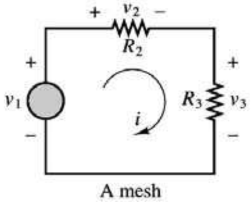

FIGURE 5.3.4 Use of KVL in mesh analysis.

The Mesh Current Method

In the mesh current method, we observe that a current flowing through a resistor in a specified direction defines the polarity of the voltage across the resistor, as illustrated in Figure 5.3.3, and that the sum of the voltages around a closed circuit must equal zero, by KVL. Once a convention is established regarding the direction of current flow around a mesh. Simple application of KVL provides the desired equation. Figure 5.3.4 illustrates this point.

The number of equations one obtains by this technique is equal to the number of meshes in the circuit. All branch currents and voltages may subsequently be obtained from the mesh currents, as will presently be shown. Since meshes are easily identified in a circuit, this method provides a very efficient and systematic procedure for the analysis of electrical circuits. The following section outlines the procedure used in applying the mesh current method to a linear circuit.

Mesh Current Analysis Method

1. Define each mesh current consistently. We shall always define mesh currents clockwise, for convenience.
2. Apply KVL around each mesh, expressing each voltage in terms of one or more mesh currents.
3. Solve the resulting linear system of equations with mesh currents as the independent variables.

In mesh analysis, it is important to be consistent in choosing the direction of current flow. To avoid confusion in writing the circuit equations, mesh currents will be defined exclusively clockwise when we are using this method.

One-Port Networks and Equivalent Circuits

This general circuit representation is shown in Figure 5.3.5. This configuration is called a **one-port network** and is particularly useful for introducing the notion of equivalent circuits. Note that the network of Figure 5.3.5 is completely described by its *i*-*v* characteristic.

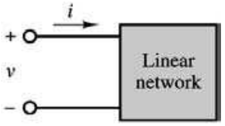

FIGURE 5.3.5 One-port network.

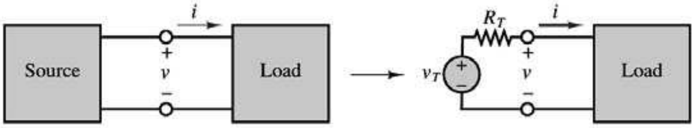

FIGURE 5.3.6 Illustration of Thévenin theorem.

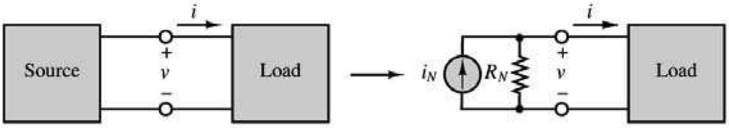

FIGURE 5.3.7 Illustration of Norton theorem.

Thévenin and Norton Equivalent Circuits

This section discusses one of the most important topics in the analysis of electrical circuits: the concept of an **equivalent circuit.** It will be shown that it is always possible to view even a very complicated circuit in terms of much simpler *equivalent* source and load circuits, and that the transformations leading to equivalent circuits are easily managed, with a little practice. In studying node voltage and mesh current analysis, you may have observed that there is a certain correspondence (called **duality**) between current sources and voltage sources, on the one hand, and parallel and series circuits, on the other. This duality appears again very clearly in the analysis of equivalent circuits: it will shortly be shown that equivalent circuits fall into one of two classes, involving either voltage or current sources and (respectively) either series or parallel resistors, reflecting this same principle of duality. The discussion of equivalent circuits begins with the statement of two very important theorems, summarized in Figure 5.3.6 and Figure 5.3.7.

The Thévenin Theorem. As far as a load is concerned, any network composed of ideal voltage and current sources, and of linear resistors, may be represented by an equivalent circuit consisting of an ideal voltage source, v_T, in series with an equivalent resistance, R_T.

The Norton Theorem. As far as a load is concerned, any network composed of ideal voltage and current sources, and of linear resistors, may be represented by an equivalent circuit consisting of an ideal current source, i_N, in parallel with an equivalent resistance, R_N.

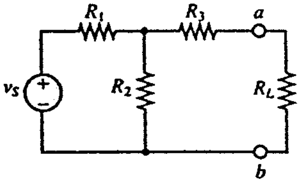
Determination of Norton or Thévenin Equivalent Resistance

The first step in computing a Thévenin or Norton equivalent circuit consists of finding the equivalent resistance presented by the circuit at its terminals. This is done by setting all sources in the circuit equal to zero and computing the effective resistance between terminals. The voltage and current sources present in the circuit are set to zero as follows: voltage sources are replaced by short circuits, current sources by open circuits. We can produce a set of simple rules as an aid in the computation of the Thévenin (or Norton) equivalent resistance for a linear resistive circuit.

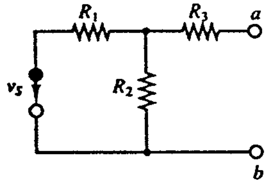
Computation of Equivalent Resistance of a One-Port Network:

1. Remove the load.
2. Zero all voltage and current sources
3. Compute the total resistance between load terminals, *with the load removed.* This resistance is equivalent to that which would be encountered by a current source connected to the circuit in place of the load.

These rules are summarized in Figure 5.3.8.



Complete circuit



Circuit with load removed for computation of R_T. The voltage source is replaced by a short circuit.

FIGURE 5.3.8 Computation of Thévenin resistance.

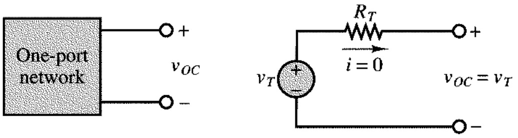


FIGURE 5.3.9 Equivalence of open-circuit and Thévenin voltage.

Computing the Thévenin Voltage

The Thévenin equivalent voltage is defined as follows: the equivalent (Thévenin) source voltage is equal to the **open-circuit voltage** present at the load terminals with the load removed.

This states that in order to compute v_T, it is sufficient to remove the load and to compute the open-circuit voltage at the one-port terminals. Figure 5.3.9 illustrates that the open-circuit voltage, v_{OC}, and the Thévenin voltage, v_T, must be the same if the Thévenin theorem is to hold. This is true because in the circuit consisting of v_T and R_T, the voltage v_{OC} must equal v_T, since no current flows through R_T and therefore the voltage across R_T is zero. Kirchhoff's voltage law confirms that

$$v_T = R_T(0) + v_{OC} = v_{OC} \tag{5.3.2}$$

Computing the Norton Current

The computation of the Norton equivalent current is very similar in concept to that of the Thévenin voltage. The following definition will serve as a starting point.

Definition. The Norton equivalent current is equal to the short-circuit current that would flow were the load replaced by a short circuit.

An explanation for the definition of the Norton current is easily found by considering, again, an arbitrary one-port network, as shown in Figure 5.3.10, where the one-port network is shown together with its Norton equivalent circuit.

It should be clear that the current, i_{SC}, flowing through the short circuit replacing the load is exactly the Norton current, i_N, since all of the source current in the circuit of Figure 5.3.10 must flow through the short circuit.

Experimental Determination of Thévenin and Norton Equivalents

Figure 5.3.11 illustrates the measurement of the open-circuit voltage and short-circuit current for an arbitrary network connected to any load and also illustrates that the procedure requires some special

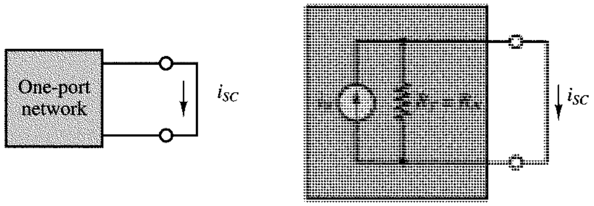

FIGURE 5.3.10 Illustration of Norton equivalent circuit.

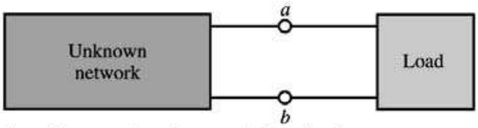
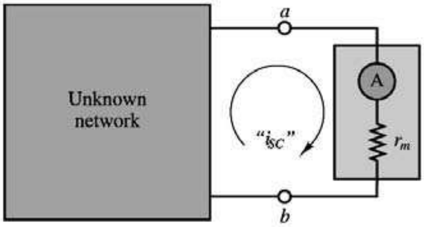
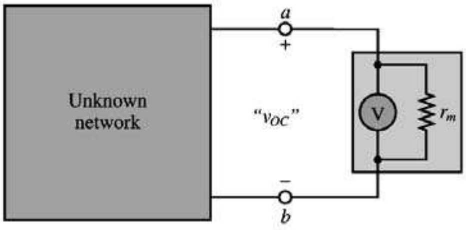


An unknown network connected to a load



Network connected for measurement of short-circuit current



Network connected for measurement of open-circuit voltage

FIGURE 5.3.11 Measurement of open-circuit voltage and short-circuit current.

attention, because of the nonideal nature of any practical measuring instrument. The figure clearly illustrates that in the presence of finite meter resistance, r_m, one must take this quantity into account in the computation of the short-circuit current and open-circuit voltage; v_{OC} and i_{SC} appear between quotation marks in the figure specifically to illustrate that the measured "open-circuit voltage" and "short-circuit current" are, in fact, affected by the internal resistance of the measuring instrument and are not the true quantities.

The following are expressions for the true short-circuit current and open-circuit voltage.

$$
\begin{aligned}
i_N &= "i_{SC}"\left(1+\frac{r_m}{R_T}\right) \\
v_T &= "v_{OC}"\left(1+\frac{R_T}{r_m}\right)
\end{aligned}
\tag{5.3.3}
$$

where i_N is the ideal Norton current, v_T the Thévenin voltage, and R_T the true Thévenin resistance.

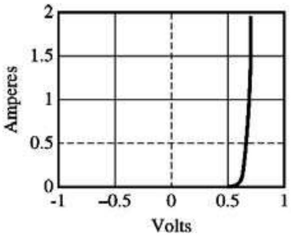


FIGURE 5.3.12 *i*-*v* characteristic of exponential resistor.

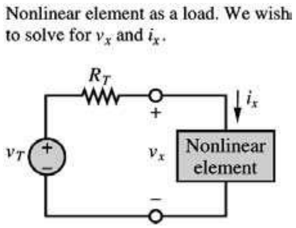

FIGURE 5.3.13 Representation of nonlinear element in a linear circuit.

Nonlinear Circuit Elements

Description of Nonlinear Elements

There are a number of useful cases in which a simple functional relationship exists between voltage and current in a nonlinear circuit element. For example, Figure 5.3.12 depicts an element with an exponential *i*-*v* characteristic, described by the following equations:

$$\begin{aligned} i &= I_0 e^{\alpha v} \qquad v > 0 \\ i &= -I_0 \qquad v \le 0 \end{aligned} \tag{5.3.4}$$

There exists, in fact, a circuit element (the semiconductor diode) that very nearly satisfies this simple relationship. The difficulty in the *i*-*v* relationship of Equation (5.3.4) is that it is not possible, in general, to obtain a closed-form analytical solution, even for a very simple circuit.

One approach to analyzing a circuit containing a nonlinear element might be to treat the nonlinear element as a load, and to compute the Thévenin equivalent of the remaining circuit, as shown in Figure 5.3.13. Applying KVL, the following equation may then be obtained:

$$v_T = R_T i_x + v_x \tag{5.3.5}$$

To obtain the second equation needed to solve for both the unknown voltage, v_x, and the unknown current, i_x, it is necessary to resort to the *i*-*v* description of the nonlinear element, namely, Equation (5.3.4). If, for the moment, only positive voltages are considered, the circuit is completely described by the following system:

$$\begin{aligned} i_x &= I_0 e^{\alpha v_x} \qquad v > 0 \\ v_T &= R_T i_x + v_x \end{aligned} \tag{5.3.6}$$

The two parts of Equation (5.3.6) represent a system of two equations in two unknowns. Any numerical method of choice may now be applied to solve the system of Equations (5.3.6).

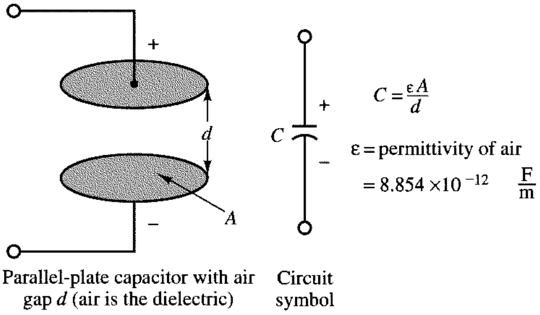

FIGURE 5.4.1 Structure of parallel-plate capacitor.

5.4 AC Network Analysis

In this section we introduce energy-storage elements, dynamic circuits, and the analysis of circuits excited by sinusoidal voltages and currents. Sinusoidal (or AC) signals constitute the most important class of signals in the analysis of electrical circuits. The simplest reason is that virtually all of the electric power used in households and industries comes in the form of sinusoidal voltages and currents.

Energy-Storage (Dynamic) Circuit Elements

The ideal resistor was introduced through Ohm's law in Section 5.2 as a useful idealization of many practical electrical devices. However, in addition to resistance to the flow of electric current, which is purely a dissipative (i.e., an energy-loss) phenomenon, electric devices may also exhibit energy-storage properties, much in the same way a spring or a flywheel can store mechanical energy. Two distinct mechanisms for energy storage exist in electric circuits: **capacitance** and **inductance**, both of which lead to the storage of energy in an electromagnetic field.

The Ideal Capacitor

A physical capacitor is a device that can store energy in the form of a charge separation when appropriately polarized by an electric field (i.e., a voltage). The simplest capacitor configuration consists of two parallel conducting plates of cross-sectional area A, separated by air (or another **dielectric**[1] material, such as mica or Teflon). Figure 5.4.1 depicts a typical configuration and the circuit symbol for a capacitor.

The presence of an insulating material between the conducting plates does not allow for the flow of DC current; thus, *a capacitor acts as an open circuit in the presence of DC currents*. However, if the voltage present at the capacitor terminals changes as a function of time, so will the charge that has accumulated at the two capacitor plates, since the degree of polarization is a function of the applied electric field, which is time-varying. In a capacitor, the charge separation caused by the polarization of the dielectric is proportional to the external voltage, that is, to the applied electric field:

$$Q = CV \tag{5.4.1}$$

where the parameter C is called the *capacitance* of the element and is a measure of the ability of the device to accumulate, or store, charge. The unit of capacitance is the coulomb/volt and is called the **farad** (F). The farad is an unpractically large unit; therefore, it is common to use microfarads (1 μF = 10^{-6} F) or picofarads (1 pF = 10^{-12} F). From Equation (5.4.1) it becomes apparent that if the external voltage applied to the capacitor plates changes in time, so will the charge that is internally stored by the capacitor:

---

[1] A dielectric material contains a large number of electric dipoles, which become polarized in the presence of an electric field.

$$q(t) = Cv(t) \tag{5.4.2}$$

Thus, although no current can flow through a capacitor if the voltage across it is constant, a time-varying voltage will cause charge to vary in time. The change with time in the stored charge is analogous to a current. The relationship between the current and voltage in a capacitor is as follows:

$$i(t) = C\frac{dv(t)}{dt} \tag{5.4.3}$$

If the above differential equation is integrated, one can obtain the following relationship for the voltage across a capacitor:

$$v_C(t) = \frac{1}{C}\int_{-\infty}^{t_0} i_C \, dt \tag{5.4.4}$$

Equation (5.4.4) indicates that the capacitor voltage depends on the past current through the capacitor, up until the present time, *t*. Of course, one does not usually have precise information regarding the flow of capacitor current for all past time, and so it is useful to define the initial voltage (or *initial condition*) for the capacitor according to the following, where t_0 is an arbitrary initial time:

$$V_0 = v_C(t = t_0) = \frac{1}{C}\int_{-\infty}^{t} i_C \, dt \tag{5.4.5}$$

The capacitor voltage is now given by the expression

$$v_C(t) = \frac{1}{C}\int_{t_0}^{t} i_C \, dt + V_0 \qquad t \geq t_0 \tag{5.4.6}$$

The significance of the initial voltage, V_0, is simply that at time t_0 some charge is stored in the capacitor, giving rise to a voltage, $v_c\,(t_0)$, according to the relationship $Q = CV$. Knowledge of this initial condition is sufficient to account for the entire past history of the capacitor current. (See Figure 5.4.2.)

From the standpoint of circuit analysis, it is important to point out that capacitors connected in series and parallel can be combined to yield a single equivalent capacitance. The rule of thumb, which is illustrated in Figure 5.4.3, is the following: capacitors in parallel add; capacitors in series combine according to the same rules used for resistors connected in parallel.

Physical capacitors are rarely constructed of two parallel plates separated by air, because this configuration yields very low values of capacitance, unless one is willing to tolerate very large plate areas. In

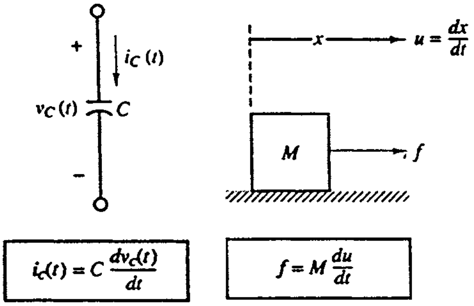

FIGURE 5.4.2 Defining equation for the ideal capacitor, and analogy with force-mass system.

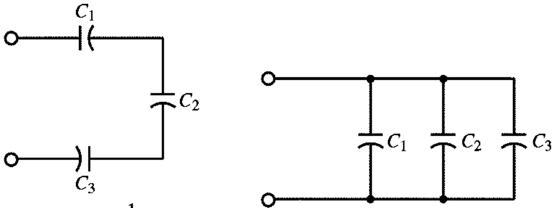

$$C_{EQ} = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3}}$$

Capacitances in series combine like resistors in parallel

$$C_{EQ} = C_1 + C_2 + C_3$$

Capacitances in parallel add

FIGURE 5.4.3 Combining capacitors in a circuit.

TABLE 5.4.1 Capacitors

Material	Capacitance Range	Maximum Voltage (V)	Frequency Range (Hz)
Mica	1 pF to 0.1 μF	100–600	10^3–10^{10}
Ceramic	10 pF to 1 μF	50–1000	10^3–10^{10}
Mylar	0.001 to 10 μF	50–500	10^2–10^8
Paper	1,000 pF to 50 μF	100–105	10^2–10^8
Electrolytic	0.1 μF to 0.2 F	3–600	10–10^4

order to increase the capacitance (i.e., the ability to store energy), physical capacitors are often made of tightly rolled sheets of metal film, with a dielectric (paper or Mylar) sandwiched in-between. Table 5.4.1 illustrates typical values, materials, maximum voltage ratings, and useful frequency ranges for various types of capacitors. The voltage rating is particularly important, because any insulator will break down if a sufficiently high voltage is applied across it.

The energy stored in a capacitor is given by:

$$W_C(t) = \frac{1}{2} C v_C^2(t) \quad \text{(J)}$$

Example 5.4.1 Capacitive Displacement Transducer and Microphone

As shown in Figure 5.3.5, the capacitance of a parallel-plate capacitor is given by the expression

$$C = \frac{\varepsilon A}{d}$$

where ε is the **permittivity** of the dielectric material, A the area of each of the plates, and d their separation. The permittivity of air is $\varepsilon_0 = 8.854 \times 10^{-12}$ F/m, so that two parallel plates of area 1 m^2, separated by a distance of 1 mm, would give rise to a capacitance of 8.854×10^{-3} μF, a very small value for a very large plate area. This relative inefficiency makes parallel-plate capacitors impractical for use in electronic circuits. On the other hand, parallel-plate capacitors find application as *motion transducers*, that is, as devices that can measure the motion or displacement of an object. In a capacitive motion transducer, the air gap between the plates is designed to be variable, typically by fixing one plate and connecting the other to an object in motion. Using the capacitance value just derived for a parallel-plate capacitor, one can obtain the expression

$$C = \frac{8.854 \times 10^{-3}\ A}{x}$$

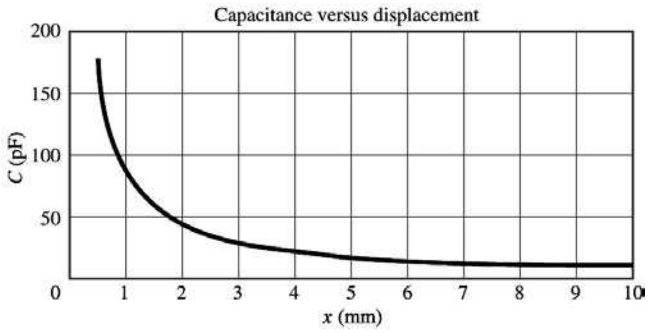

FIGURE 5.4.4 Response of a capacitive displacement transducer.

where C is the capacitance in pF, A is the area of the plates in mm^2, and x is the (variable) distance in mm. It is important to observe that the change in capacitance caused by the displacement of one of the plates is nonlinear, since the capacitance varies as the inverse of the displacement. For small displacements, however, the capacitance varies approximately in a linear fashion.

The *sensitivity, S,* of this motion transducer is defined as the slope of the change in capacitance per change in displacement, x, according to the relation

$$S = \frac{dC}{dx} = -\frac{8.854 \times 10^{-3}\ A}{2x^2} \frac{\text{pF}}{\text{mm}}$$

Thus, the sensitivity increases for small displacements. This behavior can be verified by plotting the capacitance as a function of x and noting that as x approaches zero, the slope of the nonlinear $C(x)$ curve becomes steeper (thus the greater sensitivity). Figure 5.4.4 depicts this behavior for a transducer with area equal to 10 mm^2.

This simple capacitive displacement transducer actually finds use in the popular *capacitive (or condenser) microphone*, in which the sound pressure waves act to displace one of the capacitor plates. The change in capacitance can then be converted into a change in voltage or current by means of a suitable circuit. An extension of this concept that permits measurement of differential pressures is shown in simplified form in Figure 5.4.5. In the figure, a three-terminal variable capacitor is shown to be made up of two fixed surfaces (typically, spherical depressions ground into glass disks and coated with a conducting material) and of a deflecting plate (typically made of steel) sandwiched between the glass disks. Pressure inlet orifices are provided, so that the deflecting plate can come into contact with the fluid whose pressure it is measuring. When the pressure on both sides of the deflecting plate is the same, the capacitance between terminals b and d, C_{bd}, will be equal to that between terminals b and c, C_{bc}. If any pressure differential exists, the two capacitances will change, with an increase on the side where the deflecting plate has come closer to the fixed surface and a corresponding decrease on the other side.

This behavior is ideally suited for the application of a bridge circuit, similar to the Wheatstone bridge circuit illustrated in Example 5.3.1, and also shown in Figure 5.4.5. In the bridge circuit, the output voltage, v_{out}, is precisely balanced when the differential pressure across the transducer is zero, but it will deviate from zero whenever the two capacitances are not identical because of a pressure differential across the transducer. We shall analyze the bridge circuit later in Example 5.4.2.

The Ideal Inductor

The ideal inductor is an element that has the ability to store energy in a magnetic field. Inductors are typically made by winding a coil of wire around a core, which can be an insulator or a ferromagnetic material, shown in Figure 5.4.6. When a current flows through the coil, a magnetic field is established, as you may recall from early physics experiments with electromagnets. In an ideal inductor, the resistance of the wire is zero, so that a constant current through the inductor will flow freely without causing a

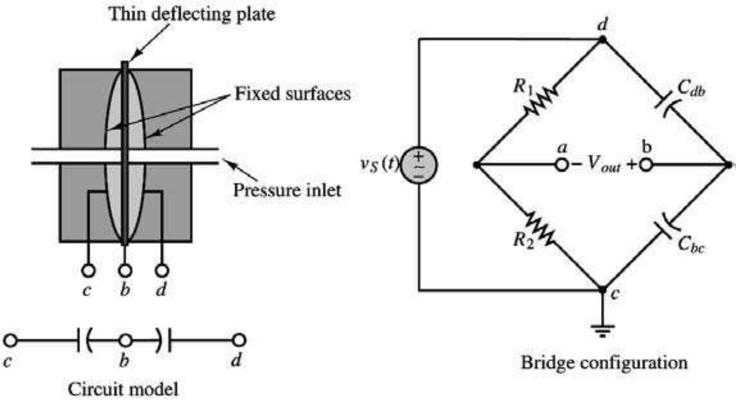

FIGURE 5.4.5 Capacitive pressure transducer and related bridge circuit.

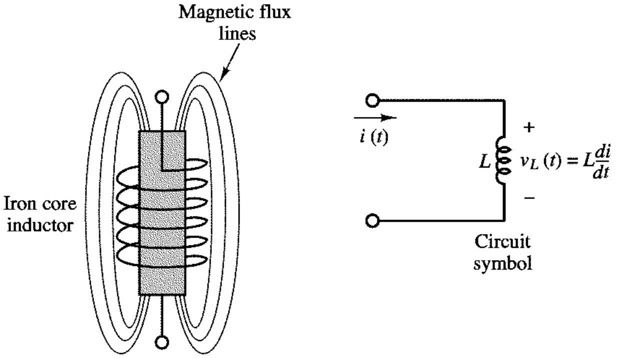

FIGURE 5.4.6 Iron-core inductor.

voltage drop. In other words, *the ideal inductor acts as a short circuit in the presence of DC currents.* If a time-varying voltage is established across the inductor, a corresponding current will result, according to the following relationship:

$$v_L(t) = L\frac{di_L}{dt} \tag{5.4.7}$$

where L is called the *inductance* of the coil and is measured **henry** (H), where

$$1\text{ H} = 1\text{ V-sec/A} \tag{5.4.8}$$

Henrys are reasonable units for practical inductors; millihenrys (mH) and microhenrys (μH) are also used.

The inductor current is found by integrating the voltage across the inductor:

$$i_L(t) = \frac{1}{L}\int_{-\infty}^{t} v_L\, dt \tag{5.4.9}$$

If the current flowing through the inductor at time $t = t_0$ is known to be I_0, with

$$I_0 = i_L(t = t_0) = \frac{1}{L}\int_{-\infty}^{t_0} v_L\, dt \tag{5.4.10}$$

then the inductor current can be found according to the equation

$$i_L(t) = \frac{1}{L}\int_{t_0}^{t} v_L \, dt + I_0 \qquad t \ge t_0 \tag{5.4.11}$$

Inductors in series add. Inductors in parallel combine according to the same rules used for resistors connected in parallel. See Figure 5.4.7 to Figure 5.4.9.

Table 5.4.2 and Figure 5.4.2, Figure 5.4.7, and Figure 5.4.9 illustrate a useful analogy between ideal electrical and mechanical elements.

The defining equation for the inductance circuit element is analogous to the equation of motion of a spring acted upon by a force.

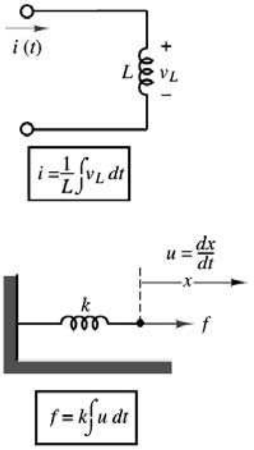

FIGURE 5.4.7 Defining equation for the ideal inductor and analogy with force-spring system.

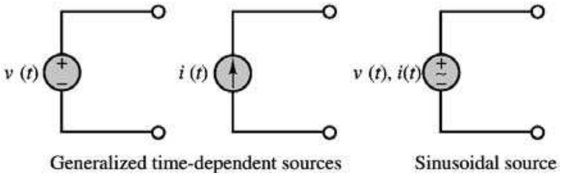

FIGURE 5.4.10 Time-dependent signal sosurces.

Time-Dependent Signal Sources

Figure 5.4.10 illustrates the convention that will be employed to denote time-dependent signal sources.

One of the most important classes of time-dependent signals is that of **periodic signals**. These signals appear frequently in practical applications and are a useful approximation of many physical phenomena. A periodic signal $x(t)$ is a signal that satisfies the following equation:

$$x(t) = x(t + nT) \qquad n = 1, 2, 3, \ldots \tag{5.4.12}$$

where T is the **period** of $x(t)$. Figure 5.4.11 illustrates a number of the periodic waveforms that are typically encountered in the study of electrical circuits. Waveforms such as the sine, triangle, square, pulse, and sawtooth waves are provided in the form of voltages (or, less frequently, currents) by commercially available **signal** (or **waveform**) **generators**. Such instruments allow for selection of the waveform peak amplitude, and of its period.

As stated in the introduction, sinusoidal waveforms constitute by far the most important class of time-dependent signals. Figure 5.4.12 depicts the relevant parameters of a sinusoidal waveform. A generalized sinusoid is defined as follows:

$$x(t) = A\cos(\omega t + \phi) \tag{5.4.13}$$

where A is the **amplitude**, ω the **radian frequency**, and ϕ the **phase**. Figure 5.4.12 summarizes the definitions of A, ω, and ϕ for the waveforms

$$x_1(t) = A\cos(\omega t) \quad \text{and} \quad x_2(t) = A\cos(\omega t + \phi)$$

where

$$\begin{aligned} f &= \text{natural frequency} = \frac{1}{T}(\text{cycles/sec, or Hz}) \\ \omega &= \text{radian frequency} = 2\pi f(\text{radians/sec}) \\ \phi &= 2\pi\frac{\Delta T}{T}(\text{radians}) = 360\frac{\Delta T}{T}(\text{degrees}) \end{aligned} \tag{5.4.14}$$

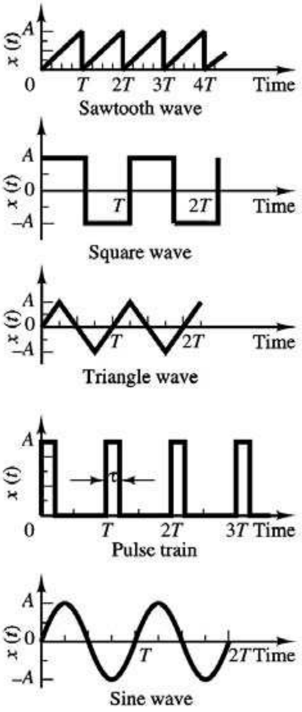

FIGURE 5.4.11 Periodic signal waveforms.

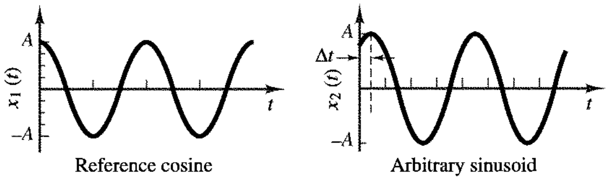

FIGURE 5.4.12 Sinusoidal waveforms.

The phase shift, ϕ, permits the representation of an arbitrary sinusoidal signal. Thus, the choice of the reference cosine function to represent sinusoidal signals — arbitrary as it may appear at first — does not restrict the ability to represent all sinusoids. For example, one can represent a sine wave in terms of a cosine wave simply by introducing a phase shift of π/2 radians:

$$A\sin(\omega t) = A\cos\left(\omega t - \frac{\pi}{2}\right) \tag{5.4.15}$$

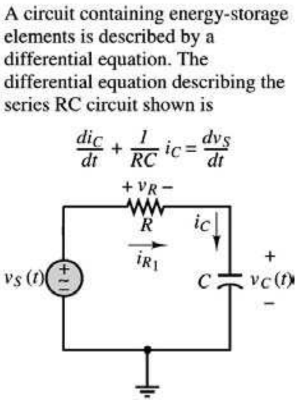
It is important to note that, although one usually employs the variable ω (in units of radians per second) to denote sinusoidal frequency, it is common to refer to natural frequency, *f*, in units of cycles per second, or **hertz** (Hz). The relationship between the two is the following:

$$\omega = 2\pi f \tag{5.4.16}$$

Average and RMS Values

Now that a number of different signal waveforms have been defined, it is appropriate to define suitable measurements for quantifying the strength of a time-varying electrical signal. The most common types of measurements are the **average** (or **DC**) **value** of a signal waveform — which corresponds to just

FIGURE 5.4.13 Averaging a signal waveform.



A circuit containing energy-storage elements is described by a differential equation. The differential equation describing the series RC circuit shown is

$$\frac{di_C}{dt}+\frac{1}{RC}i_C=\frac{dv_S}{dt}$$

FIGURE 5.4.14 Circuit containing energy-storage element.

measuring the mean voltage or current over a period of time — and the **root-mean-square** (or **rms**) **value**, which takes into account the fluctuations of the signal about its average value. Formally, the operation of computing the average value of a signal corresponds to integrating the signal waveform over some (presumably, suitably chosen) period of time. We define the time-averaged value of a signal $x(t)$ as

$$\langle x(t)\rangle=\frac{1}{T}\int_0^T x(t)\,dt \tag{5.4.17}$$

where T is the period of integration. Figure 5.4.13 illustrates how this process does, in fact, correspond to computing the average amplitude of $x(t)$ over a period of T seconds.

$$\langle A\cos(\omega t+\phi)\rangle=0$$

A useful measure of the voltage of an AC waveform is the root-mean-square, or rms, value of the signal, $x(t)$, defined as follows:

$$x_{rms}\sqrt{\frac{1}{T}\int_0^T x^2(t)\,dt} \tag{5.4.18}$$

Note immediately that if $x(t)$ is a voltage, the resulting x_{rms} will also have units of volts. If you analyze Equation (5.4.18), you can see that, in effect, the rms value consists of the square root of the average (or mean) of the square of the signal. Thus, the notation *rms* indicates exactly the operations performed on $x(t)$ in order to obtain its rms value.

Solution of Circuits Containing Dynamic Elements

The major difference between the analysis of the resistive circuits and circuits containing capacitors and inductors is now that the equations that result from applying Kirchhoff's laws are differential equations, as opposed to the algebraic equations obtained in solving resistive circuits. Consider, for example, the circuit of Figure 5.4.14 which consists of the series connection of a voltage source, a resistor, and a capacitor. Applying KVL around the loop, we may obtain the following equation:

$$v_S(t) = v_R(t) + v_C(t) \tag{5.4.19}$$

Observing that $i_R = i_C$, Equation (5.4.19) may be combined with the defining equation for the capacitor (Equation 4.6.6) to obtain

$$v_S(t) = Ri_C(t) + \frac{1}{C}\int_{-\infty}^{t} i_C \, dt \tag{5.4.20}$$

Equation (5.4.20) is an integral equation, which may be converted to the more familiar form of a differential equation by differentiating both sides of the equation, and recalling that

$$\frac{d}{dt}\left(\int_{-\infty}^{t} i_C \, dt\right) = i_C(t) \tag{5.4.21}$$

to obtain the following differential equation:

$$\frac{di_C}{dt} + \frac{1}{RC} i_C = \frac{1}{R}\frac{dv_S}{dt} \tag{5.4.22}$$

where the argument (t) has been dropped for ease of notation.

Observe that in Equation (5.4.22), the independent variable is the series current flowing in the circuit, and that this is not the only equation that describes the series *RC* circuit. If, instead of applying KVL, for example, we had applied KCL at the node connecting the resistor to the capacitor, we would have obtained the following relationship:

$$i_R = \frac{v_S - v_C}{R} = i_C = C\frac{dv_C}{dt} \tag{5.4.23}$$

or

$$\frac{dv_C}{dt} + \frac{1}{RC} v_C = \frac{1}{RC} v_S \tag{5.4.24}$$

Note the similarity between Equation (5.4.22) and Equation (5.4.24). The left-hand side of both equations is identical, except for the dependent variable, while the right-hand side takes a slightly different form. The solution of either equation is sufficient, however, to determine all voltages and currents in the circuit.

We can generalize the results above by observing that any circuit containing a single energy-storage element can be described by a differential equation of the form

$$a_1 \frac{dy(t)}{dt} + a_0(t) = F(t) \tag{5.4.25}$$

where $y(t)$ represents the capacitor voltage in the circuit of Figure 5.4.14 and where the constants a_0 and a_1 consist of combinations of circuit element parameters. Equation (5.4.25) is a **first-order ordinary differential equation** with constant coefficients.

Consider now a circuit that contains two energy-storage elements, such as that shown in Figure 5.4.15. Application of KVL results in the following equation:

$$Ri(t) + L\frac{di(t)}{dt} + \frac{1}{C}\int_{-\infty}^{t} i(t) \, dt = v_S(t) \tag{5.4.26}$$

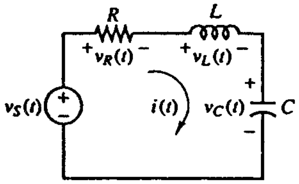


FIGURE 5.4.15 Second-order circuit.

Equation (5.4.26) is called an integro-differential equation because it contains both an integral and a derivative. This equation can be converted into a differential equation by differentiating both sides, to obtain:

$$R\frac{di(t)}{dt} + L\frac{d^2i(t)}{dt^2} + \frac{1}{C}i(t) = \frac{dv_S(t)}{dt} \tag{5.4.27}$$

or, equivalently, by observing that the current flowing in the series circuit is related to the capacitor voltage by $i(t) = Cdv_C/dt$, and that Equation (5.4.26) can be rewritten as:

$$RC\frac{dv_C}{dt} + LC\frac{d^2v_C(t)}{dt^2} + v_C(t) = v_S(t) \tag{5.4.28}$$

Note that although different variables appear in the preceding differential equations, both Equation (5.4.26) and Equation (5.4.28) can be rearranged to appear in the same general form, as follows:

$$a_2\frac{d^2y(t)}{dt^2} + a_1\frac{dy(t)}{dt} + a_0y(t) = F(t) \tag{5.4.29}$$

where the general variable $y(t)$ represents either the series current of the circuit of Figure 5.4.15 or the capacitor voltage. By analogy with Equation (5.4.25), we call Equation (5.4.29) a **second-order ordinary differential equation** with constant coefficients. As the number of energy-storage elements in a circuit increases, one can therefore expect that higher-order differential equations will result.

Phasors and Impedance

In this section, we introduce an efficient notation to make it possible to represent sinusoidal signals as *complex numbers*, and to eliminate the need for solving differential equations.

Phasors

Let us recall that it is possible to express a generalized sinusoid as the real part of a complex vector whose **argument**, or **angle**, is given by $(\omega t + \phi)$ and whose length, or **magnitude**, is equal to the peak amplitude of the sinusoid. The **complex phasor** corresponding to the sinusoidal signal $A\cos(\omega t + \phi)$ is therefore defined to be the complex number $Ae^{j\phi}$:

$$Ae^{j\phi} = \text{complex phasor notation for } A\cos(\omega t + \phi) \tag{5.4.30}$$

1. Any sinusoidal signal may be mathematically represented in one of two ways: a **time-domain form,**

$$v(t) = A\cos(\omega t + \phi)$$

   and a **frequency-domain** (or **phasor**) **form**.

$$\mathbf{V}(j\omega) = Ae^{j\phi}$$

2. A phasor is a complex number, expressed in polar form, consisting of a *magnitude* equal to the peak amplitude of the sinusoidal signal and a *phase angle* equal to the phase shift of the sinusoidal signal *referenced to a cosine signal.*
3. When using phasor notation, it is important to make a note of the specific frequency, ω, of the sinusoidal signal, since this is not explicitly apparent in the phasor expression.

Impedance

We now analyze the *i-v* relationship of the three ideal circuit elements in light of the new phasor notation. The result will be a new formulation in which resistors, capacitors, and inductors will be described in the same notation. A direct consequence of this result will be that the circuit theorems of Section 5.3 will be extended to AC circuits. In the context of AC circuits, any one of the three ideal circuit elements defined so far will be described by a parameter called **impedance**, which may be viewed as a *complex resistance*. The impedance concept is equivalent to stating that capacitors and inductors act as *frequency-dependent resistors*, that is, as resistors whose resistance is a function of the frequency of the sinusoidal excitation. Figure 5.4.16 depicts the same circuit represented in conventional form (top) and in phasor-impedance form (bottom); the latter representation explicitly shows phasor voltages and currents and treats the circuit element as a generalized "impedance". It will presently be shown that each of the three ideal circuit elements may be represented by one such impedance element.

Let the source voltage in the circuit of Figure 5.4.16 be defined by

$$v_S(t) = A\cos\omega t \quad \text{or} \quad \mathbf{V}_S(j\omega) = Ae^{j0^\circ} \tag{5.4.31}$$

without loss of generality. Then the current $i(t)$ is defined by the *i-v* relationship for each circuit element. Let us examine the frequency-dependent properties of the resistor, inductor, and capacitor, one at a time.

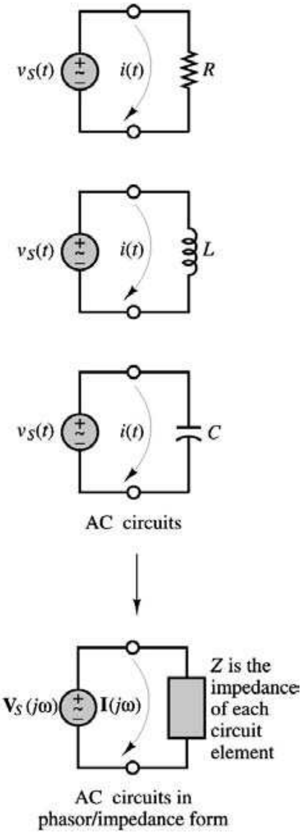

FIGURE 5.4.16 The impedance element.

The *impedance* of the resistor is defined as the ratio of the phasor voltage across the resistor to the phasor current flowing through it, and the symbol Z_R is used to denote it:

$$Z_R(j\omega) = \frac{\mathbf{V}_S(j\omega)}{\mathbf{I}(j\omega)} = R \tag{5.4.32}$$

The impedance of the inductor is defined as follows:

$$Z_L(j\omega) = \frac{\mathbf{V}_S(j\omega)}{\mathbf{I}(j\omega)} = \omega L e^{j90^\circ} = j\omega L \tag{5.4.33}$$

Note that the inductor now appears to behave like a *complex frequency-dependent resistor*, and that the magnitude of this complex resistor, ωL, is proportional to the signal frequency, ω. Thus, an inductor will "impede" current flow in proportion to the sinusoidal frequency of the source signal. This means that at low signal frequencies, an inductor acts somewhat like a short circuit, while at high frequencies it tends to behave more as an open circuit. Another important point is that *the magnitude of the impedance of an inductor is always positive*, since both L and ω are positive numbers. You should verify that the units of this magnitude are also ohms.

The impedance of the ideal capacitor, $Z_C(j\omega)$, is therefore defined as follows:

$$Z_C(j\omega) = \frac{\mathbf{V}_S(j\omega)}{\mathbf{I}(j\omega)} = \frac{1}{\omega C} e^{-j90^\circ} = \frac{-j}{\omega C} = \frac{1}{j\omega C} \tag{5.4.34}$$

where we have used the fact that $1/j = e^{-j90^\circ} = -j$. Thus, the impedance of a capacitor is also a frequency-dependent complex quantity, with the impedance of the capacitor varying as an inverse function of frequency; and so a capacitor acts like a short circuit at high frequencies, whereas it behaves more like an open circuit at low frequencies. Another important point is that *the impedance of a capacitor is always negative*, since both C and ω are positive numbers. You should verify that the units of impedance for a capacitor are ohms. Figure 5.4.17 depicts $Z_C(j\omega)$ in the complex plane, alongside $Z_R(j\omega)$ and $Z_L(j\omega)$.

The impedance parameter defined in this section is extremely useful in solving AC circuit analysis problems, because it will make it possible to take advantage of most of the network theorems developed

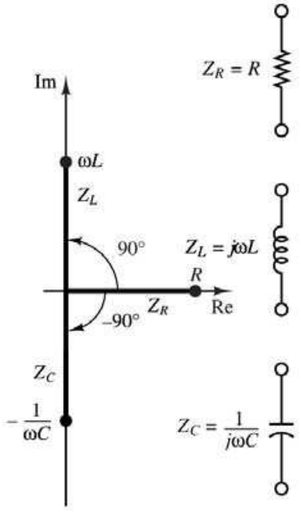

FIGURE 5.4.17 Impedances of *R*, *L*, and *C* in the complex plane.

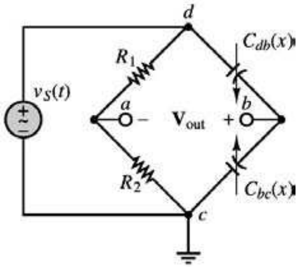

FIGURE 5.4.18 Bridge circuit for capacitive displacement transducer.

for DC circuits by replacing resistances with complex-valued impedances. In its most general form, the impedance of a circuit element is defined as the sum of a real part and an imaginary part:

$$Z(j\omega) = R(j\omega) + jX(j\omega) \tag{5.4.35}$$

where R is called the **AC resistance** and X is called the **reactance**. The frequency dependence of R and X has been indicated explicitly, since it is possible for a circuit to have a frequency-dependent resistance. The examples illustrate how a complex impedance containing both real and imaginary parts arises in a circuit.

Example 5.4.2 Capacitive Displacement Transducer

In Example 5.4.1, the idea of a capacitive displacement transducer was introduced when we considered a parallel-plate capacitor composed of a fixed plate and a movable plate. The capacitance of this variable capacitor was shown to be a *nonlinear* function of the position of the movable plate, x (see Figure 5.4.5). In this example, we show that under certain conditions the impedance of the capacitor varies as a *linear* function of displacement — that is, the movable-plate capacitor can serve as a linear transducer.

Recall the expression derived in Example 5.4.1:

$$C = \frac{8.854 \times 10^{-3} A}{x}$$

where C is the capacitance in pF, A is the area of the plates in mm^2, and x is the (variable) distance in mm. If the capacitor is placed in an AC circuit, its impedance will be determined by the expression

$$Z_C = \frac{1}{j\omega C}$$

so that

$$Z_C = \frac{x}{j\omega 8.854 A}$$

Thus, at a fixed frequency ω, the impedance of the capacitor will vary linearly with displacement. This property may be exploited in the bridge circuit of Example 5.4.1, where a differential pressure transducer was shown as being made of two movable-plate capacitors, such that if the capacitance of one increased as a consequence of a pressure differential across the transducer, the capacitance of the other had to decrease by a corresponding amount (at least for small displacements). The circuit is shown again in Figure 5.4.18 where two resistors have been connected in the bridge along with the variable capacitors (denoted by $C(x)$). The bridge is excited by a sinusoidal source.

Using phasor notation, we can express the output voltage as follows:

$$\mathbf{V}_{\text{out}}(j\omega) = \mathbf{V}_S(j\omega)\left(\frac{Z_{C_{bc}(x)}}{Z_{C_{db}(x)} + Z_{C_{bc}(x)}} - \frac{R_2}{R_1 + R_2}\right)$$

If the nominal capacitance of each movable-plate capacitor with the diaphragm in the center position is given by

$$C = \frac{\varepsilon A}{d}$$

where d is the nominal (undisplaced) separation between the diaphragm and the fixed surfaces of the capacitors (in mm), the capacitors will see a change in capacitance given by

$$C_{db} = \frac{\varepsilon A}{d - x} \quad \text{and} \quad C_{bc} = \frac{\varepsilon A}{d + x}$$

when a pressure differential exists across the transducer, so that the impedances of the variable capacitors change according to the displacement:

$$Z_{C_{db}} = \frac{d - x}{j\omega 8.854A} \quad \text{and} \quad Z_{C_{bc}} = \frac{d + x}{j\omega 8.854A}$$

and we obtain the following expression for the phasor output voltage, if we choose $R_1 = R_2$.

$$\begin{aligned}\mathbf{V}_{\text{out}}(j\omega) &= \mathbf{V}_S(j\omega)\left(\frac{\dfrac{d+x}{j\omega 8.854A}}{\dfrac{d-x}{j\omega 8.854A} + \dfrac{d+x}{j\omega 8.854A}} - \frac{R_2}{R_1 + R_2}\right) \\ &= \mathbf{V}_S(j\omega)\left(\frac{1}{2} + \frac{x}{2d} - \frac{R_2}{R_1 + R_2}\right) \\ &= \mathbf{V}_S(j\omega)\frac{x}{2d}\end{aligned}$$

Thus, the output voltage will vary as a scaled version of the input voltage in proportion to the displacement.

5.5 AC Power

The aim of this section is to introduce the student to simple AC power calculations, and to the generation and distribution of electric power.

Instantaneous and Average Power

The most general expressions for the voltage and current delivered to an arbitrary load are as follows:

$$\begin{aligned} v(t) &= V\cos(\omega t + \theta_v) \\ i(t) &= I\cos(\omega t + \theta_I) \end{aligned} \tag{5.5.1}$$

where V and I are the peak amplitudes of the sinusoidal voltage and current, respectively, and θ_V and θ_I are their angles. Two such waveforms are plotted in Figure 5.5.1, with unit amplitude and with phase angles $\theta_V = \pi/6$ and $\theta_I = \pi/3$.

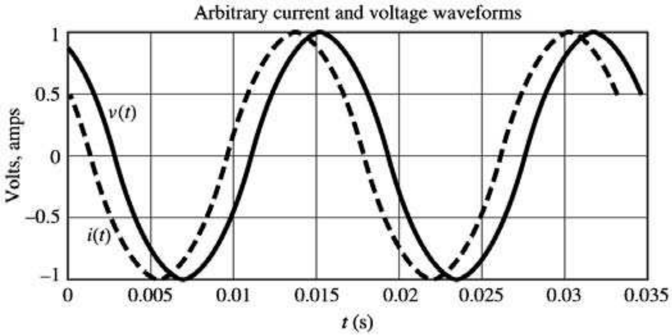

FIGURE 5.5.1 Current and voltage waveforms for illustration of AC power.

Since the **instantaneous power** dissipated by a circuit element is given by the product of the instantaneous voltage and current, it is possible to obtain a general expression for the power dissipated by an AC circuit element:

$$\begin{aligned} p(t) &= v(t)i(t) \\ &= VI\cos\left(\omega t + \theta_v\right)\cos\left(\omega t + \theta_I\right) \end{aligned} \tag{5.5.2}$$

Equation (5.5.2) can be further simplified with the aid of trigonometric identities to yield

$$p(t) = \frac{VI}{2}\cos(\theta) + \frac{VI}{2}\cos(2\omega t + \theta) \tag{5.5.3}$$

Equation (5.5.3) illustrates how the instantaneous power dissipated by an AC circuit element is equal to the sum of an average component, $VI/2\cos(\theta)$, plus a sinusoidal component, $VI/2\cos(2\omega t + \theta)$, oscillating at a frequency double that of the original source frequency.

The **average power** corresponding to the voltage and current signals of Equation (5.5.1) can be obtained by integrating the instantaneous power over one cycle of the sinusoidal signal.

$$P_{\text{av}} = \frac{VI}{2}\cos(\theta)$$

AC Power Notation

It has already been noted that AC power systems operate at a fixed frequency; in North America, this frequency is 60 cycles per second (Hz), corresponding to a radian frequency

$$\omega = 2\pi \cdot 60 = 377 \text{ rad/sec} \quad \text{AC power frequency} \tag{5.5.4}$$

In Europe and most other parts of the world, AC power is generated at a frequency of 50 Hz (this is the reason why some appliances will not operate under one of the two systems). It will therefore be understood that for the remainder of this section the radian frequency, ω, is fixed at 377 rad/sec. With knowledge of the radian frequency of all voltages and currents, it will always be possible to compute the exact magnitude and phase of any impedance in a circuit.

Power Factor

The phase angle of the load impedance plays a very important role in the absorption of power by a load impedance. As illustrated in Equation (5.5.3) and in the preceding examples, the average power dissipated by an AC load is dependent on the cosine of the angle of the impedance. To recognize the importance of this factor in AC power computations, the term cos(θ) is referred to as the **power factor** (pf). Note that the power factor is equal to 0 for a purely inductive or capacitive load and equal to 1 for a purely resistive load; in every other case,

$$0 < \text{pf} < 1 \tag{5.5.5}$$

Two equivalent expressions for the power factor are given in the following:

$$\text{pf} = \cos(\theta) = \frac{P_{\text{av}}}{\tilde{V}\tilde{I}} \quad \text{Power factor} \tag{5.5.6}$$

where $\tilde{V}$ and $\tilde{I}$ are the rms values of the load voltage and current.

Complex Power

The expression for the instantaneous power given in Equation (5.5.3) may be further expanded to provide further insight into AC power.

$$p(t) = \tilde{I}^2R + \tilde{I}^2R\cos(2\omega t) - \tilde{I}^2X\sin(2\omega t) \tag{5.5.7}$$

The physical interpretation of this expression for the instantaneous power should be intuitively appealing at this point. As Equation (5.5.7) suggests, the instantaneous power dissipated by a complex load consists of the following three components:

1. An average component, which is constant; this is called the *average power* and is denoted by the symbol P_{av}:

   $$P_{\text{av}} = \tilde{I}^2R \tag{5.5.8}$$

   where R = Re (Z).
2. A time-varying (sinusoidal) component with zero average value that is contributed by the power fluctuations in the resistive component of the load and is denoted by $p_R(t)$:

   $$\begin{aligned} p_R(t) &= \tilde{I}^2R\cos(2\omega t) \\ &= P_{\text{av}}\cos 2\omega t \end{aligned} \tag{5.5.9}$$

3. A time-varying (sinusoidal component with zero average value, due to the power fluctuation in the reactive component of the load and denoted by $p_X(t)$:

   $$\begin{aligned} p_X(t) &= -\tilde{I}^2X\sin(2\omega t) \\ &= Q\sin 2\omega t \end{aligned} \tag{5.5.10}$$

   where X = Im (Z) and Q is called the **reactive power**. *Note that since reactive elements can only store energy and not dissipate it, there is no net average power absorbed by X.*

Since P_{av} corresponds to the power absorbed by the load resistance, it is also called the **real power**, measured in units of watts (W). On the other hand, Q takes the name of *reactive power*, since it is associated with the load reactance. Table 5.5.1 shows the general methods of calculating P and Q.

TABLE 5.5.1 Real and Reactive Power

Real Power, P_{av}	Reactive Power, Q
$\tilde{V}\tilde{I}\cos(\theta)$	$\tilde{V}\tilde{I}\sin(\theta)$
I^2R	I^2X

The units of Q are **volt-amperes reactive**, or VAR. Note that Q represents an exchange of energy between the source and the reactive part of the load; thus, no net power is gained or lost in the process since the average reactive power is zero. In general, it is desirable to minimize the reactive power in a load.

The computation of AC power is greatly simplified by defining a fictitious but very useful quantity called the **complex power**, S:

$$S = \mathbf{VI}^* \quad \text{Complex power} \tag{5.5.11}$$

or

$$S = P_{\text{av}} + jQ$$

The complex power S may be interpreted graphically as a vector in the complex plane, as shown in Figure 5.5.2.

The magnitude of S, $|S|$, is measured in units of **volt-amperes** (VA) and is called **apparent power**, because this is the quantity one would compute by measuring the rms load voltage and currents without regard for the phase angle of the load. The complex power may also be expressed by the product of the square of the rms current through the load and the complex load impedance:

$$S = \tilde{I}^2 Z$$

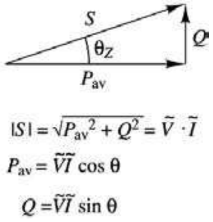
or

$$\tilde{I}^2 R + j\tilde{I}^2 R = \tilde{I}^2 Z \tag{5.5.12}$$

or, equivalently, by the ratio of the rms voltage across the load to the complex conjugate of the load impedance:

$$S = \frac{\tilde{V}^2}{Z^*} \tag{5.5.13}$$

Although the reactive power does not contribute to any average power dissipation in the load, it may have an adverse effect on power consumption because it increases the overall rms current flowing in the circuit. The presence of any source resistance (typically, the resistance of the line wires in AC power circuits) will cause a loss of power; the power loss due to this line resistance is unrecoverable and constitutes a net loss for the electric company, since the user never receives this power.



$$|S| = \sqrt{P_{\text{av}}^2 + Q^2} = \tilde{V}\cdot\tilde{I}$$

$$P_{\text{av}} = \tilde{V}\tilde{I}\cos\theta$$

$$Q = \tilde{V}\tilde{I}\sin\theta$$

FIGURE 5.5.2 The complex power triangle.

Power Factor, Revisited

The power factor, defined earlier as the cosine of the angle of the load impedance, plays a very important role in AC power. A power factor close to unity signifies an efficient transfer from the AC source to the load, while a small power factor corresponds to inefficient use of energy. It should be apparent that if a load requires a fixed amount of real power, *P*, the source will be providing the smallest amount of current when the power factor is the greatest, that is, when $\cos\theta = 1$. If the power factor is less than unity, some additional current will be drawn from the source, lowering the efficiency of power transfer from the source to the load. However, it will be shown shortly that it is possible to correct the power factor of a load by adding an appropriate reactive component to the load itself.

Since the reactive power, *Q*, is related to the reactive part of the load, its sign depends on whether the load reactance in inductive or capacitive. This leads to the following important statement:

> If the load has an inductive reactance, then θ is positive and the current *lags* (or *follows*) the voltage. Thus, when θ and *Q* are positive, the corresponding power factor is termed *lagging*. Conversely, a capacitive load will have a negative *Q*, and hence a negative θ. This corresponds to a *leading* power factor, meaning that the load current *leads* the load voltage.

Table 5.5.2 illustrates the concept and summarizes all of the important points so far. In the table, the phasor voltage *V* has a zero phase angle and the current phasor is referenced to the phase of *V*.

The distinction between leading and lagging power factors made in Table 5.5.2 is important because it corresponds to opposite signs of the reactive power: *Q* is positive if the load is inductive ($\theta > 0$) and the power factor is lagging: *Q* is negative if the load is capacitive and the power factor is leading ($\theta < 0$). It is therefore possible to improve the power factor of a load according to a procedure called **power factor correction** — that is, by placing a suitable reactance in parallel with the load so that the reactive power component generated by the additional reactance is of opposite sign to the original load reactive power. Most often the need is to improve the power factor of an inductive load because many common industrial loads consist of electric motors, which are predominantly inductive loads. This improvement may be accomplished by placing a capacitance in parallel with the load. The following example illustrates a typical power factor correction for an industrial load.

TABLE 5.5.2 Important Facts Related to Complex Power

	Resistive load	**Capacitive load**	**Inductive load**
Ohm's law	$\mathbf{V}_L = Z_L\mathbf{I}_L$	$\mathbf{V}_L = Z_L\mathbf{I}_L$	$\mathbf{V}_L = Z_L\mathbf{I}_L$
Complex impedance	$Z_L = R_L$	$Z_L = R_L - jX_L$	$Z_L = R_L + jX_L$
Phase angle	$\theta_V - \theta_I = \theta = 0$	$\theta_V - \theta_I = \theta < 0$	$\theta_V - \theta_I = \theta > 0$
Complex plane sketch			Explanation	The current is in phase with the voltage.	The current "leads" the voltage.	The current "lags" the voltage.
Power factor	Unity	Leading, < 1	Lagging, < 1
Reactive power	0	Negative	Positive

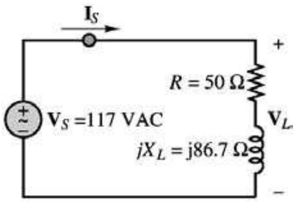

FIGURE 5.5.3 Circuit for Example 5.5.1.

Example 5.5.1

For the circuit shown in Figure 5.5.3:

1. Calculate the complex power for the load.
2. Correct the power factor by adding a suitable reactance in parallel with the load.

Solution.

1. The circuit of Figure 5.5.4 is an inductive load. The total impedance is

$$Z = R + jX_L = 50 + j86.7\ \Omega = 100\angle 60^\circ$$

The power factor is then

$$\text{pf} = \cos\theta = \cos 60^\circ = 0.5\ (\text{lagging})$$

The current drawn from the source by the load is

$$\mathbf{I}_S = \frac{\mathbf{V}_S}{Z} = \frac{117\angle 0^\circ}{100\angle 60^\circ} = 1.17\angle -60^\circ$$

and the average power is found to be

$$P = \tilde{V}_S \tilde{I}_S \cos\theta = 117 \times 1.17 \cos 60^\circ = 68.4\ \text{W}$$

while the reactive power is

$$Q_L = \tilde{V}_S \tilde{I}_S \sin\theta = 117 \times 1.17 \sin 60^\circ = 119\ \text{VAR}$$

Figure 5.5 shows the power triangle for the circuit.

2. The unity power factor for the circuit can be obtained by simply reducing the power factor angle θ to 0°. This can be accomplished by adding a capacitor to the circuit that requires –119 VAR of reactive power. The capacitive power and the inductive power will then cancel each other in the power triangle, resulting in a unity power factor, as shown in Figure 5.5.5.

   The value of capacitive reactance, X_c, required to cancel the reactive power due to the inductance is found most easily by observing that the total reactive power in the circuit must be the sum of the reactive power due to the capacitance and that due to the inductance. Observing that the capacitor sees the same voltage as the RL load, because of the parallel connection, we can write

$$X_C = \frac{\tilde{V}_S^2}{Q_C} = \frac{117^2}{119} 115\ \Omega$$

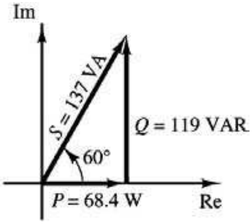

FIGURE 5.5.4 Power triangle for the circuit.

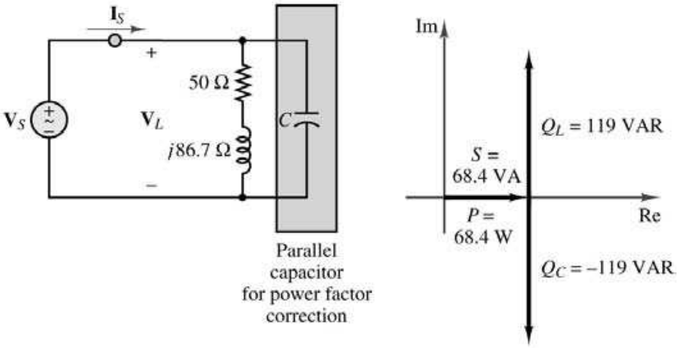

FIGURE 5.5.5 Power factor correction.

From the expression for the reactance, it is then possible to compute the value of the capacitor that will cancel the reactive power due to the inductor:

$$C = \frac{1}{\omega X_C} = \frac{1}{377 \times 115} = 23.1\ \mu\text{F}$$

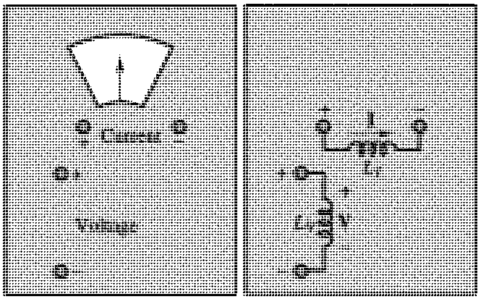
The reactive component of power needed by the inductance is now balanced by the capacitance, and all the power delivered by the source is real power. The power factor is 1.

Example 5.5.2

The instrument used to measure power is called a *wattmeter.* The external part of a wattmeter consists of four connections and a metering mechanism that displays the amount of real power dissipated by a circuit. The external and internal appearances of a wattmeter are depicted in Figure 5.5.6. Inside the wattmeter are two coils: a current-sensing coil and a voltage-sensing coil. In this example, we assume for simplicity that the impedance of the current-sensing coil, C_I, is zero and the impedance of the voltage-sensing coil, C_V, is infinite. In practice, this will not necessarily be true; some correction mechanism will be required to account for the impedance of the sensing coils.

A wattmeter should be connected as shown in Figure 5.5.7, to provide both current and voltage measurements. We see that the current-sensing coil is placed in series with the load and the voltage-sensing coil is placed in parallel with the load. In this manner, the wattmeter is seeing the current through and the voltage across the load. Remember that the power dissipated by a circuit element is related to these two quantities. The wattmeter, then, is constructed to provide a readout of the product of the rms values of the load current and the voltage, which is the real power absorbed by the load: $P = \text{Re}\ (\text{S}) = \text{Re}\ (\mathbf{VI}^*)$.

1. For the circuit shown in Figure 5.5.8, show the connections of the wattmeter, and find the power dissipated by the load.
2. Show the connections that will determine the power dissipated by R_2. What should the meter read?



External connections

Wattmeter coils (inside)

FIGURE 5.5.6 Wattmeter.

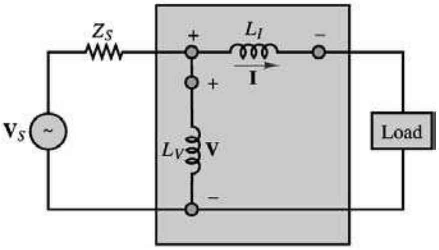


FIGURE 5.5.7 Circuit for Example 5.5.2.

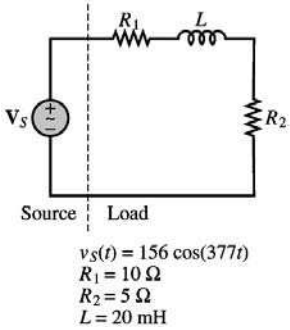

FIGURE 5.5.8 Circuit for Example 5.5.2.

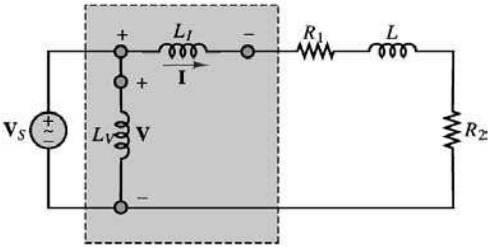

FIGURE 5.5.9 Circuit for Example 5.5.2.

Solution.

1. To measure the power dissipated by the load, we must know the current through and the voltage across the entire load circuit. This means that the wattmeter must be connected as shown in Figure 5.5.9. The wattmeter should read:

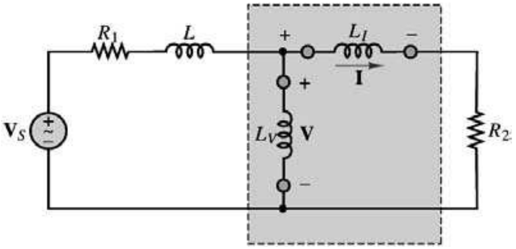

FIGURE 5.5.10 Circuit for Example 5.5.2.

$$
\begin{aligned}
P &= \mathrm{Re}\left(\mathbf{V}_S\mathbf{I}^*\right) \\
&= \mathrm{Re}\left\{\left(\frac{156}{\sqrt{2}}\angle 0^\circ\right)\left(\frac{\frac{156}{\sqrt{2}}\angle 0^\circ}{R_1 + R_2 + j\omega L}\right)^*\right\} \\
&= \mathrm{Re}\left\{110\angle 0^\circ\left(\frac{110\angle 0^\circ}{15 + j7.54}\right)^*\right\}
\end{aligned}
$$

$$
\begin{aligned}
\mathrm{Re}\left\{110\angle 0^\circ\left(\frac{110\angle 0^\circ}{16.79\angle 26.69^\circ}\right)^*\right\} &= \mathrm{Re}\left(\frac{110^2}{16.79\angle -26.69^\circ}\right) \\
&= \mathrm{Re}(720.67\angle 26.69^\circ) \\
&= 643.88 \text{ W}
\end{aligned}
$$

2. To measure the power dissipated by R_2 alone, we must measure the current through R_2 and the voltage across R_2 *alone*. The connection is shown in Figure 5.5.10. The meter will read:

$$
\begin{aligned}
P &= \tilde{I}^2 R_2 \\
&= \left(\frac{110}{\left(15^2 + 7.54^2\right)^{1/2}}\right)^2 \times 5 \\
&= \left(\frac{110^2}{\left(15^2 + 7.54^2\right)}\right)^2 \times 5 = 215 \text{ W}
\end{aligned}
$$

The measurement and correction of the power factor for the load are an extremely important aspect of any engineering application in industry that requires the use of substantial quantities of electric power. In particular, industrial plants, construction sites, heavy machinery, and other heavy users of electric power must be aware of the power factor their loads present to the electric utility company. As was already observed, a low power factor results in greater current draw from the electric utility and in greater line losses. Thus, computations related to the power factor of complex loads are of great practical utility to any practicing engineer.

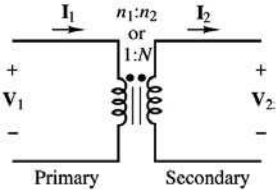

FIGURE 5.5.11 Ideal transformer.

Transformers

AC circuits are very commonly connected to each other by means of **transformers**. A transformer is a device that couples two AC circuits magnetically rather than through any direct conductive connection and permits a "transformation" of the voltage and current between one circuit and the other (for example, by matching a high-voltage, low-current AC output to a circuit requiring a low-voltage, high-current source). Transformers play a major role in electric power engineering and are a necessary part of the electric power distribution network. The objective of this section is to introduce the ideal transformer and the concepts of impedance reflection and impedance matching.

The Ideal Transformer

The ideal transformer consists of two coils that are coupled to each other by some magnetic medium. There is no electrical connection between the coils. The coil on the input side is termed the **primary**, and that on the output side the **secondary**. The primary coil is wound so that it has n_1 turns, while the secondary has n_2 turns. We define the **turns ratio** N as

$$N = \frac{n_2}{n_1} \tag{5.5.14}$$

Figure 5.5.11 illustrates the convention by which voltages and currents are usually assigned at a transformer. The dots in Figure 5.5.11 are related so the polarity of the coil voltage: coil terminals marked with a dot have the same polarity.

Since an ideal inductor acts as a short circuit in the presence of DC currents, transformers do not perform any useful function when the primary voltage is DC. However, when a time-varying current flows in the primary winding, a corresponding time-varying voltage is generated in the secondary because of the magnetic coupling between the two coils. This behavior is due to Faraday's law, as will be explained in Section 5.12. The relationship between primary and secondary current in an ideal transformer is very simply stated as follows:

$$\begin{aligned} \mathbf{V}_2 &= N\mathbf{V}_1 \\ \mathbf{I}_2 &= \frac{\mathbf{I}_1}{N} \end{aligned} \tag{5.5.15}$$

An ideal transformer multiplies a sinusoidal input voltage by a factor of N and divides a sinusoidal input current by a factor of N. If N is greater than 1, the output voltage is greater than the input voltage and the transformer is called a **step-up transformer**. If N is less than 1, then the transformer is called a **step-down transformer**, since V_2 is now smaller than V_1.

An ideal transformer can be used in either direction (i.e., either of its coils may be viewed as the input side or primary). Finally, a transformer with $N = 1$ is called an **isolation transformer** and may perform a very useful function if one needs to electrically isolate two circuits from each other; note that any DC currents at the primary will not appear at the secondary coil. An important property of ideal transformers is conservation of power; one can easily verify that an ideal transformer conserves power, since

$$S_1 = \mathbf{I}_1^*\mathbf{V}_1 = N\mathbf{I}_2^*\frac{\mathbf{V}_2}{N} = \mathbf{I}_2^*\mathbf{V}_2 = S_2 \tag{5.5.16}$$

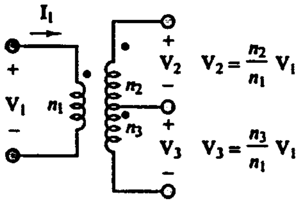

FIGURE 5.5.12 Center-tapped transformer.

That is, the power on the primary side equals that on the secondary.

In many practical circuits, the secondary is tapped at two different points, giving rise to two separate output circuits, as shown in Figure 5.5.12. The most common configuration is the **center-tapped transformer**, which splits the secondary voltage into two equal voltages of half the original amplitude. The most common occurrence of this type of transformer is found at the entry of a power line into a household, where the 240-VAC line is split into two 120-VAC lines (this may help explain why both 240- and 120-VAC power are present in your house).

Three-Phase Power

The material presented so far in this chapter has dealt exclusively with **single-phase AC power**, that is, with single sinusoidal sources. In fact, most of the AC power used today is generated and distributed as **three-phase power**, by means of an arrangement in which three sinusoidal voltages are generated out of phase with each other. The primary reason is efficiency: the weight of the conductors and other components in a three-phase system is much lower than in a single-phase system delivering the same amount of power. Further, while the power produced by a single-phase system has a pulsating nature, a three-phase system can deliver a steady, constant supply of power. A three-phase generator producing three **balanced voltages** — that is, voltages of equal amplitude and frequency displaced in phase by 120° — has the property of delivering constant instantaneous power.

Another important advantage of three-phase power is that, as will be explained in Section 5.12, three-phase motors have a nonzero starting torque, unlike their single-phase counterpart. The change to three-phase AC power system from the early DC system proposed by Edison was therefore due to a number of reasons: the efficiency resulting from transforming voltages up and down to minimize transmission losses over long distances; the ability to deliver constant power (an ability not shared by single- and two-phase AC systems); a more efficient use of conductors; and the ability to provide starting torque for industrial motors.

To begin the discussion of three-phase power, consider a three-phase source connected in the **wye** (or **Y**) **configuration**, as shown in Figure 5.5.13. Each of the three voltages is 120° out of phase with the others, so that, using phasor notation, we may write:

$$\begin{aligned} V_{an} &= \tilde{V}_{an}\angle 0^\circ \\ V_{bn} &= \tilde{V}_{bn}\angle -120^\circ \\ V_{cn} &= \tilde{V}_{cn}\angle -240^\circ = \tilde{V}_{cn}\angle 120^\circ \end{aligned} \tag{5.5.17}$$

where the quantities $\tilde{V}_{an}$, $\tilde{V}_{bn}$, and $\tilde{V}_{cn}$ are rms values and are equal to each other. To simplify the notation, it will be assumed from here on that

$$\tilde{V}_{an} = \tilde{V}_{bn} = \tilde{V}_{cn} = \tilde{V} \tag{5.5.18}$$

Section 5.12 will discuss how three-phase AC electric generators may be constructed to provide such balanced voltages. In the circuit of Figure 5.5.13, the resistive loads are also wye-connected and balanced

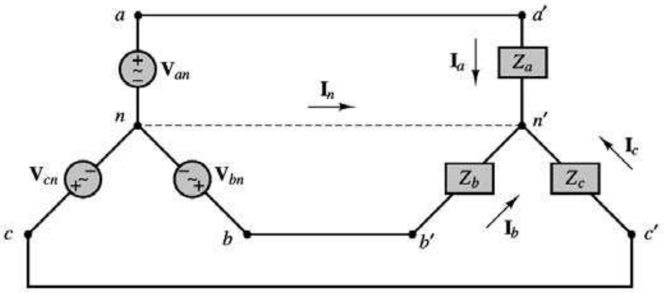

FIGURE 5.5.13 Balanced three-phase AC circuit.

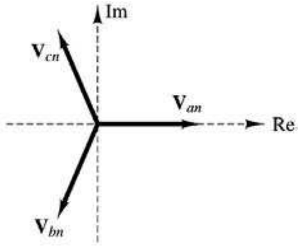

FIGURE 5.5.14 Positive, or *abc*, sequence for balanced three-phase voltages.

(i.e., equal). The three AC sources are all connected together at a node called the *neutral node*, denoted by *n*. The voltages $\tilde{V}_{an}$, $\tilde{V}_{bn}$, and $\tilde{V}_{cn}$ are called the *phase voltages* and form a balanced set in the sense that

$$\mathbf{V}_{an} + \mathbf{V}_{bn} + \mathbf{V}_{cn} = 0 \tag{5.5.19}$$

This last statement is easily verified by sketching the phasor diagram. The sequence of phasor voltages shown in Figure 5.5.14 is usually referred to as the **positive** (or *abc*) **sequence**.

Consider now the "lines" connecting each source to the load and observe that it is possible to also define **line voltages** (also called *line-to-line voltages*) by considering the voltages between the lines *aa′* and *bb′*, *aa′* and *cc′*, and *bb′* and *cc′*. Since the line voltage, say, between *aa′* and *bb′* is given by

$$\mathbf{V}_{ab} = \mathbf{V}_{an} + \mathbf{V}_{nb} = \mathbf{V}_{an} - \mathbf{V}_{bn} \tag{5.5.20}$$

the line voltages may be computed relative to the phase voltages as follows:

$$\begin{aligned} \mathbf{V}_{ab} &= \tilde{V}\angle 0° - \tilde{V}\angle -120° = \sqrt{3}\tilde{V}\angle 30° \\ \mathbf{V}_{bc} &= \tilde{V}\angle -120° - \tilde{V}\angle 120° = \sqrt{3}\tilde{V}\angle -90° \\ \mathbf{V}_{ca} &= \tilde{V}\angle 120° - \tilde{V}\angle 0° = \sqrt{3}\tilde{V}\angle 150° \end{aligned} \tag{5.5.21}$$

It can be seen, then, that the magnitude of the line voltages is equal to $\sqrt{3}$ times the magnitude of the phase voltages. It is instructive, at least once, to point out that the circuit of Figure 5.5.13 can be redrawn to have the appearance of the circuit of Figure 5.5.15.

One of the important features of a balanced three-phase system is that it does not require a fourth wire (the neutral connection), since the current $\mathbf{I}_n$ is identically zero (for balanced load $Z_a = Z_b = Z_c = Z$). Another, more important characteristic of a balanced three-phase power system is that the total power delivered to the balanced load by the three-phase generator is constant.

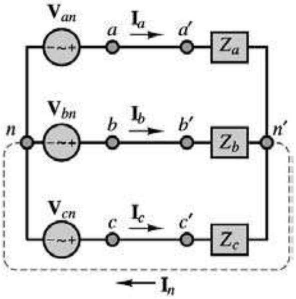

FIGURE 5.5.15 Balanced three-phase AC circuit (redrawn).

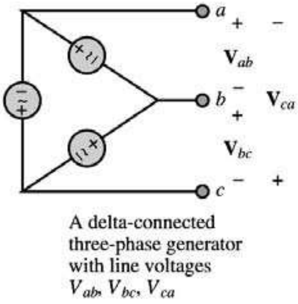

FIGURE 5.5.16 Delta-connected generators.

$$p(t) = p_a(t) + p_b(t) + p_c(t) = \frac{3\tilde{V}^2}{R}$$

It is also possible to connect the three AC sources in a three-phase system in a so-called **delta** (or Δ) **connection**, although in practice this configuration is rarely used. Figure 5.5.16 depicts a set of three delta-connected generators.

Balanced Wye Loads

Consider again the circuit of Figure 5.5.13, where now the balanced load consists of the three complex impedances

$$Z_a = Z_b = Z_c = Z_v = |Z_y|\angle\theta \tag{5.5.22}$$

From the diagram of Figure 5.5.13, it can be verified that each impedance sees the corresponding phase voltage across itself; thus, since the currents $\mathbf{I}_a$, $\mathbf{I}_b$, and $\mathbf{I}_c$ have the same rms value, $\tilde{I}$, the phase angles of the currents will differ by ±120°. It is therefore possible to compute the power for each phase by considering the phase voltage (equal to the load voltage) for each impedance, and the associated line current. Let us denote the complex power for each phase by S:

$$S = \mathbf{V} \cdot \mathbf{I}^* \tag{5.5.23}$$

so that

$$\begin{aligned} S &= P + jQ \\ &= \tilde{V}\tilde{I}\cos\theta + j\tilde{V}\tilde{I}\sin\theta \end{aligned} \tag{5.5.24}$$

where $\tilde{V}$ and $\tilde{I}$ denote, once again, the rms values of each phase voltage and line current. Consequently, the total real power delivered to the balanced wye load is $3P$, and the total reactive power is $3Q$. Thus, the total complex power, S_T, is given by

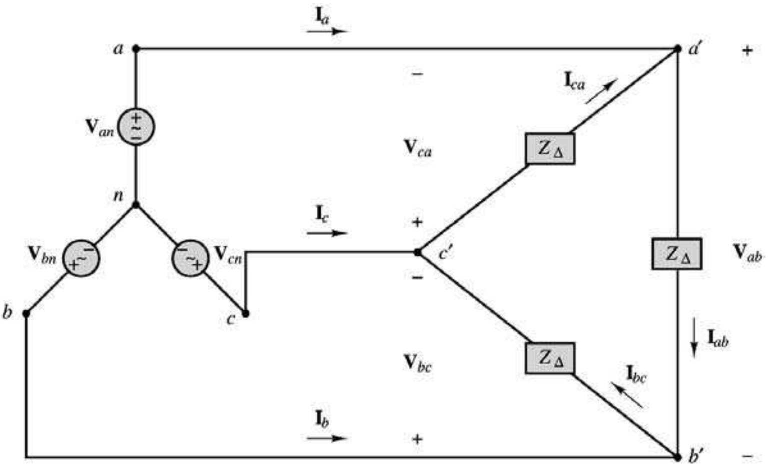

FIGURE 5.5.17 Balanced wye generators with balanced delta load.

$$
\begin{aligned}
S_T &= P_T + jQ_T = 3P + j3Q \\
&= \sqrt{(3P)^2 + (3Q)^2}\angle\theta
\end{aligned}
\tag{5.5.25}
$$

and the apparent power is

$$
\begin{aligned}
|S_T| &= 3\sqrt{(VI)^2\cos^2\theta + (VI)^2\sin^2\theta} \\
&= 3VI
\end{aligned}
$$

and the total real and reactive power may be expressed in terms of the apparent power:

$$
\begin{aligned}
P_T &= |S_T|\cos\theta \\
Q_T &= |S_T|\sin\theta
\end{aligned}
\tag{5.5.26}
$$

Balanced Delta Loads

In addition to a wye connection, it is also possible to connect a balanced load in the delta configuration. A wye-connected generator and a delta-connected load are shown in Figure 5.5.17.

It should be noted immediately that now the corresponding line voltage (not phase voltage) appears across each impedance. For example, the voltage across $Z_{c'a'}$ is $\mathbf{V}_{ca}$. Thus, the three load currents are given by the following expressions:

$$
\begin{aligned}
\mathbf{I}_{ab} &= \frac{\mathbf{V}_{ab}}{Z_\Delta} = \frac{\sqrt{3}V\angle 30^\circ}{|Z_\Delta|\angle\theta} \\
\mathbf{I}_{bc} &= \frac{\mathbf{V}_{bc}}{Z_\Delta} = \frac{\sqrt{3}V\angle -90^\circ}{|Z_\Delta|\angle\theta} \\
\mathbf{I}_{ca} &= \frac{\mathbf{V}_{ca}}{Z_\Delta} = \frac{\sqrt{3}V\angle 150^\circ}{|Z_\Delta|\angle\theta}
\end{aligned}
$$

One can readily verify that the two currents $(\mathbf{I}_a)_\Delta$ and $(\mathbf{I}_a)_y$ will be equal if the magnitude of the delta-connected impedance is three times larger than Z_y:

$$Z_\Delta = 3Z_y \tag{5.5.27}$$

This result also implies that a delta load will necessarily draw three times as much current (and therefore absorb three times as much power) as we wye load with the same branch impedance.

Generation and Distribution of AC Power

We now conclude the discussion of power systems with a brief description of the various elements of a power system. Electric power originates from a variety of sources; in Section 5.12, electric generators will be introduced as a means of producing electric power from a variety of energy-conversion processes. In general, electric power may be obtained from hydroelectric, thermoelectric, geothermal, wind, solar, and nuclear sources. The choice of a given source is typically dictated by the power requirement for the given application and by economic and environmental factors. In this section, the structure of an AC power network, from the power-generating station to the residential circuits discussed in the previous section, is briefly outlined.

A typical generator will produce electric power at 18 kV, as shown in the diagram of Figure 5.5.18. To minimize losses along the conductors, the output of the generators is processed through a step-up transformer to achieve line voltages of hundreds of kilovolts. Without this transformation, the majority of the power generated would be lost in the **transmission lines** that carry the electric current from the power station.

The local electric company operates a power-generating plant that is capable of supplying several hundred megavolt-amperes (MVA) on a three-phase basis. For this reason, the power company uses a three-phase step-up transformer at the generation plant to increase the line voltage to around 345 kV. One can immediately see that at the rated power of the generator (in MVA) there will be a significant reduction of current beyond the step-up transformer.

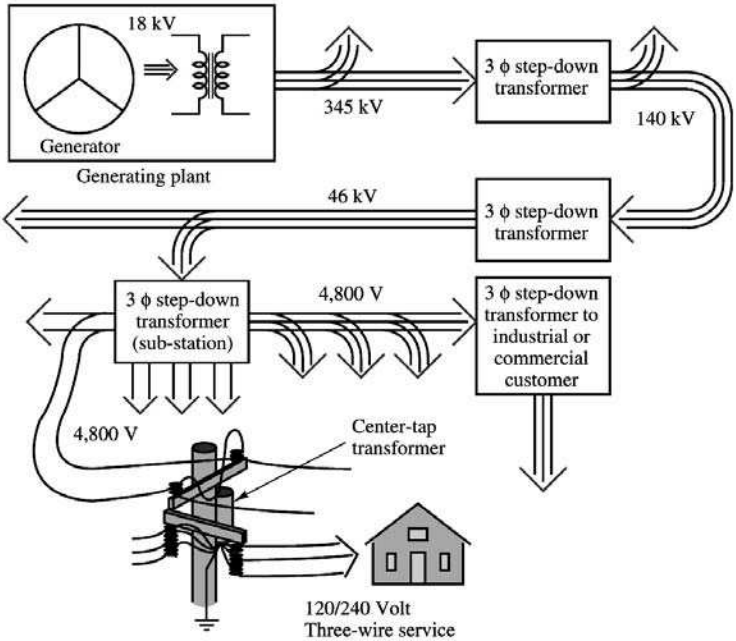

FIGURE 5.5.18 Structure of an AC power distribution network.

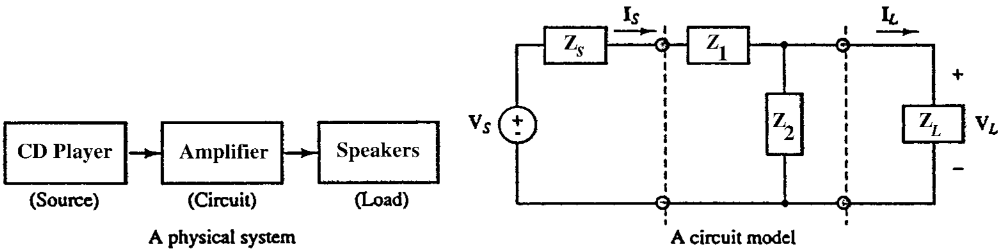

FIGURE 5.6.1 A circuit model.

Beyond the generation plant, an electric power network distributes energy to several **substations**. This network is usually referred to as the **power grid**. At the substations, the voltage is stepped down to a lower level (10 to 150 kV, typically). Some very large loads (for example, an industrial plant) may be served directly from the power grid, although most loads are supplied by individual substations in the power grid. At the local substations (one of which you may have seen in your own neighborhood), the voltage is stepped down further by a three-phase step-down transformer to 4800 V. These substations distribute the energy to residential and industrial customers. To further reduce the line voltage to levels that are safe for residential use, step-down transformers are mounted on utility poles. These drop the voltage to the 120/240-V three-wire single-phase residential service discussed in the previous section. Industrial and commercial customers receive 460- and/or 208-V three-phase service.

5.6 Frequency Response, Filters, and Transient Analysis

The aim of the present section is twofold: first, to exploit AC circuit analysis methods to study the frequency response of electric circuits; and second, to continue the discussion of dynamic circuit equations for the purpose of analyzing the transient response of electrical circuits.

The **sinusoidal frequency response** (or, simply, **frequency response**) of a circuit provides a measure of how the circuit responds to sinusoidal inputs of arbitrary frequency. In other words, given the input signal amplitude, phase, and frequency, knowledge of the frequency response of a circuit permits the computation of the output signal.

The frequency response of a circuit is a measure of the variation of a load-related voltage or current as a function of the amplitude, phase, and frequency of the excitation signal.

To express the frequency response of a circuit in terms of variation in output voltage as a function of source voltage, we use the general formula

$$H_V(j\omega) = \frac{\mathbf{V}_L(j\omega)}{\mathbf{V}_S(j\omega)} \tag{5.6.1}$$

One method that allows for representation of the load voltage as a function of the source voltage (this is, in effect, what the frequency response of a circuit implies) is to describe the source and attached circuit by means of the Thévenin equivalent circuit. The frequency response of the circuit shown in Figure 5.6.1 is given by the expression

$$\frac{\mathbf{V}_L}{\mathbf{V}_S}(j\omega) = H_V(j\omega) = \frac{Z_L Z_2}{Z_L\left(Z_S + Z_1 + Z_2\right) + \left(Z_S + Z_1\right)Z_2} \tag{5.6.2}$$

The expression for $H_V(j\omega)$ could be evaluated for any given $\mathbf{V}_S(j\omega)$ (i.e., for any given source signal amplitude, phase, and frequency) to determine what the resultant load voltage would be. Note that $H_V(j\omega)$

is a complex quantity (dimensionless, because it is the ratio of two voltages), and that it therefore follows that $\mathbf{V}_L(j\omega)$ is a phase-shifted and amplitude-scaled version of $\mathbf{V}_S(j\omega)$:

$$\mathbf{V}_L(j\omega) = H_V(j\omega) \cdot \mathbf{V}_S(j\omega) \tag{5.6.3}$$

$$V_L e^{j\phi_L} = \left|H_V\right| e^{j\phi_H} \cdot V_S e^{j\phi_S} \tag{5.6.4}$$

or

$$V_L e^{j\phi_L} = \left|H_V\right| \mathbf{V}_S\, e^{j(\phi_H + \phi_S)} \tag{5.6.5}$$

where

$$V_L = \left|H_V\right| \cdot V_S$$

and

$$\phi_L = \phi_H + \phi_S \tag{5.6.6}$$

The effect of inserting a linear circuit between a source and a load is best understood by considering that, at any given frequency, ω, the load voltage is a sinusoid at the same frequency as the source voltage, with amplitude given by $V_L = |H_V| \cdot V_S$ and phase equal to $\phi_L = \phi_H + \phi_S$, where $|H_V|$ is the magnitude of the frequency response and ϕ_H its phase angle. Both $|H_V|$ and ϕ_H are functions of frequency.

The importance and usefulness of the frequency response concept lies in its ability to summarize the response of a circuit in a single function of frequency, $H(j\omega)$, which can predict the load voltage or current at any frequency, given the input. Note that the frequency response of a circuit can be defined in four different ways:

$$\begin{aligned} H_V(j\omega) &= \frac{\mathbf{V}_L(j\omega)}{\mathbf{V}_S(j\omega)} \qquad & H_I(j\omega) &= \frac{\mathbf{I}_L(j\omega)}{\mathbf{I}_S(j\omega)} \\ H_Z(j\omega) &= \frac{\mathbf{V}_L(j\omega)}{\mathbf{I}_S(j\omega)} \qquad & H_Y(j\omega) &= \frac{\mathbf{I}_L(j\omega)}{\mathbf{V}_S(j\omega)} \end{aligned} \tag{5.6.7}$$

If $H_V(j\omega)$ and $H_I(j\omega)$ are known, one can directly derive the other two expressions:

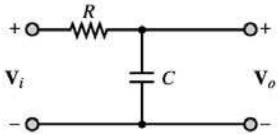
$$H_Z(j\omega) = \frac{\mathbf{V}_L(j\omega)}{\mathbf{I}_S(j\omega)} = Z_L(j\omega)\frac{\mathbf{I}_L(j\omega)}{\mathbf{I}_S(j\omega)} = Z_L(j\omega)H_I(j\omega) \tag{5.6.8}$$

$$H_Y(j\omega) = \frac{\mathbf{I}_L(j\omega)}{\mathbf{V}_S(j\omega)} = \frac{1}{Z_L(j\omega)}\frac{\mathbf{V}_L(j\omega)}{\mathbf{V}_S(j\omega)} = \frac{1}{Z_L(j\omega)}H_V(j\omega) \tag{5.6.9}$$

With these definitions in hand, it is now possible to introduce one of the central concepts of electrical circuit analysis: **filters.** The concept of filtering an electrical signal will be discussed in the next section.

Filters

There are a host of practical, everyday applications that involve filters of one kind or another. Just to mention two, filtration systems are used to eliminate impurities from drinking water, and sunglasses are used to filter out eye-damaging ultraviolet radiation and to reduce the intensity of sunlight reaching the eyes. An analogous concept applies to electrical circuits: it is possible to *attenuate* (i.e., reduce in amplitude) or altogether eliminate signals of unwanted frequencies, such as those that may be caused by electrical noise or other forms of interference. This section will be devoted to the analysis of electrical filters.



RC low-pass filter. The circuit preserves lower frequencies while attenuating the frequencies above the cutoff frequency, $\omega_0 = 1/RC$. The voltages V_i and V_0 are the filter input and output voltages respectively.

FIGURE 5.6.2 A simple RC filter.

Low-Pass Filters

Figure 5.6.2 depicts a simple **RC filter** and denotes its input and output voltages by $\mathbf{V}_i$ and $\mathbf{V}_o$. The frequency response for the filter may be obtained by considering the function.

$$H(j\omega) = \frac{\mathbf{V}_o}{\mathbf{V}_i}(j\omega) \tag{5.6.10}$$

and noting that the output voltage may be expressed as a function of the input voltage by means of a voltage divider, as follows:

$$\mathbf{V}_o(j\omega) = \mathbf{V}_i(j\omega)\frac{1/j\omega C}{R + 1/j\omega C} = \mathbf{V}_i(j\omega)\frac{1}{1 + j\omega RC} \tag{5.6.11}$$

$$H(j\omega) = \frac{\mathbf{V}_o}{\mathbf{V}_i}(j\omega) = \frac{1}{1 + j\omega CR}$$

or

$$H(j\omega) = \left|H(j\omega)\right| e^{j\phi_H(j\omega)} \tag{5.6.12}$$

with

$$\left|H(j\omega)\right| = \frac{1}{\sqrt{1 + (\omega CR)^2}} = \frac{1}{\sqrt{1 + \left(\omega/\omega_0\right)^2}} \tag{5.6.13}$$

and

$$\phi_H(j\omega) = -\arctan(\omega CR) = -\arctan\left(\frac{\omega}{\omega_0}\right) \tag{5.6.14}$$

with

$$\omega_0 = \frac{1}{RC} \tag{5.6.15}$$

The simplest way to envision the effect of the filter is to think of the phasor voltage $\mathbf{V}_i = V_i e^{j\phi_i}$ scaled by a factor of |**H**| and shifted by a phase angle ϕ_H by the filter *at each frequency*, so that the resultant output is given by the phasor $V_o e^{j\phi_o}$, with

$$\begin{aligned} V_o &= |H| \cdot V_i \\ \phi_o &= \phi_H + \phi_i \end{aligned} \tag{5.6.16}$$

and where $|H|$ and ϕ_H are functions of frequency. The frequency ω_0 is called the **cutoff frequency** of the filter and, as will presently be shown, gives an indication of the filtering characteristics of the circuit.

It is customary to represent $H(j\omega)$ in two separate plots, representing $|H|$ and ϕ_H as functions of ω. These are shown in Figure 5.6.3 in normalized form — that is, with $|H|$ and ϕ_H plotted vs. ω/ω_0, corresponding to a cutoff frequency $\omega_0 = 1$ rad/sec. Note that, in the plot, the frequency axis has been scaled logarithmically. This is a common practice in electrical engineering, because it allows viewing a very broad range of frequencies on the same plot without excessively compressing the low-frequency end of the plot. The frequency response plots of Figure 5.6.3 are commonly employed to describe the frequency response of a circuit, since they can provide a clear idea at a glance of the effect of a filter on an excitation signal. For example, the *RC* filter of Figure 5.6.2 has the property of "passing" signals at low frequencies ($\omega \ll 1/RC$) and of filtering out signals at high frequencies ($\omega \gg 1/RC$). This type of filter is called a **low-pass filter**. The cutoff frequency $\omega = 1/RC$ has a special significance in that it represents — approximately — the point where the filter begins to filter out the higher-frequency signals. The value of $H(j\omega)$ at the cutoff frequency is $1/\sqrt{2} = 0.707$. Note how the cutoff frequency depends exclusively on the values of *R* and *C*. Therefore, one can adjust the filter response as desired simply by selecting appropriate values for *C* and *R*, and therefore choose the desired filtering characteristics.

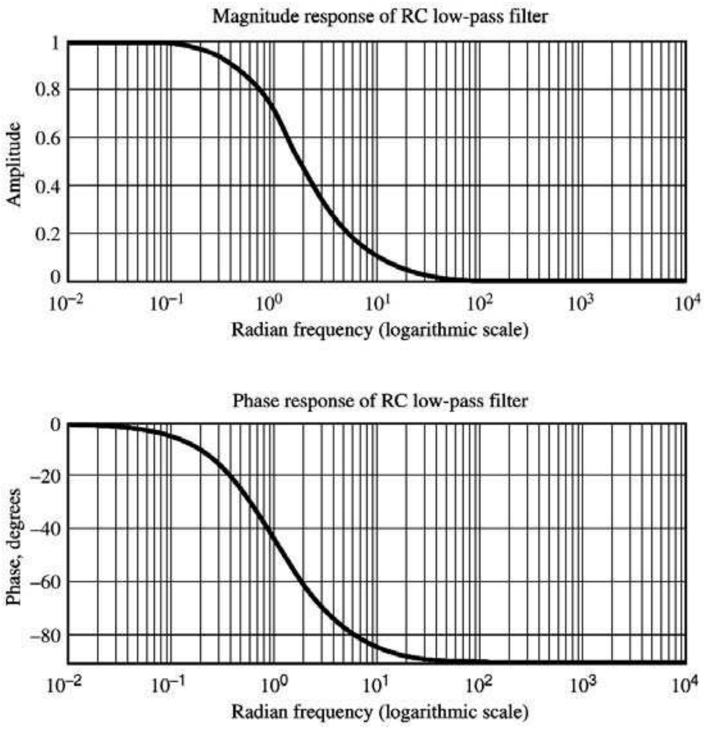


FIGURE 5.6.3 Magnitude and phase response plots for *RC* filter.

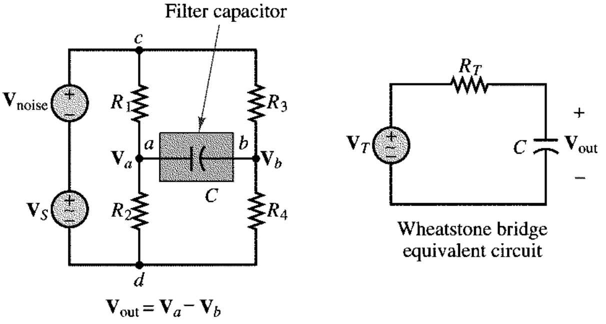

FIGURE 5.6.4 Wheatstone bridge with equivalent circuit and simple capacitive filter.

Example 5.6.1 Wheatstone Bridge Filter

The Wheatstone bridge circuit is used in a number of instrumentation applications, including the measurement of force (see Example 5.6.2, describing the strain gauge bridge). Figure 5.6.4 depicts the appearance of the bridge circuit. When undesired noise and interference are present in a measurement, it is often appropriate to use a low-pass filter to reduce the effect of the noise. The capacitor that is connected to the output terminals of the bridge in Figure 5.6.4 constitutes an effective and simple low-pass filter, in conjunction with the bridge resistance. Assume that the average resistance of each leg of the bridge is 350 Ω (a standard value for strain gauges) and that we desire to measure a sinusoidal force at a frequency of 30 Hz. From prior measurements, it has been determined that a filter with a cutoff frequency of 300 Hz is sufficient to reduce the effects of noise. Choose a capacitor that matches this filtering requirement.

Solution. By evaluating the Thévenin equivalent circuit for the Wheatstone bridge, calculating the desired value for the filter capacitor becomes relatively simple, as illustrated at the bottom of Figure 5.6.4. The Thévenin resistance for the bridge circuit may be computed by short-circuiting the two voltage sources and removing the capacitor placed across the load terminals:

$$R_T = R_1 \| R_2 + R_3 \| R_4 = 350 \| 350 + 350 \| 350 = 350\ \Omega$$

Since the required cutoff frequency is 300 Hz, the capacitor value can be computed from the expression

$$\omega_0 = \frac{1}{R_T C} = 2\pi \times 300$$

or

$$C = \frac{1}{R_T \omega_0} = \frac{1}{350 \times 2\pi \times 300} = 1.51\ \mu\text{F}$$

The frequency response of the bridge circuit is of the form

$$\frac{\mathbf{V}_{\text{out}}}{\mathbf{V}_T}(j\omega) = \frac{1}{1 + j\omega C R_T}$$

This response can be evaluated at the frequency of 30 Hz to verify that the attenuation and phase shift at the desired signal frequency are minimal:

$$\frac{\mathbf{V}_{\text{out}}}{\mathbf{V}_T}(j\omega = j2\pi \times 30) = \frac{1}{1 + j2\pi \times 30 \times 1.51 \times 10^{-6} \times 350}$$

$$= 0.9951\angle -5.7°$$

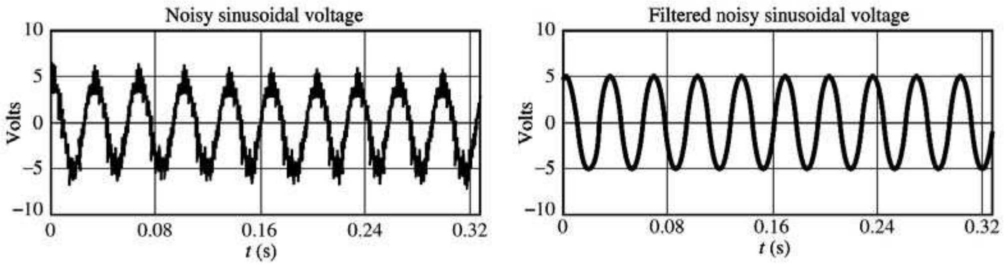

FIGURE 5.6.5 Unfiltered and filtered bridge output.

Figure 5.6.5 depicts the appearance of a 30-Hz sinusoidal signal before and after the addition of the capacitor to the circuit.

High-Pass Filters

Just as you can construct a simple filter that preserves low frequencies and attenuates higher frequencies, you can easily construct a **high-pass filter** that passes mainly those frequencies *above a certain cutoff frequency*. The analysis of a simple high-pass filter can be conducted by analogy with the preceding discussion of the low-pass filter. Consider the circuit shown in Figure 5.6.6.

The frequency response of the filter is

$$\frac{\mathbf{V}_o}{\mathbf{V}_i}(j\omega) = \frac{j\omega CR}{1 + j\omega CR}$$

or

$$H(j\omega) = |H| e^{j\phi_H}$$

with

$$H(j\omega) = \frac{\omega CR}{\sqrt{1 + (\omega CR)^2}}$$

$$\phi_H(j\omega) = 90° - \arctan(\omega CR)$$

Amplitude-and-phase response curves for the high-pass filter are shown in Figure 5.6.7. These plots have been normalized to have the filter cutoff frequency $\omega_0 = 1$ rad/sec. Note that, once again, it is possible to define a cutoff frequency at $\omega_0 = 1/RC$ in the same way as was done for the low-pass filter.

Band-Pass Filters

Building on the principles developed in the preceding sections, we can also construct a circuit that acts as a **band-pass filter**, passing mainly those frequencies *within a certain frequency range*. The analysis of

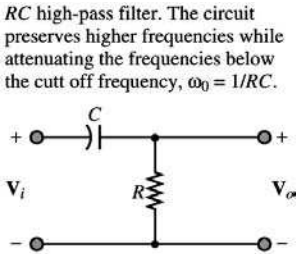

FIGURE 5.6.6 High-pass filter.

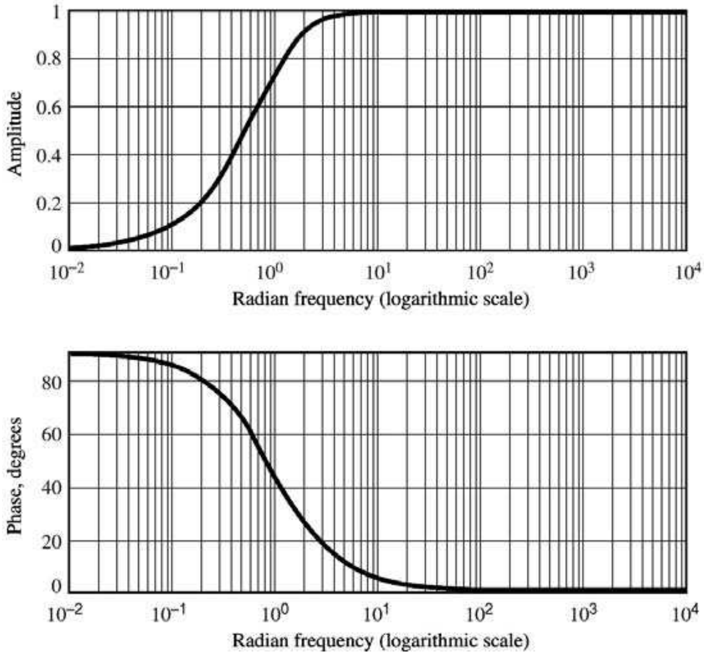

FIGURE 5.6.7 Frequency response of a high-pass filter.

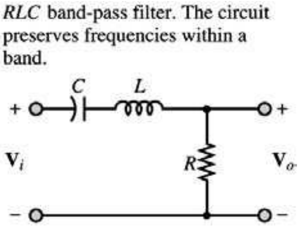

RLC band-pass filter. The circuit preserves frequencies within a band.

FIGURE 5.6.8 *RLC* band-pass filter.

a simple *second-order* band-pass filter (i.e., a filter with two energy-storage elements) can be conducted by analogy with the preceding discussions of the low-pass and high-pass filters. Consider the circuit shown in Figure 5.6.8, and the related frequency response function for the filter $H(j\omega) = (\mathbf{V}_o/\mathbf{V}_i)(j\omega)$.

We may write the frequency response of the filter as

$$\frac{\mathbf{V}_o}{\mathbf{V}_i}(j\omega) = \frac{j\omega CR}{1 + j\omega CR + (j\omega)^2 LC} \tag{5.6.17}$$

Equation (5.6.17) can often be factored into the following form:

$$\frac{\mathbf{V}_o}{\mathbf{V}_i}(j\omega) = \frac{jA\omega}{(j\omega/\omega_1 + 1)(j\omega/\omega_2 + 1)} \tag{5.6.18}$$

where ω_1 and ω_2 are the two frequencies that determine the **pass-band** (or **band-width**) of the filter — that is, the frequency over which the filter "passes" the input signal. The magnitude and phase plots for the frequency response of the band-pass filter of Figure 5.6.8 are shown in Figure 5.6.9. These plots have been normalized to have the filter pass-band centered at the frequency $\omega = 1$ rad/sec.

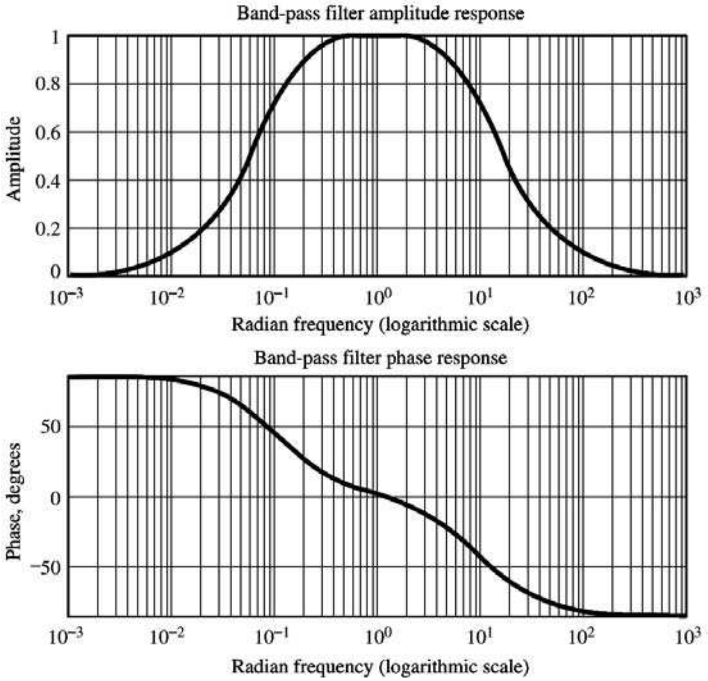

FIGURE 5.6.9 Frequency response of *RLC* band-pass filter.

The expression for the frequency response of a second-order band-pass filter (Equation (5.6.17)) can also be rearranged to illustrate two important features of this circuit: the **quality factor**, Q, and the **resonant frequency**, ω_0. Let

$$\omega_0 = \frac{1}{\sqrt{LC}} \quad \text{and} \quad Q = \omega_0 CR = \frac{R}{\omega_0 L} \tag{5.6.19}$$

Then we can write $\omega CR = \omega_0 CR(\omega/\omega_0) = Q(\omega/\omega_0)$ and rearrange Equation 5.6.18 as follows:

$$\frac{\mathbf{V}_o}{\mathbf{V}_i}(j\omega) = \frac{jQ\dfrac{\omega}{\omega_0}}{\left(\dfrac{j\omega}{\omega_0}\right)^2 + jQ\dfrac{\omega}{\omega_0} + 1} \tag{5.6.20}$$

In Equation (5.6.20), the resonant frequency, ω_0, corresponds to the center frequency of the filter, while Q, the quality factor, indicates the *sharpness* of the resonance, that is, how narrow or wide the shape of the pass-band of the filter is. The width of the pass-band is also referred to as the *bandwidth*, and it can easily be shown that the bandwidth of the filter is given by the expression

$$B = \frac{\omega_0}{Q} \tag{5.6.21}$$

Thus, a high-Q filter has a narrow bandwidth, while a low-Q filter has a large bandwidth and is therefore less selective. The quality factor of a filter provides an immediate indication of the nature of the filter.

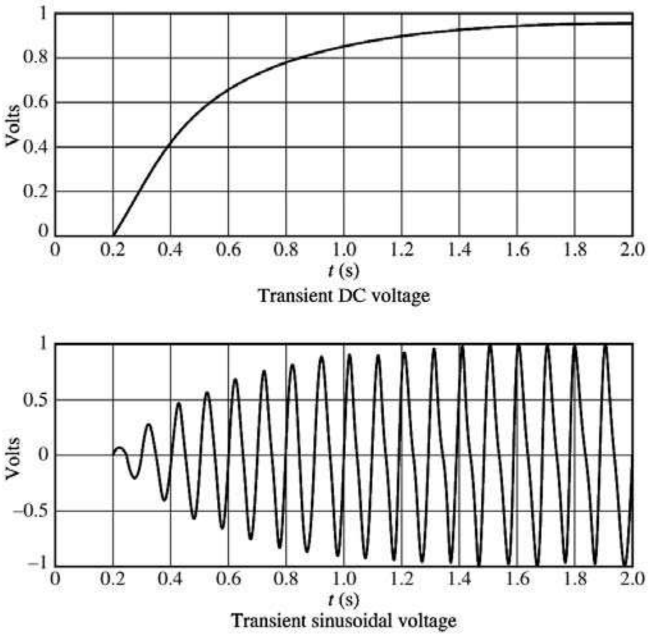

FIGURE 5.6.10 Examples of transient response.

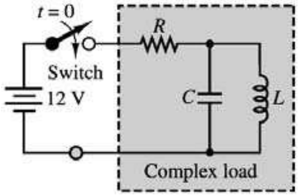

FIGURE 5.6.11 Circuit with switched DC excitation.

Transient Analysis

In analyzing the frequency response of AC circuits earlier in this chapter, we made the assumption that the particular form of the voltages and currents in the circuit was sinusoidal.

There are many signals, however, for which the steady-state sinusoidal representation is not adequate. In particular, the sinusoidal, or AC method of analysis does not apply to **transient signals**, that is, voltages and currents that vary as a function of time as a consequence of a sudden change in the input. Figure 5.6.10 illustrates the appearance of the voltage across some hypothetical load when a DC and an AC source, respectively, are abruptly switched on at time $t = 2$ sec. The waveforms in Figure 5.6.10 can be subdivided into three regions: a *steady-state region* for $0 \le t \le 0.2$ sec; a *transient region*, for 0.2 sec $\le t \le$ 2 sec (approximately); and a new steady-state region for $t > 2$ sec, where the waveform reaches a new steady-state DC or sinusoidal condition. The objective of **transient analysis** is to describe the behavior of a voltage or current during the transition that takes place between two different steady-state conditions.

You already know how to analyze circuits in a sinusoidal steady state by means of phasors. The material presented in the remainder of this chapter will provide the tools necessary to describe the *transient response* of circuits containing resistors, inductors, and capacitors. A general example of the type of circuit that will be discussed in this section is shown in Figure 5.6.11. The switch indicates that we turn the battery power on at time $t = 0$. Transient behavior may be expected whenever a source of electrical energy is switched on or off, whether it be AC or DC. A typical example of the transient response to a switched DC voltage would be what occurs when the ignition circuits in an automobile are turned on, so that a

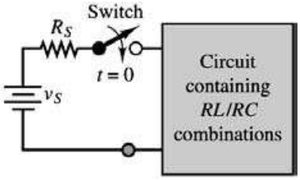

FIGURE 5.6.12 A general model of the transient analysis problem.

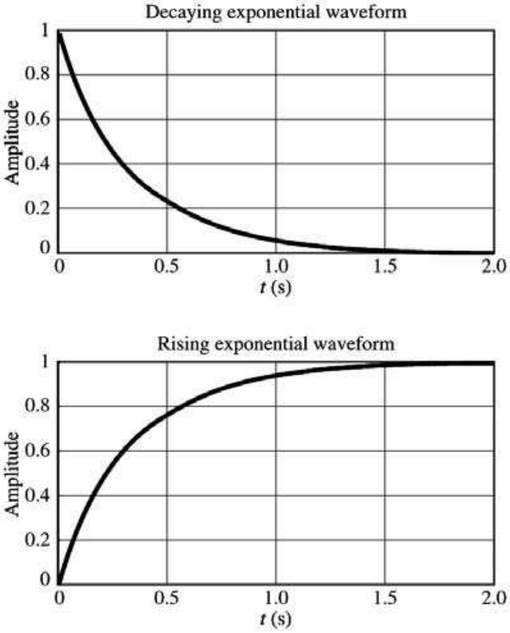

FIGURE 5.6.13 Decaying and rising exponential responses.

12-V battery is suddenly connected to a large number of electrical circuits. The degree of complexity in transient analysis depends on the number of energy-stored elements in the circuit; the analysis can become quite involved for high-order circuits. In this chapter, we shall analyze only first- and second-order circuits — that is, circuits containing one or two energy-storage elements, respectively. In electrical engineering practice, we would typically resort to computer-aided analysis for higher-order circuits.

A convenient starting point in approaching the transient response of electrical circuits is to consider the general model shown in Figure 5.6.12, where the circuits in the box consist of a combination of resistors connected to a *single energy-storage element*, either an inductor or a capacitor. Regardless of how many resistors the circuit contains, it is a **first-order circuit**. In general, the response of a first-order circuit to a switched DC source will appear in one of the two forms shown in Figure 5.6.13 which represent, in order, a **decaying exponential** and a **rising exponential** waveform. In the next sections, we will systematically analyze these responses by recognizing that they are exponential in nature and can be computed very easily once we have the proper form of the differential equation describing the circuit.

Example 5.6.2 Pulse Response

A problem of great practical importance is the transmission of voltage *pulses* along cables. Short voltage pulses are used to represent the two-level binary signals that are characteristic of digital computers; it is often necessary to transmit such voltage pulses over a long distance through **coaxial cables**, which are characterized by a finite resistance per unit length and by a certain capacitance per unit length, usually expressed in units of pF/m. A simplified model of a long coaxial cable is shown in Figure 5.6.14. It has the appearance of a low-pass filter. If a 100-m cable has a capacitance of 40 pF/m and a series resistance

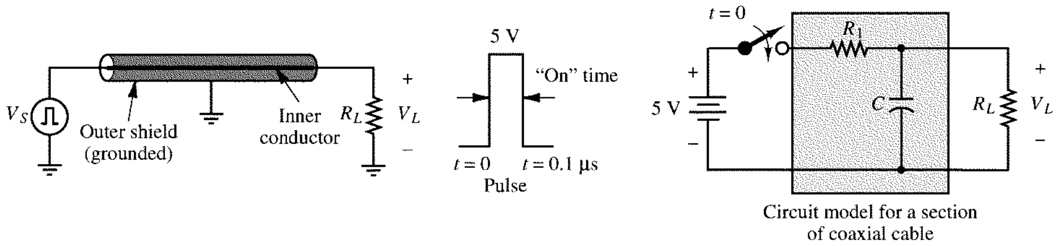

FIGURE 5.6.14 Pulse transmission in a coaxial cable.

of 0.2 Ω/m, what will the output pulse look like after traveling the length of the cable? Assume the input pulse has a duration of 0.1 μsec and has an amplitude of 5 V. The load resistance is 150 Ω.

Solution. The Thévenin equivalent circuit seen by the capacitor will vary, depending on whether the pulse is "on" or "off". In the former case, the equivalent resistance consists of the parallel combination of R_1 and R_L; in the latter case, since the switch is open, the capacitor is connected only to R_L. Thus, the effect of the pulse is to charge C through the parallel combination of R_1 and R_L during the "on" time ($0 \le t < 0.1$ μsec); the capacitor will then discharge through R_L during the "off" time. This behavior is depicted by the circuit model of Figure 5.6.14 in which the pulse signal is represented by a 5-V battery in series with a switch.

The charging time constant of the coaxial cable equivalent circuit when the switch is closed is therefore given by

$$\tau_{\text{on}} = \left(R_1 \| R_L\right)C = 17.65 \times 4000 \times 10^{-12} = 0.07\ \mu\text{sec}$$

and the transient response of the cable during the "on" time is

$$v_L(t) = 4.41\left(1 - e^{-t/\tau}\right) = 4.41\left(1 - e^{-1.42\times 10^{7} t}\right) \qquad 0 \le t \le 0.1\ \mu\text{sec}$$

where $V_T = R_L/(R_1 + R_L) \times 5 = 4.41$ V. At $t = 0.1$ μsec we calculate the load voltage to be

$$v_L(0.1\ \mu\text{sec}) = 4.41\left(1 - e^{-1.42}\right) = 3.35\ \text{V}$$

For $t \ge 0.1$ μsec, the output will naturally decay to zero, starting from the initial condition, v_L (0.1 μsec), with a time constant τ_{off} equal to

$$\tau_{\text{off}} = R_L C = 150 \times 4000 \times 10^{-12} = 0.6\ \mu\text{sec}$$

The load voltage will therefore decay according to the following expression:

$$v_L(t) = 3.35\left(e^{-1.67\times 10^{6}\left(t - 0.1\times 10^{-6}\right)}\right) \qquad t > 0.1\ \mu\text{sec}$$

The appearance of the response is shown in Figure 5.6.15. It should be apparent that as the cable becomes longer, both R_1 and C increase, and therefore the output voltage will respond more slowly to the input pulse; according to the simple model of a long coaxial cable given in this example, there is a limit to the maximum distance over which a voltage pulse can be transmitted by cable.

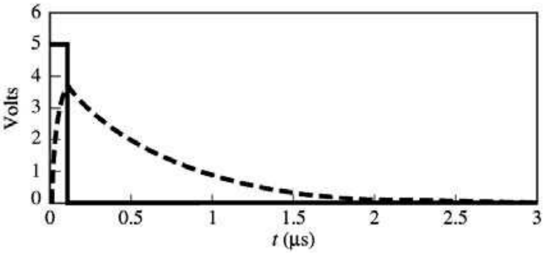

FIGURE 5.6.15 Pulse response of 100-m-long coaxial cable.

5.7 Electronics

This chapter introduces semiconductor-based electronic devices, and in so doing, it provides a transition between the fundamentals of electrical circuit analysis and the study of electronic circuits.

Semiconductors and *pn* Junctions

This section briefly introduces the mechanism of conduction in a class of materials called **semiconductors**. Semiconductors are typically materials consisting of elements from group IV of the periodic table and having electrical properties falling somewhere between those of conducting and of insulating materials. As an example, consider the conductivity of three common materials. Copper, a good conductor, has a conductivity of 0.59×16^6 S/cm; glass, a common insulator, may range between 10^{-16} and 10^{-13} S/cm; while silicon, a semiconductor, has a conductivity that varies from 10^{-8} to 10^{-1} S/cm. You see, then, that the name *semiconductor* is an appropriate one.

A conducting material is characterized by a large number of conduction-band electrons, which have a very weak bond with the basic structure of the material. Thus, an electric field easily imparts energy to the outer electrons in a conductor and enables the flow of electric current.

The free valence electrons are not the only mechanism of conduction in a semiconductor, however, Whenever a free electron leaves the lattice structure, it creates a corresponding positive charge within the lattice. The vacancy caused by the departure of a free electron is called a **hole**. Note that whenever a hole is present, we have, in effect, a positive charge. The positive charges also contribute to the conduction process, in the sense that if a valence-band electron "jumps" to fill a neighboring hole, thereby neutralizing a positive charge, it correspondingly creates a new hole at a different location. Thus, the effect is equivalent to that of a positive charge moving.

Semiconductor technology rarely employs pure, or intrinsic, semiconductors. To control the number of charge carriers in a semiconductor, the process of **doping** is usually employed. Doping consists of adding impurities to the crystalline structure of the semiconductor. The amount of these impurities is controlled, and the impurities can be of one of two types.

Semiconductors doped with donor elements conduct current predominantly by means of free electrons and are therefore called ***n*-type semiconductors**. When an acceptor element is used as the dopant, holes constitute the most common carrier, and the resulting semiconductor is said to be a ***p*-type semiconductor**. Doping usually takes place at such levels that the concentration of carriers due to the dopant is significantly greater than the intrinsic concentration of the original semiconductor. If n is the total number of free electrons and p that of holes, then in an n-type doped semiconductor, we have

$$n \gg n_i$$

and

$$p \ll p_i$$

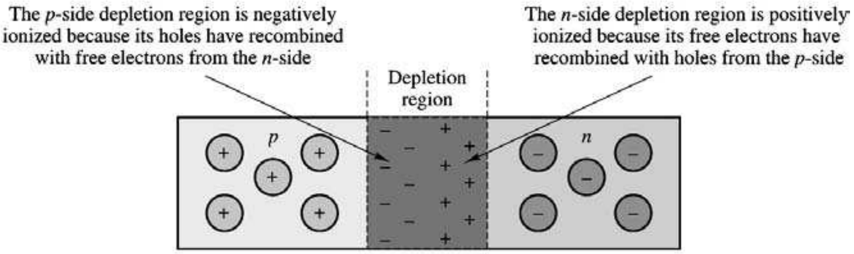

FIGURE 5.7.1 A *pn* junction.

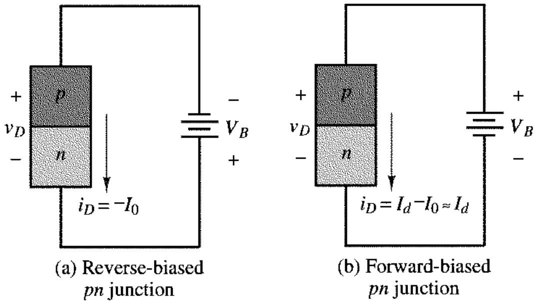

(a) Reverse-biased *pn* junction

(b) Forward-biased *pn* junction

FIGURE 5.7.2 Forward- and reverse-biased *pn* junctions.

Thus, free electrons are the **majority carriers** in an *n*-type material, while holes are the **minority carriers**. In a *p*-type material, the majority and minority carriers are reversed.

A simple section of semiconductor material does not in and of itself possess properties that make it useful for the construction of electronic circuits. However, when a section of *p*-type material and a section of *n*-type material are brought in contact to form a ***pn* junction**, a number of interesting properties arise. The *pn* junction forms the basis of the **semiconductor diode**, a widely used circuit element.

Figure 5.7.1 depicts an idealized *pn* junction, where on the *p* side, we see a dominance of positive charge carriers, or holes, and on the *n* side, the free electrons dominate. The charge separation causes a **contact potential** to exist at the junction. This potential is typically on the order of a few tenths of a volt and depends on the material (about 0.6 to 0.7 V for silicon). The contact potential is also called the *offset voltage*, V_γ.

Consider the diagrams of Figure 5.7.2, where a battery has been connected to a *pn* junction in the **reverse-biased** direction (Figure 5.7.2(a)), and in the **forward-biased** direction (Figure 5.7.2(b)). We assume that some suitable form of contact between the battery wires and the semiconductor material can be established (this is called an **ohmic contact**). The effect of a reverse bias is to increase the contact potential at the junction. Now, the majority carriers trying to diffuse across the junction need to overcome a greater barrier (a larger potential) and a wider depletion region. Thus, the diffusion current becomes negligible. The only current that flows under reverse bias is the very small reverse saturation current, so that the diode current, i_D (defined in the figure), is

$$i_D = -I_0$$

When the *pn* junction is forward-biased, the contact potential across the junction is lowered (note that V_B acts in opposition to the contact potential). Now, the diffusion of majority carriers is aided by the external voltage source; in fact, the diffusion current increases as a function of the applied voltage, according to the expression

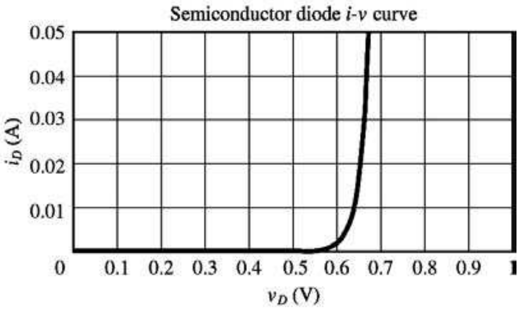

FIGURE 5.7.3 Semiconductor diode *i*-*v* characteristic.

$$I_d = I_0 e^{qv_D/kT} \tag{5.7.1}$$

where v_D is the voltage across the *pn* junction, $k = 1.381 \times 10^{-23}$ j/K is Boltzmann's constant, q the charge of one electron, and T the temperature of the material in kelvins (K). The quantity kT/q is constant at a given temperature and is approximately equal to 25 mV at room temperature. The net diode current under forward bias is given by the expression

$$i_D = I_d - I_0 = I_0\left(e^{qv_D/kT} - 1\right) \tag{5.7.2}$$

which is known as the **diode equation**. Figure 5.7.3 depicts the diode *i*-*v* characteristic described by the diode equation for a fairly typical silicon diode for positive diode voltages. Since the reverse saturation current, I_0, is typically very small (10^{-9} to 10^{-15} A), the expression

$$i_D = I_0 e^{qv_D/kT} \tag{5.7.3}$$

is a good approximation if the diode voltage, v_D, is greater than a few tenths of a volt.

The ability of the *pn* junction to essentially conduct current in only one direction — that is, to conduct only when the junction is forward-biased — makes it valuable in circuit applications. A device having a single *pn* junction and ohmic contacts at its terminals, as described in the preceding paragraphs, is called a *semiconductor diode,* or simply *diode*. As will be shown later in this chapter, it finds use in many practical circuits. The circuit symbol for the diode is shown in Figure 5.7.4, alongside with a sketch of the *pn* junction.

Circuit Models for the Semiconductor Diode

From the viewpoint of a *user* of electronic circuits (as opposed to a *designer*), it is often sufficient to characterize a device in terms of its *i*-*v* characteristic, using appropriate circuit models to determine the operating currents and voltages.

Ideal Diode Model

The large-signal model treats the diode as a simple on–off device (much like a check valve in hydraulic circuits). Figure 5.7.5 illustrates how, on a large scale, the *i*-*v* characteristic of a typical diode may be approximated by an open circuit when $v_D < 0$ and by a short circuit when $v_D \geq 0$ (recall the *i*-*v* curves of the ideal short and open circuits presented in Section 5.2). The analysis of a circuit containing a diode may be greatly simplified by using the short-circuit–open-circuit model. From here on, this diode model will be known as the **ideal diode model**. In spite of its simplicity, the ideal diode model (indicated by the symbol shown in Figure 5.7.5 can be very useful in analyzing diode circuits.

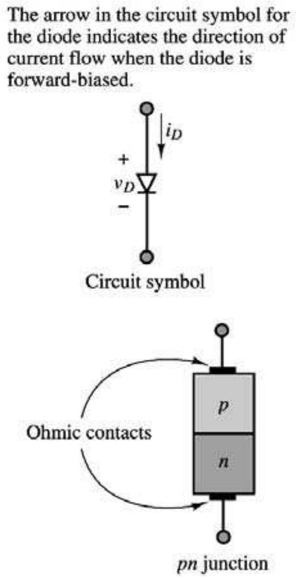

FIGURE 5.7.4 Semiconductor diode circuit symbol.

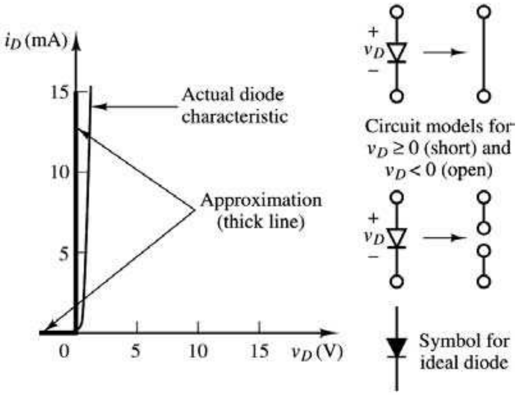

FIGURE 5.7.5 Large-signal on–off diode model.

One of the important applications of the semiconductor diode is **rectification** of AC signals, that is, the ability to convert an AC signal with zero average (DC) value to a signal with a nonzero DC value. The application of the semiconductor diode as a rectifier is very useful in obtaining DC voltage supplies from the readily available AC line voltage. Here we illustrate the basic principle of rectification using an ideal diode, for simplicity, and also because the large-signal model is appropriate when the diode is used in applications involving large AC voltage and current levels.

Consider the circuit of Figure 5.7.6, where an AC source, $v_i = 155.56 \cdot \sin \omega t$, is connected to a load by means of a series ideal diode. The diode will conduct only during the positive half-cycle of the sinusoidal voltage — that is, that the condition $v_D \geq 0$ will be satisfied only when the AC source voltage is positive — and that it will act as an open circuit during the negative half-cycle of the sinusoid ($v_D < 0$). Thus, the appearance of the load voltage will be as shown in Figure 5.7.7 with the negative portion of the sinusoidal waveform cut off. The rectified waveform clearly has a nonzero DC (average) voltage, whereas the average input waveform voltage was zero. When the diode is conducting, or $v_D \geq 0$, the unknowns v_L and i_D can be found by using the following equations:

$$i_D = \frac{v_i}{R_L} \quad \text{when} \quad v_i > 0 \tag{5.7.4}$$

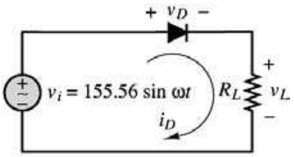

FIGURE 5.7.6

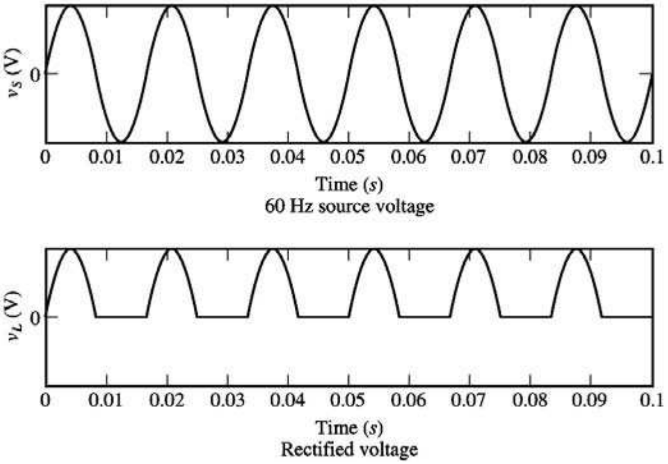

FIGURE 5.7.7 Ideal diode rectifier input and output voltages.

and

$$v_L = i_D R_L \tag{5.7.5}$$

The load voltage, v_L and the input voltage, v_i, are sketched in Figure 5.7.7. From Equation (5.7.5) it is obvious that the current waveform has the same shape as the load voltage. The average value of the load voltage is obtained by integrating the load voltage over one period and dividing by the period:

$$v_{\text{load,DC}} = \frac{\omega}{2\pi}\int_0^{\pi/\omega} 155.56 \sin \omega t \, dt = \frac{155.56}{\pi} = 49.52 \text{ V} \tag{5.7.6}$$

The circuit of Figure 5.7.6 is called a **half-wave rectifier**, since it preserves only half of the waveform. This is not usually a very efficient way of rectifying an AC signal, since half the energy in the AC signal is not recovered. It will be shown in a later section that it is possible to recover also the negative half of the AC waveform by mans of a *full-wave rectifier.*

Offset Diode Model

While the ideal diode model is useful in approximating the large-scale characteristics of a physical diode, it does not account for the presence of an offset voltage, which is an unavoidable component in semiconductor diodes. The **offset diode model** consists of an ideal diode in series with a battery of strength equal to the offset voltage (we shall use the value $V_\gamma = 0.6$ V for silicon diodes, unless otherwise indicated). The effect of the battery is to shift the characteristic of the ideal diode to the right on the voltage axis, as shown in Figure 5.93. This model is a better approximation of the large-signal behavior of a semiconductor diode than the ideal diode model.

According to the offset diode model, the diode of Figure 5.7.8 acts as an open circuit for $v_D < 0.6$ V, and it behaves like a 0.6-V battery for $v_D \geq 0.6$ V. The equations describing the offset diode model are as follows:

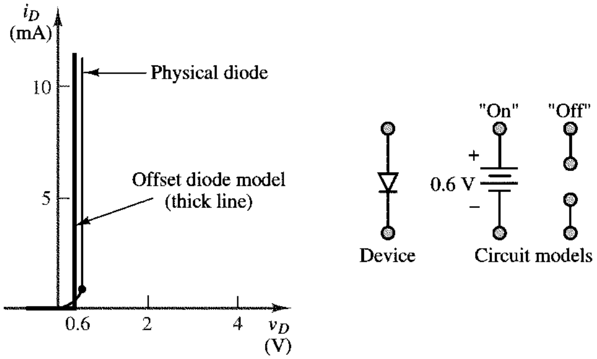

FIGURE 5.7.8

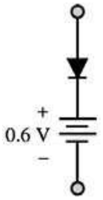

FIGURE 5.7.9 Offset diode as an extension of ideal diode model.

$$\begin{array}{ll} v_D \geq 0.6 \text{ V} & \text{Diode} \rightarrow 0.6\text{-V battery} \\ v_D < 0.6 \text{ V} & \text{Diode} \rightarrow \text{Open circuit} \end{array} \tag{5.7.7}$$

The diode offset model may be represented by an ideal diode in series with a 0.6-V ideal battery, as shown in Figure 5.7.9.

Practical Diode Circuits

The Full-Wave Rectifier

The half-wave rectifier discussed earlier is one simple method of converting AC energy to DC energy. The need for converting one form of electrical energy into the other arises frequently in practice. The most readily available form of electric power is AC (the standard 110- or 220-V rms AC line power), but one frequently needs a DC power supply, for applications ranging from the control of certain types of electric motors to the operation of electronic circuits.

The half-wave rectifier, however, is not a very efficient AC–DC conversion circuit, because it fails to utilize half the energy available in the AC waveform by not conducting current during the negative half-cycle of the AC waveform. The full-wave rectifier shown in Figure 5.7.10 offers a substantial improvement

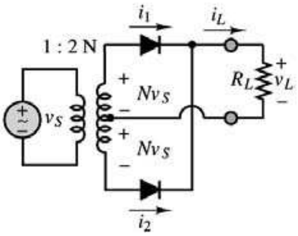

FIGURE 5.7.10 Full-wave rectifier.

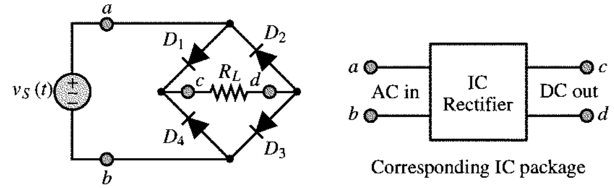
in efficiency over the half-wave rectifier. The first section of the full-wave rectifier circuit includes an AC source and a center-tapped transformer (see Section 5.5) with 1:2 N turns ratio. The purpose of the transformer is to obtain the desired voltage amplitude prior to rectification. Thus, if the peak amplitude of the AC source voltage is v_s, the amplitude of the voltage across each half of the output side of the transformer will be Nv_s; this scheme permits scaling the source voltage up or down (depending on whether N is greater or less than 1), according to the specific requirements of the application. In addition to scaling the source voltage, the transformer also isolates the rectifier circuit from the AC source voltage, since there is no direct electrical connection between the input and output of a transformer.

The Bridge Rectifier

Another rectifier circuit commonly available "off the shelf" as a single *integrated circuit package* is the *bridge rectifier*, which employs four diodes in a bridge configuration, similar to the Wheatstone bridge already explored in Section 5.2. Figure 5.7.11 depicts the bridge rectifier, along with the associated integrated circuit (IC) package.

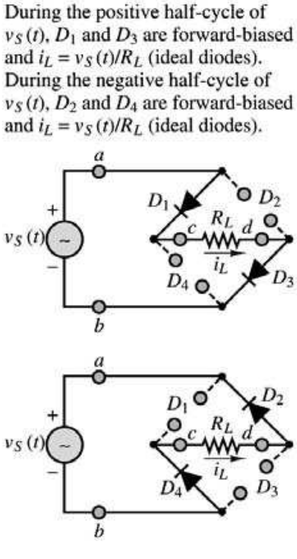
The analysis of the bridge rectifier is simple to understand by visualizing the operation of the rectifier for the two half-cycles of the AC waveform separately. The key is that, as illustrated in Figure 5.7.12, diodes D_1 and D_3 conduct during the positive half-cycle, while diodes D_2 and D_4 conduct during the negative half-cycle. Because of the structure of the bridge, the flow of current through the load resistor is in the same direction (from c to d) during both halves of the cycle; hence, the full-wave rectification of the waveform.



Bridge rectifier

Corresponding IC package

FIGURE 5.7.11 Full-wave bridge rectifier.



During the positive half-cycle of $v_S(t)$, D_1 and D_3 are forward-biased and $i_L = v_S(t)/R_L$ (ideal diodes).
During the negative half-cycle of $v_S(t)$, D_2 and D_4 are forward-biased and $i_L = v_S(t)/R_L$ (ideal diodes).

FIGURE 5.7.12 Diodes conduct.

DC Power Supplies and Voltage Regulation

The principal application of rectifier circuits is in the conversion of AC to DC power. A circuit that accomplishes this conversion is usually called a **DC power supply**. In power supply applications, transformers are employed to obtain an AC voltage that is reasonably close to the desired DC supply voltage. DC power supplies are very useful in practice: many familiar electrical and electronic appliances (e.g., radios, personal computers, TVs) require DC power to operate. For most applications, it is desirable that the DC supply be as steady and ripple-free as possible. To ensure that the DC voltage generated by a DC supply is constant, the DC supply is made up of voltage regulators, that is, devices that can hold a DC load voltage relatively constant in spite of possible fluctuations in the DC supply. This section will describe the fundamentals of voltage regulators.

A typical DC power supply is made up of the components shown in Figure 5.7.13. In the figure, a transformer is shown connecting the AC source to the rectifier circuit to permit scaling of the AC voltage to the desired level. For example, one might wish to step the 110-V rms line voltage down to 24 V rms by means of a transformer prior to rectification and filtering, to eventually obtain a 12-VDC regulated supply (*regulated* here means that the output voltage is a DC voltage that is constant and independent of load and supply variations). Following the step-down transformer are a bridge rectifier, a filter capacitor, a voltage regulator, and, finally, the load.

The most common device employed in voltage regulation schemes is the Zener diode. Zener diodes function on the basis of the reverse portion of the *i-v* characteristic of the diode with forward offset voltage V_γ and **reverse Zener voltage** V_Z.

The operation of the Zener diode may be analyzed by considering three modes of operation:

1. For $v_D \geq V_\gamma$, the device acts as a conventional forward-biased diode (Figure 5.7.14).
2. For $V_Z < v_D < V_\gamma$, the diode is reverse-biased but Zener breakdown has not taken place yet. Thus, it acts as an open circuit.
3. For $v_D \leq V_Z$, Zener breakdown occurs and the device holds a nearly constant voltage, $-V_Z$ (Figure 5.7.15).

To illustrate the operation of a Zener diode as a voltage regulator, consider the circuit of Figure 5.7.16, where the unregulated DC source, v_S, is regulated to the value of the Zener voltage, V_Z. Note how the diode must be connected "upside down" to obtain a positive regulated voltage. Note also that if v_S is greater than V_Z, it follows that the Zener diode is in its reverse-breakdown mode. Thus, one need not worry whether the diode is conducting or not in simple voltage regulator problems, provided that the unregulated supply voltage is guaranteed to stay above V_Z (a problem arises, however, if the unregulated

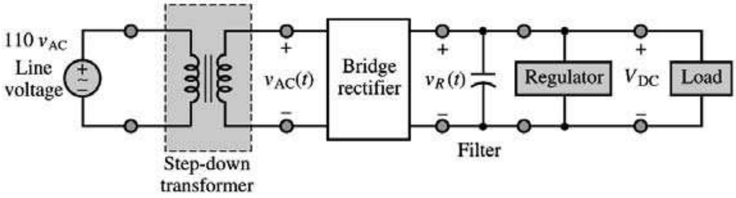


FIGURE 5.7.13 DC power supply.

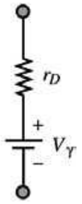

FIGURE 5.7.14 Zener diode model for forward bias.

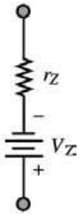

FIGURE 5.7.15 Zener diode model for reverse bias.

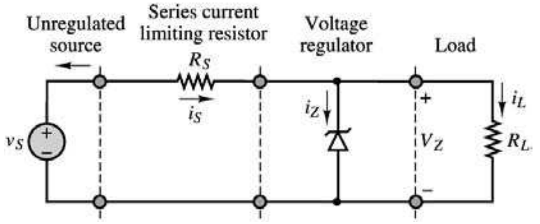

FIGURE 5.7.16 A Zener diode voltage regulator.

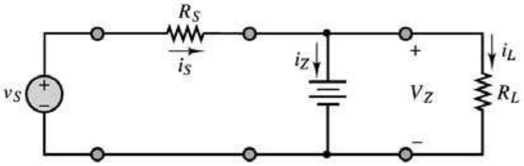

FIGURE 5.7.17 Simplified circuit for Zener regulator.

supply can drop below the Zener voltage). Assuming that the resistance r_Z is negligible with respect to R_S and R_L, we replace the Zener diode with the simplified circuit mode of Figure 5.7.17 consisting of a battery of strength V_Z.

Three simple observations are sufficient to explain the operation of this voltage regulator:

1. The load voltage must equal V_Z, as long as the Zener diode is in the reverse-breakdown mode. Then,

$$i_L = \frac{V_Z}{R_L} \tag{5.7.10}$$

2. The load current (which should be constant if the load voltage is to be regulated to sustain V_Z) is the difference between the unregulated supply current, i_s, and the diode current i_z:

$$i_L = i_S - i_Z \tag{5.7.11}$$

   This second point explains intuitively how a Zener diode operates: any current in excess of that required to keep the load at the constant voltage V_Z is "dumped" to ground through the diode. Thus, the Zener diode acts as a sink to the undesired source current.

3. The source current is given by

$$i_S \frac{v_S - V_Z}{R_S} \tag{5.7.12}$$

The Zener diode is usually rated in terms of its maximum allowable power dissipation. The power dissipated by the diode, P_Z, may be computed from

$$P_Z = i_Z V_Z \tag{5.7.13}$$

Thus, one needs to worry about the possibility that i_Z will become too large. This may occur either if the supply current is very large (perhaps because of an unexpected upward fluctuation of the unregulated supply), or if the load is suddenly removed and all of the supply current sinks through the diode. The latter case, of an open-circuit load, is an important design consideration.

Another significant limitation occurs when the load resistance is small, thus requiring large amounts of current from the unregulated supply. In this case, the Zener diode is hardly taxed at all in terms of power dissipation, but the unregulated supply may not be able to provide the current required to sustain the load voltage. In this case, regulation fails to take place. Thus, in practice, the range of load resistances for which load voltage regulation may be attained is constrained to a finite interval:

$$R_{L\,\min} \le R_L \le R_{L\,\max} \tag{5.7.14}$$

where $R_{L\max}$ is typically limited by the Zener diode power dissipation and $R_{L\min}$ by the maximum supply current.

Example 5.7.1

This example illustrates the calculation of the range of allowable load resistances for a Zener regulator design. For the Zener regulator shown in Figure 5.7.18, we want to maintain the load voltage at 14 V. Find the range of load resistances for which regulation can be obtained if the Zener diode is rated at 14 V, 5 W.

Solution. The minimum load resistance for which a regulated load voltage of 14 V may be attained is found by requiring that the load voltage be 14 V and applying KVL subject to this constraint:

$$50\left(\frac{R_{L\,\min}}{R_{L\,\min}+30}\right) = 14$$

$$\begin{aligned} R_{L\,\min} &= \frac{14}{50}\left(R_{L\,\min}+30\right) \\ &= 11.7\ \Omega \end{aligned}$$

The maximum current through the Zener diode that does not exceed the diode power rating may be computed by considering the 5-W power rating:

$$i_{Z\,\max} = \frac{5}{14} = 0.357\ \text{A}$$

The current through the 20-Ω resistor will be

$$\frac{50-14}{30} = 1.2\ \text{A}$$

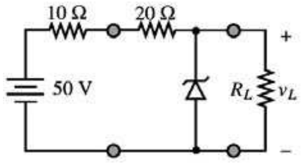

FIGURE 5.7.18 Circuit for example.

so that the maximum load resistance for which regulation occurs is

$$R_{L\max} = \frac{14}{1.2 - 0.357}$$
$$= 16.6\ \Omega$$

Finally, the range of allowable load resistances is:

$$16.6\ \Omega \geq R_L \geq 11.7\ \Omega$$

Photodiodes

Another property of semiconductor materials that finds common application in measurement systems is their response to light energy. In appropriately fabricated diodes, called **photodiodes**, when light reaches the depletion region of a *pn* junction, photons cause hole-electron pairs to be generated by a process called *photo-ionization*. This effect can be achieved by using a surface material that is transparent to light. As a consequence, the reverse saturation current depends on the light intensity (i.e., on the number of incident photons), in addition to the other factors mentioned earlier. In a photodiode, the reverse current is given by $-(I_0 + I_p)$, where I_p is the additional current generated by photo-ionization. The result is depicted in the family of curves of Figure 5.7.19, where the diode characteristic is shifted downward by an amount related to the additional current generated by photo-ionization. Figure 5.7.19 depicts the appearance of the *i-v* characteristic of a photodiode for various values of I_p, where the *i-v* curve is shifted to lower values for progressively larger values of I_p. The circuit symbol is depicted in Figure 5.7.20.

As displayed in Figure 5.7.19 are three load lines, which depict the three modes of operation of a photodiode. Curve L_1 represents normal diode operation, under forward bias. Note that the operating point of the device is in the positive *i*, positive *v* (first) quadrant of the *i-v* plane; thus, the diode dissipates positive power in this mode, and is therefore a passive device, as we already know. On the other hand, load line L_2 represents operation of the photodiode as a **solar cell**; in this mode, the operating point is in the negative *i*, positive *v*, or fourth, quadrant, and therefore the power dissipated by the diode is *negative*. In other words, the photodiode is generating power by converting light energy to electrical

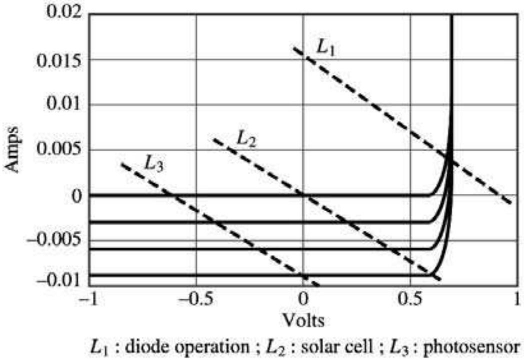

FIGURE 5.7.19 Photodiode *i-v* curves.

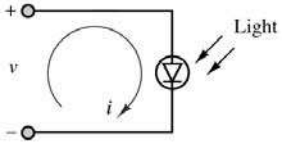

FIGURE 5.7.20 Photodiode circuit symbol.

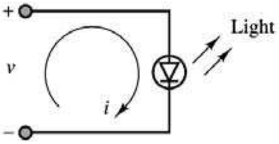

FIGURE 5.7.21 Light-emitting diode (LED) circuit symbol.

TABLE 5.7.1 LED Materials and Wavelengths

Material	Dopant	Wavelength (nm)	Color
GaAs	Zn	900	Infrared
GaAs	Si	910–1020	Infrared
GaP	N	570	Green
GaP	N	590	Yellow
GaP	Zn,O	700	Red

$GaAs_{0.15}P_{0.85}$	N	589	Yellow

energy. Note further that the load line intersects the voltage axis at zero, meaning that no supply voltage is required to bias the photodiode in the solar-cell mode. Finally, load line L_3 represents the operation of the diode as a light sensor: when the diode is reverse-biased, the current flowing through the diode is determined by the light intensity; thus, the diode current changes in response to changes in the incident light intensity.

The operation of the photodiode can also be reversed by forward-biasing the diode and causing a significant level of recombination to take place in the depletion region. Some of the energy released is converted to light energy by emission of photons. Thus, a diode operating in this mode emits light when forward-biased. Photodiodes used in this way are called **light-emitting diodes** (LEDs); they exhibit a forward (offset) voltage of 1 to 2 volts. The circuit symbol for the LED is shown in Figure 5.7.21.

Gallium arsenide (GaAs) is one of the more popular substrates for creating LEDs; gallium phosphide (GaP) and the alloy $GaAs_{1-x}P_x$ are also quite common. Table 5.7.1 lists combinations of materials and dopants used for common LEDs and the colors they emit. The dopants are used to create the necessary *pn* junction.

Example 5.7.2 Opto-Isolators

One of the common applications of photodiodes and LEDs is the **opto-coupler**, or **opto-isolator**. This device, which is usually enclosed in a sealed package, uses the light-to-current and current-to-light conversion property of photodiodes and LEDs to provide signal connection between two circuits without any need for electrical connections. Figure 5.7.22 depicts the circuit symbol for the opto-isolator.

Because diodes are nonlinear services, the opto-isolator is not used in transmitting analog signals: the signals would be distorted because of the nonlinear diode *i-v* characteristic. However, opto-isolators find a very important application when on–off signals need to be transmitted from high-power machinery to delicate computer control circuitry. The optical interface ensures that potentially damaging large currents cannot reach delicate instrumentation and computer circuits.

FIGURE 5.7.23 Controlled-source models of linear amplifier transistor operation.

Transistors

A transistor is a three-terminal semiconductor device that can perform two functions that are fundamental to the design of electronic circuits: **amplification** and **switching**. Put simply, amplification consists of magnifying a signal by transferring energy to it from an external source; whereas a transistor switch is a device for controlling a relatively large current between or voltage across two terminals by means of a small control current or voltage applied at a third terminal. In this chapter, we provide an introduction to the two major families of transistors: *bipolar junction transistors*, or *BJTs*; and *field-effect transistors*, or *FETs*.

The operation of the transistor as a linear amplifier can be explained qualitatively by the sketch of Figure 5.7.23 in which the four possible modes of operation of a transistor are illustrated by means of circuit models employing controlled sources. In Figure 5.7.23 controlled voltage and current sources are shown to generate an output proportional to an input current or voltage; the proportionality constant, μ, is called the internal *gain* of the transistor. As will be shown, the BJT acts essentially as a current-controlled device, while the FET behaves as a voltage-controlled device.

Transistors can also act in a nonlinear mode, as voltage- or current-controlled switches. When a transistor operates as a switch, a small voltage or current is used to control the flow of current between two of the transistor terminals in an on–off fashion. Figure 5.7.24 depicts the idealized operation of the transistor as a switch, suggesting that the switch is closed (on) whenever a control voltage or current is greater than zero and is open (off) otherwise. It will later become apparent that the conditions for the switch to be on or off need not necessarily be those depicted in Figure 5.7.24.

The Bipolar Junction Transistor (BJT)

The *pn* junction forms the basis of a large number of semiconductor devices. The semiconductor diode, a two-terminal device, is the most direct application of the *pn* junction. In this section, we introduce the **bipolar junction transistor** (BJT). As we did in analyzing the diode, we will introduce the physics of transistor devices as intuitively as possible, resorting to an analysis of their *i-v* characteristics to discover important properties and applications.

A BJT is formed by joining three sections of semiconductor material, each with a different doping concentration. The three sections can be either a thin *n* region sandwiched between p^+ and *p* layers, or a *p* region between *n* and n^+ layers, where the superscript "plus" indicates more heavily doped material. The resulting BJTs are called *pnp* and *npn* transistors, respectively; we shall discuss only the latter in this section. Figure 5.7.25 illustrates the approximate construction, symbols, and nomenclature for the two types of BJTs.

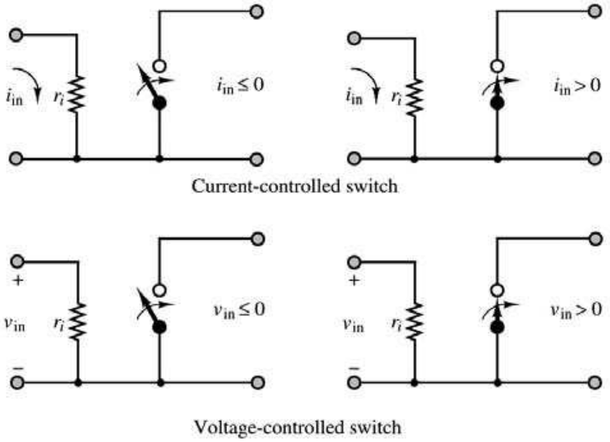

FIGURE 5.7.24 Models of ideal transistor switches.

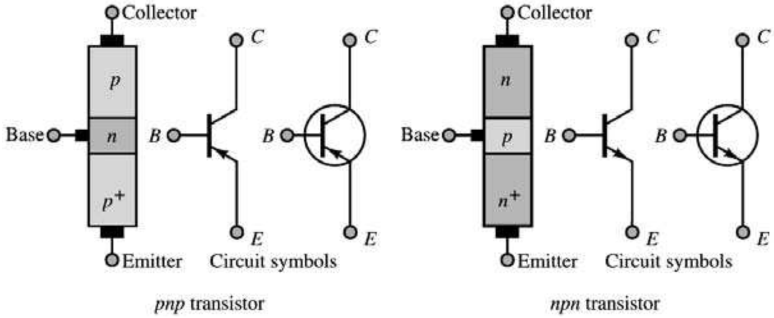

FIGURE 5.7.25 Bipolar junction transistors.

The most important property of the bipolar transistor is that the small base current controls the amount of the much larger collector current

$$I_C = \beta I_B \tag{5.7.15}$$

where β is a current amplification factor dependent on the physical properties of the transistor. Typical values of β range from 20 to 200.

The detailed operation of bipolar transistors can be explained by resorting to a detailed physical analysis of the *npn* or *pnp* structure of these devices. The reader interested in such a discussion of transistors is referred to any one of a number of excellent books on semiconductor electronics.

The focus of this section will be on the analysis of the *i-v* characteristic of the *npn* BJT, based on the circuit notation defined in Figure 5.7.26. The device *i-v* characteristics will be presented qualitatively, without deriving the underlying equations, and will be utilized in constructing circuit models for the device.

The number of independent variables required to uniquely define the operation of the transistor may be determined by applying KVL and KCL to the circuit of Figure 5.7.26. It should be apparent that two voltages and two currents are sufficient to specify the operation of the device. Note that, since the BJT is a three-terminal device, it will not be sufficient to deal with a single *i-v* characteristic; it will soon become apparent that two such characteristics are required to explain the operation of this device. One of these characteristics relates the base current, i_B, to the base-emitter voltage, v_{BE}; the other relates the collector current, i_C, to the collector-emitter voltage, v_{CE}. As will be shown, the latter characteristic actually

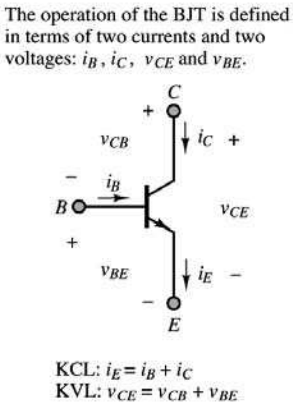

FIGURE 5.7.26 Definition of BJT voltages and currents.

consists of a *family* of curves. To determine these *i-v* characteristics, consider the *i-v* curves of Figure 5.7.27 and Figure 5.7.28 using the circuit notation of Figure 5.7.26. In Figure 5.7.27, the collector is open and the *BE* junction is shown to be very similar to a diode. The ideal current source, I_{BB}, injects a base current, which causes the junction to be forward-biased. By varying I_{BB}, one can obtain the open-collector *BE* junction *i-v* curve shown in the figure.

If a voltage source were now to be connected to the collector circuit, the voltage v_{CE} and, therefore, the collector current, i_C, could be varied, in addition to the base current, i_B. The resulting circuit is depicted in Figure 5.7.28(a). By varying both the base current and the collector-emitter voltage, one could then generate a plot of the device **collector characteristic**. This is also shown in Figure 5.7.28(b).

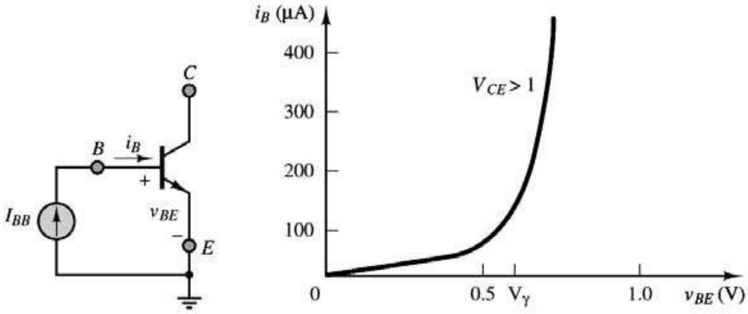

FIGURE 5.7.27 Determining the *BE* junction open-collector *i-v* characteristic.

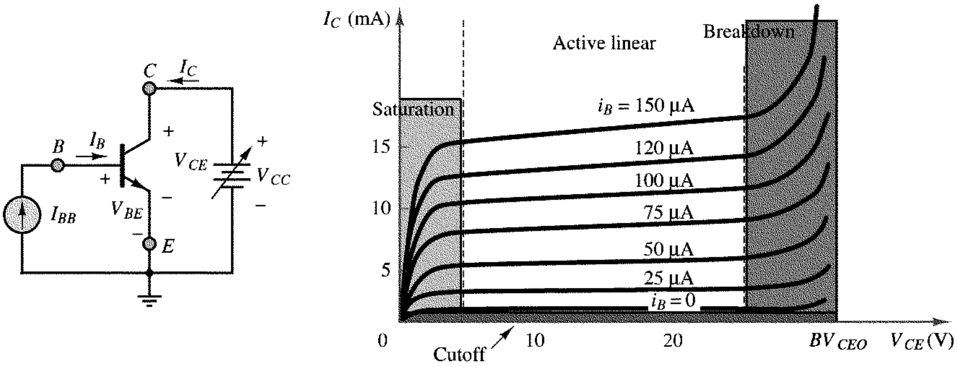

FIGURE 5.7.28 (a) Ideal test circuit to determine the *i-v* characteristic of a BJT; (b) the collector-emitter output characteristics of a BJT.

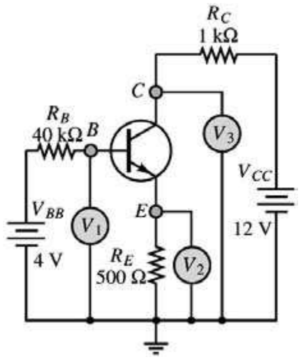

FIGURE 5.7.29 Determination of the operating state of a BJT.

Note that this figure depicts not just a single i_C-v_{CE} curve, but an entire family, since for each value of the base current, i_B, an i_C-v_{CE} curve can be generated. Four regions are identified in the collector characteristic:

1. The **cutoff region**, where both junctions are reverse-biased, the base current is very small, and essentially no collector current flows
2. The **active linear region**, in which the transistor can act as a linear amplifier, where the *BE* junction is forward-biased and the *CB* junction is reverse-biased
3. The **saturation region**, in which both junctions are forward-biased
4. The **breakdown region**, which determines the physical limit of operation of the device.

Large-Signal Model of the *npn* BJT

The large-signal model for the BJT recognizes three basic operating modes of the transistor (Figure 5.7.29). When the *BE* junction is reverse-biased, no base current (and therefore no forward collector current) flows, and the transistor acts (virtually as an open circuit; the transistor is said to be in the *cutoff region*. In practice, there is always a leakage current flowing through the collector, even when $V_{BE} = 0$ and $I_B = 0$. This leakage current is denoted by I_{CEO}. When the *BE* junction becomes forward-biased, the transistor is said to be in the *active region,* and the base current is amplified by a factor of β at the collector:

$$I_C = \beta I_B \tag{5.7.16}$$

Since the collector current is controlled by the base current, the controlled-source symbol is used to represent the collector current. Finally, when the base current becomes sufficiently large, the collector-emitter voltage, V_{CE}, reaches its saturation limit, and the collector current is no longer proportional to the base current; this is called the *saturation region*. The three conditions are described in Figure 5.7.30 in terms of simple circuit models.

Example 5.7.3 illustrates the application of this large-signal model in a practical circuit and illustrates how to determine which of the three states is applicable, using relatively simple analysis.

Example 5.7.3 LED Driver

The circuit shown in Figure 5.7.31 is being used to "drive" (i.e., provide power for) a light-emitting diode (LED) from a desktop computer. The signal available from the computer consists of a 5-V low-current output. The reason for using a BJT (rather than driving the LED directly with the signal available from the computer) is that the LED requires a substantial amount of current (at least 15 mA for the device used in this example) and the computer output is limited to 5mA. Thus, some current amplification is required. The LED has an offset voltage of 1.4 V and a maximum power dissipation rating of 280 mW. The circuit has been designed so that the transistor will be either in cutoff, when the LED is to be turned off, or in saturation, when the LED is to be turned on.

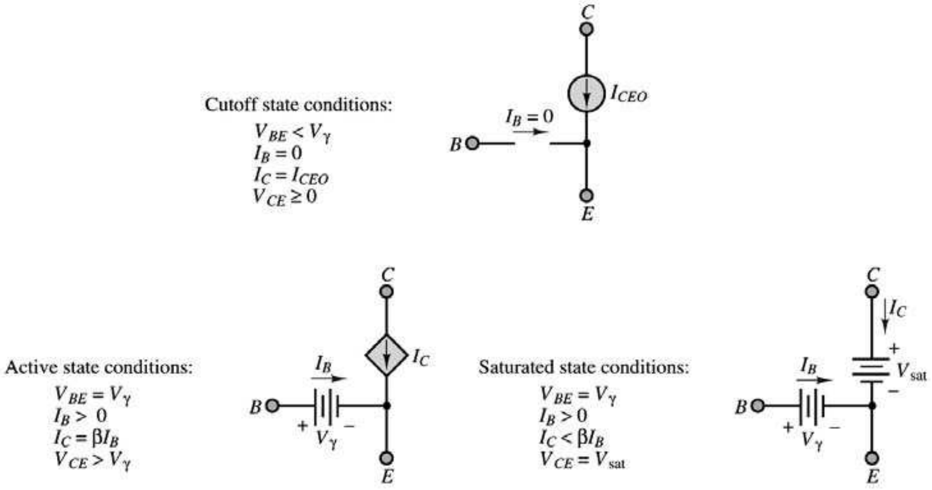

FIGURE 5.7.30 *npn* BJT large-signal model.

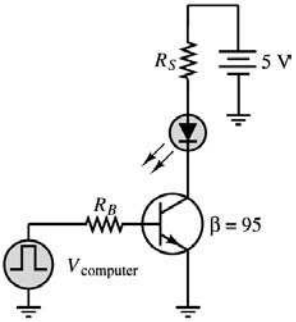

FIGURE 5.7.31 LED driver circuit.

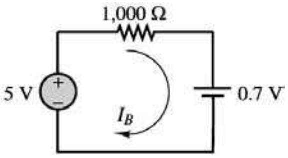

FIGURE 5.7.32 *BE* circuit for LED driver.

Assume that the base-emitter junction of the transistor has an offset voltage of 0.7 V and that R_B = 1 kΩ and R_S = 42.5 Ω.

1. When the computer is supplying 5 V to the circuit, is the transistor in cutoff, in saturation, or in the linear region of operation?
2. Determine the current in the LED when "turned on" and, thus, state whether the LED will exceed its power rating.

Solution. The base-emitter circuit is considered first, to determine whether the BE junction is forward-biased. The equivalent circuit is shown in Figure 5.7.32

Writing KVL around the base circuit, we obtain

$$(5 - 0.7) = I_B(1000)$$

or

$$I_B = 4.3 \text{ mA}$$

Since this current is greater than zero (i.e., since positive current flows into the base), the transistor is not in cutoff.

Next, we need to determine whether the transistor is in the linear active or in the saturation region. One method that can be employed to determine whether the device is in the active region is to assume that it is and to solve for the circuit that results from the assumed condition. If the resulting equations are consistent, then the assumption is justified. Assuming that the transistor is in its active region, the following equations apply:

$$I_C = \beta I_B$$

or

$$I_C = 95(4.3 \text{ mA}) = 408.5 \text{ mA}$$

With reference to the circuit of Figure 5.7.33, KVL may be applied around the collector circuit, to obtain

$$5 = 1.4 + V_{CE} + I_C R_S$$

or

$$(5 - 1.4) - 408.5(42.5) = V_{CE}$$

or

$$V_{CE} = -13.76 \text{ V}$$

This result is clearly not possible, since the supply voltage is only 5V! It must therefore be concluded that the transistor is not in the linear region and must be in saturation. To test this hypothesis, we can substitute the nominal saturation voltage for the BJT in place of V_{CE} (a typical saturation voltage would be V_{CE} sat = 0.2 V) and verify that in this case we obtain a consistent solution:

$$I_C = \frac{(5 - 1.4 - 0.2)}{42.5} = 80 \text{ mA}$$

This is a reasonable result, stating that the collector current in the saturation region for the given circuit is of the order of 80 mA.

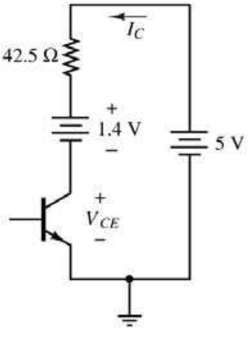

FIGURE 5.7.33 Equivalent collector circuit of LED driver, assuming that the BJT is in the linear active region.

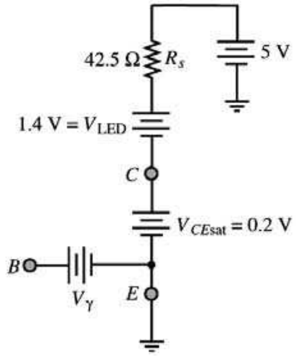

FIGURE 5.7.34 LED driver equivalent collector circuit, assuming that the BJT is in the saturation region.

In the above part, it was determined that the transistor was in saturation. Using the circuit model for saturation, we may draw the equivalent circuit of Figure 5.7.34. Since I_C = 80 mA, the power dissipated by the LED may be calculated as follows:

$$P_{\text{LED}} = I_C V_{\text{LED}} = 80 \text{ mA} \times 1.4 \text{ V} = 112 \text{ mW}$$

Thus, the power limitation of the LED will not be exceeded.

Field-Effect Transistors

The second transistor family discussed in this section operates on the basis of a principle that is quite different from that of the *pn* junction devices. The concept that forms the basis of the operation of the **field-effect transistor**, or FET, is that the width of a conducting channel in a semiconductor may be varied by the external application of an electric field. Thus, FETs behave as *voltage-controlled resistors*. This family of electronic devices can be subdivided into three groups, all of which will be introduced in the remainder of this chapter. Figure 5.7.35 depicts the classification of field-effect transistors, as well as the more commonly used symbols for these devices. These devices can be grouped into three major categories. The first two categories are both types of **metal-oxide-semiconductor field-effect transistors**, or MOSFETs: **enhancement-mode MOSFETs** and **depletion-mode MOSFETs**. The third category consists of **junction field-effect transistors**, or JFETs. In addition, each of these devices can be fabricated either as an ***n*-channel** device or as a ***p*-channel** device, where the *n* or *p* designation indicates the nature of the doping in the semiconductor channel.

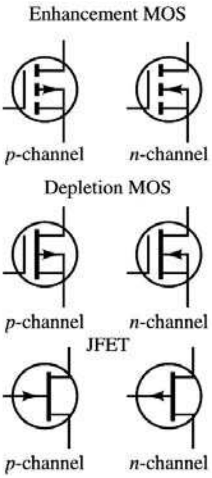

FIGURE 5.7.35 Classification of field-effect transistors.

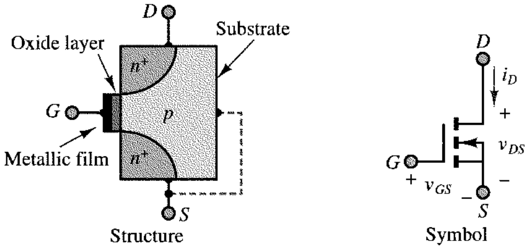

FIGURE 5.7.36 *n*-Channel enhancement MOSFET.

The construction of the MOSFET is shown in Figure 5.7.36, along with its circuit symbol. The device consists of a metal **gate**, insulated from the bulk of the *p*-type semiconductor material by an oxide layer (thus the terminology *metal-oxide-semiconductor*). Two n^+ regions on either side of the gate are called **source** and **drain**, respectively. An electric field can be applied between the gate and the *bulk* of the semiconductor by connecting the gate to a voltage source. The effect of the electric field, the intensity of which depends on the strength of the gate voltage, is to push positive charge carriers away from the surface of the bulk material. As a consequence of this effect, the *p*-type material has a lower concentration of positive charge carriers near its surface, and it behaves progressively more like intrinsic semiconductor material and then, finally, like *n*-type material as the electric field strength increases. Thus, in a narrow layer between n^+ regions, the *p*-type material is *inverted* and *n*-type charge carriers become available for conduction. This layer is called the *channel*. The device of Figure 5.7.36 takes the name *n-channel MOSFET*. It is also called an *enhancement-mode* device, because the applied electric field "enhances" the conduction in the channel by attracting *n*-type charge carriers. There are also *depletion-mode* devices, in which the application of an electric field "depletes" the channel of charge carriers, reducing the effective channel width. It is useful to think of enhancement-mode devices as being normally off: current cannot flow from drain to source unless a gate voltage is applied. On the other hand, depletion-mode devices are normally on; that is, the gate voltage is used to reduce the conduction of current from drain to source.

An analogous discussion could be carried out for *p-channel MOSFETs*. In a *p*-channel device, conduction in the channel occurs through positive charge carriers. The correspondence between *n*-channel and *p*-channel devices is akin to that between *npn* and *pnp* bipolar devices.

We are now ready to describe qualitatively the *i-v* characteristic of this enhancement-mode MOSFET, for small values of drain-to-source voltage, v_{DS}, and for constant v_{GS}, the channel has essentially constant width and therefore acts as a constant resistance. As the gate voltage is changed, this resistance can be varied over a certain range. This mode of operation, for small drain voltages, is called the **ohmic state**, and, as depicted in Figure 5.7.37, it corresponds to a linear *i-v* curve for fixed v_{GS}, as would be expected of a resistor. Thus, in the ohmic state the MOSFET acts as a **voltage-controlled resistor**.

As the drain voltage is increased, the gate-to-drain voltage, v_{GD}, decreases, reducing the electric field strength at the drain end of the device.

When $v_{GD} = v_{GS} - v_{DS} < v_T$ and $v_{DS} > v_{GS} - v_T$, the channel is *pinched down*, and the electron flow into the drain is physically limited, so that the drain current becomes essentially constant. This phenomenon

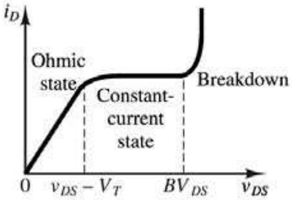

FIGURE 5.7.37 MOSFET *i-v* curve.

is clearly reflected in the curve of Figure 5.7.37, where it is shown that for drain-to-source voltages above $v_{DS} > v_{GS} - v_T$, the drain current becomes constant, independent of v_{DS}. This mode of operation is the **constant-current state.** If v_{DS} exceeds a given **drain breakdown voltage**, BV_{DS} (usually between 20 and 50 V), avalanche breakdown occurs and the drain current increases substantially. Operation in this **breakdown state** can lead to permanent damage because of the excessive heat caused by the large drain current. Finally, if v_{GS} exceeds the **gate breakdown voltage** (around 50 V), permanent damage to the oxide layer can occur. It is important to know that it is possible to generate *static* voltages of magnitude sufficient to exceed this breakdown voltage just by handling the device; thus, some attention must usually be paid to static voltage buildup in handling MOS circuits.

Transistor Gates and Switches

Transistor switching circuits form the basis of digital logic circuits. The objective of this section is to discuss the internal operation of these circuits and to provide the reader interested in the internal workings of digital circuits with an adequate understanding of the basic principles.

An **electronic gate** is a device that, on the basis of one or more input signals, produces one of two or more prescribed outputs; as will be seen shortly, one can construct both digital and analog gates. A word of explanation is required, first, regarding the meaning of the words *analog* and *digital.* An analog voltage or current — or, more generally, an analog signal — is one that varies in a continuous fashion over time, in *analogy* (hence the expression *analog*) with a physical quantity. An example of an analog signal is a sensor voltage corresponding to ambient temperature on any given day, which may fluctuate between, say, 30° and 50°F. A digital signal, on the other hand, is a signal that can take only a finite number of values; in particular, a commonly encountered class of digital signals consists of **binary signals**, which can take only one of two values (for example, 1 and 0). A typical example of a binary signal would be the control signal for the furnace in a home heating system controlled by a conventional thermostat, where one can think of this signal as being "on" (or 1) if the temperature of the house has dropped below the thermostat setting (desired value), or "off" (or 0) if the house temperature is greater than or equal to the set temperature (say, 68°F). Figure 5.7.38 illustrates the appearance of the analog and digital signals in this furnace example.

FIGURE 5.7.38 Illustration of analog and digital signals.

Analog Gates

A common form of analog gate — probably the most important, in practice — employs an FET and takes advantage of the fact that current can flow in either direction in an FET biased in the ohmic region. Recall that the drain characteristic of the MOSFET consists of three regions: ohmic, active, and breakdown. A MOSFET amplifier is operated in the active region, where the drain current is nearly constant for any given value of v_{GS}. On the other hand, a MOSFET biased in the ohmic state acts very much as a linear resistor. For example, for an *n*-channel enhancement MOSFET, the conditions for the transistor to be in the ohmic region are

$$v_{GS} > V_T \quad \text{and} \quad |v_{DS}| \le \frac{1}{4}\left(v_{GS} - V_T\right) \tag{5.7.17}$$

As long as the FET is biased within these conditions, it acts simply as a linear resistor, and it can conduct current in either direction (provided that v_{DS} does not exceed the limits stated in Equation (5.7.17). In particular, the resistance of the channel in the ohmic region is found to be

$$R_{DS} = \frac{V_T^2}{2I_{DSS}\left(v_{GS} - V_T\right)} \tag{5.7.18}$$

so that the drain current is equal to

$$i_D \approx \frac{v_{DS}}{r_{DS}} \quad \text{for} \quad |v_{DS}| \le \frac{1}{4}\left(v_{GS} - V_T\right) \quad \text{and} \quad v_{GS} > V_T \tag{5.7.19}$$

The most important feature of the MOSFET operating in the ohmic region, then, is that it acts as a voltage-controlled resistor, with the gate-source voltage, v_{GS}, controlling the channel resistance, R_{DS}. The use of the MOSFET as a switch in the ohmic region, then, consists of providing a gate-source voltage that can either hold the MOSFET in the cutoff region ($v_{GS} < V_T$) or bring it into the ohmic region. In this fashion, v_{GS} acts as a control voltage for the transistor.

Consider the circuit shown in Figure 5.7.39, where we presume that v_C can be varied externally and that v_{in} is some analog signal source that we may wish to connect to the load R_L at some appropriate time. The operation of the switch is as follows. When $v_C \le V_T$, the FET is in the cutoff region and acts as an open circuit. When $v_C > V_T$ (with a value of v_{GS} such that the MOSFET is in the ohmic region), the transistor acts as a linear resistance, R_{DS}. If $R_{DS} \ll R_L$, then $v_{\text{out}} \approx v_{\text{in}}$. By using a pair of MOSFETs, it is possible to improve the dynamic range of signals one can transmit through this analog gate.

MOSFET analog switches are usually produced in integrated circuit (IC) form and denoted by the symbol shown in Figure 5.7.40.

Digital Gates

BJT Gates. In discussing large-signal models for the BJT, we observed that the *i-v* characteristic of this family of devices includes a *cutoff* region, where virtually no current flows through the transistor. On the other hand, when a sufficient amount of current is injected into the base of the transistor, a bipolar transistor will reach *saturation*, and a substantial amount of collector current will flow. This behavior is quite well suited to the design of electronic gates and switches and can be visualized by superimposing a load line on the collector characteristic, as shown in Figure 5.7.41.

The operation of the simple **BJT switch** is illustrated in Figure 5.7.41 by means of load-line analysis. Writing the load-line equation at the collector circuit, we have

$$v_{CE} = V_{CC} - i_C R_C \qquad (5.7.20$$

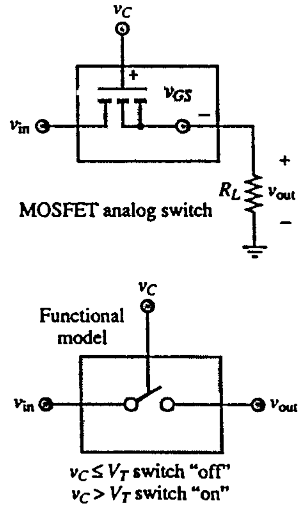

FIGURE 5.7.39 MOSFET analog switch.

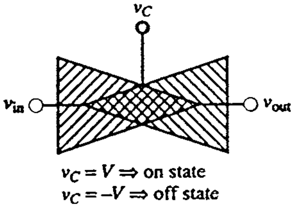

FIGURE 5.7.40 Symbol for bilateral FET analog gate.

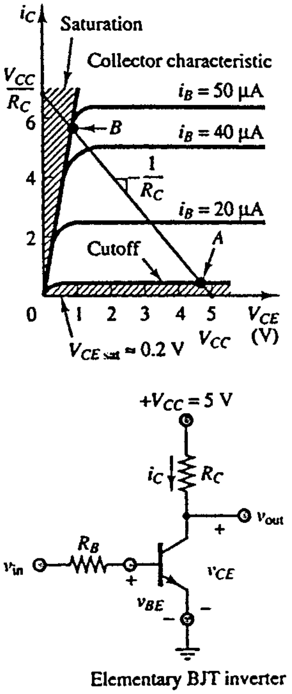

FIGURE 5.7.41 BJT switching characteristic.

and

$$v_{\text{out}} = v_{CE} \tag{5.7.21}$$

Thus, when the input voltage, v_{in}, is low (say, 0 V, for example) the transistor is in the cutoff region and little or no current flows, and

$$v_{\text{out}} = v_{CE} = V_{CC} \tag{5.7.22}$$

so that the output is "logic high."

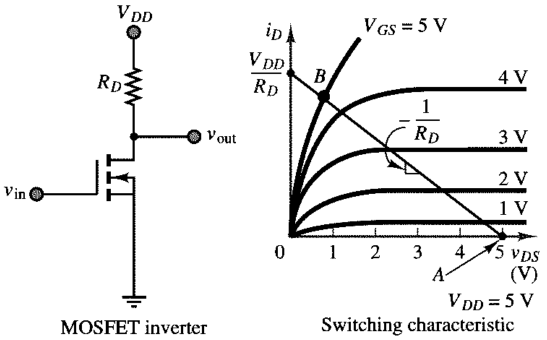
When v_{in} is large enough to drive the transistor into the saturation region, a substantial amount of collector current will flow and the collector-emitter voltage will be reduced to the small saturation value, $V_{CE\,\text{sat}}$, which is typically a fraction of a volt. This corresponds to the point labeled B on the load line. For the input voltage v_{in} to drive the BJT of Figure 5.7.41 into saturation, a base current of approximately 50 mA will be required. Suppose, then, that the voltage v_{in} could take the values 0 or 5 V. Then, if $v_{\text{in}} =$ 0 V, v_{out} will be nearly equal to V_{CC} or, again, 5 V. If, on the other hand, $v_{\text{in}} = 5$ V and R_B is, say, equal to 85 kΩ [so that the base current required for saturation flows into the base: $i_B \approx (5\text{ V} - 0.7\text{ V})/R_B =$ 50.6 μA], we have the BJT in saturation, and $v_{\text{out}} = V_{CE\,\text{sat}} \approx 0.2$ V.

Thus, you see that whenever v_{in} corresponds to a logic high (or logic 1), v_{out} takes a value close to 0 V, or logic low (or 0); conversely, $v_{\text{in}} =$"0" (logic "low") leads to $v_{\text{out}} =$ "1". The values of 5 and 0 V for the two logic levels 1 and 0 are quite common in practice and are the standard values used in a family of logic circuits denoted by the acronym TTL, which stands for **transistor-transistor logic**. One of the more common TTL blocks is the **inverter** shown in Figure 5.7.41, so called because it "inverts" the input by providing a low output for a high input, and vice versa. This type of inverting, or "negative", logic behavior is quite typical of BJT gates (and of transistor gates in general).

MOSFET Logic Gates. Having discussed the BJT as a switching element, we might quite naturally suspect that FETs may similarly serve as logic gates. In fact, in some respects, FETs are better suited to be employed as logic stages than BJTs. The *n*-channel enhancement MOSFET serves as an excellent illustration: because of its physical construction, it is normally off (that is, it is off until a sufficient gate voltage is provided), and therefore it does not require much current from the input signal source. Further, MOS devices offer the additional advantage of easy fabrication into integrated circuit form, making production economical in large volume. On the other hand, MOS devices cannot provide as much current as BJTs, and their switching speeds are not quite as fast — although these last statements may not hold true for long, because great improvements are taking place in MOS technology. Overall, it is certainly true that in recent years it has become increasingly common to design logic circuits based on MOS technology. In particular, a successful family of logic gates called *CMOS* (for *complementary metal-oxide-semiconductor*) takes advantage of both *p*- and *n*-channel enhancement-mode MOSFETs to exploit the best features of both types of transistors. CMOS logic gates (and many other types of digital circuits constructed using the same technology) consume very little supply power and have become the mainstay in pocket calculators, wristwatches, portable computers, and many other consumer electronics products. Without delving into the details of CMOS technology, we shall briefly illustrate the properties of MOSFET logic gates and of CMOS gates in the remainder of this section.

Figure 5.7.42 depicts a MOSFET switch with its drain *i-v* characteristic. Note the general similarity with the switching characteristic of the BJT shown in the previous section. When the input voltage, v_{in}, is zero, the MOSFET conducts virtually no current and the output voltage, v_{out}, is equal to V_{DD}. When v_{in} is equal to 5 V, the MOSFET Q point moves from point A to point B along with the load line, with $v_{DS} = 0.5$ V. Thus, the circuit acts as an inverter. Much as in the case of the BJT, the inverter forms the basis of all MOS logic gates.

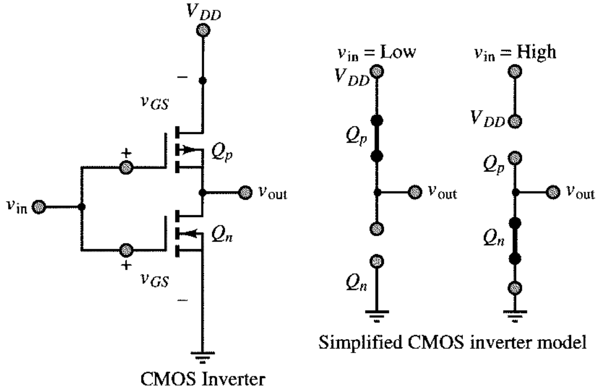
An elementary CMOS inverter is shown in Figure 5.7.43. Note first the simplicity of this configuration, which simply employs two enhancement-mode MOSFETs: *p*-channel at the top, denoted by the symbol Q_p, and *n*-channel at the bottom, denoted by Q_n. Recall from Chapter 8 that when v_{in} is low, transistor



MOSFET inverter

Switching characteristic

FIGURE 5.7.42 MOSFET switching characteristic.



CMOS Inverter

Simplified CMOS inverter model

FIGURE 5.7.43 CMOS inverter.

Q_n is off. However, transistor Q_p sees a gate-to-source voltage $v_{GS} = v_{in} - V_{DD} = -V_{DD}$; in a *p*-channel device, this condition is the counterpart of having $v_{GS} = V_{DD}$ for an *n*-channel MOSFET. Thus, when Q_n is off, Q_p is on and acts very much as a small resistance. In summary, when v_{in} is low, the output is $v_{out} \approx V_{DD}$. When v_{in} is high, the situation is reversed: Qn is now on and acts nearly as a short circuit while Q_p is open (since $v_{GS} = 0$ for Q_p). Thus, $v_{in} \approx 0$. The complementary MOS operation is depicted in Figure 5.7.43 in simplified form by showing each transistor as either a short or an open circuit, depending on it state. This simplified analysis is sufficient for the purpose of a qualitative analysis.

5.8 Power Electronics

The objective of this section is to present a survey of power electronic devices and systems. Power electronic devices form the "muscle" of many electromechanical systems. For example, one finds such devices in many appliances, in industrial machinery, and virtually wherever an electric motor is found, since one of the foremost applications of power electronic devices is to supply and control the currents and voltages required to power electric machines, such as those introduced in Section 5.12.

Classification of Power Electronic Devices

Power semiconductors can be broadly subdivided into five groups: (1) power diodes, (2) thyristors, (3) power bipolar junction transistors (BJTs), (4) insulated-gate bipolar transistors (IGBTs), and (5) static induction transistors (SITs). Figure 5.8.1 depicts the symbols for the most common power electronic devices.

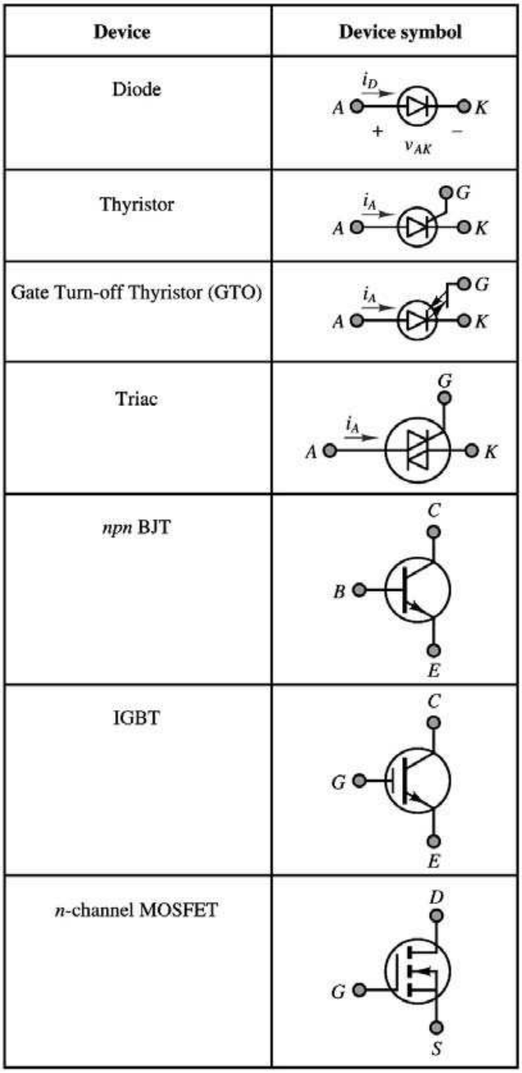


FIGURE 5.8.1 Classification of power electronic devices.

Power diodes are functionally identical to the diodes introduced in Section 5.7, except for their ability to carry much larger currents. A diode conducts in the forward-biased mode when the anode voltage (V_A) is higher than the cathode voltage (V_K). Three types of power diodes exist: general-purpose, high-speed (fast-recovery), and Schottky. Typical ranges of voltage and current are 3000 V and 3500 A for general-purpose diodes and 3000 V and 1000 A for high-speed devices. The latter have switching times as low as a fraction of a microsecond. Schottky diodes can switch much faster (in the nanosecond range) but are limited to around 100 V and 300 A. The forward voltage drop of power diodes is not much higher than that of low-power diodes, being between 0.5 and 1.2 V. Since power diodes are used with rather large voltages, the forward bias voltage is usually considered negligible relative to other voltages in the circuit, and the switching characteristics of power diodes may be considered near ideal. The principal consideration in choosing power diodes is their power rating.

Thyristors function like power diodes with an additional gate terminal that controls the time when the device begins conducting; a thyristor starts to conduct when a small gate current is injected into the gate terminal, provided that the anode voltage is greater than the cathode voltage (or $V_{AK} > 0$ V). The forward voltage drop of a thyristor is of the order of 0.5 to 2 V. Once conduction is initiated, the gate current has no further control. To stop conduction, the device must be reverse-biased; that is, one must ensure that $V_{AK} \leq 0$ V. Thyristors can be rated at up to 6000 V and 3500 A. The **turn-off time** is an important characteristic of thyristors; it represents the time required for the device current to return to zero after external switching of V_{AK}. The fastest turn-off times available are in the range of 10 μsec; however, such turn-off times are achieved only in devices with slightly lower power ratings (1200 V, 1000 A). Thyristors can be subclassified into the following groups: force-commutated and line-commutated thyristors, gate turn-off thyristors (GTOs), reverse-conducting thyristors (RCTs), static induction thyristors (SITHs), gate-assisted turn-off thyristors (GATTs), light-activated silicon-controlled rectifiers (LASCSRs), and MOS-controlled thyristors (MCTs). It is beyond the scope of this chapter to go into a detailed description of each of these types of devices; their operation is typically a slight modification of the basic operation of the thyristor. The reader who wishes to gain greater insight into this topic may refer to one of a number of excellent books specifically devoted to the subject of power electronics.

Two types of thyristor-based device deserve some more attention. The **triac**, as can be seen in Figure 5.8.1, consists of a pair of thyristors connected back to back, with a single gate; this allows for current control in either direction. Thus, a triac may be thought of as bidirectional thyristor. The **gate turn-off** thyristor (GTO), on the other hand, can be turned on by applying a short positive pulse to the gate, like a thyristor, and can also be turned off by application of a short negative pulse. Thus, GTOs are very convenient in that they do not require separate commutation circuits to be turned on and off.

Power BJTs can reach ratings up to 1200 V and 400 A, and they operate in much the same way as a conventional BJT. Power BJTs are used in power converter applications at frequencies up to around 10 kHz. **Power MOSFETs** can operate at somewhat higher frequencies (a few to several tens of kHz), but are limited in power (typically up to 1000 V, 50 A). **Insulated-gate bipolar transistors** (IGBTs) are voltage-controlled (because of their insulated gate, reminiscent of insulated-gate FETs) power transistors that offer superior speed with respect to BJTs but are not quite as fast as power MOSFETs.

Classification of Power Electronic Circuits

The devices that will be discussed in the present chapter find application in a variety of **power electronic circuits**. This section will briefly summarize the principal types of power electronic circuits and will qualitatively describe their operation. The following sections will describe the devices and their operation in these circuits in more detail.

One possible classification of power electronic circuits is given in Table 5.8.1. Many of the types of circuits are similar to circuits that were introduced in earlier chapters. Voltage regulators were introduced in Section 5.7. Power electronic switches function exactly like the transistor switches described in Section 5.7; their function is to act as voltage- or current-controlled switches to turn AC or DC supplies on and off. Transistor power amplifiers are the high-power version of the BJT and MOSFET amplifiers mentioned in Section 5.7.

TABLE 5.8.1 Power Electronic Circuits

Circuit Type	Essential Features
Voltage regulators	Regulate a DC supply to a fixed voltage output
Power amplifiers	Large-signal amplification of voltages and currents
Switches	Electronic switches (for example, transistor switches)
Diode rectifier	Converts fixed AC voltage (single- or multiphase) to fixed DC voltage
AC-DC converter (controlled rectifier)	Converts fixed AC voltage (single- or multiphase) to variable DC voltage
AC-AC converter (AC voltage controller)	Converts fixed AC voltage to variable AC voltage (single- or multiphase)
DC-DC converter (chopper)	Converts fixed DC voltage to variable DC voltage
DC-AC converter (inverter)	Converts fixed DC voltage to variable AC voltage (single- or multiphase)

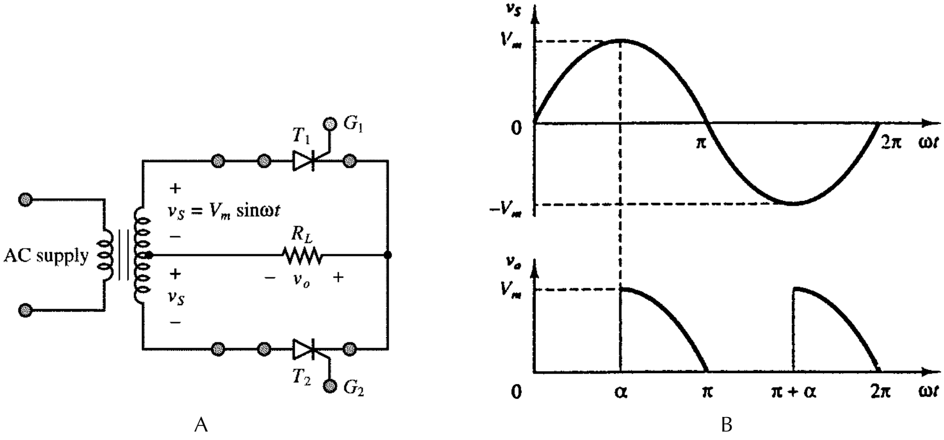

FIGURE 5.8.2 AC-DC converter circuit and waveform.

Diode rectifiers were discussed in Section 5.7 in their single-phase form; similar rectifiers can also be designed to operate with three-phase sources. The operation of a single-phase full-wave rectifier was summarized in Figure 5.8.2. AC-DC converters are also rectifiers, but they take advantage of the controlled properties of thyristors. The thyristor gate current can be timed to "fire" conduction at variable times, resulting in a variable DC output, as illustrated in Figure 5.8.2, which shows the circuit and behavior of a single-phase AC-DC converter. This type of converter is very commonly used as a supply for DC electric motors. In Figure 5.8.2 α is the firing angle of thyristor T_1, where the device starts to conduct.

AC-AC converters are used to obtain a variable AC voltage from a fixed AC source. Figure 5.8.3 shows a triac-based AC-AC converter, which takes advantage of the bidirectional capability of triacs to control the rms value of an alternating voltage. Note in particular that the resulting AC waveform is no longer a pure sinusoid even though its fundamental period (frequency) is unchanged. A DC-DC converter, also known as a *chopper*, or *switching regulator*, permits conversion of a fixed DC source to a variable DC supply. Figure 5.8.4 shows how such an effect may be obtained by controlling the base-emitter voltage of a bipolar transistor, enabling conduction at the desired time. This results in the conversion of the DC input voltage to a variable-duty-cycle output voltage, whose average value can be controlled by selecting the "on" time of the transistor. DC-DC converters find application as variable voltage supplies for DC electric motors used in electric vehicles.

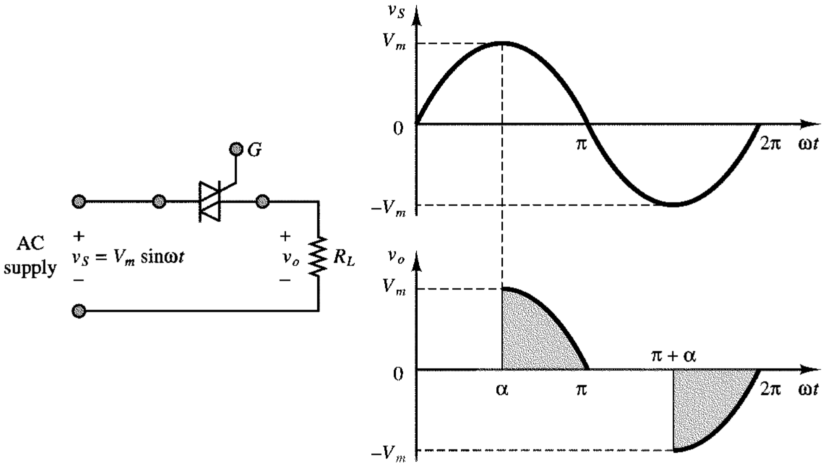

FIGURE 5.8.3 AC-AC converter circuit and waveform.

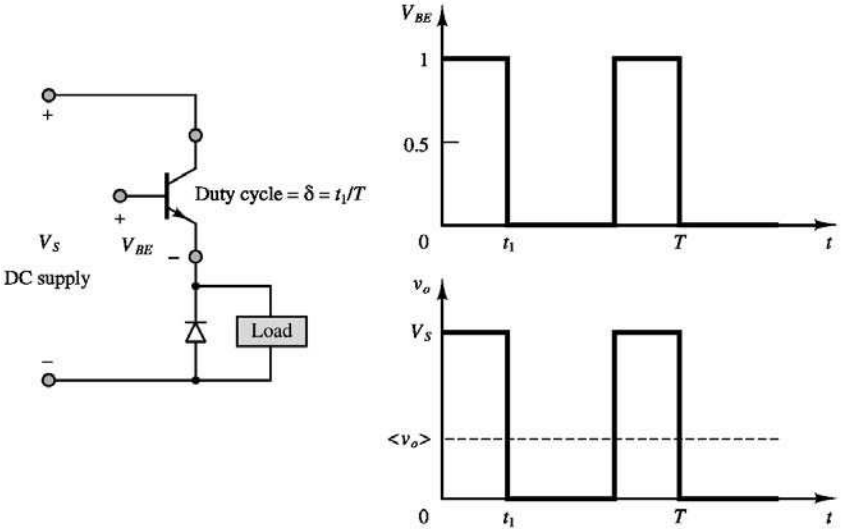

FIGURE 5.8.4 DC-DC converter circuit and waveform.

Finally, DC-AC supplies, or inverters, are used to convert a fixed DC supply to a variable AC supply; they find application in AC motor control. The operation of these circuits is rather complex; it is illustrated conceptually in the waveforms of Figure 5.8.5, where it is shown that by appropriately switching two pairs of transistors it is possible to generate an alternating current waveform (square wave).

Each of the circuits of Table 5.8.1 will now be analyzed in greater detail.

Rectifiers and Controlled Rectifiers (AC-DC Converters)

Thyristors and Controlled Rectifiers

In a number of applications, it is useful to be able to externally control the amount of current flowing from an AC source to the load. A family of power semiconductor devices called **controlled rectifiers** allows for control of the rectifiers state by means of a third input, called the gate. Figure 5.8.6 depicts the appearance of a **thyristor**, or **silicon-controlled rectifier** (SCR), illustrating how the physical structure of this device consists of four layers, alternating *p*-type and *n*-type material. Note that the circuit symbol for the thyristor suggests that this device acts as a diode, with provision for an additional external control signal.

The operation of the thyristor can be explained in an intuitive fashion as follows. When the voltage v_{AK} is negative (i.e., providing reverse bias), the thyristor acts just like a conventional *pn* junction in the off state. When v_{AK} is forward-biased *and* a small amount of current is injected into the gate, the thyristor conducts forward current. The thyristor then continues to conduct (even in the absence of gate current), provided that v_{AK} remains positive. Figure 5.8.7 depicts the *i-v* curve for the thyristor. Note that the thyristor has two stable states, determined by the bias v_{AK} and by the gate current. In summary, the thyristor acts as a diode with a control gate that determines the time when conduction begins.

A somewhat more accurate description of thyristor operation may be provided if we realize that the four-layer *pnpn* device can be modeled as a *pnp* transistor connected to an *npn* transistor. Figure 5.8.8 clearly shows that, physically, this is a realistic representation. Note that the anode current, i_A, is equal to the emitter current of the *pnp* transistor (labeled Q_p) and the base current of Q_p is equal to the collector current of the *npn* transistor, Q_n. Likewise, the base current of Q_n is the sum of the gate current and the collector current of Q_p. The behavior of this transistor model is explained as follows. Suppose, initially, i_G and i_{B_n} are both zero. Then it follows that Q_n is in cutoff, and therefore $i_{C_n} = 0$. But if $i_{C_n} = 0$, then the base current going into Q_p is also zero and Q_p is also in cutoff, and $i_{C_n} = 0$, consistent with our initial

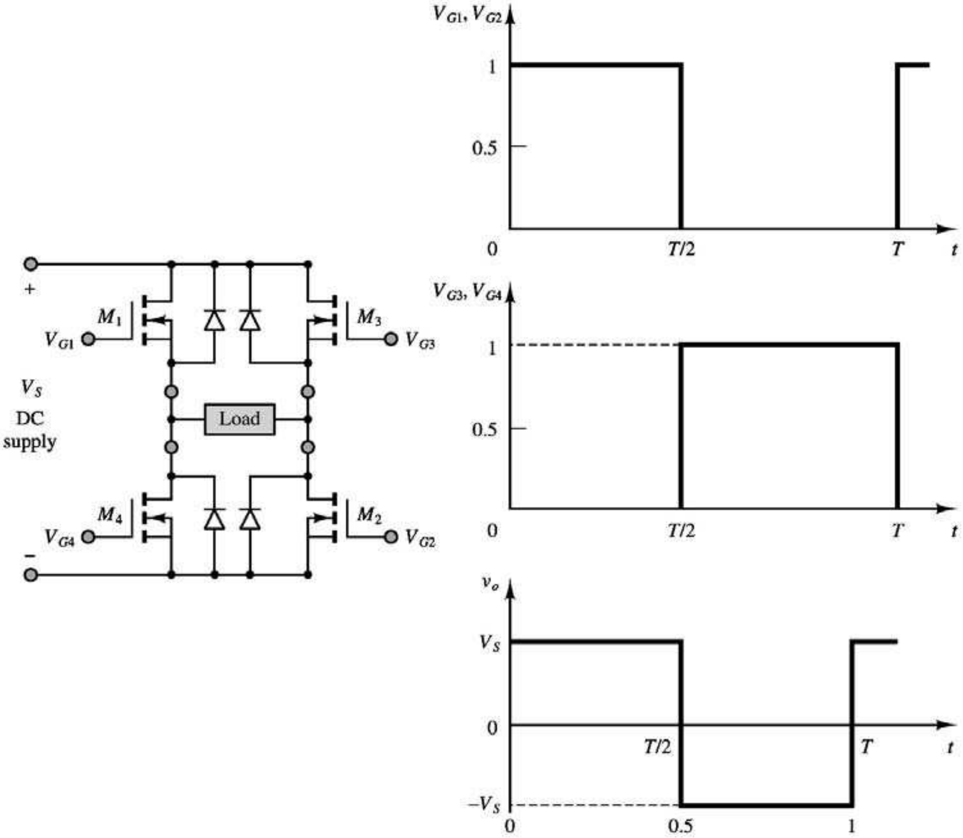

FIGURE 5.8.5 DC-AC converter circuit and waveform.

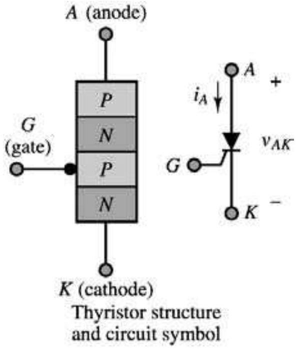

FIGURE 5.8.6 Thyristor structure and circuit symbol.

assumption. Thus, this is a stable state, in the sense that unless an external condition perturbs the thyristor, it will remain off.

Now, suppose a small pulse of current is injected at the gate. Then $i_{B_n} > 0$ and Q_n starts to conduct, provided, of course, that $v_{AK} > 0$. At this point, i_{C_n}, and therefore i_{B_p}, must be greater than zero, so that Q_p conducts. It is important to note that once the gate current has turned Q_n on, Q_p also conducts, so that $i_{C_p} > 0$. Thus, even though i_G may cease, once this "on" state is reached, $i_{C_p} = i_{B_n}$ continues to drive Q_n so that the on state is also self-sustaining. The only condition that will cause the thyristor to revert to the off state is the condition in which v_{AK} becomes negative; in this case, both transistors return to the cutoff state.

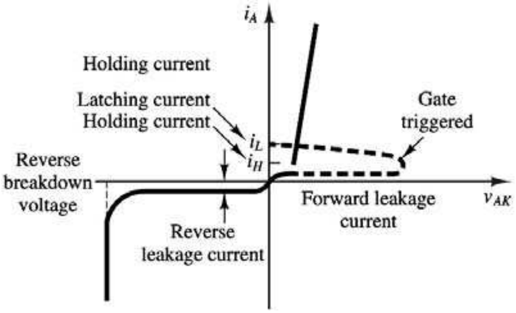

FIGURE 5.8.7 Thyristor *i*-*v* characteristic.

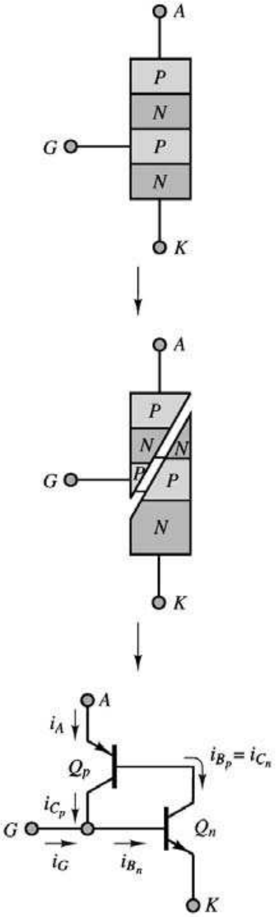

FIGURE 5.8.8 Thyristor two-transistor model.

In a typical controlled rectifier application, the device is used as a half-wave rectifier that conducts only after a trigger pulse is applied to the gate. Without concerning ourselves with how the trigger pulse is generated, we can analyze the general waveforms for the circuit of Figure 5.8.9 as follows. Let the voltage v_{trigger} be applied to the gate of the thyristor at $t = \tau$. The voltage v_{trigger} can be a short pulse, provided by a suitable trigger-timing circuit (Section 5.11 will discuss timing and switching circuits). At $t = \tau$, the thyristor begins to conduct, and it continues to do so until the AC source enters its negative cycle. Figure 5.8.10 depicts the relevant waveforms.

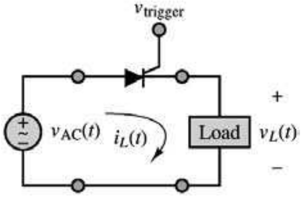

FIGURE 5.8.9 Controlled rectifier circuit.

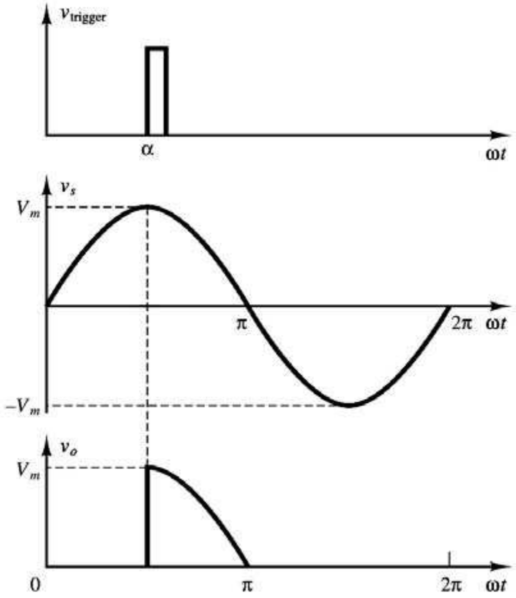

FIGURE 5.8.10 Half-wave controlled rectifier waveforms.

Note how the DC load voltage is controlled by the firing time τ, according to the following expression:

$$\langle v_L \rangle = V_L = \frac{1}{T}\int_{\tau}^{T/2} v_{\text{AC}}(t)\,dt \tag{5.8.1}$$

where T is the period of $v_{AC}(t)$, Now, if we let

$$v_{\text{AC}}(t) = A\sin\omega t \tag{5.8.2}$$

we can express the average (DC) value of the load voltage

$$V_L = \frac{1}{T}\int_{\tau}^{T/2} A\sin\omega t\,dt = (1+\cos\omega t)\frac{A}{2\pi} \tag{5.8.3}$$

in terms of the **firing angle**, α, defined as

$$\alpha = \omega t \tag{5.8.4}$$

By evaluating the integral of Equation (5.8.3), we can see that the (DC) load voltage amplitude depends on the firing angle, α:

$$V_L = (1+\cos\alpha)\frac{A}{2\pi} \tag{5.8.5}$$

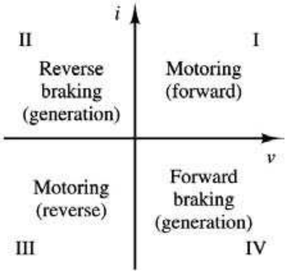

FIGURE 5.8.11 The four quadrants of an electric drive.

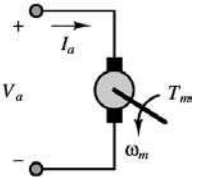

FIGURE 5.8.12 DC motor.

Electric Motor Drives

The advent of high-power semiconductor devices has made it possible to design effective and relatively low-cost electronic supplies that take full advantage of the capabilities of the devices introduced in this chapter. Electronic power supplies for DC and AC motors have become one of the major fields of application of power electronic devices. The last section of this chapter is devoted to an introduction to two families of power supplies, or **electric drives: choppers**, or **DC-DC converters**; and **inverters**, or **DC-AC converters**. These circuits find widespread application in the control of AC and DC motors in a variety of applications and power ranges.

Before we delve into the discussion of the electronic supplies, it will be helpful to introduce the concept of quadrants of operation of a drive. Depending on the direction of current flow and on the polarity of the voltage, an electronic drive can operate in one of four possible modes, as indicated in Figure 5.8.11.

Choppers (DC-DC Converters)

As the name suggests, a DC-DC converter is capable of converting a fixed DC supply to a variable DC supply. This feature is particularly useful in the control of the speed of a DC motor (described in greater detail in Section 5.12). In a DC motor, shown schematically in Figure 5.8.12, the developed torque, T_m, is proportional to the current supplied to the motor **armature**, I_a, while the **electromotive force** (emf), E_a, which is the voltage developed across the armature, is proportional to the speed of rotation of the motor, ω_m. A DC motor is an electromechanical energy-conversion system; that is, it converts electrical to mechanical energy (or vice versa if it is used as a generator); if we recall that the product of torque and speed is equal to power in the mechanical domain, and that current times voltage is equal to power in the electrical domain, we conclude that in the ideal case of complete energy conversion, we have

$$E_a \times I_a = T_m \times \omega_m \tag{5.8.6}$$

Naturally, such ideal energy conversion cannot take place; however, we can see that there is a correspondence between the four-electrical quadrants of Figure 5.8.11 and the mechanical power output of the motor: namely, if the voltage and current are both positive or both negative, the electrical power will be positive, and so will the mechanical power. This corresponds to the **forward** (*i*, *v* both positive) and **reverse** (*i*,*v* both negative) **motoring** operation. Forward motoring corresponds to quadrant I, and reverse motoring to quadrant III in Figure 5.8.12. If the voltage and current are of opposite polarity (quadrants II and IV), electrical energy is flowing back to the electric drive; in mechanical terms this corresponds to a braking condition. Operation in the fourth quadrant can lead to **regenerative braking**, so called

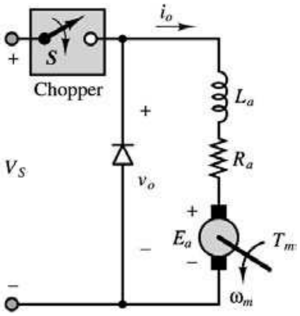

FIGURE 5.8.13 Step-down chopper (buck converter).

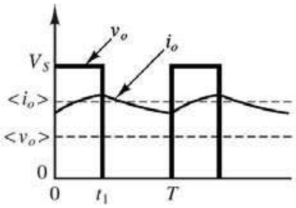

FIGURE 5.8.14 Step-down chopper waveforms.

because power is generated by making current flow back to the source. This mode could be useful, for example, to recharge a battery supply, because the braking energy can be regenerated by returning it to the electric supply.

A simple circuit that can accomplish the task of providing a variable DC supply from a fixed DC source is the **step-down chopper (buck converter)**, shown in Figure 5.8.13. The circuit consists of a "chopper" switch, denoted by the symbol S, and a free-wheeling diode. The switch can be any of the power switches described in this chapter, for example, a power BJT or MOSFET, or a thyristor; see, for example, the BJT switch of Figure 5.8.4. The circuit to the right of the diode is a model of a DC motor, including the inductance and resistance of the armature windings and the effect of the back emf E_a. When the switch is turned on (say, at $t = 0$), the supply V_s is connected to the load and $v_o = V_s$. The load current, i_o, is determined by the motor parameters. When the switch is turned off, the load current continues to flow through the free-wheeling diode, but the output voltage is now $v_o = 0$. At time T, the switch is turned on again, and the cycle repeats.

Figure 5.8.14 depicts the v_o and i_o waveforms. The average value of the output voltage, $\langle v_o \rangle$, is given by the expression

$$\langle v_o \rangle = \frac{t_1}{T} V_S = \delta V_S \tag{5.8.7}$$

where δ is the **duty cycle** of the chopper. The step-down chopper has a useful range,

$$0 \le \langle v_o \rangle \le V_S \tag{5.8.8}$$

It is also possible to increase the range of a DC-DC converter to above the supply voltage by making use of the energy-storage properties of an inductor; the resulting circuit is shown in Figure 5.8.15. When the chopper switch, S, is on, the supply current flows through the inductor and the closed switch, storing energy in the inductor; the output voltage, v_o, is zero, since the switch is a short circuit. When the switch is open, the supply current will flow through the load via the diode; but the inductor voltage is negative during the transient following the opening of the switch and therefore adds to the source voltage: the energy stored in the inductor while the switch was closed is now released and transferred to the load. This stored energy makes it possible for the output voltage to be higher than the supply voltage for a finite period of time.

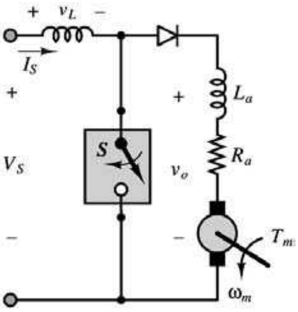

FIGURE 5.8.15 Step-up chopper (boost converter).

Let t_1 once again be the time during which the chopper conducts; neglecting for the moment the ripple in the supply current, the energy stored in the inductor during this period is

$$W_i = V_S I_S t_1 \tag{5.8.9}$$

When the chopper is off, the energy released to the load is

$$W_i = \left(\langle v_o \rangle - V_S\right) I_S \left(T - t_1\right) \tag{5.8.10}$$

If the system is lossless, the two energy expressions must be equal:

$$V_S I_S t_1 = \left(\langle v_o \rangle - V_S\right) I_S \left(T - t_1\right) \tag{5.8.11}$$

and we can determine the average output voltage to be

$$\langle v_o \rangle = V_S \frac{t_1 + T - t_1}{T - t_1} = V_S \frac{T}{T - t_1} = V_S \frac{1}{1 - \delta} \tag{5.8.12}$$

Since the duty cycle, δ, is always less than 1, the theoretical range of the supply is

$$V_S \le \langle v_o \rangle < \infty \tag{5.8.13}$$

The waveforms for the boost converter are shown in Figure 5.8.16.

A step-up chopper can also be used to provide regenerative braking: if the "supply" voltage is the motor armature voltage and the output voltage is the fixed DC supply (battery) voltage, then power can be made to flow from the motor to the DC supply (i.e., recharging the battery). This configuration is shown in Figure 5.8.17.

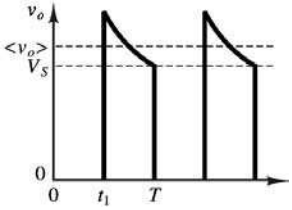

FIGURE 5.8.16 Step-up chopper output voltage waveform.

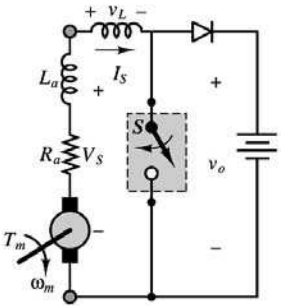

FIGURE 5.8.17 Step-up chopper used for regenerative braking.

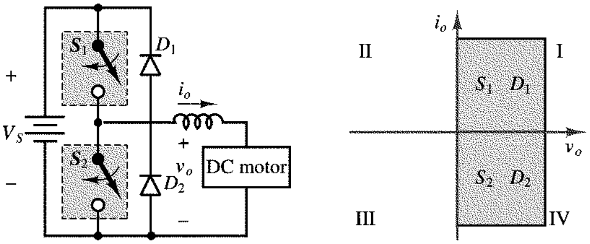

FIGURE 5.8.18 Two-quadrant chopper.

Finally, the operation of the step-down and step-up choppers can be combined into a **two-quadrant chopper**, shown in Figure 5.8.18. The circuit shown schematically in Figure 5.8.18 can provide both regenerative braking and motoring operation in a DC motor. When switch S_2 is open and switch S_1 serves as a chopper, the circuit operates as a step-down chopper, precisely as was described earlier in this section (convince yourself of this by redrawing the circuit with S_2 and D_2 replaced by open circuits). Thus, the drive and motor operate in the first quadrant (motoring operation). The output voltage, v_o, will switch between V_S and zero, as shown in Figure 5.8.14, and the load current will flow in the direction indicated by the arrow in Figure 5.8.18 diode D_1 free-wheels whenever S_1 is open. Since both output voltage and current are positive, the system operates in the first quadrant.

When switch S_1 is open and switch S_2 serves as a chopper, the circuit resembles a step-up chopper. The source is the motor emf, E_a, and the load is the battery; this is the situation depicted in Figure 5.8.17. The current will now be negative, since the sum of the motor emf and the voltage across the inductor (corresponding to the energy stored during the "on" cycle of S_2) is greater than the battery voltage. Thus, the drive operates in the fourth quadrant.

Inverters (DC-AC Converters)

As will be explained in Section 5.12, variable-speed drives for AC motors require a multiphase variable-frequency, variable-voltage supply. Such drives are called *DC-AC converters*, or *inverters*. Inverter circuits can be quite complex, so the objective of this section is to present a brief introduction to the subject, with the aim of illustrating the basic principles. A **voltage source inverter** (VSI) converts the output of a fixed DC supply (e.g., a battery) to a variable-frequency AC supply. Figure 5.8.19 depicts a **half-bridge VSI**; once again, the switches can be either bipolar or MOS transistors, or thyristors. The operation of this circuit is as follows. When switch S_1 is turned on, the output voltage is in the positive half-cycle, and $v_o = V_S/2$. The switching sequence of S_1 and S_2 is shown in Figure 5.8.20. It is important that each switch be turned off before the other is turned on; otherwise, the DC supply would be short-circuited. Since the load is always going to be inductive in the case of a motor drive, it is important to observe that the load current, i_o, will lag the voltage waveform, as shown in Figure 5.8.20. As shown in this figure, there will be some portions of the cycle in which the voltage is positive but the current is negative. The function of diodes D_1 and D_2 is precisely to conduct the load current whenever it is of direction opposite to the

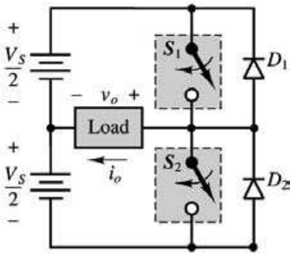

FIGURE 5.8.19 Half-bridge voltage source inverter.

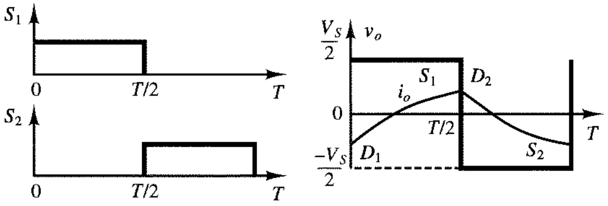

FIGURE 5.8.20 Half-bridge voltage source inverter waveforms.

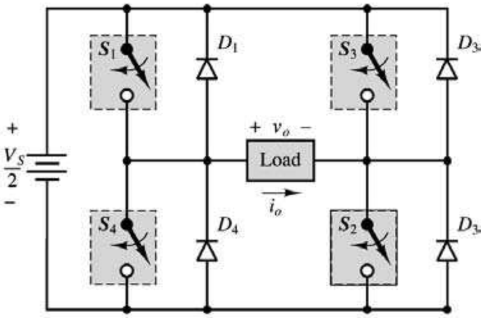

FIGURE 5.8.21 Full-bridge voltage source inverter.

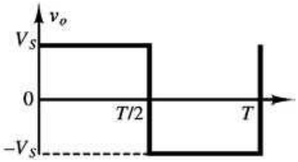

FIGURE 5.8.22 Half-bridge voltage source inverter output voltage waveform.

polarity of the voltage. Without these diodes, there would be no load current in this case. Figure 5.8.20 also shows which element is conducting in each portion of the cycle.

A full-bridge version of the VSI can also be designed as shown in Figure 5.8.21; the associated output voltage waveform is shown in Figure 5.8.22. A 3-phase VSI is shown in Figure 5.8.23.

5.9 Operational Amplifiers

In this section we will analyze the properties of a general-purpose amplifier circuit known as the *operational amplifier.*

The Operational Amplifier

An **operational amplifier** is an **integrated circuit**, that is, a large collection of individual electrical and electronic circuits integrated on a single silicon wafer. An operational amplifier — or op-amp — can perform a great number of operations, such as addition, filtering, or integration, which are all based on

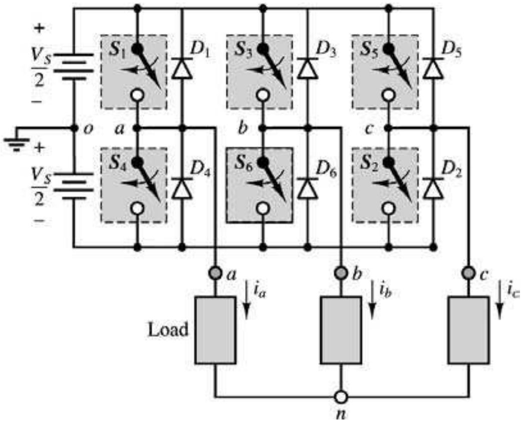

FIGURE 5.8.23 Three-phase voltage source inverter.

the properties of ideal amplifiers and of ideal circuit elements. The introduction of the operational amplifier in integrated circuit form marked the beginning of a new era in modern electronics. Since the introduction of the first IC op-amp, the trend in electronic instrumentation has been to move away from the discrete (individual-component) design of electronic circuits, toward the use of integrated circuits for a large number of applications. This statement is particularly true for applications of the type the nonelectrical engineer is likely to encounter: op-amps are found in most measurement and instrumentation applications, serving as extremely versatile building blocks for any application that requires the processing of electrical signals.

In the following pages, simple circuit models of the op-amp will be introduced. The simplicity of the models will permit the use of the op-amp as a circuit element, or building block, without the need to describe its internal workings in detail. Integrated circuit technology has today reached such an advanced stage of development that it can be safely stated that for the purpose of many instrumentation applications, the op-amp can be treated as an ideal device. Following the introductory material presented in this chapter, more advanced instrumentation applications will be explored in Section 5.11.

The Open-Loop Model

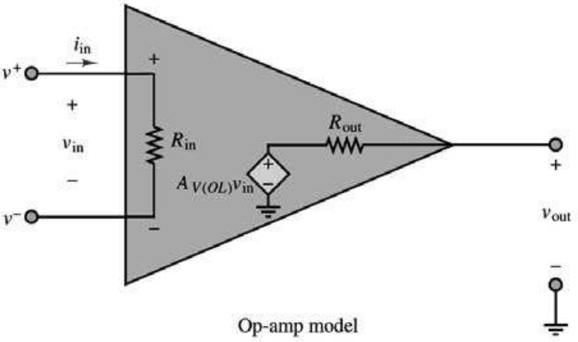
The ideal operational amplifier behaves very much as an ideal **differential amplifier**, that is, a device that amplifies the difference between two input voltages. Operational amplifiers are characterized by near-infinite input resistance and very small output resistance. As shown in Figure 5.9.1 the output of the op-amp is an amplified version of the difference between the voltages present at the two inputs:

$$v_{\text{out}} = A_{V(OL)}\left(v^{+} - v^{-}\right) \tag{5.9.1}$$

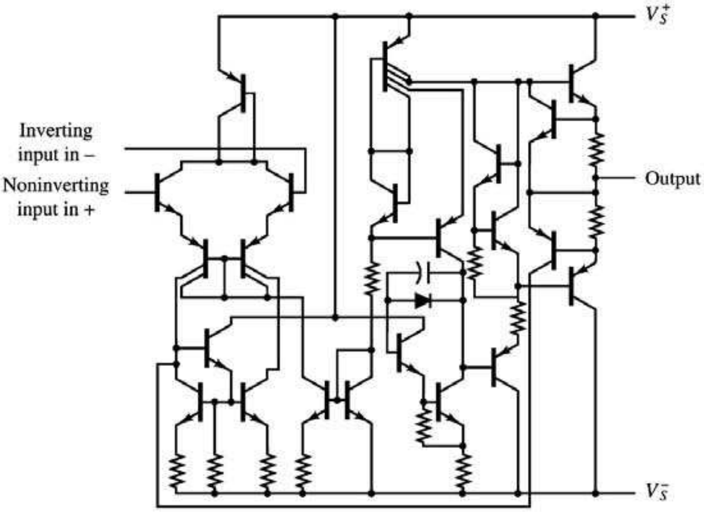
The input denoted by a positive sign is called the **noninverting input** (or terminal), while that represented with a negative sign is termed the **inverting input** (or terminal). The amplification factor, or gain, $A_{V(OL)}$, is called the **open-loop voltage gain** and is quite large by design, typically of the order of 10^5 to 10^7; it will soon become apparent why a large open-loop gain is a desirable characteristic. Together with the high input resistance and low output resistance, the effect of a large amplifier open-loop voltage gain, $A_{V(OL)}$, is such that op-amp circuits can be designed to perform very nearly as ideal voltage or current amplifiers. In effect, to analyze the performance of an op-amp circuit, only one assumption will be needed: that the current flowing into the input circuit of the amplifier is zero, or

$$i_{\text{in}} = 0 \tag{5.9.2}$$

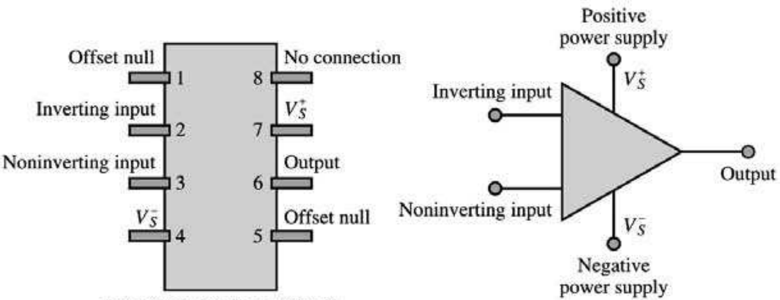
This assumption is justified by the large input resistance and large open-loop gain of the operational amplifier. The model just introduced will be used to analyze three amplifier circuits in the next part of this section.



Op-amp model



IC op-amp diagram



Integrated circuit operational amplifier (IC op-amp)

Simplified circuit symbol

FIGURE 5.9.1 Operational amplifier model symbols, and circuit diagram.

The Operational Amplifier in the Closed-Loop Mode

The Inverting Amplifier. One of the more popular circuit configurations of the op-amp, because of its simplicity, is the so-called inverting amplifier, shown in Figure 5.9.2.

$$v_S = -v_{\text{out}}\left(\frac{1}{R_F/R_S} + \frac{1}{A_{V(OL)}R_F/R_S} + \frac{1}{A_{V(OL)}}\right) \tag{5.9.3}$$

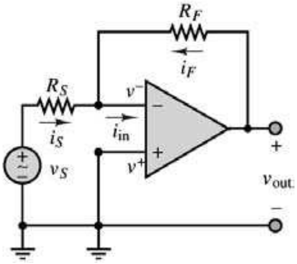


FIGURE 5.9.2 Inverting amplifier.

If the open-loop gain of the amplifier, $A_{V(OL)}$, is sufficiently large, the terms $1/(A_{V(OL)}R_F/R_S)$ and $1/A_{V(OL)}$, are essentially negligible, compared with $1/(R_F/R_S)$. As stated earlier, typical values of $A_{V(OL)}$ range from 10^5 to 10^7, and thus it is reasonable to conclude that, to a close approximation, the following expression describes the closed-loop gain of the inverting amplifier:

$$v_{out} = -\frac{R_F}{R_S}v_S \quad \text{Inverting amplifier closed-loop gain} \tag{5.9.4}$$

Next, we show that by making an additional assumption it is possible to simplify the analysis considerably. Consider that, as was shown for the inverting amplifier, the inverting terminal voltage is given by

$$v^- = -\frac{v_{out}}{A_{V(OL)}} \tag{5.9.5}$$

Clearly, as $A_{V(OL)}$ approaches infinity, the inverting-terminal voltage is going to be very small (practically, of the order of microvolts). It may then be assumed that *in the inverting amplifier*, v^- is virtually zero:

$$v^- \approx 0 \tag{5.9.6}$$

This assumption prompts an interesting observation (which may not yet appear obvious at this point): the effect of the feedback connection from output to inverting input is to force the voltage at the inverting input to be equal to that at the noninverting input.

This is equivalent to stating that for an op-amp *with negative feedback*,

$$v^- \approx v^+ \tag{5.9.7}$$

The analysis of the operational amplifier can now be greatly simplified if the following two assumptions are made:

$$\begin{aligned} &1. \quad i_{in} = 0 \\ &2. \quad v^- = v^+ \end{aligned} \tag{5.9.8}$$

This technique will be tested in the next subsection by analyzing a noninverting amplifier configuration.

A useful op-amp circuit that is based on the inverting amplifier is the **op-amp summer**, or **summing amplifier**. This circuit, shown in Figure 5.9.3, is used to add signal sources. The primary advantage of using the op-amp as a summer is that the summation occurs independently of load and source impedances, so that sources with different internal impedances will not interact with each other.

$$v_{out} = -\sum_{n=1}^{N} \frac{R_F}{R_{S_n}} v_{S_n} \tag{5.9.9}$$

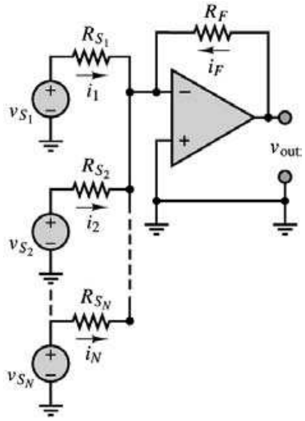

FIGURE 5.9.3 Summing amplifier.

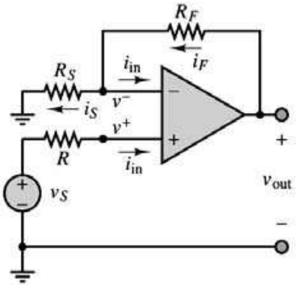

FIGURE 5.9.4 Noninverting amplifier.

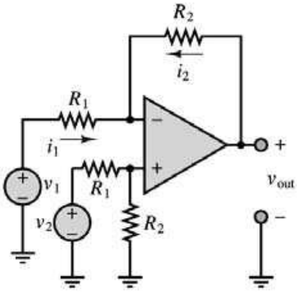

FIGURE 5.9.5 Differential amplifier.

That is, the output consists of the weighted sum of N input signal sources, with the weighting factor for each source equal to the ratio of the feedback resistance to the source resistance.

The Noninverting Amplifier. To avoid the negative gain (i.e., phase inversion) introduced by the inverting amplifier, a noninverting amplifier configuration is often employed. A typical noninverting amplifier is shown in Figure 5.9.4; note that the input signal is applied to the noninverting terminal this time.

$$\frac{v_{out}}{v_S} = 1 + \frac{R_F}{R_S} \quad \text{Noninverting amplifier closed-loop gain}$$

The Differential Amplifier. The third closed-loop model examined in this chapter is a combination of the inverting and noninverting amplifiers; it finds frequent use in situations where the difference between two signals needs to be amplified. The basic differential amplifier circuit is shown in Figure 5.9.5, where the two sources, v_1 and v_2, may be independent of each other, or may originate from the same process, as they do in Example 5.9.1.

The following expression for the output voltage is obtained:

$$v_{\text{out}} = R_2\left[\frac{-v_1}{R_1} + \frac{1}{R_1 + R_2}v_2 + \frac{R_2}{R_1(R_1 + R_2)}v_2\right]$$

$$= \frac{R_2}{R_1}(v_2 - v_1)$$

In practice, it is often necessary to amplify the difference between two signals that are both corrupted by noise or some other form of interference. In such cases, the differential amplifier provides an invaluable tool in amplifying the desired signal while rejecting the noise. Example 5.9.1 provides a realistic look at a very common application of the differential amplifier.

Example 5.9.1 An EKG Amplifier

This example illustrates the principle behind a two-lead electrocardiogram (EKG) measurement. The desired cardiac waveform is given by the difference between the potentials measured by two electrodes suitably placed on the patient's chest, as shown in Figure 5.9.6. A healthy, noise-free EKG waveform, $v_1 - v_2$, is shown in Figure 5.9.7.

Unfortunately, the presence of electrical equipment powered by the 60-Hz, 110-VAC line current causes undesired interference at the electrode leads: the lead wires act as antennas and pick up some of the 60-Hz signal in addition to the desired EKG voltage. In effect, instead of recording the desired EKG signals, v_1 and v_2, the two electrodes provide the following inputs to the EKG amplifier, shown in Figure 5.9.8.

Lead 1:

$$v_1(t) + v_n(t) = v_1(t) + V_n\cos(377t + \phi_n)$$

Lead 2:

$$v_2(t) + v_n(t) = v_2(t) + V_n\cos(377t + \phi_n)$$

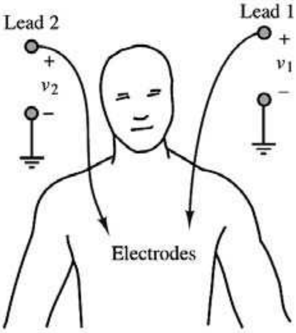

FIGURE 5.9.6 Two-lead electrocardiogram.

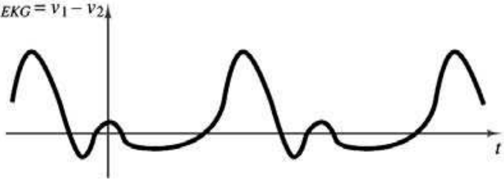

FIGURE 5.9.7 EKG waveform.

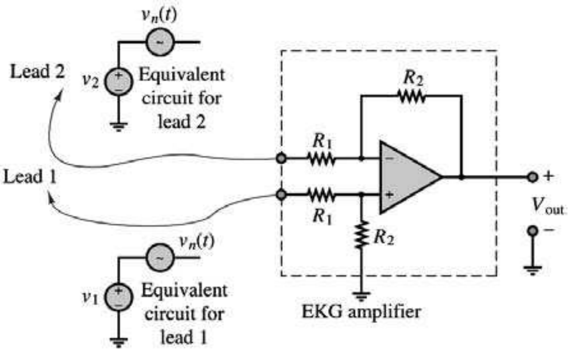

FIGURE 5.9.8 EKG amplifier.

The interference signal, $V_n \cos(377t + \phi n)$, is approximately the same at both leads, because the electrodes are chosen to be identical (e.g., they have the same lead lengths) and are in close proximity to each other. Further, the nature of the interference signal is such that it is common to both leads, since it is a property of the environment the EKG instrument is embedded in. On the basis of the analysis presented earlier, then,

$$v_{out} = \frac{R_2}{R_1}\left[\left(v_1 + v_n(t)\right) - \left(v_2 + v_n(t)\right)\right]$$

or

$$v_{out} = \frac{R_2}{R_1}\left(v_1 - v_2\right)$$

Thus, the differential amplifier nullifies the effect of the 60-Hz interference, while amplifying the desired EKG waveform.

The preceding example introduced the concept of so-called **common-mode** and **differential-mode signals**. In the EKG example, the desired differential-mode EKG signal was amplified by the op-amp while the common-mode disturbance was canceled. Thus, the differential amplifier provides the ability to reject common-mode signal components (such as noise or undesired DC offsets) while amplifying the differential-mode components. This is a very desirable feature in instrumentation systems. In practice, rejection of the common-mode signal is not always complete: some of the common-mode signal component will always appear in the output. This fact gives rise to a figure of merit called the *common-mode rejection ratio*, which is discussed later in this section.

Often, to provide impedance isolation between bridge transducers and the differential amplifier stage, the signals v_1 and v_2 are amplified separately. This technique gives rise to the so-called **instrumentation amplifier** (IA), shown in Figure 5.9.9. Example 5.9.2 illustrates the calculation of the closed-loop gain for a typical instrumentation amplifier.

Example 5.9.2 Instrumentation Amplifier

In this example, we compute the closed-loop gain of the instrumentation amplifier of Figure 5.9.9.

Solution. To carry out the desired analysis as easily as possible, it is helpful to observe that resistor R_1 is shared by the two input amplifiers. This corresponds to having each amplifier connected to a resistor equal to $R_1/2$, as shown in Figure 5.9.10(a). Because of the symmetry of the circuit, one can view the shared resistor as being connected to ground in the center, so that the circuit takes the form of a noninverting amplifier, with closed-loop gain given by

$$A = 1 + \frac{2R_2}{R_1} \tag{5.9.10}$$

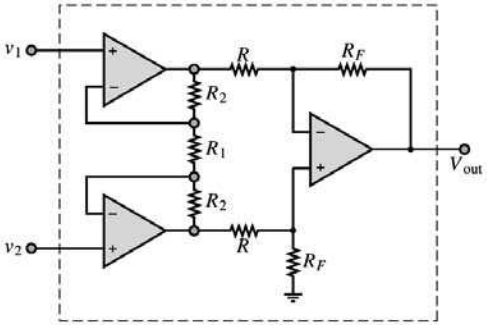

FIGURE 5.9.9 Instrumentation amplifier.

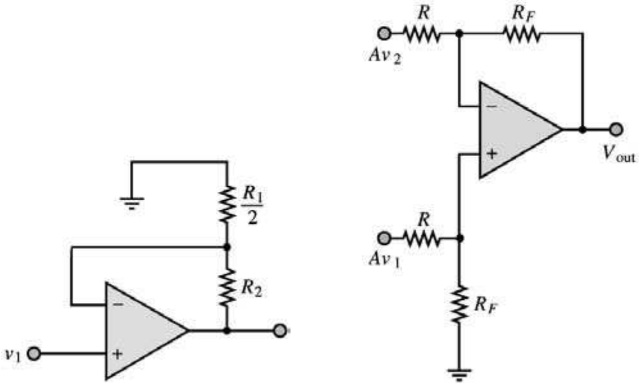

ab

FIGURE 5.9.10 (a) and (b).

Thus, each of the input voltages is amplified by this gain, and the overall gain of the instrumentation amplifier can then be computed by considering that the voltage difference ($Av_1 - Av_2$) is then amplified by the differential amplifier stage, with gain R_F/R, as shown in Figure 5.9.10(b):

$$v_{out} = \frac{R_F}{R}(Av_1 - v_2) = \frac{R_F}{R}\left(1 + \frac{2R_2}{R_1}\right)(v_1 - v_2) \tag{5.9.11}$$

Active Filters

The class of filters one can obtain by means of op-amp designs is called **active filters**, because op-amps can provide amplification (gain) in addition to the filtering effects already studied in Section 5.6 for passive circuits (i.e., circuits comprising exclusively resistors, capacitors, and inductors).

The easiest way to see how the frequency response of an op-amp can be shaped (almost) arbitrarily is to replace the resistors R_F and R_S in Figure 5.9.2 and Figure 5.9.4 with impedances Z_F and Z_S, as shown in Figure 5.9.11. It is a straightforward matter to show that in the case of the inverting amplifier, the expression for the closed loop gain is given by

$$\frac{\mathbf{V}_{out}}{\mathbf{V}_S}(j\omega) = -\frac{Z_F}{Z_S} \tag{5.9.12}$$

whereas for the noninverting case, the gain is

$$\frac{\mathbf{V}_{out}}{\mathbf{V}_S}(j\omega) = 1 + \frac{Z_F}{Z_S} \tag{5.9.13}$$

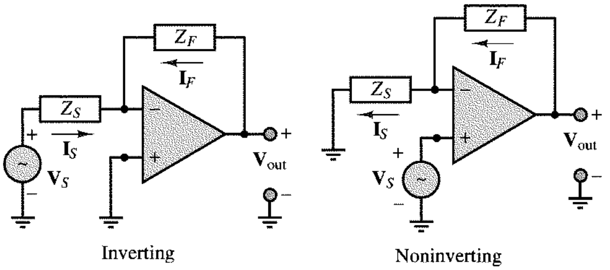

FIGURE 5.9.11 Op-amp circuits employing complex impedances.

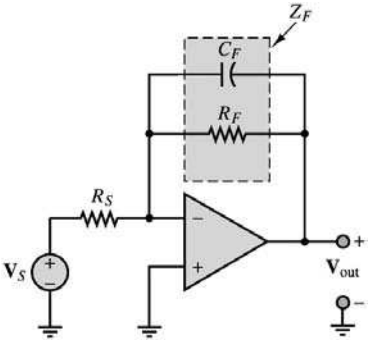

FIGURE 5.9.12 Active low-pass filter.

where Z_F and Z_S can be arbitrarily complex impedance functions and where $\mathbf{V}_S$, $\mathbf{V}_{out}$, $\mathbf{I}_F$, and $\mathbf{I}_S$ are all phasors. Thus, it is possible to shape the frequency response of an ideal op-amp filter simply by selecting suitable ratios of feedback impedance to source impedance. The simplest op-amp low-pass filter is shown in Figure 5.9.12. The closed-loop gain $A_{LP}(j\omega)$ is then computed to be

$$A_{LP}(j\omega) = -\frac{Z_F}{Z_S} = -\frac{R_F/R_S}{1 + j\omega C_F R_F}$$

It should be apparent that the response of this op-amp filter is just an amplified version of that of the passive filter. Figure 5.9.13 depicts the amplitude response of the active low-pass filter (in the figure, $R_F/R_S = 10$ and $1/R_F C_F = 1$) in two different graphs; the first two plots the amplitude ratio $\mathbf{V}_{out}/\mathbf{V}_S$ vs. radian frequency, ω, on a logarithmic scale, while the second plots the amplitude ratio $20 \log_{10} (\mathbf{V}_{out}/\mathbf{V}_S)$ (in units of dB), also vs. ω on a logarithmic scale.

A high-pass active filter can easily be obtained by using the circuit shown in Figure 5.9.14. The following gain function for the op-amp circuit can be derived:

$$\begin{aligned} A_{HP}(j\omega) &= -\frac{Z_F}{Z_S} = -\frac{R_F}{R_S + 1/j\omega C_S} \\ &= -\frac{j\omega C_S R_F}{1 + j\omega R_S C_S} \end{aligned} \tag{5.9.14}$$

The high-pass response is depicted in Figure 5.9.15 in both linear and dB plots (in the figure, $R_F/R_S = 10$, $1/R_S C = 1$).

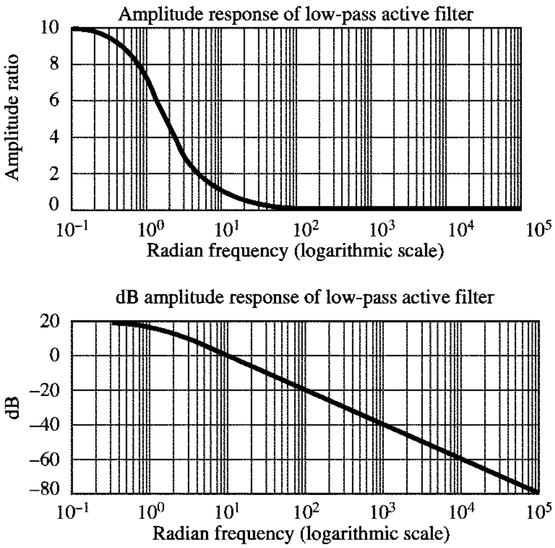

FIGURE 5.9.13 Normalized response of active low-pass filter.

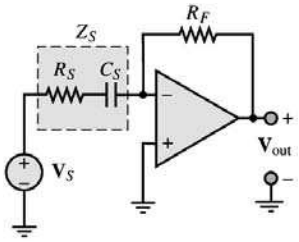

FIGURE 5.9.14 Active high-pass filter.

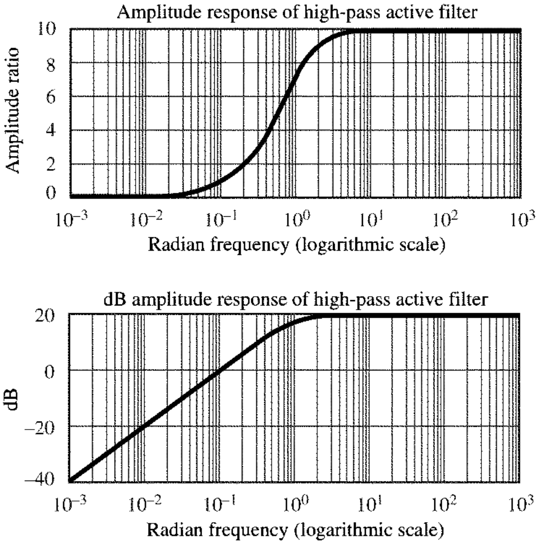

FIGURE 5.9.15 Normalized response of active high-pass filter.

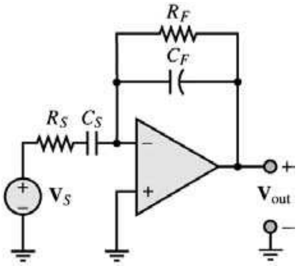

FIGURE 5.9.16 Active band-pass filter.

The band-pass filter of Figure 5.9.16 can be shown to have the following frequency response:

$$A_{BP}(j\omega) = -\frac{Z_F}{Z_S} = -\frac{j\omega C_S R_F}{\left(1 + j\omega C_F R_F\right)\left(1 + j\omega C_S R_S\right)} \tag{5.9.15}$$

The form of the op-amp response we just obtained should not appear as a surprise. It is very similar (although not identical) to the product of the low-pass and high-pass responses:

$$A_{LP}(j\omega) = -\frac{R_F / R_S}{1 + j\omega C_F R_F} \tag{5.9.16}$$

$$A_{HP}(j\omega) = -\frac{j\omega C_S R_F}{1 + j\omega R_S C_S} \tag{5.9.17}$$

In particular, the denominator of $A_{BP}(j\omega)$ is exactly the product of the denominators of $A_{LP}(j\omega)$ and $A_{HP}(j\omega)$. It is particularly enlightening to rewrite $A_{LP}(j\omega)$ in a slightly different form, after making the observation that each *RC* product corresponds to some "critical" frequency:

$$\omega_1 = \frac{1}{R_F C_S} \qquad \omega_{LP} = \frac{1}{R_F C_F} \qquad \omega_{HP} = \frac{1}{R_S C_S} \tag{5.9.18}$$

It is easy to verify that for the case where

$$\omega_{HP} > \omega_{LP} \tag{5.9.19}$$

the response of the op-amp filter may be represented as shown in Figure 5.9.17 in both linear and dB plots (in the figure, $\omega_1 = 1$, $\omega_{HP} = 1000$, $\omega_{HP} = 10$). The dB plot is very revealing, for its shows that, in effect, the band-pass response is the graphical superposition of the low-pass and high-pass responses shown earlier. The two 3-dB (or cutoff) frequencies are the same as in $A_{LP}(j\omega)$, $1/R_F C_F$; and in $A_{HP}(j\omega)$, $1/R_S C_S$. The third frequency, $\omega_1 = 1/R_F C_S$, represents the point where the response of the filter crosses the 0-dB axis (rising slope). Since 0 dB corresponds to a gain of 1, this frequency is called the **unity gain frequency**.

The ideas developed thus far can be employed to construct more complex functions of frequency. In fact, most active filters one encounters in practical applications are based on circuits involving more than one or two energy-storage elements. By constructing suitable functions for Z_F and Z_S, it is possible to realize filters with greater frequency selectivity (i.e., sharpness of cutoff), as well as flatter band-pass or band-rejection functions (that is, filters that either allow or reject signals in a limited band of frequencies). A few simple applications are investigated in the homework problems. One remark that should be made in passing, though, pertains to the exclusive use of capacitors in the circuits analyzed thus far.

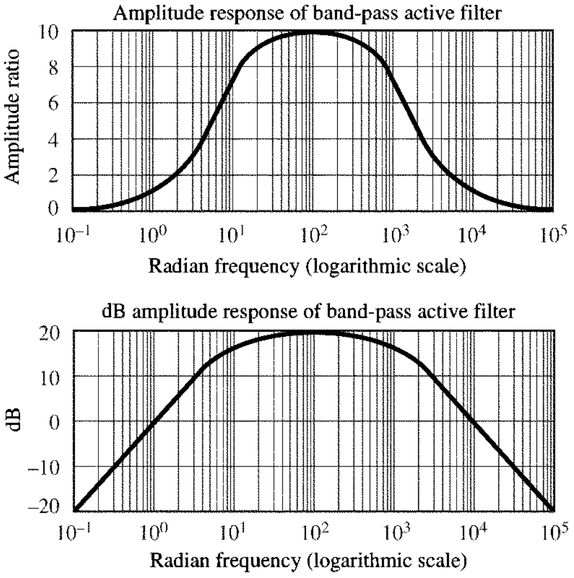

FIGURE 5.9.17 Normalized response of active band-pass filter.

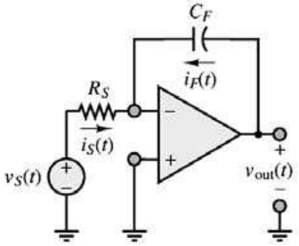

FIGURE 5.9.18 Op-amp integrator.

Integrator and Differentiator Circuits

The Ideal Integrator

Consider the circuit of Figure 5.9.18, where $v_s(t)$ is an arbitrary function of time (e.g., a pulse train, a triangular wave, or a square wave). The op-amp circuit shown provides an output that is proportional to the integral of $v_s(t)$.

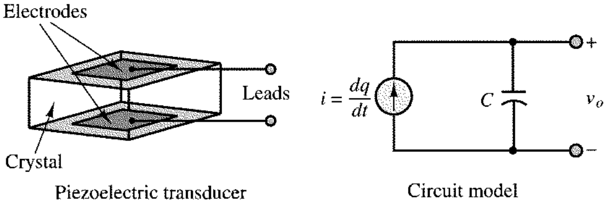
$$v_{\text{out}} = -\frac{1}{R_S C_F}\int_{-\infty}^{t} v_S(t')\,dt' \tag{5.9.20}$$

This equation states that the output voltage is the integral of the input voltage.

There are numerous applications of the op-amp integrator, most notably the **analog computer**. The following example illustrates the operation of the op-amp integrator.

Example 5.9.3 Charge Amplifiers

One of the most common families of transducers for the measurement of force, pressure, and acceleration is that of **piezoelectric transducers**. These transducers contain a piezoelectric crystal, a crystal that generates an electric charge in response to deformation. Thus, if a force is applied to the crystal (leading to a displacement), a charge is generated within the crystal. If the external force generates a displacement x_i, then the transducer will generate a charge q according to the expression



Piezoelectric transducer

Circuit model

FIGURE 5.9.19 Piezolectric transducer.

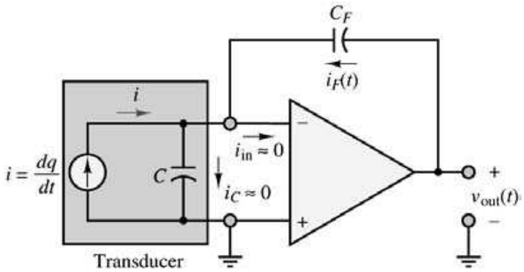


FIGURE 5.9.20 Charge amplifier.

$$q = K_p x_i$$

Figure 5.9.19 depicts the basic structure of the piezoelectric transducer and a simple circuit model. The model consists of a current source in parallel with a capacitor, where the current source represents the rate of change of the charge generated in response to an external force and the capacitance is a consequence of the structure of the transducer, which consists of a piezoelectric crystal (e.g., quartz or Rochelle salt) sandwiched between conducting electrodes (in effect, this is a parallel-plate capacitor).

Although it is possible, in principle, to employ a conventional voltage amplifier to amplify the transducer output voltage, v_o, given by

$$v_o = \frac{1}{C}\int i\,dt = \frac{1}{C}\int \frac{dq}{dt}\,dt = \frac{q}{C} = \frac{K_p x_i}{C}$$

it is often advantageous to use a **charge amplifier**. The charge amplifier is essentially an integrator circuit, as shown in Figure 5.9.20 characterized by an extremely high input impedance. The high impedance is essential; otherwise, the charge generated by the transducer would leak to ground through the input resistance of the amplifier.

Because of the high input impedance, the input current into the amplifier is negligible; further, because of the high open-loop gain of the amplifier, the inverting-terminal voltage is essentially at ground potential. Thus, *the voltage across the transducer is effectively zero*. As a consequence, to satisfy KCL, the feedback current, $i_F(t)$ must be equal and opposite to the transducer current, i:

$$i_F(t) = -i$$

and since

$$v_{\text{out}}(t) = \frac{1}{C_F} i_F(t)\,dt$$

it follows that the output voltage is proportional to the charge generated by the transducer, and therefore to the displacement:

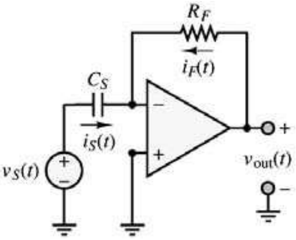

FIGURE 5.9.21 Op-amp differentiators.

$$v_{out}(t) = \frac{1}{C_F}\int -i\,dt = \frac{1}{C_F}\int -\frac{dq}{dt}\,dt = -\frac{q}{C_F} = -\frac{K_p x_i}{C_F}$$

Since the displacement is caused by an external force or pressure, this sensing principle is widely adopted in the measurement of force and pressure.

The Ideal Differentiator

Using an argument similar to that employed for the integrator, we can derive a result for the ideal differentiator circuit of Figure 5.9.21. The relationship between input and output is obtained by observing that

$$i_S(t) = C_S \frac{dv_S(t)}{dt} \tag{5.9.21}$$

and

$$i_F(t) = \frac{v_{out}(t)}{R_F} \tag{5.9.22}$$

so that the output of the differentiator circuit is proportional to the derivative of the input:

$$v_{out}(t) = -R_F C_S \frac{dv_S(t)}{dt} \tag{5.9.23}$$

Although mathematically attractive, the differentiation property of this op-amp circuit is seldom used in practice, because differentiation tends to simplify any noise that may be present in a signal.

Physical Limitations of Op-Amps

Thus far, the operational amplifier has been treated an ideal device, characterized by infinite input resistance, zero output resistance, and infinite open-loop voltage gain. Although this model is adequate to represent the behavior of the op-amp in a large number of applications, it is important to realize that practical operational amplifiers are not ideal devices, but exhibit a number of limitations that should be considered in the design of instrumentation. In particular, in dealing with relatively large voltages and currents, and in the presence of high-frequency signals, it is important to be aware of the nonideal properties of the op-amp. In the present section, we examine the principal limitations of the operational amplifier.

Voltage Supply Limits

The effect of limiting supply voltages is that amplifiers are capable of amplifying signals *only within the range of their supply voltages*;

$$V_S^- < v_{out} < V_S^+ \tag{5.9.24}$$

For most op-amps, the limit is actually approximately 1.5 V less than the supply voltages.

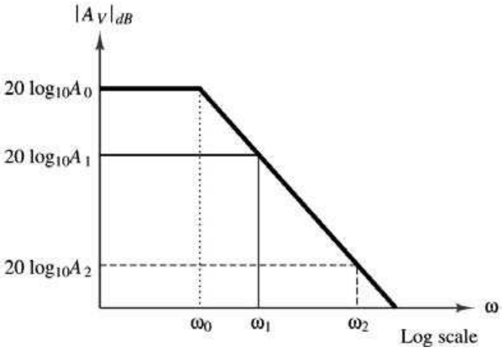

FIGURE 5.9.22

Frequency Response Limits

Another property of all amplifiers that may pose severe limitations to the op-amp is their finite bandwidth. We have so far assumed, in our ideal op-amp model, that the open-loop gain is a very large constant. In reality, $A_{V(OL)}$ is a function of frequency and is characterized by a low-pass response. For a typical op-amp,

$$A_{V(OL)}(j\omega) = \frac{A_0}{1 + j\omega/\omega_0} \tag{5.9.25}$$

The finite bandwidth of the practical op-amp results in a fixed **gain-bandwidth product** for any given amplifier. The effect of a constant gain-bandwidth product is that as the closed-loop gain of the amplifier is increased, its 3-dB bandwidth is proportionally reduced, until, in the limit, if the amplifier were used in the open-loop mode, its gain would be equal to A_0 and its 3-dB bandwidth would be equal to ω_0. Thus, *the product of gain and bandwidth in any given op-amp is constant*. That is,

$$A_0 \times \omega_0 = A_1 \times \omega_1 = A_2 \times \omega_2 = K \tag{5.9.26}$$

as is shown in Figure 5.9.22.

Input Offset Voltage

Another limitation of practical op-amps results because even in the absence of any external inputs, it is possible that an **offset voltage** will be present at the input of an op-amp. This voltage is usually denoted by $\pm V_{os}$ and it is caused by mismatches in the internal circuitry of the op-amp. The offset voltage appears as a differential input voltage between the inverting and noninverting input terminals. The presence of an additional input voltage will cause a DC bias error in the amplifier output, which can be modeled as shown in Figure 5.9.23.

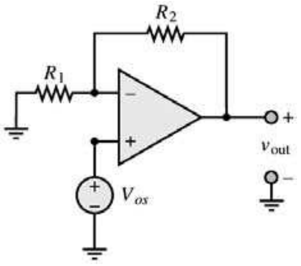

FIGURE 5.9.23 Op-amp input offset voltage.

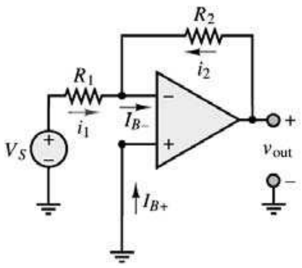

FIGURE 5.9.24

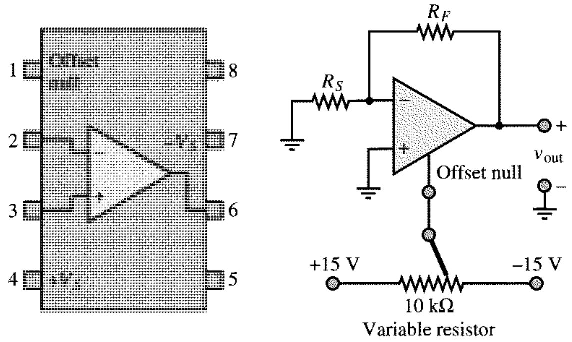

FIGURE 5.9.25 Output off-set voltage adjustment.

Input Bias Currents

Another nonideal characteristic of op-amps results from the presence of small input bias currents at the inverting and noninverting terminals. Once again, these are due to the internal construction of the input stage of an operational amplifier. Figure 5.9.24 illustrates the presence of nonzero input bias currents (I_B) going into an op-amp.

Typical values of I_B depend on the semiconductor technology employed in the construction of the op-amp. Op-amps with bipolar transistor input stages may see input bias currents as large as 1 μA, while for FET input devices, the input bias currents are less than 1 nA. Since these currents depend on the internal design of the op-amp, they are not necessarily equal. One often designates the **input offset current** I_{os} as

$$I_{os} = I_{B+} - I_{B-} \tag{5.9.27}$$

The latter parameter is sometimes more convenient from the standpoint of analysis.

Output Offset Adjustment

Both the offset voltage and the input offset current contribute to an output offset voltage $V_{out,os}$. Some op-amps provide a means for minimizing $V_{out,os}$. For example, the μA741 op-amp provides a connection for this procedure. Figure 5.9.25 shows a typical pin configuration for an op-amp in an eight-pin dual-in-line package (DIP) and the circuit used for nulling the output offset voltage. The variable resistor is adjusted until v_{out} reaches a minimum (ideally, 0 V). Nulling the output voltage in this manner removes the effect of both input offset voltage and current on the output.

Slew Rate Limit

Another important restriction in the performance of a practical op-amp is associated with rapid changes in voltage. The op-amp can produce only a finite rate of change at its output. This limit rate is called the **slew rate**. Consider an ideal step input, where at t = 0 the input voltage is switched from zero to V

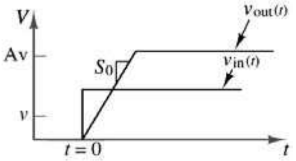

FIGURE 5.9.26 Slew rate limit in op-amps.

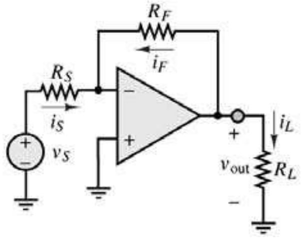

FIGURE 5.9.27

volts. Then we would expect the output to switch from 0 to $A \cdot V$ volts, where A is the amplifier gain. However, $v_{out}(t)$ can change at only a finite rate; thus,

$$\left|\frac{dv_{out}(t)}{dt}\right|_{max} = S_0 = \text{Slew rate} \tag{5.9.28}$$

Figure 5.9.26 shows the response of an op-amp to an ideal step change in input voltage, Here S_0, the slope of $v_{out}(t)$, represents the slew rate.

Short-Circuit Output Current

Recall the model for the op-amp, which represented the internal circuits of the op-amp in terms of an equivalent input resistance, R_{in}, and a controlled voltage source, $A_V\, v_{in}$. In practice, the internal source is not ideal, because it cannot provide an infinite amount of current (either to the load or to the feedback connection, or both). The immediate consequence of this nonideal op-amp characteristic is that the maximum output current of the amplifier is limited by the so-called short-circuit output current, I_{SC}:

$$|I_{out}| < I_{SC} \tag{5.9.29}$$

To further explain this point, consider that the op-amp needs to provide current to the feedback path (in order to "zero" the voltage differential at the input) and to whatever load resistance, R_L, may be connected to the output. Figure 5.9.27 illustrates this idea for the case of an inverting amplifier, where I_{SC} is the load current that would be provided to a short-circuit load ($R_L = 0$).

Common-Mode Rejection Ratio (CMRR)

Example 5.9.2 introduced the notion of differential-mode and common-mode signals. If we define A_{dm} as the **differential-mode gain** and A_{cm} as the **common-mode gain** of the op-amp, the output of an op-amp can then be expressed as follows:

$$v_{out} = A_{dm}(v_2 - v_1) + A_{cm}\left(\frac{v_2 - v_1}{2}\right) \tag{5.9.30}$$

Under ideal conditions, A_{cm} should be exactly zero, since the differential amplifier should completely reject common-mode signals. The departure from this ideal condition is a figure of merit for a differential amplifier and is measured by defining a quantity called the **common-mode rejection ratio** (CMRR).

The CMRR is defined as the ratio of the differential-mode gain to the common-mode gain and should ideally be infinite:

$$\mathrm{CMRR} = \frac{A_{dm}}{A_{cm}}$$

The CMRR is often expressed in units of decibels (dB).

5.10 Digital Circuits

The objective of this section is to discuss the essential features of digital logic circuits, which are at the heart of digital computers.

Analog and Digital Signals

One of the fundamental distinctions in the study of electronic circuits (and in the analysis of any signals derived from physical measurements) is that between analog and digital signals. As discussed in the preceding chapter, an **analog signal** is an electrical signal whose value varies in analogy with a physical quantity (e.g., temperature, force, or acceleration). For example, a voltage proportional to a measured variable pressure or to a vibration naturally varies in an analog fashion. Figure 5.10.1 depicts an arbitrary analog function of time, $f(t)$. We note immediately that for each value of time, t, $f(t)$ can take one value among any of the values in a given range. For example, in the case of the output voltage of an op-amp, we expect the signal to take any value between $+V_{\text{sat}}$ and $-V_{\text{sat}}$, where V_{sat} is the supply-imposed saturation voltage.

A **digital signal**, on the other hand, can take only a *finite number of values.* This is an extremely important distinction, as will be shown shortly. An example of a digital signal is a signal that allows display of a temperature measurement on a digital readout. Let us hypothesize that the digital readout is three digits long and can display numbers from 0 to 100, and let us assume that the temperature sensor is correctly calibrated to measure temperatures from 0 to 100°F. Further, the output of the sensor ranges from 0 to 5 V, where 0 V corresponds to 0°F and 5 V to 100°F. Therefore, the calibration constant of the sensor is $k_T = (100° - 0°)/(5 - 0) = 20°/\text{V}$. Clearly, the output of the sensor is an analog signal; however, the display can show only a finite number of readouts (101, to be precise). Because the display itself can only take a value out of a discrete set of states — the integers from 0 to 100 — we call it a digital display, indicating that the variable displayed is expressed in digital form.

Now, each temperature on the display corresponds to a *range of voltages:* each digit on the display represents one hundredth of the 5-V range of the sensor, or 0.05 V = 50 m V. Thus, the display will read 0 if the sensor voltage is between 0 and 49 mV, 1 if it is between 50 and 99 mV, and so on. Figure 5.10.2 depicts the staircase function relationship between the analog voltage and the digital readout. This **quantization** of the sensor output voltage is, in effect, an approximation. If one wished to know the temperature with greater precision, a greater number of display digits could be employed.

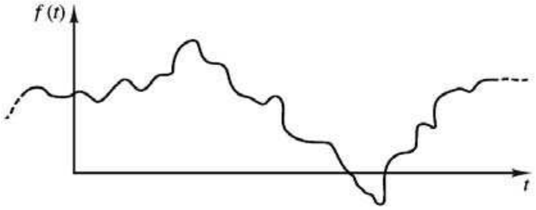

FIGURE 5.10.1 Analog signal.

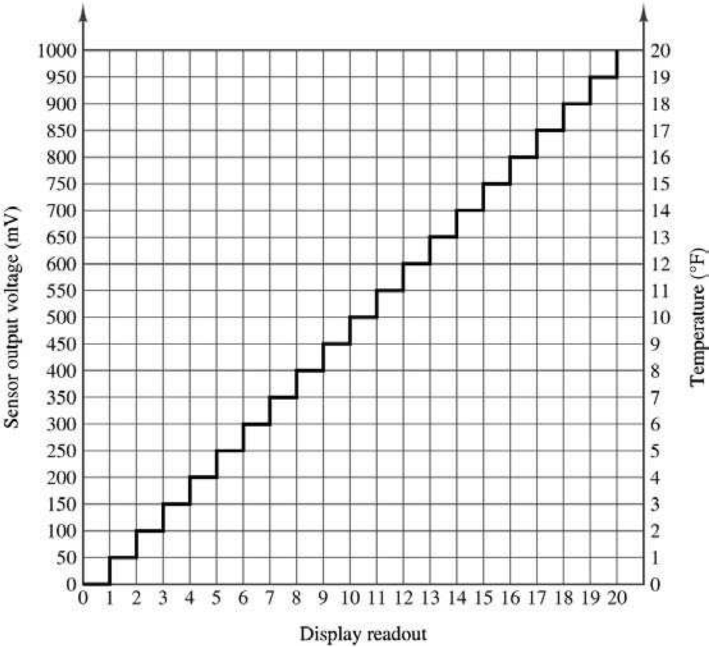

FIGURE 5.10.2 Digital representation of an analog signal.

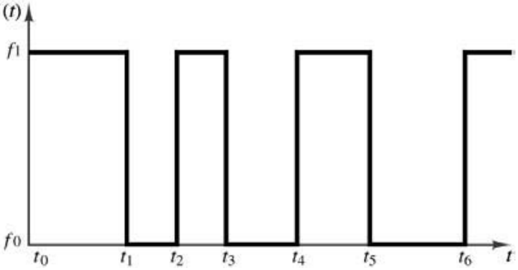

FIGURE 5.10.3 A binary signal.

The most common digital signals are binary signals. A **binary signal** is a signal that can take only one of two discrete values and is therefore characterized by transitions between two states. Figure 5.10.3 displays a typical binary signal. In binary arithmetic (which we discuss in the next section), the two discrete values f_1 and f_0 are represented by the numbers 1 and 0. In binary voltage waveforms, these values are represented by two voltage levels. For example, in the TTL convention, these values are (nominally) 5 and 0 V, respectively; in CMOS circuits, these values can vary substantially. Other conventions are also used, including reversing the assignment — for example, by letting a 0-V level represent a logic 1 and a 5-V level represent a logic 0. Note that in a binary waveform, knowledge of the transition between one stage and another (e.g., from f_0 to f_1 at $t = t_2$) is equivalent to knowledge of the state. Thus, digital logic circuits can operate by detecting transitions between voltage levels. The transitions are often called **edges** and can be positive (f_0 to f_1) or negative (f_1 to f_0). Virtually all of the signals handled by a computer are binary. From here on, whenever we speak of digital signals, you may assume that the text is referring to signals of the binary type, unless otherwise indicated.

The Binary Number System

The binary number system is a natural choice for representing the behavior of circuits that operate in one of two states (on or off, 1 or 0, or the like). The diode and transistor gates and switches studied in Section 5.7 fall in this category. Table 5.10.1 shows the correspondence between decimal and binary number systems for decimal numbers up to 16.

Table 5.10.1 shows that it takes four binary digits, also called **bits**, to represent the decimal numbers up to 15. Usually, the rightmost bit is called the **least significant bit**, or LSB, and the leftmost bit is called the **most significant bit**, or MSB. Since binary numbers clearly require a larger number of digits than decimal numbers, the digits are usually grouped in sets of four, eight, or sixteen. Four bits are usually termed a **nibble**, eight bits are called a **byte**, and sixteen bits (or two bytes) form a **word**.

Addition and Subtraction

The operations of addition and subtraction are based on the simple rules shown in Table 5.10.2. Figure 5.10.4 provides three examples.

The procedure for subtracting binary numbers is based on the rules of Table 5.10.3. A few examples of binary subtraction are given in Figure 5.10.5, with their decimal counterparts.

TABLE 5.10.2 Rules for Addition

FIGURE 5.10.5 Examples of binary subtraction.

Multiplication and Division

Whereas in the decimal system the multiplication table consists of $10^2 = 100$ entries, in the binary system we only have $2^2 = 4$ entries. Table 5.10.4 represents the complete multiplication table for the binary number system.

TABLE 5.10.4 Rules for Multiplication

$0 \times 0 = 0$
$0 \times 1 = 0$
$1 \times 0 = 0$
$1 \times 1 = 1$

Division in the binary system is also based on rules analogous to those of the decimal system, with the two basic laws given in Table 5.10.5. Once again, we need be concerned with only two cases, and just as in the decimal system, division by zero is not contemplated.

TABLE 5.10.5 Rules for Division

$0 \div 1 = 0$
$1 \div 1 = 1$

Conversion from Decimal to Binary

The conversion of a decimal number to its binary equivalent is performed by successive division of the decimal number by 2, checking for the remainder each time. Figure 5.10.6 illustrates this idea with an example.

Remainder
$49 \div 2 = 24 + 1$
$24 \div 2 = 12 + 0$
$12 \div 2 = 6 + 0$
$6 \div 2 = 3 + 0$
$3 \div 2 = 1 + 1$
$1 \div 2 = 0 + 1$
$49_{10} = 110001_2$

FIGURE 5.10.6 Example of conversion from decimal to binary.

2 \times 0.12 & = & 0.24 \rightarrow 0 \\
2 \times 0.24 & = & 0.48 \rightarrow 0 \\
2 \times 0.48 & = & 0.96 \rightarrow 0 \\
2 \times 0.96 & = & 1.92 \rightarrow 1 \\
2 \times 0.92 & = & 1.84 \rightarrow 1 \\
2 \times 0.84 & = & 1.68 \rightarrow 1 \\
2 \times 0.68 & = & 1.36 \rightarrow 1 \\
2 \times 0.36 & = & 0.72 \rightarrow 0 \\
2 \times 0.72 & = & 1.44 \rightarrow 1
\end{array}$$

$$0.53_{10} = 0.10000111101$$

FIGURE 5.10.7 Conversion from decimal to binary.

The same technique can be used for converting decimal fractional numbers to their binary form, provided that the whole number is separated from the fractional part and each is converted to binary form (separately), with the results added at the end. Figure 5.10.7 outlines this procedure by converting the number 37.53 to binary form.

Complements and Negative Numbers

To simplify the operation of subtraction in digital computers, **complements** are used almost exclusively. In practice, this corresponds to replacing the operation $X - Y$ with operation $X + (-Y)$. This procedure results in considerable simplification, since the computer hardware need include only adding circuitry. Two types of complements are used with binary numbers: the **one's complement** and the **two's complement**.

The one's complement of an n-bit binary number is obtained by subtracting the number itself from $(2^n - 1)$. Two examples are as follows:

$$\begin{aligned}
a &= 0101 \\
\text{One' s complement of } a &= \left(2^4 - 1\right) - a \\
&= (1111) - (0101) \\
&= 1010 \\
b &= 101101 \\
\text{One' s complement of } b &= \left(2^6 - 1\right) - b \\
&= (111111) - (101101) \\
&= 010010
\end{aligned}$$

The two's complement of n-bit binary number is obtained by subtracting the number itself from 2^{n}. Two's complements of the same numbers a and b used in the preceding illustration are computed as follows:

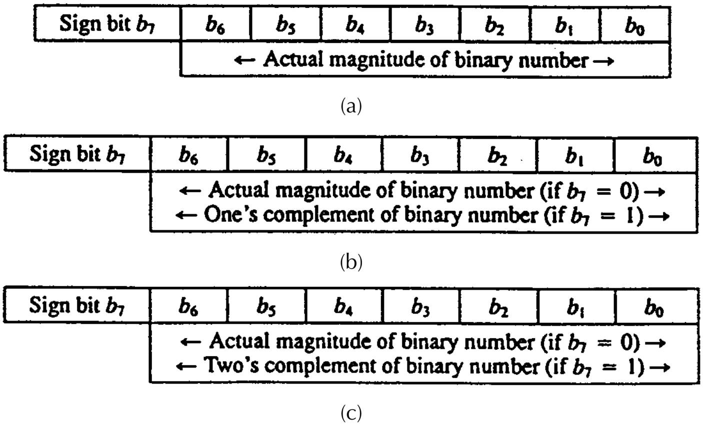

FIGURE 5.10.8 (a) Eight-bit sign-magnitude binary number; (b) eight-bit one's complement binary number; (c) eight-bit two's complement binary number.

$$a = 0101$$

$$\text{Two's complement of } a = 2^4 - a$$

$$= (10000) - (0101)$$

$$= 1011$$

$$b = 101101$$

$$\text{Two's complement of } b = 2^6 - b$$

$$= (1000000) - (101101)$$

$$= 010011$$

Different conventions exist in the binary system to represent whether a number is negative or positive. These are summarized in Figure 5.10.8.

The Hexadecimal System

It should be apparent by now that representing numbers in base 2 and base 10 systems is purely a matter of convenience, given a specific application. Another base frequently used is the **hexadecimal system**, a direct derivation of the binary number system. In the hexadecimal (or hex) code, the bits in a binary number are subdivided into groups of four. Since there are 16 possible combinations for a four-bit number, the natural digits in the decimal system (0 through 9) are insufficient to represent a hex digit. To solve this problem, the first six letters of the alphabet are used, as shown in Table 5.10.6. Thus, in hex code, an eight-bit word corresponds to just two digits; for example:

$$1010\ 0111_2 = A7_{16}$$

$$0010\ 1001_2 = 29_{16}$$

Binary Codes

In this subsection, we describe two common binary codes that are often used for practical reasons. The first is a method of representing decimal numbers in digital logic circuits that is referred to as **binary-coded decimal**, or BCD, **representation**. In effect, the simplest BCD representation is just a sequence of

TABLE 5.10.6 Hexadecimal Code

F	1111

four-bit binary numbers that stops after the first ten entries, as shown in Table 5.10.7. There are also other BCD codes, all reflecting the same principle: that each decimal digit is represented by a fixed-length binary word. One should realize that although this method is attractive because of its direct correspondence with the decimal system, it is not efficient. Consider, for example, the decimal number 68. Its binary representation by direct conversion is the seven-bit number 1000100. On the other hand, the corresponding BCD representation would require eight bits:

$$68_{10} = 01101000_{\mathrm{BCD}}$$

TABLE 5.10.7 BCD Code

0	0000
1	0001

3	0011
4	0100
5	0101
6	0110
7	0111
8	1000
9	1001

Another code that finds many applications is the **Gray code**. This is simply a reshuffling of the binary code with the property that any two consecutive numbers differ only by one bit. Table 5.10.8 illustrates the three-bit Gray code. The Gray code can be very useful in practical applications, because in counting up or down according to this code, the binary representation of a number changes only one bit at a time.

Boolean Algebra

The mathematics associated with the binary number system (and with the more general field of logic) is called *Boolean algebra*. The variables in a Boolean, or logic, expression can take only one of two values, usually represented by the numbers 0 and 1. These variables are sometimes referred to as true (1) and false (0). This convention is normally referred to as **positive logic**. There is also a **negative logic** convention in which the roles of logic 1 and logic 0 are reversed. In this book we shall employ only positive logic.

Analysis of **logic functions**, that is, functions of logical (Boolean) variables, can be carried out in terms of truth tables. A truth table is a listing of all the possible values each of the Boolean variables can take,

TABLE 5.10.8 Three-Bit Gray Code

and of the corresponding value of the desired function. In the following paragraphs we shall define the basic logic functions upon which Boolean algebra is founded, and we shall describe each in terms of a set of rules and a truth table; in addition, we shall also introduce **logic gates**. Logic gates are physical devices that can be used to implement logic functions. Elementary logic gates were introduced in Section 5.7.

AND and OR Gates

The basis of **Boolean algebra** lies in the operations of **logical addition**, or the **OR** operation; and **logical multiplication**, or the **AND** operation. Both of these find a correspondence in simple logic gates, as we shall presently illustrate. Logical addition, although represented by the symbol +, differs from conventional algebraic addition, as shown in the last rule listed in Table 5.10.9. Note that this rule also differs from the last rule of binary addition studied in the previous section. Logical addition can be represented by the logic gate called an **OR gate**, whose symbol and whose inputs and outputs are shown in Figure 5.10.9. The OR gate represents the following logical statement:

$$\text{If either } X \text{ or } Y \text{ is true (1), then } Z \text{ is true (1)} \tag{5.10.1}$$

This rule is embodied in the electronic gates discussed in Chapter 9, in which a logic 1 corresponds, say, to a 5-V signal and a logic 0 to a 0-V signal.

Logical multiplication is denoted by the center dot (·) and is defined by the rules of Table 5.10.10. Figure 5.10.10 depicts the **AND gate**, which corresponds to this operation. The AND gate corresponds to the following logical statement:

$$\text{If both } X \text{ and } Y \text{ are true (1), then } Z \text{ is true (1)} \tag{5.10.2}$$

Truth table

FIGURE 5.10.10 Logical multiplication and the AND gate.

One can easily envision logic gates (AND and OR) with an arbitrary number of inputs; three- and four-input gates are not uncommon.

The rules that define a logic function are often represented in tabular form by means of a **truth table**. Truth tables for the AND and OR gates are shown in Figure 5.10.9 and Figure 5.10.10. A truth table is nothing more than a tabular summary of all of the possible outputs of a logic gate, given all the possible input values. If the number of inputs is 3, the number of possible combinations grows from 4 to 8, but the basic idea is unchanged. Truth tables are very useful in defining logic functions. A typical logic design problem might specify requirements such as "the output Z shall be logic 1 only when the condition ($X = 1$ AND $Y = 1$) OR ($W = 1$) occurs, and shall be logic 0 otherwise." The truth table for this particular logic function is shown in Figure 5.10.11 as an illustration. The design consists, then, of determining the combination of logic gates that exactly implements the required logic function. Truth tables can greatly simplify this procedure.

The AND and OR gates form the basis of all logic design in conjunction with the **NOT gate**. The NOT gate is essentially an inverter, and it provides the complement of the logic variable connected to its input. The complement of a logic variable X is denoted by $\overline{X}$. The NOT gate has only one input, as shown in Figure 5.10.12

Logic gate realization of the statement "the output Z shall be logic 1 only when the condition ($X = 1$ AND $Y = 1$) OR ($W = 1$) occurs, and shall be logic 0 otherwise."

Solution using logic gates

FIGURE 5.10.13 Solution of a logic problem using logic gates.

To illustrate the use of the NOT gate, or inverter, we return to the design example of Figure 5.10.11, where we required that the output of a logic circuit be $Z = 1$ only if $X = 0$ AND $Y = 1$ OR if $W = 1$. We recognize that except for the requirement $X = 0$, this problem would be identical if we stated it as follows: "The output Z shall be logic 1 only when the condition ($\overline{X} = 1$ AND $Y = 1$) OR ($W = 1$) occurs, and shall be logic 0 otherwise." If we use an inverter to convert X to $\overline{X}$, we see that the required condition becomes $\overline{X} = 1$ AND $Y = 1$) OR ($W = 1$). The formal solution to this elementary design exercise is illustrated in Figure 5.10.13.

In the course of the discussion of logic gates, extensive use will be made of truth tables to evaluate logic expressions. A set of basic rules will facilitate this task. Table 5.10.11 lists some of the rules of Boolean algebra:

TABLE 5.10.11 Rules of Boolean Algebra

1.	$0 + X = X$	
2.	$1 + X = 1$	
3.	$X + X = X$	
4.	$X + \overline{X} = 1$	
5.	$0 \cdot X = 0$	
6.	$1 \cdot X = X$	
7.	$X \cdot X = X$	
8.	$X \cdot \overline{X} = 0$	
9.	$\overline{\overline{X}} = X$	
10.	$X + Y = Y + X$	Commutative law
11.	$X \cdot Y = Y \cdot X$	
12.	$X + (X + Z) = (X + Y) + Z$	Associative law
13.	$X \cdot (Y \cdot Z) = (X \cdot Y) \cdot Z$	
14.	$X \cdot (Y + Z) = X \cdot Y + X \cdot Z$	Distributive law
15.	$X + X \cdot Z = X$	Absorption law
16.	$X \cdot (X + Y) = X$	
17.	$(X + Y) \cdot (X + Z) = X + Y \cdot Z$	
18.	$X + \overline{X} \cdot Y = X + Y$	
19.	$X \cdot Y + Y \cdot Z + \overline{X} \cdot Z = X \cdot Y + \overline{X} \cdot Z$	

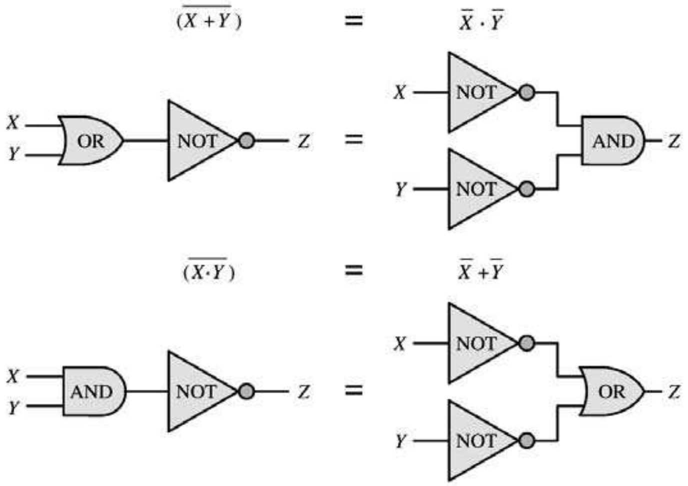

FIGURE 5.10.14 De Morgan's laws.

To complete the introductory material on Boolean algebra, a few paragraphs need to be devoted to two very important theorems, called **De Morgan's theorems**. These are stated here in the form of logic functions:

$$\left(\overline{X+Y}\right)=\bar{X}\cdot\bar{Y} \tag{5.10.3}$$

$$\left(\overline{X\cdot Y}\right)=\bar{X}+\bar{Y} \tag{5.10.4}$$

These two laws state a very important property of logic functions: any logic function can be implemented using only OR and NOT gates, or using only AND and NOT gates.

De Morgan's laws can easily be visualized in term of logic gates, as shown in Figure 5.10.14. The associated truth tables are proof of these theorems.

The importance of De Morgan's laws is in the statement of the **duality** that exists between AND and OR operations: any function can be realized by just one of the two basic operations, plus the complement operation. This gives rise to two families of logic functions: **sums of products** and **products of sums**, as shown in Figure 5.10.15. Any logical expression can be reduced to either one of these two forms. Although the two forms are equivalent, it may well be true that one of the two has a simpler implementation (fewer gates). Example 5.10.1 illustrates this point.

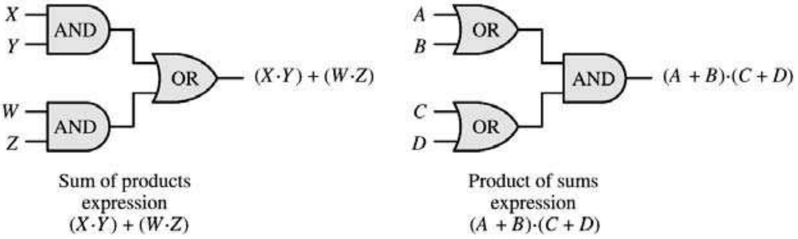

FIGURE 5.10.15 Sun-of-products and product-of-sums logic functions.

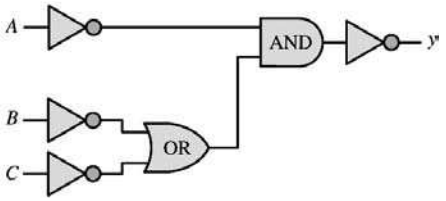

FIGURE 5.10.16 Figure for Example 5.10.1.

Example 5.10.1

Use De Morgan's theorem to realize the function $y = A + (B \cdot C)$ as a product-of-sums expression, and implement it using AND, OR, and NOT gates.

Solution. Knowing that $\overline{\overline{y}} = y$, we can apply the first of De Morgan's laws to the complement of the function y to obtain the expression

$$\overline{y} = \overline{A + (B \cdot C)} = \overline{A} \cdot \left(\overline{B \cdot C}\right) = \overline{A} \cdot \left(\overline{B} + \overline{C}\right)$$

Thus,

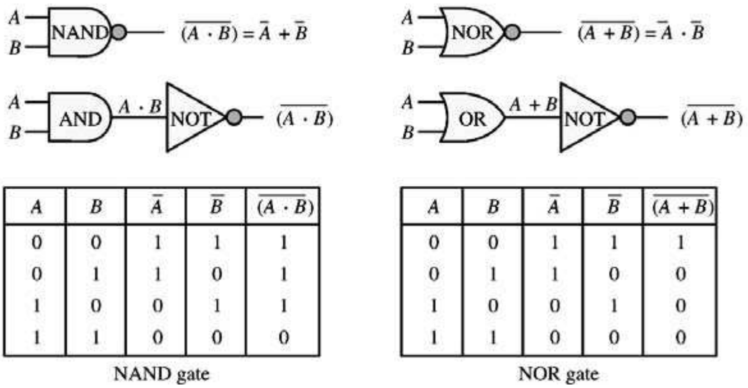
$$\overline{\overline{y}} = y = \overline{\overline{A} \cdot \left(\overline{B} + \overline{C}\right)}$$

Using logic gates, we can then implement the function as shown in Figure 5.10.16

NAND and NOR Gates

In addition to the AND and OR gates we have just analyzed, the complementary forms of these gates, called NAND and NOR, are very commonly used in practice. In fact, NAND and NOR gates form the basis of most practical logic circuits. Figure 5.10.17 depicts these two gates and illustrates how they can be easily interpreted in terms of AND, OR, and NOT gates by virtue of De Morgan's laws. You can readily verify that the logic function implemented by the NAND and NOR gates corresponds, respectively, to AND and OR gates followed by an inverter. It is very important to note that, by De Morgan's laws, the NAND gate performs a *logical addition* on the *complements* of the inputs. while the NOR gate performs a *logical multiplication* on the *complements* of the inputs. Functionally, then, any logic function could be implemented with either NOR or NAND gates only.

In the next section we shall learn how to systematically approach the design of logic functions. First, we provide a few examples to illustrate logic design with NAND and NOR gates.



A	B	$\overline{A}$	$\overline{B}$	$(\overline{A \cdot B})$

FIGURE 5.10.19 XOR gate.

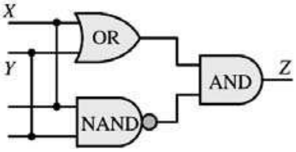

FIGURE 5.10.20 Realization of an XOR gate.

Example 5.10.2

Realize the following function using only NAND and NOR gates:

$$y = \overline{(A \cdot B) + C}$$

Solution. Since the term in parentheses appears as a complement product, it can be obtained by means of a NAND gate. Further, once the function $\overline{(A \cdot B)}$ has been realized, we can see that y is the complemented sum of two terms — that is, it can be obtained directly with a NOR gate. The resulting logic circuit is shown in Figure 5.10.18.

Can you find another solution to this problem that employs only two gates?

The XOR (Exclusive OR) Gate

It is rather common practice for a manufacturer of integrated circuits to provide common combinations of logic circuits in a single integrated circuit package. An example of this idea is provided by the **exclusive OR** (XOR) **gate**, which provides a logic function similar, but not identical, to the OR gate we have already studied. The XOR gate acts as an OR gate, except when its inputs are all logic 1s; in this case, the output is a logic 0 (thus the term *exclusive*). Figure 5.10.19 shows the logic circuit symbol adopted for this gate, and the corresponding truth table. The logic function implemented by the XOR gate is the following: "either X or Y, but not both." This description can be extended to an arbitrary number of inputs.

The symbol adopted for the exclusive OR operation is ⊕, and so we shall write

$$Z = X \oplus Y$$

to denote this logic operation. The XOR gate can be obtained by a combination of the basic gates we are already familiar with. For example, if we observe that the XOR function corresponds to $Z = X \oplus Y = (X + Y) \cdot X \cdot\ (\overline{X + Y})$, we can realize the XOR gate by means of the circuit shown in Figure 5.10.20.

Karnaugh Maps and Logic Design

In examining the design of logic functions by means of logic gates, we have discovered that more than one solution is usually available for the implementation of a given logic expression. It should also be clear by now that some combinations of gates can implement a given function more efficiently than

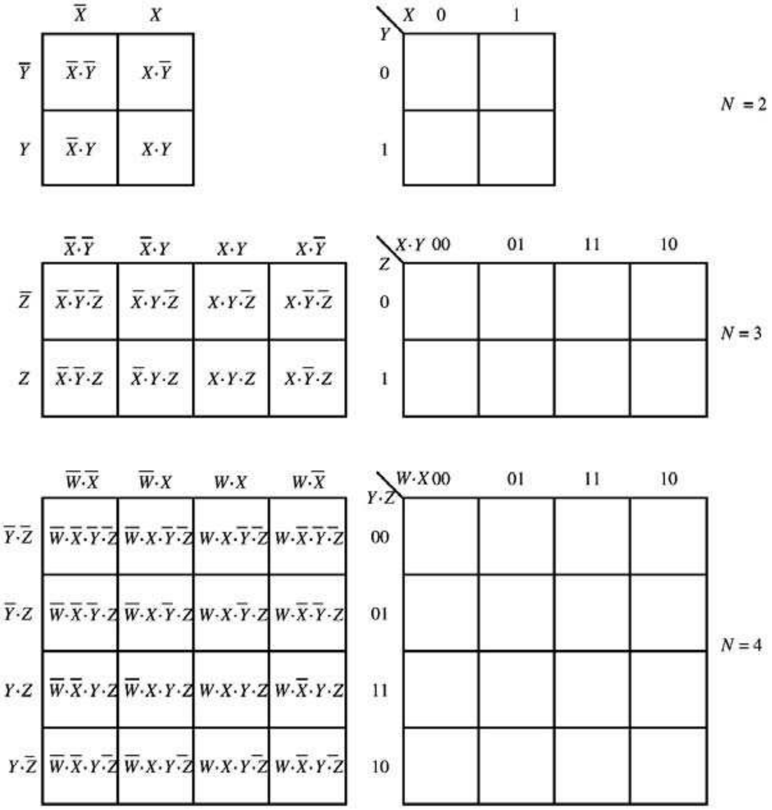

FIGURE 5.10.21 Two-, three-, and four-variable Karnaugh maps.

others. How can we be assured of having chosen the most efficient realization? Fortunately, there is a procedure that utilizes a map describing all possible combinations of the variables present in the logic function of interest. This map is called a **Karnaugh map**, after its inventor. Figure 5.10.21 depicts the appearance of Karnaugh maps for two-, three-, and four-variable expressions in two different forms. As can be seen, the row and column assignments for two or more variables are arranged so that all adjacent terms change by only one bit. For example, in the three- or four-variable map, the columns next to column 01 are columns 00 and 10. Also note that each map consists of 2^N **cells**, where N is the number of logic variables.

Each cell in a Karnaugh map contains a **minterm**, that is, a product of the N variables that appear in our logic expression (in either uncomplemented or complemented form). For example, for the case of three variables ($N = 3$), there are $2^3 = 8$ such combination, or minterms: $\overline{X} \cdot \overline{Y} \cdot \overline{Z}$, $\overline{X} \cdot \overline{Y} \cdot Z$, $\overline{X} \cdot Y \cdot \overline{Z}$, $\overline{X} \cdot Y \cdot Z$, $X \cdot \overline{Y} \cdot \overline{Z}$, $X \cdot \overline{Y} \cdot Z$, $X \cdot Y \cdot \overline{Z}$, and $X \cdot Y \cdot Z$. The content of each cell — that is, the minterm — is the product of the variables appearing at the corresponding vertical and horizontal coordinates. For example, in the three-variable map, $X \cdot Y \cdot \overline{Z}$ appears at the intersection of $X \cdot Y$ and $\overline{Z}$. The map is filled by placing a value of 1 for any combination of variables for which the desired output is a 1. For example, consider the function of three variables for which we desire to have an output of 1 whenever the variables X, Y, and Z have the following values:

$$\begin{array}{lll} X = 0 & Y = 1 & Z = 0 \\ X = 0 & Y = 1 & Z = 1 \\ X = 1 & Y = 1 & Z = 0 \\ X = 1 & Y = 1 & Z = 1 \end{array}$$

FIGURE 5.10.23 Karnaugh map for a four-variable expression.

The same truth table is shown in Figure 5.10.22 together with the corresponding Karnaugh map.

The Karnaugh map provides an immediate view of the values of the function in graphical form. Further, the arrangement of the cells in the Karnaugh map is such that any two adjacent cells contain minterms that vary in only one variable. This property, as will be verified shortly, is quite useful in the design of logic functions by means of logic gates, especially if we consider the map to be continuously wrapping around itself, as if the top and bottom, and right and left edges were touching each other. For the three-variable map given in Figure 5.10.21, for example, the cell $X \cdot \overline{Y} \cdot \overline{Z}$ is adjacent to $\overline{X} \cdot \overline{Y} \cdot \overline{Z}$ if we "roll" the map so that the right edge touches the left. Note that these two cells differ only in the variable X, a property we earlier claimed adjacent cells have.

Shown in Figure 5.10.23 is a more complex, four-variable logic function which will serve as an example in explaining how Karnaugh maps can be used directly to implement a logic function. First, we define a subcube as a set of 2^m adjacent cells, for $m = 1, 2, 3, \ldots, N$. Thus, a subcube can consist of 1, 2, 4, 8, 16, 32, … cells. All possible subcubes for the four-variable map of Figure 5.10.23 are shown in Figure 5.10.24. Note that there are no four-cell subcubes in this particular case. Note also that there is some overlap between subcubes.

Sum-of-Products Realizations

Although not explicitly stated, the logic functions of the preceding section were all in sum-of-products form. As you know, it is also possible to realize logic functions in product-of-sums form. This section

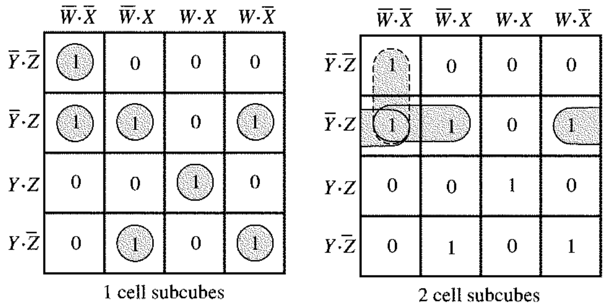

FIGURE 5.10.24 One- and two-cell subcubes for the Karnaugh map of Figure 5.10.23.

discusses the implementation of logic functions in sum-of-products form and gives a set of design rules. The next section will do the same for product-of-sums form logical expressions. The following rules are a useful aid in determining the minimal sum-of-products expression:

1. Begin with isolated cells. These must be used as they are, since no simplification is possible.
2. Find all cells that are adjacent to only one other cell, forming two-cell subcubes.
3. Find cells that form four-cell subcubes, eight-cell subcubes, and so forth.
4. The minimal expression is formed by the collection of the *smallest number of maximal subcubes.*

The following examples illustrate the application of these principles to a variety of problems.

Product-of-Sums Realizations

Thus far, we have exclusively worked with sum-of-products expressions, that is, logic functions of the form $A \cdot B + C \cdot D$. We know, however, that De Morgan's laws state that there is an equivalent form that appears as a product of sums, for example, $(W + Y) \cdot (Y + Z)$. The two forms are completely equivalent, logically, but one of the two forms may lead to a realization involving a smaller number of gates. When using Karnaugh maps, we may obtain the product-of-sums form very simply by following these rules:

1. Solve for the 0s exactly as for the 1s in sum-of-products expressions.
2. Complement the resulting expression.

The same principles stated earlier apply in covering the map with subcubes and determining the minimal expression. The following examples illustrate how one form may result in a more efficient solution than the other.

Example 5.10.3

This example illustrates the design of a logic function using both sum-of-products and product-of-sums implementations, thus showing that it may be possible to realize some savings by using one implementation rather than the other.

1. Realize the function *f* by a Karnaugh map using 0s.
2. Realize the function *f* by a Karnaugh map using 1s.

x	y	z	f
0	0	0	0
0	0	1	1
0	1	0	1
0	1	1	1
1	0	0	1
1	0	1	1
1	1	0	0
1	1	1	0

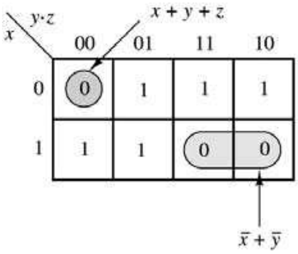

FIGURE 5.10.25 Figure for Example 5.10.3.

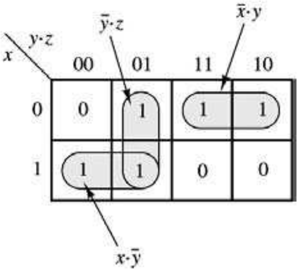

FIGURE 5.10.26 Figure for Example 5.10.3.

Solution.

1. Using 0s, we obtain the Karnaugh map of Figure 5.10.25, leading to the product-of-sums expression

$$f = (x + y + z) \cdot (\bar{x} + \bar{y})$$

which requires five gates.

2. If 1s are used, as shown in Figure 5.10.26, a sum-of-products expression is obtained, of the form

$$f = \bar{x} \cdot y + x \cdot \bar{y} + \bar{y} \cdot z$$

which requires seven gates.

Example 5.10.4 Safety Circuit for Operation of a Stamping Press

In this example, the techniques illustrated in the preceding example will be applied to a practical situation. To operate a stamping press, an operator must press two buttons (b_1 and b_2) 1 m apart from each other and away from the press (this ensures that the operator's hands cannot be caught in the press). When the buttons are pressed, the logical variables b_1 and b_2 are equal to 1. Thus, we can define a new variable $A = b_1 \cdot b_2$; when $A = 1$, the operator's hands are safely away from the press. In addition to the safety requirement, however, other conditions must be satisfied before the operator can activate the press. The press is designed to operate on one of two workpieces, part I and part II, but not both. Thus, acceptable logic states for the press to be operated are "part I is in the press, but not part II" and "part II is in the press, but not part I." If we denote the presence of part I in the press by the logical variable $B = 1$ and the presence of part II by the logical variable $C = 1$, we can then impose additional requirements on the operation of the press. For example, a robot used to place either part in the press could activate a pair of switches (corresponding to logical variables B and C) indicating which part, if any, is in the press. Finally, in order for the press to be operable, it must be "ready", meaning that it has to have completed any previous stamping operation. Let the logical variable $D = 1$ represent the ready condition. We have now represented the operation of the press in terms of four logical variables, summarized in the truth table of Table 5.10.12. Note that only two combinations of the logical variables will result in operation of the press: $ABCD = 1011$ and $ABCD = 1101$. You should verify that these two conditions correspond

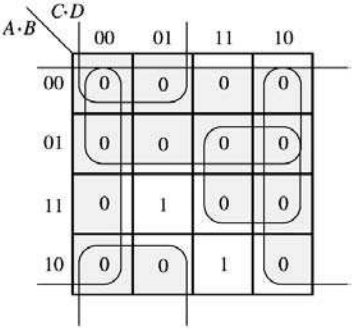

FIGURE 5.10.27 Figure for Example 5.10.4.

TABLE 5.10.12 Conditions for Operation of Stamping Press

Note: ↑ Both buttons (b_1, b_2) must be pressed for this to be a 1.

to the desired operation of the press. Using a Karnaugh map, realize the logic circuitry required to implement the truth table shown.

Solution. Table 5.10.12 can be converted to a Karnaugh map, as shown in Figure 5.10.27. Since there are many more 0s than 1s in the table, the use of 0s in covering the map will lead to greater simplification. This will result in a product-of-sums expression. The four subcubes shown in Figure 5.10.27 yield the equation

$$A \cdot D \cdot (C + B) \cdot \left(\overline{C} + \overline{B}\right)$$

By De Morgan's law, this equation is equivalent to

$$A \cdot D \cdot (C + B) \cdot \overline{(C \cdot B)}$$

which can be realized by the circuit of Figure 5.10.28.

For the purpose of comparison, the corresponding sum-of-products circuit is shown in Figure 5.10.29. Note that this circuit employs a greater number of gates and will therefore lead to a more expensive design.

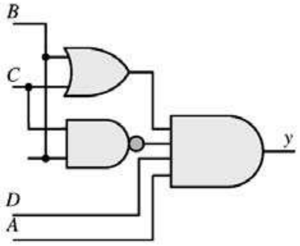

FIGURE 5.10.28 Figure for Example 5.10.4.

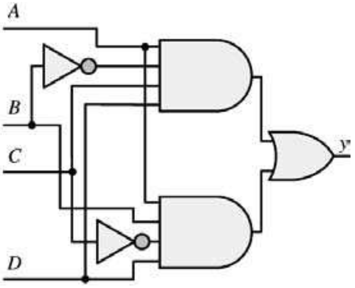

FIGURE 5.10.29 Figure for Example 5.10.4.

Don't Care Conditions

Another simplification technique may be employed whenever the value of the logic function to be implemented can be either a 1 or a 0. This condition may result from the specification of the problem and is not uncommon. Whenever it does not matter whether a position in the map is filled by a 1 or a 0, we use a so-called **don't care** entry, denoted by an x. Then the don't care can be used as either a 1 or a 0, depending on which results in a greater simplification (i.e., helps in forming the smallest number of maximal subcubes).

Combinational Logic Modules

The basic logic gates described in the previous section are used to implement more advanced functions and are often combined to form logic modules, which, thanks to modern technology, are available in compact integrated circuit (IC) packages. In this section and the next, we discuss a few of the more common **combinational logic modules**, illustrating how these can be used to implement advanced logic function.

Multiplexers

Multiplexers, or **data selectors**, are combinational logic circuits that permit the selection of one of many inputs. A typical multiplexer (MUX) has 2^n **data lines**, n **address lines**, and one output. In addition, other control inputs (e.g., enables) may exist. Standard, commercially available MUXs allow for n up to 4; however, two or more MUXs can be combined if a greater range is needed. The MUX allows for one of 2^n inputs to be selected as the data output; the selection of which input is to appear at the output is made by way of the address lines. Figure 5.10.30 depicts the block diagram of a four-input MUX. The input data lines are labeled D_0, D_1, D_2, and D_3; the **data select**, or address, **lines** are labeled I_0 and I_1; and the output is available in both complemented and uncomplemented form, and is thus labeled F, or $\overline{F}$. Finally, an **enable** input, labeled E, is also provided, as a means of enabling or disabling the MUX: if $E = 1$, the MUX is disabled; if $E = 0$, it is enabled. The negative logic (MUX off when $E = 1$ and on when $E = 0$) is represented by the small "bubble" at the enable input, which represents a complement operation (just as at the output of NAND and NOR gates). The enable input is useful whenever one is interested in a cascade of MUXs; this would be of interest if we needed to select a line from a large number, say $2^8 = 256$. Then two 4-input MUXs could be used to provide the data selection of 1 of 8.

Truth table of 4-to-1 MUX

FIGURE 5.10.30 4:1 MUX.

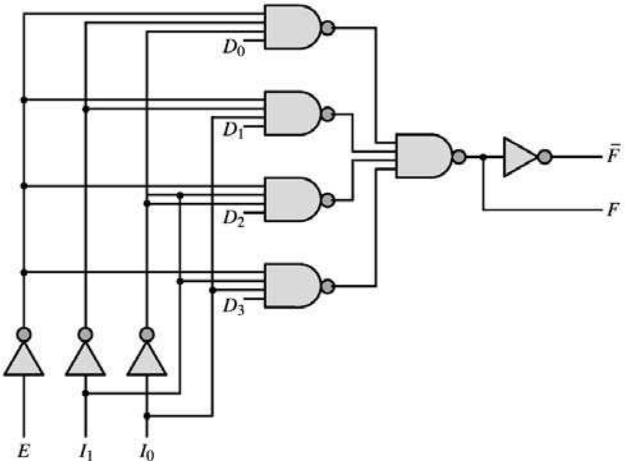

FIGURE 5.10.31 Internal structure of the 4:1 MUX.

The material described in the previous sections is quite adequate to describe the internal workings of a multiplexer. Figure 5.10.31 shows the internal construction of 4:1 MUX using exclusively NAND gates (inverters are also used, but the reader will recall that a NAND gate can act as an inverter if properly connected).

In the design of digital systems (for example, microcomputers), a single line is often required to carry two or more different digital signals. However, only one signal at a time can be placed on the line. A MUX will allow us to select, at different instants, the signal we wish to place on this single line. This property is shown here for a 4:1 MUX. Figure 5.10.32 depicts the functional diagram of a 4:1 MUX, showing four data lines, D_0 through D_3, and two select lines, I_0 and I_1.

The data selector function of a MUX is best understood in terms of Table 5.10.13. In this truth table, the x's represent don't care entries. As can be seen from the truth table, the output selects one of the data lines depending on the values of I_1 and I_0, assuming that I_0 is the least significant bit. As an example, $I_1I_0 = 10$ selects D_2, which means that the output, F, will select the value of the data line D_2. Therefore $F = 1$ if $D_2 = 1$ and $F = 0$ if $D_2 = 0$.

Read-Only Memory (ROM)

Another common technique for implementing logic functions uses a **read-only memory**, or ROM. As the name implies, a ROM is a logic circuit that holds in storage ("memory") information — in the form of binary numbers — that cannot be altered but can be "read" by a logic circuit. A ROM is an array of

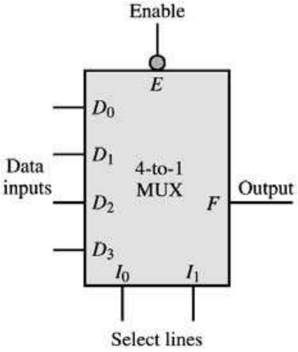

FIGURE 5.10.32 Functional diagram of four-input MUX.

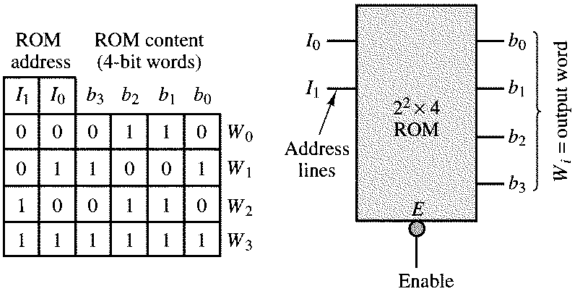
TABLE 5.10.13

I_1	I_0	D_3	D_2	D_1	D_0	F
0	0	x	x	x	0	0
0	0	x	x	x	1	1
0	1	x	x	0	x	0
0	1	x	x	1	x	1
1	0	x	0	x	x	0
1	0	x	1	x	x	1
1	1	0	x	x	x	0
1	1	1	x	x	x	1

memory cells, each of which can store either a 1 or a 0. The array consists of $2^m \times n$ cells, where n is the number of bits in each word stored in ROM. To access the information stored in ROM, m address lines are required. When an address is selected, in a fashion similar to the operation of the MUX, the binary word corresponding to the address selected appears at the output, which consists of n bits, that is, the same number of bits as the stored words. In some sense, a ROM can be thought of as a MUX that has an output consisting of a word instead of a single bit.

Figure 5.10.33 depicts the conceptual arrangement of a ROM with $n = 4$ and $m = 2$. The ROM table has been filled with arbitrary 4-bit words, just for the purpose of illustration. In Figure 5.10.33, if one were to select an enable input of 0 (i.e., on) and values for the address lines of $I_0 = 0$ and $I_1 = 1$, the output word would be $W_2 = 0110$, so that $b_0 = 0$, $b_1 = 1$, $b_2 = 1$, $b_3 = 0$. Depending on the content of the ROM and the number of address and output lines, one could implement an arbitrary logic function.

Unfortunately, the data stored in read-only memories must be entered during fabrication and cannot be altered later. A much more convenient type of read-only memory is the **erasable programmable read-only memory** (EPROM), the content of which can be easily programmed and stored and may be changed if needed. EPROMs find use in many practical applications because of their flexibility in content and



ROM address		ROM content (4-bit words)				
I_1	I_0	b_3	b_2	b_1	b_0	
0	0	0	1	1	0	W_0

1	1	1	1	1	1	W_3

FIGURE 5.10.33 Read-only memory.

ease of programming. The following example illustrates the use of an EPROM to perform the linearization of a nonlinear function.

Example 5.10.5 EPROM-Based Lookup Table

One of the most common applications of EPROMs is the *arithmetic lookup table*. A lookup table is similar in concept to the familiar multiplication table and is used to store precomputed values of certain functions, eliminating the need for actually computing the function. A practical application of this concept is present in every automobile manufactured in the U.S. since the early 1980s, as part of the exhaust emission control system. In order for the catalytic converter to minimize the emissions of exhaust gases (especially hydrocarbons, oxides of nitrogen, and carbon monoxide), it is necessary to maintain the *air-to-fuel ratio* (A/F) as close as possible to the stoichiometric value, that is, 14.7 parts of air for each part of fuel. Most modern-day engines are equipped with fuel injection systems that are capable of delivering accurate amounts of fuel to each individual cylinder; thus, the task of maintaining an accurate A/F amounts to measuring the mass of air that is aspirated into each cylinder and computing the corresponding mass of fuel. Many automobiles are equipped with a *mass airflow sensor*, capable of measuring the mass of air drawn into each cylinder during each engine cycle. Let the output of the mass airflow sensor be denoted by the variable M_A, and let this variable represent the mass of air (in g) actually entering a cylinder during a particular stroke. It is then desired to compute the mass of fuel, M_F (also expressed in g), required to achieve an A/F of 14.7. This computation is simply

$$M_F = \frac{M_A}{14.7}$$

Although the above computation is a simple division, its actual calculation in a low-cost digital computer (such as would be used on an automobile) is rather complicated. It would be much simpler to tabulate a number of values of M_A, to precompute the variable M_F, and then to store the result of this computation into an EPROM. If the EPROM address were made to correspond to the tabulated values of air mass and the content at each address to the corresponding fuel mass (according to the precomputed values of the expression $M_F = M_A/14.7$), it would not be necessary to perform the division by 14.7. For each measurement of air mass into one cylinder, an EPROM address is specified and the corresponding content is read. The content at the specific address is the mass of fuel required by the particular cylinder.

In practice, the fuel mass needs to be converted into a time interval corresponding to the duration of time during which the fuel injector is open. This final conversion factor can also be accounted for in the table. Suppose, for example, that the fuel injector is capable of injecting K_F g of fuel per second; then the time duration, T_F, during which the injector should be open in order to inject M_F g of fuel into the cylinder is given by

$$T_F = \frac{M_F}{K_F} \text{ s}$$

Therefore, the complete expression to be precomputed and stored in the EPROM is

$$T_F = \frac{M_A}{14.7 \times K_F} \text{ s}$$

Figure 5.10.34 illustrates this process graphically.

To provide a numerical illustration, consider a hypothetical engine capable of aspirating air in the range $0 < M_A < 0.51$ g and equipped with fuel injectors capable of injecting at the rate of 1.36 g/sec. Thus, the relationship between T_F and M_A is

$$T_F = 50 \times M_A \text{ msec} = 0.05 M_A \text{ sec}$$

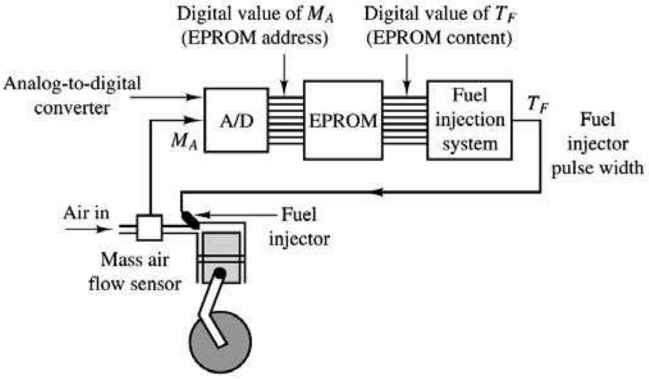

FIGURE 5.10.34 Use of EPROM lookup table in automotive fuel injection system.

M_A(g) × 10^{-2}	Address (digital value of M_A)	Content (digital value of T_F)	T_F(ms) × 10^{-1}

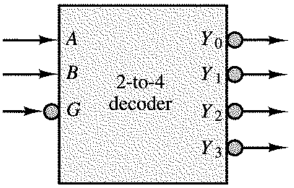
FIGURE 5.10.35 Lookup table for automotive fuel injection application.

If the digital value of M_A is expressed in dg (decigrams, or tenths of g), the lookup table of Figure 5.10.35 can be implemented, illustrating the conversion capabilities provided by the EPROM. Note that in order to represent the quantities of interest in an appropriate binary format compatible with the 8-bit EPROM, the units of air mass and of time have been scaled.

Decorders and Read and Write Memory

Decoders, which are commonly used for applications such as address decoding or memory expansion, are combinational logic circuits as well. Our reason for introducing decoders is to show some of the internal organization of semiconductor memory devices.

Figure 5.10.36 shows the truth table for a 2:4 decoder. The decoder has an enable input, $\overline{G}$, and select inputs, B and A. It also has four outputs, Y_0 through Y_3. When the enable input is logic 1, all decoder outputs are forced to logic 1 regardless of the select inputs.



Inputs			Outputs			
Enable	Select					
$\overline{G}$	A	B	Y_0	Y_1	Y_2	Y_3
1	X	X	1	1	1	1
0	0	0	0	1	1	1
0	0	1	1	0	1	1
0	1	0	1	1	0	1
0	1	1	1	1	1	0

FIGURE 5.10.36 2:4 decoder.

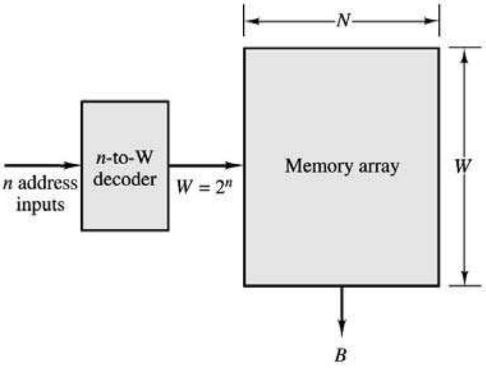


FIGURE 5.10.37 Internal organization of SRAM.

This simple description of decoders permits a brief discussion of the internal organization of an SRAM (**static random-access** or **read and write memory**). SRAM is internally organized to provide memory with high speed (i.e., short access time), a large bit capacity, and low cost. The memory array in this memory device has a column length equal to the number of words, W, and a row length equal to the number of bits per word, N. To select a word, an n-to-W decoder is needed. Since the address inputs to the decoder select only one of the decoder's outputs, the decoder selects one word in the memory array. Figure 5.10.37 shows the internal organization of a typical SRAM.

Thus, to choose the desired word from the memory array, the proper address inputs are required. As an example, if the number of words in the memory array is 8, a 3:8 decoder is needed. Data sheets for 2:4 and 3:8 decoders from a CMOS family data book are provided at the end of the chapter.

Sequential Logic Modules

Combinational logic circuits provide outputs that are based on a combination of present inputs only. On the other hand, sequential logic circuits depend on present and past input values. Because of this "memory" property, sequential circuits can store information; this capability opens a whole new area of application for digital logic circuits.

Latches and Flip-Flops

The basic information-storage device in a digital circuit is called a **flip-flop**. There are many different varieties of flip-flops; however, all flip-flops share the following characteristics:

1. A flip-flop is a **bistable device**; that is, it can remain in one of two stable states (0 and 1) until appropriate conditions cause it to change state. Thus, a flip-flop can serve as a memory element.
2. A flip-flop has two outputs, one of which is the complement of the other.

RS Flip-Flop. It is customary to depict flip-flops by their block diagram and a name — such as Q or X — representing the output variable. Figure 5.10.38 represents the so-called **RS flip-flop**, which has two inputs, denoted by S and R, and two outputs, Q and $\overline{Q}$. The value of Q is called the state of the flip-flop. If $Q = 1$, we refer to the device as *being in the 1 state*. Thus, we need define only one of the two outputs of the flip-flop. The two inputs, R and S, are used to change the state of the flip-flop, according to the following rules:

1. When $R = S = 0$, the flip-flop remains in its present state (whether 1 or 0).
2. When $S = 1$ and $R = 0$, the flip-flop is *set* to the 1 state (thus, the letter S, for **set**).
3. When $S = 0$ and $R = 1$, the flip-flop is *reset* to the 0 state (thus, the letter R, for **reset**).
4. It is not permitted for both S and R to be equal to 1. (This would correspond to requiring the flip-flop to set and reset at the same time.)

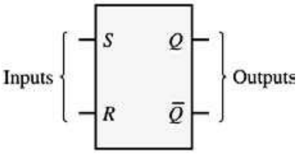

FIGURE 5.10.38 *RS* flip-flop.

0	1	0
0	0	0
1	0	1
0	0	1

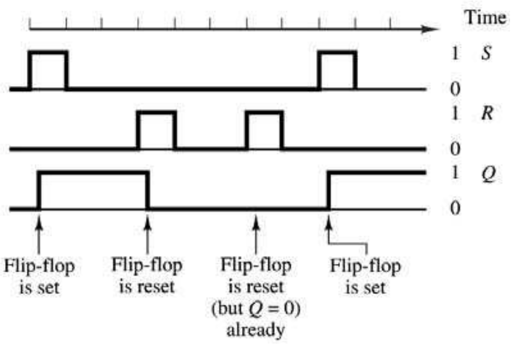

FIGURE 5.10.39 Timing diagram for the *RS* flip-flop.

The rules just described are easily remembered by noting that 1s on the *S* and *R* inputs correspond to the set and reset commands, respectively.

A convenient means of describing the series of transitions that occur as the signals sent to the flip-flop inputs change is the **timing diagram**. A timing diagram is a graph of the inputs and outputs of the *RS* flip-flop (or any other logic device) depicting the transitions that occur over time. In effect, one could also represent these transitions in tabular form; however, the timing diagram provides a convenient visual representation of the evolution of the state of the flip-flop. Figure 5.10.39 depicts a table of transitions for an *RS* flip-flop *Q*, as well as the corresponding timing diagram.

It is important to note that the *RS* flip-flop is **level-sensitive.** This means that the set and reset operations are completed only after the *R* and *S* inputs have reached the appropriate levels. Thus, in Figure 5.10.39 we show the transitions in the *Q* outputs as occurring with a small delay relative to the transitions in the *R* and *S* inputs.

It is instructive to illustrate how an *RS* flip-flop can be constructed using simple logic gates. For example, Figure 5.10.40 depicts a realization of such a circuit consisting of four gates: two inverters and two NAND gates (actually, the same result could be achieved with four NAND gates). Consider the case in which the circuit is in the initial state $Q = 0$ (and therefore $\overline{Q} = 1$). If the input $S = 1$ is applied, the top NOT gate will see inputs $\overline{Q} = 1$ and $\overline{S} = 0$, so that $Q = (\overline{\overline{S} \cdot \overline{Q}}) = (\overline{0 \cdot 1}) = 1$ — that is, the flip-flop is set. Note that when Q is set to 1, $\overline{Q}$ becomes 0. This, however, does not affect the state of the Q output, since replacing $\overline{Q}$ with 0 in the expression

$$Q = \left(\overline{\overline{S} \cdot \overline{Q}}\right)$$

does not change the result:

$$Q = \left(\overline{0 \cdot 0}\right) = 1$$

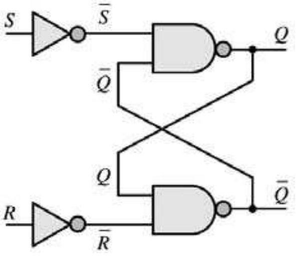

FIGURE 5.10.40 Logic gate implementation of the *RS* flip-flop.

Thus, the cross-coupled feedback from outputs Q and $\overline{Q}$ to the input of the NAND gates is such that the set condition sustains itself. It is straightforward to show (by symmetry) that a 1 input on the R line causes the device to reset (i.e., causes $Q = 0$) and that this condition is also self-sustaining.

An extension of the *RS* flip-flop includes an additional enable input that is *gated* into each of the other two inputs. Figure 5.10.41 depicts an *RS* flip-flop consisting of two NOR gates. In addition, an enable input is connected through two AND gates to the *RS* flip-flop, so that an input to the R and S line will be effective only when the enable input is 1. Thus, any transitions will be controlled by the enable input, which acts as a synchronizing signal. The enable signal may consist of a **clock**, in which case the flip-flop is said to be **clocked** and its operation is said to be **synchronous**.

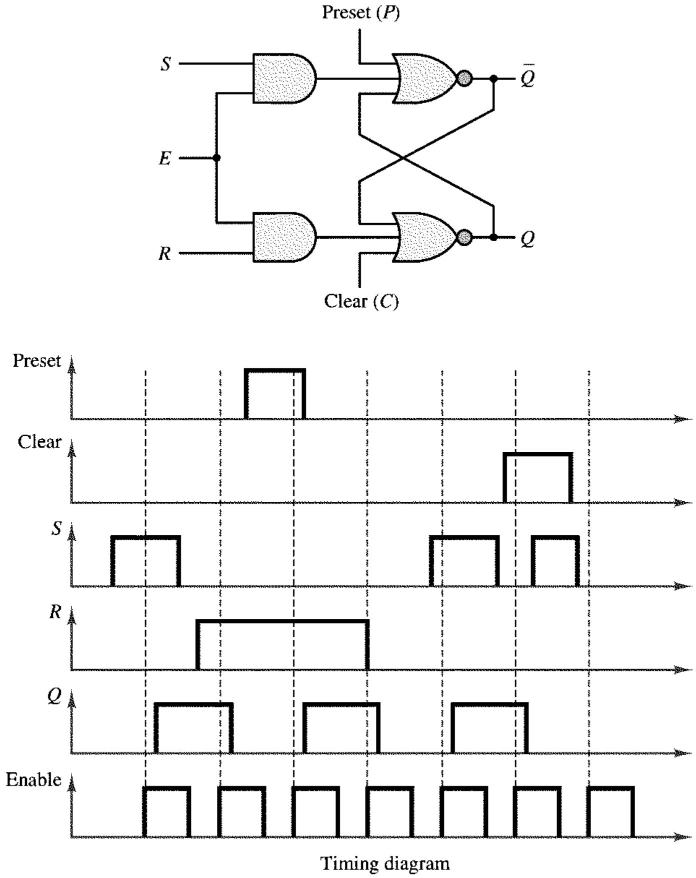

FIGURE 5.10.41 *RS* flip-flop with enable, preset, and clear lines.

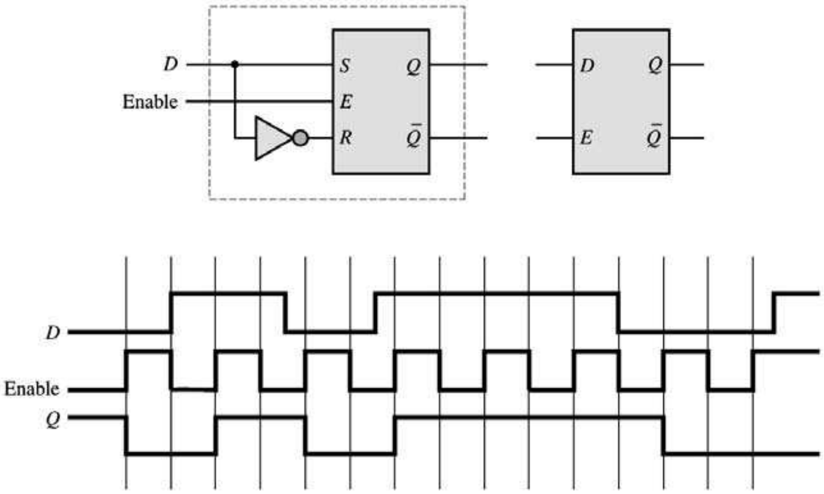

FIGURE 5.10.42 Data latch.

The same circuit of Figure 5.10.41 can be used to illustrate two additional features of flip-flops: the **preset** and **clear** functions, denoted by the inputs P and C, respectively. When P and C are 0, they do not affect the operation of the flip-flop. Setting $P = 1$ corresponds to setting $S = 1$, and therefore causes the flip-flop to go into the 1 state, thus, the term *preset*: this function allows the user to preset the flip-flop to 1 at any time. When C is 1, the flip-flop is reset, or *cleared* (i.e., Q is made equal to 0). Note that these direct inputs are, in general, asynchronous; therefore, they allow the user to preset or clear the flip-flop at any time. A set of timing waveforms illustrating the function of the enable, preset, and clear inputs is also shown in Figure 5.10.41. Note how transitions occur only when the enable input goes high (unless the preset or clear inputs are used to override the RS inputs).

Another extension of the RS flip-flop, called the **data latch**, is shown in Figure 5.10.42. In this circuit, the R input is always equal to the inverted S input, so that whenever the enable input is high, the flip-flop is set. This device has the dual advantage of avoiding the potential conflict that might arise if both R and S were high and reducing the number of input connections by eliminating the reset input. This circuit is called a data latch because once the enable input goes low, the flip-flop is latched to the previous value of the input. Thus this device can serve as a basic memory element.

D Flip-Flop. The ***D* flip-flop** is an extension of the data latch that utilizes two RS flip-flops, as shown in Figure 5.10.43. In this circuit, a clock is connected to the enable input of each flip-flop. Since Q_1 sees an inverted clock signal, the latch is enabled when the clock waveform goes low. However, since Q_2 is disabled when the clock is low, the output of the D flip-flop will not switch to the 1 state until the clock goes high, enabling the second latch and transferring the state of Q_1 to Q_2. It is important to note that the D flip-flop changes state only on the positive edge of the clock waveform: Q_1 is set on the negative edge of the clock, and Q_2 (and therefore Q) is set on the positive edge of the clock, as shown in the timing diagram of Figure 5.10.43. This type of device is said to be **edge-triggered**. This feature is indicated by the "knife edge" drawn next to the CLK input in the device symbol. The particular device described here is said to be positive edge-triggered, or **leading edge-triggered**, since the final output of the flip-flop is set on a positive-going clock transition.

On the basis of the rules stated in this section, the state of the D flip-flop can be described by means of the following truth table:

D	CLK	Q
0	≠	0
1	≠	1

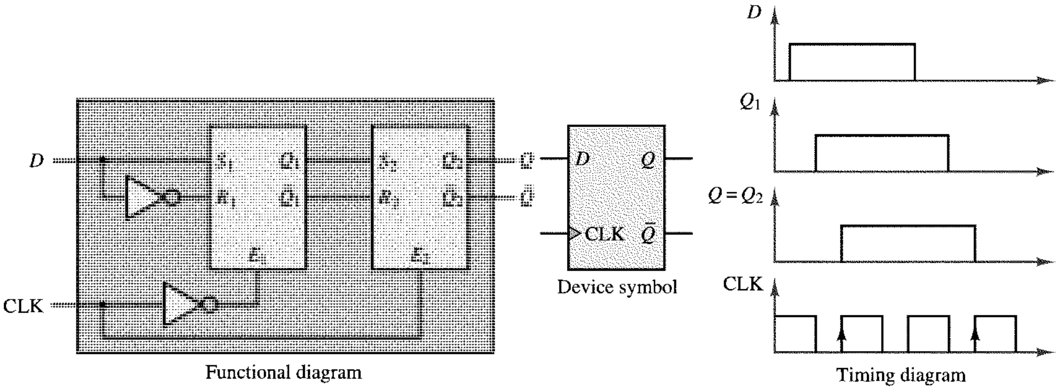

FIGURE 5.10.43 D flip-flop.

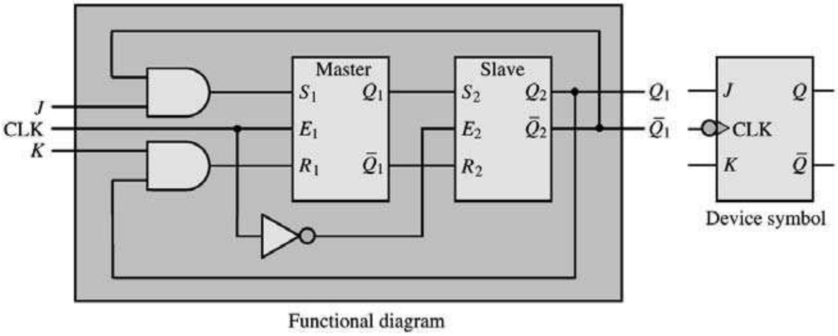

FIGURE 5.10.44 *JK* flip-flop.

where the symbol ↑ indicates the occurrence of a positive transition.

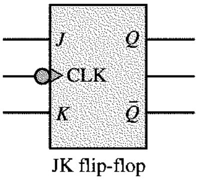
JK Flip-Flop. Another very common type of flip-flop is the ***JK* flip-flop**, shown in Figure 5.10.44. The *JK* flip-flop operates according to the following rules:

- When J and K are both low, no change occurs in the state of the flip-flop.
- When $J = 0$ and $K = \downarrow$, the flip-flop is reset to 0.
- When $J = \downarrow$ and $K = 0$, the flip-flop is set to 1.
- When both J and K are high, the flip-flop will toggle between states at every transition of the clock input.

The symbol ↓ denotes a negative transition.

Note that, functionally, the operation of the *JK* flip-flop can also be explained in terms of two *RS* flip-flops. When the clock waveform goes high, the "master" flip-flop is enabled; the "slave" receives the state of the master upon a negative clock transition. The "bubble" at the clock input signifies that the device is negative or **trailing edge-triggered**. This behavior is similar to that of an *RS* flip-flop, except for the $J = 1$, $K = 1$ condition, which corresponds to a toggle mode rather than to a disallowed combination of inputs.

Figure 5.10.45 depicts the truth table for the *JK* flip-flop. It is important to note that when both inputs are 0 the flip-flop remains in its previous state at the occurrence of a clock transition; when either input is high and the other is low, the *JK* flip-flop behaves like the *RS* flip-flop, whereas if both inputs are high, the output "toggles" between states every time the clock waveform undergoes a negative transition.



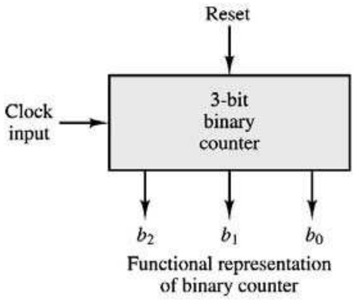
J_n	K_n	Q_{n+1}
0	0	Q_n
0	1	0 (reset)
1	0	1 (set)
1	1	$\bar{Q}_n$ (toggle)

FIGURE 5.10.45 Truth table for the *JK* flip-flop.

Digital Counters

One of the more immediate applications of flip-flops is in the design of **counters**. A counter is a sequential logic device that can take one of *N* possible states, stepping through these states in a sequential fashion. When the counter has reached its last state, it resets to zero and is ready to start counting again. For example, a three-bit **binary up counter** would have $2^3 = 8$ possible states, and might appear as shown in the functional block of Figure 5.10.46. The input clock waveform causes the counter to step through the eight states, making one transition for each clock pulse. We shall shortly see that a string of *JK* flip-flops can accomplish this task exactly. The device shown in Figure 5.10.46 also displays a reset input, which forces the counter to equal 0: $b_2b_1b_0 = 000$.

Although binary counters are very useful in many applications, one is often interested in a **decade counter**, that is, a counter that counts from 0 to 9 and then resets. A four-bit binary counter can easily be configured in principle to provide this function by means of simple logic that resets the counter when it has reached the count $1001_2 = 9_{10}$. As shown in Figure 5.10.47, if we connect bits b_3 and b_1 to a four-input AND gate, along with $\bar{b}_2$ and $\bar{b}_0$, the output of the AND gate can be used to reset the counter after a count of 10. Additional logic can provide a "carry" bit whenever a reset condition is reached,



Functional representation of binary counter

Input pulses	State b_2	b_1	b_0

7	0	1	1	1
8	1	0	0	0
9	1	0	0	1

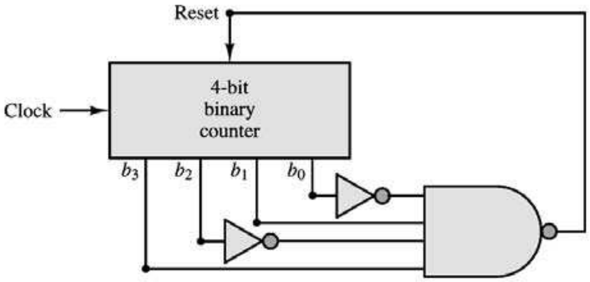

FIGURE 5.10.47 Decade counter.

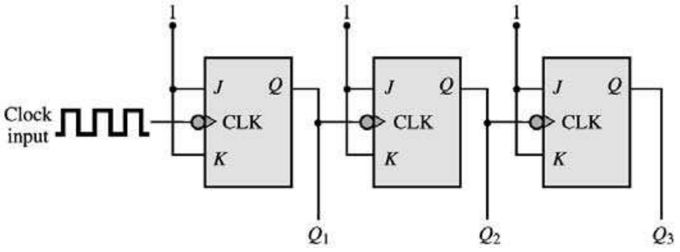
which could be passed along to another decade counter, enabling counts up to 99. Decade counters can be cascaded so as to represent decimal digits in succession.

Although the decade counter of Figure 5.10.47 is attractive because of its simplicity, this configuration would never be used in practice because of the presence of **propagation delays**. These delays are caused by the finite response time of the individual transistors in each logic device and cannot be guaranteed to be identical for each gate and flip-flop. Thus, if the reset signal — which is presumed to be applied at exactly the same time to each of the four *JK* flip-flops in the four-bit binary counter — does not cause the *JK* flip-flops to reset at exactly the same time on account of different propagation delays, then the binary word appearing at the output of the counter will change from 1001 to some other number, and the output of the four-input NAND gate will no longer be high. In such a condition, the flip-flops that have not already reset will then not be able to reset, and the counting sequence will be irreparably compromised.

What can be done to obviate this problem? The answer is to use a systematic approach to the design of sequential circuits making use of **state transition diagrams**. This topic is discussed in the references.

A simple implementation of the binary counter we have described in terms of its functional behavior is shown in Figure 5.10.48. The figure depicts a three-bit binary **ripple counter**, which is obtained from a cascade of three *JK* flip-flops. The transition table shown in the figure illustrates how the *Q* output of each state becomes the clock input to the next stage, while each flip-flop is held in the toggle mode. The output transitions assume that the clock, CLK, is a simple square wave (all *JK*s are negative edge-triggered).

This 3-bit ripple counter can easily be configured as a divide-by-8 mechanism, simply by adding an AND gate. To divide the input clock rate by 8, one output pulse should be generated for every eight clock pulses. If one were to output a pulse every time a binary 111 combination occurs, a simple AND gate would suffice to generate the required condition. This solution is shown in Figure 5.10.49. Note that the



Input	Q_3	Q_2	Q_1
⎍	0	0	0
⎍	0	0	1
⎍	0	1	0
⎍	0	1	1
⎍	1	0	0
⎍	1	0	1
⎍	1	1	0
⎍	1	1	1

FIGURE 5.10.48 Ripple counter.

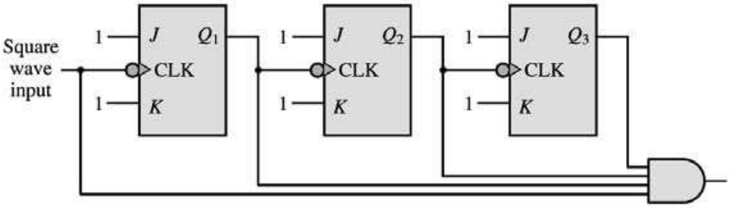


FIGURE 5.10.49 Divide-by-8 circuit.

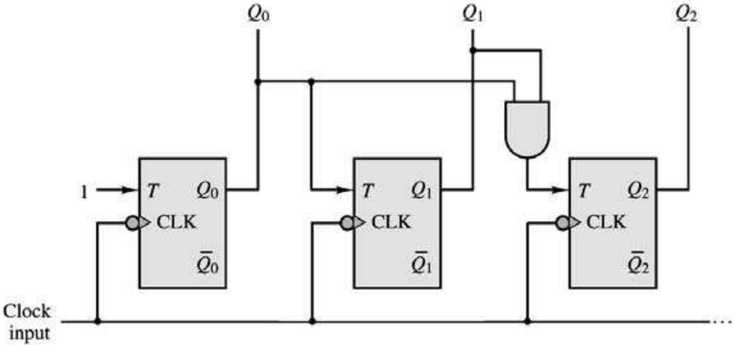

FIGURE 5.10.50 Three-bit synchronous counter.

square wave is also included as an input to the AND gate; this ensures that the output is only as wide as the input signal. This application of ripple counters is further illustrated in the following example.

A slightly more complex version of the binary counter is the so-called **synchronous counter**, in which the input clock drives all of the flip-flops simultaneously. Figure 5.10.50 depicts a three-bit synchronous counter. In this figure, we have chosen to represent each flip-flop as a *T* flip-flop. The clocks to all the flip-flops are incremented simultaneously. The reader should verify that Q_0 toggles to 1 first and then Q_1 toggles to 1, and that the AND gate ensures that Q_2 will toggle only after Q_0 and Q_1 have both reached the 1 state ($Q_0 \cdot Q_1 = 1$).

Other common counters are the **ring counter** and the **up-down counter**, which has an additional select input that determines whether the counter counts up or down.

Example 5.10.6 Measurement of Angular Position

One type of angular position encoder is the slotted encoder shown in Figure 5.10.51. This encoder can be used in conjunction with a pair of counters and a high-frequency clock to determine the speed of rotation of the slotted wheel. As shown in Figure 5.10.52, a clock of known frequency is connected to a counter while another counter records the number of slot pulses detected by an optical slot detector as the wheel rotates. Dividing the counter values, one could obtain the speed of the rotating wheel in radians per second. For example, assume a clocking frequency of 1.2 kHz. If both counters are started at zero and at some instant the timer counter reads 2850 and the encoder counter reads 3050, then the speed of the rotating encoder is found to be

$$1200\frac{\text{cycles}}{\text{second}}\cdot\frac{2850\text{ slots}}{3050\text{ cycles}} = 1121.3\frac{\text{slots}}{\text{second}}$$

and

$$1121.3\ \text{slots/sec} \times 1^\circ\ \text{per slot} \times 2\pi/360\ \text{rad/degree} = 19.6\ \text{rad/sec}$$

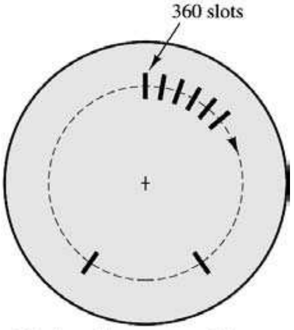

FIGURE 5.10.51

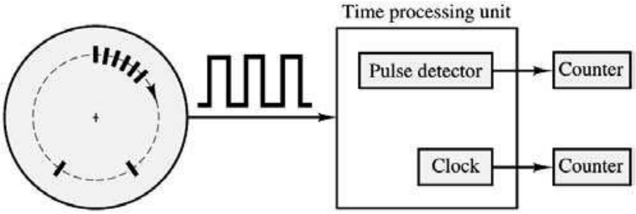

FIGURE 5.10.52 Calculating the speed of rotation of the slotted wheel.

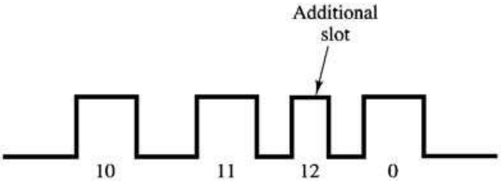

FIGURE 5.10.53 PMA pulse sequence.

If this encoder is connected to a rotating shaft, it is possible to measure the angular position and velocity of the shaft. Such shaft encoders are used in measuring the speed of rotation of electric motors, machine tools, engines, and other rotating machinery. A typical application of the slotted encoder is to compute the ignition and injection timing in an automotive engine. In an automotive engine, information related to speed is obtained from the camshaft and the flywheel, which have known reference points. The reference points determine the timing for the ignition firing points and fuel injection pulses and are identified by special slot patterns on the camshaft and crankshaft. Two methods are used to detect the special slots (reference points): *period measurement with additional transition detection* (PMA, and *period measurement with missing transition detection* (PMM). In the PMA method, an additional slot (reference point) determines a known reference position on the crankshaft or camshaft. In the PMM method, the reference position is determined by the absence of a slot. Figure 5.10.53 illustrates a typical PMA pulse sequence, showing the presence of an additional pulse. The additional slot may be used to determine the timing for the ignition pulses relative to a known position of the crankshaft. Figure 5.10.54 depicts a typical PMM pulse sequence. Because the period of the pulses is known, the additional slot of the missing slot can be easily detected and used as a reference position. How would you implement these pulse sequences using ring counters?

Registers

A register consists of a cascade of flip-flops that can store binary data, one bit in each flip-flop. The simplest type of register is the parallel input–parallel output register shown in Figure 5.10.55. In this register, the “load” input pulse, which acts on all clocks simultaneously, causes the parallel inputs $b_0b_1b_2b_3$

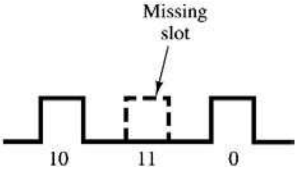

FIGURE 5.10.54 PMA pulse sequence.

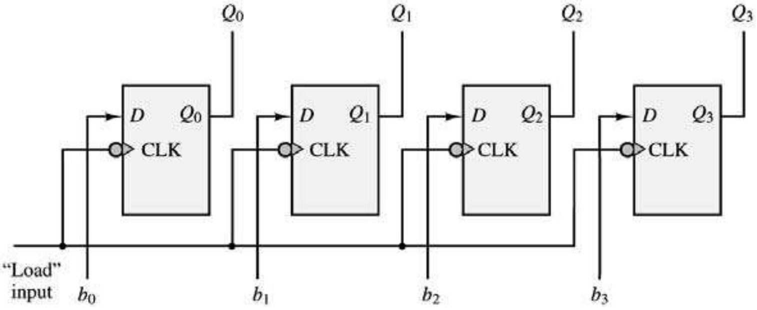

FIGURE 5.10.55 Four-bit parallel register.

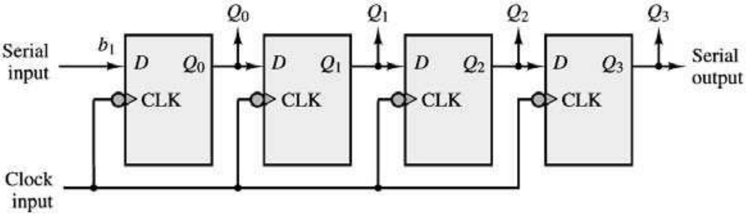

FIGURE 5.10.56 Four-bit shift register.

to be transferred to the respective flip-flops. The *D* flip-flop employed in this register allows the transfer from b_n to Q_n to occur very directly. Thus, *D* flip-flops are very commonly used in this type of application. The binary word $b_3b_2b_1b_0$ is now "stored", each bit being represented by the state of a flip-flop. Until the "load" input is applied again and a new word appears at the parallel inputs, the register will preserve the stored word.

The construction of the parallel register presumes that the *N*-bit word to be stored is available in parallel form. However, it is often true that a binary word will arrive in serial form, that is, one bit at a time. A register that can accommodate this type of logic signal is called a **shift register**. Figure 5.10.56 illustrates how the same basic structure of the parallel register applies to the shift register, except that the input is now applied to the first flip-flop and shifted along at each clock pulse. Note that this type of register provides both a serial and a parallel output.

5.11 Measurements and Instrumentation

Measurement Systems and Transducers

Measurement Systems

In virtually every engineering application there is a need for measuring some physical quantities, such as forces, stresses, temperatures, pressures, flows, or displacements. These measurements are performed by physical devices called **sensors** or **transducers**, which are capable of converting a physical quantity to a more readily manipulated electrical quantity. Most sensors, therefore, convert the change of a physical

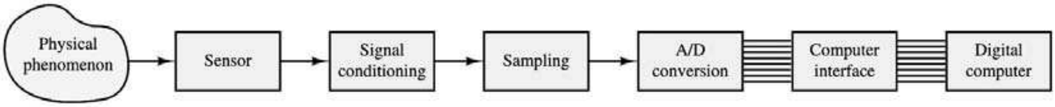

FIGURE 5.11.1 Measurement system.

quantity (e.g., humidity, temperature) to a corresponding (usually proportional) change in an electrical quantity (e.g., voltage or current). Often, the direct output of the sensor requires additional manipulation before the electrical output is available in a useful form. For example, the change in resistance resulting from a change in the surface stresses of a material — the quantity measured by the resistance strain gauges described in Section 5.2 — must first be converted to a change in voltage through a suitable circuit (the Wheatstone bridge) and then amplified from the millivolt to the volt level. The manipulations needed to produce the desired end result are referred to as *signal conditioning*. The wiring of the sensor to the signal conditioning circuitry requires significant attention to *grounding* and *shielding* procedures, to ensure that the resulting signal is as free from noise and interference as possible. Very often, the conditioned sensor signal is then converted to *digital* form and recorded in a computer for additional manipulation, or is displayed in some form. The apparatus used in manipulating a sensor output to produce a result that can be suitably displayed or stored is called a **measurement system**. Figure 5.11.1 depicts a typical computer-based measurement system in block diagram form.

Sensor Classification

There is no standard and universally accepted classification of sensors. Depending on one's viewpoint, sensors may be grouped according to their physical characteristics (e.g., electronic sensors, resistive sensors), or by the physical variable or quantity measured by the sensor (e.g., temperature, flow rate). Other classifications are also possible. Table 5.11.1 presents a partial classification of sensors grouped according to the variable sensed; we do not claim that the table is complete, but we can safely state that most of the engineering measurements of interest to the reader are likely to fall in the categories listed in Table 5.11.1. Also included in the table are section or example references to sensors described in this chapter.

A sensor is usually accompanied by a set of specifications that indicate its overall effectiveness in measuring the desired physical variable. The following definitions will help the reader understand sensor data sheets:

Accuracy: Conformity of the measurement to the true value, usually in percent of full-scale reading
Error: Difference between measurement and true value, usually in percent of full-scale reading
Precision: Number of significant figures of the measurement
Resolution: Smallest measurable increment
Span: Linear operating range
Range: The range of measurable values
Linearity: Conformity to an ideal linear calibration curve, usually in percent of reading or of full-scale reading (whichever is greater)

Motion and Dimensional Measurements

The measurement of motion and dimension is perhaps the most commonly encountered engineering measurement. Measurements of interest include absolute position, relative position (displacement), velocity, acceleration, and jerk (the derivative of acceleration). These can be either translational or rotational measurements; usually, the same principle can be applied to obtain both kinds of measurements. These measurements are often based on changes in elementary properties, such as changes in the resistance of an element (e.g., strain gauges, potentiometers), in an electric field (e.g., capacitive sensors), or in a magnetic field (e.g., inductive, variable-reluctance, or eddy current sensors). Other mechanisms may be based on special materials (e.g., piezoelectric crystals), or on optical signals and imaging systems.

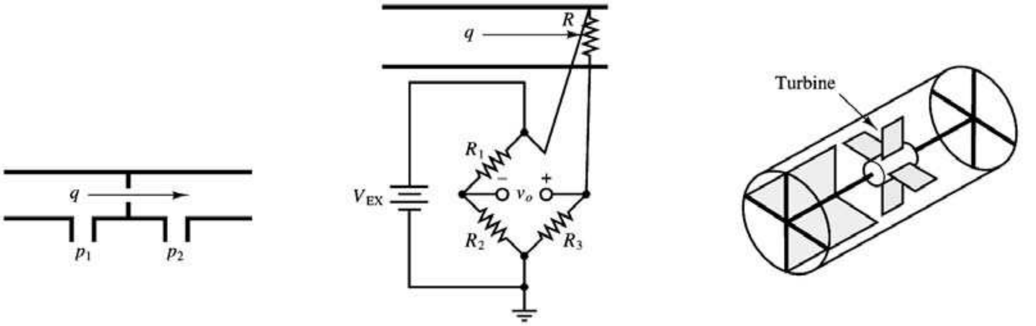
Force, Torque, and Pressure Measurements

Another very common class of measurements is that of pressure and force, and the related measurement of torque. Perhaps the single most common family of force and pressure transducers comprises those based on strain gauges (e.g., load cells, diaphragm pressure transducers). Also very common are piezoelectric transducers. Capacitive transducers again find application in the measurement of pressure.

Flow Measurementrs

In many engineering applications it is desirable to sense the flow rate of a fluid, whether compressible (gas) or incompressible (liquid). The measurement of fluid flow rate is a complex subject; in this section we simply summarize the concepts underlying some of the most common measurement techniques. Shown in Figure 5.11.2 are three different types of flow rate sensors. The sensor in Figure 5.11.2(a) is based on **differential pressure measurement** and on a **calibrated orifice**: the relationship between pressure across the orifice, $p_1 - p_2$, and flow rate through the orifice, q, is predetermined through the calibration; therefore, measuring the differential pressure is equivalent to measuring flow rate.

The sensor in Figure 5.11.2(b) is called a **hot-wire anemometer**, because it is based on a heated wire that is cooled by the flow of a gas. The resistance of the wire changes with temperature, and a Wheatstone bridge circuit converts this change in resistance to a change in voltage. Also commonly used are **hot-film anemometers**, where a heated film is used in place of the more delicate wire. A very common application of the latter type of sensor is in automotive engines, where control of the air-to-fuel ratio depends on measurement of the engine intake mass airflow rate.



Differential-pressure flowmeter: A calibrated orifice and a pair of pressure transducers permit the measurement of flow rate.
(a)

Hot-wire anemometer: A heated wire is cooled by the gas flow. The resistance of the wire changes with temperature.
(b)

Turbine flowmeter: Fluid flow induces rotation of the turbine; measurement of turbine velocity provides an indication of flow rate.

TABLE 5.11.2 Thermocouple Data

Type	Elements +/–	Seebeck Coefficient (μV/°C)	Range (°C)	Range (mV)
E	Chromel/constantan	58.70 at 0°C	–270 to 1000	–9.835 to 76.358
J	Iron/constantan	50.37 at 0°C	–210 to 1200	–8.096 to 69.536
K	Chromel/alumel	39.48 at 0°C	–270 to 1372	–6.548 to 54.874
R	Pt(10%)–Rh/Pt	10.19 at 600°C	–50 to 1768	–0.236 to 18.698
T	Copper/constantan	38.74 at 0°C	–270 to 400	–6.258 to 20.869
S	Pt(13%)–Rh/Pt	11.35 at 600°C	–50 to 1768	–0.226 to 21.108

Figure 5.11.2(c) depicts a **turbine flowmeter**, in which the fluid flow causes a turbine to rotate; the velocity of rotation of the turbine (which can be measured by a noncontact sensor — e.g., a magnetic pickup) is related to the flow velocity.

Besides the techniques discussed in this chapter, many other techniques exist for measuring fluid flow, some of significant complexity.

Temperature Measurements

One of the most frequently measured physical quantities is temperature. The need to measure temperature arises in just about every field of engineering. This subsection is devoted to summarizing two common temperature sensors — the **thermocouple** and the **resistance temperature detector** (RTD) — and their related signal conditioning needs.

Thermocouples. A thermocouple is formed by the junction of two dissimilar metals. This junction results on an open-circuit **thermoelectric voltage** due to the **Seebeck effect**, named after Thomas Seebeck, who discovered the phenomenon in 1821. Various types of thermocouples exist; they are usually classified according to the data of Table 5.11.2. The Seebeck coefficient shown in the table is specified at a given temperature because the output voltage of a thermocouple, v, has a nonlinear dependence on temperature. This dependence is typically expressed in terms of a polynomial of the following form:

$$T = a_0 + a_1 v + a_2 v^2 + a_3 v^3 + \ldots + a_n v^n \tag{5.11.1}$$

For example, the coefficients of the J thermocouple in the range –100 to + 1000°C are as follows:

$$a_0 = -0.048868252 \qquad a_1 = 19{,}873.14503 \qquad a_2 = -128{,}614.5353$$

$$a_3 = 11{,}569{,}199.78 \qquad a_4 = -264{,}917{,}531.4 \qquad a_5 = 2{,}018{,}441{,}314$$

The use of a thermocouple requires special connections, because the junction of the thermocouple wires with other leads (such as voltmeter leads, for example) creates additional thermoelectric junctions that in effect act as additional thermocouples. For example, in the J thermocouple circuit of Figure 5.11.3, junction J_1 is exposed to the temperature to be measured, but junctions J_2 and J_3 also generate a thermoelectric voltage, which is dependent on the temperature at these junctions, that is, the temperature at the voltmeter connections. One would therefore have to know the voltages at these junctions as well, in order to determine the actual thermoelectric voltage at J_1. To obviate this problem, a reference junction at known temperature can be employed; a traditional approach involves the use of a **cold junction**, so called because it consists of an ice bath, one of the easiest means of obtaining a known reference temperature. Figure 5.11.4 depicts a thermocouple measurement using an ice bath. The voltage measured in Figure 5.11.4 is dependent on the temperature difference $T_1 - T_{\text{ref}}$, where $T_{\text{ref}} = 0$°C. The connections to the voltmeter are made at an *isothermal block*, kept at a constant temperature; note that the same metal is used in both of the connections to the isothermal block. Thus (still assuming a J thermocouple), there is no difference between the thermoelectric voltages at the two copper-iron junctions; these will add to zero at the voltmeter. The voltmeter will therefore read a voltage proportional to $T_1 - T_{\text{ref}}$.

An ice bath is not always a practical solution. Other cold junction temperature compensation techniques employ an additional temperature sensor to determine the actual temperature of the junctions J_2 and J_3 of Figure 5.11.3

Resistance Temperature Detectors (RTDs). A resistance temperature detector (RTD) is a variable-resistance device whose resistance is a function of temperature. RTDs can be made with both positive and negative temperature coefficients and offer greater accuracy and stability than thermocouples. **Thermistors** are part of the RTD family. A characteristic of all RTDs is that they are *passive* devices, that is,

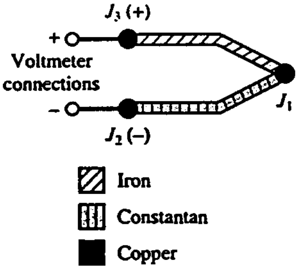

FIGURE 5.11.3 J thermocouple circuit.

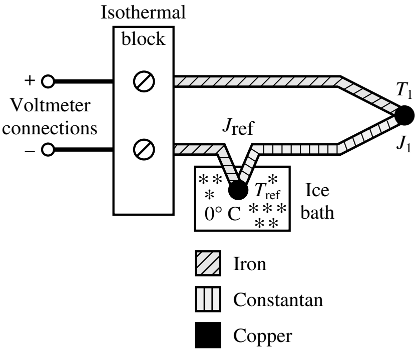

FIGURE 5.11.4 Cold-junction-compensated thermocouple circuit.

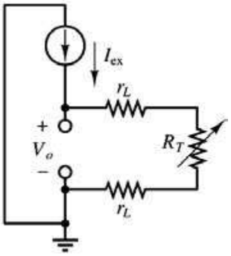

FIGURE 5.11.5 Effect of connection leads on RTD temperature measurement.

they do not provide a useful output unless excited by an external source. The change in resistance in an RTD is usually converted to a change in voltage by forcing a current to flow through the device. An indirect result of this method is a **self-heating error**, caused by the i^2 R heating of the device. Self-heating of an RTD is usually denoted by the amount of power that will raise the RTD temperature by 1°C. Reducing the excitation current can clearly help reduce self-heating, but it also reduces the output voltage.

The RTD resistance has a fairly linear dependence on temperature, a common definition of the **temperature coefficient** of an RTD is related to the change in resistance from 0 to 100°C. Let R_0 be the resistance of the device at 0°C and R_{100} the resistance at 100°C. Then the temperature coefficient, α, is defined to be

$$\alpha = \frac{R_{100} - R_0}{100 - 0} \frac{\Omega}{^\circ\mathrm{C}} \tag{5.11.2}$$

A more accurate representation of RTD temperature dependence can be obtained by using a nonlinear (cubic) equation and published tables of coefficients. As an example, a platinum RTD could be described either by the temperature coefficient $\alpha = 0.003911$, or by the equation

$$\begin{aligned} R_T &= R_0\left(1 + AT - BT^2 - CT^3\right) \\ &= R_0\left(1 + 3.6962\times10^{-3}T - 5.8495\times10^{-7}T^2 - 4.2325\times10^{-12}T^3\right) \end{aligned} \tag{5.11.3}$$

where the coefficient C is equal to zero for temperatures above 0°C.

Because RTDs have fairly low resistance, they are sensitive to error introduced by the added resistance of the lead wires connected to them; Figure 5.11.5 depicts the effect of the lead resistances, r_L, on the RTD measurement. Note that the measured voltage includes the resistance of the RTD as well as the resistance of the leads. If the leads used are long (greater than 3 m is a good rule of thumb), then the measurement will have to be adjusted for this error. Two possible solutions to the lead problems are the *four-wire* RTD measurement circuit and the *three-wire* Wheatstone bridge circuit, shown in Figure 5.11.6(a) and (b), respectively. In the circuit of Figure 5.11.6(a), the resistance of the lead wires from the excitation, r_{L1} and r_{L4}, may be arbitrarily large, since the measurement is affected by the resistance of only the output lead wires, r_{L2} and r_{L3}, which can be kept small by making these leads short. The circuit of Figure 5.11.6(b) takes advantage of the properties of the Wheatstone bridge to cancel out the unwanted effect of the lead wires while still producing an output dependent on the change in temperature.

Wiring, Grounding, and Noise

The importance of proper circuit connections cannot be overemphasized. Unfortunately, this is a subject that is rarely taught in introductory electrical engineering courses. The present section summarizes some important considerations regarding signal source connections, various types of input configurations, noise sources and coupling mechanisms, and means of minimizing the influence of noise on a measurement.

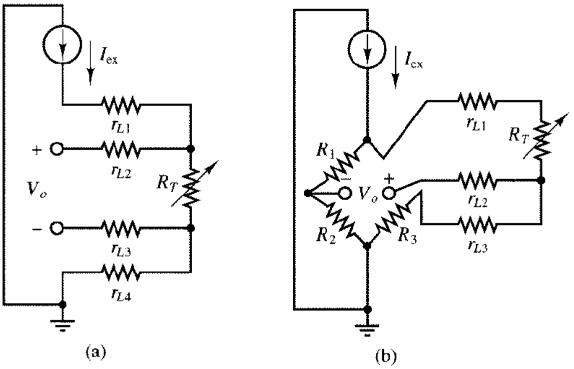

FIGURE 5.11.6 Four-wire RTD circuit (a) and three-wire Wheatstone bridge RTD circuit (b).

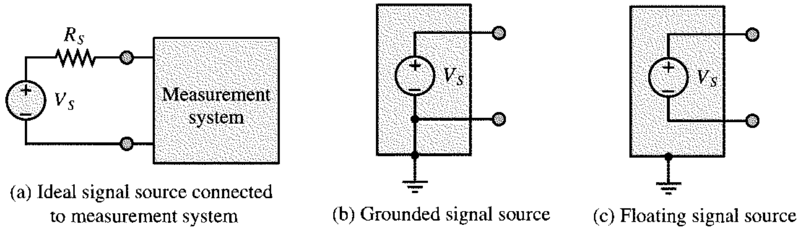
Signal Sources and Measurement System Configurations

Before proper connection and wiring techniques can be presented, we must examine the difference between **grounded** and **floating signal sources**. Every sensor can be thought of as some kind of signal source; a general representation of the connection of a sensor to a measurement system is shown in Figure 5.11.7(a). The sensor is modeled as an ideal voltage source in series with a source resistance. Although this representation does not necessarily apply to all sensors, it will be adequate for the purposes of the present section. Figure 5.7.11(b) and Figure 5.7.11(c) show two types of signal sources: grounded and floating. A grounded signal source is one in which a ground reference is established — for example, by connecting the *signal low* lead to a case or housing. A floating signal source is one in which neither signal lead is connected to ground; since ground potential is arbitrary, the signal source voltage levels (*signal low* and *signal high*) are at an unknown potential relative to the case ground. Thus, the signal is said to be *floating*. Whether a sensor can be characterized as a grounded or a floating signal source ultimately depends on the connection of the sensor to its case, but the choice of connection may depend on the nature of the source. For example, the thermocouple described earlier is *intrinsically* a floating signal source, since the signal of interest is a difference between voltages. The same thermocouple *could* become a grounded signal source if one or its two leads were directly connected to ground, but this is usually not a desirable arrangement for this particular sensor.

In analogy with a signal source, a measurement system can be either **ground-referenced** or **differential.** In a ground-referenced system, the signal low connection is tied to the instrument case ground; in a differential system, neither of the two signal connections is tied to ground. Thus, a differential measurement system is well suited to measuring the difference between two signal levels (such as the output of an ungrounded thermocouple).

One of the potential dangers in dealing with grounded signal sources is the introduction of **ground loops**. A ground loop is an undesired current path caused by the connection of two reference voltages to each other. This is illustrated in Figure 5.11.8, where a grounded signal source is shown connected to



(a) Ideal signal source connected to measurement system

(b) Grounded signal source

(c) Floating signal source

FIGURE 5.11.7 Measurement system and types of signal sources.

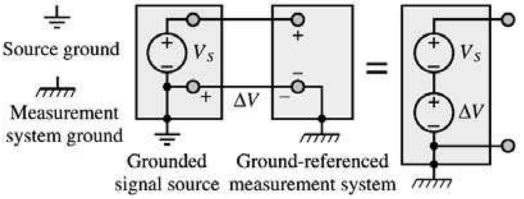


FIGURE 5.11.8 Ground loop in ground-referenced measurement system.

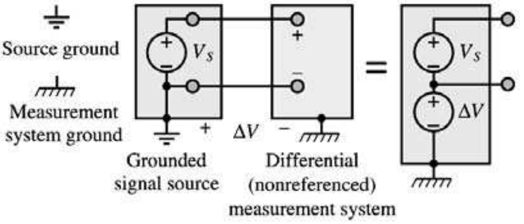

FIGURE 5.11.9 Differential (nonreferenced) measurement system.

a ground-referenced measurement system. Notice that we have purposely denoted the signal source ground and the measurement system ground by two distinct symbols, to emphasize that these are not necessarily at the same potential — as also indicated by the voltage difference ΔV. Now, one might be tempted to tie the two grounds to each other, but this would only result in a current flowing from one ground to the other, through the small (but nonzero) resistance of the wire connecting the two. The net effect of this ground loop would be that the voltage measured by the instrument would include the unknown ground voltage difference ΔV, as shown in Figure 5.11.8. Since this latter voltage is unpredictable, you can see that ground loops can cause substantial errors in measuring systems. In addition, ground loops are the primary cause of conducted noise, as explained later in this section.

A differential measurement system is often a way to avoid ground loop problems because the signal source and measurement system grounds are not connected to each other, and especially because the signal low input of the measuring instrument is not connected to either instrument case ground. The connection of a grounded signal source and a differential measurement system is depicted in Figure 5.11.9.

If the signal source connected to the differential measurement system is floating, as shown in Figure 5.11.10, it is often a recommended procedure to reference the signal to the instrument ground by means of two identical resistors that can provide a return path to ground for any currents present at the instrument. An example of such input currents could be the input bias currents inevitably present at the input of an operational or instrumentation amplifier.

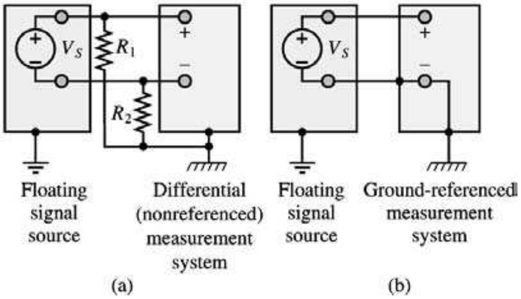

FIGURE 5.11.10 Measuring signals from a floating source: (a) differential input; (b) single-ended input.

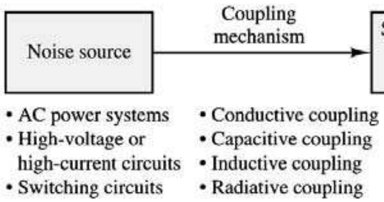

FIGURE 5.11.11 Noise sources and coupling mechanisms.

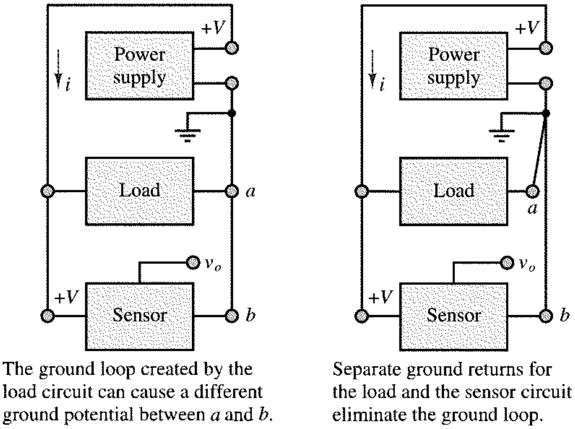
The simple concepts illustrated in the preceding paragraphs and figures can assist the user and designer of instrumentation systems in making the best possible wiring connections for a given measurement.

Noise Sources and Coupling Mechanisms

Noise — meaning any undesirable signal interfering with a measurement — is an unavoidable element of all measurements. Figure 5.11.11 depicts a block diagram of the three essential stages of a noisy measurement: **a noise source, a noise coupling mechanism**, and a sensor or associated signal-conditioning circuit. Noise sources are always present and are often impossible to eliminate completely; typical sources of noise in practical measurements are the electromagnetic fields caused by fluorescent light fixtures, video monitors, power supplies, switching circuits, and high-voltage (or current) circuits. Many other sources exist, of course, but often the simple sources in our everyday environment are the most difficult to defeat.

Figure 5.11.11 also indicates that various coupling mechanisms can exist between a noise source and an instrument. Noise coupling can be conductive; that is, noise currents may actually be conducted from the noise source to the instrument by physical wires. Noise can also be coupled capacitively, inductively and radiatively.

Figure 5.11.12 illustrates how interference can be **conductively coupled** by way of a ground loop. In the figure, a power supply is connected to both a load and a sensor. We shall assume that the load may be switched on and off, and that it carriers substantial currents. The top circuit contains a ground loop: the current i from the supply divides between the load and sensor; since the wire resistance is nonzero, a large current flowing through the load may cause the ground potential at point a to differ from the potential at point b. In this case, the measured sensor output is no longer, v_o, but it is now equal to $v_o + v_{ba}$, where v_{ba} is the potential difference from point b to point a. Now, if the load is switched on and off and its current is therefore subject to large, abrupt changes, these changes will be manifested in the voltage v_{ba} and will appear as noise on the sensor output.



The ground loop created by the load circuit can cause a different ground potential between *a* and *b*.

Separate ground returns for the load and the sensor circuit eliminate the ground loop.

FIGURE 5.11.12 Conductive coupling: ground loop and separate ground returns.

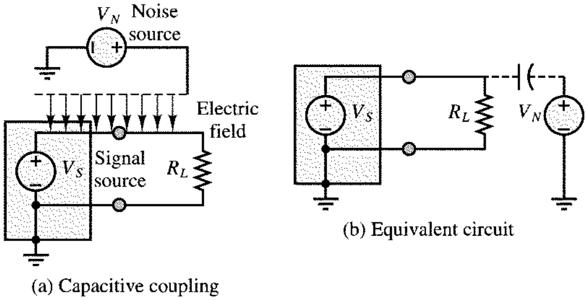


FIGURE 5.11.13 Capacitive coupling and equivalent-circuit representation.

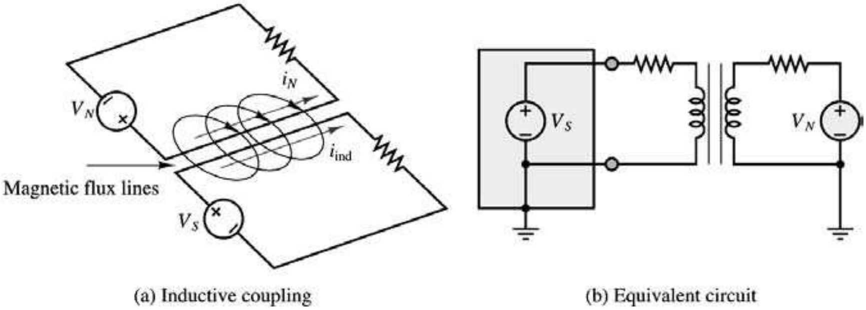

FIGURE 5.11.14 Inductive coupling and equalent-circuit representation.

This problem can be cured simply and effectively by providing separate *ground returns* for the load and sensor, thus eliminating the ground loop.

The mechanism of **capacitive coupling** is rooted in electric fields that may be caused by sources of interference. The detailed electromagnetic analysis can be quite complex, but to understand the principle, refer to Figure 5.11.13(a), where a noise source is shown to generate an electric field. If a noise source conductor is sufficiently close to a conductor that is part of the measurement system, the two conductors (separated by air, a dielectric) will form a capacitor, through which any time-varying currents can flow. Figure 5.11.13(b) depicts an equivalent circuit in which the noise voltage V_N couples to the measurement circuit through an imaginary capacitor, representing the actual capacitance of the noise path.

The dual of capacitive coupling is **inductive coupling**. This form of noise coupling is due to the magnetic field generated by current flowing through a conductor. If the current is large, the magnetic fields can be significant, and the **mutual inductance** between the noise source and the measurement circuit causes the noise to couple to the measurement circuit. Thus, inductive coupling, as shown in Figure 5.11.14 results when undesired (unplanned) magnetic coupling ties the noise source to the measurement circuit.

Noise Reduction

Various techniques exist for minimizing the effect of undesired interference, in addition to proper wiring and grounding procedures. The two most common methods are **shielding** and the use of **twisted-pair wire**. A shielded cable is shown in Figure 5.11.15. The shield is made of a copper braid or of foil and is usually grounded at the source end, *but not at the instrument end*, because this would result in a ground loop. The shield can protect the signal from a significant amount of electromagnetic interference, especially at lower frequencies. Shielded cables with various numbers of conductors are available commercially. However, shielding cannot prevent inductive coupling. The simplest method for minimizing inductive coupling is the use of twisted-pair wire; the reason for using twisted pair is that untwisted wire can offer

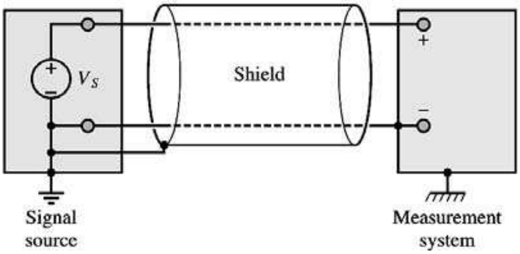

FIGURE 5.11.15 Shielding.

large loops that can couple a substantial amount of electromagnetic radiation. Twisting drastically reduces the loop area, and with it the interference. Twisted pair is available commercially.

Signal Conditioning

A properly wired, grounded, and shielded sensor connection is a necessary first stage of any well-designed measurement system. The next stage consists of any **signal conditioning** that may be required to manipulate the sensor output into a form appropriate for the intended use. Very often, the sensor output is meant to be fed into a digital computer, as illustrated in Figure 5.11.1. In this case, it is important to condition the signal so that it is compatible with the process of data acquisition. Two of the most important signal-conditioning functions are *amplification* and *filtering*. Both are discussed in the present section.

Instrumentation Amplifiers

An **instrumentation amplifier** (IA) is a differential amplifier with very high input impedance, low bias current, and programmable gain that finds widespread application when low-level signals with large common-mode components are to be amplified in noisy environments. This situation occurs frequently when a low-level transducer signal needs to be preamplified, prior to further signal conditioning (e.g., filtering).

The functional structure of an IC instrumentation amplifier is depicted in Figure 5.11.16. Specifications for a common IC instrumentation amplifier (and a more accurate circuit description) are shown in.

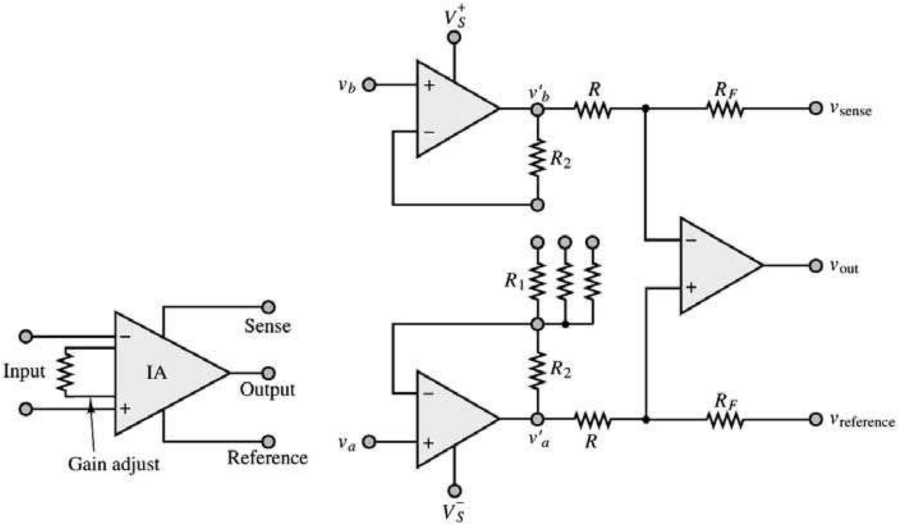

FIGURE 5.11.16 IC instrumentation amplifier.

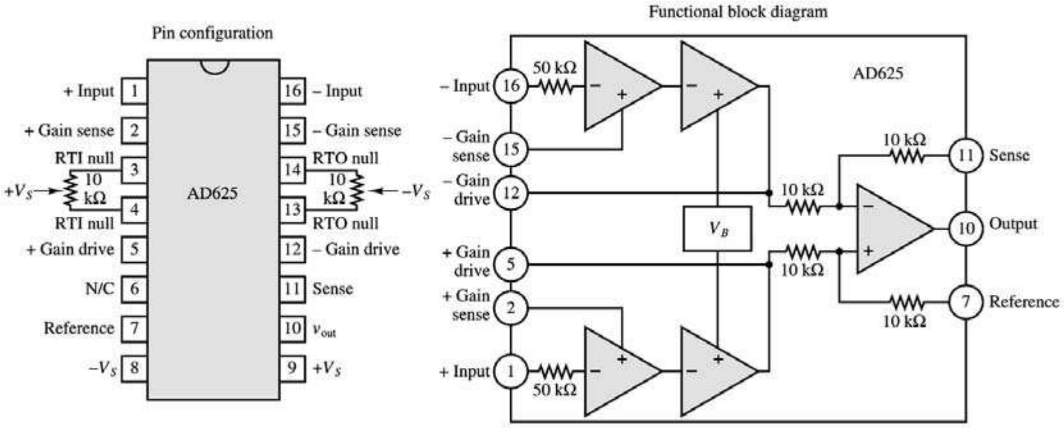

FIGURE 5.11.17 AD625 instrumentation amplifier data sheet.

Figure 5.11.17 Among the features worth mentioning here are the programmable gains, which the user can set by suitably connecting one or more of the resistors labeled R_1 to the appropriate connection. Note that the user may also choose to connect additional resistors to control the amplifier gain, without adversely affecting the amplifier's performance, since R_1 requires no matching. In addition to the pin connection that permits programmable gains, two additional pins are provided, called **sense** and **reference**. These additional connections are provided to the user for the purpose of referencing the output voltage to a signal other than ground, by means of the reference terminal, or of further amplifying the output current (e.g., with a transistor stage), by connecting the sense terminal to the output of the current amplifier.

Active Filters

The need to filter sensor signals that may be corrupted by noise or other interfering or undesired inputs has already been approached in two earlier chapters. In Section 5.6, simple passive filters made of resistors, capacitors, and inductors were analyzed. It was shown that three types of filter frequency response characteristics can be achieved with these simple circuits: low-pass, high-pass, and band-pass. In Section 5.9, the concept of active filters was introduced, to suggest that it may be desirable to exploit the properties of operational amplifiers to simplify filter design, to more easily match source and load impedances, and to eliminate the need for inductors. The aim of this section is to discuss more advanced active filter designs, which find widespread application in instrumentation circuits.

Figure 5.11.18 depicts the general characteristics of a low-pass active filter, indicating that within the pass-band of the filter, a certain deviation from the nominal filter gain, A, is accepted, as indicated by the minimum and maximum pass-band gains, $A + \varepsilon$ and $A - \varepsilon$. The width of the pass-band is indicated by the cutoff frequency, ω_c. On the other hand, the stop-band, starting at the frequency ω_s, does not

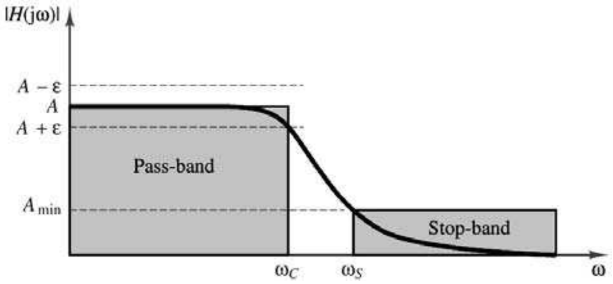

FIGURE 5.11.18 Prototype low-pass filter response.

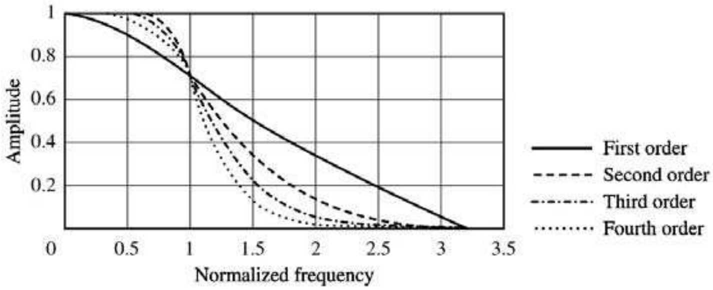

FIGURE 5.11.19 Butterworth low-pass filter frequency response.

TABLE 5.11.3 Butterworth Polynomials in Quadratic Form

Order, n	Quadratic Factors
1	$(s + 1)$
2	$(s^2 + \sqrt{2}s + 1)$
3	$(s + 1)\ (s^2 + s + 1)$
4	$(s^2 + 0.7654s + 1)\ (s^2 + 1.8478s + 1)$
5	$(s + 1)\ (s^2 + 0.6180s + 1)\ (s^2 + 1.6180s + 1)$

allow a gain greater than $A_{\min}$. Different types of filter designs achieve different types of frequency responses, which are typically characterized either by having a particularly flat pass-band frequency response (**Butterworth filters**) or by a very rapid transition between pass-band and stop-band (**Chebyshev filters**, and **Cauer**, or **elliptical, filters**), or by some other characteristic, such as a very linear phase response (**Bessel filters**). Achieving each of these properties usually involves trade-offs; for example, a very flat pass-band response will usually result in a relatively slow transition from pass-band to stop-band.

In addition to selecting a filter from a certain family, it is also possible to select the *order* of the filter; this is equal to the order of the differential equation that describes the input-output relationship of a given filter. In general, the higher the order, the faster the transition from pass-band to stop-band (at the cost of greater phase shifts and amplitude distortion, however). Although the frequency response of Figure 5.11.18 pertains to a low-pass filter, similar definitions also apply to the other types of filters.

Butterworth filters are characterized by a *maximally flat* pass-band frequency response characteristic; their response is defined by a magnitude-squared function of frequency:

$$\left|H(j\omega)\right|^2 = \frac{H_0^2}{1+\varepsilon^2\omega^{2n}} \tag{5.11.14}$$

where $\varepsilon = 1$ for maximally flat response and n is the order of the filter. Figure 5.11.19 depicts the frequency response (normalized to $\omega_c = 1$) of first-, second-, third-, and fourth-order Butterworth low-pass filters. The **Butterworth polynomials**, given in Table 5.11.3 in factored form, permit the design of the filter by specifying the denominator as a polynomial in s. For $s = j\omega$, one obtains the frequency response of the filter.

Figure 5.11.20 depicts the normalized frequency response of first- to fourth-order low-pass Chebyshev filters ($n = 1$ to 4), for $\varepsilon = 1.06$. Note that a certain amount of ripple is allowed in the pass-band; the amplitude of the ripple is defined by the parameter ε and is constant throughout the pass-band. Thus, these filters are also called **equiripple filters**. Cauer, or elliptical, filters are similar to Chebyshev filters, except for being characterized by equiripple both in the pass-band and in the stop-band. Design tables exist to select the appropriate order of Butterworth, Chebyshev, or Cauer filter for a specific application.

Three common configurations of second-order active filters, which can be used to implement **second-order** (or **quadratic**) **filter sections** using a single of op-amp, are shown in Figure 5.11.21. These filters

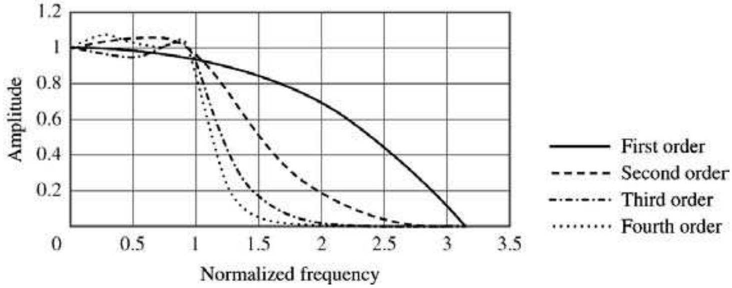

FIGURE 5.11.20 Chebyshev low-pass filter frequency response.

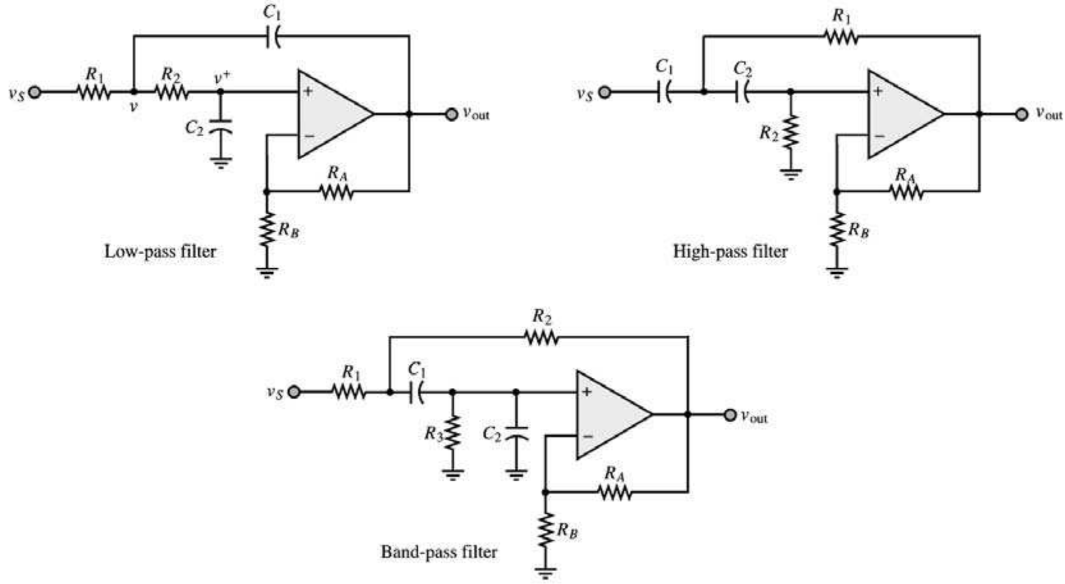

FIGURE 5.11.21 Sallen and Key active filters.

are called **constant-*K***, or **Sallen and Key, filters** (after the name of the inventors). The analysis of these active filters, although somewhat more involved than that of the active filters presented in the preceding chapter, is based on the basic properties of the ideal operational amplifier discussed earlier. Consider, for example, the low-pass filter of Figure 5.11.21. The first unusual aspect of the filter is the presence of both negative and **positive feedback**; that is, feedback connections are provided to both the inverting and the noninverting terminals of the op-amp. The analysis method consists of finding expressions for the input terminal voltages of the op-amp, V^+ and V^-, and using these expressions to derive the input-output relationship for the filter. The frequency response of the low-pass filter is given by

$$H(j\omega) = \frac{K\left(1/R_1R_2C_1C_2\right)}{(j\omega)^2 + \left[\frac{1}{R_1C_1} + \frac{1}{R_2C_1} + \frac{1}{R_2C_2}(1-K)\right] + \frac{1}{R_1R_2C_1C_2}} \tag{5.11.5}$$

This frequency response can be expressed in more general form as follows:

$$H(j\omega) = \frac{H_0 \omega_C^2}{(j\omega)^2 + (\omega_C/Q) j\omega + \omega_C^2}$$

where

$$H_0 = K \tag{5.11.6}$$

is the DC gain of the filter, and where

$$\omega_C = \sqrt{\frac{1}{R_1 R_2 C_1 C_2}}$$

is the cutoff frequency, and where

$$\frac{1}{Q} = \sqrt{\frac{R_2 C_1 C_2}{R_1 C_1}} + \sqrt{\frac{R_1 C_2}{R_2 C_1}} + (1-K)\sqrt{\frac{R_1 C_1}{R_2 C_2}} \tag{5.11.17}$$

is the inverse of the **quality factor**, Q. The Q of a filter is related to the overshoot in the transient response of the filter; and to the peaking (i.e., sharpness of the resonant peak) of the frequency response, a high-Q circuit will display more peaking, or overshoot, than a low-Q circuit.

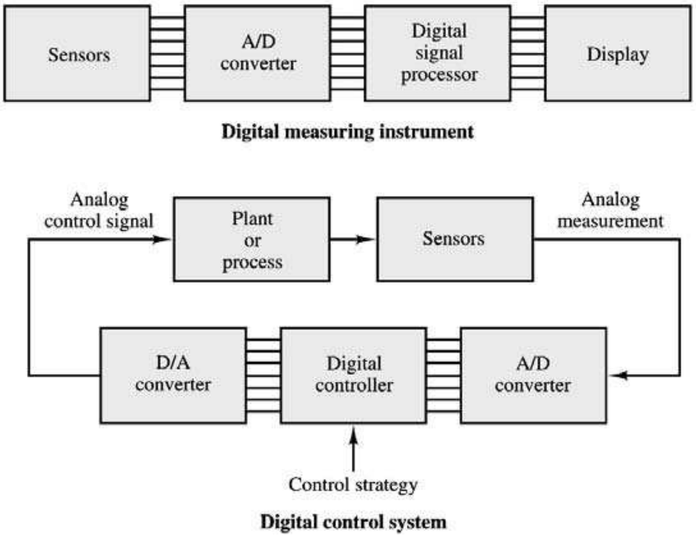
Analog-to-Digital and Digital-to-Analog Conversion

To take advantage of the capabilities of a microcomputer, it is necessary to suitably interface signals to and from external devices with the microcomputer. Such signals may be analog or digital. Depending on the nature of the signal, either an analog or a digital interface circuit will be required. The advantages in memory storage, programming flexibility, and computational power afforded by today's digital computers are such that the instrumentation designer often chooses to convert an analog signal to an equivalent digital representation, to exploit the capabilities of a microprocessor in processing the signal. In many cases, the data converted from analog to digital form remain in digital form for ease of storage, or for further processing. In some instances it is necessary to convert the data back to analog form. The latter condition arises frequently in the context of control system design, where an analog measurement is converted to digital form and processed by a digital computer to generate a control action (e.g., raising or lowering the temperature of a process, or exerting a force or a torque); in such cases, the output of the digital computer is converted back to analog form, so that a continuous signal becomes available to the actuators. Figure 5.11.22 illustrates the general appearance of a digital measuring instrument and of a digital controller acting on a plant or process.

The objective of this section is to describe how the digital-to-analog (D/A) and analog-to-digital (A/D) conversion blocks of Figure 5.11.22 function. After illustrating discrete circuits that can implement simple A/D and D/A converters, we shall emphasize the use of ICs specially made for these tasks. Nowadays, it is uncommon (and impractical) to design such circuits using discrete components: the performance and ease of use of IC packages make them the preferred choice in virtually all applications.

Digital-to-Analog Converters

We discuss digital-to-analog conversion first because it is a necessary part of analog-to-digital conversion in many A/D conversion schemes. A **digital-to-analog converter** (DAC) will convert a binary word to an analog output voltage (or current). The binary word is represented in terms of 1s and 0s, where typically (but not necessarily) 1s correspond to a 5-V level and 0s to a 0-V signal. As an example, consider a four-bit binary word:



Digital measuring instrument

Digital control system

FIGURE 5.11.22 Block diagrams of a digital measuring instrument and a digital control system.

$$B = \left(b_3 b_2 b_1 b_0\right)_2 = \left(b_3 \cdot 2^3 + b_2 \cdot 2^2 + b_1 \cdot 2^1 + b_0 \cdot 2^0\right)_{10} \tag{5.11.8}$$

The analog voltage corresponding to the digital word *B* would be

$$v_a = \left(8b_3 + 4b_2 + 2b_1 + b_0\right)\delta v \tag{5.11.9}$$

where δv is the smallest *step size* by which v_a can increment. This least step size will occur whenever the least significant bit (LSB), b_0, changes from 0 to 1, and is the smallest increment the digital number can make. We shall also shortly see that the analog voltage obtained by the D/A conversion process has a "staircase" appearance because of the discrete nature of the binary signal.

The step size is determined on the basis of each given application and is usually determined on the basis of the number of bits in the digital word to be converted to an analog voltage. We can see that, by extending the previous example for an *n*-bit word, the maximum value v_a can attain is

$$\begin{aligned} v_{a\,\max} &= \left(2^{n-1} + 2^{n-2} + \ldots + 2^1 + 2^0\right)\delta v \\ &= \left(2^n - 1\right)\delta v \end{aligned} \tag{5.11.10}$$

It is relatively simple to construct a DAC by taking advantage of the summing amplifier illustrated in Section 5.9. Consider the circuit shown in Figure 5.11.23, where each bit in the word to be converted is represented by means of a 5-V source and a switch. When the switch is closed, the bit takes a value of 1 (5 V); when the switch is not closed, the bit has value 0. Thus, the output of the DAC is proportional to the word $b_{n-1} \ldots b_{n-2} \ldots b_1 b_0$.

If we select

$$R_i = \frac{R_0}{2^i} \tag{5.11.11}$$

we can obtain weighted gains for each bit so that

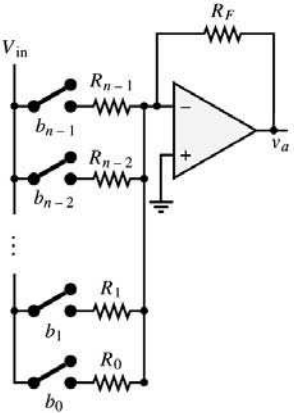


FIGURE 5.11.23 *n*-bit digital-to-analog converter (DAC).

$$v_a = -\frac{R_F}{R_0}\left(2^{n-1}b_{n-1} + \ldots + 2^1 b_1 + 2^0 b_0\right)\cdot 5\ \text{V} \tag{5.11.12}$$

and so that the analog output voltage is proportional to the decimal representation of the binary word.

The practical design of a DAC is generally not carried out in terms of discrete components, because of problems such as the accuracy required of the resistor value. Many of the problems associated with this approach can be solved by designing the complete DAC circuit in integrated circuit (IC) form. The specifications stated by the IC manufacturer include the resolution, that is, the minimum nonzero voltage; the full-scale accuracy; the output range; the output settling time; the power supply requirements; and the power dissipation. The following example illustrates the use of a common integrated circuit DAC.

Example 5.11.1

A typical DAC one would use in conjunction with the 8086 microprocessor is the AD558. This is an IC that can be used in a "stand-alone" configuration (without a microprocessor) or with a microprocessor interfaced to it.

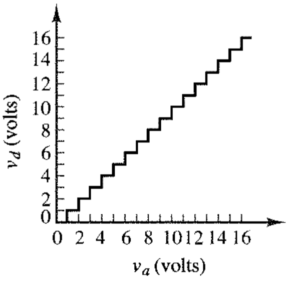
1. If one were to set up the AD558 for an output swing of 0 to 10 V, what would be the smallest voltage output increment attainable?
2. On what is the maximum operating frequency (the largest frequency on which the DAC can perform conversion) of the AD558 dependent? Determine the maximum frequency attainable if the converter is to be run at full-scale input.

Solution.

1. Since this DAC is an eight-bit device, the total number of digital increments one could expect is 256. Thus, the finest voltage steps one could expect at the output would be

   $$\frac{10}{255} = 39.2\ \text{mV}$$

   This means that for every increment of one bit, the output would jump (in a stepwise fashion) by 39.2 mV.
2. The maximum frequency at which a DAC can run is dependent on the settling time. This is defined as the time it takes for the output to settle to within one half of the least significant bit of its final value. Thus, only one transition can be made per settling time. The settling time for the AD558 depends on the voltage range and is defined for a positive-going full-scale step to ±1/2 LSB. The settling time is 1 μsec, and the corresponding maximum conversion frequency is 1 MHz.



Quantized voltage v_d	Binary representation b_3	b_2	b_1	b_0
0	0	0	0	0
1	0	0	0	1
2	0	0	1	0
3	0	0	1	1
4	0	1	0	0

14	1	1	1	0
15	1	1	1	1

FIGURE 5.11.24 A digital voltage representation of an analog voltage.

Analog-to-Digital Converters

You should by now have developed an appreciation for the reasons why it is convenient to process data in digital form. The device that makes conversion of analog signals to digital form is the **analog-to-digital converter** (ADC), and, just like the DAC, it is also available as a single IC package. In addition to discussing analog-to-digital conversion, we shall also introduce the *sample-and-hold amplifier.*

Quantization. The process of converting an analog voltage (or current) to digital form requires that the analog signal be quantized and encoded in binary form. The process of **quantization** consists of subdividing the range of the signal into a finite number of intervals; usually, one employs $2^n - 1$ intervals, where n is the number of bits available for the corresponding binary word. Following this quantization, a binary word is assigned to each interval (i.e., to each range of voltages or currents); the binary word is then the digital representation of any voltage (current) that falls within that interval. You will note that the smaller the interval, the more accurate the digital representation is. However, some error is necessarily always present in the conversion process; this error is usually referred to as **quantization error**. Let v_a represent the analog voltage and v_d its quantized counterpart, as shown in Figure 5.11.24 for an analog voltage in the range 0 to 0 16 V. In the figure, the analog voltage v_a takes on a value of $v_d = 0$ whenever it is in the range 0 to 1 V; for $1 \le v_a < 2$, the corresponding value is $v_d = 1$; for $2 \le v_a < 3$, $v_d = 2$; and so on, until, for $15 \le v_a < 16$, we have $v_d = 15$. You see that if we now represent the quantized voltage v_d by its binary counterpart, as shown in the table of Figure 5.11.24, each 1-V analog interval corresponds to a unique binary word. In this example, a four-bit word is sufficient to represent the analog voltage, although the representation is not very accurate. As the number of bits increases, the quantized voltage is closer and closer to the original analog signal; however, the number of bits required to represent the quantized value increases.

Tracking ADC. Although not the most efficient in all applications, the **tracking ADC** is an easy starting point to illustrate the operation of an ADC, in that it is based on the DAC presented in the previous section. The tracking ADC, shown in Figure 5.11.25, compares the analog input signal with the output of a DAC; the comparator output determines whether the DAC output is larger or smaller than the analog input to be converted to binary form. If the DAC output is smaller, then the comparator output will cause an up-down counter to count up, until it reaches a level close to the analog signal; if the DAC output is larger than the analog signal, then the counter is forced to count down. Note that the rate at which the up-down counter is incremented is determined by the external clock, and that the binary counter output corresponds to the binary representation of the analog signal. A feature of the tracking ADC is that it follows ("tracks") the analog signal by changing one bit at a time.

Integrating ADC. The **integrating ADC** operates by charging and discharging a capacitor, according to the following principle: if one can ensure that the capacitor charges (discharges) linearly, then the time it will take for the capacitor to discharge is linearly related to the amplitude of the voltage that has charged

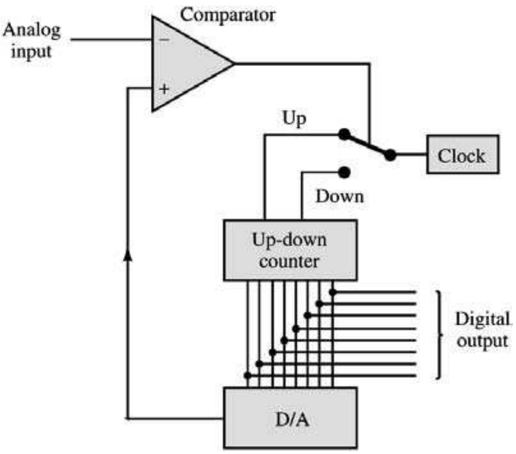

FIGURE 5.11.25 Tracking ADC.

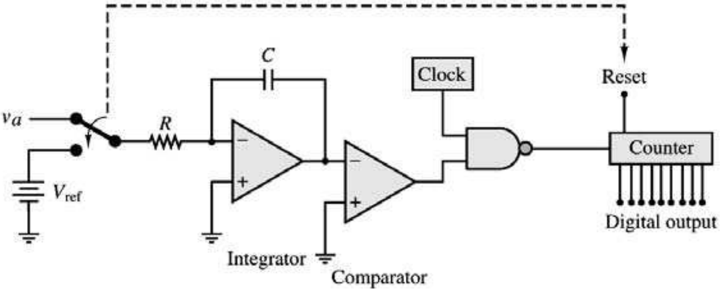

FIGURE 5.11.26 Integrating ADC.

the capacitor. In practice, to limit the time it takes to perform a conversion, the capacitor is not required to charge fully. Rather, a clock is used to allow the input (analog) voltage to charge the capacitor for a short period of time, determined by a fixed number of clock pulses. Then the capacitor is allowed to discharge through a known circuit, and the corresponding clock count is incremented until the capacitor is fully discharged. The latter condition is verified by a comparator, as shown in Figure 5.11.26. The clock count accumulated during the discharge time is proportional to the analog voltage.

In the figure, the switch causes the counter to reset when it is connected to the reference voltage, V_{ref}. The reference voltage is used to provide a known, linear discharge characteristic through the capacitor (see the material on the op-amp integrator in Section 5.9. When the comparator detects that the output of the integrator is equal to zero, it switches state and disables the NAND gate, thus stopping the count. The binary counter output is now the digital counterpart of the voltage v_a.

Other common types of ADC are the so-called successive-approximation ADC and the flash ADC.

Flash ADC. The **flash ADC** is fully parallel and is used for high-speed conversion. A resistive divider network of 2^n resistors divides the known voltage range into that many equal increments. A network of $2^n - 1$ comparators then compares the unknown voltage with that array of test voltages. All comparators with inputs exceeding the unknown are “on”; all others are “off”. This comparator code can be converted to conventional binary by a digital priority encoder circuit. For example, assume that the three-bit flash ADC of Figure 5.11.27 is set up with $V_{ref} = 8$ V. An input of 6.2 V is provided. If we number the comparators from the top of Figure 5.11.27, the state of each of the seven comparators is as given in Table 5.11.4.

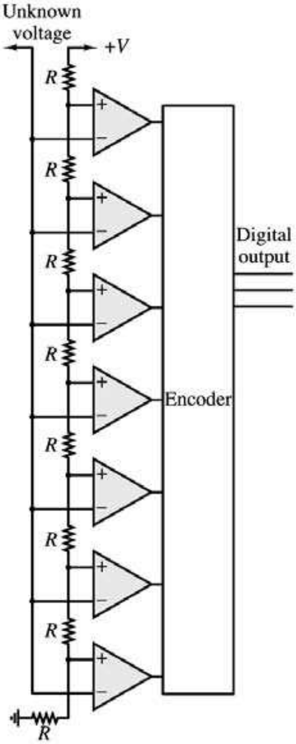

FIGURE 5.11.27 A three-bit flash ADC.

TABLE 5.11.4 State of Comparators in a 3-Bit Flash ADC

Comparator	Input on + Line	Input on – Line	Output
1	7 V	6.2 V	H
2	6 V	6.2 V	L
3	5 V	6.2 V	L
4	4 V	6.2 V	L
5	3 V	6.2 V	L
6	2 V	6.2 V	L
7	1 V	6.2 V	L

To resolve the uncertainty generated by the finite ADC conversion time of any practical converter, it is necessary to use a sample-and-hold amplifier. The objective of such an amplifier is to "freeze" the value of the analog waveform for a time sufficient for the ADC to complete its task.

A typical sample-and-hold amplifier is shown in Figure 5.11.28. It operates as follows. A MOSFET analog switch is used to "sample" the analog waveform. Recall that when a voltage pulse is provided to the sample input of the MOSFET switch (the gate), the MOSFET enters the ohmic region and in effect becomes nearly a short circuit for the duration of the sampling pulse. While the MOSFET conducts, the analog voltage, v_a, charges the "hold" capacitor, C, at a fast rate through the small "on" resistance of the MOSFET. The duration of the sampling pulse is sufficient to charge C to the voltage v_a. Because the MOSFET is virtually a short circuit for the duration of the sampling pulse, the charging (RC) time constant is very small, and the capacitor charges very quickly. When the sampling pulse is over, the MOSFET returns to its nonconducting state, and the capacitor holds the sampled voltage without discharging, thanks to the extremely high input impedance of the voltage-follower (buffer) stage. Thus, v_{SH} is the sampled-and-held value of v_a at any given sampling time.

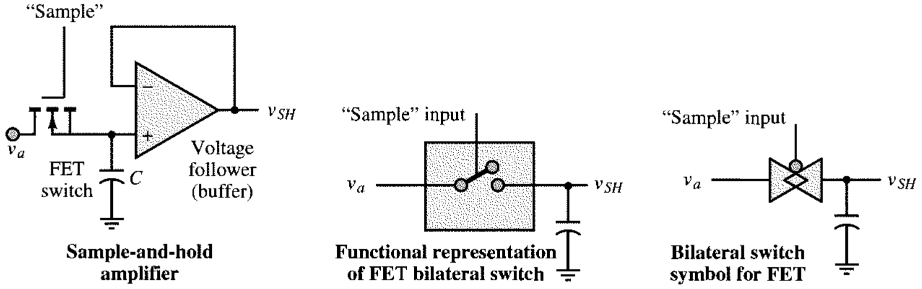

FIGURE 5.11.28 Description of the sample-and-hold process.

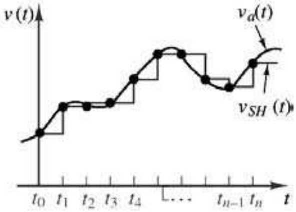

FIGURE 5.11.29 Sampled data.

The appearance of the output of a typical sample-and-hold circuit is shown in Figure 5.11.29, together with the analog signal to be sampled. The time interval between samples, or **sampling interval**, $t_n - t_{n-1}$, allows the ADC to perform the conversion and make the digital version of the sampled signal available, say, to a computer or to another data acquisition and storage system. The sampling interval needs to be at least as long as the A/D conversion time, of course, but it is reasonable to ask how frequently one needs to sample a signal to preserve its fundamental properties (e.g., peaks and valleys, "ringing", fast transition). One might instinctively be tempted to respond that it is best to sample as frequently as possible, within the limitations of the ADC, so as to capture all the features of the analog signal. In fact, this is not necessarily the best strategy. How should we select the appropriate sampling frequency for a given application? Fortunately, an entire body of knowledge exists with regard to sampling theory, which enables the practicing engineer to select the best sampling rate for any given application. Given the scope of this chapter, we have chosen not to delve into the details of sampling theory, but, rather, to provide the student with a statement of the fundamental result: the **Nyquist sampling criterion**. The Nyquist criterion states that to prevent aliasing[2] when sampling a signal, *the sample rate should be selected to be at least twice the highest-frequency component present in the signal.* Thus, if we were sampling an audio signal (say, music), we would have to sample at a frequency of at least 40 kHz (twice the highest audible frequency, 20 kHz). In practice, it is advisable to select sampling frequencies substantially greater than the Nyquist rate; a good rule of thumb is five to ten times greater. The following example illustrates how the designer might take the Nyquist criterion into account in designing a practical A/D conversion circuit.

Example 5.11.2

A typical ADC one would use in conjunction with the 8086 microprocessor is the AD574. This is a successive-approximation converter.

1. What is the accuracy (in volts) the AD574 can provide if $V_{CC} =$ 15.0 V and $0 \leq \text{Vin} \leq 15.0$ V?
2. On the basis of the data sheet, what is the highest-frequency signal you could convert using the AD574? (Assume that $V_{CC} =$ 15.0 V.)
3. If the maximum conversion time available were 40 msec, what would be the highest-frequency signal you could expect to sample on the basis of the Nyquist criterion?

---

[2] Aliasing is a form of signal distortion that occurs when an analog signal is sampled at an insufficient rate.

Solution.

1. According to the data sheet, the least significant bit (LSB) of this converter limits its accuracy, meaning that the output is accurate within ± 1 bit. For the 0- to 15-V swing, this gives a voltage accuracy of

$$\frac{V_{\max} - V_{\min}}{2^n - 1} \quad \text{or} \quad \frac{15}{2^{12} - 1} \times (\pm 1 \text{ bit}) = \pm 3.66 \text{ mV}$$

2. On the basis of the data sheet, the maximum conversion time is 35 μsec. Therefore, the highest frequency of data conversion using the AD574 is

$$f_{\max} = \frac{1}{35\ \mu\text{s}} = 28.57 \text{ kHz}$$

   Thus, the highest signal frequency that could be represented, according to the Nyquist principle, is

$$\frac{1}{2} f_{\max} = \frac{28.57 \times 10^3}{2} = 14.285 \text{ kHz}$$

   This is the maximum theoretical signal frequency that can be represented without distortion, according to the Nyquist principle.
3. Following the same procedure discussed in part 2,

$$\frac{1}{2} f_{\max} = \left(\frac{1}{40 \times 10^{-6}}\right)\left(\frac{1}{2}\right) = 12.5 \text{ kHz}$$

Data Acquisition Systems

A typical data acquisition system, shown in Figure 5.11.30, often employs an *analog multiplexer*, to process several different input signals. A bank of bilateral analog MOSFET switches provides a simple and effective means of selecting which of the input signals should be sampled and converted to digital form. Control logic, employing standard gates and counters, is used to select the desired *channel* (input-signal) and to trigger the sampling circuit and the ADC. When the A/D conversion is completed, the ADC sends an appropriate *end of conversion* signal to the control logic, thereby enabling the next channel to be sampled.

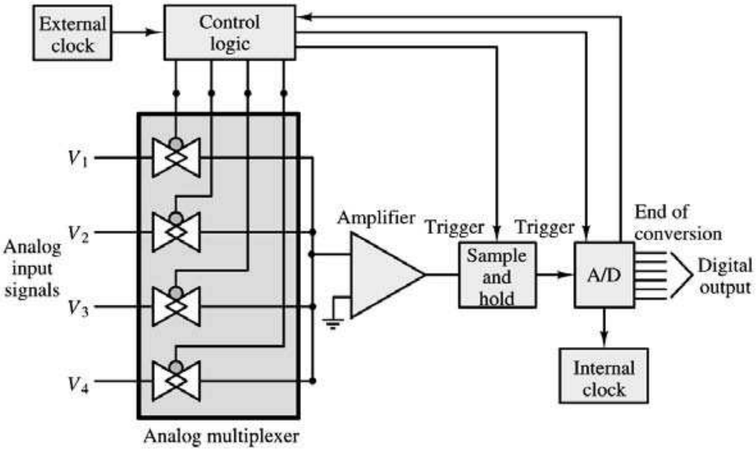

FIGURE 5.11.30 Data acquisition system.

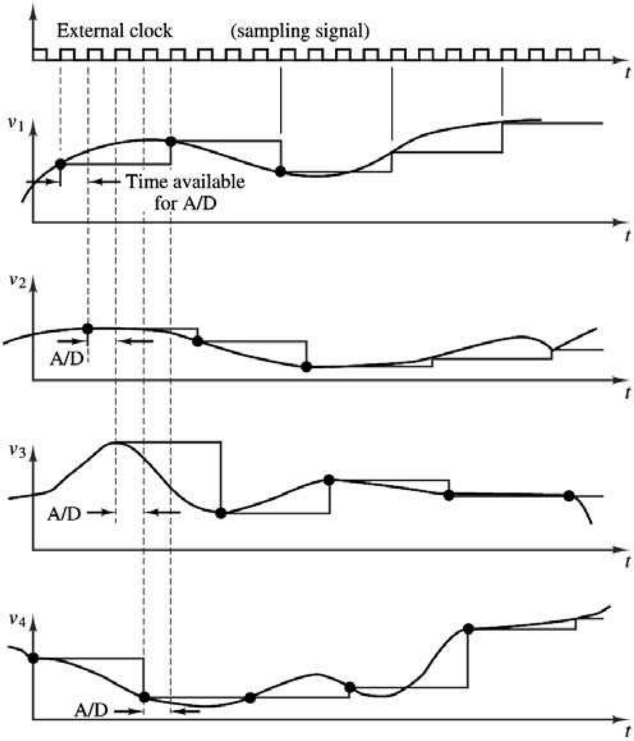

FIGURE 5.11.31 Multiplexed sampled data.

In the block diagram of Figure 5.11.30, four analog inputs are shown; if these were to be sampled at regular intervals, the sequence of events would appear as depicted in Figure 5.11.31. We notice, from a qualitative analysis of the figure, that the effective sampling rate for each channel is one fourth the actual external clock rate; thus, it is important to ensure that the sampling rate for each individual channel satisfies the Nyquist criterion. Further, although each sample is held for four consecutive cycles of the external clock, we must notice that the ADC can use only one cycle of the external clock to complete the conversion, since its services will be required by the next channel during the next clock cycle. Thus, the internal clock that times the ADC must be sufficiently fast to allow for a complete conversion of any sample within the design range.

Timer ICs: the NE555

This section introduces a multipurpose integrated circuit that can perform basic timing functions. The NE555 is a timer circuit capable of producing accurate time delays (pulses) or oscillation. In the time-delay, or monostable, mode, the time delay or pulse duration is controlled by an external RC network. In the astable, or clock generator, mode, the frequency is controlled by two external resistors and one capacitor. Figure 5.11.32 depicts typical circuits for monostable and astable operation of the NE555. Note that the threshold level and the trigger level can also be externally controlled. For the monostable circuit, the pulse width can be computed from the following equation:

$$T = 1.1 R_1 C \tag{5.11.13}$$

For the astable circuit, the positive pulse width can be computed from the following equation:

$$T_+ = 0.69\left(R_1 + R_2\right)C \tag{5.11.14}$$

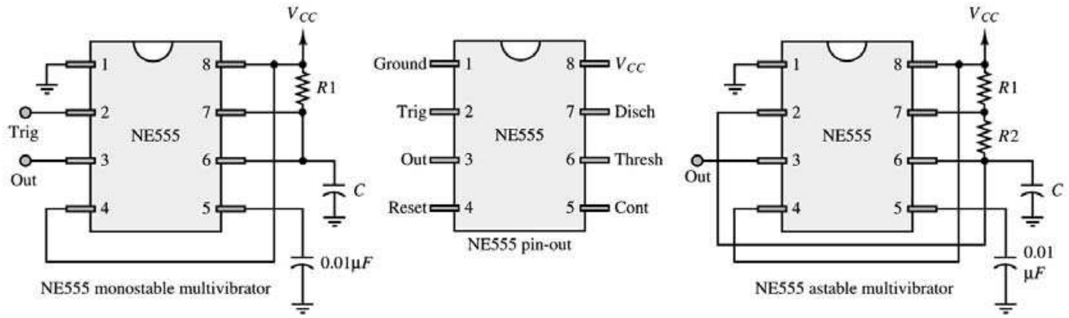

FIGURE 5.11.32 NE555 timer.

and the negative pulse width can be computed from

$$T_- = 0.69 R_2 C \tag{5.11.15}$$

Data Transmission in Digital Instruments

One of the necessary aspects of data acquisition and control systems is the ability to transmit and receive data. Often, a microcomputer-based data acquisition system is interfaced to other digital devices, such as digital instruments or other microcomputers. In these cases it is necessary to transfer data directly in digital form. In fact, it is usually preferable to transmit data that are already in digital form, rather than analog voltages or currents. Among the chief reasons for the choice of digital over analog is that digital data are less sensitive to noise and interference than analog signals: in receiving a binary signal transmitted over a data line, the only decision to be made is whether the value of a bit is 0 or 1. Compared with the difficulty in obtaining a precise measurement of an analog voltage or current, either of which could be corrupted by noise or interference in a variety of ways, the probability of making an error in discerning between binary 0s and 1s is very small. Further, as will be shown shortly, digital data are often coded in such a way that many transmission errors may be detected and corrected for. Finally, storage and processing of digital data are much more readily accomplished than would be the case with analog signals. This section explores a few of the methods that are commonly employed in transmitting digital data; both parallel and serial interfaces are considered.

Digital signals in a microcomputer are carried by a bus, consisting of a set of parallel wires each carrying one bit of information. In addition to the signal-carrying wires, there are also control lines that determine under what conditions transmission may occur. A typical computer data bus consists of eight parallel wires and therefore enables the transmission of one byte; digital data are encoded in binary according to one of a few standard codes, such as the BCD code described in Section 5.10, or the ASCII code, which is summarized in Table 5.11.5. This bus configuration is usually associated with **parallel transmission**, whereby all of the bits are transmitted simultaneously, along with some control bits.

Figure 5.11.33 depicts the general appearance of a parallel connection. Parallel data transmission can take place in one of two modes: **synchronous** or **asynchronous**. In synchronous transmission, a timing clock pulse is transmitted along with the data over a control line. The arrival of the clock pulse indicates that valid data have also arrived. While parallel synchronous transmission can be very fast, it requires the added complexity of a synchronizing clock and is typically employed only for internal computer data transmission. Further, this type of communication can take place only over short distances (approximately 4 m). Asynchronous data transmission, on the other hand, does not take place at a fixed clock rate, but requires a **handshake protocol** between sending and receiving ends. The handshake protocol consists of the transmission of *data ready* and *acknowledge* signals over two separate control wires. Whenever the sending device is ready to transmit data, it sends a pulse over the *data ready* line. When this signal reaches

the receiver, and if the receiver is ready to receive the data, an *acknowledge* pulse is sent back, indicating that the transmission may occur; at this point, the parallel data are transmitted.

Perhaps the most common parallel interface is based on the **IEEE 488 standard**, leading to the so-called IEEE 488 bus, also referred to as GPIB (for **general-purpose instrument bus**).

The IEEE 488 Bus

The IEEE 488 bus, shown in Figure 5.11.34, is an eight-bit parallel asynchronous interface that has found common application in digital instrumentation applications. The physical bus consists of 16 lines, of which 8 are used to carry the data, 3 for the handshaking protocol, and the rest to control the data flow. The bus permits connection of up to 15 instruments and data rates of up to 1 Mbyte/sec. There is a

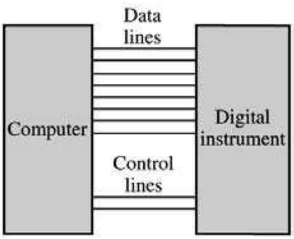

FIGURE 5.11.33 Parallel data transmission.

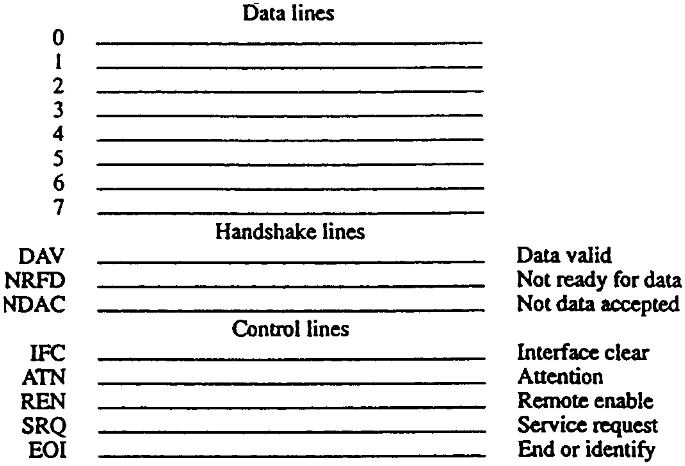

FIGURE 5.11.34 IEEE 488 bus.

limitation, however, in the maximum total length of the bus cable, which is 20 m. The signals transmitted are TTL-compatible and employ negative logic, whereby a logic 0 corresponds to a TTL high state (>2 V) and a logic 1 to a TTL low state (<0.8 V). Often, the eight-bit word transmitted over an IEEE 488 bus is coded in ASCII format (see Table 5.11.5).

In an IEEE 488 bus system, devices may play different roles and are typically classified as *controllers*, which manage the data flow; *talkers* (e.g., a digital voltmeter), which can only send data; *listeners* (e.g., a printer), which can only receive data; and *talkers/listeners* (e.g., a digital oscilloscope), which can receive as well as transmit data. The simplest system configuration might consist of just a talker and a listener. If more than two devices are present on the bus, a controller is necessary to determine when and how data transmission is to occur on the bus. For example, one of the key rules implemented by the controller is that only one talker can transmit at any one time; it is possible, however, for several listeners to be active on the bus simultaneously. If the data rates of the different listeners are different, the talker will have to transmit at the slowest rate, so that all of the listeners are assured of receiving the data correctly.

The set of rules by which the controller determines the order in which talking and listening are to take place is determined by a **protocol**. One aspect of the protocol is the handshake procedure, which enables the transmission of data. Since different devices (with different data rate capabilities) may be listening to the same talker, the handshake protocol must take into account these different capabilities. Let us discuss a typical handshake sequence that leads to transmission of data on an IEEE 488 bus. The three handshake lines used in the IEEE 488 have important characteristics that give the interface system wide flexibility, allowing interconnection of multiple devices that may operate at different speeds. The slowest active device controls the rate of data transfer, and more than one device can accept data simultaneously. The timing diagram of Figure 5.11.35 is used to illustrate the sequence in which the handshake and data transfer are performed:

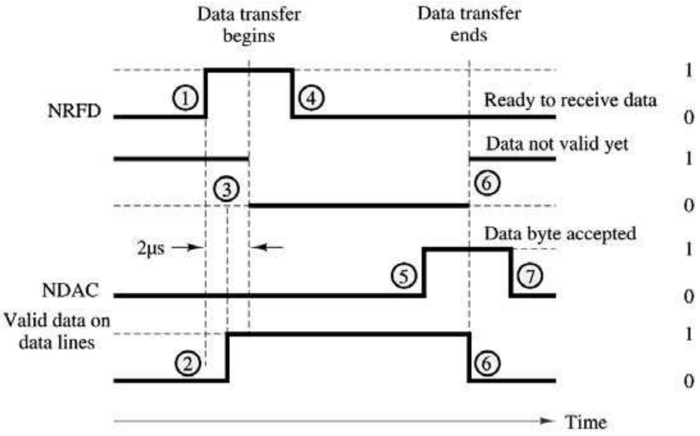

FIGURE 5.11.35 IEEE 488 data transmission protocol.

1. All active listeners use the not ready for data (NRFD) line to indicate their state of readiness to accept a new piece of information. Nonreadiness to accept data is indicated if the NRFD line is held at 0 V. If even one active listener is not ready, the NRFD line of the entire bus is kept at 0 V and the active talker will not transmit the next byte. When all active listeners are ready and they have released the NRFD line, it now goes high.
2. The designated talker drives all eight data input/output lines, causing valid data to be placed on them.
3. Two microseconds after putting valid data on the data lines, the active talker pulls the data valid (DAV) line to 0 V and thereby signals the active listeners to read the information on the data bus. The 2-μsec interval is required to allow the data put on the data lines to reach (settle to) valid logic levels.
4. After the DAV is asserted, the listeners respond by pulling the NRFD line back down to zero. This prevents any additional data transfers from being initiated. The listeners also begin accepting the data byte at their own rates.
5. When each listener has accepted the data, it releases the not data accepted (NDAC) line. Only when the last active listener has released its hold on the NDAC line will that line go to its high-voltage-level state.
6. (a) When the active talker sees that NDAC has come up to its high state, it stops driving the data line. (b) At the same time, the talker releases the DAV line, ending the data transfer. The talker may now put the next byte on the data bus.
7. The listeners pull down the NDAC line back to 0 V and put the byte “away”.

Each of the instruments present on the data bus is distinguished by its own address, which is known to the controller; thus, the controller determines who the active talkers and listeners are on the bus by *addressing* them. To implement this and other functions, the controller uses the five control lines. Of these, ATN (attention) is used as a switch to indicate whether the controller is addressing or instructing the devices on the bus, or whether data transmission is taking place: when ATN is logic 1, the data lines contain either control information or addresses; with ATN = 1, only the controller is enabled to talk. When ATN = 0, only the devices that have been addressed can use the data lines. The IFC (interface clear) line is used to initialize the bus, or to clear it and reset it to a known condition in case of incorrect transmission. The REN (remote enable) line enables a remote instrument to be controlled by the bus; thus, any function that might normally be performed manually on the instrument (e.g., selecting a range or mode of operation) is now controlled by the bus via the data lines. The SRQ (service request) line is used by instruments on the bus whenever the instrument is ready to send or receive data; however, it is the controller who decides when to service the request. Finally, the EOI (end or identify) line can be used in two modes; when it is used by a talker, it signifies the end of a message; when it is used by the controller, it serves as a *polling* line, that is, a line used to interrogate the instrument about its data output.

Although it was mentioned earlier that the IEEE 488 bus can be used only over distances of up to 20 m, it is possible to extend its range of operation by connecting remote IEEE 488 bus systems over telephone communication lines. This can be accomplished by means of *bus extenders*, or by converting the parallel data to serial form (typically, in RS-232 format) and by transmitting the serial data over the phone lines by means of a modem. Serial communications and the RS-232 standard are discussed in the next section.

The RS-232 Standard

The primary reason why parallel transmission of data is not used exclusively is the limited distance range over which it is possible to transmit data on a parallel bus. Although there are techniques which permit extending the range for parallel transmission, these are complex and costly. Therefore, **serial transmission** is frequently used whenever data is to be transmitted over a significant distance. Since serial data travel along one single path and are transmitted one bit at a time, the cabling costs for long distances are relatively low; further, the transmitting and receiving units are also limited to processing just one signal and are also much simpler and less expensive. Two modes of operation exist for serial transmission: **simplex**, which corresponds to transmission in one direction only; and **duplex**, which permits transmission in either direction. Simplex transmission requires only one receiver and one transmitter, at each end of the link; on the other hand, duplex transmission can occur in one of two manners: **half-duplex** and **full-duplex**. In the former, although transmission can take place in both directions, it cannot occur simultaneously in both directions; in the latter case, both ends can simultaneously transmit and receive. Full-duplex transmission is usually implemented by means of four wires.

The data rate of a serial transmission line is measured in bits per second, since the data are transmitted one bit at a time. The unit of 1 bit/sec is called a **baud**; thus, reference is often made to the baud rate of a serial transmission. The baud rate can be translated into a parallel transmission rate in words per second if the structure of the word is known; for example, if a word consists of 10 bits (start and stop bits plus an 8-bit data word) and the transmission takes place at 1200 baud, 120 words are being transmitted every second. Typical data rates for serial transmission are standardized; the most common rates (familiar to the users of personal computer modem connections) are 300, 600, 1200, and 2400 baud. Baud rates can be as low as 50 baud or as high as 19,200 baud.

Like parallel transmission, serial transmission can also occur either synchronously or asynchronously. In the serial case, it is also true that asynchronous transmission is less costly but not as fast. A handshake protocol is also required for asynchronous serial transmission, as explained in the following. The most popular data-coding scheme for serial transmission is, once again, the ASCII code, consisting of a 7-bit word plus a **parity bit**, for a total of 8 bits per character. The role of the parity bit is to permit error detection in the event of erroneous reception (or transmission) of a bit. To see this, let us discuss the sequence of handshake events for asynchronous serial transmission and the use of parity bits to correct for errors. In serial asynchronous systems, handshaking is performed by using start and stop bits at the beginning and end of each character that is transmitted. The beginning of the transmission of a serial asynchronous word is announced by the "start" bit, which is always a 0-state bit. For the next five to eight successive bit times (depending on the code and the number of bits that specify the word length in the code), the line is switched to the 1 and 0 states required to represent the character being sent. Following the last bit of the data and the parity bit (which will be explained next), there is 1 bit or more in the 1 state, indicating "idle". The time period associated with this transmission is called the "stop" bit interval.

If noise pulses affect the transmission line, it is possible that a bit in the transmission could be misread. Thus, following the 5 to 8 transmitted data bits, there is a party bit that is used for error detection. Here is how the parity bit works. If the transmitter keeps track of the number of 1s in the word being sent, it can send a parity bit, a 1 or a 0, to ensure that the total number of 1s sent is always even (even parity) or odd (odd parity). Similarly, the receiver can keep track of the 1s received to see whether there was an error with the transmission. If an error is detected, retransmission of the word can be repeated.

Serial data transmission occurs most frequently according to the **RS-232 standard**. The RS-232 standard is based on the transmission of voltage pulses at a preselected baud rate; the voltage pulses are in the range –3 to –15 V for a logic 0 and in the range of +3 to +15 V for a logic 1. It is important to note that this amounts to a negative logic convention and that the signals are *not* TTL-compatible. The distance over which such transmission can take place is up to approximately 17 m (50 ft). The RS-232 standard was designed to make the transmission of digital data compatible with existing telephone lines; since phone lines were originally designed to carry analog voice signals, it became necessary to establish some standard procedures to make digital transmission possible over them. The resulting standard describes the mechanical and electrical characteristics of the interface between *data terminal equipment* (DTE) and *data communication equipment* (DCE). DTE consists of computers, terminals, digital instruments, and related peripherals; DCE includes all of those devices that are used to encode digital data in a format that permits their transmission over telephone lines. Thus, the standard specified how data should be presented by the DTE to the DCE so that digital data can be transmitted over voice lines.

A typical example of DCE is the **modem**. A modern converts digital data to audio signals that are suitable for transmission over a telephone line and is also capable of performing the reverse function, by converting the audio signals back to digital form. The term *modem* stands for *mod*ulate-*dem*odulate, because a modem modulates to a sinusoidal carrier using digital pulses (for transmission) and demodulates the modulated sinusoidal signal to recover the digital pulses (at reception). Three methods are commonly used for converting digital pulses to an audio signal: **amplitude-shift keying, frequency-shift keying**, and **phase-shift keying**, depending on whether the amplitude, phase, or frequency of the sinusoid is modulated by the digital pulses. Figure 5.11.36 depicts the essential block of a data transmission system based on the RS-232 standard, as well as examples of digital data encouded for transmission over a voice line.

In addition to the function just described, however, the RS-232 standard also provides a very useful set of specifications for the direct transmission of digital data between computers and instruments. In other words, communication between digital terminal instruments may occur directly in digital form (i.e., without digital communication devices encoding the digital data with analog voice lines). Thus, this standard is also frequently used for direct digital communication.

The RS-232 standard can be summarized as follows:

- Data signals are encoded according to a negative logic convention using voltage levels of –3 to –15 V for logic 1 and +3 to +15 V for logic 0.
- Control signals use a positive logic convention (opposite to that of data signals).
- The maximum shunt capacitance of the load cannot exceed 2500 pF; this, in effect, limits the maximum length of the cables used in the connection.
- The load resistance must be between 300 Ω and 3 kΩ.
- Three wires are used for data transmission. One wire each is used for receiving and transmitting data; the third wire is a signal return line (signal ground). In addition, there are 22 wires that can be used for a variety of control purposes between the DTE and DCE.
- The male part of the connector is assigned to the DTE and the female part to the DCE. Figure 5.11.37 labels each of the wires in the 25-pin connector. Since each side of the connector has a *receive* and a *transmit* line, it has been decided by convention that the DCE transmits on the transmit line and receives on the receive line, while the DTE receives on the transmit line and transmits on the receive line.
- The baud rate is limited by the length of the cable; for a 17-m length, any rate from 50 baud to 19.2 kbaud is allowed. If a longer cable connection is desired, the maximum baud rate will decrease according to the length of the cable and **line drivers** can be used to amplify the signals, which are transmitted over twisted-air wires. Line drivers are simply signal amplifiers that are used directly

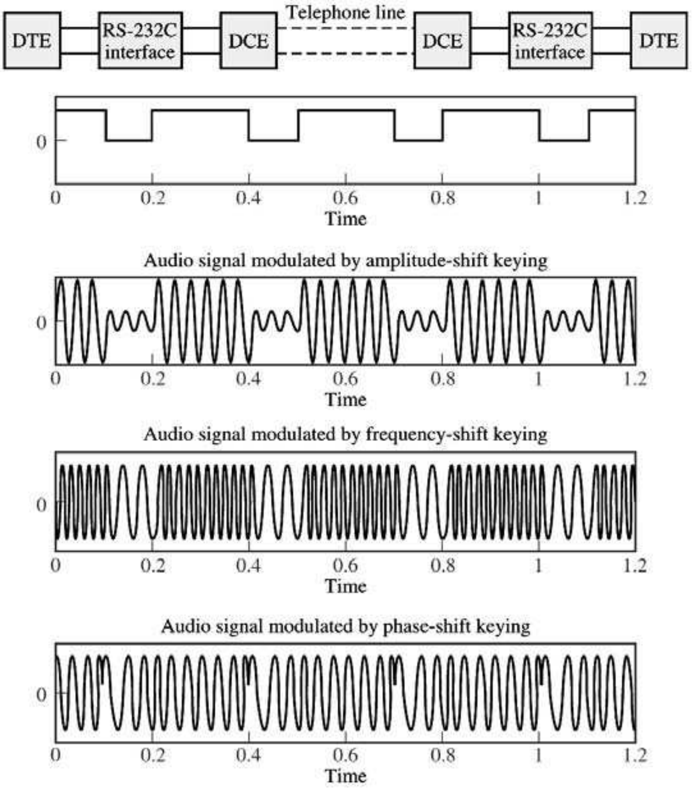

FIGURE 5.11.36 Digital data encoded for analog transmission.

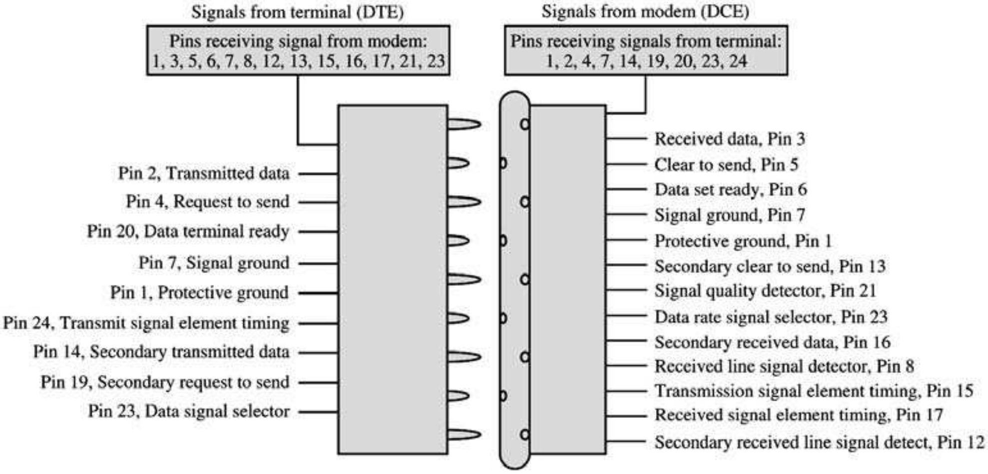

FIGURE 5.11.37 RS-232 connections.

on the digital signal, prior to encoding. For example, the signal generated by a DTE device (say, a computer) may be transmitted over a distance of up to 3300 m (at a rate of 600 baud) prior to being encoded by the DCE.

- The serial data can be encoded according to any code, although the ASCII code is by far the most popular.

Other Communication Network Standards

In addition to the popular RS-232 and IEEE bus standards we should mention other communication standards that have become or are rapidly becoming commonplace. One is the *Ethernet*, which operates at 10 Mb/sec and is based on IEEE Standard 802.3. This is commonly used in office networks. Higher speed networks include FDDI (fiber distributed data interface), which specifies an optical fiber ring with a data rate of 100 Mb/sec, and ATM (asynchronous transfer mode), a packet oriented transfer mode moving data in fixed-size packets called cells. ATM does not operate at a fixed speed. Typical speed is 155 Mb/sec, but there are implementations running as fast as 2 Gb/sec.

5.12 Electromechanical Systems

The objective of this section is to introduce the fundamental notions of electromechanical energy conversion, leading to an understanding of the operation of various electromechanical transducers

The Magnetic Field and Faraday's Law

The quantities used to measure the strength of a magnetic field are the **magnetic flux**, ϕ, in units of **webers** (Wb); and the **magnetic flux density**, B, in units of webers per square(Wb/m^2), or **teslas** (T). The latter quantity, as well as the associated **magnetic field intensity,** H (in units of amperes per meter, or A/m), are vectors. Thus, the density of the magnetic flux and its intensity are in general described in vector form, in terms of the components present in each spatial direction (e.g., on the x, y, and z axes). In discussing magnetic flux density and field intensity in this chapter and the next, we shall almost always assume that the field is a *scalar field*, that is, that it lies in a single spatial direction. This will simplify many explanations.

It is customary to represent the magnetic field by means of the familiar *lines of force* (a concept also due to Faraday); we visualize the strength of a magnetic field by observing the density of these lines in space. You probably know from a previous course in physics that such lines are closed in a magnitude field, that is, that they form continuous loops exiting at a magnetic north pole (by definition) and entering at a magnetic south pole. The relative strengths of the magnetic fields generated by two magnets could be depicted as shown in Figure 5.12.1.

Magnetic fields are generated by electric charge in motion, and their effect is measured by the force they exert on a moving charge. As you may recall from previous physics courses, the vector force **f** exerted on a charge of q moving at velocity **u** in the presence of a magnetic field with flux density **B** is given by the equation

$$\mathbf{f} = q\mathbf{u} \times \mathbf{B} \tag{5.12.1}$$

where the symbol × denotes the (vector) cross product. If the charge is moving at a velocity **u** in a direction that makes an angle θ with the magnetic field, then the magnitude of the force is given by

$$f = quB\sin\theta \tag{5.12.2}$$

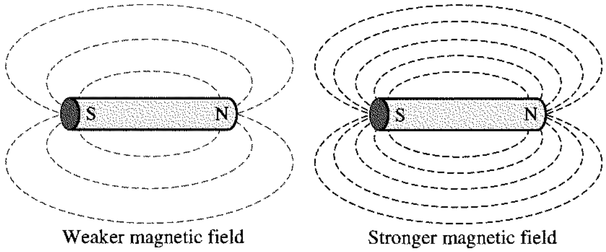

FIGURE 5.12.1 Lines of force in a magnetic field.

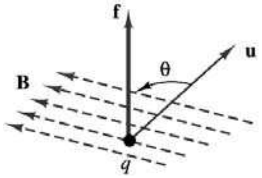

FIGURE 5.12.2 Charge moving in a constant magnetic field.

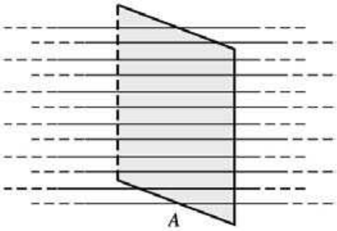

FIGURE 5.12.3 Magnetic flux lines crossing a surface.

and the direction of this force is at right angles with the plane formed by the vectors **B** and **u**. This relationship is depicted in Figure 5.12.2.

The magnetic flux, ϕ, is then defined as the integral of the flux density over some surface area. For the simplified (but often useful) case of magnetic flux lines perpendicular to a cross-sectional area A, we can see that the flux is given by the following integral:

$$\phi = \int_A B \, dA \tag{5.12.3}$$

in webers (Wb), where the subscript A indicates that the integral is evaluated over the surface A. Furthermore, if the flux were to be uniform over the cross-sectional area A (a simplification that will be useful), the preceding integral could be approximated by the following expression:

$$\phi = B \cdot A \tag{5.12.4}$$

Figure 5.12.3 illustrates this idea by showing hypothetical magnetic flux lines traversing a surface, delimited in the figure by a thin conducting wire.

Faraday's law states that if the imaginary surface A were bounded by a conductor — for example, the thin wire of Figure 5.12.3 — then a *changing* magnetic field would induce a voltage, and therefore a current, in the conductor. More precisely, Faraday's law states that a time-varying flux causes an induced **electromotive force**, or emf, e, as follows:

$$e = -\frac{d\phi}{dt} \tag{5.12.5}$$

In practical applications, the size of the voltages induced by the changing magnetic field can be significantly increased if the conducting wire is coiled many times around, so as to multiply the area crossed by the magnetic flux lines many times over. For an N-turn coil with cross-sectional area A, for example, we have the emf

$$e = N\frac{d\phi}{dt} \tag{5.12.6}$$

Figure 5.12.4 shows an N-turn coil *linking* a certain amount of magnetic flux; you can see that if N is very large and the coil is tightly wound (as is usually the case in the construction of practical devices),

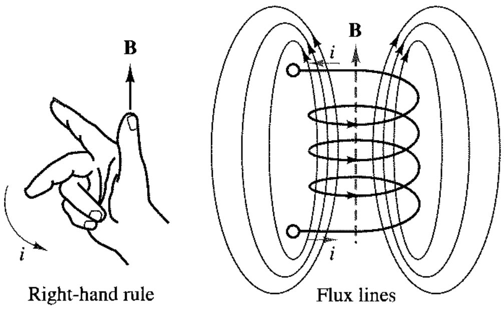

FIGURE 5.12.4 Concept of flux linkage.

it is not unreasonable to presume that each turn of the coil links the same flux. It is convenient, in practice, to define the **flux linkage**, λ, as

$$\lambda = N\phi \tag{5.12.7}$$

so that

$$e = \frac{d\lambda}{dt} \tag{5.12.8}$$

In the analysis of linear circuits, we implicitly assumed that the relationship between flux linkage and current was a linear one:

$$\lambda = Li \tag{5.12.9}$$

so that the effect of a time-varying current was to induce a transformer voltage across an inductor coil, according to the expression

$$v = L\frac{di}{dt} \tag{5.12.10}$$

This is, in fact, the defining equation for the ideal **self-inductance**, L. In addition to self-inductance, however, it is also important to consider the **magnetic coupling** that can occur between neighboring circuits. Self-inductance measures the voltage induced in a circuit by the magnetic field generated by a current flowing in the same circuit. It is also possible that a second circuit in the vicinity of the first may experience an induced voltage as a consequence of the magnetic field generated in the first circuit. This principle underlies the operation of all transformers.

Self- and Mutual Inductance

Figure 5.12.5 depicts a pair of coils, one of which, L_1, is excited by a current, i_1, and therefore develops a magnetic field and a resulting induced voltage, v_1, The second coil, L_2, is not energized by a current, but links some of the flux generated by the current i_1 and L_1 because of its close proximity to the first coil. The magnetic coupling between the coils established by virtue of their proximity is described by a quantity called **mutual inductance** and defined by the symbol M. The mutual inductance is defined by the equation

$$v_2 = M\frac{di_1}{dt} \tag{5.12.11}$$

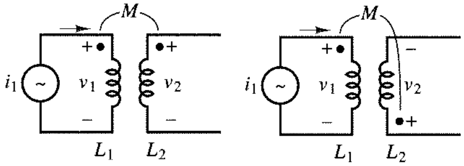

FIGURE 5.12.5 Mutual inductance.

The dots shown in the two figures indicate the polarity of the coupling between the coils. If the dots are at the same end of the coils, the voltage induced in coil 2 by a current in coil 1 has the same polarity as the voltage induced by the same current in coil 1; otherwise, the voltages are in opposition, as shown in the lower part of Figure 5.12.5. Thus, the presence of such dots indicates that magnetic coupling is present between two coils, It should also be pointed out that if a current (and therefore a magnetic field) were present in the second coil, an additional voltage would be induced across coil 1. The voltage induced across a coil is, in general, equal to the sum of the voltages induced by self-inductance and mutual inductance.

Example 5.12.1 Linear Variable Differential Transformer (LVDT)

The linear variable differential transformer (LVDT) is a displacement transducer based on the mutual inductance concept just discussed. Figure 5.12.6 shows a simplified representation of an LVDT, which consists of a primary coil, subject to AC excitation (v_{ex}) and of a pair of identical secondary coils, which are connected so as to result in the output voltage

$$v_{out} = v_1 - v_2$$

The ferromagnetic core between the primary and secondary coils can be displaced in proportion to some external motion, x, and determines the magnetic coupling between primary and secondary coils. Intuitively, as the core is displaced upward, greater coupling will occur between the primary coil and the top secondary coil, thus inducing a greater voltage in the top secondary coil. Hence, $v_{out} > 0$ for positive displacements. The converse is true for negative displacements. More formally, if the primary coil has resistance R_p and self-inductance L_p, we can write

$$iR_p + L_p \frac{di}{dt} = v_{ex}$$

and the voltages induced in the secondary coils are given by

$$v_1 = M_1 \frac{di}{dt}$$

$$v_2 = M_2 \frac{di}{dt}$$

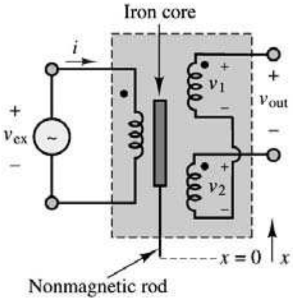

FIGURE 5.12.6 Linear variable differential transformer.

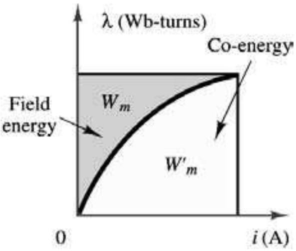

FIGURE 5.12.7

so that

$$v_{\text{out}} = (M_1 - M_2)\frac{di}{dt}$$

where M_1 and M_2 are the mutual inductances between the primary and the respective secondary coils, It should be apparent that each of the mutual inductances is dependent on the position of the iron core. For example, with the core at the *null position,* $M_1 = M_2$ and $v_{\text{out}} = 0$. The LVDT is typically designed so that $M_1 - M_2$ is linearly related to the displacement of the core, x.

Because the excitation is by necessity an AC signal, the output voltage is actually given by the difference of two sinusoidal voltages at the same frequency and is therefore itself a sinusoid, whose amplitude and phase depend on the displacement, x. Thus, v_{out} is an *amplitude-modulated* (AM) signal. To recover a signal proportional to the actual displacement, it is therefore necessary to use a demodulator circuit.

In practical electromagnetic circuits, the self-inductance of a circuit is not necessarily constant; in particular, the inductance parameter, L, is not constant, in general, but depends on the strength of the magnetic field intensity, so that it will not be possible to use such a simple relationship as $v = L\, di/dt$, with L constant. If we revisit the definition of the transformer voltage,

$$e = N\frac{d\phi}{dt} \tag{5.12.12}$$

We see that in an inductor coil, the inductance is given by

$$L = \frac{N\phi}{i} = \frac{\lambda}{i} \tag{5.12.13}$$

This expression implies that the relationship between current and flux in a magnetic structure is linear (the inductance being the slope of the line). In fact, the properties of ferromagnetic materials are such that the flux-current relationship is nonlinear, so that the simple linear inductance parameter used in electric circuit analysis is not adequate to represent the behavior of the magnetic circuits of the present chapter. In any practical situation, the relationship between the flux linkage, λ, and the current is nonlinear, and might be described by a curve similar to that shown in Figure 5.12.7. Wherever the i-λ curve is not a straight line, it is more convenient to analyze the magnetic system in terms of energy calculations, since the corresponding circuit equation would be nonlinear.

In a magnetic system, the energy stored in the magnetic field is equal to the integral of the instantaneous power, which is the product of voltage and current, just as in a conventional electrical circuit.

$$W_m = \int ei\, dt \tag{5.12.14}$$

However, in this case, the voltage corresponds to the induced emf, according to Faraday's law:

$$e = \frac{d\lambda}{dt} = N\frac{d\phi}{dt} \tag{5.12.15}$$

and is therefore related to the rate of change of the magnetic flux. The energy stored in the magnetic field could therefore be expressed in terms of the current by the integral

$$W_m = \int ei\,dt = \int \frac{d\lambda}{dt} i\,dt = \int i\,d\lambda \tag{5.12.16}$$

It should be straightforward to recognize that this energy is equal to the area above the λ-*i* curve of Figure 5.12.7. From the same figure, it is also possible to define a fictitious (but sometimes useful) quantity called **co-energy**, equal to the area under and identified by the symbol W'_m. From the figure, it is also possible to see that the co-energy can be expressed in terms of the stored energy by means of the following relationship:

$$W'_m = i\lambda - W_m \tag{5.12.17}$$

Ampère's Law

As explained in the previous section, Faraday's law is one of two fundamental laws relating electricity to magnetism. The second relationship, which forms a counterpart to Faraday's law, is **Ampère's law**. Qualitatively, Ampère's law states that the magnetic field intensity, **H**, in the vicinity of a conductor is related to the current carried by the conductor; thus Ampère's law establishes a dual relationship with Faraday's law.

In the previous section, we described the magnetic field in terms of its flux density, **B**, and flux ϕ, To explain Ampère's law and the behavior of magnetic materials, we need to define a relationship between the magnetic field intensity, **H**, and the flux density, **B**. These quantities are related by:

$$\begin{aligned}\mathbf{B} &= \mu\mathbf{H} \\ &= \mu_r\mu_0\mathbf{H} \quad \text{Wb/m}^2 \text{ or T}\end{aligned} \tag{5.12.18}$$

where the parameter μ is a scalar constant for a particular physical medium (at least, for the applications we consider here) and is called the **permeability** of the medium. The permeability of a material can be factored as the product of the permeability of free space, $\mu_0 = 4\pi \times 107$ H/m, times the relative permeability, μ_r, which varies greatly according to the medium. For example, for air and for most electrical conductors and insulators, μ_r is equal to 1. For ferromagnetic materials, the value of μ_r can take values in the hundreds or thousands. The size of μ_r represents a measure of the magnetic properties of the material. A consequence of Ampère's law is that the larger the value of μ, the smaller the current required to produce a large flux density in an electromagnetic structure. Consequently, many electromechanical devices make use of ferromagnetic materials, called iron cores, to enhance their magnetic properties. Table 5.12.1 gives approximate values of μ_r for some common materials.

Conversely, the reason for introducing the magnetic field intensity is that it is dependent of the properties of the materials employed in the construction of magnetic circuits. Thus, a given magnetic field intensity, **H**, will give rise to different flux densities in different materials. It will therefore be useful to define *sources* of magnetic energy in terms of the magnetic field intensity, so that different magnetic structures and materials can then be evaluated or compared for a given source. In analogy with electromotive force, this "source" will be termed **magnetomotive force** (mmf). As stated earlier, both the magnetic flux density and field intensity are vector quantities; however, for ease of analysis, scalar fields will be chosen by appropriately selecting the orientation of the fields, wherever possible.

TABLE 5.12.1 Relative Permeabilities for Common Materials

Material	μ_r
Air	1
Permalloy	100,000
Cast steel	1,000
Sheet steel	4,000
Iron	5,195

The field generated by a single conducting wire is not very strong; however, if we arrange the wire into a tightly wound coil with many turns, we can greatly increase the strength of the magnetic field. For such a coil with N turns, one can verify visually that the lines of force associated with the magnetic field link all of the turns of the conducting coil, so that we have effectively increased the current linked by the flux lines N-fold. The product $N \cdot i$ is a useful quantity in electromagnetic circuits and is called the magnetomotive force, $\mathcal{F}$ (often abbreviated mmf), in analogy with the electromotive force defined earlier:

$$\mathcal{F} = Ni \quad \text{ampere-turns } (A \cdot t) \tag{5.12.19}$$

Typical arrangements are the iron-core inductor and the toroid of Figure 5.12.8. The flux densities for these inductors are given by the expressions

$$B = \frac{\mu N i}{l} \quad \text{Flux density for tightly wound circular coil} \tag{5.12.20}$$

$$B = \frac{\mu N i}{2\pi r_2} \quad \text{Flux density for toroidal coil} \tag{5.12.21}$$

Intuitively, the presence of a high-permeability material near a source of magnetic flux causes the flux to preferentially concentrate in the high-μ material, rather than in air, much as a conducting path concentrates the current produced by an electric field in an electric circuit. Figure 5.12.9 depicts an example of a simple electromagnetic structure, which, as we shall see shortly, forms the basis of the practical transformer.

Table 5.12.2 summarizes the variables introduced thus far in the discussion of electricity and magnetism.

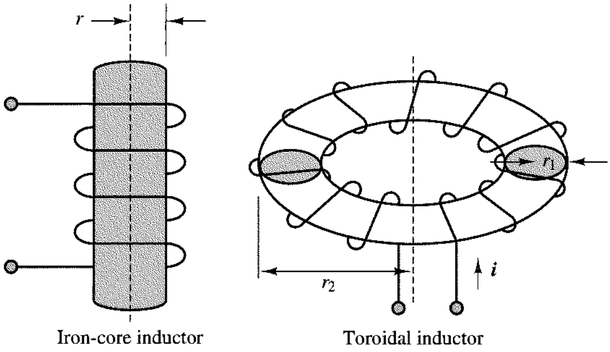

FIGURE 5.12.8 Practical inductors.

TABLE 5.12.2 Magnetic Variables and Units

Variable	Symbol	Units
Current	I	A
Magnetic flux density	B	Wb/m² = T
Magnetic flux	ϕ	Wb
Magnetic field intensity	H	A/m
Electromotive force	e	V
Magnetomotive force	$\mathcal{F}$	A · t
Flux linkage	λ	Wb · t

Magnetic Circuits

It is possible to analyze the operation of electromagnetic devices such as the one depicted in Figure 5.12.9 by means of magnetic equivalent circuits, similar in many respects to the equivalent electrical circuits of the earlier chapters. Before we can present this technique, however, we need to make a few simplifying approximations. The first of these approximations assumes that there exists a **mean path** for the magnetic flux, and that the corresponding mean flux density is approximately constant over the cross-sectional area of the magnetic structure. Thus, a coil wound around a coil with cross-sectional area A will have flux density

$$B = \frac{\phi}{A} \qquad (5.12.22)$$

where A is assumed to be perpendicular to the direction of the flux lines. Figure 5.12.9 illustrates such a mean path and the cross-sectional area, A. Knowing the flux density, we obtain the field intensity:

$$H = \frac{B}{\mu} = \frac{\phi}{A\mu} \qquad (5.12.23)$$

But then, knowing the field intensity, we can relate the mmf of the coil, $\mathcal{F}$, to the product of the magnetic field intensity, H, and the length of the magnetic (mean) path, l, for one leg of the structure:

$$\mathcal{F} = N \cdot i = H \cdot l \qquad (5.12.24)$$

In summary, the mmf is equal to the magnetic flux times the length of the magnetic path, divided by the permeability of the material times the cross-sectional area:

TABLE 5.12.3 Analogy between Electric and Magnetic Circuits

Electrical Quantity	Magnetic Quantity
Electrical field intensity, E, V/m	Magnetic field intensity, H, A · t/m
Voltage, v, V	Magnetomotive force, $\mathcal{F}$, A · t
Current, i, A	Magnetic flux, ϕ, Wb
Current density, J, A/m^2	Magnetic flux density, B, Wb/m^2
Resistance, R, Ω	Reluctance, $\mathcal{R} = l/\mu A$, A · t/Wb
Conductivity, σ, l/Ω · m	Permeability, μ, Wb/A · m

$$\mathcal{F} = \phi \frac{l}{\mu A} \tag{5.12.25}$$

A review of this formula reveals that the magnetomotive force, $\mathcal{F}$, may be viewed as being analogous to the voltage source in a series electrical circuit, and that the flux, ϕ, is then equivalent to the electrical current in a series circuit and the term $l/\mu A$ to the *magnetic resistance* of one leg of the magnetic circuit. You will note that the term $l/\mu A$ is very similar to the term describing the resistance of a cylindrical conductor of length l and cross-sectional A, where the permeability, μ, is analogous to the conductivity, σ. The term $l/\mu A$ occurs frequently enough to be assigned the name of reluctance, and the symbol $\mathcal{R}$.

In summary, when an N-turn coil carrying a current i is wound around a magnetic core such as the one indicated in Figure 5.12.9, the mmf, $\mathcal{F}$, generated by the coil produces a flux, ϕ, that is *mostly* concentrated with the core and is assumed to be uniform across the cross section. Within this simplified picture, then, the analysis of a magnetic circuit is analogous to that of resistive electrical circuits. This analogy is illustrated in Table 5.12.3 and in the examples in this section.

The usefulness of the magnetic circuit analogy can be emphasized by analyzing a magnetic core similar to that of Figure 5.12.9, but with a slightly modified geometry. Figure 5.12.10 depicts the magnetic structure and its equivalent circuit analogy. In the figure, we see that the mmf, $\mathcal{F}$ = Ni, excites the magnetic circuit, which is composed of four legs: two of mean path length l_1 and cross-sectional area $A_1 = d_1 w$, and the other two of mean length l_2 and cross section $A_2 = d_2 w$. Thus, the reluctance encountered by the flux in its path around the magnetic core is given by the quantity $\mathcal{R}_{\text{series}}$, with

$$\mathcal{R}_{\text{series}} = 2\mathcal{R}_1 + 2\mathcal{R}_2$$

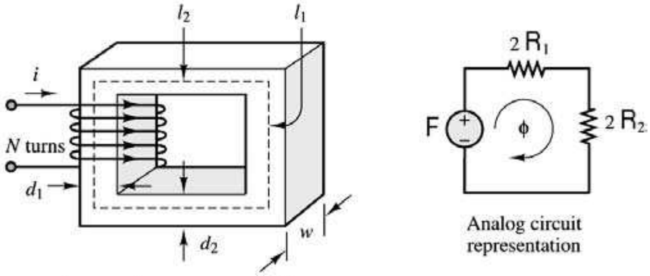
and

$$\mathcal{R}_1 = \frac{l_1}{\mu A_1} \qquad \mathcal{R}_2 = \frac{l_2}{\mu A_2} \tag{5.12.26}$$

It is important at this stage to review the assumptions and simplifications made in analyzing the magnetic structure of Figure 5.12.10:

1. All of the magnetic flux is linked by all of the turns of the coil.
2. The flux is confined exclusively within the magnetic core.
3. The density of the flux is uniform across the cross-sectional area of the core.

You can probably see intuitively that the first of these assumptions might not hold true near the ends of the coil, but that it might be more reasonable if the coil is tightly wound. The second assumption is equivalent to stating that the relative permeability of the core is infinitely higher than that of air (presuming that this is the medium surrounding the core): if this were the case, the flux would indeed be



A magnetic structure excited by a magnetomotive force $F = Ni$

Analog circuit representation

FIGURE 5.12.10 Analogy between magnetic and electric circuits.

confined within the core. It is worthwhile to note that we made a similar assumption when we treat wires in electric circuits as perfect conductors: the conductivity of copper is substantially greater than that of free space, by a factor of approximately 10^{15}. In the case of magnetic materials, however, even for the best alloys, we have a relative permeability only on the order of 10^3 to 10^4. Thus, an approximation that is quite appropriate for electric circuits is not nearly as good in the case of magnetic circuits. Some of the flux in a structure such as those of Figure 5.12.9 and Figure 5.12.10 would thus not be confined within the core (this is usually referred to as **leakage flux**). Finally, the assumption that the flux is uniform across the core cannot hold for a finite-permeability medium, but it is very helpful in giving an approximate *mean* behavior of the magnetic circuit.

The magnetic circuit analogy is therefore far from being exact. However, short of employing the tools of electromagnetic field theory and of vector calculus, or advanced numerical simulation software, it is the most convenient tool at the engineer's disposal for the analysis of magnetic structures.

Example 5.12.2 Magnetic Reluctance Position Sensor

A simple magnetic structure, very similar to those examined in the previous examples, finds very common application in the so-called variable-reluctance position sensor, which, in turn, finds widespread application in a variety of configurations for the measurement of linear and angular position and velocity. Figure 5.12.11 depicts one particular configuration that is used in many applications. In this structure, a permanent magnet with a coil of wire wound around it forms the sensor; a steel disk (typically connected to a rotating shaft) has a number of tabs that pass between the pole pieces of the sensor. The area of the tab is assumed equal to the area of the cross section of the pole pieces and is equal to a^2. The reason for the name *variable-reluctance sensor* is that the reluctance of the magnetic structure is variable, depending on whether or not a ferromagnetic tab lies between the pole pieces of the magnet.

The principle of operation of the sensor is that an electromotive force, e_s, is induced across the coil by the change in magnetic flux caused by the passage of the tab between the pole pieces when the disk

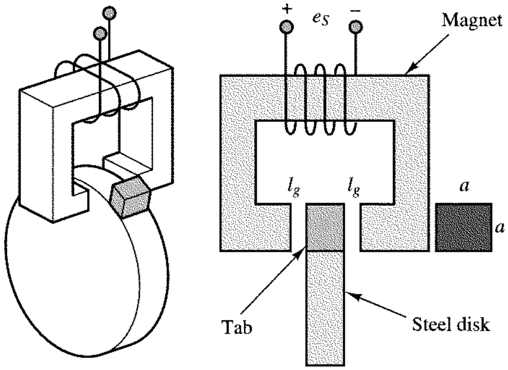


FIGURE 5.12.11 Variable-reluctance position sensor.

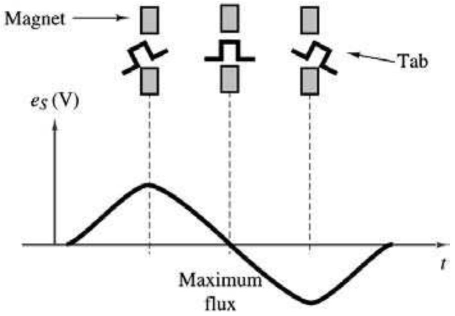

FIGURE 5.12.12 Variable-reluctance position sensor waveform.

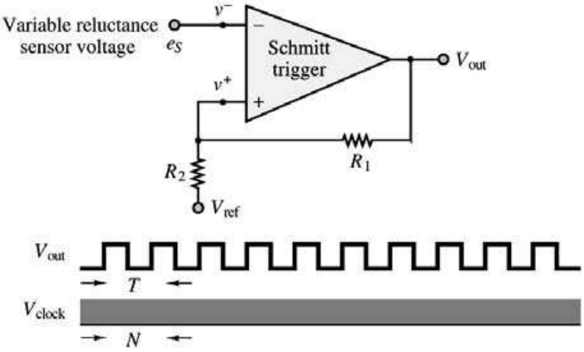

FIGURE 5.12.13 Signal processing for a 60-tooth wheel RPM sensor.

is in motion. As the tab enters the volume between the pole pieces, the flux will increase because of the lower reluctance of the configuration, until it reaches a maximum when the tab is centered between the poles of the magnet. Figure 5.12.12 depicts the approximate shape of the resulting voltage, which, according to Faraday's law, is given by

$$e_S = -\frac{d\phi}{dt}$$

The rate of change of flux is dictated by the geometry of the tab and of the pole pieces, and by the speed of rotation of the disk. It is important to note that, since the flux is changing only if the disk is rotating, this sensor cannot detect the static position of the disk.

One common application of this concept is in the measurement of the speed of rotation of rotating machines, including electric motors and internal combustion engines. In these applications, use is made of a *60-tooth wheel*, which permits the conversion of the speed rotation directly to units of revolutions per minute. The output of a variable-reluctance position sensor magnetically coupled to a rotating disk equipped with 60 tabs (teeth) is processed through a comparator or Schmitt trigger circuit. The voltage waveform generated by the sensor is nearly sinusoidal when the teeth are closely spaced, and it is characterized by one sinusoidal cycle for each tooth on the disk. If a negative zero-crossing detector is employed, the trigger circuit will generate a pulse corresponding to the passage of each tooth, as shown in Figure 5.12.13. If the time between any two pulses is measured by means of a high-frequency clock, the speed of the engine can be directly determined in units of rev/min by means of a digital counter.

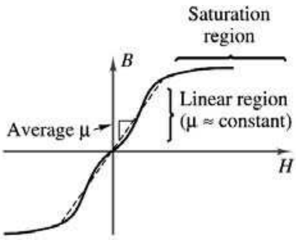

FIGURE 5.12.14 Permeability and magnetic saturation effects.

Magnetic Materials and *B-H* Curves

In the analysis of magnetic circuits presented in the previous sections, the relative permeability, μ_r, was treated as a constant. In fact, the relationship between the magnetic flux density, **B**, and the associated field intensity, **H**,

$$\mathbf{B} = \mu \mathbf{H} \tag{5.12.27}$$

is characterized by the fact that the relative permeability of magnetic materials is not a constant, but is a function of the magnetic field intensity. In effect, all magnetic materials exhibit a phenomenon called **saturation**, whereby the flux density increases in proportion to the field intensity until it cannot do so any longer. Figure 5.12.14 illustrates the general behavior of all magnetic materials. You will note that since the *B-H* curve shown in the figure is nonlinear, the value of μ (which is the slope of the curve) depends on the intensity of the magnetic field.

To understand the reasons for the saturation of a magnetic material, we need to briefly review the mechanism of magnetization. The basic idea behind magnetic materials is that the spin of electrons constitutes motion of charge and therefore leads to magnetic effects, as explained in the introductory section of this chapter. In most materials, the electron spins cancel out, on the whole, and no net effect remains. In ferromagnetic materials, on the other hand, atoms can align so that the electron spins cause a net magnetic effect. In such materials, there exist small regions with strong magnetic properties (called **magnetic domains**), the effects of which are neutralized in unmagnetized material by other, similar regions that are oriented differently, in a random pattern. When the material is magnetized, the magnetic domains tend to align with each other, to a degree that is determined by the intensity of the applied magnetic field.

In effect, the large number of miniature magnets within the material are *polarized* by the external magnetic field. As the field increases, more and more domains become aligned. When all of the domains have become aligned, any further increase in magnetic field intensity does not yield an increase in flux density beyond the increase that would be caused in a nonmagnetic material. Thus, the relative permeability, μ_r, approaches 1 in the saturation region. It should be apparent that an exact value of μ_r cannot be determined; the value of μ_r used in the earlier examples is to be interpreted as an average permeability, for intermediate values of flux density. As a point of reference, commercial magnetic steels saturate at flux densities around a few teslas. Figure 5.12.17, shown later in this section, will provide some actual *B-H* curves for common ferromagnetic materials.

The phenomenon of saturation carries some interesting implications with regard to the operation of magnetic circuits: the results of the previous section would seem to imply that an increase in the mmf (that is, an increase in the current driving the coil) would lead to a proportional increase in the magnetic flux. This is true in the *linear region* of Figure 5.12.14; however, as the material reaches saturation, further increases in the driving current (or, equivalently, in the mmf) do not yield further increases in the magnetic flux.

There are two more features that cause magnetic materials to further deviate from the ideal model of the linear *B-H* relationship: **eddy currents** and **hysteresis**. The first phenomenon consists of currents that are caused by any time-varying flux in the core material. As you know, a time-varying flux will

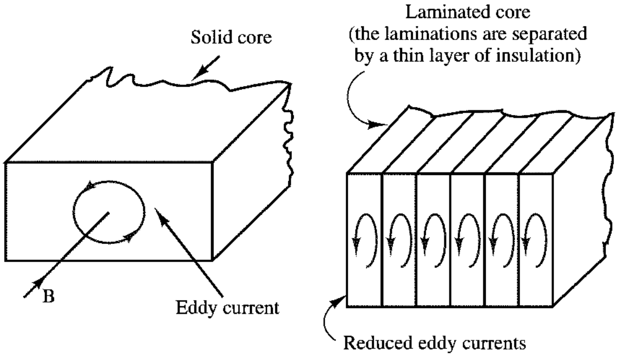

FIGURE 5.12.15 Eddy currents in magnetic structures.

induce a voltage, and therefore a current. When this happens inside the magnetic core, the induced voltage will cause "eddy" currents (the terminology should be self-explanatory) in the core, which depend on the resistivity of the core. Figure 5.12.15 illustrates the phenomenon of eddy currents. The effect of these currents is to dissipate energy in the form of heat. Eddy currents are reduced by selecting high-resistivity core materials, or by *laminating* the core, introducing tiny, discontinuous air gaps between core layers (see Figure 5.12.15). Lamination of the core reduces eddy currents greatly without affecting the magnetic properties of the core.

It is beyond the scope of this section to quantify the losses caused by induced eddy currents, but it will be important to be aware of this source of energy loss.

Hysteresis is another loss mechanism in magnetic materials; it displays a rather complex behavior, related to the magnetization properties of a material. The curve of Figure 5.12.16 reveals that the *B-H* curve for a magnetic material during magnetization (as *H* is increased) is displaced with respect to the curve that is measured when the material is demagnetized. To understand the hysteresis process, consider a core that has been energized for some time, with a field intensity of $H_1 A \cdot$ t/m. As the current required to sustain the mmf corresponding to H_1 is decreased, we follow the hysteresis curve from the point α to the point β. When the mmf is exactly zero, the material displays the **remanent** (or **residual**) **magnetization** B_r. To bring the flux density to zero, we must further decrease the mmf (i.e., produce a negative current), until the field intensity reaches the value $-H_0$ (point γ on the curve). As the mmf is made more negative, the curve eventually reaches the point α'. If the excitation current go the coil is now increased, the magnetization curve will follow the path $\alpha' = \beta' = \gamma' = \alpha$, eventually returning to the original point in the *B-H* plane, but via a different path.

The result of this process, by which an *excess magnetomotive force* is required to magnetize or demagnetize the material, is a net energy loss. It is difficult to evaluate this loss exactly; however, it can be shown that it is related to the area between the curves of Figure 5.2.16. There are experimental techniques that enable the approximate measurement of these losses.

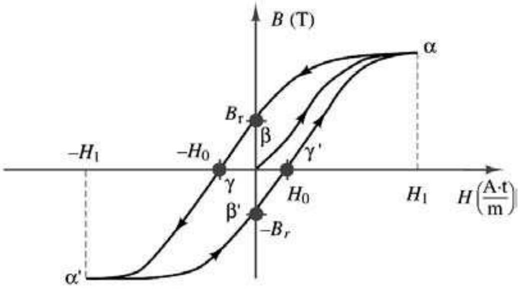

FIGURE 5.12.16 Hysteresis in magnetization curves.

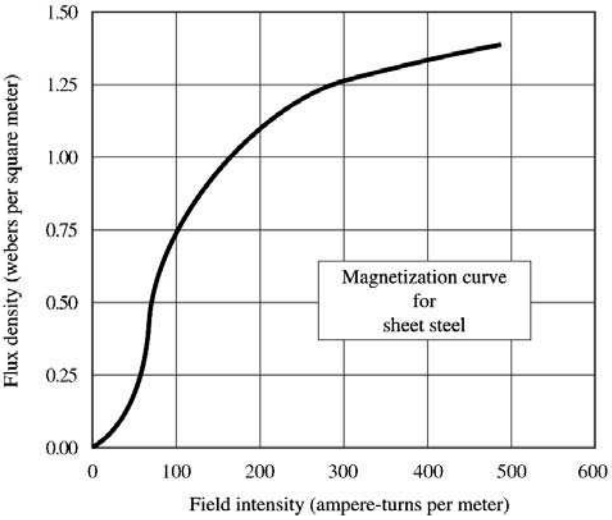
Figure 5.2.17(a) to Figure 5.2.17(c) depict magnetization curves for three very common ferromagnetic materials: cast iron, cast steel, and sheet steel.

Electromechanical Energy Conversion

From the material developed thus far, it should be apparent that electromagnetomechanical devices are capable of converting mechanical forces and displacements to electromagnetic energy, and that the converse is also possible. The objective of this section is to formalize the basic principles of energy conversion in electromagnetomechanical systems, and to illustrate its usefulness and potential for application by presenting several examples of **energy transducers**. A transducer is a device that can convert electrical to mechanical energy (in this case, it is often called an **actuator**), or vice versa (in which case it is called a sensor).



(c)

FIGURE 5.12.17 (c) magnetization curve for sheet steel.

Several physical mechanisms permit conversion of electrical to mechanical energy and back, the principal phenomena being the **piezoelectric effect**, consisting of the generation of a change in electric field in the presence of strain in certain crystals (e.g., quartz), and **electrostriction** and **magnetostriction**, in which changes in the dimension of certain materials lead to a change in their electrical (or magnetic) properties. Although these effects lead to some interesting applications, this chapter is concerned only with transducers in which electrical energy is converted to mechanical energy through the coupling of a magnetic field. It is important to note that all rotating machines (motors and generators) fit the basic definition of electromechanical transducers we have just given.

Forces in Magnetic Structures

It should be apparent by now that it is possible to convert mechanical forces to electrical signals, and vice versa, by means of the coupling provided by energy stored in the magnetic field. In this subsection, we discuss the computation of mechanical forces and of the corresponding electromagnetic quantities of interest; these calculations are of great practical importance in the design and application of electromechanical actuators. For example, a problem of interest is the computation of the current required to generate a given force in an electromechanical structure. This is the kind of application that is likely to be encountered by the engineer in the selection of an electromechanical device for a given task.

As already seen in this chapter, an electromechanical system includes an electrical system and a mechanical system, in addition to means through which the two can interact. The principal focus of this chapter has been the coupling that occurs through an electromagnetic field common to both the electrical and the mechanical system; to understand electromechanical energy conversion, it will be important to understand the various energy storage and loss mechanisms in the electromagnetic field. Figure 5.12.18 illustrates the coupling between the electrical and mechanical systems. In the mechanical system, energy loss can occur because of the heat developed as a consequence of *friction*, while in the electrical system, analogous losses are incurred because of *resistance*. Loss mechanisms are also present in the magnetic coupling medium, since *eddy current losses* and *hysteresis losses* are unavoidable in ferromagnetic materials. Either system can supply energy, and either system can store energy. Thus, the figure depicts the flow of energy from the electrical to the mechanical system, accounting for these various losses. The same flow could be reversed if mechanical energy were converted to electrical form.

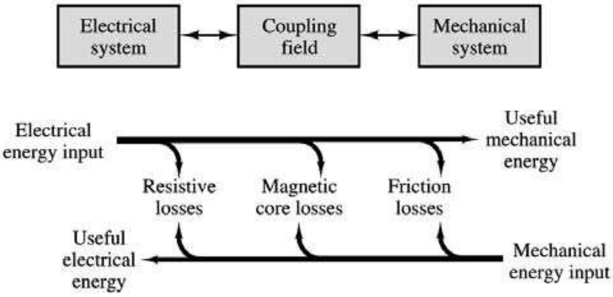


FIGURE 5.12.18 Electromechanical system.

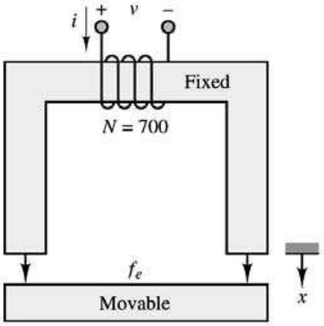

FIGURE 5.12.19 Simple electromagnet.

Moving-Iron Transducers

One important class of electromagnetomechanical transducers is that of **moving-iron transducers**. The aim of this section is to derive an expression for the magnetic forces generated by such transducers and to illustrate the application of these calculations to simple, yet common devices such as electromagnets, solenoids, and relays. The simplest example of a moving-iron transducer is the electromagnet of Figure 5.12.19, in which the U-shaped element is fixed and the bar is movable. In the following paragraphs, we shall derive a relationship between the current applied to the coil, the displacement of the movable bar, and the magnetic force acting in the air gap.

The principle that will be applied throughout the section is that in order for a mass to be displaced, some work needs to be done; this work corresponds to a change in the energy stored in the electromagnetic field, which causes the mass to be displaced. With reference to Figure 5.12.19, let f_e represent the magnetic force acting on the bar and x the displacement of the bar, in the direction shown. Then the net work into the electromagnetic field, W_m, is equal to the sum of the work done by the electrical circuit plus the work done by the mechanical system. On the basis of a linear approximation, it can be shown that the stored energy in a magnetic structure is given by the expression

$$W_m = \frac{\phi \mathcal{F}}{2} \tag{5.12.28}$$

and since the flux and the mmf are related by the expression

$$\phi = \frac{Ni}{\mathcal{R}} = \frac{\mathcal{F}}{\mathcal{R}} \tag{5.12.29}$$

the stored energy can be related to the reluctance of the structure according to

$$W_m = \frac{\phi^2 \mathcal{R}(x)}{2} \tag{5.12.30}$$

where the reluctance has been explicitly shown to be a function of displacement, as is the case in a moving-iron transducer. Finally, then, we shall use the following approximate expression to compute the magnetic force acting on the moving iron:

$$f = -\frac{dW_m}{dx} = -\frac{\phi^2}{2}\frac{d\mathcal{R}(x)}{dx} \tag{5.12.31}$$

Example 5.12.13 An Electromagnet

An electromagnet is used to support a solid piece of steel as shown in Figure 5.12.19. A force of 8900 N is required to support the weight. The cross-sectional area of the magnet core (the fixed part) is 0.01 m^2. Determine the minimum current that can keep the weight from falling for $x = 1.5$ mm. Assume negligible reluctance for the steel parts, and negligible fringing in the air gap.

Solution. We have already shown that in magnetic structures with air gaps, the reluctance is mostly due to the air gaps. This explains the assumption that the reluctance of the structure is negligible. For the structure of Figure 5.12.19, the reluctance is therefore given by

$$\mathcal{R}(x) = \frac{l}{\mu_0 A}$$

where $A = 0.01$ m^2 and $l = 2x$, and therefore

$$\mathcal{R}(x) = \frac{2x}{4\pi \times 10^{-7} \times 0.01} = \frac{x}{1.2566 \times 10^{-8}}$$

The magnitude of the force in the air gap is given by the expression

$$\begin{aligned}|f| &= \frac{\phi^2}{2}\frac{d\mathcal{R}(x)}{dx} = \frac{N^2 i^2}{2\mathcal{R}^2}\frac{d\mathcal{R}(x)}{dx} \\ &= \frac{i^2}{2}\frac{N^2}{\mathcal{R}^2}\frac{d\mathcal{R}}{dx} = \frac{i^2}{2}(700)^2\frac{6.2832 \times 10^{-9}}{x^2} = 8900 \text{ N}\end{aligned}$$

from which the current can be computed:

$$i^2 = 2 \times \frac{8900\left(1.5 \times 10^{-3}\right)^2}{(700)^2\left(6.2832 \times 10^{-9}\right)} 6.504 \text{ A}$$

or

$$i = 2.55 \text{ A}$$

You should recognize the practical importance of these calculations in determining approximate current requirements and force-generation capabilities of electromechanical transducers.

Moving-Coil Transducers

Another important class of electromagnetomechanical transducers is that of **moving-coil transducers**. This class of transducers includes a number of common devices, such as microphones, loudspeakers, and

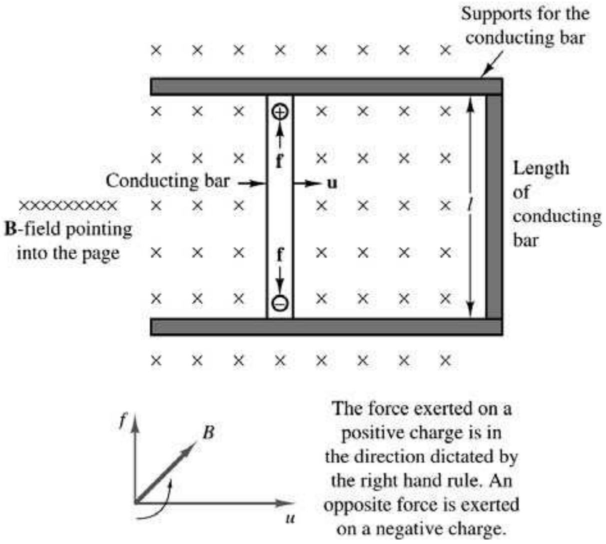

FIGURE 5.12.20 A simple electromechanical motion transducer.

all electric motors and generators. The aim of this section is to explain the relationship between a fixed magnetic field, the emf across the moving coil, and the forces and motions of the moving element of the transducer.

Motor Action. A moving-coil transducer can act as a motor when an externally supplied current flowing through the electrically conducting part of the transducer is converted into a force that can cause the moving part of the transducer to be displaced. Such a current would flow, for example, if the support of Figure 5.12.20 were made of conducting material, so that the conductor and the right-hand side of the support "rail" were to form a loop (in effect, a 1-turn coil).

The phenomenon we have just described is sometimes referred to as the "*Bli* law".

Generator Action. The other mode of operation of a moving-coil transducer occurs when an external force causes the coil (i.e., the moving bar, in Figure 5.12.20) to be displaced. This external force is converted to an emf across the coil, as will be explained in the following paragraphs.

It is important to observe that since positive and negative charges are forced in opposite directions in the transducer of Figure 5.12.20, a potential difference will appear across the conducting bar; this potential difference is the electromotive force, or emf. The emf must be equal to the force exerted by the magnetic field. In short, the electric force per unit charge (or electric field) e/l must equal the magnetic force per unit charge $f/q = Bu$. Thus, the relationship

$$e = Blu \tag{5.12.32}$$

which holds whenever **B, l,** and **u** are mutually perpendicular, as in Figure 5.12.20.

It was briefly mentioned that the *Blu* and *Bli* laws indicate that, thanks to the coupling action of the magnetic field, a conversion of mechanical to electrical energy — or the converse — is possible. The simple structure of Figures 5.12.20 can, again, serve as an illustration of this energy-conversion process, although we have not yet indicated how these idealized structures can be converted into a practical device. In this section we shall begin to introduce some physical considerations. Before we proceed any further, we should try to compute the power — electrical and mechanical — that is generated (or is required) by our ideal transducer. The electrical power is given by

$$P_E = ei = Blui \quad \text{(W)} \tag{5.12.33}$$

while the mechanical power required, say, to move the conductor from left to right is given by the product of force and velocity:

$$P_M - f_{\text{ext}}u = Bliu \quad (\text{W}) \tag{5.12.34}$$

Example 5.12.4 The Loudspeaker

A loudspeaker, shown in Figure 5.12.21, uses a permanent magnet and a moving coil to produce the vibrational motion that generates the pressure waves we perceive as sound. Vibration of the loudspeaker is caused by changes in the input current to a coil; the coil is, in turn, coupled to a magnetic structure that can produce time-varying forces on the speaker diaphragm. A simplified model for the mechanics of the speaker is also shown in Figure 5.12.21. The force exerted on the coil is also exerted on the mass of the speaker diaphragm, as shown in Figure 5.12.22, which depicts a free-body diagram of the forces acting on the loudspeaker diaphragm.

The force exerted on the mass, f_i, is the magnetic force due to current flow in the coil. The electrical circuit that describes the coil is shown in Figure 5.12.23, where L represents the inductance of the coil, R represents the resistance of the windings, and e is the emf induced by the coil moving through the magnetic field.

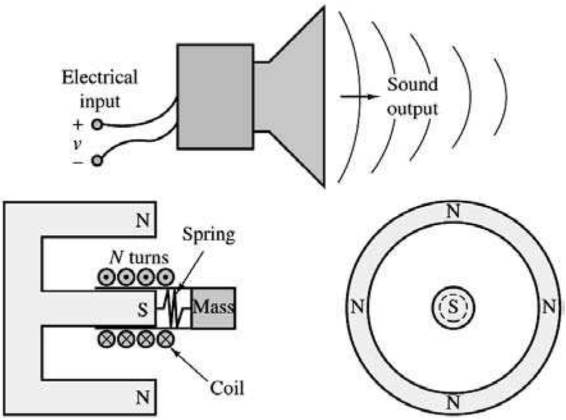

FIGURE 5.12.21 Loudspeaker.

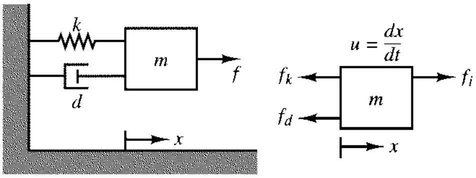

FIGURE 5.12.22 Forces acting on loudspeaker diaphragm.

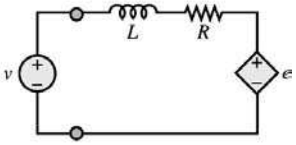

FIGURE 5.12.23 Model of transducer electrical field.

Determine the frequency response, (**U**/**V**)($j\omega$), of the speaker using phasor analysis if the model parameters are

$$L \approx 0 \text{ H} \qquad R = 8\ \Omega \qquad m = 0.001 \text{ kg} \qquad d = 22.75$$

$$k \approx 500{,}000 \text{ N/m} \qquad N = 47 \qquad B = 1T \qquad \text{Radius of coil} = 5 \text{ cm}$$

Solution: To determine the frequency response of the loudspeaker, we need to write the fundamental equations that describe the two subsystems that make up the loudspeaker. The electrical subsystem is described by the usual KVL relationship, applied to the circuit of Figure 5.12.23.

$$v = L\frac{di}{dt} + Ri + e$$

where e is the emf generated by the motion of the coil in the magnetic field. Next, according to Newton's law, we can write a force balance equation to describe the dynamics of the mechanical subsystem:

$$m\frac{du}{dt} = f_i - f_d - f_k = f_i - du - kx$$

Now, the coupling between the electrical and mechanical systems is expressed in each of the two preceding equations by the terms e and f_i:

$$e = Blu$$

$$f_i = Bli$$

Since we desire the frequency response, we use phasor techniques to represent the electrical and mechanical subsystem equations:

$$\mathbf{V}(j\omega) = j\omega L\mathbf{I}(j\omega) + R\mathbf{I}(j\omega) + Bl\mathbf{U}(j\omega) \qquad \text{Electrical equation}$$

$$(j\omega m + d)\mathbf{U}(j\omega) + \frac{K}{j\omega}\mathbf{U}(j\omega) = Bl\mathbf{I}(j\omega) \qquad \text{Mechanical equation}$$

Having assumed that the inductance of the coil is negligible, we are able to simplify the electrical equation and to solve for **I**($j\omega$):

$$\mathbf{I}(j\omega) = \frac{\mathbf{V}(j\omega) - Bl\mathbf{U}(j\omega)}{R}$$

Substituting this equivalence into the mechanical equation and accounting for the length of the coil, $l = 2\pi Nr$, the final expression for the frequency response of the loudspeaker is then given by

$$\frac{\mathbf{U}}{\mathbf{V}}(j\omega) = \frac{2\pi NBr}{Rm} \times \frac{j\omega}{(j\omega)^2 + j\omega\left(\dfrac{d + \dfrac{(2\pi)^2 B^2 N^2 r^2}{R}}{m}\right) + \dfrac{k}{m}}$$

or, numerically,

$$\frac{\mathbf{U}}{\mathbf{V}}(j\omega) = \frac{2\pi\times 47\times 1\times 0.05}{8(0.001)} \times \frac{j\omega}{(j\omega)^2 + j\omega\left(\dfrac{22.75+\dfrac{(2\pi)^2(1)^2(47)^2(0.05)^2}{8}}{0.001}\right)+\dfrac{500,000}{0.001}}$$

$$\approx \frac{1,845 j\omega}{\left(j\omega + 13.8\times 10^3\right)\left(j\omega + 36.2\times 10^3\right)}$$

$$= \frac{0.051\left(\dfrac{j\omega}{13.8\times 10^3}\right)}{\left(1+\dfrac{j\omega}{36.2\times 10^3}\right)\left(1+\dfrac{j\omega}{13.8\times 10^3}\right)}$$

This frequency response shows that the speaker has a lower cutoff frequency f_{ct} = 13,800/2π ≈ 2200 Hz and an upper cutoff frequency of f_{ch} = 36,000/2π ≈ 5800 Hz. In practice, a loudspeaker with such a frequency response would be useful only as a midrange speaker.

Rotating Electric Machines

The range of sizes and power ratings and the different physical features of rotating machines are such that the task of explaining the operation of rotating machines in a single chapter may appear formidable at first. Some features of rotating machines, however, are common to all such devices. This introductory section is aimed at explaining the common properties of all rotating electric machines. We begin our discussion with reference to Figure 5.12.24, in which a hypothetical rotating machine is depicted in a cross-sectional view. In the figure, a box with a cross inscribed in it indicates current flowing into the page, while a dot represents current out of the plane of the page.

In Figure 5.12.24, we identify a **stator**, of cylindrical shape, and a **rotor**, which, as the name indicates, rotates inside the stator, separated from the latter by means of an air gap. The rotor stator each consist of a magnetic core, some electrical insulation, and the windings necessary to establish a magnetic flux (unless this is created by a permanent magnet). The rotor is mounted on a bearing-supported shaft, which can be connected to *mechanical loads* (if the machine is a motor) or to a *prime mover* (if the machine is a generator) by means of belts, pulleys, chains, or other mechanical couplings. The windings carry the electric currents that generate the magnetic fields and flow to the electrical loads, and also provide the closed loops in which voltages will be induced (by virtue of Faraday's law, as discussed in the previous section).

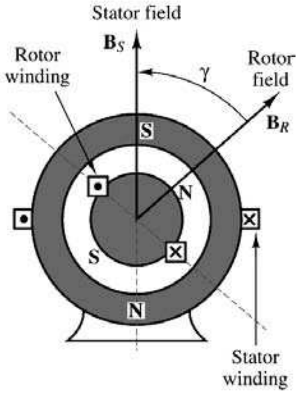

FIGURE 5.12.24 A rotating electric machine.

TABLE 5.12.4 Configurations of the Three Types of Electric Machines

Machine Type	Winding	Winding Type	Location	Current
DC	Input and output	Armature	Rotor	AC (winding) DC (at brushes)
	Magnetizing	Field	Stator	DC
Synchronous	Input and output	Armature	Stator	AC
	Magnetizing	Field	Rotor	DC
Induction	Input	Primary	Stator	AC
	Output	Secondary	Rotor	AC

Basic Classification of Electric Machines

An immediate distinction can be made between different types of windings characterized by the nature of the current they carry. If the current serves the sole purpose of providing a magnetic field and is independent of the load, it is called a *magnetizing*, or excitation, current, and the winding is termed a **field winding**. Field currents are nearly always DC and are of relatively low power, since their only purpose is to magnetize the core (recall the important role of high-permeability cores in generating large magnetic fluxes from relatively small currents). On the other hand, if the winding carries only the load current, it is called an **armature**. In DC and AC synchronous machines, separate windings exist to carry field and armature currents. In the induction motor, the magnetizing and load currents flow in the same winding, called the *input winding*, or *primary*; the output winding is then called the *secondary.* As we shall see, this terminology, which is reminiscent of transformers, is particularly appropriate for induction motors, which bear a significant analogy to the operation of the transformers. Table 5.12.4 characterizes the principal machines in terms of their field and armature configuration.

It is also useful to classify electric machines in terms of their energy-conversion characteristics. A machine acts as a **generator** if it converts mechanical energy from a prime mover — e.g., an internal combustion engine — to electrical form. Examples of generators are the large machines used in power-generating plants, or the common automotive alternator. A machine is classified as a **motor** if it converts electrical energy to mechanical form. The latter class of machines is probably of more direct interest to you, because of its widespread application in engineering practice. Electric motors are used to provide forces and torques to generate motion in countless industrial applications. Machine tools, robots, punches, presses, mills, and propulsion systems for electric vehicles are but a few examples of the application of electric machines in engineering.

Note that in Figure 5.12.24 we have explicitly shown the direction of two magnetic fields: that of the rotor, $\mathbf{B}_R$, and that of the stator, $\mathbf{B}_S$. Although these fields are generated by different means in differential machines (e.g., permanent magnets, AC currents, DC currents), the presence of these fields is what causes a rotating machine to turn and enables the generation of electric power. In particular, we see that in Figure 5.12.24 the north pole of the rotor field will seek to align itself with the south pole of the stator field. It is this magnetic attraction force that permits the generation of torque in an electric motor; conversely, a generator exploits the laws of electromagnetic induction to convert a changing magnetic field to an electric current.

To simplify the discussion in later sections, we shall presently introduce some basic concepts that apply to all rotating electric machines. Referring to Figure 5.12.25, we note that all machines the force on a wire is given by the expression

$$\mathbf{f} = i_w \mathbf{I} \times \mathbf{B} \tag{5.12.35}$$

where i_w is the current in the wire, $\mathbf{I}$ is a vector along the direction of the wire, and × denotes the cross product of two vectors. Then the torque for a multiturn coil becomes

$$T = KBi_w \sin\alpha \tag{5.12.36}$$

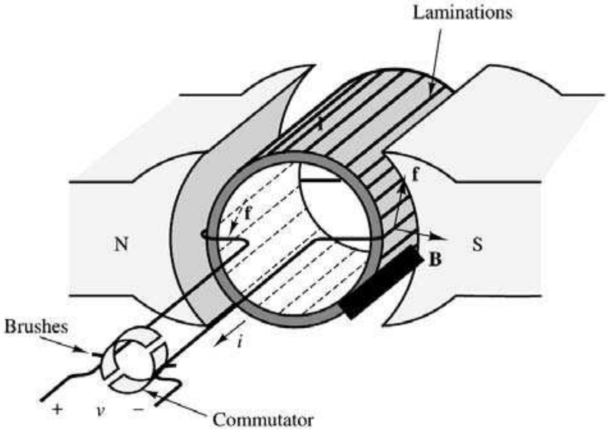

FIGURE 5.12.25 Stator and rotor fields and the force acting on a rotating machine.

where

B = magnetic flux density caused by the stator field
K = constant depending on coil geometry
α = angle between **B** and the normal to the plane of the coil

Other Characteristics of Electric Machines

As already stated earlier in this chapter, electric machines are **energy-conversion devices**, and we are therefore interested in their energy-conversion **efficiency**. Typical applications of electric machines as motors or generators must take into consideration the energy losses associated with these devices. Figure 5.12.26 represents the various loss mechanisms you must consider in analyzing the efficiency of an electric machine for the case of direct-current machines. It is important for you to keep in mind this conceptual flow of energy when analyzing electric machines. The sources of loss in a rotating machine can be separated into three fundamental groups: electrical (I^2R) losses, core losses, and mechanical losses.

I^2R losses are usually computed on the basis of the DC resistance of the windings at 75°C; in practice, these losses vary with operating conditions. The difference between the nominal and actual I^2R is usually lumped under the category of *stray-load loss*. In direct-current machines, it is also necessary to account for the *brush contact loss* associated with slip rings and commutators.

Mechanical losses are due to *friction* (mostly in the bearings) and *windage,* that is, the air drag force that opposes the motion of the rotor. In addition, if external devices (e.g., blowers) are required to circulate air through the machine for cooling purposes, the energy expended by these devices is also included in the mechanical losses.

Open-circuit core losses consist of hysteresis and eddy current losses, with only the excitation winding energized. Often these losses are summed with friction and windage losses to give rise to the *no-load rotational loss*. The latter quantity is useful if one simply wishes to compute efficiency. Since open-circuit core losses do not account for the changes in flux density caused by the presence of load currents, an additional magnetic loss is incurred that is not accounted for in this term. *Stray-load losses* are used to lump the effects of nonideal current distribution in the windings and of the additional core losses just mentioned. Stray-load losses are difficult to determine exactly and are often assumed to be equal to 1.0% of the output power for DC machines; these losses can be determined by experiment in synchronous and induction machines.

The performance of an electric machine can be quantified in a number of ways. In the case of an electric motor, it is usually portrayed in the form of a graphical **torque-speed characteristic.** The torque-speed characteristic of a motor describes how the torque supplied by the machine varies as a function of the speed of rotation of the motor for steady speeds. As we shall see in later sections, the torque-speed

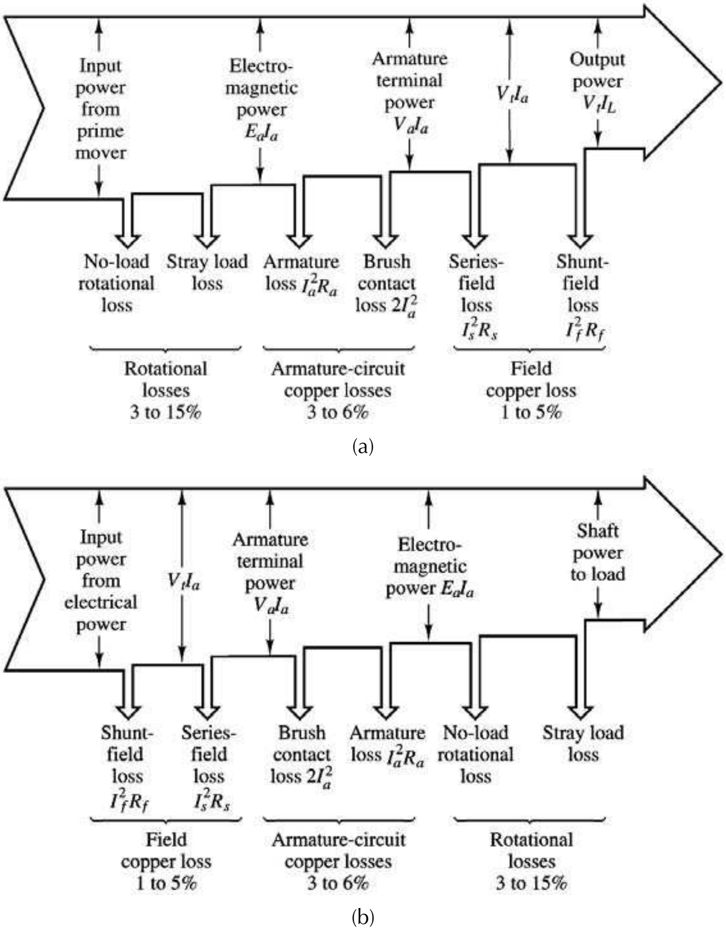

FIGURE 5.12.26 (a) Generator losses, direct current; (b) motor losses, direct current.

curves vary in shape with the type of motor (DC, induction, synchronous) and are very useful in determining the performance of the motor when connected to a mechanical load. Figure 5.12.27 depicts the torque-speed curve of a hypothetical motor. We shall presently describe the essential elements of such a graphical representation of motor performance, and we shall later return to analyze the typical performance curve of each type of motor we encounter in our discussion. It is quite likely that in most

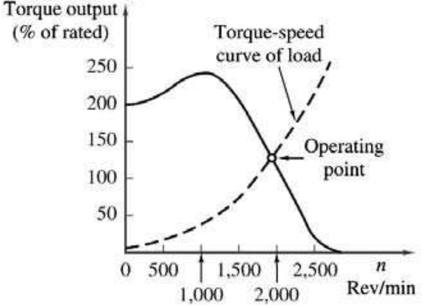

FIGURE 5.12.27 Torque-speed curve for an electric motor.

engineering applications, the engineer is required to make a decision regarding the performance characteristics of the motor best suited to a specified task. In this context, the torque-speed curve of a machine is a very useful piece of information.

The first feature we note of the torque-speed characteristic is that it bears a strong resemblance to the *i-v* characteristics used in earlier chapters to represent the behavior of electrical sources. It should be clear that, according to this torque-speed curve, the motor is not an ideal source of torque (if it were, the curve would appear as a horizontal line across the speed range). One can readily see, for example, that the hypothetical motor represented by the curves of Figure 5.12.27 would produce maximum torque in the range of speeds between approximately 800 and 1400 rev/min. What determines the actual speed of the motor (and therefore its output torque and power) is the torque-speed characteristic of the load connected to it, much as a resistive load determines the current drawn from a voltage source. In the figure, we display the torque-speed curve of a load, represented by the dashed line; the operating point of the motor-load pair is determined by the intersection of the two curves.

Another important observation pertains to the fact that the motor of Figure 5.12.27 produces a nonzero torque at zero speed. This fact implies that as soon as electric power is connected to the motor, the latter is capable of supplying a certain amount of torque; this zero-speed torque is called the **starting torque**. If the load the motor is connected to requires less than the starting torque the motor can provide, then the motor can accelerate the load, until the motor speed and torque settle to a stable value, at the operating point. The motor-load pair of Figure 5.12.27 would behave in the manner just described. However, there may well be circumstances in which a motor might not be able to provide a sufficient starting torque to overcome the static load torque that opposes its motion. Thus, we see that a torque-speed characteristic can offer valuable insight into the operation of a motor. As we proceed to discuss each type of machine in greater detail, we shall devote some time to the discussion of its torque-speed curve.

The most common means of conveying information regarding electric machines is the *nameplate*. Typical information conveyed by the nameplate is

1. Type of device (e.g., DC motor, alternator)
2. Manufacturer
3. Rated voltage and frequency
4. Rated current and volt-amperes
5. Rated speed and horsepower

The **rated voltage** is the terminal voltage for which the machine was designed, and which will provide the desired magnetic flux. Operation at higher voltages will increase magnetic core losses, because of excessive core saturation. The **rated current** and **rated volt-amperes** are an indication of the typical current and power levels at the terminal that will not cause undue overheating due to copper losses (I^2R losses) in the windings. These ratings are not absolutely precise, but they give an indication of the range of excitations for which the motor will perform without overheating. Peak power operation in a motor may exceed rated torque (horsepower) or currents by a substantial factor (up to as much as six or seven times the rated value); however, continuous operation of the motor above the rated performance will cause the machine to overheat, and possibly to sustain damage. Thus, it is important to consider both peak and continuous power requirements when selecting a motor for a specific application. An analogous discussion is valid for the speed rating: while an electric machine may operate above rated speed for limited periods of time, the large centrifugal forces generated at high rotational speeds will eventually cause undesirable mechanical stresses, especially in the rotor windings, leading eventually even to self-destruction.

Another important feature of electric machines is the **regulation** of the machine speed or voltage, depending on whether it is used as a motor or as a generator, respectively. Regulation is the ability to maintain speed or voltage constant in the face of load variations. The ability to closely regulate speed in a motor or voltage in a generator is an important feature of electric machines; regulation is often improved by means of feedback control mechanisms, some of which will be briefly introduced in this chapter. We shall take the following definitions as being adequate for the intended purpose of this chapter.

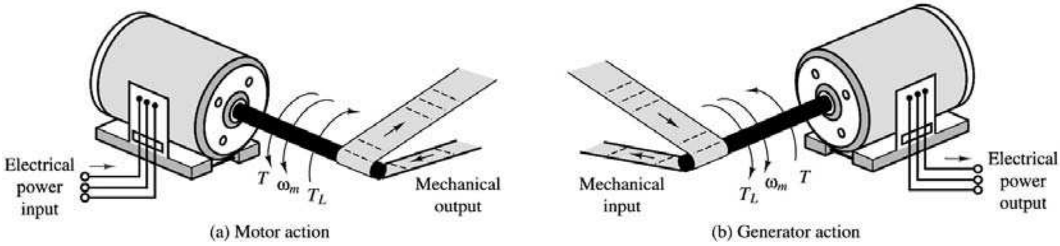

FIGURE 5.12.28 Generator and motor action in an electric machine.

$$\text{Speed regulation} = \frac{\text{Speed at no load} - \text{Speed at rated load}}{\text{Speed at rated load}} \tag{5.12.37}$$

$$\text{Voltage regulation} = \frac{\text{Voltage at no load} - \text{Voltage at rated load}}{\text{Voltage at rated load}} \tag{5.12.38}$$

Please note that the rated value is usually taken to be the nameplate value, and that the meaning of *load* changes depending on whether the machine is a motor, in which case the load is mechanical, or a generator, in which case the load is electrical.

Basic Operation of All Rotating Machines

We have already seen how the magnetic field in electromechanical devices provides a form of coupling between electrical and mechanical systems. Intuitively, one can identify two aspects of this coupling, both of which play a role in the operation of electric machines: (1) magnetic attraction and repulsion forces generate mechanical torque, and (2) the magnetic field can induce a voltage in the machine windings (coils) by virtue of Faraday's law. Thus, we may think of the operation of an electric machine in terms of either a motor or a generator, depending on whether the input power is electrical and mechanical power is produced (motor action), or the input power is mechanical and the output power is electrical (generator action). Figure 5.12.28 illustrates the two cases graphically.

The coupling magnetic field performs a dual role, which may be explained as follows. When a current i flow through conductors placed in a magnetic field, a force is produced on each conductor, according to Equation (5.12.35). If these conductors are attached to a cylindrical structure, a torque is generated, and if the structure is free to rotate, then it will rotate at an angular velocity ω_m. As the conductors rotate, however, they move through a magnetic field and cut through flux lines, thus generating an electromotive force in opposition to the excitation. This emf is also called "counter" emf; it opposes the source of the current i. If, on the other hand, the rotating element of the machine is driven by a prime mover (for example, an internal combustion engine), then an emf is generated across the coil that is rotating in the magnetic field (the armature). If a load is connected to the armature, a current i will flow to the load, and this current flow will in turn cause a reaction torque on the armature that opposes the torque imposed by the prime mover.

You see, then, that for energy conversion to take place, two elements are required: (1) a coupling field, **B**, usually generated in the field winding; and (2) an armature winding that supports the load current, i, and the emf, e.

Magnetic Poles in Electric Machines

Before discussing the actual construction of a rotating machine, we should spend a few paragraphs to illustrate the significance of **magnetic poles** in an electric machine. In an electric machine, torque is developed as a consequence of magnetic forces of attraction and repulsion between magnetic poles on the stator and on the rotor; these poles produce a torque that accelerates the rotor and a reaction torque on the stator. Naturally, we would like a construction such that the torque generated as a consequence

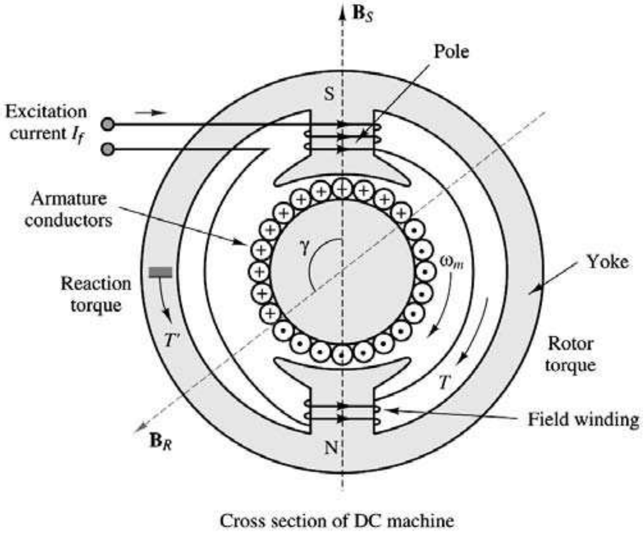

FIGURE 5.12.29 A two-pole machine with salient stator poles.

of the magnetic forces is continuous and in a constant direction. This can be accomplished if the number of rotor poles is equal to the number of stator poles. It is also important to observe that the number of poles must be even, since there have to be equal numbers of north and south poles.

Figure 5.12.29 depicts a two-pole machine in which the stator poles are constructed in such a way as to project closer to the rotor than to the stator structure. This type of construction is rather common, and poles constructed in this fashion are called **salient poles**. Note that the rotor could also be constructed to have salient poles.

To understand magnetic polarity, we need to consider the direction of the magnetic field in a coil carrying current. Figure 5.12.30 shows how the *right-hand rule* can be employed to determine the direction of the magnetic flux. If one were to grasp the coil with the right hand, with the fingers curling in the direction of current flow, then the thumb would be pointing in the direction of the magnetic flux. Magnetic flux is by convention viewed as entering the south pole and exiting from the north pole. Thus, to determine whether a magnetic pole is north or south, we must consider the direction of the flux. Figure 5.12.31 shows a cross section of a coil wound around a pair of salient rotor poles. In this case, one can readily identify the direction of the magnetic flux and therefore the magnetic polarity of the poles by applying the right-hand rule, as illustrated in the figure.

Often, however, the coil windings are not arranged as simply as in the case of salient poles. In many machines, the windings are embedded in slots cut into the stator or rotor, so that the situation is similar

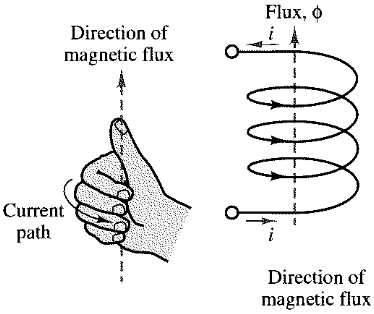

FIGURE 5.12.30 Right-hand rule.

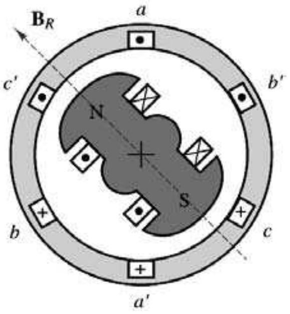

FIGURE 5.12.31 Magnetic field in a salient rotor winding.

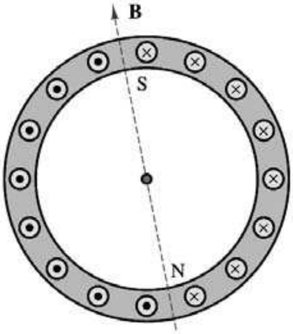

FIGURE 5.12.32 Magnetic field of stator.

to that of the stator depicted in Figure 5.12.32. This figure is a cross section in which the wire connections between "crosses" and "dots" have been cut away. In Figure 5.12.32, the dashed line indicates the axis of the stator flux according to the right-hand rule, indicating that the slotted stator in effect behaves like a pole pair. The north and south poles indicated in the figure are a consequence of the fact that the flux exits the bottom part of the structure (thus, the north pole indicated in the figure) and enters the top half of the structure (thus, the south pole). In particular, if you consider that the windings are arranged so that the current entering the right-hand side of the stator (to the right of the dashed line) flows through the back end of the stator and then flows outward from the left-hand side of the stator slots (left of the dashed line), you can visualize the windings in the slots as behaving in a manner similar to the coils of Figure 5.12.31, where the flux axis of Figure 5.12.32 corresponds to the flux axis of each of the coils of Figure 5.12.31. The actual circuit that permits current flow is completed by the front and back ends of the stator, where the wires are connected according to the pattern *a*-*a*′, *b*-*b*′, *c*-*c*′, as depicted in the figure.

Another important consideration that facilitates understanding the operation of electric machines pertains to the use of AC currents. It should be apparent by now that if the current flowing into the slotted stator is alternating, the direction of the flux will also alternate, so that in effect the two poles will reverse polarity every time the current reverses direction, that is, every half-cycle of the sinusoidal current. Further — since the magnetic flux is approximately proportional to the current in the coil — as the amplitude of the current oscillates in a sinusoidal fashion, so will the flux density in the structure. Thus, *the magnetic field developed in the stator changes both spatially and in time.*

This property is typical of AC machines, where a *rotating magnetic field* is established by energizing the coil with an alternating current. As we shall see in the next section, the principles underlying the operation of DC and AC machines are quite different: in a direct-current machine, there is no rotating field, but a mechanical switching arrangement (the *commutator*) makes it possible for the rotor and stator magnetic fields to always align at right angles to each other.

Direct-Current Machines

As explained in the introductory section, direct-current (DC) machines are easier to analyze than their AC counterparts, although their actual construction is made rather complex by the need to have a commutator, which reverses the direction of currents and fluxes to produce a net torque. The objective of this section is to describe the major construction features and the operation of direct-current machines, as well as to develop simple circuit models that are useful in analyzing the performance of this class of machines.

Physical Structure of DC Machines

A representative DC machine was depicted in Figure 5.12.29, with the magnetic poles clearly identified for both the stator and the rotor. Note the salient pole construction of the stator and the slotted rotor. As previously stated, the torque developed by the machine is a consequence of the magnetic forces between stator and rotor poles. This torque is maximum when the angle γ between the rotor and stator poles is 90°. Also, as you can see from the figure, in a DC machine the armature is usually on the rotor, and the field winding is on the stator.

To keep this torque angle constant as the rotor spins on its shaft, a mechanical switch, called a **commutator**, is configured so the current distribution in the rotor winding remains constant and therefore the rotor poles are consistently at 90° with respect to the fixed stator poles. In a DC machine, the magnetizing current is DC, so that there is no spatial alternation of the stator poles due to time-varying currents. To understand the operation of the commutator, consider the simplified diagram of Figure 5.12.33. In the figure, the brushes are fixed, and the rotor revolves at an angular velocity ω_m; the instantaneous position of the rotor is given by the expression $\theta = \omega_m t - \gamma$.

The commutator is fixed to the rotor and is made up in this example of six segments that are made of electrically conducting material but are insulated from each other. Further, the rotor windings are configured so that they form six coils, connected to the commutator segments as shown in Figure 5.12.33.

As the commutator rotates counterclockwise, the rotor magnetic field rotates with it up to $\theta = 30°$. At that point, the direction of the current changes in coils L_3 and L_6 as the brushes make contact with the next segment. Now the direction of the magnetic field is –30°. As the commutator continues to rotate, the direction of the rotor field will again change from –30° to +30°, and it will switch again when the brushes switch to the next pair of segments. In this machine, then, the torque angle, γ, is not always 90°, but can vary by as much as ±30°; the actual torque produced by the machine would fluctuate by as much as ±14%, since the torque is proportional to $\sin \gamma$. As the number of segments increases, the torque fluctuation produced by the commutation is greatly reduced. In a practical machine, for example, one might have as many as 60 segments, and the variation of γ from 90° would be only ±3°, with a torque fluctuation of less than 1%. Thus, the DC machine can produce a nearly constant torque (as a motor) or voltage (as a generator).

FIGURE 5.12.34

Configuration of DC Machines

In DC machines, the field excitation that provides the magnetizing current is occasionally provided by an external source, in which case the machine is said to be **separately excited** (Figure 5.12.34(a)). More often, the field excitation is derived from the armature voltage and the machine is said to be **self-excited.** The latter configuration does not require the use of a separate source for the field excitation and is therefore frequently preferred. If a machine is in the separately excited configuration, an additional source, V_f, is required. In the self-excited case, one method used to provide the field excitation is to connect the field in parallel with the armature, since the field winding typically has significantly higher resistance than the armature circuit (remember that it is the armature that carries the load current), this will not draw excessive current from the armature. Further, a series resistor can be added to the field circuit to provide the means for adjusting the field current independent of the armature voltage. This configuration is called a **shunt-connected** machine and is depicted in Figure 5.12.34(b). Another method for self-exciting a DC machine consists of connecting the field in series with the armature, leading to the **series-connected** machine, depicted in Figure 5.12.34(c); in this case, the field winding will support the entire armature current, and thus the field coil must have low resistance (and therefore relatively few turns). This configuration is rarely used for generators, since the generated voltage and the load voltage must always differ by the voltage drop across the field coil, which varies with the load current. Thus, a series generator would have poor (large) regulation. However, series-connected motors are commonly used in certain applications, as will be discussed in a later section.

The third type of DC machine is the **compound-connected** machine, which consists of a combination of the shunt and series configurations. Figure 5.12.34(d) and Figure 5.12.34(e) show the two types of connections, called the **short shunt** and the **long shunt**, respectively. Each of these configurations may be connected so that the series part of the field adds to the shunt part (**cumulative compounding**) or so that it subtracts (**differential compounding**).

DC Machine Models

As stated earlier, it is relatively easy to develop a simple model of a DC machine, which is well suited to performance analysis, without the need to resort to the details of the construction of the machine itself. This section will illustrate the development of such models in two steps. First, steady-state models relating field and armature currents and voltages to speed and torque are introduced; second, the differential equations describing the dynamic behavior or DC machines are derived.

When a field excitation is established, a magnetic flux, ϕ, is generated by the field current, I_f. From Equation (5.12.36) we know that the torque acting on the rotor is proportional to the product of the magnetic field and the current in the load-carrying wire; the latter current is the armature current, I_a (i_w, in Equation 5.12.36). Assuming that, by virtue of the cummutator, the torque angle, γ, is kept very close to 90°, and therefore $\sin\gamma = 1$, we obtain the following expression for the torque (in units of N-m) in a DC machine:

$$T = k_T \phi I_a \qquad \text{for } \gamma = 90° \tag{5.12.39}$$

You may recall that this is simply a consequence of the *Bli* law of Chapter 15. The mechanical power generated (or absorbed) is equal to the product of the machine torque and the mechanical speed of rotation, ω_m (in rad/sec), and is therefore given by

$$P_m = \omega_m T = \omega_m k_T \phi I_a \tag{5.12.40}$$

Recall now that the rotation of the armature conductors in the field generated by the field excitation causes a **back emf**, E_b, in a direction that opposes the rotation of the armature. According to the *Blu* law then, this back emf is given by the expression.

$$E_b = k_a \phi \omega_m \tag{5.12.41}$$

where k_a is called the **armature constant** and is related to the geometry and magnetic properties of the structure. The voltage E_b represents a countervoltage (opposing the DC excitation) in the case of a motor, and the generated voltage in the case of a generator. Thus, the electric power dissipated (or generated) by the machine is given by the product of the back emf and the armature current:

$$P_e = E_b I_a \tag{5.12.42}$$

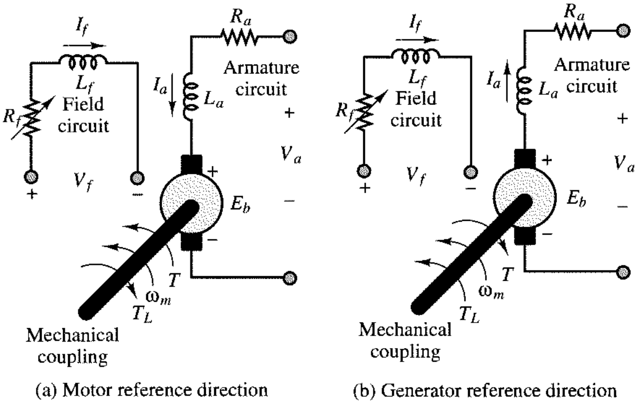
The constants k_T and k_a in Equation (5.12.39) and Equation (5.12.41) are related to geometry factors, such as the dimension of the rotor and the number of turns in the armature winding; and to properties of materials, such as the permeability of the magnetic materials. Note that in the ideal energy-conversion case, $P_m = P_e$, and therefore $k_a = k_T$. We shall, in general, assume such ideal conversion of electrical to mechanical (or vice versa) and will therefore treat the two constants as being identical: $k_a = k_T$. The constant k_a is given by

$$k_a = \frac{pN}{2\pi M} \tag{5.12.43}$$

where

p = number of magnetic poles
N = number of conductors per coil
M = number of parallel paths in armature winding

An important observation concerning the units of angular speed must be made at this point. The equality (under the no-loss assumption) between the constants k_a and k_T in Equation (5.12.39) and Equation (5.12.41) results from the choice of consistent units, namely, volts and amperes for the electrical quantities, and newton-meters and radians per second for the mechanical quantities. You should be aware that it is fairly common practice to refer to the speed of rotation of an electric machine in units of revolutions per minute (rev/min). In this book, we shall uniformly use the symbol n to denote angular speed in rev/min; the following relationship should be committed to memory:



(a) Motor reference direction (b) Generator reference direction

FIGURE 5.12.35 Electrical circuit model of a separately excited DC machine.

$$n(\text{rev/min}) = \frac{60}{2\pi}\omega_m \ (\text{rad/sec}) \tag{5.12.44}$$

If the speed is expressed in rev/min, the armature constant changes as follows:

$$E_b = k'_a \phi n \tag{5.12.45}$$

where

$$k'_a = \frac{pN}{60M} \tag{5.12.46}$$

Having introduced the basic equations relating torque, speed, voltages, and currents in electric machines, we may now consider the interaction of these quantities in a DC machine at steady state, that is, operating at constant speed and field excitation. Figure 5.12.35 depicts the electrical circuit model of a separately excited DC machine, illustrating both motor and generator action. It is very important to note the reference direction of armature current flow and of the developed torque, in order to make a distinction between the two modes of operation. The field excitation is shown as a voltage, V_f, generating the field current, I_f, that flows through a variable resistor, R_f, and through the field coil, L_f. The variable resistor permits adjustment of the field excitation. The armature circuit, on the other hand, consists of a voltage source representing the back emf, E_b, the armature resistance, R_a, and the armature voltage, V_a. This model is appropriate both for motor and for generator action. When $V_a < E_b$, the machine acts as a generator (I_a flows out of the machine). When $V_a > E_b$, the machine acts as a motor (I_a flows into the machine). Thus, according to the circuit model of Figure 5.12.35, the operation of a DC machine at steady state (i.e., with the inductors in the circuit replaced by short circuits) is described by the following equations:

$$\begin{aligned} I_f &= \frac{V_f}{R_f} \quad \text{and} \quad V_a = R_a I_a + E_b \quad (\text{motor action}) \\ I_f &= \frac{V_f}{R_f} \quad \text{and} \quad V_a = -R_a I_a + E_b \quad (\text{generator action}) \end{aligned} \tag{5.12.47}$$

Equation pair (5.12.47) together with Equation (5.12.39) and Equation (5.12.41) may be used to determine the steady-state operating condition of a DC machine.

The circuit model of Figure 5.12.35 permits the derivation of a simple set of differential equations that describe the *dynamic* analysis of a DC machine. The dynamic equations describing the behavior of a separately excited DC machine are as follows:

$$V_a(t) = I_a(t)R_a + L_a \frac{dI_a(t)}{dt} + E_b(t) \qquad \text{(armature circuit)} \tag{5.12.48a}$$

$$V_f(t) = I_f(t)R_f + L_f \frac{dI_f(t)}{dt} \qquad \text{(field circuit)} \tag{5.12.48b}$$

These equations can be related to the operation of the machine in the presence of a load. If we assume that the motor is rigidly connected to an inertial load with moment of inertia J and that the friction losses in the load are represented by a viscous friction coefficient, b, then the torque developed by the machine (in the motor mode of operation) can be written as follows:

$$T(t) = T_L + b\omega_m(t) + J\frac{d\omega_m(t)}{dt} \tag{5.12.49}$$

where T_L is the load torque. T_L is typically either constant or some function of speed, ω_m, in a motor. In the case of a generator, the load torque is replaced by the torque supplied by a prime mover, and the machine torque, $T(t)$, opposes the motion of the prime mover, as shown in Figure 5.12.35. Since the machine torque is related to the armature and field currents by Equation (5.12.39), Equation (5.12.48) and Equation (5.12.49) are coupled to each other; this coupling may be expressed as follows:

$$T(t) = k_a\phi I_a(t) \tag{5.12.50}$$

or

$$k_a\phi I_a(t) = T_L + b\omega_m(t) + J\frac{d\omega_m(t)}{dt} \tag{5.12.51}$$

The dynamic equations described in this section apply to any DC machine. In the case of a *separately excited* machine, a further simplification is possible, since the flux is established by virtue of a separate field excitation, and therefore

$$\phi = \frac{N_f}{\mathcal{R}} I_f = k_f I_f \tag{5.12.52}$$

where N_f is the number of turns in the field coil, $\mathcal{R}$ is the reluctance of the structure, and I_f is the field current.

AC Machines

From the previous sections, it should be apparent that it is possible to obtain a wide range of performance characteristics from DC machines, as both motors and generators. A logical question at this point should be, would it not be more convenient in some cases to take advantage of the single- or multiphase AC power that is available virtually everywhere than to expend energy and use additional hardware to rectify and regulate the DC supplies required by direct-current motors? The answer to this very obvious question is certainly a resounding yes. In fact, the AC induction motor is the workhorse of many industrial applications, and synchronous generators are used almost exclusively for the generation of electric power worldwide. Thus, it is appropriate to devote a significant portion of this chapter to the study of AC machines, and of induction motors in particular. The objective if this section is to explain the basic operation of both synchronous and induction machines, and to outline their performance characteristics. In doing so, we shall also point out the relative advantages and disadvantages of these machines in comparison with direct-current machines.

Rotating Magnetic Fields

As mentioned in earlier, the fundamental principle of operation o AC machines is the generation of a rotating magnetic field, which causes the rotor to turn at a speed that depends on the speed of rotation of the magnetic field. We shall now explain how a rotating magnetic field can be generated in the stator and air gap of an AC machine by means of AC currents.

Consider the stator shown in Figure 5.12.36, which supports windings, *a-a′*, *b-b′*, and *c-c′*. The coils are geometrically spaced 120° apart, and a three-phase voltage is applied to the coils. As you may recall from the discussion of AC power in Section 5.5, the currents generated by a three-phase source are also spaced by 120°, as illustrated in Figure 5.12.37. The phase voltages referencing the neutral terminal would then be given by the expressions

$$v_a = A\cos(\omega_e t)$$

$$v_b = A\cos\left(\omega_e t - \frac{2\pi}{3}\right)$$

$$v_c = A\cos\left(\omega_e t + \frac{2\pi}{3}\right)$$

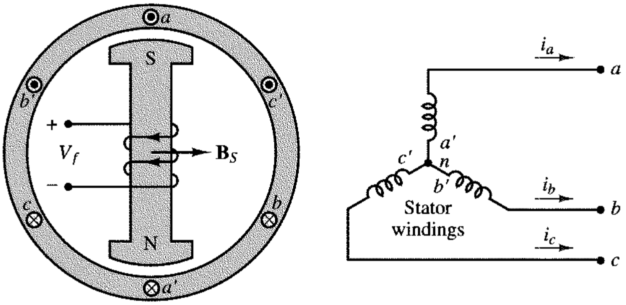


FIGURE 5.12.36 Two-pole three-phase stator.

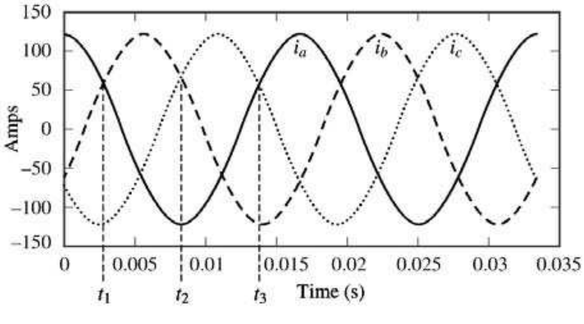

FIGURE 5.12.37 Three-phase stator winding currents.

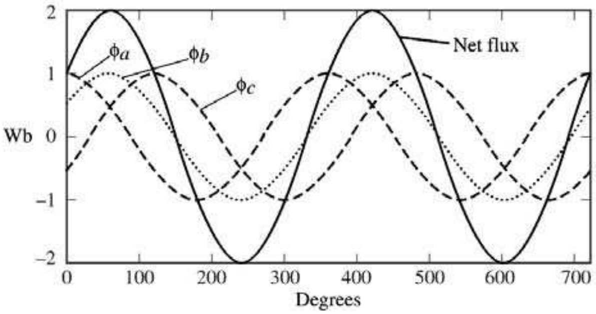

FIGURE 5.12.38 Flux distribution in a three-phase stator winding as a function of angle of rotation.

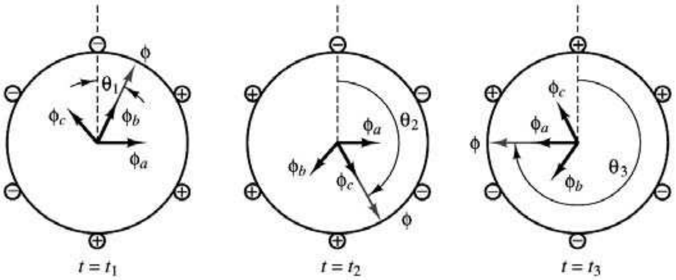

FIGURE 5.12.39 Rotating flux in a three-phase machine.

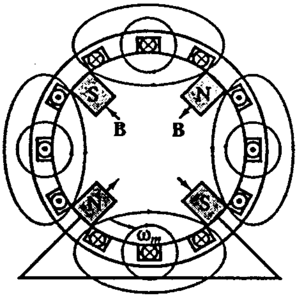

FIGURE 5.12.40 Four-pole stator.

where ω_e is the frequency of the AC supply, or line frequency. The coils in each winding are arranged in such a way that the flux distribution generated by any one winding is approximately sinusoidal. Such a flux distribution may be obtained by appropriately arranging groups of coils for each winding over the stator surface. Since the coils are spaced 120° apart, the flux distribution resulting from the sum of the contributions of the three windings is the sum of the fluxes due to the separate windings, as shown in Figure 5.12.38. Thus, the flux in a three-phase machine rotates in space according to the vector diagram of Figure 5.12.39, and is constant in amplitude. A stationary observer on the machine's stator would see a sinusoidally varying flux distribution as shown in Figure 5.12.38.

Since the resultant flux of Figure 5.12.38 is generated by the currents of Figure 5.12.37, the speed of rotation of the flux must be related to the frequency of the sinusoidal phase currents. In the case of the stator of Figure 5.12.36, the number of magnetic poles resulting from the winding configuration is two; however, it is also possible to configure the windings so that they have more poles. For example, Figure 5.12.40 depicts a simplified view of a four-pole stator.

In general, the speed of the rotating magnetic field is determined by the frequency of the excitation current, *f*, and by the number of poles present in the stator, *p*, according to the equation

$$n_s = \frac{120f}{p} \text{ rev/min}$$

or

$$\omega_s = \frac{2\pi n_s}{60} = \frac{2\pi \times 2f}{p} \tag{5.12.53}$$

where n_s (or ω_s) is usually called the **synchronous speed**.

The Induction Motor

The induction motor is the most widely used electric machine because of its relative simplicity of construction. The stator winding of an induction machine is similar to that of a synchronous machine; thus, the description of the three-phase winding of Figure 5.12.36 also applies to induction machines. The primary advantage of the induction machine, which is almost exclusively used as a motor (its performance as a generator is not very good), is that no separate excitation is required for the rotor. The rotor typically consists of one of two arrangements: **a squirrel cage** or a **wound rotor**. The former contains conducting bars short-circuited at the end and embedded within it; the latter consists of a multiphase winding similar to that used for the stator, but electrically short-circuited.

In either case, the induction motor operates by virtue of currents induced from the stator field in the rotor. In this respect, its operation is similar to that of a transformer, in that currents in the stator (which acts as a primary coil) induce currents in the rotor (acting as a secondary coil). In most induction motors, no external electrical connection is required for the rotor, thus permitting a simple, rugged construction, without the need for slip rings or brushes. Unlike the synchronous motor, the induction motor does not operate at synchronous speed, but at a somewhat lower speed, which is dependent on the load. Figure 5.12.41 illustrates the appearance of a squirrel-cage induction motor. The following discussion will focus mainly on this very common configuration.

You are by now acquainted with the notion of a rotating stator magnetic field. Imagine now that a squirrel-cage rotor is inserted in a stator in which such a rotating magnetic field is present. The stator field will induce voltages in the cage conductors, and if the stator field is generated by a three-phase source, the resulting rotor currents — which circulate in the bars of the squirrel cage, with the conducting path completed by the shorting rings at the end of the cage — are also three-phase, and are determined by the magnitude of the induced voltages and by the impedance of the rotor. Since the rotor currents are induced by the stator field, the number of poles and the speed of rotation of the induced magnetic field are the same as those of the stator field, *if the rotor is at rest.* Thus, when a stator field is initially applied, the rotor field is synchronous with it, and the fields are stationary with respect to each other. Thus, according to the earlier discussion, a *starting torque* is generated.

If the starting torque is sufficient to cause the rotor to start spinning, the rotor will accelerate up to its operating speed. However, an induction motor can never reach synchronous speed; if it did, the rotor would appear to be stationary with respect to the rotating stator field, since it would be rotating at the same speed. But in the absence of relative motion between the stator and rotor fields, no voltage would be induced in the rotor. Thus, an induction motor is limited to speeds somewhere below the synchronous speed, n_s. Let the speed of rotation of the rotor be n; then, the rotor is losing ground with respect to the rotation of the stator field at a speed $(n_s - n)$. In effect, this is equivalent to backward motion of the rotor at the **slip speed**, defined by $(n_s - n)$. The **slip**, s, is usually defined as a fraction of n_s:

$$s = \frac{n_s - n}{n_s} \tag{5.12.54}$$

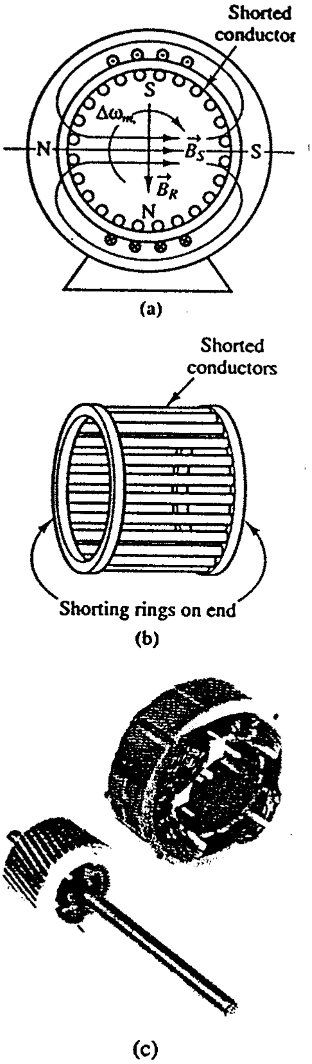

FIGURE 5.12.41 (a) Squirrel-cage induction motor; (b) conductors in rotor; (c) photo of squirrel-cage induction motor.

which leads to the following expression for the motor speed:

$$n = n_s(1 - s) \tag{5.12.55}$$

The slip, s, is a function of the load, and the amount of slip in a given motor is dependent on its construction and rotor type (squirrel cage or wound rotor). Since there is a relative motion between the stator and rotor fields, voltages will be induced in the rotor at a frequency called the **slip frequency**, related to the relative speed of the two fields. This gives rise to an interesting phenomenon: the rotor field travels relative to the rotor at the slip speed sn_s, but the rotor is mechanically traveling at the speed $(1 - s)n_s$, so that the net effect is that the rotor field travels at the speed

$$sn_s + (1 - s)n_s = n_s \tag{5.12.56}$$

that is, at synchronous speed. The fact that the rotor field rotates at synchronous speed — although the rotor itself does not — is extremely important, because it means that the stator and rotor fields will continue to be stationary with respect to each other, and therefore a net torque can be produced.

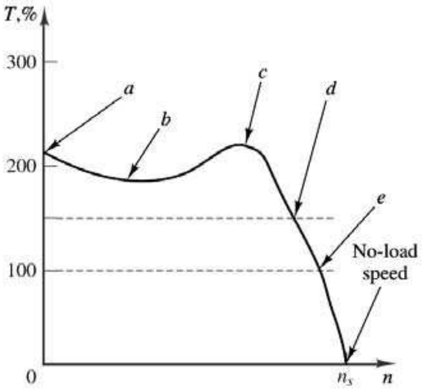

FIGURE 5.12.42 Performance curve for induction motor.

As in the case of DC and synchronous motors, important characteristics of induction motors are the starting torque, the maximum torque, and the torque-speed curve.

Performance of Induction Motors

The performance of induction motors can be described by torque-speed curves similar to those already used for DC motors. Figure 5.12.42 depicts an induction motor torque-speed curve, with five torque ratings marked *a* through *e*. Point *a* is the *starting torque*, also called **breakaway torque**, and is the torque available with the rotor "locked", that is, in a stationary position. At this condition, the frequency of the voltage induced in the rotor is highest, since it is equal to the frequency of rotation of the stator field; consequently, the inductive reactance of the rotor is greatest. As the rotor accelerates, the torque drops off, reaching a maximum value called the **pull-up torque** (point *b*); this typically occurs somewhere between 25 and 40% of synchronous speed. As the rotor speed continues to increase, the rotor reactance decreases further (since the frequency of the induced voltage is determined by the relative speed of rotation of the rotor with respect to the stator field). The torque becomes a maximum when the rotor inductive reactance is equal to the rotor resistance; maximum torque is also called **breakdown torque** (point *c*). Beyond this point, the torque drops off, until it is zero at synchronous speed, as discussed earlier. Also marked on the curve are the *150% torque* (point *d*), and the *rated torque* (point *e*).

A general formula for the computation of the induction motor steady-state torque-speed characteristic is

$$T = \frac{1}{\omega_e} \frac{m V_S^2 R_R / s}{\left[\left(R_S + \frac{R_R}{s}\right)^2 + \left(X_S + X_R\right)^2\right]} \tag{5.12.57}$$

where *m* is the number of phases.

Different construction arrangements permit the design of induction motors with different torque-speed curves, thus permitting the user to select the motor that best suits a given application. Figure 5.12.43 depicts the four basic classifications, classes A, B, C, and D, as defined by NEMA. The determining features in the classification are the locked-rotor torque and current, the breakdown torque, the pull-down torque, and the percent slip. Class A motors have a higher breakdown torque than class B motors, and a slip of 5% or less. Motors in this class are often designed for a specific application. Class B motors are general-purpose motors; this is the most commonly used type of induction motor, with typical values of slip of 3 to 5%. Class C motors have a high starting torque for a given starting current, and a low slip. These motors are typically used in applications demanding high starting torque but having relatively normal running loads, once running speed has been reached. Class D motors are characterized by high starting torque, high slip, low starting current, and low full-load speed. A typical value of slip is around 13%.

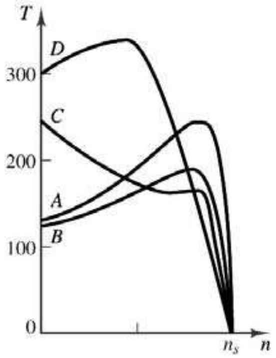

FIGURE 5.12.43 Induction motor classification.

Factors that should be considered in the selection of an AC motor for a given application are the *speed range*, both minimum and maximum, and the speed variation. For example, it is important to determine whether constant speed is required; what variation might be allowed, either in speed or in torque; or whether variable-speed operation is required, in which case a variable-speed drive will be needed. The torque requirements are obviously important as well. The starting and running torque should be considered; they depend on the type of load. Starting torque can vary from a small percentage of full-load to several times full-load torque. Furthermore, the excess torque available at start-up determines the *acceleration characteristics* of the motor. Similarly, *deceleration characteristics* should be considered, to determine whether external braking might be required.

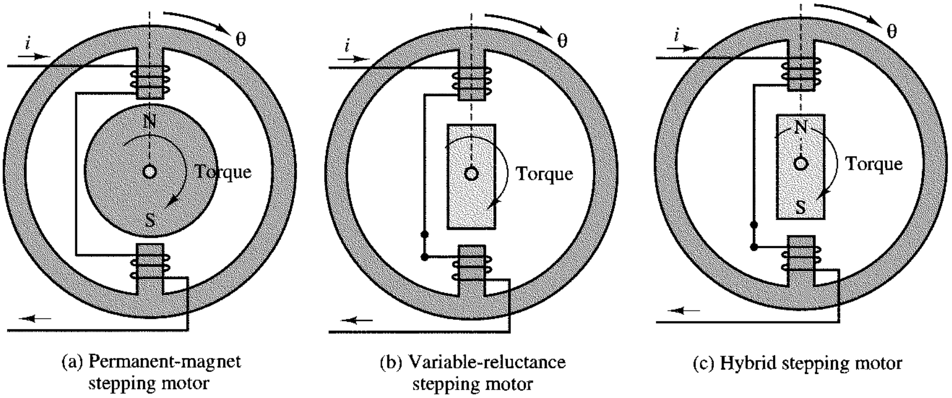
Another factor to be considered is the *duty cycle* of the motor. The duty cycle, which depends on the nature of the application, is an important consideration when the motor is used in repetitive, noncontinuous operation, such as is encountered in some types of machine tools. If the motor operates at zero or reduced load for periods of time, the duty cycle — that is, the percentage of the time the motor is loaded — is an important selection criterion. Last, but by no means least, are the *heating properties* of a motor. Motor temperature is determined by internal losses and by ventilation; motors operating at a reduced speed may not generate sufficient cooling, and forced ventilation may be required.

Stepping Motors

Stepping, or **stepper, motors** are motors that convert digital information to mechanical motion. The principles of operation of stepping motors have been known since the 1920s; however, their application has seen a dramatic rise with the increased use of digital computers. Stepping motors, as the name suggests, rotate in distinct steps, and their position can be controlled by means of logic signals. Typical applications of stepping motors are line printers, positioning of heads in magnetic disks drives, and any other situation where continuous or stepwise displacements are required.

Stepping motors can generally be classified in one of three categories: variable-reluctance, permanent-magnet, and hybrid types. It will soon be shown that the principles of operation of each of these devices bear a definite resemblance to those of devices already encountered in this book. Stepping motors have a number of special features that make them particularly useful in practical applications. Perhaps the most important feature of a stepping motor is that the angle of rotation of the motor is directly proportional to the number of input pulses; further, the angle error per step is very small and does not accumulate. Stepping motors are also capable of rapid response to starting, stopping, and reversing commands, and can be driven directly by digital signals. Another important feature is a self-holding capability that makes it possible for the rotor to be held in the stopped position without the use of brakes. Finally, a wide range of rotating speeds — proportional to the frequency of the pulse signal — may be attained in these motors.

Figure 5.12.44 depicts the general appearance of three types of stepping motors. The **permanent-magnet-rotor stepping motor**, Figure 5.12.44(a), permits a nonzero holding torque when the motor is not energized. Depending on the construction of the motor, it is typically possible to obtain step angles



(a) Permanent-magnet stepping motor

(b) Variable-reluctance stepping motor

(c) Hybrid stepping motor

FIGURE 5.12.44 Stepping motor configurations.

of 7.5, 11.25, 15, 18, 45, or 90°. The angle of rotation is determined by the number of stator poles, as will be illustrated shortly in an example. The **variable-reluctance stepping motor,** Figure 5.12.44(b), has an iron multipole rotor and a laminated wound stator, and rotates when the teeth on the rotor are attracted to the electromagnetically energized stator teeth. The rotor inertia of a variable-reluctance stepping motor is low, and the response is very quick, but the allowable load inertia is small. When the windings are not energized, the static torque of this type of motor is zero. Generally, the step angle of the variable-reluctance stepping motor is 15°.

The **hybrid stepping motor**, Figure 5.12.44(c), is characterized by multitoothed stator and rotor, the rotor having an axially magnetized concentric magnet around its shaft. It can be seen that this configuration is a mixture of the variable-reluctance and permanent-magnet types. This type of motor generally has high accuracy and high torque and can be configured to provide a step angle as small as 1.8°.

For any of these configurations, the principle of operation is essentially the same: when the coils are energized, magnetic poles are generated in the stator, and the rotor will align in accordance with the direction of the magnetic field developed in the stator. By reversing the phase of the currents in the coils or by energizing only some of the coils (this is possible in motors with more than two stator poles), the alignment of the stator magnetic field can take one of a discrete number of positions; if the currents in the coils are pulsed in the appropriate sequence, the rotor will advance in a step-by-step fashion. Thus, this type of motor can be very useful whenever precise incremental motion must be attained. As mentioned earlier, typical applications are printer wheels, computer disk drives, and plotters. Other applications are found in the control of the position of valves (e.g., control of the throttle valve in an engine or of a hydraulic valve in a fluid power-system), and in drug-dispensing apparatus for clinical applications.

The Universal Motor

If it were possible to operate a DC motor from a single-phase AC supply, a wide range of simple applications would become readily available. Recall that the direction of the torque produced by a DC machine is determined by the direction of current flow in the armature conductors and by the polarity of the field; torque is developed in a DC machine because the commutator arrangement permits the field and armature currents to remain in phase, thus producing torque in a constant direction. A similar result can be obtained by using an AC supply, and by connecting the armature and field windings in series, as shown in Figure 5.12.45. A series DC motor connected in this configuration can therefore operate on a single-phase AC supply, and is referred to as a **universal motor**. An additional consideration is that, because of the AC excitation, it is necessary to reduce AC core losses by laminating the stator; thus, the universal motor differs from the series DC motor in its construction features. Typical torque-speed curves for AC and DC operation of a universal motor are shown in Figure 5.12.46. As shown in Figure 5.12.45,

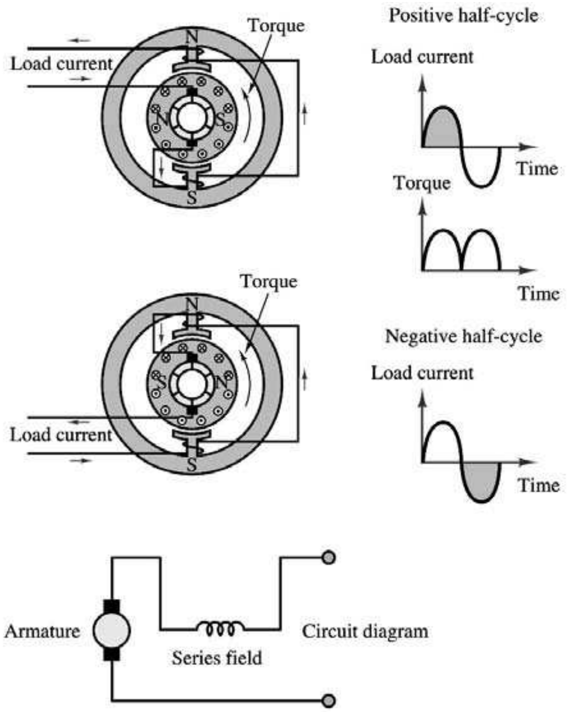


FIGURE 5.12.45 Operation and circuit diagram of a universal motor.

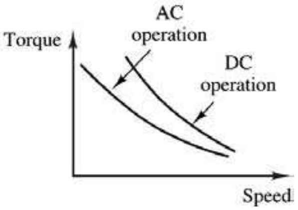

FIGURE 5.12.46 Torque-speed curve of a universal motor.

the load current is sinusoidal and therefore reverses direction each half-cycle; however, the torque generated by the motor is always in the same direction, resulting in a pulsating torque, with nonzero averaging value.

As in the case of a DC series motor, the best method for controlling the speed of a universal motor is to change its (rms) input voltage. The higher the rms input voltage, the greater the resulting speed of the motor. Approximate torque-speed characteristics of a universal motor as a function of voltage are shown in Figure 5.12.47.

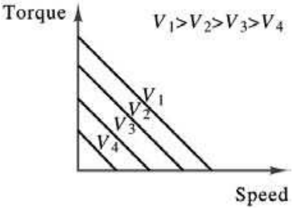

FIGURE 5.12.47 Torque-speed characteristics of a universal motor.

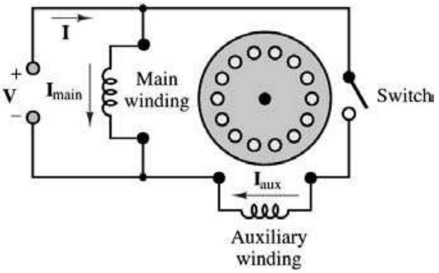

FIGURE 5.12.48 Split-phase motor.

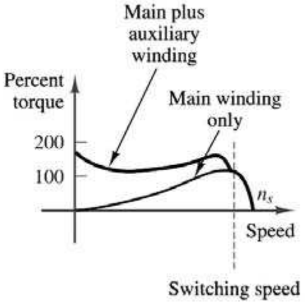

FIGURE 5.12.49 Torque-speed curve of split-phase motor.

Single-Phase Induction Motors

Thus far, we have not mentioned how the initial starting torque can be provided to a single-phase motor. In practice, single-phase motors are classified by their starting and running characteristics, and several methods exist to provide nonzero starting torque. The aim of this section is to classify single-phase motors by describing their configuration on the basis of the method of starting. For each class of motor, a torque-speed characteristic will also be described.

Split-Phase Motors

Split-phase motors are constructed with two separate stator windings, called **main** and **auxiliary windings**; the axes of the two windings are actually at 90° with respect to each other, as shown in Figure 5.12.48. The auxiliary winding current is designed to be out of phase with the main winding current, as a result of different reactances of the two windings. Different winding reactances can be attained by having a different ratio of resistance to inductance — for example, by increasing the resistance of the auxiliary winding. In particular, the auxiliary winding current, $\mathbf{I}_{aux}$, leads the main winding current, $\mathbf{I}_{main}$. The net effect is that the motor sees a two-phase (unbalanced) current that results in a rotating magnetic field, as in any polyphase stator arrangement. Thus, the motor has a nonzero starting torque, as shown in Figure 5.12.49. Once the motor, a centrifugal switch is used to disconnect the auxiliary winding, since a single winding is sufficient to sustain the motion of the rotor. The switching action permits the use of relatively high-resistance windings, since these are not used during normal operation and therefore one need not be concerned with the losses associated with a higher-resistance winding. Figure 5.12.49 also depicts the combined effect of the two modes of operation of the split-phase motor.

Split-phase motors have appropriate characteristics (at very low cost) for fans, blowers, centrifugal pumps, and other applications in the range of 1/20 to 1/2 hp.

Capacitor-Type Motors

Another method for obtaining a phase difference between currents that will give rise to a rotating magnetic field is by the addition of a capacitor. Motors that use this arrangement are termed **capacitor-type motors**. These motors make different use of capacitors to provide starting or running capabilities, or a combi-

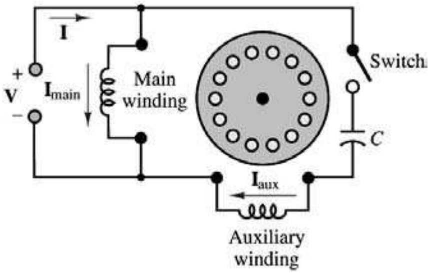

FIGURE 5.12.50 Capacitor-start motor.

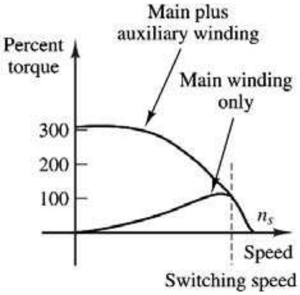

FIGURE 5.12.51 Torque-speed curve for a capacitor-start motor.

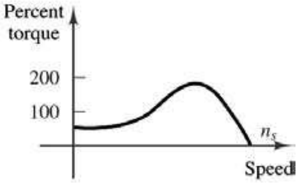

FIGURE 5.12.52 Torque-speed curve for a permanent split-capacitor motor.

nation of the two. The **capacitor-start motor** is essentially identical to the split-phase motor, except for the addition of a capacitor in series with the auxiliary winding, as shown in Figure 5.12.50. The addition of the capacitor changes the reactance of the auxiliary circuit in such a way as to cause the auxiliary current to lead the main current. The advantage of using the capacitor as a means for achieving a phase split is that greater starting torque may be obtained than with the split-phase arrangement. A centrifugal switching arrangement is used to disconnect the auxiliary winding above a certain speed, in the neighborhood of 75% of synchronous speed.

Figure 5.12.51 depicts the torque-speed characteristic of a capacitor-start motor. Because of their higher starting torque, these motors are very useful in connection with loads that present a high static torque. Examples of such loads are compressors, pumps, and refrigeration and air-conditioning equipment.

It is also possible to use the capacitor-start motor without the centrifugal switch, leading to a simpler design. Motors with this design are called **permanent split-capacitor motors**; they offer a compromise between running and starting characteristics. A typical torque-speed curve is shown in Figure 5.12.52.

A further compromise can be achieved by using two capacitors, one to obtain a permanent phase split and the resulting improvement in running characteristics, the other to improve the starting torque. A small capacitance is sufficient to improve the running performance, while a much larger capacitor provides the temporary improvement in starting torque. A motor with this design is called a **capacitor-start capacitor-run motor**; its schematic diagram is shown in Figure 5.12.53. Its torque-speed characteristic is similar to that of a capacitor-start motor.

Shaded-Pole Motors

The last type of single-phase induction motor discussed in this chapter is the **shaded-pole motor**. This type of motor operates on a different principle from the motors discussed thus far. The stator of a shaded-pole motor has a salient pole construction, as shown in Figure 5.12.54, that includes a shading coil

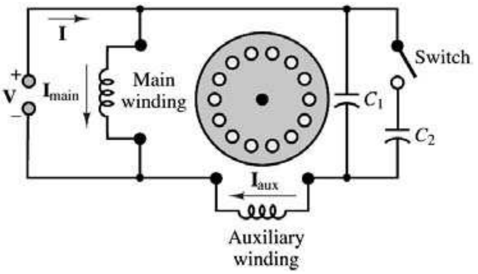

FIGURE 5.12.53 Capacitor-start capacitor-run motor.

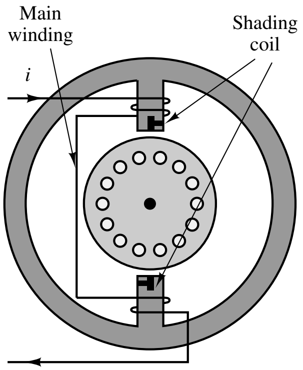

FIGURE 5.12.54 Shaded-pole motor.

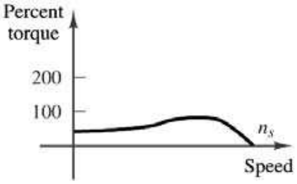

FIGURE 5.12.55 Torque-speed curve of a shaded-pole motor.

consisting of a copper band wound around part of each pole. The flux in the shaded portion of the pole lags behind the flux in the unshaded part, achieving an effect similar to a rotation of the flux in the direction of the shaded part of the pole. This flux rotation in effect produces a rotating field that enables the motor to have a starting torque. This construction technique is rather inexpensive and is used in motors up to about 1/20 hp.

A typical torque-speed characteristic for a shaded-pole motor is given in Figure 5.12.55.

Summary of Single-Phase Motor Characteristics

For basic classes of single-phase motors are commonly used:

1. Single-phase induction motors are used for the larger home and small business tasks, such as furnace oil burner pumps, or hot water or hot air circulators. Refrigerator compressors, lathes, and bench-mounted circular saws are also powered with induction motors.
2. Shaded-pool motors are used in the smaller sizes for quite, low-cost applications. The size range is for 1/30 hp (24.9 W) to 1/2 hp (373 W), particularly for fans and similar drives in which the starting torque is low.
3. Universal motors will operate on any household AC frequency or on DC without modification or adjustment. They can develop very high speed while loaded, and very high power for their size. Vacuum cleaners, sewing machines, kitchen food mixers, portable electric drills, portable circular saws, and home motion-picture projectors are examples of applications of universal motors.
4. The capacitor-type motor finds its widest field of application at low speeds (below 900 rev/min) and in ratings from 3/4 hp (0.5595 kW) to 3 hp (2.238 kW) at all speeds, especially in fan drives.

6.1 Human–Machine Interaction

Thomas B. Sheridan

Over the years, machines of all kinds have improved and become more reliable. However, machines typically operate as components of larger systems, such as transportation, communication, manufacturing, defense, health care, and so on. Although many aspects of such systems can be and have been automated, the human operator is retained in many cases. This may be because of economics, tradition, cost, or (most likely) capabilities of the human to perceive patterns of information and weigh subtle factors in making control decisions, which the machine cannot match.

Although the public as well as those responsible for system operation usually demand a human operator, "human error" is a major reason for system failure. Aside from prevention of error, getting the best performance out of the system means that human and machine must be working together effectively — that they be properly "impedance matched." Therefore, the performance capabilities of the human relative to those of the machine must be taken into account in system design.

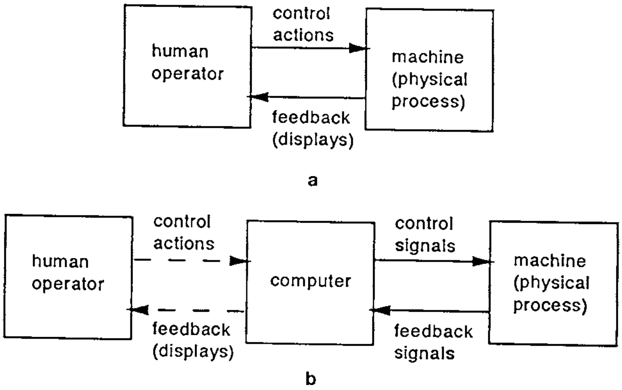

FIGURE 6.1.1 Direct manual control (a) and supervisory control (b).

Efforts to "optimize" the human–machine interaction are meaningless in the mathematical sense of optimization because most important interactions between human and machine cannot be reduced to a mathematical form, and the objective function (defining what is good) is not easily obtained in any given context. For this reason, engineering the human–machine interaction, much as in management or medicine, remains an art more than a science based on laboratory experiments and practical experience.

In the broadest sense, engineering the human–machine interface includes all of *ergonomics* or *human factors engineering,* and goes well beyond design of displays and control devices. Ergonomics includes not only questions of sensory physiology (whether the operator can see the displays or hear the auditory warnings), but also questions of *biomechanics* — how the body moves and whether the operator can reach and apply proper force to the controls. It further includes the fields of operator selection and training; human performance under stress; human factors in maintenance; and many other aspects of the relation of the human to technology. This section focuses primarily on human–machine interaction in control of systems.

The human–machine interactions in control are considered in terms of Figure 6.1.1. In Figure 6.1.1a, the human directly controls the machine, i.e., the control loop to the machine is closed through physical sensors; displays; human senses (visual, auditory, tactile); brain; human muscles; control devices; and machine actuators. Figure 6.1.1b illustrates what has come to be called a *supervisory control system*, wherein the human intermittently instructs a computer as to goals, constraints, and procedures, then turns a task over to the computer to perform automatic control for some period of time.

Displays and control devices can be *analogic* (movement signal directions and extent of control action; isomorphic with the world, such as an automobile steering wheel or computer mouse controls; or a moving needle or pictorial display element). On the other hand, they can be *symbolic* (dedicated buttons or general purpose keyboard controls, icons or alarm light displays). In normal human discourse, speech (symbolic) and gestures (analogic) are used and alphanumeric text (symbolic) and draw pictures (analogic) are written on paper. The system designer must decide which types of displays or controls best suit a particular application and/or what mix to use. The designer must be aware of important criteria such as whether, for a proposed design, changes in the displays and controls caused by the human operator correspond in a natural and common-sense way to "more" or "less" of some variable as expected by that operator and correspond to cultural norms (such as reading from left to right in western countries), and whether the movement of the display elements correspond geometrically to movements of the controls.

Direct Manual Control

In the 1940s, aircraft designers appreciated the need to characterize the transfer function of the human pilot in terms of a differential equation. Indeed, this is necessary for any vehicle or controlled physical process for which the human is the controller (see Figure 6.1.2). In this case, the human operator **H** and

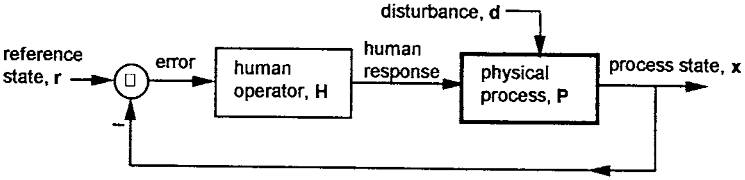

FIGURE 6.1.2 Direct manual control loop analysis.

the physical process **P** lie in the closed loop (where **H** and **P** are Laplace transforms of the component transfer functions), and the **HP** combination determines whether the closed loop is inherently stable (i.e., the closed loop characteristic equation $1 + HP = 0$ has only negative real roots).

In addition to the stability criterion are the criteria of rapid response of process state **x** to a desired or reference state **r** with minimum overshoot, zero steady state error between **r** and output **x**, and reduction to near zero of the effects of any disturbance input **d**. (The latter effects are determined by the closed loop transfer functions $\mathbf{x} = \mathbf{HP}/(1 + \mathbf{HP})\ \mathbf{r} + 1/(1 + \mathbf{HP})\ \mathbf{d}$, where, if the magnitude of **H** is large enough, $\mathbf{HP}/(1 + \mathbf{HP})$ approaches unity and $1/(1 + \mathbf{HP})$ approaches 0. Unhappily, some ingredients of **H** produce delays in combination with magnitude and thereby can cause instability. Therefore, **H** must be chosen carefully by the human for any given **P**.)

Research to characterize the pilot in these terms resulted in the discovery that the human adapts to a wide variety of physical processes so as to make $\mathbf{HP} = \mathbf{K}(1/\mathbf{s})(e^{-sT})$. In other words, the human adjusts **H** to make **HP** constant. The term **K** is an overall amplitude or gain; $(1/\mathbf{s})$ is the Laplace transform of an integrator; and (e^{-sT}) is a delay **T** long (the latter time delay is an unavoidable property of the nervous system). Parameters **K** and **T** vary modestly in a predictable way as a function of the physical process and the input to the control system. This model is now widely accepted and used, not only in engineering aircraft control systems, but also in designing automobiles, ships, nuclear and chemical plants, and a host of other dynamic systems.

Supervisory Control

Supervisory control may be defined by the analogy between a supervisor of subordinate staff in an organization of people, and the human overseer of a modern computer-mediated semiautomatic control system. The supervisor gives human subordinates general instructions that they in turn may translate into action. The supervisor of a computer-controlled system does the same.

Defined strictly, *supervisory control* means that one or more human operators are setting initial conditions for, intermittently adjusting, and receiving high-level information from a computer that closes a control loop in a well-defined process through artificial sensors and effectors. For some time period, the computer controls the process automatically.

By a less strict definition "supervisory control" is used when a computer transforms human operator commands to generate detailed control actions, or makes significant transformations of measured data to produce integrated summary displays. In this latter case the computer need not have the capability to commit actions based upon new information from the environment, whereas in the first it necessarily must. The two situations may appear similar to the human supervisor because the computer mediates human outputs and inputs, and the supervisor is thus removed from detailed events at the low level.

A supervisory control system is represented in Figure 6.1.3. Here the human operator issues commands to a *human-interactive* computer capable of understanding high-level language and providing integrated summary displays of process state information back to the operator. Typically located in a control room, cockpit, or office near the supervisor, this computer in turn communicates with at least one, and probably many (thus the dotted lines), *task-interactive* computers located with the equipment they are controlling. The task-interactive computers thus receive subgoal and conditional branching information from the

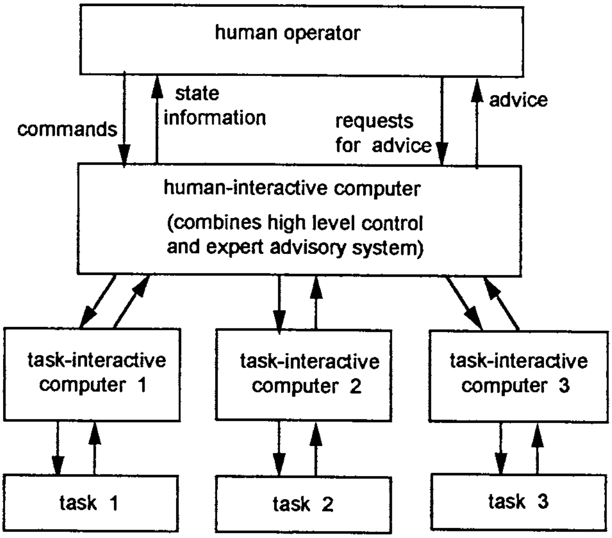

FIGURE 6.1.3 Supervisory control.

human-interactive computer. Using such information as reference inputs, task-interactive computers serve to close low-level control loops between artificial sensors and mechanical actuators, i.e., they accomplish the low-level automatic control.

The low-level task typically operates at some physical distance from the human operator and his human-friendly, display-control computer. Therefore, the communication channels between computers may be constrained by multiplexing, time delay, or limited bandwidth. The task-interactive computer, of course, sends analog control signals to and receives analog feedback signals from the controlled process, and the latter does the same with the environment as it operates (vehicles moving relative to air, sea, or Earth; robots manipulating objects; process plants modifying products; etc.).

Supervisory command and feedback channels for process state information are shown in Figure 6.1.3 to pass through the left side of the human-interactive computer. On the right side are represented decision-aiding functions, with requests of the computer for advice and displayed output of advice (from a data base, expert system, or simulation) to the operator. Many new developments in computer-based decision aids for planning, editing, monitoring, and failure detection are being used as an auxiliary part of operating dynamic systems. Reflection upon the nervous system of higher animals reveals a similar kind of supervisory control wherein commands are sent from the brain to local ganglia, and peripheral motor control loops are then closed locally through receptors in the muscles, tendons, or skin. The brain, presumably, does higher level planning based on its own stored data and "mental models," an internalized expert system available to provide advice and permit trial responses before commitment to actual response.

Theorizing about supervisory control began as aircraft and spacecraft became partially automated. It became evident that the human operator was being replaced by the computer for direct control responsibility and was moving to a new role of monitor and goal-constraint setter. An added incentive was the U.S. space program, which posed the problem of how a human operator on Earth could control a manipulator arm or vehicle on the Moon through a three-second communication round-trip time delay. The only solution that avoided instability was to make the operator a supervisory controller communicating intermittently with a computer on the moon, which in turn closed the control loop there. The rapid development of microcomputers has forced a transition from manual control to supervisory control in a variety of industrial and military applications (Sheridan, 1992).

Now, some examples of human–machine interaction will be considered, particularly those illustrating supervisory control in its various forms. First, three forms of vehicle control will be considered, namely,

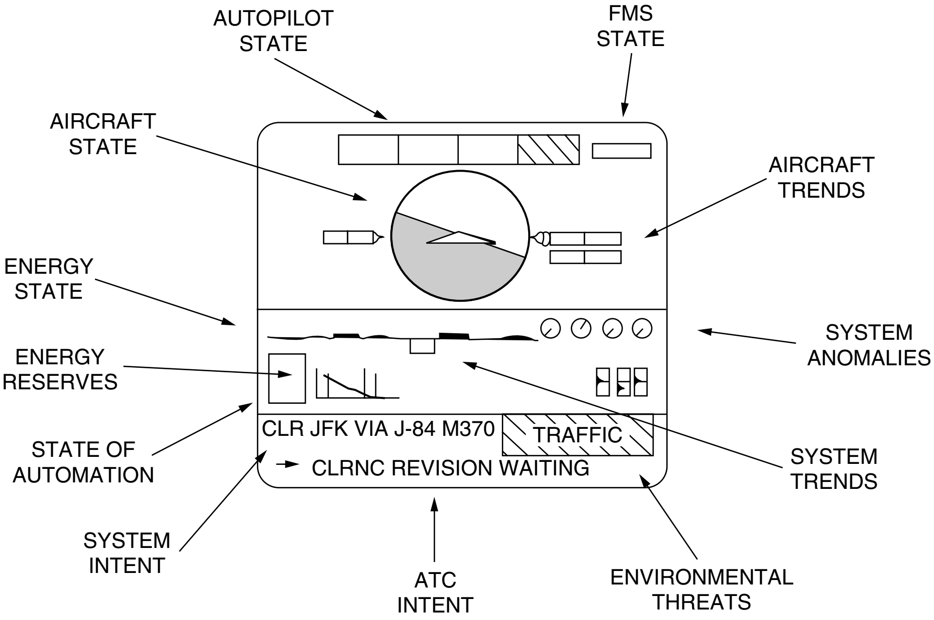

FIGURE 6.1.4 Pilot information requirements. (From Billings, 1991.)

control of modern aircraft, "intelligent" highway vehicles, and high-speed trains — all of which have human operators in the vehicles as well as humans in centralized traffic control centers. Second, telerobots for space, undersea, and medical applications will be discussed.

Advanced Control of Commercial Aircraft

Flight Management Systems

Aviation has appreciated the importance of human–machine interaction from its beginning, and today exemplifies the most sophisticated forms of such interaction. Although there have been many good examples of display and control design over the years, the current development of the flight management systems (FMSs) is the epitome. It also provides an excellent example of supervisory control in which the pilot flies the aircraft by communicating in high-level language through a computer intermediary.

The FMS is a centralized computer that interacts with a great variety of sensors and communication from the ground, as well as many displays and controls within the aircraft. It embodies many functions and mediates most of the pilot information requirements shown in Figure 6.1.4. Gone are the days when each sensor had its own display, operating independently of all other sensor-display circuits. The FMS, for example, brings together all of the various autopilot modes, from long-standing, low-level control modes wherein the aircraft is commanded to go to and hold a commanded altitude, heading, and speed, to more sophisticated modes in which the aircraft is instructed to fly a given course, consisting of a sequence of waypoints (latitudes and longitudes) at various altitudes, and even land automatically at a given airport on a given runway.

Figure 6.1.5 illustrates one type of display mediated by the FMS — in this case integrating many formerly separate components of information. Mostly, it is a multicolor plan-view map showing position and orientation of important objects relative to one's aircraft (the triangle at the bottom):

- Heading (compass arc at top, present heading 175°)
- Groundspeed plus wind speed and wind direction (upper left)
- Actual altitude relative to desired altitude (vertical scale on right side)
- Programmed course connecting various waypoints (OPH and FLT)

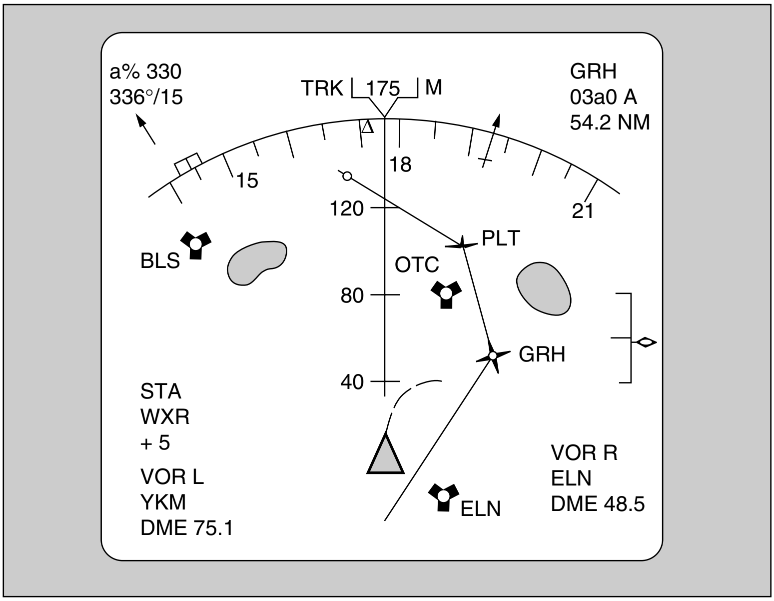

FIGURE 6.1.5 Integrated aircraft map display. (From Billings, 1991.)

- Salient VOR radar beacons to the right and left of present position/direction with their codes and frequencies (lower left and right corners)
- Location of key VORs along the course (three-cornered symbols)
- Location of weather to be avoided (two gray blobs)
- Predicted trajectory based on present turn rate, showing that the right turn is appropriately getting back on course

Programming the FMS is done through a specialized keyboard and text display unit (Figure 6.1.6) having all the alphanumeric keys plus a number of special function keys. The displays in this case are specialized to the different phases of a flight (taxi, takeoff, departure, en route approach, land, etc.), each phase with up to three levels of pages.

The FMS makes clear that designing displays and controls is no longer a matter of what can be built — the computer allows essentially any conceivable display or control to be realized. The computer can also provide a great deal of real-time advice, especially in emergencies, based on its many sensors and stored knowledge about how the aircraft operates. However, pilots are not sure that they need all the information that aircraft designers would like to give them and have an expression "killing us with kindness" to refer to this plethora of available information. The question is what should be designed based on the needs and capabilities of the pilot.

Boeing, McDonnell Douglas, and Airbus have different philosophies for designing the FMS. Airbus has been the most aggressive in automating, intending to make piloting easier and safer for pilots from countries with less well-established pilot training. Unfortunately, of the modern commercial jets, these most automated aircraft have had the most accidents — a fact that has precipitated vigorous debate about how far to automate.

Air Traffic Control

As demands for air travel continue to increase, so do demands for air traffic control. Given what is currently regarded as safe separation criteria, air space over major urban areas is already saturated, so simply adding more airports is not acceptable (in addition to which residents do not want more airports,

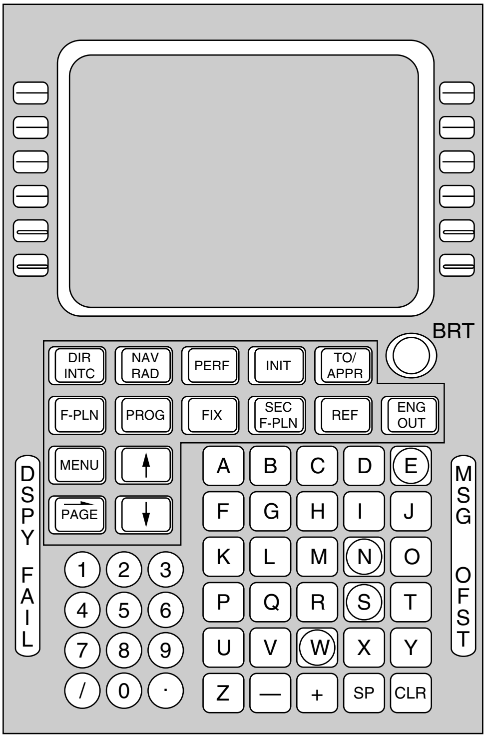

FIGURE 6.1.6 Flight management system control and display unit. (From Billings, 1991.)

with their noise and surface traffic). The need is to reduce separations in the air, as well as to land aircraft closer together or on parallel runways simultaneously. This puts much greater demands on air traffic controllers, particularly at the terminal area radar control centers (TRACONs); here trained operators stare at blips on radar screens and verbally guide pilots entering the terminal airspace from various directions and altitudes into orderly descent and landing patterns with proper separation between aircraft.

Currently, many changes being introduced into air traffic control have profound implications for human–machine interaction. Previously, communication between pilots and air traffic controllers was entirely by voice; now digital communication between aircraft and ground (a system called *datalink)* allows more, as well as more reliable, two-way communication so that weather and runway and wind information, clearances, etc. can be displayed to pilots visually. However, pilots are not so sure that they want this additional technology. They fear the demise of the "partyline" of voice communications with which they are so familiar that permits all pilots in an area to listen in on other pilots' conversations.

New aircraft-borne radar allows pilots to detect air traffic in their own vicinity. Improved ground-based radar detects microbursts or wind shear, which can easily put an aircraft out of control. Both types of radar pose challenges as to how best to warn the pilot and provide guidance as to how to respond. They also pose a cultural change in air traffic control because heretofore pilots have been dependent upon air traffic controllers to advise them of weather conditions and other air traffic. Furthermore, because of the new weather and collision avoidance technology, current plans call for radically altering the rules whereby high-altitude commercial aircraft must stick to well-defined traffic lanes. Instead, pilots will have great flexibility as to altitude (to find the most favorable winds and therefore save fuel) and be able to take great-circle routes straight to their destinations (also saving fuel). However, air traffic controllers are not sure they want to give up the power they have had and become passive observers and monitors who function only in emergencies.

Intelligent Highway Vehicles

Vehicle Guidance and Navigation Systems

The combination of GPS (global positioning system) satellites, high-density computer storage of map data, electronic compass, synthetic speech synthesis, and computer-graphic displays allows cars and trucks to know where they are located on the Earth to within 10 m or less, and can guide a driver to a programmed destination by a combination of a map display and speech. Some human factors challenges are in deciding how to configure the map (how much detail to present; whether to make the map north-up with a moving dot representing one's own vehicle position; or current heading up and rapidly changing with every turn). The computer graphics can also be used to show the turns to anticipate and which lane to get in.

Synthetic speech can reinforce these turn anticipations, caution the driver if he is perceived to be headed in the wrong direction or off-course, and even guide him or her back on course. An interesting question is what the computer should say in each situation to get the driver's attention, to be understood quickly and unambiguously but without being an annoyance. Another question is whether such systems will distract the driver's attention from the primary tasks, thereby reducing safety. The major vehicle manufacturers have developed such systems, which have been evaluated for reliability and human use and are beginning to be marketed in the U.S., Europe, and Japan.

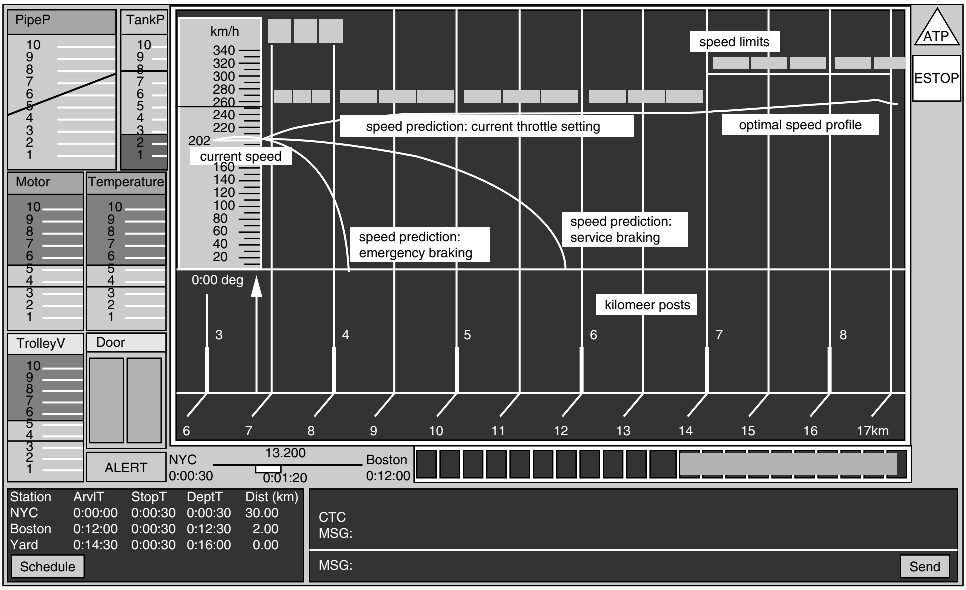
Smart Cruise Control

Standard cruise control has a major deficiency in that it knows nothing about vehicles ahead, and one can easily collide with the rear end of another vehicle if not careful. In a smart cruise control system, a microwave or optical radar detects the presence of a vehicle ahead and measures that distance. The question is what to do with this information. Should the driver be warned with some visual or auditory alarm (auditory is better because the driver need not be looking in the right place)? Can a warning be too late to elicit braking, or surprise the driver so that he brakes too suddenly and causes a rear-end accident to his own vehicle? Should the computer automatically apply the brakes by some function of distance to the obstacle ahead, speed, and closing deceleration? If the computer did all the braking, would the driver become complacent and not pay attention, to the point that a serious accident would occur if the radar failed to detect an obstacle, say a pedestrian or bicycle, or the computer failed to brake? Should braking be some combination of human and computer braking, and if so by what algorithm? These are human factors questions currently being researched.

It is interesting to note that current developmental systems only decelerate and downshift, mostly because if the vehicle manufacturers sell vehicles that claim to perform braking, they would be open to a new and worrisome area of litigation. The same radar technology that can warn the driver or help control the vehicle can also be applied to cars overtaking from one side or the other. Another set of questions then arises as to how and what to communicate to the driver and whether to trigger some automatic control maneuver in certain cases.

Advanced Traffic Management Systems

Automobile congestion in major cities has become unacceptable, and advanced traffic management systems are being built in many of these cities to measure traffic flow at intersections (by some combination of magnetic loop detectors, optical sensors, and other means) and regulate stop lights and message signs. These systems can also issue advisories of accidents ahead by means of variable message signs or radio and give advice of alternate routings. In emergencies, they can dispatch fire, police, ambulances, or tow trucks, and in the case of tunnels, can shut down entering traffic completely if necessary. These systems are operated by a combination of computers and humans from centralized control rooms. The operators look at banks of video monitors, which let them see the traffic flow at different locations, and computer-graphic displays of maps, alarm windows, and textual messages. The operators get advice from computer-based "expert systems" that suggest best responses based on measured inputs, and the operator must decide whether to accept the computer's advice, whether to seek further information, and how to respond.



Station	ArvlT	StopT	DeptT	Dist (km)
NYC	0:00:00	0:00:30	0:00:30	30.00
Boston	0:12:00	0:00:30	0:12:30	2.00
Yard	0:14:30	0:00:30	0:16:00	0.00

FIGURE 6.1.7 Prototype of computer-generated display for high-speed trains. (From Askey, 1995.)

High-Speed Train Control

With respect to new electronic technology for information sensing, storage, and processing, railroad technology has lagged behind that of aircraft and highway vehicles, but currently is catching up. The role of the human operator in future rail systems is being debated because, for some limited right-of-way trains (e.g., in airports), one can argue that fully automatic control systems now perform safely and efficiently. The train driver's principal job is speed control (although he must perform many other monitoring duties); in a train this task is much more difficult than in an automobile because of the huge inertia of the train — it takes 2 to 3 km to stop a high-speed train.

Speed limits are fixed at reduced levels for curves, bridges, grade-crossings, and densely populated areas; while wayside signals temporarily command lower speeds if maintenance is being performed on the track; there are poor environmental conditions such as rock slides or deep snow are present; or, especially, if another train is ahead. The driver must obey all speed limits and reach the next station on time. Learning to maneuver the train with its long time constants can take months, given that the driver's only input currently for the speed control task is an indication of current speed.

The authors' laboratory has proposed a new computer-based display that helps the driver anticipate the future effects of current throttle and brake actions. Based on a dynamic model of the train, this approach gives an instantaneous prediction of future train position and speed based on current acceleration, so speed can be plotted on the display, assuming the operator holds to current brake–throttle settings. It also plots trajectories for maximum emergency braking and maximum service braking. In addition, the computer generates a speed trajectory that adheres to all (known) future speed limits, gets the train to the next station on time, and minimizes fuel/energy. Figure 6.1.7 shows the laboratory version of this display, which is currently being evaluated.

Telerobots for Space, under the Sea, and Medicine

When nuclear power was first adopted in the late 1940s, engineers began the development of master-slave remote manipulators, by which a human operator at one location could position and orient a device attached to his hand, and a servomechanism-controlled gripper would move in correspondence and

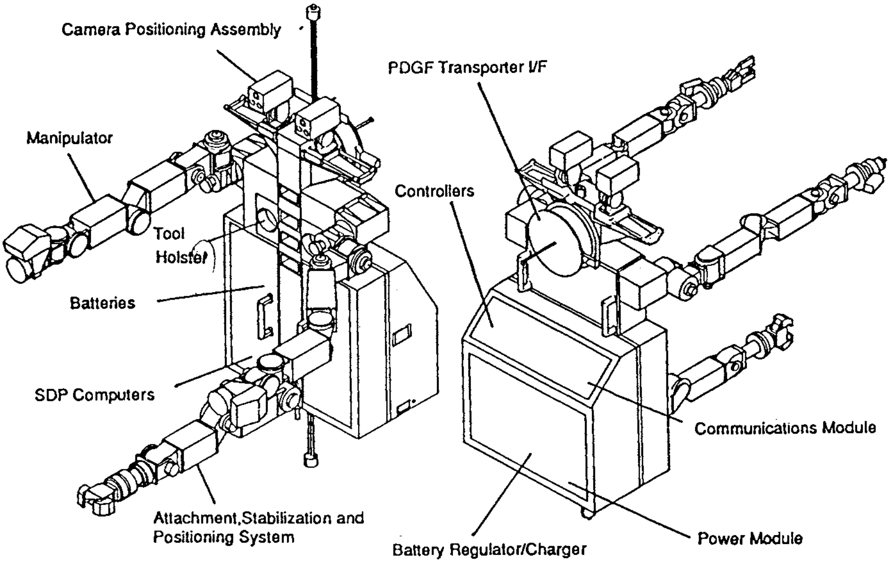


FIGURE 6.1.8 Flight telerobotic servicer prototype design. (Courtesy of NASA.)

handle objects at another location. At about the same time, remotely controlled wheeled vehicles, submarines, and aircraft began to be developed. Such manipulators and vehicles remotely controlled by humans are called *teleoperators.*

Teleoperator technology got a big boost from industrial robot technology, which came in a decade or so later and provided improved vision, force, and touch sensors, actuators, and control software. Large teleoperators were developed for rugged mining and undersea tasks and small teleoperators for delicate tasks such as eye surgery. Eventually, teleoperators were equipped with sensitive force feedback, so that the human operator can see the objects in the remote environment and also feel them in his grasp.

Supervisory controlled teleoperators were developed because, during the time of the Apollo flights to the Moon, the desire to control lunar manipulators and vehicles from Earth was stimulated and unavoidable round trip time delays of 3 sec (speed of light from Earth to Moon and back) would not permit simple closed loop control. The human could communicate a subgoal to be reached and a procedure for getting there, and the teleoperator would be turned loose for some short period to perform automatically. Such a teleoperator is called a *telerobot.*

Figure 6.1.8 shows the flight telerobotic servicer (FTS) developed by Martin Marietta for the U.S. Space Station Freedom. It has two seven-degree of freedom (DOF) arms (including gripper) and one five DOF “leg” for stabilizing itself while the arms work. It has two video “eyes” to present a stereo image to its human operator. It can be configured as a master–slave teleoperator (under direct human control) or as a telerobot (able to execute small programmed tasks using its own eyes and force sensors). Unfortunately the FTS project was canceled by Congress.

Figure 6.1.9 shows the remotely operated submersible *Jason* developed by Woods Hole Oceanographic Institution. It is the “big brother” of *Jason Junior*, which swam into the interior of the ship *Titanic* and made a widely viewed video record when the latter was first discovered. It has a single manipulator arm, sonar and photosensors, and four thrusters that can be oriented within limited range and enable it to move in any direction. It is designed for depths up to 6000 m — rather severe pressures. It, too, can be operated in direct teleoperator mode or as a telerobot.

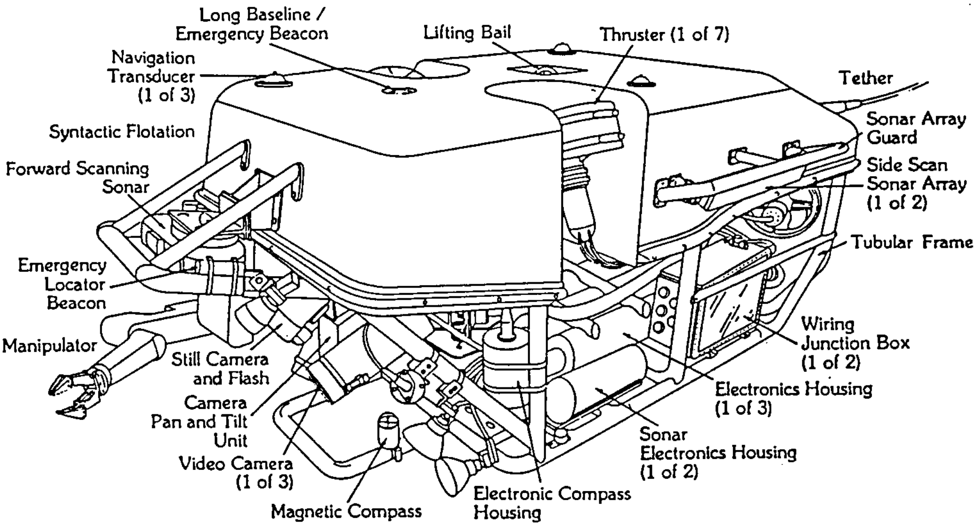

FIGURE 6.1.9 Deep ocean submersible Jason. (Courtesy of Woods Hole Oceanographic Institution.)

Common Criteria for Human Interface Design

Design of operator control stations for teleoperators poses the same types of problems as design of controls and displays for aircraft, highway vehicles, and trains. The displays must show the important variables unambiguously to whatever accuracy is required, but more than that must show the variables in relation to one another so as to portray the current "situation" clearly *(situation awareness* is currently a popular test of the human operator in complex systems). Alarms must get the operator's attention; indicate what is abnormal by text, symbol, or location on a graphic display; determine where in the system the failure occurred, what the urgency is, and if response is urgent; and even suggest what action to take. (For example, the ground proximity warning in an aircraft gives a loud "Whoop, whoop!" followed by a distinct spoken command, "Pull up, pull up!") Controls — whether analogic joysticks, master-arms, or knobs — or symbolic special-purpose buttons or general purpose keyboards must be natural and easy to use and require little memory of special procedures (computer icons and windows do well here). The placement of controls and instruments and their mode and direction of operation must correspond to the desired direction and magnitude of system response.

Human Workload and Human Error

As noted previously, new technology allows combination, integration, and simplification of displays compared to the intolerable plethora of separate instruments in older aircraft cockpits and plant control rooms. The computer has taken over more and more functions from the human operator. These changes potentially make the operator's task easier. However, they also allow for much more information to be presented, more extensive advice to be given, etc.

These advances have elevated the stature of the human operator from that of providing physical energy and control, to that of providing only continuous control, to finally serving as a supervisor or a robotic vehicle or system. "Expert systems" can now answer the operator's questions, much as does a human consultant, or whisper suggestions in his ear even if he does not request them. These changes seem to add many cognitive functions that were not present at an earlier time. They make the operator into a monitor of the automation who is supposed to step in when required to set things straight. Unfortunately, people are not always reliable monitors and interveners.

Mental Workload

Under such complexity, it is imperative to know whether the mental workload of the operator is too great for safety. Human–machine systems engineers have sought to develop measures of mental workload, the idea being that as mental load increases the risk of error increases; however, presumably measurable mental load comes before actual lapse into error. Three approaches have been developed for measuring mental workload:

1. Subjective rating scale, typically a 10-level category scale with descriptors for each category from no load to unbearable load
2. Use of physiological indices that correlate with subjective scales, including heart rate and the variability of heart rate; certain changes in the frequency spectrum of the voice; electrical resistance of the skin; diameter of the pupil of the eye; and certain changes in the evoked brain wave response to sudden sound or light stimuli
3. Use of what is called a secondary task, an easily measurable additional task that consumes all of the operator's attention remaining after the requirements of the primary task are satisfied

The latter technique has been used successfully in the laboratory, but has shortcomings in practice in that operators may refuse to cooperate.

Such techniques are now routinely applied to critical tasks such as aircraft landing, air traffic control, certain planned tasks for astronauts, and emergency procedures in nuclear power plants. The evidence suggests that supervisory control relieves mental load when things are going normally, but when automation fails, the human operator is subjected to a rapidly increased mental load.

Human Error

Human error has long been of interest, but only in recent decades has a serious effort been made to understand human error in terms of categories, causation, and remedy. Human errors can be classified in several ways. One is according to whether it is an error of *omission* (something not done that was supposed to have been done) or *commission* (something done that was not supposed to have been done). Another is *slip* (a correct intention for some reason not fulfilled) vs. a *mistake* (an incorrect intention that was fulfilled). Errors may also be classified according to whether they are in sensing, perceiving, remembering, deciding, or acting.

Some special categories of error worth noting are associated with following procedures in operation of systems. One, for example, is called a *capture error*, wherein the operator, who is very accustomed to a series of steps, say A, B, C, and D, intends at another time to perform E, B, C, F. However, he is "captured" by the familiar sequence B, C and does E, B, C, D.

As to effective therapies for human error, proper design to make operation easy and natural and unambiguous is surely the most important. If possible, the system design should allow for error correction before the consequences become serious. Active warnings and alarms are necessary when the system can detect incipient failures in time to take such corrective action. Training is probably next most important after design, but any amount of training cannot compensate for an error-prone design. Preventing exposure to error by guards, locks, or an additional "execute" step can help make sure that the most critical actions are not taken without sufficient forethought. Least effective are written warnings such as posted decals or warning statements in instruction manuals, although many tort lawyers would say the opposite.

Trust, Alienation, and How Far to Go with Automation

Trust

If an operator does not trust his sensors and displays, expert advisory system, or automatic control system, he will not use them or will avoid using them, if possible. On the other hand, if an operator comes to place too much trust in such systems, he will let down his guard, become complacent, and, when it fails, not be prepared. The question of operator trust in automation is an important current issue in human–machine interface design. It is desirable that operators trust their systems, but it is also desirable that they be alert, aware of the situation, and ready to take over.

Alienation

The new human–machine interaction can have a set of broader social effects that can be discussed under the rubric of *alienation*:

1. People worry that computers can do some tasks, such as memory and calculation, much better than they can. Surely, people should not try to compete in this arena.
2. Supervisory control tends to make people remote from the ultimate operations they are supposed to be overseeing — remote in space, desynchronized in time, and interacting with a computer instead of the end product or service.
3. People lose the perceptual–motor skills that, in many cases, gave them their identity. They become "deskilled" and, if ever called upon to use their previous well-honed skills, they cannot.
4. Increasingly, people who use computers in supervisory control or in other ways, whether intentionally or not, are denied access to the knowledge to understand what is going on inside the computer.
5. Partly as a result of the preceding factor, the computer becomes mysterious, and the untutored user comes to attribute more capability, wisdom, or blame to the computer than is appropriate.
6. Because computer-based systems are growing more complex and people are being "elevated" to roles of supervising larger and larger aggregates of hardware and software, the stakes naturally become higher. A human error before might have gone unnoticed and been easily corrected; now such an error could precipitate a disaster.
7. The last factor in alienation is similar to the first, but all encompassing — namely, the fear that a "race" of machines is becoming more powerful than the human race.

The preceding seven factors and the fears that they engender, whether justified or not, must be reckoned with. Computers must be made not only "human friendly" but also not alienating with respect to these broader factors. Operators and users must become computer literate at the level of sophistication with which they can deal.

How Far to Go with Automation

The trend toward supervisory control is definitely changing the role of the human operator, posing fewer requirements on continuous sensory–motor skill and more on planning, monitoring, and supervising the computer. As computers take over more sensory–motor skill functions, new questions are raised regarding how the interface should be designed to provide the best cooperation between human and machine. Among these questions are: To what degree should the system be automated? How much "help" from the computer is desirable? What are the points of diminishing returns?

Table 6.1.1 lists 10 levels of automation, from 0 to 100% computer control. Obviously, few tasks have achieved 100% computer control; however, new technology pushes relentlessly in that direction. It is

TABLE 6.1.1 Scale of Degrees of Automation

1	The computer offers no assistance; the human must do it all
2	The computer offers a complete set of action alternatives, and
3	Narrows the selection down to a few, or
4	Suggests one alternative, and
5	Executes that suggestion if the human approves, or
6	Allows the human a restricted time to veto before automatic execution, or
7	Executes automatically, then necessarily informs the human, or
8	Informs the human only if asked, or
9	Informs the human only if it, the computer, decides to do so
10	The computer decides everything and acts autonomously, ignoring the human

Source: From Sheridan, 1987.

instructive to consider the various intermediate levels of Table 6.1.1 not only in terms of how capable and reliable the technology is, but also in terms of what is desirable in terms of the human operators' and general public's safety and satisfaction. The current controversy about how much to automate large commercial transport aircraft is often couched in these terms.

6.2 The Need for Control of Mechanical Systems

Peter S. Curtiss

Process control typically involves some mechanical system that needs to be operated in such a fashion that the output of the system remains within its design operating range. The objective of a process control loop is to maintain the process at the setpoint under the following dynamic conditions:

- The setpoint is changed.
- The load on the process is changed.
- The transfer function of the process is changed or a disturbance is introduced.

Classical Control System Representation

Feedback-Loop System

A *feedback* (or *closed-loop*) system contains a process, a sensor, and a controller. Figure 6.2.1 shows some of the components and terms used when discussing feedback loop systems.

- *Process.* A process is a system that produces a motion, temperature change, flow, pressure, or many other actions as a function of the actuator position and external inputs. The output of the process is called the process value. If a positive action in the actuator causes an increase in the process value, the process is called *direct acting*. If positive action in the actuator decreases the process value, it is called reverse *acting*.
- *Sensor.* A sensor is a pneumatic, fluidic, electronic, or other device that produces some kind of signal indicative of the process value.
- *Setpoint.* The setpoint is the desired value for a process output. The difference between the setpoint and the process value is called the process error.
- *Controller.* A controller sends signals to an actuator to effect changes in a process. The controller compares the setpoint and the process value to determine the process error. It then uses this error to adjust the output and bring the process back to the setpoint. The controller gain dictates the amount that the controller adjusts its output for a given error.
- *Actuator.* An actuator is a pneumatic, fluidic, electric, or other device that performs any physical action that will control a process.
- *External disturbances.* An external disturbance is any effect that is unmeasured or unaccounted for by the controller.

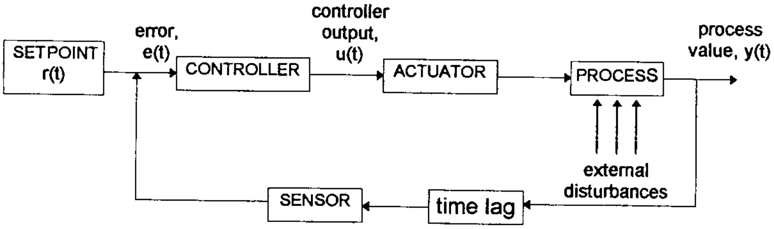

FIGURE 6.2.1 Typical feedback control schematic diagram.

- *Time constants*. The time constant of a sensor or process is a quantity that describes the dynamic response of the device or system. Often the time constant is related to the mass of an object or other dynamic effect in the process. For example, a temperature sensor may have a protective sheath around it that must first be warmed before the sensor registers a change of temperature. Time constants can range from seconds to hours.
- *Dead time*. The dead time or lag time of a process is the time between the change of a process and the time this change arrives at the sensor. The delay time is not related to the time constant of the sensor, although the effects of the two are similar. Large dead times must be properly treated by the control system to prevent unstable control.
- *Hysteresis*. Hysteresis is a characteristic response of positioning actuators that results in different positions, depending on whether the control signal is increasing or decreasing.
- *Dead band*. The dead band of a process is that range of the process value in which no control action is taken. A dead band is usually used in *two*-position control to prevent "chattering" or in split-range systems to prevent sequential control loops from fighting each other.
- *Control point*. The control point is the actual, measured value of a process (i.e., the setpoint + steady-state offset + compensation).
- *Direct/reverse action*. A direct-acting process will increase in value as the signal from the controller increases. A reverse-acting process will decrease in value as the signal from the controller increases.
- *Stability*. The *stability* of a feedback control loop is an indication of how well the process is controlled or, alternatively, how controllable the process is. The stability is determined by any number of criteria, including overshoot, settling time, correction of deviations due to external disturbances, etc.
- *Electric control*. Electric control is a method of using low voltages (typically 24 VAC) or line voltages (110 VAC) to measure values and effect changes in controlled variables.
- *Electronic control*. Electronic controls use solid-state electronic components *that are* used for measurement and amplification of measured signals and the generation of proportional control signals.
- *Pneumatic control*. Pneumatic controls use compressed air as the medium for measuring and controlling processes.
- *Open-loop systems*. An open-loop system is one in which no feedback *occurs, e.g., a* whole-house attic fan. It will continue to run even though the house may have already cooled off. Also, timed on/off devices are open loops.

Examples

Direct-Acting Feedback Control

A classic control example is a reservoir in which the fluid must be maintained at a constant level. Figure 6.2.2 shows this process schematically; the key features of this direct-acting system are labeled. The control action of this system will be referred to shortly after defining some terms are defined:

- *Cascaded (master–slave) control loops*. If a process consists of several subprocesses, each with a relatively different transfer function, it is often useful to use cascaded control loops. For example, consider a building housing a manufacturing line in which 100% outside air is used that must also have very strict control of room air temperature. The room temperature is controlled by changing the position of a valve on a coil at the main air-handling unit that supplies the zone. Typically, the time constant of the coil will be much smaller than the time constant of the room. A single feedback loop would probably result in poor control because both processes involve so much dead time. The solution is to use two controllers: the first (the master) compares the room temperature to the thermostat setting and sends a signal to the second (the slave), which uses that signal as its own setpoint for controlling the coil valve. The slave controller measures the output

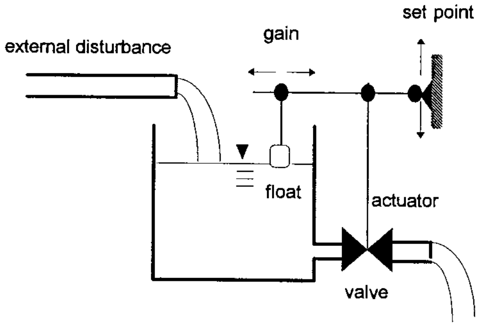

FIGURE 6.2.2 Example of a controlled process.

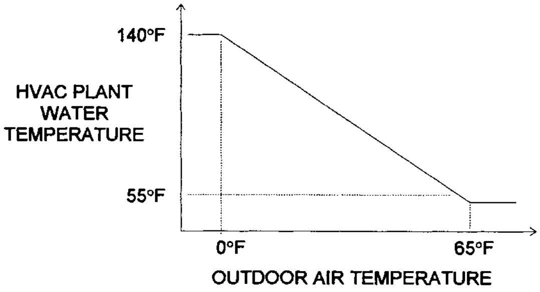

FIGURE 6.2.3 Example of the effect of compensation control.

of the coil, not the temperature of the room. The controller gain on the master can be set lower than that of the slave to prevent excessive cycling.

- *Sequential control loops.* Sometimes control action is needed at more than one point in a process. An example of this is an air-handling unit that contains heating and cooling coils in order to maintain a fixed outlet air temperature in any season. Typically, a *sequential* (or *split-range*) system in an air-handling unit will have three temperature ranges of operation: the first for heating mode; the last for cooling mode; and a middle dead-band region in which neither the cooling nor heating coils are operating. Most sequential loops are simply two different control loops acting from the same sensor. The term *sequential* refers to the fact that in most of these systems the components are in series in the air or water stream.
- *Combined feed-forward/feedback loops.* As pointed out earlier, feed-forward loops can be used when the effects of an external disturbance on a system are known. An example of this is outside air temperature reset control used to modify supply air temperatures. The control loop contains a discharge air temperature sensor (the *primary* sensor) and an outdoor air temperature sensor (the *compensation* sensor). The designer should have some idea about the influence of the outside temperature on the heating load and can then assign an *authority* to the effect of the outside air temperature on the controller setpoint. As the outdoor temperature increases, the control point decreases and vice versa (see Figure 6.2.3).
- *Predictive control.* Predictive control uses a model of the process to predict what the process value will be at some point in the future based upon current and past conditions. The controller then specifies a control action to be taken *in* the present that will reduce future process errors.
- *Adaptive control.* Adaptive controllers modify their gains dynamically in order to adapt to current process conditions.
- *Supervisory controllers.* Supervisory controllers are used to govern the operation of an entire plant and/or control system. These may be referred to as *distributed control systems* (DCSs), which can be used to govern the control of individual feedback loops and can also be used to ensure some

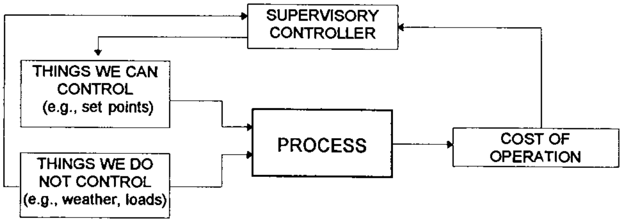

FIGURE 6.2.4 Typical supervisory controller.

kind of optimal performance of the entire plant. The controller will vary setpoints and operating modes in an attempt to minimize a cost function. Figure 6.2.4 shows a basic diagram of a supervisory controller.

6.3 Control System Analysis

Peter S. Curtiss

The Linear Process Approximation

To design controllers, it is necessary to have a dynamic process as well as control system representation. This section describes the key points of the most common such representation — that of linear processes and their controls. A process is basically a collection of mechanical equipment in which an input is changed or transformed somehow to produce an output. Many processes will be near steady state, while others may be in a more or less constant state of change. Building control systems are used as an illustration.

Steady-State Operation

The true response of a seemingly simple process can be, in fact, quite complex. It is very difficult to identify and quantify every single input due to the stochastic nature of life. However, practically any process can be approximated by an equation that takes into account the known input variables and produces a reasonable likeness to the actual process output.

It is convenient to use differential equations to describe the behavior of processes. For this reason, the "complexity" of the function will be denoted by the number of terms in the corresponding differential equation (i.e., the *order* or *degree* of the differential equation). In a linear system analysis, a step change in the control signal is usually considered and the response observed. The following descriptions will assume a step input to the function, as shown in Figure 6.3.1

Note that a step change such as this is usually unlikely in most fields of control outside of electronic systems and even then can only be applied to a digital event such as a power supply being switched on or a relay being energized. Zero-order system output has a one-to-one correspondence to the input:

$$y(t) = a_0 \cdot u(t)$$

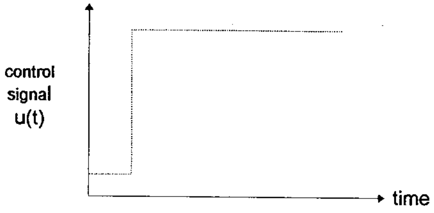

FIGURE 6.3.1 Step change in control signal.

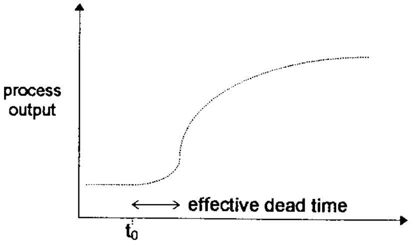

FIGURE 6.3.2 Effective dead time of a process subjected to a step change in controlled signal.

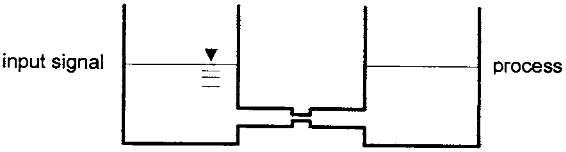

FIGURE 6.3.3 Connected water containers used for example of dynamic response.

First-order functions will produce a time-varying output with a step-change as input:

$$\frac{dy(t)}{dt} + a_1 \cdot y(t) = b_1 \cdot u(t)$$

and higher order functions will produce more complex outputs.

The function that relates the process value to the controller input is called the *transfer function* of the process. The time between the application of the step change, t_0, and the time at which the full extent of the change in the process value has been achieved is called the *transfer period*. A related phenomenon is process dead time. If sufficient physical distance is present between the process output and the sensor assigned to measuring it, then one observes dead time during which the process output is not affected by the control signal (as in Figure 6.3.2).

The *process gain* (or *static gain*) is the ratio of the percentage change of the process output to the corresponding percentage change of the control signal for a given response. For example, gain can be positive (as in a heating coil) or negative (as in a cooling coil).

Dynamic Response

In practice, very few processes are controlled in a step-wise fashion. Usually, the control signal is constantly modulating much the way that one makes small changes to the steering wheel of a car when driving down the highway. The dynamic process of level control in buckets filled with water is now considered. (See Figure 6.2.3.)

Imagine that the level of water in a bucket on the left is the control signal and the level of water in a bucket on the right is the process value. It is obvious that a step change in the control signal will bring about a first-order response of the process value. Suppose, however, that a periodic signal is applied to the level of the bucket on the left. If the frequency of the signal is small enough, a response in the level in the bucket on the right varies as a function of this driving force, but with a delay and a decrease in the amplitude.

Here the *dynamic process gain* is less than one even though the static process gain is 1. This process has no dead time; as soon as the control signal begins to increase, the process value will also begin to increase. The dynamic process gain, therefore, can be defined similarly to that of the static gain — it is the ratio of the amplitude of the two signals, comparable to the normalized ranges used in the static gain definition.

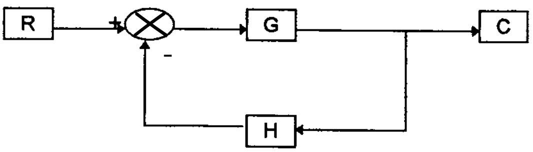

FIGURE 6.3.4 Generalized feedback loop.

The dynamic gain, as its name suggests, is truly dynamic. It will change according to the transfer function as well as to the frequency of the control signal. As the frequency increases, the output will lag even farther behind the input and the gain will continue to decrease. At one point, the frequency may be exactly right to cancel any past effects of the input signal (i.e., the phase shift is 180°) and the dynamic gain will approach zero. If the frequency rises further, the process output may decrease as the control signal increases (easily the case with a building cooling or heating coil due to the mass effects) and the dynamic gain will be negative. At this point, it is convenient to define a feedback loop mathematically. A general feedback loop is shown in Figure 6.3.4.

The controller, actuator, and process have been combined into the *forward transfer function* (or *open-loop transfer function*) **G** and the sensor and dead time have been combined into the *feedback path* transfer function **H**. The overall *closed-loop transfer function* is defined as

$$\frac{\mathrm{C}}{\mathrm{R}}=\frac{\mathrm{G}}{1+\mathrm{G}\cdot\mathrm{H}}$$

The right-hand side of this equation is usually a ratio of two polynomials when using Laplace or *z* transforms. The roots of the numerator are called the *zeros* of the transfer function and the roots of the denominator are called the *poles* (Shinners, 1978).

The denominator of the closed loop transfer function, $\mathbf{1 + G \cdot H}$, is called the *characteristic function.* When the characteristic function is set equal to zero, it yields the *characteristic equation*

$$1 + \mathrm{G} \cdot \mathrm{H} = 0$$

The characteristic equation can be used to assess process control stability during system design.

Representation of Processes in *t*, *s*, and *z* Domains

How a process truly behaves can never be known. The world is an inherently stochastic place and any model of a system is going to approximate at best. Nonetheless, it is necessary to choose some kind of representation in order to perform any useful analysis. This section will consider three different domains: the continuous time domain; the frequency domain; and the discrete time domain. The frequency domain is useful for certain aspects of controller design and the discrete time domain is used in digital controllers.

Continuous Time Domain Representation of a Process

In the time domain, a process is represented by a differential equation such as:

$$\frac{d^n y}{dt^n}+a_1\frac{d^{n-1}y}{dt^{n-1}}+a_2\frac{d^{n-2}y}{dt^{n-2}}+\ldots+a_{n-1}\frac{dy}{dt}+a_n y=b_0\frac{d^m u}{dt^m}+b_1\frac{d^{m-1}u}{dt^{m-1}}+\ldots+b_{m-1}\frac{du}{dt}+b_m u$$

This is just a generalization of the first-order system equation described earlier.

Frequency Domain Representation of a Process — Laplace Transforms

The solution of higher order system models, closed form solution, is difficult in the time domain. For this reason, process transfer functions are often written using Laplace transforms. A Laplace transform is a mapping of a continuous time function to the frequency domain and is defined as

$$F(s) = \int_0^{\infty} f(t)e^{-st}dt$$

This formulation allows one to greatly simplify problems involving ordinary differential equations that describe the behavior of systems. A transformed differential equation becomes purely algebraic and can be easily manipulated and solved. These solutions are not of great interest in modern control system design, but the transformed system + controller differential equation is very useful in assessing control stability. This is the single key aspect of Laplace transforms that is of most interest. Of course, it is possible to solve only the governing differential equation for the system directly and explore stability in that fashion.

The Laplace transform of the previous differential equation is

$$s^n Y(s) + A_1 s^{n-1} Y(s) + \ldots + A_{n-1} sY(s) + A_n Y(s) = B_0 s^m \mathrm{U}(s) + B_1 s^{n-1} \mathrm{U}(s) + \ldots + B_{n-1} s U(s) + B_\mathrm{n} \mathrm{U}(s)$$

This equation can be rewritten as

$$Y(s)\cdot(s^\mathrm{n} + A_1 s^{n-1} + \ldots + A_{n-1} s + A_\mathrm{n}) = U(s)\cdot(B_0 s^\mathrm{m} + B_1 s^{n-1} + \ldots + B_{n-1} s + B_n)$$

so that the transfer function is found from

$$\frac{Y(s)}{U(s)} = \frac{s^m + B_1 s^{m-1} + \ldots + B_{m-1}s + A_m}{s^n + A_1 s^{n-1} + \ldots + A_{n-1}s + A_n}$$

This is the expression used for stability studies.

Discrete Time Domain Representation of a Process

A process in the discrete time domain is described (Radke and Isermann, 1989) by

$$\begin{aligned} y(k) &= a_1 y(k-1) + a_2 y(k-2) + a_3 y(k-3) + \ldots \\ &\quad + b_1 u(k-1) + b_2 u(k-2) + b_3 u(k-3) + \ldots \end{aligned}$$

This representation is of use when one is designing and analyzing the performance of direct digital control (DDC) systems. Note that the vectors **a** and **b** are *not* the same as for the continuous time domain equation. The z-transform uses the backward shift operator and therefore the z-transform of the discrete time equation is given by

$$y\left(1 - a_1 z^{-1} - a_2 z^{-2} - a_3 z^{-3} + \ldots\right) = u\left(b_1 z^{-1} - b_2 z^{-2} - b_3 z^{-3} + \ldots\right)$$

The transfer function can now be found:

$$\frac{y}{u} = \frac{b_1 z^{-1} - b_2 z^{-2} - b_3 z^{-3} + \ldots}{1 - a_1 z^{-1} - a_2 z^{-2} - a_3 z^{-3} + \ldots}$$

z-Transform Details

Because z-transforms are important in modern control design and are not treated elsewhere in this handbook, some basics of their use are given next. More and more control applications are being turned over to computers and DDC systems. In such systems, the sampling is not continuous as required for a Laplace transform. The control loop schematic is shown in Figure 6.3.5.

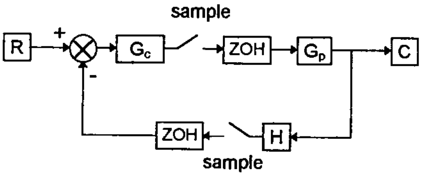

FIGURE 6.3.5 Sampled feedback loop.

It would be prohibitively expensive to include a voltmeter or ohmmeter on each loop; therefore, the controller employs what is called a *zero-order hold.* This basically means that the value read by the controller is "latched" until the next value is read in. This discrete view of the world precludes the use of Laplace transforms for analyses, thus making it necessary to find some other means of simplifying the simulation of processes and controllers. The following indicates briefly how *z*-transforms of controlled processes can be derived and how they are used in a controls application. In the design section of this chapter, the *z*-transform will be used to assess controller stability.

Recall that the Laplace transform is given as

$$\mathscr{L}\left\{f(t)\right\} = \int_0^\infty f(t)e^{-st}dt$$

Now suppose a process that is sampled at a discrete, constant time interval T. The index k will be used to count the intervals

At time $t = 0$, $k = 0$,
At time $t = T$, $k = 1$,
At time $t = 2T$, $k = 2$,
At time $t = 3T$, $k = 3$,

and so forth. The equivalent Laplace transform of a process that is sampled at a constant interval T can be represented as

$$\mathscr{L}\left\{f^*(t)\right\} = \sum_{k=0}^{\infty} f(kT)e^{-s\cdot kT}$$

Substituting the *backward-shift operator* z for e^{Ts} results in the definition of the *z*-transform:

$$Z\left\{f(t)\right\} = \sum_{k=0}^{\infty} f(kT)z^{-k}$$

6.4 Control System Design and Application

Peter S. Curtiss

Controllers

Controllers are akin to processes in that they have gains and transfer functions. Generally, there is no dead time in a controller or it is so small as to be negligible.

Steady-State Effects of Controller Gain

Recall that the process static gain can be viewed as the total change in the process value due to a 100% change in the controller output. A proportional controller acts like a multiplier between an *error signal* and this process gain. Under stable conditions, therefore, there must be some kind of error to yield any controller output. This is called the steady-state or static *offset*.

Dynamic Effects of Controller Gain

Ideally, a controller gain value is chosen that compensates for the dynamic gain of the process under normal operating conditions. The total loop dynamic gain can be considered as the product of the process, feedback, and controller gains. If the total dynamic loop gain is one, the process will oscillate continuously at the natural frequency of the loop with no change in amplitude of the process value. If the loop gain is greater than one, the amplitude will increase with each cycle until the limits of the controller or process are reached or until something fails. If the dynamic loop gain is less than one, the process will eventually settle down to stable control.

Controller Bias

The controller bias is a constant offset applied to the controller output. It is the output of the controller if the error is zero:

$$u = K \cdot e + M$$

where M is the bias. This is useful for processes that become nonlinear at the extremes or for processes in which the normal operating conditions are at a nonzero controller output.

PID Controllers

Many mechanical systems are controlled by proportional-integral-derivative (PID) controllers. Many permutations of such controllers use only certain portions of the PID controllers or use variations of this kind of controller. This subsection considers this very common type of controller.

Proportional Control

Proportional control results in action that is linear with the error. The proportional term, $K_p \cdot e$, has the greatest effect when the process value is far from the desired setpoint. However, very large values of K_p will tend to force the system into oscillatory response. The proportional gain effect of the controller goes to zero as the process approaches setpoint. Purely proportional control should therefore only be used when

- The time constant of the process is small and thus a large controller gain can be used.
- The process load changes are relatively small so that the steady-state offset is limited.
- The steady-state offset is within an acceptable range.

Integral Control

Integral makes a process adjustment based on the cumulative error, not its current value. The integral term K_i is the reciprocal of the reset time, T_r, of the system. The reset time is the duration of each error summing cycle. Integral control can cancel any steady-state offsets that would occur when using purely proportional control. This is sometimes called *reset* control.

Derivative Control

Derivative makes a process adjustment based on the current rate of change of the process control error. Derivative control is typically used in cases in which a large time lag occurs between the controlled device and the sensor used for the feedback. This term has the overall effect of preventing the actuator signal from going too far in one direction or another and can be used to limit excessive overshoot.

PID Controller in Time Domain

The PID controller can be represented in a variety of ways. In the time domain, the output of the controller is given by

$$u(t) = K_p\left[e(t) + K_i\int_0^t e(t)\,dt + K_d\frac{de(t)}{dt}\right]$$

PID Controller in the *s* Domain

It is relatively straightforward to derive the Laplace transform of the time domain PID equation. The transfer function of the controller is

$$\frac{U(s)}{E(s)} = \left[K_p + \frac{K_pK_i}{s} + K_pK_ds\right]$$

This controller transfer function can be multiplied by the process transfer function to yield the overall forward transfer function **G** of an *s*-domain process model. The criteria described earlier can then be used to assess overall system stability.

PID Controller in the *z* Domain

Process data are measured discretely at time intervals Δt, and the associated PID controller can be represented by

$$u(k) = K_p\left[e(k) + K_i\Delta t\sum_{i=0}^{k} e(i) + K_d\frac{e(k) - e(k-1)}{\Delta t}\right]$$

The change of the output from one time step to the next is given by $u(k) - u(k-1)$, so the PID *difference equation* is:

$$u(k) - u(k-1) = K_p\left[\left(1 + \frac{K_d}{\Delta t}\right)e(k) + \left(K_i\Delta t - 1 - 2\frac{K_d}{\Delta t}\right)e(k-1) + \left(\frac{K_d}{\Delta t}\right)e(k-2)\right]$$

and can be simplified as

$$u(k) - u(k-1) = q_0e(k) + q_1e(k-1) + q_2e(k-2)$$

where

$$q_0 = K_p\left(1 + \frac{K_d}{\Delta t}\right); \quad q_1 = K_p\left(K_i\Delta t - 1 - 2\frac{K_d}{\Delta t}\right); \quad q_2 = K_p\left(\frac{K_d}{\Delta t}\right)$$

Note that this can be written as

$$u\left(1 - z^{-1}\right) = e\left(q_0 + q_1z^{-1} + q_2z^{-2}\right)$$

The *z*-domain transfer function of the PID controller is then given as

$$\frac{u(z)}{e(z)} = \frac{q_0 + q_1z^{-1} + q_2z^{-2}}{1 - z^{-1}} = \frac{q_0z^2 + q_1z + q_2}{z^2 - z}$$

Controller Performance Criteria and Stability

Performance Indices

Obviously, in feedback loops one wishes to reduce the process error quickly and stably. The control systems engineer can use different cost functions in the design of a given controller depending on the criteria for the controlled process. Some of these cost functions (or *performance indices*) are listed here:

ISE	Integral of the square of the error	$\int e^2$
ITSE	Integral of the time and the square of the error	$\int te^2$
ISTAE	Integral of the square of the time and the absolute error	$\int t^2 \lvert e \rvert$
ISTSE	Integral of the square of the time and the square of the error	$\int t^2 e^2$

These indices are readily calculated in with DDC systems and can be used to compare the effects of different controller settings, gains, and even control methods.

Stability

Stability in a feedback loop means that the feedback loop will tend to converge on a value as opposed to exhibiting steady-state oscillations or divergence. Recall that the closed loop transfer function is given by

$$\frac{C}{R} = \frac{G}{1+GH}$$

and that the denominator, 1 + *GH*, when equated to zero, is called the characteristic equation. Typically, this equation will be a polynomial in *s* or *z* depending on the method of analysis of the feedback loop. Two necessary conditions for stability are that (1) all powers of *s* must be present in the characteristic equation from zero to the highest order; and (2) all coefficients in the characteristic equation must have the same sign. Note that the process may still be unstable even when these conditions are satisfied.

Roots of the Characteristic Equation

The roots of the characteristic equation play an important role in determining the stability of a process. These roots can be real and/or imaginary and can be plotted as shown in Figure 6.4.1. In the *s*-domain, if all the roots are in the left half-plane (i.e., to the left of the imaginary axis), then the feedback loop is guaranteed to be asymptotically stable and will converge to a single output value. If one or more roots are in the right half-plane, then the process is unstable. If one or more roots lie on the imaginary axis and none are in the right half-plane, then the process is considered to be marginally stable.

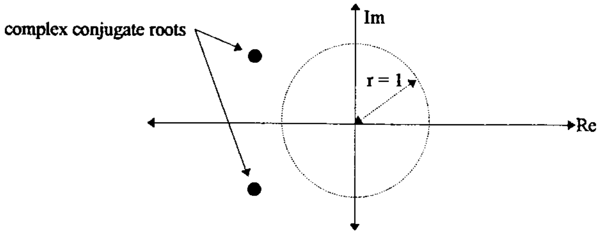

FIGURE 6.4.1 Placement of roots in the imaginary plane (showing unit circle).

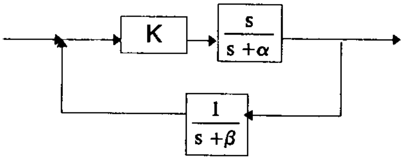

FIGURE 6.4.2 Simple feedback control loop.

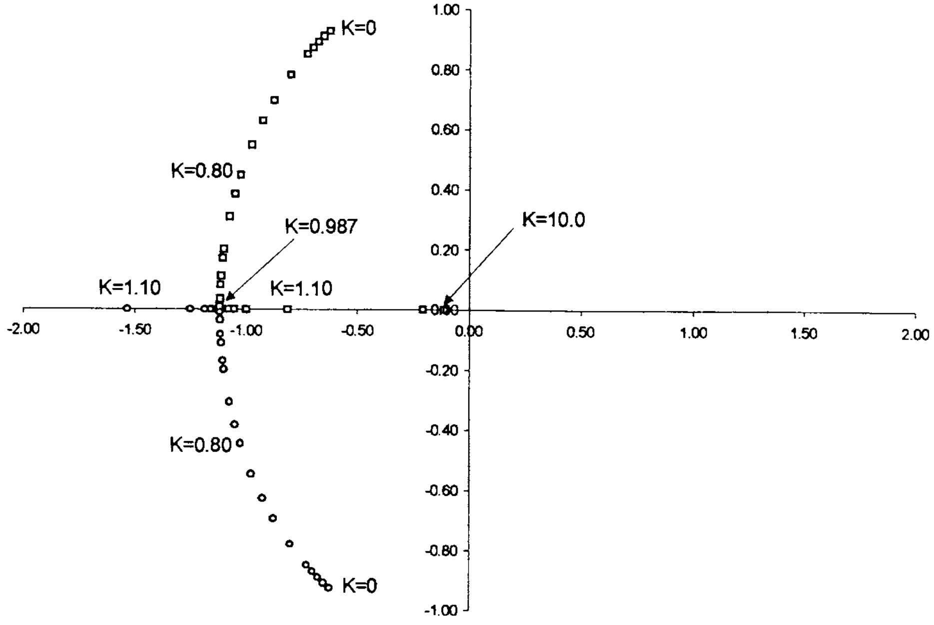

FIGURE 6.4.3 Root locus of $s^2 + (1.25 + K)s + 1.25 = 0$.

In the z-domain, if all the roots lie within the unit circle about the origin, then the feedback loop is asymptotically stable and will converge. If one or more roots lie outside the unit circle, then the process is unstable. If one or more roots lie on the unit circle and none are outside the unit circle, then the process is marginally stable.

Root locus example: Consider the feedback loop shown in Figure 6.4.2. The characteristic equation is given by $1 + GH = 0$, or

$$1+K\left(\frac{s}{s+\alpha}\right)\left(\frac{1}{s+\beta}\right)=0$$

For different values of K the roots of this equation can be plotted. The graph in Figure 6.4.3 shows an example plot when the characteristic equation is given by $s^2 + (1.25 + K)s + 1.25 = 0$. The plot shows that a system described by this characteristic demonstrates stable response for a process gain of $0.0 \leq K \leq 10.0$. For gains greater than 10, at least one root exists in the right half-plane and the process is not under stable control. Note that the root locus plot is always symmetric about the real axis and that the number of separate segments of the locus is equal to the number of roots of the characteristic equation (i.e., the number of poles of the closed-loop transfer function).

Routh–Hurwitz Stability Criteria

The Routh–Hurwitz method is an tabular manipulation of the characteristic equation in the frequency domain and is used to assess stability. If the characteristic equation is given by

$$a_0 s^n + a_1 s^{n-1} + \ldots + a_{n-1} s + a_n = 0$$

then the Routh–Hurwitz method constructs a table from the coefficients as follows:

$$\begin{array}{ccccc}
s^n & a_0 & a_2 & a_4 & \cdots \\
s^{n-1} & a_1 & a_3 & a_5 & \cdots \\
s^{n-2} & X_1 & X_2 & X_3 & \cdots \\
s^{n-3} & Y_1 & Y_2 & Y_3 & \cdots \\
\vdots & \vdots & \vdots & \vdots & \cdots
\end{array}$$

where

$$X_1 = \frac{a_1 a_2 - a_0 a_3}{a_1}; \qquad X_2 = \frac{a_1 a_4 - a_0 a_5}{a_1}; \qquad X_3 = \frac{a_1 a_6 - a_0 a_7}{a_1} \cdots$$

$$Y_1 = \frac{X_1 a_3 - a_1 X_2}{X_1}; \qquad Y_2 = \frac{X_1 a_5 - a_1 X_3}{X_1} \cdots$$

and so forth. The number of roots in the right-hand plane of the *s*-domain is equal to the number of sign changes in the first column, i.e., the column containing a_0, a_1, X_1, Y_1, etc. In other words, if all the elements in the first column have the same sign, then no roots are in the right-hand plane and the process is stably controlled. Also, for special cases of the characteristic equation:

- If the first element of any row is zero but the remaining elements are not, then use some small value ε and interpret the final results as $\varepsilon \to 0$.
- If one of the rows before the final row is entirely zeros, then (1) there is at least one pair of real roots of equal magnitude but opposite signs; or (2) there is at least one pair of imaginary roots that lie on the imaginary axis; or (3) there are complex roots symmetric about the origin.

Field Commissioning — Installation, Calibration, Maintenance

Tuning of Feedback Loops

The *tuning* of a controller involves finding controller gains that will ensure at least a critically damped response of the process to a change in setpoint or process disturbance. A good starting point for PID constants is that derived during the design phase by the stability assessment approaches described earlier. However, real processes do not necessarily behave as their models would suggest and actual field tuning of controls is needed during the system commissioning process.

Pole-Zero Cancellation

One method of obtaining the desired critically damped response of a process is to determine the closed-loop transfer function in the form

$$\frac{C}{R} = \frac{(s + A_1)(s + A_2)\ldots(s + A_m)}{(s + B_1)(s + B_2)\ldots(s + B_n)}$$

The coefficients *A* and *B* will depend on the process characteristics and the controller gains. The objective of pole-zero cancellation is to find values for the controller gains that will set some numerator

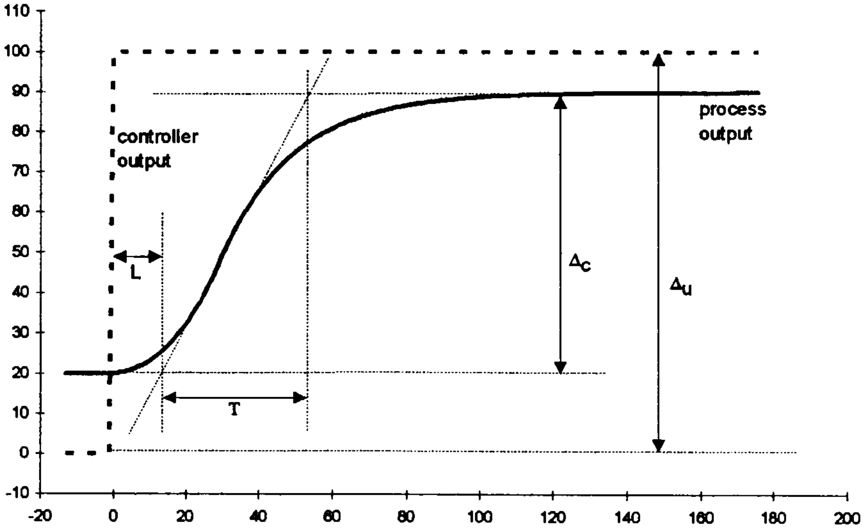

FIGURE 6.4.4 Reaction curve components.

coefficients equal to those in the denominator, effectively canceling terms. As can be imagined, however, this can be a very difficult exercise, particularly when working with complex roots of the equations. This method can only be used with very simple system models.

Reaction Curve Techniques

Often it is advisable to test a feedback loop *in situ*. Several techniques have been developed that allow for the derivation of "good" PID constants for a given open-loop response. Consider the process response shown in Figure 6.4.4 where Δ_c is the change of process output; Δ_u is the change of controller; L is the time between change and intersection; and T is the time between lower intersection and upper intersection. The following variables can be defined: $A = \Delta_u/\Delta_c$; $B = T/L$, and $R = L/T$. These values can be used with the equations given in Table 6.4.1 to estimate "decent" control constants. The users of these constants

TABLE 6.4.1 Equations for Finding PID Constants Using Zeigler–Nichols and Cohen and Coon Reaction Curve Tests

P + I	$0.45\ K_p^*$	$0.8T^*$	—
P + I + D	$0.6\ K_p^*$	$0.5T^*$	$0.125T^*$

should be aware, however, that they are based on the typical response of second-order systems and may not provide good values for all processes.

Ultimate Frequency

The ultimate frequency test involves increasing the proportional gain of a process until it begins steady-state oscillations. K_p^* is defined as the proportional gain that results in steady oscillations of the controlled system and T^* is the period of the oscillations. The desired controller gains are given in Table 6.4.2. Note that the use of the ultimate period test is not always easy to do in practice and may be prohibited in certain cases by a process operations manager.

6.5 Advanced Control Topics

Peter S. Curtiss, Jan Kreider, Ronald M. Nelson, and Shou-Heng Huang

Neural Network-Based Predictive/Adaptive Controllers

Neural networks are powerful modeling tools used for predicting nonlinear behavior of processes and require a minimum of knowledge about the physical system involved. This approach can be used to predict the behavior of a process and can calculate the future value of the process variables. The effects of current modifications to the future value of the controlled process can be easily quantified and used to obtain the desired process response.

Overview of Neural Networks

The artificial neural network attempts to mimic a few aspects of the behavior of biological neural networks. Inputs to a biological nerve cell are carried along the dendrites of that cell. These inputs come from the positive impulse signals of other cells but may be converted to negative signals by the chemical interactions at the synapse between the cells. All of the inputs are then carried to the soma where they add or subtract from the overall potential difference between the interior of the soma and the surrounding fluid. Once the cell potential rises above a certain level, the cell “fires” and sends signals to other cells along its axon.

The artificial cell behaves in much the same way, except that the output signal is analog instead of digital. Signals from sending cells are passed along to a receiving cell through a series of connections. Each connection has an associated weighting factor that acts as a multiplier on the signal from the sending cell. All the inputs to a cell are summed (along with a cell bias, if included) and the resulting value is used to generate the output of the receiving cell. The output of the cell is referred to as the cell *activation* and the function that uses the net input to generate the cell activation is called the *activation function*. The latter can theoretically be of any form, although linear and sigmoidal functions are frequently used. Figure 6.5.1 shows a comparison between a biological cell and an artificial cell.

When many different cells are combined together into a richly connected network (Figure 6.5.2), the result can behave mathematically as a nonlinear regression capable of mapping inputs to outputs for complex relationships. The trick is to find a series of weights W that allow the network to provide the desired outputs using specific inputs. A number of references to network training are cited in the bibliography at the end of this chapter.

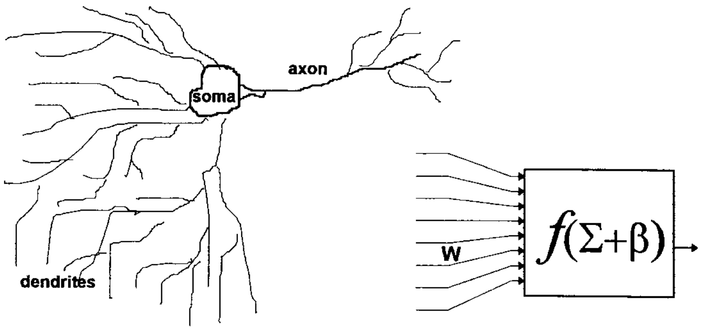

FIGURE 6.5.1 Biological cell vs. artificial cell.

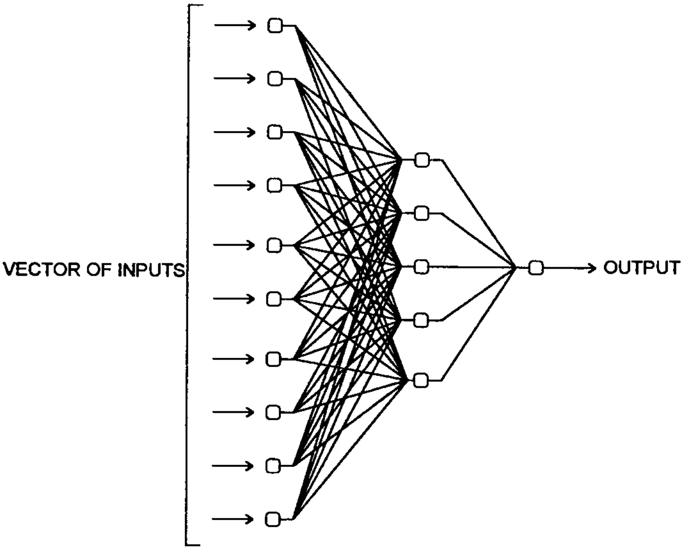

FIGURE 6.5.2 Artificial neural network consisting of several layers of mathematical models of biological neurons.

Using Networks for Controlling Feedback Loop Processes

Neural networks offer the potential for and have demonstrated improved control of processes through predictive techniques. The concept is fairly simple: train a network to predict the dynamic behavior of a process and then use these predictions to modify the controller output to place the process at a desired setpoint $R(t)$ at some time in the future. Initial results from computer simulations of such a controller are presented in Curtiss et al. (1993a, b, c). Anderson (1989) described a computer simulation in which a network was trained to recognize the dynamic properties of an inverted pendulum (e.g., a broom balanced on an open palm). A control system was developed in which the angle and position of the pendulum were used to move the supporting base in order to maintain the pendulum upright. A neural network-based predictive controller is outlined in the classic discussion by Nguyen and Widrow (1989) on the "truck backer-upper" problem in which a tractor-trailer is backed into position at a loading dock.

Properly tuned fixed-gain controllers will usually work over a relatively wide range of process operation provided that the external perturbations and influences are small or time invariant. With nonlinear processes, however, a conventional control algorithm can lead to unstable control if the gains were chosen for a range different from the current operating conditions.

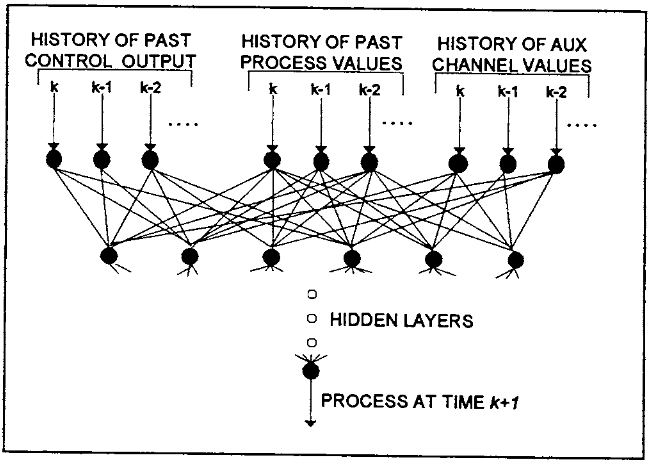

FIGURE 6.5.3 Network used for process prediction.

Architecture of the Network

With the neural network approach, it is possible to overcome these problems by using as many additional salient inputs (the *auxiliary* inputs) as necessary and by incorporating an inherently nonlinear model to accomplish the control objectives. The network is trained using examples of the time-dependent relationship between a value of the feedback and previous values of the feedback, the controller output, and the auxiliary inputs. An example of the network architecture required for this is shown in Figure 6.5.3. In practice, it is not necessary to limit the number of previous measurements of any of the inputs, although the final size of the network and the corresponding training time and memory requirements need to be taken into consideration.

The network, once trained, can predict the future feedback value for any controller output. The trick is to find the controller output that causes the future process value to match the setpoint. This is accomplished by finding the derivative of the future error with respect to the current controller signal. Starting with the current process conditions, the feedback value is predicted at each time step into the future over a preset time window as shown in Figure 6.5.4. During each step of the prediction, the values for the controller output and auxiliary inputs are held constant. This simulation is performed twice: the first time with a small increase in the controller output and the second time with a small decrease. This allows for calculation of the change of the future process value (and thus the change of the future error) as a function of the change in the current controller output. The controller output is then modified by

$$\Delta U(t) = -G_{net} \cdot E_f(t) \frac{\partial E_f(t)}{\partial U(t)}$$

where E_f is the future error and G_{net} is the network controller gain. For a multiple-output controller, the additional outputs are simply added as more outputs of the network and the future predictions repeated several times to find the correct partial derivatives.

Many different variations on this theme are possible — for example, using the sum of the absolute values of all the errors over the prediction window (or the sum of the square of the errors, etc.) instead of simply the future error. Computer simulated results of such tests are provided by Curtiss et al. (1993c).

Estimating Size of the Prediction Time Window

It is possible to use the network model to determine the size of the time window by estimating the amount of time required for the process to reach some future steady state after a simulated change in the controller output. An example of such an open-loop response is shown in Figure 6.5.5. Here the

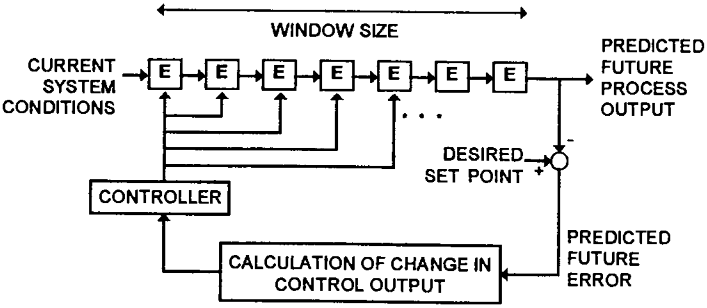

FIGURE 6.5.4 Schematic of procedure for determining future process value and error.

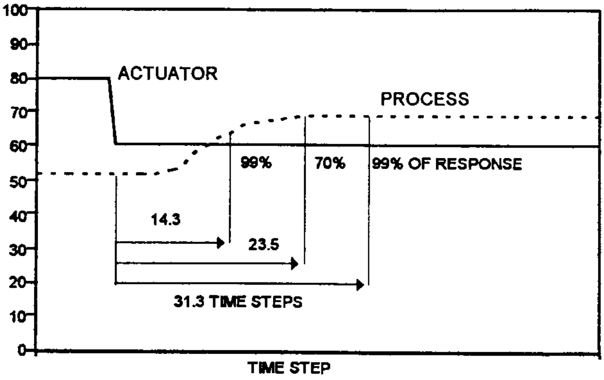

FIGURE 6.5.5 Example of computer-simulated process step change (used to determine size of time window.)

network is simulating the response of a reverse-acting process after a decrease in actuator position at time step 0. About 70% (ln2) of total rise time is achieved after 15 time steps. This kind of calculation can be performed during the control sequence and should indicate the proper time window size.

Example of PID vs. Network Controller

Figure 6.5.6 shows an example of a process under PID control that demonstrates nonlinearity at different ranges of actuator position. Figure 6.5.7 shows the same process under the influence of a predictive neural network controller that had been trained on the process. Note that the network-based controller does not show the same problems of unstable control in certain actuator ranges. The size of the time window (15 time steps) was determined using the method discussed in the previous subsection.

Using Networks as Supervisory Controllers

The previous section discussed the use of neural networks to minimize a predicted error of a feedback-loop process. It is possible to apply a similar methodology for supervisory plant control to optimize the process according to some cost function. A network is first trained to predict the cost function under a wide range of operating conditions. This network is then used to predict what will happen with different control strategies. Figure 6.5.8 shows a schematic of this technique. The left side of the figure shows the training mode, where the network is attempting to associate the various plant inputs with the cost function output. There can be multiple inputs, including uncontrollable variables (e.g., ambient conditions, plant loads, etc.) and controlled variables (i.e., the various process setpoints.)

Once the network is sufficiently trained, it is used to find values for the setpoints under any set of uncontrolled variables. The technique for doing so is similar to the back-propagation training technique of the network. The inputs corresponding to the controlled variables are replaced with *virtual nodes*

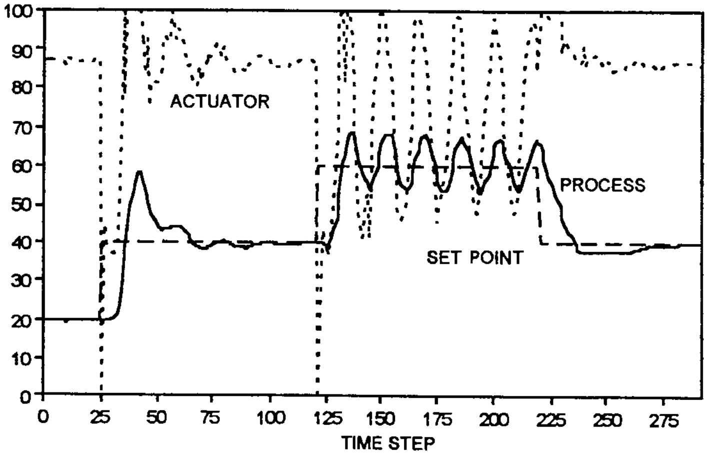

FIGURE 6.5.6 Example of computer simulation using PID controller.

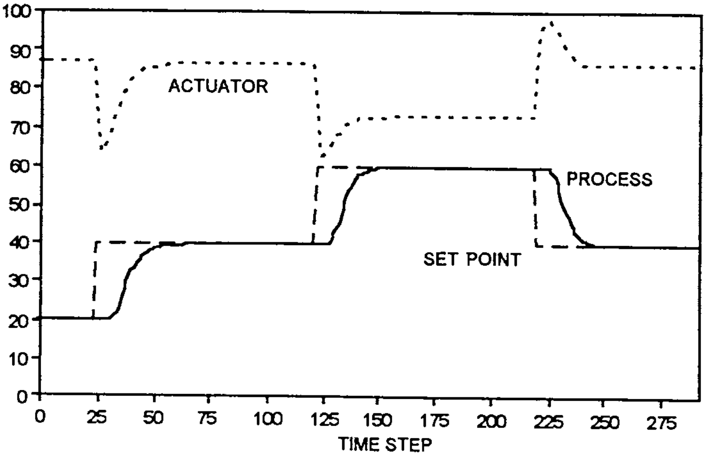

FIGURE 6.5.7 Example of computer simulation using neural network controller.

whose outputs are always unity. These nodes are connected to the predictor network through adjustable weights.

The optimization occurs by finding values for these weights that allow the model to predict a desired output. These weights can be found through any number of search methods, including the gradient descent technique used in back-propagation training. In this case, the predictor network is "trained" normally, except that all weights in the network are static except those connected to the virtual nodes. Once weights have been found that produce the desired output, the setpoints can be found from direct interpretation of these weights. Constraints can be imposed on the weights through physical limitations (e.g., freezing points) or from predictions from local-loop neural network controllers.

Fuzzy Logic Controllers

Fuzzy logic controllers use conditional relationships to analyze one or more inputs — that is, the inputs are subject to a series of *if…then* queries to produce some intermediate values. An example would be something like a simple cruise control on an automobile:

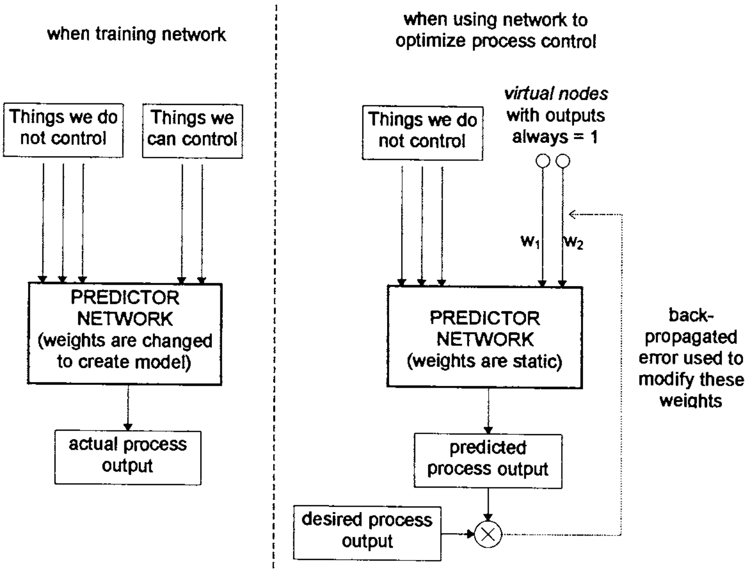

FIGURE 6.5.8 Using network model to optimize process control.

- *If* vehicle speed = much lower than setpoint, *then* need to increase speed = large
- *If* vehicle speed = slightly lower than setpoint, *then* need to increase speed = small

These intermediate values are then used to determine the actual change of speed in the car:

- *If* need to increase speed = large, *then* increase of throttle position = 10%
- *If* need to increase speed = small, *then* increase of throttle position = 3%

In fuzzy control, the satisfaction of a particular *if* statement may not lead to or be restricted by a true or false response. A range of weighting coefficients is assigned to a particular conditional, with the coefficients generally decreasing as the certainty of a specific condition decreases.

In the preceding example, "need to increase speed = large" may be assigned a certainty of 1 when the speed of the vehicle is less than 50% of the desired speed of the car. This certainty will decrease as the speed of the car increases, so that "need to increase speed = large" may be 0 when the speed of the car is greater than 90% of the desired speed, but the certainty of "need to increase speed = small" will be large. It is possible that, for a given speed of the car, two or more conditions may be satisfied with different magnitudes of certainty. These conditions can then be applied to the output rules along with their respective certainties to determine the actual increase (or decrease) in the controller output. When the speed of the car is below the desired speed, the initial rules may yield, for example:

- Need to increase speed = large with certainty = 0.3
- Need to increase speed = small with certainty = 0.7

The actual output would then be

$$\text{Increase of throttle position} = (0.3 \times 10\% + 0.7 \times 3\%)/(0.3 + 0.7) = 5.1\%$$

The following subsection formalizes some of these ideas and includes a detailed example. The chapter on mathematics contains the formalism underlying fuzzy set theory and fuzzy logic. The reader is referred to that chapter and one that follows for the technical basis for fuzzy logic controllers.

Fuzzy Logic Controllers for Mechanical Systems

Introduction

In the last decade, fuzzy logic controllers (FLCs) have been receiving more attention (Daley and Gill, 1985; Leigh and Wetton, 1983; Xu, 1989; Yasunobu and Miyamoto, 1985), not only in test cases but also in real industrial process control applications, including building mechanical systems (Meijer, 1992; Sakai and Ohkusa, 1985; Ono et al., 1989; Togai and Maski 1991; Huang and Nelson, 1991). The basic idea of this approach is to incorporate the experience of human operators in the design of controllers. From a set of linguistic rules describing operators' control strategies, a control algorithm can be constructed (Ralston and Ward, 1985).

Computer simulations and experiments have shown that FLCs may have better performance than those obtained by conventional controllers. In particular, FLCs appear very useful when the processes are too complex for analysis using conventional control algorithms or when the available information is qualitative, inexact, or uncertain. Thus, fuzzy logic control may be viewed as a compromise between conventional precise mathematical control and human-like decision making, as indicated by Gupta (Gupta and Tsukamoto, 1980).

However, fuzzy logic controllers sometimes fail to obtain satisfactory results with the initial rule set drawn from the operators' experiences. This is because some differences exist between the way a plant is operated by an experienced operator and by a fuzzy logic controller using the rules based directly on his experience. It is often difficult to express human experience exactly using linguistic rules in a simple form. Sometimes no experience is available that can be used to construct control rules for FLCs. In these cases, it is necessary to design, develop, and modify control rules for FLCs to obtain optimal performance. Few discussions have been undertaken about rule development and adjustment strategies for FLCs (Scharf and Mandic, 1985; Ollero and Williams, 1989; Sheridah, 1984; Wakileh and Gill, 1988).

Basic Aspects of an FLC

An FLC includes three parts: fuzzifier; fuzzy reasoning unit; and defuzzifier. The fuzzifier converts ordinary inputs into their fuzzy counterparts; the fuzzy reasoning unit creates fuzzy control signals based on these fuzzy variables and the defuzzifier converts the fuzzy control signals into the real control outputs. The block diagram of a fuzzy control system is shown in Figure 6.5.9, where e, d, and u are tracking error, derivative error, and output control action; $\tilde{e}$, $\tilde{d}$, and $\tilde{u}$ are their fuzzy counterparts, respectively; y is the controlled parameter; and r is the set point for y. K_p is the scale factor for e; K_d is the scale factor for d; and K_o is the output gain.

The control rules expressed in natural language are expressed in the following form:

$$\text{IF } (e \text{ is } A) \text{ AND } (d \text{ is } B) \text{ THEN } (u \text{ is } C)$$

where A, B, and C are fuzzy subsets defined on the universes of discourse of e, d, and u, respectively. Every rule is interpreted into a fuzzy reasoning matrix:

$$R_k = \left[A_k(e) \otimes B_k(d) \right]^{\Theta} \otimes C_k(u) \qquad k = (1, N)$$

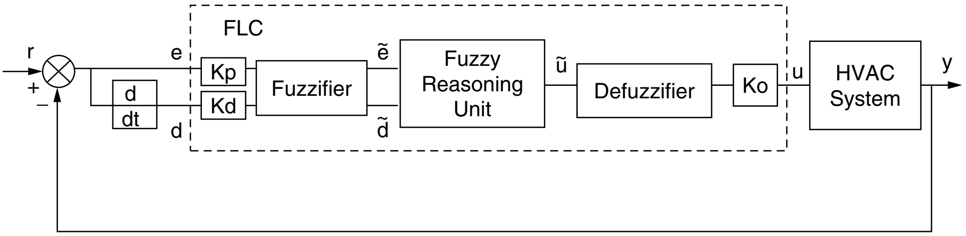

FIGURE 6.5.9 The block diagram of a fuzzy control system.

TABLE 6.5.1 The Membership Function of Input of FLC

$A(e)$, $B(d)$	–6	–5	–4	–3	–2	–1	0	1	2	3	4	5	6

NL	1.0	0.8	0.5	0.1	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0

where N is the number of rules, the symbol $\otimes$ denotes aggregation operator, and the symbol Θ denotes an align-turning operator (see Chap. 19). The general fuzzy relation matrix R can be constructed as the union of the individual rules:

$$R = \bigcup_{k=1}^{N} R_k$$

This matrix represents the relationship between the fuzzy inputs and the fuzzy control output. The fuzzy control output can then be calculated from the known fuzzy input $\tilde{e}$ and $\tilde{d}$ by:

$$\tilde{u} = \left[\tilde{e} \otimes \tilde{d}\right]^{\Theta} \circ R$$

where the symbol $\circ$ denotes the max–min composition operator (see Chapter 19).

The input universe of discourse for tracking error e or derivative error d is divided into several degrees connected with a number of fuzzy subsets by membership functions. In this study, e and d can each range from –6 to +6, and 13 degrees are used:

–6, –5, –4, –3, –2, –1, 0, 1, 2, 3, 4, 5, 6.

Also, seven fuzzy subsets are defined as:

NL, NM, NS, ZZ, PS, PM, PL

where the first letters N and P mean negative and positive; the second letters L, M, and S mean large, middle, and small; and ZZ means zero.

These degrees and fuzzy subsets are shown in Table 6.5.1, which uses a 1.0-0.8-0.5-0.1 distribution. For example, if $e = 3$, then its membership in PL is 0.1, its membership in PM is 0.8, etc. A similar analysis is given to the outputs for the control action indicated in Table 6.5.2, which uses a 1.0-0.7-0.2 distribution.

The fuzzifier converts ordinary inputs into their fuzzy counterparts. In this study, a fuzzy singleton is used as a fuzzification strategy, which interprets an input, e (or d), into a fuzzy value, $\tilde{e}$ (or $\tilde{d}$), with membership function (μ) equal to zero except at the element nearest to the real input, where $\mu = 1.0$. For example, if $e = 3.2$ and the nearest element is 3, then the fuzzy singleton will be:

$$\tilde{d} = (0, 0, 0, 0, 0, 0, 0, 0, 0, 1, 0, 0, 0.)$$

This fuzzy singleton has membership function $\mu = 1.0$ at the point of element $e = 3$. The defuzzifier converts the fuzzy control output created by the rule-based fuzzy reasoning unit into a real control action. In this study, weighted combination method is used as defuzzification strategy, which can be explained by the following example:

TABLE 6.5.2 The Membership Function of Output of FLC

$C(u)$	–6	–5	–4	–3	–2	–1	0	1	2	3	4	5	6

Note: Abbreviations mean that the output control actions are Very Strong; Strong; SUbstrong; Medium; Slightly Small; Small; and TIny.

If

$$\tilde{u} = (0, 0, 0, 0, 0, 0, 0, 0.2, 0.4, 0.8, 0.7, 0.5, 0.1.)$$

then

$$u = [0.2(1) + 0.4(2) + 0.8(3) + 0.7(4) + 0.5(5) + 0.1(6)]/[0.2 + 0.4 + 0.8 + 0.7 + 0.5 + 0.1] = 3.4$$

Rule Refinement

An FLC is characterized by a set of linguistic statements that are usually in the form of "if–then"' rules. The initial set of rules is usually constructed based on the operators' experiences, or sometimes by analyzing the dynamic process of the controlled plant. Both approaches require modifying the initial set of rules to obtain an optimal rule set. This is called *rule refinement*.

Figure 6.5.10 shows an initial rule set analyzed on a "linguistic plane." The horizontal axis expresses the fuzzy subsets defined on the universe of discourse for the tracking error (e), and the vertical axis expresses the fuzzy subsets defined on the universe of discourse for the derivative error (d). Both have seven fuzzy "values": NL, NM, NS, ZZ, PS, PM, and PL. Output control action levels are on the cross points of these fuzzy values; these are also fuzzy subsets having seven values from level 1 (tiny) to level 7 (very strong). For example, the cross point of e = NM and d = PM indicates u = level 5. This corresponds to the rule:

IF (e is NM) AND (d is PM) THEN (u is level 5)

For example, the initial rule set could be based on the following control strategies. First, it tries to keep a proportional relationship between the control action (u) and the tracking error (e). Note that if the derivative error (d) is ZZ, then the output control action (u) increases from level 1 to level 7 when the tracking error (e) changes from NL to PL. Second, the influence of derivative error (d) is considered such that if it is positive, then the control action (u) is increased a little bit, and if it is negative, then the control action (u) is decreased. For example, if the tracking error (e) keeps PM, the control action (u) increases from level 6 to level 7 when the derivative error (d) is positive, and it decreases from level 6 to level 5 when the derivative error (d) is negative.

Consider a second order plant with a transfer function:

$$H(s) = \frac{1.0}{s^2 + 0.1s + 1.0}$$

that is controlled using the initial rule set to respond to a step input for computer simulation.

The performance trajectory of the FLC is shown by the arrows in Figure 6.5.10 and the dynamic process of the normalized controlled parameter (CP) is shown in Figure 6.5.11, where the horizontal axis indicates the number of sample period (SP). The dynamic process can be divided into two stages.

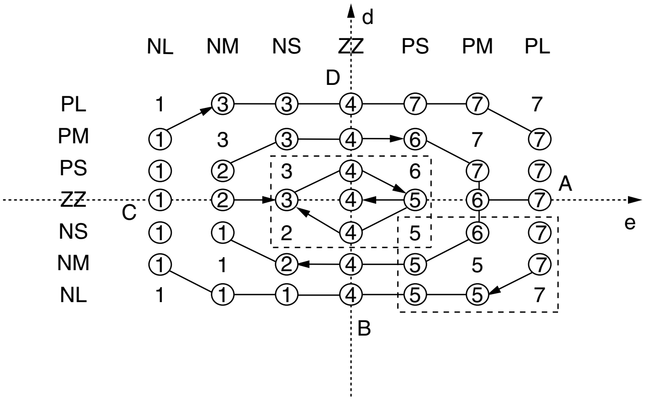

FIGURE 6.5.10 The initial rule set and performance trajectory on the linguistic plane.

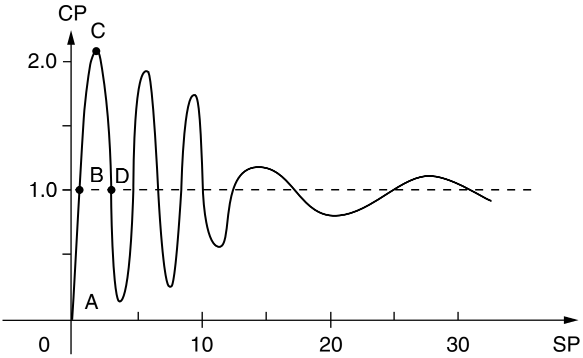

FIGURE 6.5.11 The dynamic process corresponding to Figure 6.5.10.

At the first stage, there is a strong oscillation with a higher frequency and, at the second stage, there is a moderate swing with a smaller frequency. Looking at the performance trajectory in the linguistic plane reveals that the stronger oscillation occurs at the out-cycle (points further from the center). As time increases, the state moves to the in-cycle near the center of the plane and becomes moderate. This shows that FLCs have the desirable property of a structure-variable controller. The rules at the out-cycle belong to one kind of structure for the first stage, and the rules at the in-cycle belong to another structure for the second stage.

If the initial rule set does not satisfy a good design for a controller, then it can be modified by intuitive reasoning. A rule set is often symmetrically positioned about the central point, which is the desired stable operating point at which the tracking error (e) and the derivative error (d) equal zero and the control action (u) is medium. When a positive step increase is imposed to the set point, the tracking error (e) has the biggest value and the derivative error (d) is zero at the beginning time (point A in the linguistic plane). With the regulating action, the tracking error (e) will decrease, the derivative error (d) will be negative, and the performance trajectory will enter into the right-bottom block in the linguistic plane. Thus, the rules in this area have the most important effect on the behavior of the first stage of the dynamic process. The most important area responsible for the behavior of the second stage is the central block.

To avoid strong oscillations, it is apparent that the control actions in the right-bottom block should be decreased. The modified rule set and its simulation of response to a step input are shown in Figure 6.5.12. The performance trajectory expressed in the linguistic plane is just like spiral (Figure 6.5.12). It can be seen that the performance of the control system has been improved, but a small oscillation still exists and a little overshoot is indicated by point C in Figure 6.5.13. Once again, the rule set is modified and the final rule set and its simulation of response to a step input are shown in Figure 6.5.16 and Figure 6.5.17.

	NL	NM	NS	ZZ	PS	PM	PL

NL	1	1	1	2	3	③	5

FIGURE 6.5.14 The third rule set on the linguistic plane.

The final rule set gives good performance with a short rise time and a very small overshoot and is considered satisfactory.

By analyzing the performance trajectory on the linguistic plane, a rule set is refined. It relies heavily on intuitive reasoning when comparing the dynamic process of the controlled parameter for the present rule set with the desired one.

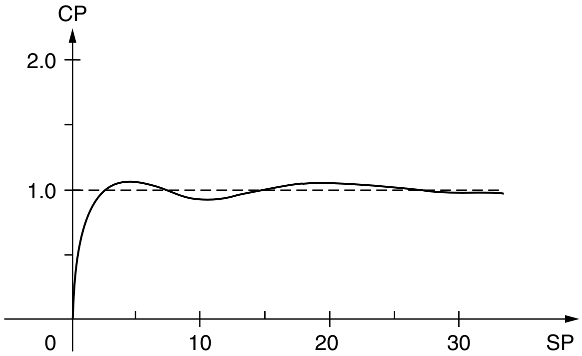

FIGURE 6.5.15 The dynamic process corresponding to Figure 6.5.14.

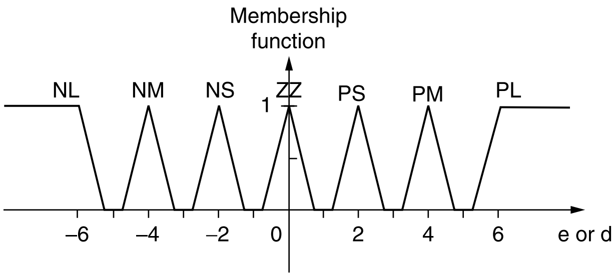

FIGURE 6.5.16 Noncomplete membership function.

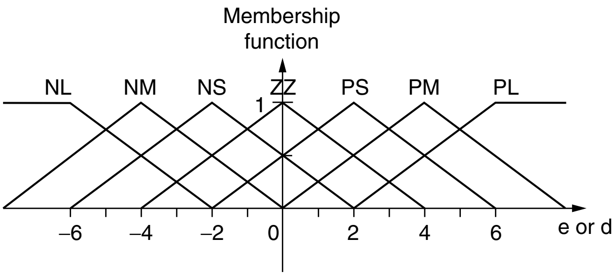

FIGURE 6.5.17 Heavy overlap membership function.

Completeness and Interaction of Rules and Selection of Membership Functions

The second significant influence on the behavior of an FLC is the membership functions. They should be chosen carefully in the adjustment process. As mentioned previously, the fuzzy subsets, language variables, NL, NM, NS, ZZ, PS, PM, and PL, are defined on the universe discourse of tracking error (e) or derivative error (d). Some possible membership functions are shown in Figure 6.5.16 through Figure 6.5.18. The membership functions should be chosen to make these language variables have suitable coverage on the universe of discourse.

For the case of Figure 6.5.16, the whole range is not covered by these language variables. For some values of e or d, the membership functions of all language variables are zero. In this case, an empty output control action could be created. This means that the control actions are lost for those points not covered by any input fuzzy subset. This is referred to as the noncompleteness of control rules. FLCs should satisfy the condition of completeness for their membership functions; the membership function shown in Figure 6.5.17 cannot be used for an effective fuzzy logic controller. In other words, the union of all fuzzy subsets, X_i, i = [1,7], should be greater than zero for all e $\in$ E, i.e.,

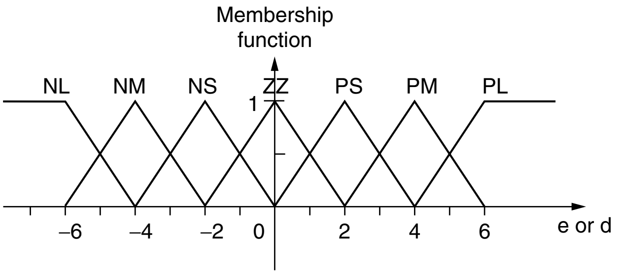

FIGURE 6.5.18 Moderate overlap membership function.

$$\forall e \in E \qquad \bigcup_{i=1}^{7} X_i(e) > 0$$

On the other hand, interaction can take place among the rules if the overlap of fuzzy subsets occurs on the range of the universe of discourse. In this case, the membership functions have the forms shown in Figure 6.5.17 and Figure 6.5.18. The interaction tends to smooth out the set of control rules. Consider the single-input–single-output case for simplicity. The rule set is:

$$\text{IF } (e \text{ is } A_i), \text{ THEN } (u \text{ is } C_i) \; i = [1,\mathrm{N}]$$

where N is the number of rules in the set. These rules are incorporated into a fuzzy relation matrix as follows:

$$R = \bigcup_{i=1}^{N} R_i = \bigcup_{i=1}^{N} \left(A_i \otimes C_i \right)$$

If the fuzzy value of input e is known as $\tilde{e}$, the fuzzy output $\tilde{u}$ then can be calculated as follows:

$$\tilde{u} = \tilde{e} \circ R$$

If $\tilde{e}$ is A_i, $\tilde{u}$ is expected to be C_i. However, now the interaction of rules due to overlap results in:

$$C_i \subseteq A_i \circ R$$

The equality is established only when no overlap occurs. This analysis is based on the fuzzy logic scheme including max–min composition operator. A more detailed example of the numeric calculation is given in the next subsection.

If the overlap is heavy, as shown in Figure 6.5.17, large deformation will occur and the control rules will lose their original shape. In the limit, as the membership functions become unity for all values, the output of the FLC will always be the same fuzzy quantity. This means that the fuzzy reasoning system conveys no valuable information and the FLC has lost its efficacy.

A moderate overlap, shown in Figure 6.5.18, is desirable to allow for reasoning with uncertainty and the need for completeness of the control rules. How does one determine the "size" of overlap? At present, intuitive judgment is used to choose membership functions when adjusting an FLC. There appears to be some latitude in choosing the amount of overlap on which the performance of an FLC does not change significantly. The quantitative analysis will be given after further research.

When the control rules are modified in the linguistic plane, the overlapping membership functions let the rules near the performance trajectory have an effect on the output control actions. This is because interactions occur among the neighboring rules.

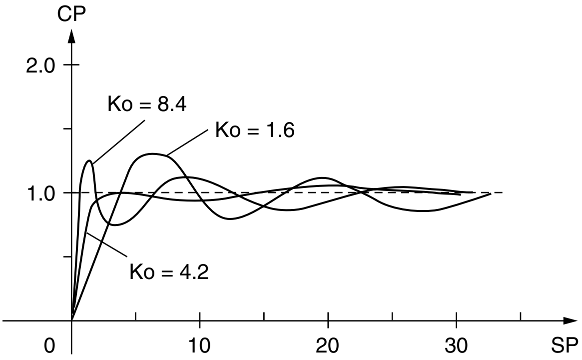

FIGURE 6.5.19 The influence of K_o on the behavior of FLCs.

Scale Factors and Output Gain

The scale factors, K_p and K_d, and the output gain, K_o, shown in Figure 6.5.19, also have significant influence on the behavior of an FLC. Their influence is not as complicated as those of rules and membership functions. The adjustment for the scale factors and output gain is comparatively simple.

The scale factor K_p relates the actual range of tracking error (e) to the universe of discourse (E) defined in the fuzzy logic system. In this work, E consists of 13 degrees as indicated earlier. Then K_p is determined as the ratio of the range of E to the range of the real variable:

$$K_p = \frac{E_{\max} - E_{\min}}{e_{\max} - e_{\min}}$$

For scale factor K_d, similar analysis leads to:

$$K_d = \frac{D_{\max} - D_{\min}}{d_{\max} - d_{\min}} \tag{6.5.1}$$

where D is the universe of discourse for derivative error (d) defined in the fuzzy logic system. Small K_p or K_d will narrow the control band, while large K_p or K_d will lead to loss of control for large inputs.

The output gain K_o is defined as follows:

$$K_o = \frac{u_{\max} - u_{\min}}{U_{\max} - U_{\min}} \tag{6.5.2}$$

This is the ratio of range of real output control action (u) to the range of its universe of discourse (U) defined in the fuzzy logic system. K_o acts as an amplification factor of the whole FLC.

Figure 6.5.19 shows the influence of K_o on the step response simulation of an FLC with the final rule set used in Figure 6.5.14. Increasing K_o results in a shorter rise time. The performance trajectory in the linguistic plane will become steeper for the first stage and oscillation occurs. Decreasing K_o results in a longer rise time and the performance trajectory in the linguistic plane will become moderate during the first stage. However, in this simulation, oscillation still occurred. This is because different K_o, larger or smaller, results in a new route of the performance trajectory, which will activate the different rules that might cause oscillation. Therefore, the influence of output gain, K_o, should be considered together with the change of the activated rules.

Conclusion

A fuzzy logic controller can perform much better than a conventional one, such as a PID controller, if the FLC has been well constructed. The main disadvantage of using FLCs today seems to be the lack of a systematic procedure for the design of FLCs. The general method for designing an FLC is to use trial and observation. No useful mathematical tool has yet been developed for the design of an FLC because of its fuzziness, complexity, and nonparameterization.

Three significant elements have notable influence on the behavior of a fuzzy logic controller:

- Control rules expressed in linguistic language
- Membership functions defined for fuzzy subsets
- Scale factors attached to the input and the output gains

The control rules play the main role in forming the dynamics of FLCs. The rule set can be analyzed and modified using the performance trajectory technique and evaluated using the dynamic process curve of the controlled parameter. The membership functions define the "shape" of fuzzy subsets. They should have appropriate width to avoid noncompleteness and suitable interaction among the fuzzy control rules. The scale factors (K_p and K_d) and output gain (K_o) serve as amplification factors.

At present, each application must be individually designed. The initial sets of rules are specifically set up for different applications. Work is now under way to develop a self-adaptive fuzzy logic controller, which will choose the initial set of rules automatically according to the process dynamics and refine it on the basis of the global performance evaluation.

6.6 Control of Distributed Generation Technologies

Peter S. Curtiss and Jan F. Kreider

Distributed power generation (DG) is any small-scale power generation technology that provides electric power at a site closer to customers than central station generation; it is usually interconnected to the distribution system or directly to the customer's facilities (Curtiss et al., 1999). Distributed generation technologies include small combustion turbine generators; internal combustion; reciprocating engines and generators; photovoltaic panels; wind turbines; and fuel cells. Table 6.6.1 provides an overview of feasible DG technologies using present or near-future technologies.

Distributed generation can provide a multitude of services to utilities and consumers, including standby generation; peak shaving capability; baseload generation; or cogeneration. Less well-understood benefits including ancillary services such as voltage/VAR support, network stability, and others may ultimately be of more economic benefit than simple energy-related benefits.

Electric restructuring has spurred the consideration of DG power because the buyers and sellers of electricity will need to be more responsive to market forces. Central utilities suffer from the burden of significant stranded costs; however, DG avoids this cost. DG is a priority in parts of the country where the spinning reserve margins are shrinking, where industrial and commercial users and transmission and distribution (T&D) constraints are limiting power flows (DCPA, 1998).

TABLE 6.6.1 Summary of Distributed Generation Technologies

	IC Engine	Turbine	PVs	Wind Turbine	Fuel Cells
Dispatchable	Yes	Yes	No	No	Yes
Capacity range (MW)	0.05–5	0.025–25	0.001–1	0.01–1	0.2–2
Efficiency	35%	15–35%	6–19%	25%	30–55%
Capital cost ($/kW)	200–350	450–850	~6000	~1000	~3500
O&M cost (¢/kWh)	~1	0.5–0.65	0.1–0.4	~1	0.1–0.2

Notes: Efficiencies of fossil and renewable DG technologies are not directly comparable. O&M costs do not include fuel.

Control Techniques

The control techniques chosen for distributed generation will depend on the type of equipment installed (Curtiss, 2000). In the case of wind or solar power generation, the main goal is to get as much energy out of the system as possible in order to recoup the installation cost. For combustion-based processes, however, the cost of fuel and maintenance must also be taken into account. The goal of the control scheme is to determine whether the on-site generation should be operating during a particular hour. Generally, a simple hour-ahead control method is sufficient if the start-up transients of the generator are not too inefficient. Otherwise, it is necessary to develop methods that perform a certain degree of prediction to determine the effects of scheduled dispatch over the period of several hours or even several days.

Threshold Control

In threshold control, the turbines run whenever the building electrical load is greater than a predetermined threshold. The number of turbines initially installed is equal to the difference between the annual peak and the threshold, divided by the nominal power output of each installed unit:

$$Number\ installed = \frac{kW_{PEAK} - kW_{THRESHOLD}}{kW_{UNIT}}$$

If the electrical load of the building is greater than the threshold, then the number of turbines operating is equal to that required to reduce the grid load to the threshold limit:

$$Number\ operating = \frac{kW_{BUILDING} - kW_{THRESHOLD}}{kW_{UNIT}}$$

A problem with this control method is deciding where to assign the threshold limit. A high limit means the turbine is used for peak shaving and will reduce the number of operating hours. A low limit forces the generators to run more often and is akin to base loading. A threshold of zero indicates that the generators would try to operate whenever possible. This specific case is referred to as *always-on* control.

Buyback Priority

Buyback priority is used in cases in which the building operator wishes to produce electricity and sell any or all of the produced power back to the utility. There are two versions of buyback control; one takes advantage of a simple buyback rate and the other responds to net metering, in which the value of produced power is used to offset the traditional electrical bill.

Simple Buyback

In the case of simple buyback the generators would normally use the threshold control scheme as described previously. If the buyback cost is greater than the equivalent cost of gas, then all the generators run and the excess is sold to the utility. The number of turbines installed depends on the projected income the building operator expects to make from selling electricity. The control method finds the incremental sum of all fuel used to get the total cost for the hour:

$$\text{Total cost} = \Delta\$\text{kWh}_{\text{GRID}} + \Delta\$\text{Btu}_{\text{GRID}} - \Delta\$\text{kWh}_{\text{BUYBACK}}$$

The Δ$ term implies that the non-RTP gas and electric costs are evaluated on a monthly (i.e., billing period) incremental basis. For example, the change of the grid electricity bill is

$$\Delta\$\text{kWh}_{\text{GRID}} = \text{M}\$(\text{kWh}_1, \text{kWh}_2, \ldots, \text{kWh}_{N-1}) - \text{M}\$(\text{kWh}_1, \text{kWh}_2, \ldots, \text{kWh}_N)$$

where M$ is the monthly bill amount (including consumption and demand fees, surcharges, and taxes) based on *N* hourly electricity use values for that billing period. This allows the true bills to be calculated, including any time-of-use and block components.

Unfortunately, these latter components also affect the linearity of the cost function — the cost function is not necessarily linear under these conditions. The algorithm for determining whether to use buyback, therefore, should (1) determine the loads on the building for a given hour; (2) calculate the total cost function for all integral numbers of generators operating, from zero to the number installed; and (3) find the number of generators, which minimizes the total cost function.

Net Metering Control

In the net metering scenario, the electrical meter "runs backwards" if excess electricity is produced on site. Once the meter reaches zero, buyback rates apply. As with the buyback priority control, the incremental sum of all fuel uses is calculated to get the total cost for the hour:

$$\text{Total cost} = \Delta\$\text{kWh}_{\text{GRID}} + \Delta\$\text{Btu}_{\text{GRID}} - \Delta\$\text{kWh}_{\text{BUYBACK}}.$$

The Δ$ terms are the incremental costs as discussed in the buyback priority control. Consequently, the control algorithm is the same as in the buyback priority with the exception that the $\Delta\$\text{kWh}_{\text{GRID}}$ term here refers to the adjusted (i.e., rolled back) meter usage and the $\Delta\$\text{kWh}_{\text{BUYBACK}}$ amount is decreased by the kWh that go into reducing $\Delta\$\text{kWh}_{\text{GRID}}$.

If the monthly sum is positive (i.e., more electricity has been used from the grid than produced on site), then the monthly bill is based on simple effective aggregation of hourly consumption plus demand and fees. Otherwise, the customer is refunded the value of excess electricity produced as dictated by buyback rate.

Cooling/Heating Priority Control

In some cases, distributed generation will be applied to satisfy a cooling load (through auxiliary absorption cooling or direct electrical connection to conventional cooling equipment) or a heating load (through heat recovery). In this mode of control, the generators operate primarily to satisfy these loads and the satisfaction of the electrical load is a secondary benefit. The number of generators installed is sufficient to meet the annual peak thermal load and the control algorithm has the generators operating as required to meet the thermal load of the building. No consideration is given to the value of electricity.

Optimal Control

Ideally, distributed generation would be operated using an algorithm that reduces the operating cost over the lifetime of the equipment such that the cost to the building operator is minimized. If the building is subject to a real-time pricing rate schedule then the optimization can be trivial; the costs of grid electricity and locally produced electricity are compared at each hour and, when the former is more expensive, the on-site generators are operated. However, more conventional rate structures such as block rates and time-of-use rates as accumulated over a billing period can make the calculation of instantaneous "next kWh" costs much more difficult. In this case, the electricity bill C_{ELEC} at any given hour is

$$C_{ELEC} = \Phi_{KWH}\begin{bmatrix} kWh_{BLDG}(1) - kWh_{GEN}(1) \\ kWh_{BLDG}(2) - kWh_{GEN}(2) \\ \cdots \\ kWh_{BLDG}(k) - kWh_{GEN}(k) \end{bmatrix}$$

$$+\Phi_{KW}\begin{bmatrix} kW_{BLDG}(1) - kW_{GEN}(1) \\ kW_{BLDG}(2) - kW_{GEN}(2) \\ \cdots \\ kW_{BLDG}(k) - kW_{GEN}(k) \end{bmatrix}$$

where Φ_{KWH} is the utility function used to calculate the bill based on consumption; Φ_{KW} is the function used for demand; $kWh_{BLDG}(1)$ is the total electric load at hour 1; $kWh_{GEN}(1)$ is the kWh offset from the on-site generation equipment at hour 1; and so forth.

The calculation must be performed for each hour of the billing period to account for the hourly building load, any time-of-use components of the utility rate, and any ambient temperature or solar dependencies of the generation equipment. If the generators use natural gas to produce electricity (an internal combustion engine, microturbine, or fuel cell), then a similar calculation is performed for the gas consumption. Assuming no demand component for gas, the total gas bill up to hour k of the billing period is given as

$$C_{GAS} = \Phi_{GAS} \begin{bmatrix} Btu_{BLDG}(1) + Btu_{GEN}(1) \\ Btu_{BLDG}(2) + Btu_{GEN}(2) \\ \cdots \\ Btu_{BLDG}(k) + Btu_{GEN}(k) \end{bmatrix}$$

where $\mathrm{Btu}_{\mathrm{GEN}}$ is the incremental gas consumption of the generation equipment at each hour. Note that $\mathrm{kWh}_{\mathrm{GEN}}$, $\mathrm{kW}_{\mathrm{GEN}}$, and $\mathrm{Btu}_{\mathrm{GEN}}$ can have zero values at any hour, depending on whether the generation equipment is operating for that hour. To determine if the generators should operate at hour $k + 1$, the total cost $C_{\mathrm{ELEC}} + C_{\mathrm{GAS}}$ should be evaluated twice: once using values for the terms $\mathrm{kWh}_{\mathrm{GEN}}$, $\mathrm{kW}_{\mathrm{GEN}}$, and $\mathrm{Btu}_{\mathrm{GEN}}$ based on the estimated generator performance and then again with these values set to zero. If the former is greater than the latter, then the generators should not be run for that hour.

Complete Optimization

The procedure just described is sufficient for performing an optimization based on a single type of generation equipment without accounting for any other inputs. To be truly optimal, however, the algorithm should account for any different capacities of generators installed, any utility incentives, and the variable operation and maintenance costs experienced during operation. Such an optimization uses an algorithm similar to that described here.

The structure and calculation methods used for the electricity and gas utility rate schedules must be known. The optimization routine must also be able to keep track of all data acquired during a given billing period and provide cost estimates for the current hour. Any utility-sponsored incentives and rebates should be tallied, along with the method of their application (e.g., by kilowatt hours produced, kilowatts installed, etc.)

At each hour of the billing period, the optimization routine determines the number of generators that should run for that hour. This requires a prediction of the building load data for that hour, including:

- whole building kWh use
- whole building Btu use
- kWh used for domestic water heating
- Btu used for domestic water heating
- kWh used for space heating
- Btu used for space heating
- kWh used for space cooling

The electrical and thermal output from each generation device in the building must then be determined. This may require monitoring of the ambient temperature, wind speed, and insolation.

Parametrics are then run examining the benefit of operating each generator, accounting for any generators that may already be operating and for any part-load characteristics of generators that are not operating at full load. The cost function in the analysis is truly a cost function; the costs of providing on-site electrical and thermal costs are compared with those of grid consumption and the lowest-cost option is chosen. To assess these costs properly, the grid electricity consumption $\mathrm{kWh}_{\mathrm{GRID}}$ is adjusted by the decrease of grid electricity consumption due to distributed power generation:

$$\mathrm{kWh}_{\mathrm{GRID}} = \mathrm{kWh}_{\mathrm{BLDG}} - \mathrm{kWh}_{\mathrm{GEN}} - \mathrm{kWh}_{\mathrm{COOL}}$$

where kWh_{BLDG} is the building load and kWh_{GEN} is the amount of electricity from the generators. The term kWh_{COOL} is nonzero if the generator provides direct cooling through absorption cooling and must be corrected for the nominal efficiency of the conventional cooling equipment:

$$kWh_{COOL} = \frac{\sum \dot{Q}_{COOL}}{COP_{COOL}}$$

where the summation is taken over all devices that provide supplemental cooling.

If the distributed generation equipment includes any gas-fired devices, the incremental cost of natural gas consumption must also be taken into account,

$$\text{Btu}_{\text{GRID}} = \text{Btu}_{\text{BLDG}} + \text{Btu}_{\text{GEN}} - \text{Btu}_{\text{HEAT}}$$

where Btu_{BLDG} is the building load and Btu_{GEN} is the consumption of gas by the generators:

$$Btu_{GEN} = \sum W_{GEN}(PLR)$$

where the summation is taken over all devices that convert gas to electricity.

The work term must also be corrected by the part load efficiency of any generators that are not at full load. The term Btu_{HEAT} represents any credit that can be applied due to heat recovery from the generators that precludes the use of conventional space or water heating sources. As with the cooling term, this credit is adjusted by the nominal efficiency of the conventional sources:

$$Btu_{HEAT} = \frac{\sum \dot{Q}_{HEAT}}{\eta_{HEAT}}$$

The total operating cost can now be calculated from the incremental rates, incentives, and maintenance costs:

$$\begin{aligned}
C_{TOTAL} = \Phi_{KWH} &\begin{bmatrix} kWh_{BLDG}(1) - kWh_{GEN}(1) \\ kWh_{BLDG}(2) - kWh_{GEN}(2) \\ \vdots \\ kWh_{BLDG}(k) - kWh_{GEN}(k) \end{bmatrix} \\
+ \Phi_{KW} &\begin{bmatrix} kW_{BLDG}(1) - kW_{GEN}(1) \\ kW_{BLDG}(2) - kW_{GEN}(2) \\ \vdots \\ kW_{BLDG}(k) - kW_{GEN}(k) \end{bmatrix} \\
+ \Phi_{GAS} &\begin{bmatrix} Btu_{BLDG}(1) + Btu_{GEN}(1) \\ Btu_{BLDG}(2) + Btu_{GEN}(2) \\ \vdots \\ Btu_{BLDG}(k) + Btu_{GEN}(k) \end{bmatrix} \\
- \Phi_{CRED} &\left[\sum kWh_{GEN} \right] \\
+ \Phi_{O\&M} &\left[kW_{INST} + \sum kWh_{GEN} \right]
\end{aligned}$$

where Φ_{CRED} represents a positive cash flow based on any utility incentives that are provided, including transmission loss credits, wheeling charge credits, voltage support credits, etc. The term $\Phi_{O\&M}$ is used to account for any operation and maintenance costs that arise from operating the generation equipment.

Finally, a cost matrix is compiled that represents all reasonable combinations of generation available to that building. The combination with the lowest cost is chosen and implemented.

This chapter describes the primary as well as derived energy sources. The objective is to provide information on the extent, availability, measurements and estimation, properties, and limitations of each type of resource. These considerations are important for an engineer to know and understand before attempting selection and design of an energy conversion system. The chapter also includes environmental impacts of energy resources since the environmental aspects are expected to play a major role in the selection of energy resources. In addition, there is a brief discussion of the costs associated with each resource to help in the economic analysis and comparison of the resources.

The chapter starts with an introduction and background of a historical perspective on energy use and projections of the future energy needs in the U.S., the industrialized countries, and the world. The primary energy sources described in this chapter include fossil fuels such as coal, natural gas, petroleum (including their synthetic derivatives), biomass (including refuse-derived biomass fuels), nuclear, solar radiation, wind, geothermal, and ocean. In addition there is a brief section on derived energy sources including electricity. So, the terminology and units used for each energy resource and their equivalence are provided.

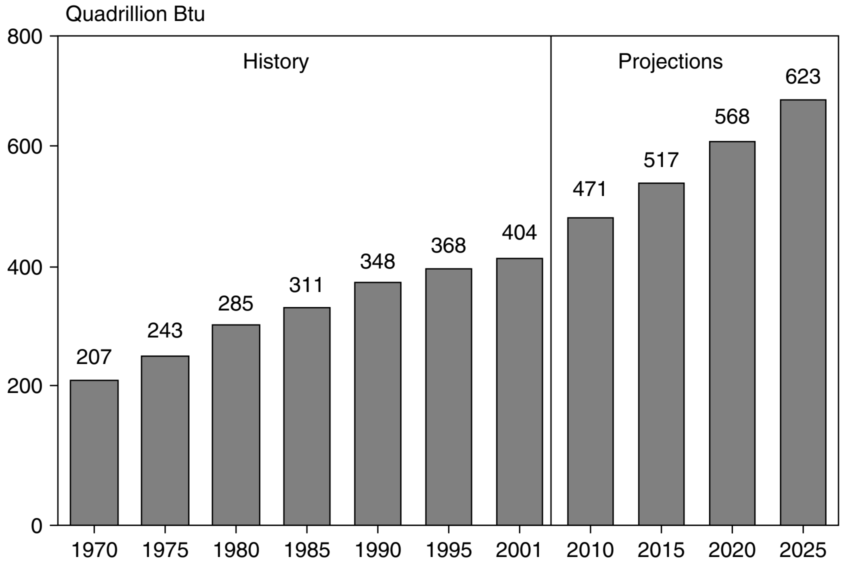

FIGURE 7.1.1 Historical and projected energy consumption. (From EIA. *International Energy Outlook 2001,* U.S. DOE, DOE/EIA-0484 (2001), Washington, D.C.)

7.1 Introduction

D. Yogi Goswami

Global energy consumption in the last 50 years has increased at a very rapid rate. Present trends in global population growth, rapid industrialization, and urbanization in major population centers of the world suggest that the world energy demand will continue to increase in the next 50 years (U.S. DOE, 2001). Figure 7.1.1 shows the historical and projected world energy consumption compiled by the Energy Information Agency.

The energy resources available to furfill the world demand include

Fossil fuels (oil, coal, natural gas)
Nuclear fuels
Geothermal
Solar radiation
Hydropower
Biomass (crops, wood, municipal solid waste)
Wind
Ocean

Out of all the energy resources, fossil fuels have been used the most (88% of total consumption) because of their extremely high energy densities and simplicity of conversion and use. Figure 7.1.2 shows the world energy consumption by resource.

Recent concerns about the environment are expected to increase the use of natural gas for power production. Renewable energy resources, such as solar energy, wind, and biomass, are also expected to increase their share of the energy use. There is a strong sentiment in the world in favor of exploiting renewable energy resources, especially because of environmental concerns. How far that sentiment translates into practical use will depend on the development of the renewable energy technologies and prices of the fossil fuels.

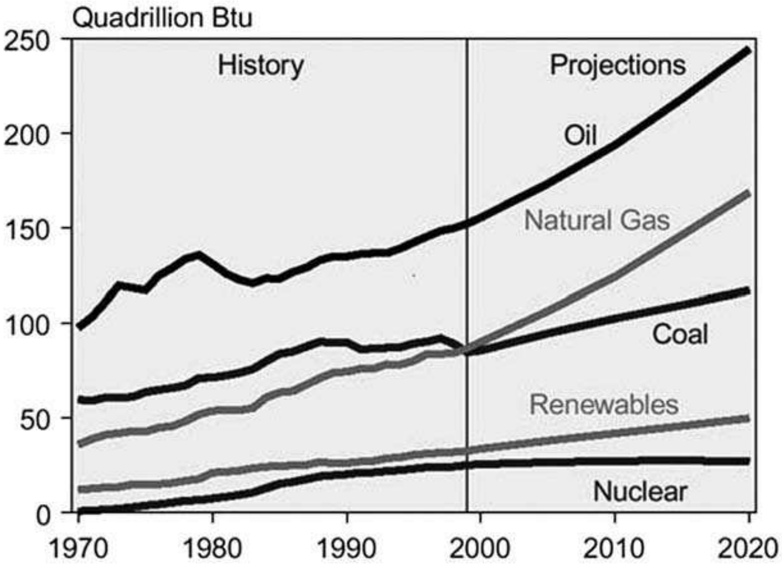

FIGURE 7.1.2 World energy consumption by resource. (From EIA. *International Energy Outlook 2001,* U.S. DOE, DOE/EIA-0484 (2001), Washington, D.C.)

Defining Terms

MTOE: Mega tons of oil equivalent; 1 MTOE = 42.63×10^{12} Btu.
Quadrillion Btu: 10^{15} British thermal units (Btu), also known as Quad; 1 Btu = 1055 joules).

7.2 Types of Derived Energy

D. Yogi Goswami

Energy from renewable and nonrenewable fuels can be converted to the derived energy forms — thermal, mechanical, and electrical, which are useful for various end uses such as transportation, buildings (heating, cooling, lighting), agricultural, and industrial. The derived energy forms are easily transformed from one type to the other. Figure 7.2.1 shows the projected U.S. energy use by end-use sector.

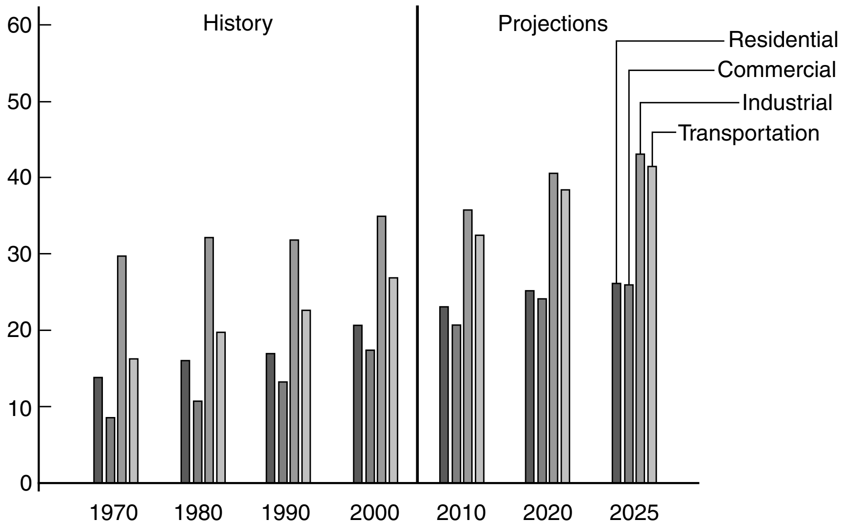

FIGURE 7.2.1 Projected U.S. energy use by end-use sector. (From EIA. *Annual Energy Outlook,* 2001, U.S. DOE, DOE/EIA-0383 (2001), Washington, D.C.)

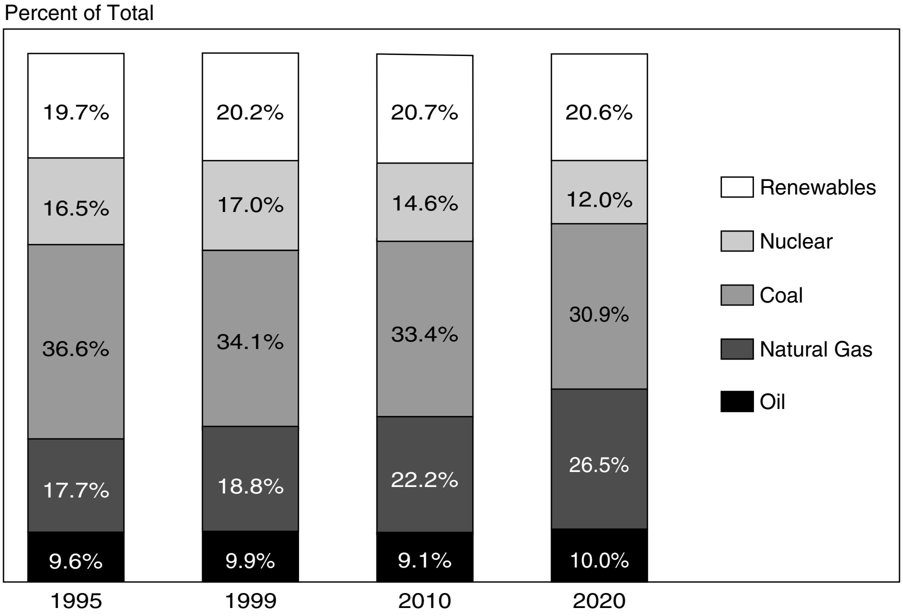

FIGURE 7.2.2 World electricity output. (From EIA. *International Energy Outlook,* 2001, U.S. DOE, DOE/EIA-0484 (2001), Washington, D.C.)

Transportation is mainly dependent on oil resources. Efforts to reduce urban air pollution are expected to increase the use of electricity as the preferred energy form for urban transportation. For most of the other end uses electricity will continue to be the preferred energy form. Therefore, it is important to understand the activity in the area of electricity production. Figure 7.2.2 shows the world installed electricity generation capacity by primary energy sources. The United States produces 770 GW (gigawatts), representing more than 25% of the world electricity capacity. Other major electricity producers are Russia, Europe, Japan, and China. It is expected that China, India, and Southeast Asian countries will add major electricity capacity in the next 20 years.

Integrated resource planning (IRP), or least-cost planning, is the process used to optimize the resource options and minimize the total consumer costs including environmental and health costs that may be attributed to the resource. IRP examines all of the options, including the demand-side options, to minimize the total costs. There is considerable emphasis on IRP in a number of states in United States for future electric capacity and on **demand-side management** (DSM) for the current capacity (Kreith and Burmeister, 1993). The IRP process generally includes some combination of the following steps (Kreith and Burmeister, 1993): development of a load forecast; inventory of existing resources; identification of additional electrical capacity needs; demand-side management programs; screening and identification of options that are feasible; uncertainty analysis in view of uncertainty of future load, fuel prices, capital costs, etc; and selection of a resource or a mix of resources.

Demand Side Management DSM refers to a mix of electrical utility-sponsored custom incentives and disincentives that influence the amount and timing of customer demand in order to better utilize the available resources. Kreith and Burmeister (1993) and SERI (1991) list a number of DSM strategies.

Defining Terms

Demand-side management (DSM): Refers to a mix of incentives and disincentives that influence the amount and timing of energy use in order to better utilize the available resources.

Integrated resource planning (IRP): The process to optimize the resource options and minimize the total consumer costs including environmental and health costs that may be all attributed to the resource.

7.3 Fossil Fuels

Coal

Robert Reuther

Coal Composition and Classification

Coal is a sedimentary rock formed by the accumulation and decay of organic substances, derived from plant tissues and exudates, which have been buried over periods of geological time, along with various mineral inclusions. Coal is classified by **type** and **rank.** Coal type classifies coal by the plant sources from which it was derived. Coal rank classifies coal by its degree of metamorphosis from the original plant sources and is therefore a measure of the age of the coal. The process of metamorphosis or aging is termed **coalification.**

The study of coal by type is known as coal petrography. Coal type is determined from the examination of polished sections of a coal sample using a reflected-light microscope. The degree of reflectance and the color of a sample are identified with specific residues of the original plant tissues. These various residues

TABLE 7.3.1 Coal Maceral Groups and Macerals

Maceral Group	Maceral	Derivation
Vitrinite	Collinite	Humic gels
	Telinite	Wood, bark, and cortical tissue
	Pseudovitrinite	? (Some observers place in the inertinite group)
Exinite	Sporinite	Fungal and other spores
	Cutinite	Leaf cuticles
	Alginite	Algal remains
Inertinite	Micrinite	Unspecified detrital matter, <0μ
	Macrinite	Unspecified detrital matter, 10–100 μ
	Semifusinite	"Burned" woody tissue, low reflectance
	Fusinite	"Burned" woody tissue, high reflectance
	Sclerotinite	Fungal sclerotia and mycelia

Source: Modified from Berkowitz, N., *An Introduction to Coal Technology*. Academic Press, New York, 1979. With permission.

are referred to as **macerals**. Macerals are collected into three main groups: vitrinite, inertinite, and exinite (sometimes referred to as liptinite). The maceral groups and their associated macerals are listed in Table 7.3.1, along with a description of the plant tissue from which each distinct maceral type is derived.

Coal rank is the most important property of coal because rank initiates the classification of coal for use. Coalification describes the process that the buried organic matter undergoes to become coal. When first buried, the organic matter has a certain elemental composition and organic structure. However, as the material becomes subjected to heat and pressure, the composition and structure slowly change. Certain structures are broken down, and others are formed. Some elements are lost through volatilization, while others are concentrated through a number of processes, including exposure to underground flows, which carry away some elements and deposit others. Coalification changes the values of various properties of coal. Thus, coal can be classified by rank through the measurement of one or more of these changing properties.

In the United States and Canada, the rank classification scheme defined by the American Society of Testing and Materials (ASTM) has become the standard. In this scheme, the properties of **gross calorific value** and **fixed carbon** or **volatile matter** content are used to classify a coal by rank. Gross calorific value is a measure of the energy content of the coal and is usually expressed in units of energy per unit mass. Calorific value increases as the coal proceeds through coalification. Fixed carbon content is a measure of the mass remaining after heating a dry coal sample under conditions specified by the ASTM.

Fixed carbon content also increases with coalification. The conditions specified for the measurement of fixed carbon content result in being able, alternatively, to use the volatile matter content of the coal, measured under dry, ash-free conditions, as a rank parameter. The rank of a coal proceeds from lignite, the "youngest" coal, through sub-bituminous, bituminous, and semibituminous, to anthracite, the "oldest" coal. The subdivisions within these rank categories are defined in Table 7.3.2. (Some rank schemes include meta-anthracite as a rank above, or "older" than, anthracite. Others prefer to classify such deposits as graphite — a minimal resource valuable primarily for uses other than as a fuel.)

According to the ASTM scheme, coals are ranked by calorific value up to the high-volatile A bituminous rank, which includes coals with calorific values (measured on a moist, mineral matter-free basis) greater than 14,000 Btu/lb (32,564 kJ/kg). At this point, fixed carbon content (measured on a dry, mineral matter-free basis) takes over as the rank parameter. Thus, a high-volatile A bituminous coal is defined as having a calorific value greater than 14,000 Btu/lb, but a fixed carbon content less than 69 wt%. The requirement for having two different properties with which to define rank arises because calorific value increases significantly through the lower-rank coals, but very little (in a relative sense) in the higher ranks; fixed carbon content has a wider range in higher rank coals, but little (relative) change in the lower ranks. The most widely used classification scheme outside North America is that developed under the jurisdiction of the International Standards Organization, Technical Committee 27, Solid Mineral Fuels.

TABLE 7.3.2 Classification of Coals by Rank

Coal Analysis and Properties

The composition of a coal is typically reported in terms of its **proximate analysis** and its **ultimate analysis**. The proximate analysis of a coal is made up of four constituents: volatile matter content; fixed carbon content; moisture content; and ash content, all of which are reported on a weight percent basis. The measurement of these four properties of a coal must be carried out according to strict specifications codified by the ASTM. Note that the four constituents of proximate analysis do not exist, per se, in the coal, but are measured as analytical results upon treating the coal sample to various conditions.

ASTM volatile matter released from coal includes carbon dioxide, inorganic sulfur- and nitrogen-containing species, and organic compounds. The percentages of these various compounds or species released from the coal varies with rank. Volatile matter content can typically be reported on a number of bases, such as moist; dry, mineral matter-free (dmmf); moist, mineral matter-free; moist, ash-free; and dry, ash-free (daf), depending on the condition of the coal on which the measurements were made.

Mineral matter and ash are two distinct entities. Coal does not contain ash, even though the ash content of a coal is reported as part of its proximate analysis. Instead, coal contains mineral matter, which can be present as distinct mineral entities or inclusions and as material intimately bound with the organic matrix of the coal. Ash, on the other hand, refers to the solid inorganic material remaining *after combusting* a coal sample. Proximate ash content is the ash remaining after the coal has been exposed to air under specific conditions codified in ASTM Standard Test Method D 3174. It is reported as the mass percent remaining upon combustion of the original sample on a dry or moist basis.

Moisture content refers to the mass of water released from the solid coal sample when it is heated under specific conditions of temperature and residence time as codified in ASTM Standard Test Method D 3173.

The fixed carbon content refers to the mass of organic matter remaining in the sample after the moisture and volatile matter are released. It is primarily made up of carbon. However, hydrogen, sulfur, and nitrogen also are typically present. It is reported by difference from the total of the volatile matter, ash, and moisture contents on a mass percent of the original coal sample basis. Alternatively, it can be reported on a dry basis; a dmmf basis; or a moist, mineral matter-free basis.

The values associated with a proximate analysis vary with rank. In general, volatile matter content decreases with increasing rank, while fixed carbon content correspondingly increases. Moisture and ash also decrease, in general, with rank. Typical values for proximate analyses as a function of the rank of a coal are provided in Table 7.3.3.

The ultimate analysis provides the composition of the organic fraction of coal on an elemental basis. Like the proximate analysis, the ultimate analysis can be reported on a moist or dry basis and on an ash-containing or ash-free basis. The moisture and ash reported in the ultimate analysis are found from the corresponding proximate analysis. Nearly every element on Earth can be found in coal. However, the important elements that occur in the organic fraction are limited to only a few. The most important of these include carbon; hydrogen; oxygen; sulfur; nitrogen; and, sometimes, chlorine. The scope, definition of the ultimate analysis, designation of applicable standards, and calculations for reporting results on different moisture bases can be found in ASTM Standard Test Method D 3176M. Typical values for the ultimate analysis for various ranks of coal found in the U.S. are provided in Table 7.3.4. Other important properties of coal include swelling, caking, and coking behavior; ash fusibility; reactivity; and calorific value.

Calorific value measures the energy available in a unit mass of coal sample. It is measured by ASTM Standard Test Method D 2015M, Gross Calorific Value of Solid Fuel by the Adiabatic Bomb Calorimeter, or by ASTM Standard Test Method D 3286, Gross Calorific Value of Solid Fuel by the Isothermal-Jacket Bomb Calorimeter. In the absence of a directly measured value, the gross calorific value, Q, of a coal (in Btu/lb) can be estimated using the Dulong formula (Elliott and Yohe, 1981):

$$Q = 14{,}544C + 62{,}028\left[H - \left(O/8\right)\right] + 4{,}050S$$

where C, H, O, and S are the mass fractions of carbon, hydrogen, oxygen, and sulfur, respectively, obtained from the ultimate analysis.

Swelling, caking, and coking all refer to the property of certain bituminous coals to change in size, composition, and, notably, strength, when slowly heated in an inert atmosphere to between 450 and 550 or 600°F. Under such conditions, the coal sample initially becomes soft and partially devolatilizes. With further heating, the sample takes on a fluid characteristic. During this fluid phase, further devolatilization causes the sample to swell. Still further heating results in the formation of a stable, porous, solid material with high strength. Several tests have been developed, based on this property, to measure the degree and suitability of a coal for various processes. Some of the more popular tests are the free swelling index (ASTM Test Method D 720); the Gray–King assay test (initially developed and extensively used in Great Britain); and the Gieseler plastometer test (ASTM Test Method D 2639), as well as a host of dilatometric methods (Habermehl et al., 1981).

The results of these tests are often correlated with the ability of a coal to form a coke suitable for iron making. In the iron-making process, the high carbon content and high surface area of the coke are used in reducing iron oxide to elemental iron. The solid coke must also be strong enough to provide the structural matrix upon which the reactions take place. Bituminous coals that have good coking properties are often referred to as metallurgical coals. (Bituminous coals without this property are, alternatively, referred to as steam coals because of their historically important use in raising steam for conversion to mechanical energy or electricity generation.)

Ash fusibility is another important property of coals. This is a measure of the temperature range over which the mineral matter in the coal begins to soften, eventually to melt into a slag, and to fuse together. This phenomenon is important in combustion processes; it determines if and at what point the resultant ash becomes soft enough to stick to heat exchanger tubes and other boiler surfaces or at what temperature it becomes molten so that it flows (as slag), making removal as a liquid from the bottom of a combustor possible.

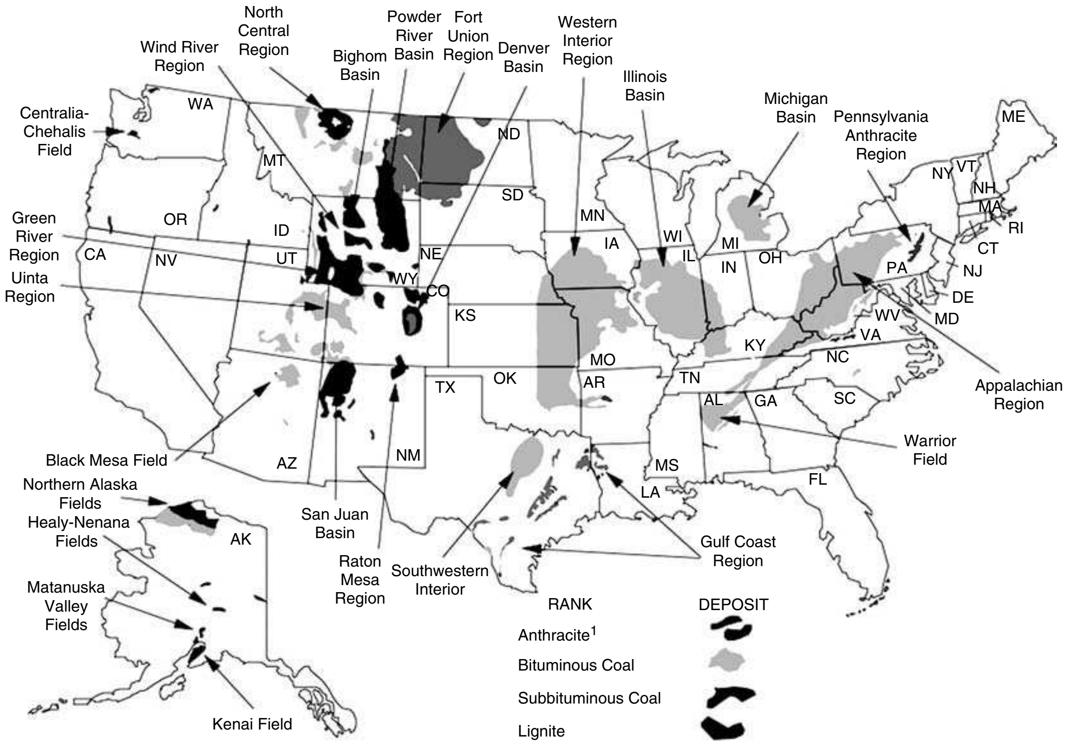
Reactivity of a coal is a very important property fundamental to all coal conversion processes (such as combustion, gasification, and liquefaction). In general, lower rank coals are more reactive than higher rank coals. This is due to several different characteristics of coals, which vary with rank as well as with type. The most important characteristics are the surface area of the coal, its chemical composition, and the presence of certain minerals that can act as catalysts in the conversion reactions. The larger surface area present in lower rank coals translates into a greater degree of penetration of gaseous reactant molecules into the interior of a coal particle. Lower rank coals have a less aromatic structure than higher ranks. This corresponds to the presence of a higher proportion of lower energy, more reactive chemical bonds. Lower rank coals also tend to have higher proximate ash contents, and the associated mineral matter is more distributed, even down to the atomic level. Any catalytically active mineral matter is thus more highly dispersed.

However, the reactivity of a coal also varies depending upon what conversion is attempted. That is, the reactivity of a coal toward combustion (or oxidation) is not the same as its reactivity toward liquefaction, and the order of reactivity established in a series of coals for one conversion process will not necessarily be the same as that for another process.

Coal Reserves

Coal is found throughout the U.S. and the world. It is the most abundant fossil energy resource in the U.S. and the world, comprising 95% of U.S. fossil energy resources and 70% of world fossil energy resources on an energy content basis. All coal ranks can be found in the U.S. The largest resources in the U.S. are made up of lignite and sub-bituminous coals, which are found primarily in the western part of the country, including Alaska. Bituminous coals are found principally in the Midwest states, northern Alaska, and the Appalachian region. Principal deposits of anthracite coal are found in northeastern Pennsylvania.

The Alaskan coals have not been extensively mined because of their remoteness and the harsh climate. Of the other indigenous coals, the anthracite coals have been heavily mined to the point that little economic resource remains. The bituminous coals continue to be heavily mined in the lower 48 states, especially those with sulfur contents less than 2.5 wt%. The lignite and subbituminous coals in the western U.S. have been historically less heavily mined because of their distance from large population centers and because of their low calorific values and high moisture and ash contents. However, with the enactment of the 1990 Clean Air Act Amendments, these coals are now displacing high sulfur-containing



Note: Alaska not to scale of conterminous United States. Small fields and isolated occurrences are not shown.

1 Principal anthracite deposits are in Pennsylvania. Small deposits occur in Alaska, Arkansas, Colorado, Massachusetts-Rhode Island, New Mexico, Utah, Virginia, Washington, and West Virginia.

FIGURE 7.3.1 U.S. coal deposits.

coals for use in the eastern U.S. A map showing the general distribution of coal in the U.S. is included as Figure 7.3.1.

The amount of coal that exists is not known exactly and is continually changing as old deposits are mined out and new deposits are discovered or reclassified. Estimates are published by many different groups throughout the world. In the U.S., the Energy Information Administration (EIA), an office within the U.S. Department of Energy, gathers and publishes estimates from various sources. The most commonly used definitions for classifying the estimates are provided below.

Important Terminology: Resources, Reserves, and the Demonstrated Reserve Base[1]

Resources are naturally occurring concentrations or deposits of coal in the Earth's crust, in such forms and amounts that economic extraction is currently or potentially feasible.

Measured resources refers to coal for which estimates of the rank and quantity have been computed to a high degree of geologic assurance, from sample analyses and measurements from closely spaced and geologically well-known sample sites. Under the U.S. Geological Survey (USGS) criteria, the

---

[1] For a full discussion of coal resources and reserve terminology as used by EIA, USGS, and the Bureau of Mines, see U.S. Coal Reserves, 1996, Appendix A, "Specialized Resource and Reserve Terminology."

Sources: U.S. Department of the Interior, Coal Resource Classification System of the U.S. Bureau of Mines and the U.S. Geological Survey, Geological Survey Bulletin 1450-B (1976). U.S. Department of the Interior, Coal Resource Classification System of the U.S. Geological Survey, Geological Survey Circular 891 (1983) U.S. Department of the Interior, A Dictionary of Mining, Mineral, and Related Terms, Bureau of Mines (1968).

points of observation are no greater than ½ mile apart. Measured coal is projected to extend as a ¼-mile-wide belt from the outcrop or points of observation or measurement.

Indicated resources refers to coal for which estimates of the rank, quality, and quantity have been computed to a moderate degree of geologic assurance, partly from sample analyses and measurements and partly from reasonable geologic projections. Under the USGS criteria, the points of observation are from ½ to 1½ miles apart. Indicated coal is projected to extend as a ½-mile-wide belt that lies more than ¼ mile from the outcrop or points of observation or measurement.

Demonstrated resources are the sum of measured resources and indicated resources.

Demonstrated reserve base (DRB; or simply "reserve base" in USGS usage) is, in its broadest sense, defined as those parts of identified resources that meet specified minimum physical and chemical criteria related to current mining and production practices, including those for quality, depth, thickness, rank, and distance from points of measurement. The "reserve base" is the in-place demonstrated resource from which reserves are estimated. The reserve base may encompass those parts of a resource that have a reasonable potential for becoming economically recoverable within planning horizons that extend beyond those that assume proven technology and current economics.

Inferred resources refers to coal of a low degree of geologic assurance in unexplored extensions of demonstrated resources for which estimates of the quality and size are based on geologic evidence and projection. Quantitative estimates are based on broad knowledge of the geologic character of the bed or region from which few measurements or sampling points are available and on assumed continuation from demonstrated coal for which geologic evidence exists. The points of measurement are from 1½ to 6 miles apart. Inferred coal is projected to extend as a 2¼-mile-wide belt that lies more than ¾ mile from the outcrop or points of observation or measurement. Inferred resources are not part of the DRB.

Recoverable refers to coal that is, or can be, extracted from a coalbed during mining.

Reserves relates to that portion of demonstrated resources that can be recovered economically with the application of extraction technology available currently or in the foreseeable future. Reserves include only recoverable coal; thus, terms such as "minable reserves," "recoverable reserves," and "economic reserves" are redundant. Even though "recoverable reserves" is redundant, implying recoverability in both words, EIA prefers this term specifically to distinguish recoverable coal from in-ground resources, such as the demonstrated reserve base, that are only partially recoverable.

Minable refers to coal that can be mined using present-day mining technology under current restrictions, rules, and regulations.

The demonstrated reserve base for coals in the U.S. as of January 1, 2001, is approximately 501.1 billion (short) tons. It is broken out by rank, state, and mining method (surface or underground) in Table 7.3.5. As of December 31, 1999 (December 31, 2000, for the U.S.), the world recoverable reserves are estimated to be 1083 billion (short) tons. A breakdown by region and country is provided in Table 7.3.6. The recoverability factor for all coals can vary from approximately 40 to over 90%, depending on the individual deposit. The recoverable reserves in the U.S. represent approximately 54% of the demonstrated reserve base as of January 1, 2001. Thus, the U.S. contains approximately 25% of the recoverable reserves of coal in the world.

Transportation

Most of the coal mined and used domestically in the U.S. is transported by rail from the mine mouth to its final destination. In 1998, 1,119 million short tons of coal were distributed domestically. Rail constituted 58.3% of the tonnage, followed by water at 21.4%; truck at 11.0%; and tramway, conveyor, or slurry pipeline at 9.2%. The remaining 0.1% is listed as "unknown method." Water's share includes transportation on the Great Lakes, all navigable rivers, and on tidewaters (EIA, 1999).

In general, barge transportation is cheaper than rail transportation. However, this advantage is reduced for distances over 300 miles (Villagran, 1989). For distances less than 100 miles, rail is very inefficient, and trucks are used primarily, unless water is available as a mode of transport.

[a] Billion short tons.

[b] Lignite resources are not mined underground in the U.S.

[c] Georgia, Maryland, North Carolina, and Tennessee.

[d] Arkansas, Kansas, Louisiana, and Michigan.

[e] Arizona, Idaho, Oregon, and South Dakota.

Notes: (s) = Less than 0.05 billion short tons. Data represent known measured and indicated coal resources meeting minimum seam and depth criteria, in the ground as of January 1, 2001. These coal resources are not totally recoverable. Net recoverability ranges from 0 percent to more than 90 percent. Fifty-four percent of the demonstrated reserve base of coal in the United States is estimated to be recoverable. Totals may not equal sum of components due to independent rounding.

[a] Millions of tons.

Notes: The estimates in this table are dependent on the judgment of each reporting country to interpret local economic conditions and its own mineral assessment criteria in terms of specified standards of the World Energy Council. Consequently, the data may not all meet the same standards of reliability, and some data may not represent reserves of coal known to be recoverable under current economic conditions and regulations. Some data represent estimated recovery rates for highly reliable estimates of coal quantities in the ground that have physical characteristics like those of coals currently being profitably mined. U.S. coal rank approximations are based partly on Btu content and may not precisely match borderline geologic ranks. Data for the U.S. represent recoverable coal estimates as of December 31, 2000. Data for other countries are as of December 31, 1999.

Sources: World Energy Council, Survey of Energy Resources 2001, October 2001. U.S. Energy Information Administration. Unpublished file data of the Coal Reserves Data Base (February 2002).

Prior to the signing of the 1990 Clean Air Act Amendments, most coal was transported to the closest power plant or other end-use facility to reduce transportation costs. Because most coal-fired plants are east of the Mississippi River, most of the coal was transported from eastern coal mines. However, once

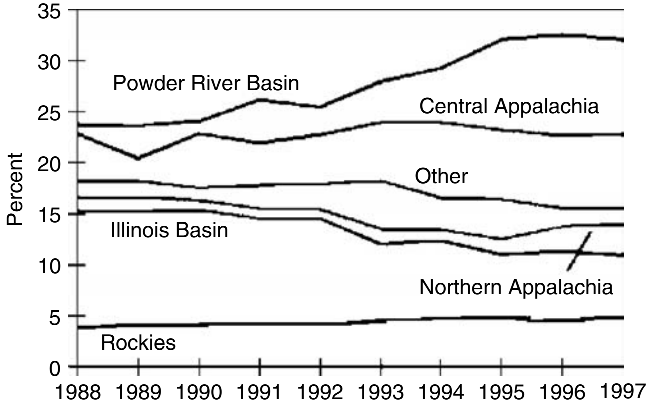

FIGURE 7.3.2 Supply region shares of domestic coal distribution. (From Energy Information Administration, EIA-6, "Coal Distribution Report.")

the Amendments, which required sulfur emissions to be more strictly controlled, began to be enforced, the potential economic advantage of transporting and using low-sulfur western coals compared to installing expensive cleanup facilities in order to continue to use high-sulfur eastern coals began to be considered. This resulted in increasing the average distance coal was shipped from 640 miles in 1988 to 793 miles in 1997.

In comparing shipments from coal-producing regions, the trend of Figure 7.3.2 shows that an increasing share of coal was shipped from the low-sulfur coal producing Powder River Basin between 1988 and 1997 and that less coal was shipped from the high-sulfur coal producing Central Appalachian Basin. Overall, coal use continued to increase at about 2.2% per year over this timeframe.

The cost of transporting coal decreased between 1988 and 1997, due to the increased competition from the low-sulfur western coals following passage of the Clean Air Act Amendments in 1990. This decrease held for all sulfur levels, except for a slight increase in medium sulfur B coals over the last couple of years, as shown in Figure 7.3.3.

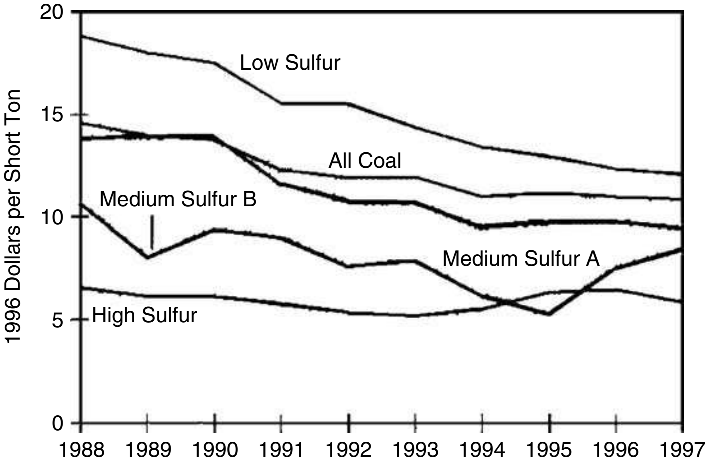

FIGURE 7.3.3 Average rate per ton for contract coal shipments by rail, by sulfur category, 1988 to 1997. Notes: low sulfur = less than or equal to 0.6 lb of sulfur per million Btu; medium sulfur A = 0.61 to 1.25 lb per million Btu; medium sulfur B = 1.26 to 1.67 lb per million Btu; high sulfur = greater than 1.67 lb per million Btu. 1997. (From Energy Information Administration, Coal Transportation Rate Database).

Environmental Aspects

Richard Bajura

Along with coal production and use comes a myriad of potential environmental problems, most of which can be ameliorated or effectively addressed during recovery, processing, conversion, or reclamation. Underground coal reserves are recovered using the two principal methods of room-and-pillar mining (60%) and longwall mining (40%). In room-and-pillar mining, coal is removed from the seam in a checkerboard pattern (the "room") as viewed from above, leaving pillars of coal in an alternate pattern to support the roof of the mine. When using this technology, generally half of the reserves are left underground. Depending upon the depth of the seam and characteristics of the overburden, subsidence due to the removal of the coal may affect the surface many years after the mining operation is completed. Because of the danger of collapse and movement of the surface, undermined lands are not used as building sites for large, heavy structures.

Longwall mining techniques employ the near-continuous removal of coal in rectangular blocks with a vertical cross section equal to the height of the seam multiplied by the horizontal extent (width) of the panel being mined. As the longwall cutting heads advance into the coal seam, the equipment is automatically moved forward. The roof of the mine collapses behind the shields, and most of the effects of subsidence are observed on the surface within several days of mining. If the longwall mining operation proceeds in a continuous fashion, subsidence may occur smoothly so that little damage occurs to surface structures. Once subsidence has occurred, the surface remains stable into the future. Longwall mining operations may influence water supplies as a result of fracturing of water-bearing strata far removed from the panel being mined.

When coal occurs in layers containing quartz dispersed in the seam or in the overburden, miners are at risk of exposure to airborne silica dust, which is inhaled into their lungs. Coal workers' pneumoconiosis, commonly called black lung disease, reduces the ability of a miner to breathe because of the effects of fibrosis in the lungs.

Surface mining of coal seams requires the removal of large amounts of overburden, which must eventually be replaced into the excavated pit after the coal resource is extracted. When the overburden contains large amounts of pyrite, exposure to air and water produces a discharge known as acid mine drainage, which can contaminate streams and waterways. Iron compounds formed as a result of the chemical reactions precipitate in the streams and leave a yellow- or orange-colored coating on rocks and gravel in the streambeds. The acid caused by the sulfur in the pyrite has been responsible for significant destruction of aquatic plants and animals. New technologies have been and continue to be developed to neutralize acid mine drainage through amendments applied to the soil during the reclamation phases of the mining operation. Occasionally, closed underground mines fill with water and sufficient pressure is created to cause "blowouts" where the seams reach the surface. Such discharges have also been responsible for massive fish kills in receiving streams.

The potential for acid rain deposition from sulfur and nitrogen oxides released to the atmosphere during combustion is a significant concern. About 95% of the sulfur oxide compounds can be removed through efficient stack gas cleaning processes such as wet and dry scrubbing. Also, techniques are available for removing much of the sulfur from the coal prior to combustion. Combustion strategies are also being developed that reduce the formation and subsequent release of nitrogen oxides.

The potential for greenhouse warming due to emissions of carbon dioxide during combustion (as well as methane during mining and mine reclamation) has also been raised as a significant concern. Because coal is largely composed of carbon with relatively little hydrogen, its combustion leads to a higher level of carbon dioxide emissions per unit of energy released than for petroleum-based fuels or natural gas.

Defining Terms

Coalification: the physicochemical transformation that coal undergoes after being buried and subjected to elevated temperature and pressure. The classification of a particular coal by rank is a measure of the extent of its coalification. Thus, coalification is a measure of the "age" of a particular coal.

Fixed carbon content: one of the constituents that make up the proximate analysis of a coal. It is normally measured by difference. That is, one measures the volatile matter content and the moisture and ash contents, if the fixed carbon content is reported on a basis containing one or both of those constituents, and subtracts the result(s) from 100% to find the fixed carbon content. One should not confuse the fixed carbon content of a coal with its (elemental) carbon content found in the ultimate analysis. Although carbon is certainly in the material making up the fixed carbon content, it is not all of the carbon present in the original coal, and other elements are also present.

Gross calorific value: calorific value is a measure of the energy content of a material — in this case, a coal sample. Calorific value is measured by ASTM Standard Test Method D 2015M, Gross Calorific Value of Solid Fuel by the Adiabatic Bomb Calorimeter, or by ASTM Standard Test Method D 3286, Gross Calorific Value of Solid Fuel by the Isothermal-Jacket Bomb Calorimeter. The *gross* calorific value takes into account the additional heat gained by condensing any water present in the products of combustion, in contrast to the *net* calorific value, which assumes that all water remains in the vapor state.

Maceral: an organic substance or optically homogeneous aggregate of organic substance in a coal sample that possesses distinctive physical and chemical properties.

Proximate analysis: a method to measure the content of four separately identifiable constituents in a coal: volatile matter content; fixed carbon content; moisture content; and ash content, all of which are reported on a weight percent basis. The standard method for obtaining the proximate analysis of coal or coke is defined by the ASTM in Standard Test Method D 3172.

Rank: a classification scheme for coals that describes the extent of coalification that a particular coal has undergone. The structure, chemical composition, and many other properties of coals vary systematically with rank. The standard method for determining the rank of a coal sample is defined by the ASTM in Standard Test Method D 388.

Type: a classification scheme for coals that references the original plant material from which the coal was derived.

Ultimate analysis: a method to measure the elemental composition of a coal sample. Typical ultimate analyses include carbon, hydrogen, oxygen, sulfur, and nitrogen contents, but other elements can also be reported. These other elements are usually not present to any appreciable extent. However, if they are reported, the sum of all the elements reported (including moisture and ash content) should equal 100%. The standard method for the ultimate analysis of coal or coke is defined by the ASTM in Standard Test Method D 3176.

Volatile matter content: the mass of material released upon heating the coal sample under specific conditions, defined by the ASTM Standard Test Method D 3175.

Further Information

An excellent resource for understanding coal, its sources, uses, limitations, and potential problems is the book by Elliott referenced under Elliott and Yohe (1981) and Habermehl et al. (1981). A reader wishing an understanding of coal topics could find no better resource. Another comprehensive book, which includes more-recent information but is not quite as weighty as Elliott's (664 pages vs. 2374 pages), is

The Chemistry and Technology of Coal, edited (second edition, revised and expanded) by James G. Speight. For information specific to the environmental problems associated with the use of coal, the reader is referred to Norbert Berkowitz's chapter entitled "Environmental Aspects of Coal Utilization" in *An Introduction to Coal Technology.* For information on the standards for coal analyses and descriptions of the associated procedures, the reader is referred to any recent edition of the ASTM's *Annual Book of ASTM Standards.* Section 5 covers petroleum products, lubricants, and fossil fuels, including coal and coke.

Oil

Philip C. Crouse

Overview

The U.S. Department of Energy's Energy Information Administration (EIA) annually provides a wealth of information concerning most energy forms including fossil fuels. The oil and natural gas sections are extracted summaries for the most germane information concerning oil and natural gas. Fossil fuel energy continues to account for over 85% of all world energy in 2000. The EIA estimates that in 2025, fossil fuels will still dominate energy resources with natural gas having the most growth. The base case of the EIA predicts that world energy consumption will grow by 60% over the next two decades. Figure 7.3.4 shows steady growth in global energy consumption. The projections show that in 2025 the world will consume three times the energy it consumed in 1970.

In the United States, wood served as the preeminent form of energy for about half of the nation's history. Around the 1880s, coal became the primary source of energy. Despite its tremendous and rapid expansion, coal was overtaken by petroleum in the middle of the 1900s. Natural gas, too, experienced rapid development into the second half of the 20th century, and coal began to expand again. Late in the 1900s, nuclear electric power was developed and made significant contributions.

Although the world's energy history is one of large-scale change as new forms of energy have been developed, the outlook for the next couple of decades is for continued growth and reliance on the three major fossil fuels of petroleum, natural gas, and coal. Only modest expansion will take place in renewable resources and relatively flat generation from nuclear electric power, unless major breakthroughs occur in energy technologies. Table 7.3.7 shows EIA's estimate of growth of selected energy types with oil needs dominating the picture over the next 20 years.

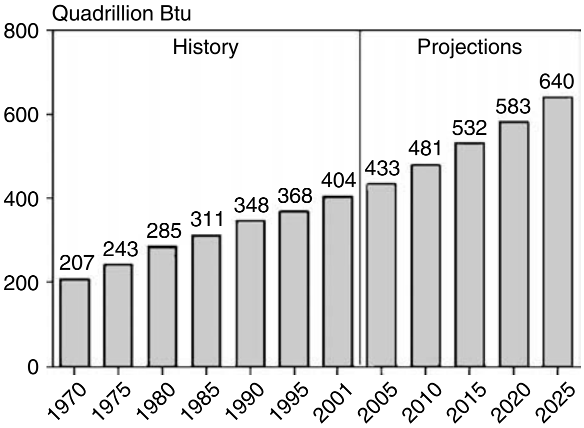

FIGURE 7.3.4 World energy consumption, 1970–2025. (History from EIA, International Energy Annual 2001, DOE/EIA-0219(2001), Washington, D.C., Feb. 2003, www.eia.doe.gov/iea/. Projections from EIA, System for the analysis of Global Energy Markets (2003).)

Crude Oil Classification and World Reserves

Obtaining accurate estimates of world petroleum and natural gas resources and reserves is difficult and uncertain, despite excellent scientific analysis made over the years. Terminology standards used by industry to classify resources and reserves has progressed over the last 10 years with the Society of

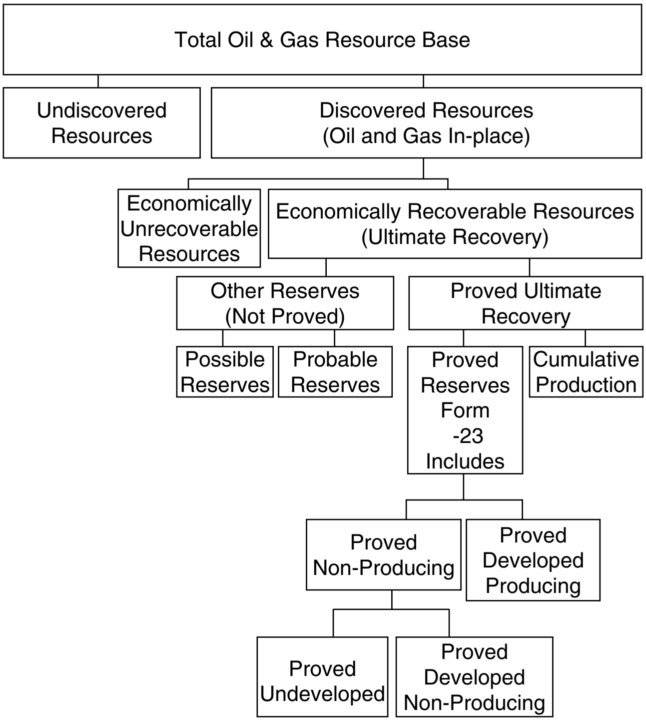

FIGURE 7.3.5 Components of the oil and gas resource base. (From EIA, Office of Gas and Oil.)

Petroleum Evaluation Engineers leading an effort to establish a set of standard definitions that would be used by all countries in reporting reserves. Classifications of reserves, however, continue to be a source of controversy in the international oil and gas community. This subsection uses information provided by the Department of Energy classification system. The next chart shows the relationship of resources to reserves. **Recoverable reserves** include discovered and undiscovered resources. **Discovered resources** are those resources that can be economically recovered. Figure 7.3.5 shows the relationship of petroleum resource and reserves terms.

Discovered resources include all production already out of the ground and reserves. Reserves are further broken down into proved reserves and other reserves. Again, many different groups classify reserves in different ways, such as measured, indicated, internal, probable, and possible. Most groups break reserves into producing and nonproducing categories. Each of the definitions is quite voluminous and the techniques for qualifying reserves vary globally. Table 7.3.8 shows estimates made by the EIA for total world oil resources.

Standard Fuels

Petroleum is refined into petroleum products that are used to meet individual product demands. The general classifications of products are:

1. NATURAL GAS LIQUIDS AND LIQUEFIED REFINERY GASES. This category includes ethane (C_2H_6); ethylene (C_2H_4); propane (C_3H_8); propylene (C_3H_6); butane and isobutane (C_4H_{10}); and butylene and isobutylene (C_4H_8).
2. FINISHED PETROLEUM PRODUCTS. This category includes motor gasoline; aviation gasoline; jet fuel; kerosene; distillate; fuel oil; residual fuel oil; petrochemical feed stock; naphthas; lubricants; waxes; petroleum coke; asphalt and road oil; and still gas.

[a] Billion barrels.

Note: Resources include crude oil (including lease condensates) and natural gas plant liquids.

Source: U.S. Geological Survey, *World Petroleum Assessment 2000*, web site http://greenwood.cr.usgs.gov/energy/WorldEnergy/DDS-60.

- *Motor gasoline* includes reformulated gasoline for vehicles and oxygenated gasoline such as gasohol (a mixture of gasoline and alcohol).
- *Jet fuel* is classified by use such as industrial or military and naphtha and kerosene type. Naphtha fuels are used in turbo jet and turbo prop aircraft engines and exclude ram-jet and petroleum rocket fuel.
- *Kerosene* is used for space heaters, cook stoves, wick lamps, and water heaters.
- *Distillate fuel oil* is broken into subcategories: No. 1 distillate, No. 2 distillate, and No. 4 fuel oil, which is used for commercial burners.
- *Petrochemical feedstock* is used in the manufacture of chemicals, synthetic rubber, and plastics.
- *Naphthas* are petroleums with an approximate boiling range of 122 to 400°F.
- *Lubricants* are substances used to reduce friction between bearing surfaces, as process materials, and as carriers of other materials. They are produced from distillates or residues. Lubricants are paraffinic or naphthenic and separated by viscosity measurement.
- *Waxes* are solid or semisolid material derived from petroleum distillates or residues. They are typically a slightly greasy, light colored or translucent, crystallizing mass.
- *Asphalt* is a cement-like material containing bitumens. *Road oil* is any heavy petroleum oil used as a dust pallatine and road surface treatment.
- *Still gas* is any refinery by-product gas. It consists of light gases of methane; ethane; ethylene; butane; propane; and the other associated gases. Still gas is typically used as a refinery fuel.

Table 7.3.9 shows *world refining capacity* as of January 1, 2002. The number of oil refineries continues to grow as demands for petroleum products have continued to grow.

Natural Gas

Philip C. Crouse

Overview

Natural gas has been called the environmentally friendly fossil fuel because it releases fewer harmful contaminants. World production of dry natural gas was 73.7 trillion ft^3 and accounted for over 20% of world energy production. In 1990 Russia accounted for about one third of world natural gas. With about one quarter of the world's 1990 natural gas production, the second largest producer was the U.S.

According to the U.S. Department of Energy, natural gas is forecast to be the fastest growing primary energy. Consumption of natural gas is projected to nearly double between 2001 and 2025, with the most robust growth in demand expected among the developing nations. The natural gas share of total energy consumption is projected to increase from 23% in 2001 to 28% in 2025.

Natural gas traded across international borders has increased from 19% of the world's consumption in 1995 to 23% in 2001. The EIA notes that pipeline exports grew by 39% and liquefied natural gas (LNG) trade grew by 55% between 1995 and 2001. LNG has become increasingly competitive, suggesting the possibility for strong worldwide LNG growth over the next two decades. Figure 7.3.6 shows projections of natural gas consumption in 2025 to be five times the consumption level in 1970.

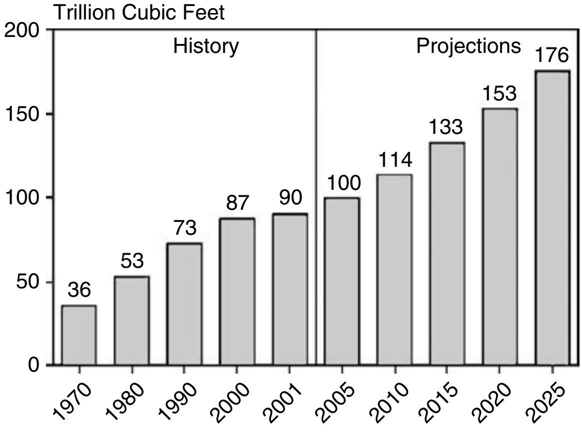

FIGURE 7.3.6 World natural gas consumption, 1970–2025. (History from EIA, International Energy Annual 2001, DOE/EIA-0219(2001), Washington, D.C., Feb. 2003, www.eia.doe.gov/iea/. Projections from EIA, System for the analysis of Global Energy Markets (2003).)

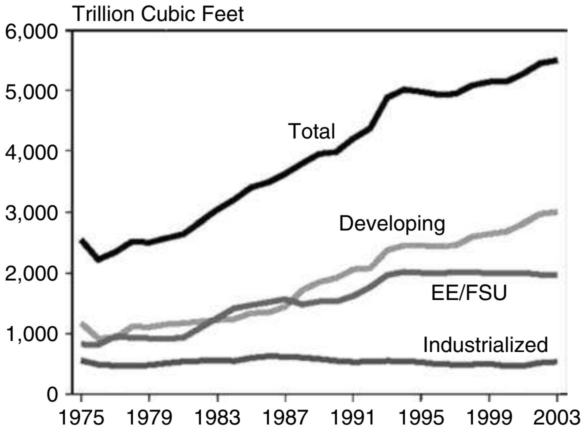

FIGURE 7.37 World natural gas reserves by region, 1975–2003. (Data for 1975–1993 from Worldwide oil and gas at a glance, *International Petroleum Encyclopedia,* Tulsa, OK: PennWell Publishing, various issues. Data for 1994–2003 from *Oil & Gas Journal*, various issues.)

Reserves and Resources

Since the mid-1970s, world natural gas reserves have generally trended upward each year As of January 1, 2003, proved world natural gas reserves, as reported by *Oil & Gas Journal*, were estimated at 5,501 trillion ft^3. Over 70% of the world's natural gas reserves are located in the Middle East and the EE/FSU, with Russia and Iran together accounting for about 45% of the reserves. Reserves in the rest of the world are fairly evenly distributed on a regional basis.

The U.S. Geological Survey (USGS) regularly assesses the long-term production potential of worldwide petroleum resources (oil, natural gas, and natural gas liquids). According to the most recent USGS estimates, released in the *World Petroleum Assessment 2000*, the mean estimate for worldwide undiscovered gas is 4839 trillion ft^3. Outside the U.S. and Canada, the rest of the world reserves have been largely unexploited. Outside the U.S., the world has produced less than 10% of its total estimated natural gas endowment and carries more than 30% as remaining reserves. Figure 7.3.7 shows world natural gas reserves by region from 1975 to 2003. Table 7.3.10 shows natural gas reserves of the top 20 countries compared to world reserves. Russia, Iran, and Qatar account for over half of estimated world gas reserves.

Natural Gas Production Measurement

Natural gas production is generally measured as "dry" natural gas production. It is determined as the volume of natural gas withdrawn from a reservoir less (1) the volume returned for cycling and repressuring reservoirs; (2) the shrinkage resulting from the removal of lease condensate and plant liquids; and (3) the nonhydrocarbon gases. The parameters for measurement are 60°F and 14.73 lb standard per square inch absolute.

World Production of Dry Natural Gas

From 1983 to 1992, dry natural gas production grew from 54.4 to 75 trillion ft^3. The breakdown by region of world is shown in Table 7.3.11.

Compressed Natural Gas

Environmental issues have countries examining and supporting legislation to subsidize the development of cleaner vehicles that use compressed natural gas (CNG). Even with a push toward the use of CNG-burning vehicles, the numbers are quite small when compared with gasoline vehicles. Recent efforts toward car power have been focused on hybrid electric-gasoline cars and fuel cell vehicles.

TABLE 7.3.10 World Natural Gas Reserves by Country as of January 1, 2003

Liquefied Natural Gas (LNG)

Natural gas can be liquefied by lowering temperature until a liquid state is achieved. It can be transported by refrigerated ships. The process of using ships and providing special-handling facilities adds significantly to the final LNG cost. LNG projects planned by a number of countries may become significant over the next 20 years, with shipments of LNG exports ultimately accounting for up to 25% of all gas exports.

Physical Properties of Hydrocarbons

The most important physical properties from a crude oil classification standpoint are density or specific gravity and the viscosity of liquid petroleum. Crude oil is generally lighter than water. A Baume-type scale is predominantly used by the petroleum industry and is called the API (American Petroleum Institute) gravity scale (see Table 7.3.12). It is related directly to specific gravity by the formula:

$$\varphi = (141.5)/(131.5 + °\mathrm{API})$$

TABLE 7.3.12 Relation of API Gravity, Specific Gravity, and Weight per Gallon of Gasoline

Degree API	Specific Gravity	Weight of Gallon (lb)
8	1.014	8.448
9	1.007	8.388
10	1.000	8.328
15	0.966	8.044
20	0.934	7.778
25	0.904	7.529
30	0.876	7.296
35	0.850	7.076
40	0.825	6.870
45	0.802	6.675
50	0.780	6.490
55	0.759	6.316
58	0.747	6.216

Note: The specific gravity of crude oils ranges from about 0.75 to 1.01.

TABLE 7.3.13 Other Key Physical Properties of Hydrocarbons

Compound	Molecular Weight	Boiling Point at 14.7 psia in °F	Liquid Density at 14.7 psia and 60°F-lb/gal
Methane	16.04	–258.7	2.90
Ethane	30.07	–125.7	4.04
Propane	44.09	–43.7	4.233

n-Decane	142.3	345.4	6.121

where φ = specific gravity. Temperature and pressure are standardized at 60°F and 1 atm pressure.

Other key physical properties involve the molecular weight of the hydrocarbon compound and the boiling point and liquid density. Table 7.3.13 shows a summation of these properties.

Defining Terms

API gravity: A scale used by the petroleum industry for specific gravity.

Discovered resources: Include all production already out of the ground and reserves.

Proved resources: Resources that geological and engineering data demonstrate with reasonable certainty to be recoverable in future years from known reservoirs under existing economic and operating conditions.

Recoverable resources: Include discovered resources.

Further Information

The Energy Information Agency of the U.S. Department of Energy, Washington, D.C., publishes *International Energy Outlook* and other significant publications periodically.

7.4 Biomass Energy

Ralph P. Overend and Lynn L. Wright

Biomass energy encompasses a wide variety of energy technologies that use renewable plant matter, or phytomass, derived from photosynthesis as a feedstock to produce solid, liquid, and gaseous biofuels or used directly as an energy source producing heat and electricity. Biorefinery concepts are being developed that could result in the production of multiple energy carriers, as well as bioproducts from the same biomass resource.

Biomass Feedstock Technologies

Photosynthesis

Biomass fuels are derived from green plants, which capture solar energy and store it as chemical energy through the **photosynthetic** reduction of atmospheric carbon dioxide. Plant leaves are biological solar collectors while the stems, branches, and roots are the equivalent of batteries storing energy-rich complex carbon compounds. Elemental analysis shows that wood and grasses are about 50% carbon. The average photosynthetic efficiency of converting solar energy into energy stored in organic carbon compounds on an annual basis varies from less than 0.5% in temperate and tropical grasslands to about 1.5% in moist tropical forests (Cralle and Vietor, 1989). Although seemingly quite low, the worldwide annual storage of photosynthetic energy in terrestrial biomass is huge, representing approximately 10 times world annual use of energy (Hall et al., 1993). This annual energy storage reflects the diversity and adaptability of terrestrial plants in many different climate zones, from the polar regions to the tropics.

Biomass Residue Resources

The majority of biomass energy used today is derived from residues associated with the production of timber and food crops in the field and the forest, as well as in their processing into final products. On the average, for each tonne of grain or timber harvested, there is an equivalent amount of stalk, straw, or forest residues such as branch materials. Residues from agricultural crops, such as cereal straws, are already used for bioenergy in many parts of the world and represent a large, immediately accessible resource for bioenergy in the United States. Agriculture residue recovery in the U.S. will have the most potential in high-yield cropland areas, especially those in which no-till management systems are used. Under such conditions, some portion of the crop residue may be sustainably and economically recoverable for bioenergy.

Under conventional management practices, corn stover, wheat straw, and other crop residues often have greater economic value because they are left on the land to restore nutrients, reduce erosion, and stabilize soil structure. Sustainably recoverable agricultural crop residues in the U.S. are estimated to be less than136 Mt (Walsh et al., 2000; Gallagher et al., 2003) (all biomass amounts are on a dry basis). Crop residues worldwide are estimated to have an energy value of 12.5 EJ (Hall et al., 1993).

Recoverable wood residues from all sources in the U.S. are estimated to be approximately 94.3 Mt (McKeever, 2003). This includes 67.6 Mt of logging residues; 16.4 Mt of construction and demolition wastes; and 8.7 Mt of recoverable solid wood from the postconsumer urban residue stream (or municipal solid waste stream). Primary timber mills produce about 73.7 Mt of residues; however, about 97% of this is already utilized.

A potentially large wood residue resource consists of the small-diameter growing trees and woody debris that need to be removed from U.S. forests to reduce hazardous fuel loading in forest fire mitigation. Small-diameter wood is already harvested for fuelwood in many parts of the world. The estimated forest residues, worldwide have an energy value of 13.5 EJ (Hall et al., 1993). Forest industry processing residues (e.g., sawdust or black liquor from pulping processes) are already used for energy in most cases.

Potential Forestry Biomass Resources Worldwide

The amount of harvestable woody biomass produced by natural forests on an annual basis ranges from about 2 to 6 t ha^{-1} y^{-1} (with the higher yields usually in tropical regions); this could be increased to 4 to

12 t ha^{-1} y^{-1} if brought under active management. Such management would include optimizing harvesting strategies for production, fertilization, and replanting natural stands with faster-growing species. As of 1990, 10% of world forests, or 355 Mha, were actively managed. If managed forests were increased to 20%, and if 20% of the harvested material were used for energy, the annual worldwide resource of wood for energy from currently forested land would amount to between 284 to 852 Mt of available wood, or about 5.6 to 17 EJ of primary energy based on potential yield ranges of managed forests. The most optimistic estimates of biomass potential would provide a total primary energy resource of about 30 EJ from managed forests (Sampson et al., 1993).

Potential Energy Crop Production

Significantly increasing the world's biomass energy resources will require the production of high-yield crops dedicated to conversion to bioenergy. The most environmentally beneficial dedicated crop production systems will be the production of perennial plants, using genetically superior materials, established on previously cropped land, and managed as agricultural crops. Perennials such as annually harvested grasses or short rotation trees harvested on a cycle of 3 to 10 years minimize soil disturbance, increase the build-up of soil carbon, provide wildlife habitat, and generally require fewer inputs of chemicals and water for a given level of production.

Energy crop yields will be highest in locations where genetically superior material is planted on land with plenty of access to sunshine and water. In the moist tropics and subtropics, as well as in irrigated desert regions, yields in the range of 20 to 30 t ha^{-1} y^{-1} are achievable with grasses and trees (e.g., eucalypts and tropical grasses, and hybrid poplars in the irrigated Pacific Northwest of the U.S.). Without irrigation, temperate woody crops would be expected to yield 9 to 13 t ha^{-1} y^{-1} of harvestable biomass, though several experimental trials have demonstrated yields of improved genotypes of poplars in the range of 12 to 20 t ha^{-1} y^{-1} and best yields up to 27 t ha^{-1} y^{-1} (Wright, 1994). Unimproved temperate perennial grasses with no irrigation typically yield about 7 to 11 t ha^{-1} y^{-1}; selected grasses in experimental trials have commonly achieved yields of 11 to 22 t ha^{-1} y^{-1} with occasional yields of 16 to 27 t ha^{-1} y^{-1} in some years. Although grass yields vary from year to year, the Alamo variety of switchgrass has averaged around 23 t ha^{-1} y^{-1} (10 dry ton/acre/year) over 12 years in the southeastern U.S., where a long growing season favors warm-season grasses (McLaughlin and Kszos, personal communication).

Temperate shelterbelts and tropical agroforestry plantings could also contribute greatly to biomass energy resources. Assuming a range of possible yields, the primary energy resource potential of converting 10 to 15% of cropland to energy crops has been estimated to range from a low of 18 EJ to a high of 49 EJ. A further 25 to 100 EJ has been estimated to be available from the conversion of grasslands and degraded areas to the production of biomass energy resources worldwide (Sampson et al., 1993).

Terrestrial and Social Limitations

M.J.R. Cannell provides estimates of theoretical, realistic, and conservative/achievable capacity of biofuel plantations of trees or annual crops to produce primary energy and offset global carbon emissions between 2050 to 2100 (Cannell, 2003). The theoretical estimate of biomass energy potential assumes 600 to 800 Mha, or a maximum of 55% of current cropland area (although including large areas of previous crop land that are now degraded) and average yields increasing from 10 to 25 t ha^{-1} y^{-1} providing 150 to 300 EJ. The realistic estimate of biomass energy potential assumes 200 to 400 Mha (14 to 28% of current cropland area) and average yields of 10 t ha^{-1} y^{-1} (37 to 74 EJ); the conservative/achievable estimate assumes 50 to 200 Mha of current cropland and average yields of 10 t ha^{-1} y^{-1} (9 to 37 EJ).

Cannell's conservative estimate recognizes that developing countries continue to face food and water shortages and increasing populations, and that substantial economic and policy obstacles must be overcome. Additionally, the life cycle environmental and social impacts are not always strongly positive, depending on the crop management systems used and the conversion process employed.

Biomass Facility Supply Considerations

The location of large biorefinery facilities will be limited by local biomass supply availability and price considerations. Siting opportunities for facilities in the U.S. that require 500 t d^{-1} or less of biomass

TABLE 7.4.1 Impact of Facility Size and Energy Crop Productivity on Area Required

[b] Efficiency: present = 50%; future = 60%.

delivered at prices of 40 \$ t^{-1} or greater will be abundant, especially if dedicated crops are included in the supply mix. U.S. locations with abundant supplies of biomass delivered at 20 \$ t^{-1} or less will be quite limited. As facility size increases to 2000 t d^{-1} (the smallest size being considered for most biorefineries), up to 10,000 dt/day, suitable locations will become increasingly limited and/or prices will be considerably higher (Graham et al., 1995).

Facilities with the capability of processing a wide variety of feedstock types may gain a price benefit from seasonal feedstock switching (such as using corn stover in fall, woody crops in winter, and grasses in summer) and from using opportunity feedstock (such as trees blown down from storms). Facilities with a large demand for feedstocks with specific characteristics will depend upon crops genetically selected and tailored for the specific process. The higher feedstock prices would presumably be offset by the economies of scale leading to reductions in processing costs (Jenkins, 1997).

Acceptance of biomass facility siting will depend in part on the land area changes required to supply a facility. For economic analysis, it is normally assumed that biomass supplies will be available within an 80 km radius (although in many situations worldwide supply is coming from longer distances, with international trading emerging in some areas). An approximate idea of the hectares and percent land area within an 80 km radius required as a function of the biomass yield that can be sustainably harvested/collected from the land is provided in Table 7.4.1. The lower yield is representative of levels of agricultural residues (such as corn stover and wheat straw) that could be collected in some areas.

Dedicated energy crops will vary between 9 and 18 t ha^{-1} y^{-1} in the near future and could rise higher. Facility demands would be expected to decrease in the future as conversion technology efficiencies increase, requiring less land per unit of final product output. Table 7.4.2 shows the expected yield of typical secondary energy products from the same daily biomass inputs. The efficiencies are described as *present*, representing the state of the art today, and *future*, in which there are foreseeable changes in the technology.

Biomass Conversion Technologies

The energy services that can be satisfied by biomass are the supply of heat and combined heat and power, as well as the conversion of biomass into other energy forms such as electricity, liquid, and gaseous fuels identified (see Table 7.4.2). The transformation of the energy in the raw biomass to other forms of energy and fuels requires an acknowledgment of the physical and chemical differences between biomass resources in order to effect the most efficient transformation at the desired scale of operation. Each conversion process must take into account the differences in biomass physical characteristics on receipt at the processing facility and its proximate composition, which can vary widely in terms of moisture and ash content. Many processes require knowledge of the elemental composition and may even need information at the ultra-structural and polymeric level.

Physical Characteristics

Physical properties are important in the design and handling of biomass fuels and feedstocks at processing plants. In the raw state, woody biomass has a relatively low bulk density compared with fossil fuels. Bituminous coal or crude oil, for example, has a volume of 30 $dm^3\ GJ^{-1}$, while solid wood has around 90 $dm^3\ GJ^{-1}$. In chip form, the volume increases to 250 $dm^3\ GJ^{-1}$ for hardwood species and 350 $dm^3\ GJ^{-1}$ for coniferous species. Straw has even less energy density, ranging from 450 $dm^3\ GJ^{-1}$ for large round bales to 1 to 2 $m^3\ GJ^{-1}$ for chopped straw, similar to bagasse. The cell walls of biomass fibers have densities of about 1.5 $g\ cm^{-3}$; however, the large volume of the vascular elements that make up the fibers results in the low energy densities described previously. The fibrous nature also precludes close packing, which is the reason that chips and chopped straw have densities that are so low.

Size reduction of biomass resources is often more difficult than with minerals because the materials are naturally strong fibers, and the production of uniform particle size feedstocks is correspondingly difficult. The size reduction challenge is often mitigated in combustion and gasification on account of the high chemical reactivity of the biomass materials. However, when it is necessary to have penetration of chemicals into the structure of the biomass or to create access for biological agents as in acid and enzymatic hydrolysis of biomass, a higher degree of size reduction will be required. The energy requirements for size reduction are proportional to the surface exposure and rise in inverse proportion to the cube of the average length, so although moderate amounts of energy are required at particle sizes of several millimeters, the energy penalty at the 100-μm size is considerable.

Chemical Characteristics

Proximate Analysis

The value of the proximate analysis is that it identifies the fuel value of the as-received biomass material; provides an estimate of the ash handling and water removal requirements; and describes something of the characteristics in burning (Table 7.4.3). Generally, highly volatile fuels, such as biomass, need to have specialized combustor designs to cope with the rapid evolution of gas. Coals with very high fixed carbon need to be burnt on a grate because they take a long time to burn out if they are not pulverized to a very small size.

The energy content of biomass is always reported for dry material; however, most woody crops are harvested in a green condition with as much as 50% of their mass water. Two different heating value reporting conventions are in use. The term *higher heating value*, or HHV, refers to the energy released in combustion when the water vapor resulting from the combustion is condensed, thus releasing the latent heat of evaporation. Much of the data from North America are reported in this way. The *lower*

[a] Dry basis, weight percent.

heating value, or LHV, reports the energy released when the water vapor remains in a gaseous state. The HHV and LHV are the same for pure carbon, which only produces carbon dioxide when burned. For hydrogen, one molecule of water is produced for each molecule of hydrogen, and the HHV is 18.3% greater than the LHV. The HHV is 11.1% greater than the LHV for the combustion of one molecule of methane (CH_4).

Ultimate Analysis

The elemental composition of the fuel biomass is usually reported on a totally dry basis and includes the ash. Table 7.4.4 gives the ultimate analysis for several different fuels.

Polymeric Composition

Biomass conversion technologies that depend on the action of microorganisms are very sensitive to the ultrastructure and polymeric composition of biomass feedstocks. In ethanol production and in anaerobic digestion, a complex sequence of biochemical events take place in which the polymers are broken down into smaller units and hydrolysed to give simple sugars, alcohols, and acids that can be processed into fuel molecules. Wood, grasses, and straws are collectively called lignocellulosics and consist mainly of fibers composed of lignin, cellulose, and hemicellulose. Cellulose, hemicellulose, and lignin are different carbon–hydrogen–oxygen polymers with differing energy contents and chemical reactivities.

Lignocellulosics typically contain cellulose (40 to 50%) and hemicellulose (25 to 30%) along with lignin (20 to 30%), some extractives, and inorganic materials. Cellulose is depolymerized and hydrolyzed to glucose, a six-carbon sugar (C-6), while hemicellulose is a complex mixture of mainly five-carbon sugar (C-5) precursors with xylose, a major product. Lignin is a complex polymer based on phenyl propane monomeric units. Each C_9 monomer is usually substituted with methoxy groups on the aromatic ring, occurring mainly in syringyl (dimethoxy) and guaiacyl (monomethoxy) forms for which the ratio is a signature characteristic of grasses, hardwoods, and softwoods.

Other major plant components containing polymers of carbon, hydrogen, and oxygen that are also used for energy include:

- Starches that are the major part of the cereal grains, as well as the starch from tubers such as mannioc and potatoes
- Lipids produced by oil seed-bearing plants such as soya, rape, or palms, which are possible diesel fuel substitutes when they are esterified with simple alcohols such as methanol and ethanol
- Simple sugars produced by sugar beet in temperate climates or sugar cane in the tropics, which can be directly fermented to alcohols

In addition to the carbon, hydrogen, and oxygen polymers, there are more complex polymers such as proteins (which can contain sulfur in addition to nitrogen), extractives, and inorganic materials. The inorganic materials range from anions such as chlorine, sulphate, and nitrates, and cations such as potassium, sodium, calcium, and magnesium as major constituents. Many trace elements, including manganese and iron, are the metallic elements in key enzyme pathways involved in cell wall construction.

Combustion Applications

More than 95% of the worldwide use of biomass is through its combustion. The majority is used in developing countries for use in *daily living*, to provide heat for cooking and space heating. In the industrialized countries, a parallel in the cold regions of the northern hemisphere is the *community applications* of district heating. *Industrial applications* — especially of CHP (combined heat and power) — are important in industrialized countries as well as in the agricultural processing sector of developing countries. In several countries, biomass is burned directly to produce electricity without the coproduction of heat; however, like coal and oil-fired steam electricity generation, this is relatively inefficient.

Daily Living

Half of all solid biomass combustion worldwide goes into cooking and space heating at the household level, serving the primary fuel needs of over 2 billion people. The typical final energy demand for cooking is around 12 MJ a day for a household in Southeast Asia. This demand can be met with around 20 MJ d^{-1} of primary energy input using LPG (propane or butane) or kerosene with a typical conversion efficiency of 60 to 75%. Biomass efficiencies are much lower, ranging between 10 and 20%; thus, the required primary energy input is between 60 and 120 MJ d^{-1}. The three-stone stove has been extensively studied and has a peak power rating of 5 kW in the startup and a simmer rate of around 2 kW. The measured efficiency with a skilled operator is 10 to 15%. Daily household biomass consumption is therefore in the region of 2 to 4 kg d^{-1} or about 0.5 to 1.0 t y^{-1}.

The low efficiency of use is mainly due to poor combustion efficiency and inadequate heat transfer to the cooking vessels. The poor combustion results in the loss of fuel as solid particulate (soot), unburnt hydrocarbons and carbon monoxide; these are often referred to as the products of incomplete combustion (PIC). The heat transfer problem is related to the poor contact between the hot gases from the burner and the pot, and its fouling with PIC (Prasad, 1985). The PICs are not only a loss of fuel value, but are also toxic chemicals to which human exposure should be minimized.

Carbon monoxide is a chemical asphyxiant, and the aldehydes, phenols, and other partial combustion products are skin, eye, and lung irritants; some, such as benzopyrenes, are even carcinogens. Because many stoves are used in enclosed spaces and do not have chimneys, the household is exposed to these hazards; eye and lung damage is experienced especially by women and children, who work closely with the stoves while cooking. The epidemiological data on this are extensive (Ezzati and Kammen 2001), and large efforts to improve the efficiency and minimize the emissions in cookstoves are underway. The health impacts are of such a magnitude that subsidized alternative fuels such as LPG could be a significant social benefit while reducing the impacts of biomass harvesting

Space Heating

Space heating with wood in the form of logs is very common in forested areas of the northern hemisphere and Latin America with wood stoves supplying a household heat requirement of 30 to 100 kW. The thermal efficiencies are about 60 to 70%. Log burning is controlled by air starvation to reduce power output and may result in severe emissions of PIC, causing poor air quality in regions with high densities of wood-fueled space heating. Residential wood stoves using advanced combustion system designs or catalysts reduce PIC. Legislation has mandated emissions testing of new appliances before sale to ensure that they meet new source performance standards (NSPS) in the U.S. The use of dry prepared fuels such as pellets (manufactured by drying, grinding, and compression into a pellet about 1 to 2 cm in diameter) allows combustion to be efficiently managed so that PIC are extremely low with 75 to 80% thermal efficiency.

Community Systems

Biomass use in community district heating (DH) systems results in improved thermal efficiency with reduced emissions because of the scale of the equipment. Europe has seen large-scale adoption of biomass-fired district heating. There are over 300 round wood-fired DH schemes in Austria with an average heating effect of 1 MW or less, serving villages of 500 to 3000 inhabitants with minigrids using hot water distribution. Using straw, 54 Danish systems cover larger population centers and range in size from 600 kW to 9MW. Larger scale DH systems can be CHP units producing process steam for industries, heating for households, and electricity for the grid with high-quality emissions control systems. In Finland, even larger units are serving cities, e.g., the Forssa wood-fired CHP–DH plant is rated at 17.2 MW_e and 48 MW_{th} district heating, generating steam at 6.6 MPa and 510°C, with a bubbling fluidized bed boiler. The seasonal efficiency, which includes a condensing steam cycle in the summer, is 78%.

Industrial Applications — Combined Heat and Power (CHP) or Cogeneration

Many industrial processes, such as pulp production or cane sugar manufacture, have large heat requirements that are satisfied by generating low pressure steam at 1.7 MPa and 250° using their own process residues such as hog fuel (a mix of wood and bark); black liquor (the lignin by-product of pulp manufacture in kraft pulp mills); or bagasse (the fibrous residue after the pressing of sugar cane). A proportion of the steam is used in direct drives for the process plant's needs. Often, because the primary goal has been to eliminate residue disposal, the systems have not operated at maximum efficiency.

In industries such a pulp and paper (P&P), the trend is already toward requiring higher power–heat (P/H) ratios because steam demand is trending down due to energy conservation practices and electricity demand is rising to supply the increasing environmental and process needs. The thermal demand reduction is a consequence of improvements in drying and evaporation technologies, which have decreased from 8.6 to only 4 GJ adt^{-1} (adt = air dry tonne of pulp). The average pulp mill energy consumption has gone from 17 GJ adt^{-1} in the 1980s to 7 to 8 GJ adt^{-1} in the 1990s.

The application of advanced power generation cycles in the pulp and paper industry using black liquor and wood residues as feedstocks would give large increases in electricity export from that industry. Similar energy conservation trends in the sugar industry can reduce the requirement of steam to process cane from 58.5% (tonne steam/tonne of cane processed) to less than 35%. If investments in energy conservation and adoption of integrated gasification combined cycle (IGCC) technology were applied worldwide, the annual amount of power that could be produced from the large sugar cane resource would be >650 TWh based on the current >1.0 Gt of cane. Current cane generation is estimated to be 30 to 50 TWh y^{-1} because only sufficient electricity is generated in most instances to power the mill in season.

Electric Power Generation from Biomass

Prime Mover Systems and Fuels

Power generation takes place in *prime movers*, a technical term to describe engines of all kinds attached to alternators to generate electricity. Prime movers include the:

- Steam engine
- Steam turbine engine (the Rankine cycle)
- Internal combustion engine (ICE), which comes in two types: the Otto or gasoline-based spark ignition (SI) engine, and the diesel or compression ignition (CI) engine
- Gas turbine engine (Brayton cycle)
- Stirling engine

Each of these requires that the raw biomass be processed to some level and then used in the prime mover. Eventually fuel cells will replace the prime mover and alternator requirement by generating electricity directly from biomass-derived hydrogen fuels.

The steam cycle (already discussed) uses combustor and boiler combinations to generate steam, requiring that the fuel be reduced in size (perhaps dried to some level) and have physical contaminants removed.

The high-pressure steam is then expanded through a steam engine at small scales or through a turbine at larger scales. The efficiency of conversion technologies for combustion steam boiler systems is very scale dependent — a small steam engine or turbine would not exceed 10%. However, typically sufficient biomass is available over a transportation radius of 10 to 80 km to operate a unit in the range of 10 to 50 MW electricity output. Current Rankine cycles, at that scale, operate in the range of 25 to 30% efficiency and, as a consequence, require approximately 0.75 to 1 t of dry biomass to produce 1 MWh of electricity.

Industrial and power generation boilers range in size from 100 to 300 MW thermal output. The major types of boilers are: pile burners; grate boilers; suspension fired boilers; fluidized beds; and circulating fluid beds. Recent trends in power generation are to use circulating and bubbling fluidized bed combustors, although the majority of units in current service are stoker-fired moving grate units.

Biomass resources can be used in ICEs and gas turbine systems only if they are converted into clean liquid or gaseous fuels. Ethanol, biodiesel from lipids, or Fischer–Tropsch liquids can be used with little alteration to SI or CI engines. Gaseous fuels include the mixture of methane and carbon dioxide (biogas) produced by the action of microorganisms on biomass in anaerobic digestion (AD). AD is conducted at an industrial scale, using sewage or effluent streams containing high levels of soluble sugars, alcohols, and acids, as well as in landfills.

The installed landfill power generation capacity in the U.S. is now in excess of 1 GW (Goldstein, 2002). The energy content of biogas is typically 20 to 25 MJ Nm^{-3} or between 50 and 60% that of natural gas. Fuel gases can also be produced by thermal gasification; when this is carried out at small scales, the gasifying agent is usually air. The product gas, which has a low calorific value (LCV) with a heating value of 12 to 15% that of natural gas, is often called a producer gas. LCV gas at about 5 to 6 MJ Nm^{-3} has carbon monoxide (CO), hydrogen (H_2), and methane (CH_4) as the main fuel components, diluted with a lot of nitrogen and carbon dioxide. Larger scale processes can utilize pure oxygen, enriched air, or an indirect heating method to produce medium calorific value (MCV) gas in the range of 15 to 25 MJ Nm^{-3} heating value with essentially the same fuel gas components but with much less inert diluent. Clean MCV gases can be burnt without much modification of ICEs or gas turbines.

Cofiring Biomass with Coal

In a biomass/coal cofiring operation, a biomass fuel is used to replace a portion of the coal fed to an existing coal-fired boiler. This has been practiced, tested, or evaluated for a variety of boiler technologies. There are four types of coal boilers: pulverized coal (PC); cyclone; stoker; and fluidized bed. PC boilers are the most common type in the U. S., representing about 92% of the U.S. coal-generating capacity, with cyclone boilers as the next most common, with about 7% representation. Demonstrations have been undertaken at coal plants ranging in size from about 30 MW_e through to 700 MW_e. Wood residues, hybrid poplar, and switchgrass have all been tested as supplemental fuels, and several utilities have biomass cofiring plants in commercial operation.

Solid biomass can be fed to coal boilers by blending biomass on the coal pile or separately injecting biomass into the boiler. Introducing blended feeds to PC boilers can cause operational problems with the pulverizer, so the biomass proportion is limited to no more than 2 to 3% by heat input (4 to 5% by mass). Separate injection allows for the introduction of higher biomass percentages to the PC boiler — typically up to 15% on a heat input basis (about 30% by mass).

However, separate injection requires additional fuel handling equipment and increased fuel preparation. Capital costs for the blended feed approach are typically \$50/100 kW^{-1}. For the separate feed approach, capital costs are typically higher, in the range of \$175/200 kW^{-1}. Cofiring can reduce boiler efficiency to some degree. For example, cofiring in a PC boiler with 10% of the heat input from wood may decrease the boiler efficiency by 0.5 to 1.5%; after "tuning" the boiler's combustion output and adjusting for any efficiency losses, the combustion efficiency to electricity would be approximately 33%.

Because coal plants comprise more than half of U.S. power plant capacity currently in operation, cofiring technology has the advantage of improving environmental performance at existing power plants, while providing fuel source flexibility and using proven and familiar equipment. It reduces air pollution

TABLE 7.4.5 Heating Values of Fuel Gases

	HHV[a]	LHV[b]	HHV[a]	LHV[b]
	Btu ft^{-3} [c]		MJ Nm^{-3} [d]	
Hydrogen	325	275	12.75	10.79
Carbon monoxide	322	322	12.63	12.63
Methane	1013	913	39.74	35.81
Ethane	1792	1641	69.63	63.74
Propane	2590	2385	99.02	91.16
Butane	3370	3113	128.39	118.56

Note: Conversion factors for 1 MJ Nm^{-3} at 273.15 K and 101.325 kPa. | 25.45 Btu ft^{-3} at 60°F and 14.73 psia. Inverse 1 Btu ft^{-3} at 60°F and 30 in. Hg. | 0.0393 MJ Nm^{-3}.

emissions, GHG emissions, and the amount of waste ash generated as a by-product of the combustion. In addition, it requires relatively low up-front capital expenses compared to other renewable energy options; this makes it a straightforward and inexpensive way to diversify the fuel supply and divert biomass from landfill disposal.

Thermal Gasification Technologies

The conversion of biomass into a gaseous fuel opens up modern applications in electric power generation, the manufacture of liquid fuels, and the production of chemicals from biomass. The chemistry of gasification of biomass is best viewed as an extension of the pyrolysis process. Pyrolysis is simply defined as the chemical changes occurring in the solid biomass when heat is applied to a material in the absence of oxygen. The products of biomass pyrolysis include water, charcoal (or more correctly *char*, a carbonaceous solid), oils or tars, and permanent gases including methane, hydrogen, carbon monoxide, and carbon dioxide.

The majority of gasifiers are partial oxidation reactors, in which just sufficient air or oxygen is introduced to burn part of the input biomass to provide the heat for pyrolysis and gasification. If the oxidant is air, the product gas is diluted by the nitrogen present**.** Although air is 79% nitrogen, the stoichiometry of partial oxidation is such that the final LCV product, gas, has about 50% nitrogen as a diluent. The energy content of the typical gases produced in biomass gasification **is** shown in Table 7.4.5. The use of pure oxygen as the gasification agent eliminates the nitrogen diluent and can produce medium calorific value (MCV) gases in the range of 10 to 20 MJ Nm^{-3}.

An alternative strategy is to carry out the gasification process by means of indirect heat the product stream is even higher in calorific value, because neither nitrogen nor the carbon dioxide produced from the combustion in-situ of the partial oxidation processes is present in the product gas stream. The challenges to achieve a clean and useable fuel gas have been addressed through gasifier design and postgasification processing to remove tar and particulate contaminants from the gas stream.

Gasifier Systems

The main challenge in gasification is enabling the pyrolysis and gas-reforming reactions to take place, using the minimum amount of energy, in reactors that are economical to construct. During a history dating back to the late 18th century, an extraordinary number of different designs and process configurations have been proposed. Prior to the development of fluidized bed technologies in the 1920s, the majority of the gasifiers were so-called fixed bed units. The flow of gasifying agents, usually air and steam, could be cocurrent with the biomass feed, or countercurrent; these are often described, respectively, as downdraft and updraft gasifiers.

Downdraft gasification was widely used during the Second World War as an on-board fuel gas generator to offset the lack of gasoline. Millions of units were constructed and then abandoned as soon as petroleum supplies resumed. Units derived from the automotive application are marketed today as stationary generating sets equipped with ICEs, with SI or CI for power production in remote locations and in developing countries without grid systems.

The simplest and oldest gasifier is the counterflow moving bed, which consists of an insulated shaft into which the feedstock (typically pieces larger than 3 cm on a side) are fed. The shaft is filled to a depth of 0.5 to 2 times the vessel diameter, and the mass of material is supported on a grate. The oxidant (air or enriched air/oxygen) and sometimes steam are introduced below the grate. The grate material is ignited and the hot gases flow up through the bed, exchanging heat with the down-flowing biomass material and, at the same time, pyrolyzing and drying it. At steady state, the bed level is maintained by continuous additions of the feed.

The product gases include the desired fuel gases (methane, carbon monoxide, hydrogen, and C_2 hydrocarbons), nitrogen, carbon dioxide, and water vapor, which exit at relatively low temperatures (<250°C). The water arises from the moisture content of the feed and the products of combustion. The gas also contains several percent of condensable tars. Because the temperatures in the combustion zone can be very high, problems with the formation of slags (molten mixtures that can impede the oxidant flow) may occur. Some of the systems are constructed deliberately to form a molten ash or slag, and this is handled by dropping the slag into a receiving tank, where it solidifies and shatters to an easily handled aggregate.

The throughput of air-based systems is relatively low, handling about 150 kg m^{-2} h^{-1} of dry biomass. This operational limitation is due to the need to reduce the rate of heat generation at the grate to avoid slagging in dry systems. The lower throughput rate also helps to manage the problems of maintaining a uniform flow of the descending material to avoid channeling and even greater reductions in throughput. The largest units are typically 3 to to 4 m in diameter and handle between 50 and 100 t d^{-1} of material with a rating of 10 to 20 MW_{th} input. The hot gas efficiency can be as high as 80% conversion of the input energy into a fuel gas and sensible heat. The cold gas efficiency will be about 70%.

If the gas is maintained at temperature and then fired in a kiln or boiler, the presence of tars and particulate are of little consequence because the tars are combusted in the excess air and the particulate is removed in the kiln exhaust or boiler flue gas system. Such close-coupled systems are quite common applications of biomass gasification in several industries and the basis of district heating systems used in Finland. The gas typically has a heating value of 6 MJ Nm^{-3} on a dry basis and is richer in methane, ethene, and ethyne than most other gasifier systems using air. For engine applications the gas must be cleaned up and cooled to ambient temperatures. Typically, this is done with some sort of aqueous quench and scrubbing system (e.g., a wet electrostatic precipitator) to remove tar and particulate matter, and the tar/water removed must be separated and then treated for release to the environment.

Fluidized beds can remove the grate limitation of the moving bed gasifier because, due to their high mixing rates and outstanding heat transfer rates, they can achieve through-puts of over 1500 kg m^{-2} h^{-1} of dry biomass. The two modes of fluidized bed operation involve bubbling (BFB) and circulating (CFB) solids. In a BFB, the inert fluid bed medium (silica sand, dolomite, alumina, and olivine) is retained in the body of the bed, which is expanded and in motion (literally bubbling) due to the flow of the fluidizing gas medium into the bed. The terminal velocity of a particle in the flow is still higher than the linear flow rate of the gas and thus remains in the body of the unit. In the CFB, the gas flow is increased to the point that the terminal velocity of the particle is exceeded and it is transferred out of the expanded bed and captured in a cyclone for return to cycle.

The effective rating of a 3-m diameter unit is over 50 MW_{th} input of biomass. Because the combustion process and the pyrolysis process are now mixed, the exit gas temperatures are typically 700 to 800°C.

Due to cracking processes, the tar production is lower and mainly composed of secondary and tertiary tar components; however, the tolerance of high moisture content feedstocks is much more limited than the countercurrent moving bed unit. The system design is also more complex, requiring blowers to inject the oxidant at the base of the fluidized bed. In addition to the expansion of the gas due to temperature, the gas volume increases due to the formation of the fuel gas. This necessitates careful design of the CFB and the freeboard in a BFB; in a CFB, this is accommodated by the fact that the entire bed is in circulation. The oxidant requirement is typically 0.3 kg O_2 kg^{-1} of dry feedstock.

The highest reactivity gasification systems are entrained flow units in which the feedstock is finely divided and burnt in a substoichometric flame at high temperatures. The postcombustion gases are then allowed to reach chemical equilibrium before being quenched. Such units produce very few higher hydrocarbons and tar materials. The challenge for biomass is to obtain a sufficient rate of fuel injection to the flame. One configuration is the Koppers–Totzek gasifier. For fossil fuels, the Texaco gasifier uses a dense slurry of coal or petroleum coke in water as the feed to a pressurized oxygen flame, producing a hydrogen and carbon monoxide mixture for use as a syngas or as a fuel in gas turbines.

Cocurrent moving bed gasifiers (also known as downdraft and cross-draft units) were widespread during World War II (various estimates put the number at over 1 million). Like the other gasifiers described earlier, the design is a partial oxidation system. The physical arrangement is a shaft reactor into which the biomass is introduced at the top; the material then flows down to an oxidation zone, where the air is admitted. This zone feeds heat back to the incoming biomass to pyrolyze the material into gases, tars, and charcoal. The charcoal is partially combusted in the oxidation zone, and the products of pyrolysis flow through the incandescent combustion zone to be cracked into, primarily, hydrogen and carbon monoxide as the fuel gases, with few or no tars passing through. The combusted gases flow on through the hot charcoal, reacting with it, until the rate of reaction effectively goes to zero because the reactions are very endothermic.

The net result is a gas at about 500°C that is very low in condensible tars; other than carbon dioxide, water vapor, and nitrogen, the fuel gases are mainly hydrogen and carbon monoxide with only a small amount of methane and higher hydrocarbons. The low tar production is the reason this was the favored system for on-road vehicles in the 1940s. Like all moving bed reactors, the operation depends on the presence of an adequate void space between particles. The wood feedstock must produce a char that has sufficient strength to support the column of feedstock without crushing and blocking the flow.

The overall efficiency is lower than the countercurrent system for two reasons. Chemically, it is not possible to convert the charcoal fully; the sensible heat from the combustion zone is not transferred to the incoming feed material, but rather must be heat exchanged with air oxidant prior to being quenched. Because of the need for uniformity of mass and heat transfer in the high-temperature reaction zone, the diameter of such units is generally limited to less than 1.5 m and, with typical throughputs of 300 kg m^{-2} h^{-1} of dry biomass, the size of units ranges from 100 kW_{th} to 2 MW_{th} input. The chemistry of this gasifier has a lot in common with iron blast furnaces and is significantly different from the other gasifiers, which have very high burdens of liquids such as tars in the product gas.

Medium calorific value (MCV) gas can be produced without using oxygen or air in gasification. This requires an independent source of heat to be transferred to the biomass to pyrolize the feedstock under conditions of high severity, i.e., long residence times at high temperatures. To this end, proposals have been made to use concentrated solar energy or high-temperature nuclear reactors as the heat source in the gasification of a wide range of feedstocks. In the case of biomass, the pyrolysis gasification process will provide a char stream with slow or fast pyrolysis to temperatures of 600 to 750°C, in amounts representing between 12 and 25% of the input biomass. This contains sufficient energy to drive the pyrolysis process.

A number of developments in which biomass is pyrolized using a solid heat carrier in an inert atmosphere or steam or product MCV gas to generate the MCV fuel gas and char are already in the demonstration phase. The char and the cooled heat carrier, which can be silica sand, alumina, or a mineral such as olivine, are then transferred to a separate air combustion unit in which the char is combusted to heat up the heat carrier, which is then returned to the pyrolysis gasification unit. Mechanical separation and isolation devices in the heat carrier circulation loops prevent the passage of fuel gas from the gasifier to the oxidation conditions of the combustor. The transportation mechanism is via fluidization of the heat carrier.

To this end, a group in Austria constructed a version with a CFB combustion unit and BFB pyrolysis gasifier; in the U.S., units have been constructed with a CFB pyrolysis reactor and a BFB combustor as well as a dual CFB configuration scaled up to 60 MW_{th} biomass input. Another variant, developed by Manufacturing and Technology Conversion International, Inc. (MTCI), a U.S. company, was a BFB pyrolysis and steam char reaction system with the heat supply from immersed heat exchanger bundles in the bed. The heat exchanger bundles are fueled with part of the product gas, and the char from pyrolysis is consumed, as in the cocurrent gasifier.

Commercialization

Use of gasifiers as precombustors in which the hot gases are passed through a high-temperature duct into a boiler or industrial process kiln has been widespread; cofiring is an example. Foster Wheeler Energia Oy CFB has been supplying a LCV gas for several years to an existing large-scale utility boiler at the Kymijärvi 167 MW_e and 240 MW_{th} fossil-fired plant close to Lahti, Finland. A combination of forestry residues, industrial wood residues, and recycled fuel (a clean fraction of the municipal waste stream composed mainly of wood, paper, and cardboard separated at the source) is the fuel source. This project builds on many years of successful operation of biomass CFBs in thermal applications and substitutes for about 15% of the total fuel used in the boiler.

Applications in which clean gases (free of particulate and tar) are utilized occur mainly in the development and demonstration stages, with the exception of deployment of cocurrent gasifier–ICE generator sets. In 2000, Sydkraft A.B. successfully completed a high-pressure LCV gas biomass integrated gasification and combined cycle (IGCC) operation, which was part of the Värnamo (Sweden) district heating system. This first complete biomass-fueled pressurized CFB IGCC was fueled with about 18 MW_t equivalent of wood residues and produced about 6 MW_e (4 from the gas turbine, 2 from the steam cycle) and 9 MW_{th}. The LCV gas is cooled to 350 to 400°C before it is cleaned in metal filters and then passed to the Typhoon gas turbine, which is manufactured by Alstom. The project demonstrated more than 1500 h of IGCC operation on the product gas prior to its shutdown at the end of the demonstration phase (Stahl et al., 2000).

Small-scale gasifiers for the production of fuel gas for cooking, as well as the demonstration of electricity in ICEs, are already commercial in India and China. Their introduction has been accelerated by the use of moderate government subsidies, especially for communities not served by the electricity grid. In development circles, such systems are often referred to as village power systems. Considerable discussion among the OECD nations concerns the use of distributed energy resources, which would provide local power and heat (e.g., CHP units) while remaining connected to the grid. Many of these units are based on natural gas; however, when the economics and availability of biomass are appropriate, gasification is considered; demonstrations of gasfier–ICEs with CHP applications in district heating have taken place in Denmark.

Biological Process Technologies

The polymers that make up biomass are produced through photosynthetically driven biological reactions at the cellular level in the plant. The resulting phytomass is then fuel and food (or feedstock) for a large number of the fauna on Earth. From simple bacteria to large mammals, the processes to digest and metabolize plant polymers have evolved over billions of years. In a number of instances, the biological degradation processes have been harnessed in industrial conversion processes to produce biofuels and bioproducts to serve humanity. Of the many processes, only two have attained large-scale use: anaerobic digestion and ethanol production.

Anaerobic Digestion

Anaerobic microorganisms convert the biodegradable fraction of organic materials to carbon dioxide and methane in the absence of oxygen. Commercial-scale anaerobic digestion has been used in many parts of the world for many years and is only beginning to be commercial in the U.S. Several utilities are currently producing "green energy" with biogas from landfills. Biogas from anaerobic digesters on dairy and hog farms and cattle feed lots is beginning to contribute to the energy mix in the U.S.

Ethanol Production

Ethanol is currently the most important liquid fuel produced from biomass. It is produced by fermentation of sugars. The fermentable sugars can be obtained directly from sugar cane and sugar beet, or they can be produced by means of the hydrolysis of starches or cellulose and hemicelluloses. Starch crops include cereals, and manioc in tropical countries, while cellulose and hemicellulose are the major polymers of wood, grasses, straws, and stalks. The production from sugar cane in Brazil has been in the range of 11 to 13 GL y^{-1} for the last few years; in the U.S., the annual production has grown rapidly from 5.42 GL in 2000 to 8.08 GL in 2002. This growth is primarily due to legislation banning the use of methyl tertiary–butyl ether as an octane enhancer in several state markets.

Over 90% of the U.S. production is from corn, which is processed in wet or dry mills. Corn kernels have about 70 to 75% starch content; approximately 10% protein (gluten); 4 to 5% germ (the source of corn oil); and 3 to 4% fiber content. Dry milling consists of grinding the whole kernel into a flour and then slurrying this with enzymes to break down the starch to fermentable sugars. The stillage separated from the beer is composed of coarse grain and a wide range of soluble materials. The solubles are concentrated by evaporation into a syrup (condensed distillers solubles), which is then added to the coarse grain to produce dried distillers grain with solubles or DDGS. This is marketed as a feed for animals. Dry milling theoretically produces about 460 L of ethanol per tonne of corn.

Wet milling is an example of a biomass refinery. The corn kernels are steeped in dilute sulfurous acid for 48 h in a mild prehydroylsis process prior to a grinding step to separate the corn germ. Corn oil is recovered from the germ as high-value cooking oil. The starch and the gluten protein are then separated. The gluten is dried and sold as a 60% protein feed to mainly poultry markets. The starch fraction is the source of dried or modified cornstarches and a syrup converted enzymatically into high-fructose corn syrup or passed to a fermentation step producing ethanol and other fermentation-derived chemicals.

Yields of ethanol are somewhat lower than those from dry milling at around 440 L t^{-1} of corn. According to the National Corn Growers Association (www.ncga.com), corn utilization rates of the 246.25 Mt, 2002 harvest (9.695 billion bushel) were: 58% as feed; 19% as export grain; 6% as high-fructose corn syrup; 9% as fuel ethanol; and 8% from all other applications (including breakfast cereal, cornstarches, and seed corn).

Since the inception of the corn-to-ethanol process technology in the 1970s, continuous improvement has occurred in terms of yield, process efficiency, reduced capital investment, and nonfeed operating costs. The industry average yield has gone from 360 L t^{-1} (2.4 USgal/bu) to 410 L t^{-1} (2.75 USgal/bu), while the capital cost has declined from 220 to about 115 \$ L^{-1} d^{-1} capacity (2.5 down to 1.3 USD per annual gallon of capacity), according to the industry.

Liquid Fuels and Bioproducts from Lignocellulosics

Lignocellulosics (such as wood, straw, and grasses) contain cellulose (40 to 50%) and hemicellulose (25 to 30%). There is considerable ethanol potential through fermentation of the sugars derived from these polymers, producing similar theoretical yields per tonne as corn, i.e., 450 L t^{-1} and a price structure, which is more stable relative to the fuel markets than foodstuffs. Alternative processes would include thermochemical routes through the production of synthesis gas and its catalytic synthesis to mixed alcohols, Fischer–Tropsch liquids, or hydrogen — a future transportation fuel (Table 7.4.2).

Current RD&D in the U.S. is focused on the development of two product platforms: a sugar platform that inherits much of the prior research into the production of ethanol from lignocellulosic biomass, and a syngas platform evolved from the development of biomass gasifiers primarily for power production

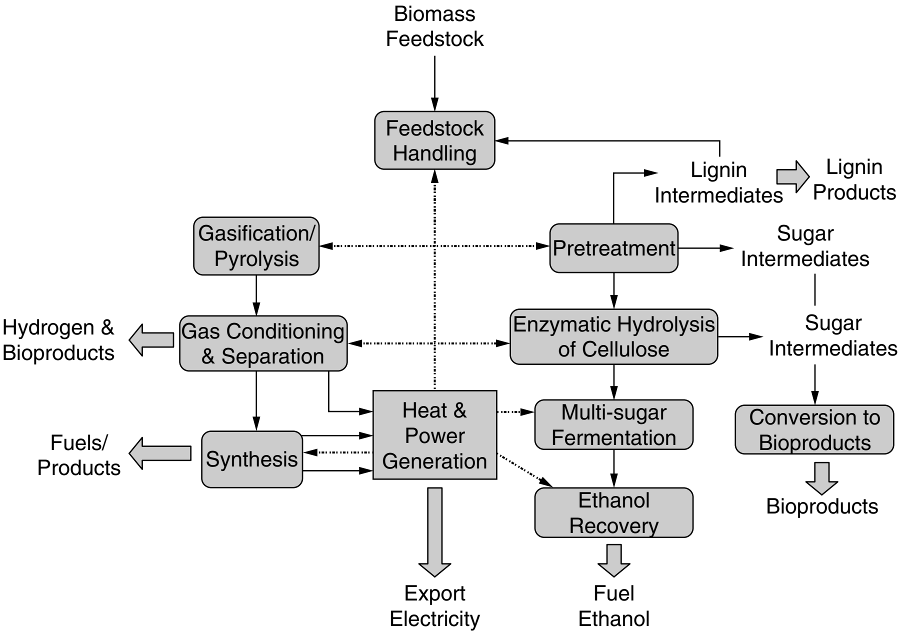

FIGURE 7.4.1 The U.S. RD&D approach to the sugar and syngas platforms.

coupled with the extensive downstream catalysis developments of the petrochemical industry. The syngas platform is also the basis for the combustion units for the utilities component of the platforms, which are shown diagramatically in Figure 7.4.1.

The sugar platform inherits over two decades of work on the ethanol conversion process from lignocellulosics (Wyman, 1994). The polymers involved are much more recalcitrant than starches and, because of the complex nature of lignocellulosics, they require extensive effort to break down the lignin, cellulose, and hemicellulose structure so that the individual polymers become available for hydrolysis. Cellulose is hydrolyzed to glucose, a six-carbon sugar (C-6), while hemicellulose is a complex mixture of mainly five-carbon sugar (C-5) precursors, with xylose as a major product. Although the C-6 sugars are relatively easy to ferment with yeasts, such as *Saccharomyces* spp., the C-5 sugars have not been as easy to ferment to ethanol (Zhang et al., 1995). The pretreatment stages can include steam, acid, and alkali treatments, while the hydrolysis steps can be carried out with acids or enzymes. Because of inhibition of the enzymatic hydrolysis by the sugars produced, the National Renewable Energy Laboratory (NREL) developed a simultaneous saccharification and fermentation process to remove the sugars as they are formed by producing ethanol in the same reactor. Such process integration will be the key to producing low-cost sugars and thus ethanol or other bioproducts in the future (Lynd et al., 1999).

The syngas platform using biomass would enable the production of renewable liquid fuels and chemicals such as ammonia and hydrogen by well-established and proven syngas technologies. Today these processes utilize the syngas produced by the steam reforming of natural gas or use syngas from coal gasification. The production of liquid fuels from syngas has a long history dating from the pioneering work of Fischer and Tropsch to synthesize hydrocarbon fuels in Germany in the 1920s. The process was implemented in Germany in the 1930s where nine plants operated during World War II on syngas from coal gasification; after the war, until the mid 1950s, they operated on syngas from the gasification of heavy oil. In the 1950s, South Africa constructed the first of the South African Synthetic Oil Limited (SASOL) plants, an activity that has continued its development to the present day using syngas produced from coal and natural gas. Both of these developments were initiated during times of petroleum shortages, to fuel the transportation systems of Germany and South Africa.

Continuing research and development is based on the environmental advantages of producing zero sulfur fuels, with combustion properties tailored to specific engine designs to minimize emissions from petroleum-derived fuels. At the time of writing, there are at least six developers of what are known as Fischer–Tropsch liquids (FTL) plants, which are scaled to use remote and difficult-to-get-to-market sources of natural gas as the feedstock for the syngas. FTL processes use catalysts based mainly on iron, cobalt, ruthenium, and potassium and have been extensively characterized. They operate at high pressures between 2.5 and 4.5 MPa, and temperatures between 220 and 450°C. The reactors range from fixed catalyst beds to bubbling as well as circulating fluidized beds. The product distribution depends on the polymerization on the surface of the catalyst. The hydrocarbon chains are built up one carbon atom at a time — a process known as homologation. Polymer growth of this type is now understood to take place via what is known as the Anderson–Shulz–Flory mechanism, and it is not possible to produce a single compound with a fixed number of carbon atoms or even a narrowly defined distribution of molecular weights.

Extensive product recycling and recirculation of unreacted syngas can be used to reduce the number of small hydrocarbon molecules (e.g., C_1 to C_5); however, production of wax-like molecules with as many as 30 to 50 carbon atoms also exists. The conversion per pass of the syngas over the catalysts is often limited, due in part to the fact that the polymerization reaction is exothermic and the equilibrium mixtures obtained are very temperature sensitive, affecting the yield and proportions of the desired products. The recycle processes are very energy intensive and reduce the throughput of the catalyst system.

Recent progress in enhancing the yields of gasoline and diesel products has been made partly by optimization of the catalysts and operating conditions, and also by companies such as Shell with its Shell Middle Distillate Synthesis (SMDS) process in which the higher molecular weight waxes are hydrotreated over selective catalysts to increase the yield of the desired range of hydrocarbons C_8 through C_{20}. The smaller carbon number products, C_1 to C_5, are also reformed to increase the hydrogen to the overall process. Other innovations in the FTL arena include slurry reactors, which use very finely divided catalysts suspended in an oil medium. Such reactors often demonstrate much increased conversion in a single pass and offer economies with respect to recycle energy and investment. However, from the chemical engineering perspective; such three-phase reaction systems have required a lot of R&D and development.

An alternative production process would use a high conversion single-pass catalyst such as a slurry reactor and then utilize the tail gas after the catalyst as fuel for a gas turbine combined cycle. Such a process would then coproduce electricity, heat, and a liquid fuel and offer lower investment costs and higher overall efficiency.

Higher alcohols are produced from syngas over typical Fischer–Tropsch catalysts under conditions of greater severity than those used predominantly in the production of hydrocarbons. Pressures are between 5 and 15 MPa and are generally at temperatures higher than FTL synthesis. The Anderson–Shulz–Flory mechanism does not appear to determine the product distribution, although homologation through the addition of one carbon atom at a time is followed, so that product methanol is recycled over the catalyst to grow into higher alcohols.

Changes in catalyst composition can determine the isomer composition of the higher ($>C_3$) alcohols. Also, mixed thermochemical syngas and biotechnology routes to ethanol are under development. Ethanol can be synthesized from syngas using an anaerobic bacterium, *Clostridium ljungdahlii.* The growth conditions of the bacterium are managed so as to maximize the ethanol yield over the production of acetate (as acetic acid) from the key biological pathway intermediate acetyl-CoA, which is derived from the syngas. Although not yet commercialized, many of the development challenges of producing the bacterium and making effective gas–liquid contactors and bioreactors have been overcome. Yields are similar to those from the inorganic high temperature Fischer–Tropsch catalysts.

Further information

Combustion is widely described in the literature. The International Energy Agency recently produced an extremely useful reference book on the topic of biomass combustion: van Loo, S. and J. Koppejan, Eds. (2002). *Handbook of Biomass Combustion and Cofiring*. Enschede, Netherlands, Twente University Press (A multiauthor IEA Bioenergy collaboration Task 32 publication).

Power generation is described and analyzed in: EPRI (1997). *Renewable Energy Technology Characterizations*. Washington, D.C., Electric Power Research Institute.

Gasification in general and synthetic liquid fuels are well described in: Probstein, R. F. and R. E. Hicks (1982). *Synthetic Fuels*. New York, McGraw–Hill Inc.

Anaerobic digestion is the subject of a wonderful handbook that is only available in German at present: Schulz, H. and B. Eder (2001). *Bioga Praxis: grundlagen, planung, anlagenbau, beispiele*. Freiburg, Germany, Ökobuch Verlag, Staufen bei Freiburg.

Ethanol from lignocellulosics as well as a useful section on starch ethanol can be obtained in: Wyman, C. E., Ed. (1996). *Handbook on Bioethanol: Production and Utilization*. Applied Energy Technology Series. Washington, D.C., Taylor and Francis.

Additional information on ethanol can be obtained from the Web sites of the National Corn Growers Association (http://www.ncga.com) and the Renewable Fuels Association (http://www.ethanolrfa.org/).

The last three decades of biomass activity in the United States are described in: Chum, H. L. and R. P. Overend (2003). *Biomass and Bioenergy in the United States*. In *Advances in Solar Energy: an Annual Review of Research and Development*. Ed. Y. Goswami. American Solar Energy Society, Boulder, CO. USA. 83–148.

Additional information on energy efficiency and renewable energy technologies can be obtained from the U.S. Energy Efficiency and Renewable Energy Websites http://www.eere.energy.gov/biomass.html, and http://www.eere.energy.gov/RE/bioenergy.html. Also the Website http://bioenergy.ornl.gov/ provides useful resource information and many links to other bioenergy Websites.

7.5 Nuclear Resources

James S. Tulenko

The Nuclear Fuel Cycle

Sources of Nuclear Fuels and World Reserves

Nuclear power can use two naturally occurring elements, uranium and thorium, as the sources of its fissioning energy. Uranium can be a fissionable source (fuel) as mined (Candu Reactors in Canada), while thorium must be converted in a nuclear reactor into a fissionable fuel. Uranium and thorium are relatively plentiful elements ranking about 60th out of 80 naturally occurring elements. All isotopes of uranium and thorium are radioactive. Today, natural uranium contains, in atomic abundance, 99.2175% Uranium-238 (U^{238}); 0.72% Uranium-235 (U^{235}); and 0.0055% Uranium-234 (U^{234}). Uranium has atomic number 92, meaning all uranium atoms contain 92 protons, with the rest of the mass number being composed of neutrons. Uranium-238 has a half-life of 4.5×10^9 years (4.5 billion years), U-235 has a half-life of 7.1×10^8 years (710 million years), and U-234 has a half-life of 2.5×10^5 years (250 thousand years). Since the age of the earth is estimated at 3 billion years, roughly half of the U-238 present at creation has decayed away, while the U-235 has changed by a factor of sixteen. Thus, when the earth was created, the uranium-235 enrichment was on the order of 8%, enough to sustain a natural reactor of (there is evidence of such an occurrence in Africa). The U-234 originally created has long disappeared, and the U-234 currently present occurs as a product of the decay of U-238.

Uranium was isolated and identified in 1789 by a German scientist, Martin Heinrich Klaproth, who was working with pitchblend ores. No one could identify this new material he isolated, so in honor of the planet Uranus which had just been discovered, he called his new material Uranium. It wasn't until 1896, when the French scientist Henri Becquerel accidentally placed some uranium salts near some paper-wrapped photographic plates, that radioactivity was discovered.

Until 1938, when the German scientists Otto Hahn and Fritz Shassroen succeeded in uranium fission by exposure to neutrons, uranium had no economic significance except in coloring ceramics, where it proved valuable in creating various shades of orange, yellow, brown, and dark green. When a uranium atom is fissioned it releases 200 million electron volts of energy; the burning of a carbon (core) atom releases 4 electron volts. This diffenence of 50 million times in energy release shows the tremendous difference in magnitude between chemical and nuclear energy.

Uranium is present in the earth's crust to the extent of four parts per million. This concentration makes uranium about as plentiful as beryllium, hafnium, and arsenic; and greater in abundance than tungsten, molybdenum, and tantalum. Uranium is an order of magnitude more plentiful than silver and a hundred times more plentiful than gold. It has been estimated that the amount of uranium in the earth's crust to a depth of 12 miles is of the order of 100 trillion tons.

Thorium, which is composed of only one isotope, Thorium-232, has a half-life of 14 billion years (1.4×10^{10} yr), is more than three times more abundant than uranium, and is in the range of lead and gallium in abundance. Thorium was discovered by Berjelius in 1828 and named after Thor, the Scandinavian god of war. For reference, copper is approximately five times more abundant than thorium and twenty times more abundant than uranium.

Uranium is chemically a reactive element; therefore, while it is relatively abundant, it is found chemically combined as an oxide (U_3O_8 or UO_2) and never as a pure metal. Uranium is obtained in three ways, either by underground mining, open pit mining, or in situ leaching. An economic average ore grade is normally viewed as .2% (4 pounds per short ton), though recently ore grades as low as .1% have been exploited. A large quantity of uranium exists in sea-water which has an average concentration of 3×10^{-3} ppm, yielding an estimated uranium quantity available in sea-water of 4000 million tons. A pilot operation was successfully developed by Japan to recover uranium from sea-water, but the cost was about $900/lb, and the effort was shut down as uneconomical.

The major countries with reserves of urnaium in order of importance are Australia, United States, Russia, Canada, South Africa, and Nigeria. The countries with major thorium deposits are India, Brazil, and the United States. It is estimated that for a recovery value of $130/kg ($60/lb), the total uranium reserves in these countries are approximately 1.5 million tonnes of uranium in the U.S., 1 million tonnes of uranium in Australia, .7 million tonnes of uranium in Canada, and 1.3 million tonnes of uranium in the former Soviet Union. As mentioned earlier, thorium reserves are approximately four times greater. With the utilization of breeder reactors, there is enough uranium and thorium to provide electrical power for the next thousand years at current rates of usage.

Processing of Nuclear Fuel

Once the uranium ore is mined it is sent to a concentrator (mill) where it is ground, treated, and purified. Since the ore is of a grade of .1 to .2% uranium, a ton of ore contains only between 1 to 2 kilograms of uranium per 1000 kilograms of ore. Thus, thousands to tonnes of ore have to be extracted and sent to a mill to produce a relatively small quantity of uranium. In the concentration process approximately 95% of the ore is recovered as U_3O_8 (yellowcake) to a purity grade of about 80%. Thus, assuming 0.15% uranium ore, the milling and processing of a metric ton (1000 kg) of ore yields a concentrate of 1.781 kg (1.425 kg of uranium and 0.356 kg of impurities). For this reason the mills must be located relatively close to the mine site. The ore tailings (waste) amounts to 998.219 kg and contains quantities of radon and other urnaium decay products and must be disposed of as a radioactive waste.

The U_3O_8 concentrate is then taken to a conversion plant where the concentrate is further purified (the 20% impurities are removed) and the uranium yellowcake is converted to uranium hexafluoried UF_6). The uranium hexafluoride is a gas at fairly low temperature and is an ideal material for the U-235 isotope enriching processes of either gaseous diffusion or gaseous centrifuge. The UF_6 is shipped in steel cylinders in a solid state, and UF_6 is vaporized by putting the cylinder in a steam bath.

If the uranium is to be enriched to 4% U^{235}, then 1 kilogram of 4% U^{235} product will require 7.4 kilograms of natural uranium feed and will produce 6.4 kilograms of waste uranium (tails or depleted uranium) with a U^{235} isotope content of 0.2%. This material is treated as a radioactive waste. Large quantities of tails (depleted uranium) exist as UF_6 in their original shipping containers at the enriching plants. Depleted uranium (a dense material) has been used as shields for radioactive sources, armor piercing shells, balancing of helicopter rotor tips, yacht hold ballast, and balancing of passenger aircraft.

The enriched UF_6 is then sent to a fabrication plant where it is converted to a uranium dioxide (UO_2) powder. The powder is pressed and sintered into cylindrical pellets which are placed in zircaloy tubes (an

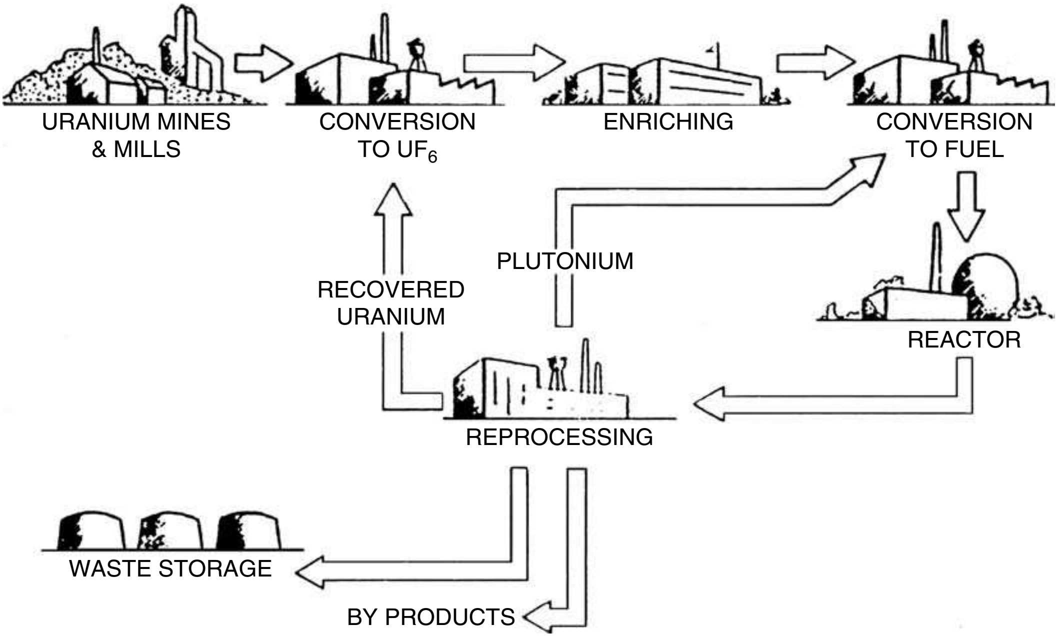

FIGURE 7.5.1 The nuclear fuel cycle.

alloy of zirconium), pressurized with helium, and sealed. The rods are collected in an array (~17 × 17) bound together by spacer grids, with top and bottom end fittings connected by tie rods or guide tubes. Pressurized water reactor fuel assemblies, each containing approximately 500 kilograms of uranium, are placed in a reactor for 3 to 4 years. A single fuel assembly produces 160,000,000 kilowatt hours of electricity and gives 8,000 people their yearly electric needs for its three years of operation. When the fuel assembly is removed from the reactor it must be placed in a storage pond to allow for removal of the decay heat. After approximately five years of wet storage, the fuel assembly can be removed to dry storage in concrete or steel containers. In the United States the current plan is to permanently store the nuclear fuel, with the Department of Energy assuming responsiblility for the "spent" fuel. The money for the government to handle the storage comes from a fee of 1 mill per kilowatt hour paid by consumers of nuclear-generated electricity. A mill is a thousandth of a dollar or a tenth of a penny. Thus, the fuel assembly described above would have collected $160,000 in the waste fund for the Department of Energy to permanently store the fuel. In Europe, when the fuel is taken out of wet storage it is sent to a reprocessing plant where the metal components are collected for waste disposal; and the fuel is chemically recovered as 96% uranium, which is converted to uranium dioxide for recycling to the enrichment plant, 1% plutomium, which is converted to fuel or placed in storage, and 3% fission products which are encased in glass and permanently stored.

The important thing to remenber about the fuel cycle is the small quantitiy of radioactive fission products (1.5 kilograms) which are created as radioactive waste in producing power which can serve the yearly eletricity needs of 8,000 people for the three years that it operates. The schematic of the entire fuel cycle showing both the United States system (once-through) and the European (recycle) system is given in Figure 7.51.

7.6 Solar Energy Resources

D. Yogi Goswami

The sun is a vast nuclear power plant of the fusion variety which generates power in the form of radiant energy at a rate of 3.8×10^{23} kW. An extremely small fraction of this is intercepted by Earth, but even this small fraction amounts to the huge quantity of 1.8 × 10^{14} kW. On the average, about 60% of this energy incident at the outer edge of the atmosphere, reaches the surface. To compare these numbers with our energy needs, consider the present electrical-generating capacity in the United States, which is approximately of 7 × 10^8 kW. This is equivalent to an average solar radiation falling on only 1000 square miles in a cloudless desert area. It must, however, be remembered that solar energy is distributed over the entire surface of Earth facing the sun, and it seldom exceeds 1.0 kW/m^2. Compared to other sources, such as fossil fuels or nuclear power plants, solar energy has a very low energy density. However, solar radiation can be concentrated to achieve very high energy densities. Indeed, temperatures as high as 3000 K have been achieved in solar furnaces.

Solar energy technology has been developed to a point where it can replace most of the fossil fuels or fossil fuel-derived energy. In many applications it is already economical, and it is a matter of time before it becomes economical for other applications as well.

This section deals in the availability of solar radiation, including methods of measurement, calculation, and available data.

Solar Energy Availability

Detailed information about solar radiation availability at any location is essential for the design and economic evaluation of a solar energy system. Long-term measured data of solar radiation are available for a large number of locations in the United States and other parts of the world. Where long-term measured data are not available, various models based on available climatic data can be used to estimate the solar energy availability. The solar energy is in the form of electromagnetic radiation with the wavelengths ranging from about 0.3 μm (10^{-6} m) to over 3 μm, which correspond to ultraviolet (less than 0.4 μm), visible (0.4 and 0.7 μm), and infrared (over 0.7 μm). Most of this energy is concentrated in the visible and the near-infrared wavelength range (see Figure 7.6.1). The incident solar radiation, sometimes called **insolation**, is measured as irradiance, or the energy per unit time per unit area (or power per unit area). The units most often used are watts per square meter (W/m^2), British thermal units per hour per square foot (Btu/hr-ft^2), and Langleys (calories per square centimeter per minute, cal/cm^2-min).

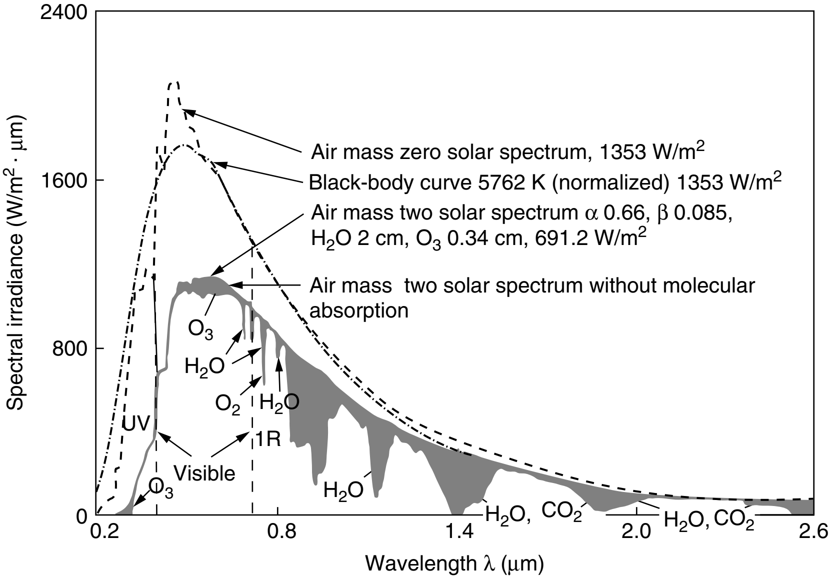

FIGURE 7.6.1 Spectral distribution of solar energy at sea level. (Reprinted by permission from Goswami, D.Y., Kreith, F., and Kreider, J.F., *Principles of Solar Engineering*, Taylor and Francis, Philadelphia, PA, 2000.)

The amount of solar radiation falling on a surface normal to the rays of the sun outside the atmosphere of the earth (extraterrestrial) at mean Earth-sun distance (D) is called the **solar constant**, I_o. Measurements by NASA indicated the value of solar constant to be 1353 W/m^2 (±1.6%). This value was revised upward and the present accepted value of the solar constant is 1377 W/m^2 (Quinlan, 1979) or 437.1 Btu/hr-ft^2 or 1.974 langleys. The variation in seasonal solar radiation availability at the surface of Earth can be understood from the geometry of the relative movement of Earth around the sun.

Earth-Sun Relationships

Figure 7.6.2 shows the annual motion of Earth around the sun. The **extraterrestrial solar radiation** varies throughout the year because of the variation in the Earth-sun distance (D) as:

$$I = I_o \left(D/D_o \right)^2 \tag{7.6.1}$$

which may be approximated as (Spencer, 1971)

$$\left(D/D_o \right)^2 = 1.00011 + 0.034221\cos(x) + 0.00128\sin(x) + 0.000719\cos(2x) + 0.000077\sin(2x) \tag{7.6.2}$$

where

$$x = 360(N-1)/365° \tag{7.6.3}$$

and N = Day number (starting from January 1 as 1). The axis of the Earth is tilted at an angle of 23.45° to the plane of its elliptic path around the sun. This tilt is the major cause of the seasonal variation of solar radiation available at any location on Earth. The angle between the Earth-sun line and a plane through the equator is called **solar declination**, δ. The declination varies between –23.45° to +23.45° in 1 year. It may be estimated by the relation:

$$\delta = 23.45° \sin\left[360(284+N)/365°\right] \tag{7.6.4}$$

The apparent motion of the sun around the earth is shown in Figure 7.6.3. The **solar altitude angle**, β, and the **solar azimuth angle**, Φ, describe the position of the sun at any time.

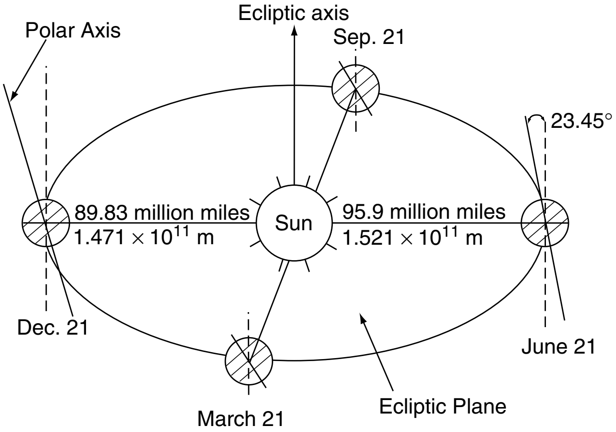

FIGURE 7.6.2 Annual motion of the Earth around the sun. (Adapted from Goswami, D.Y., Kreith, F., and Kreider, J., *Principles of Solar Engineering*, Taylor and Francis, Philadelphia, PA, 2000.)

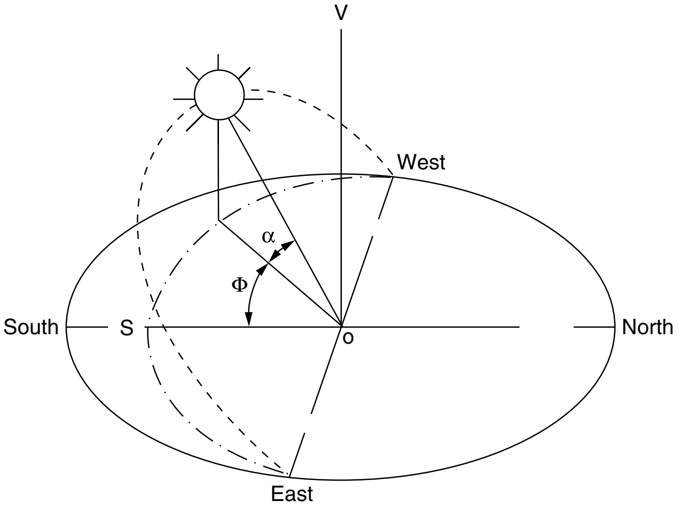

FIGURE 7.6.3 Apparent daily path of the sun across the sky from sunrise to sunset, showing the solar altitude and azimuth angles.

Solar Time

The sun angles are found from the knowledge of solar time, which differs from the local time. The relationship between solar time and local standard time (LST) is given by

$$\text{Solar Time} = \text{LST} + \text{ET} + 4\left(L_{st} - L_{loc}\right) \tag{7.6.5}$$

where ET is the **equation of time**, which is a correction factor in minutes that accounts for the irregularity of the motion of the Earth around the sun. L_{st} is the standard time meridian and L_{loc} is the local longitude. ET can be calculated from the following empirical equation:

$$\text{ET(in minutes)} = 9.87\sin 2B - 7.53\cos B - 1.5\sin B \tag{7.6.6}$$

where $B = 360(N - 81)/365°$.

The sun angles α (altitude) and Φ (azimuth) can be found from the equations:

$$\sin\alpha = \cos\ell\cos\delta\cos H + \sin\ell\sin\delta \tag{7.6.7}$$

where ℓ = latitude angle,

$$\sin\Phi = \cos\delta\sin H/\cos\alpha \tag{7.6.8}$$

and

$$H = \text{Hour angle} = \frac{\text{Number of minutes from local solar noon}}{4\ \text{min/degree}} \tag{7.6.9}$$

(At solar noon, $H = 0$, so $\alpha = 90 - |\ell - \delta|$ and $\Phi = 0$.)

TABLE 7.6.1 Average Values of Atmospheric Optical Depth (τ) and Sky Diffuse Factor (C) for 21st Day of Each Month

Source: Threlkeld, J.L. and Jordan, R.C., *ASHRAE Trans.*, 64, 45, 1958.

Solar Radiation on a Surface

As solar radiation, I, passes through the atmosphere, some of it is absorbed by air and water vapor, while some gets scattered by molecules of air, water vapor, aerosols, and dust particles. The part of solar radiation that reaches the surface of the Earth with essentially no change in direction is called **direct or beam normal radiation**, I_{bN}. The scattered radiation reaching the surface from the atmosphere is called **diffuse radiation**, I_d.

I_{bN} can be calculated from the extraterrestrial solar irradiance, I, and the atmospheric optical depth τ as (Goswami et al., 1981; ASHRAE, 1995)

$$I_{\mathrm{bN}} = Ie^{-\tau \sec \theta_z} \tag{7.6.10}$$

where θ_z is the solar zenith angle (angle between the sun rays and the vertical). The atmospheric optical depth determines the attenuation of the solar radiation as it passes through the atmosphere. Threlkeld and Jordan (1958) calculated values of τ for average atmospheric conditions at sea level with a moderately dusty atmosphere and amounts of precipitable water vapor equal to the average value for the United States for each month. These values are given in Table 7.6.1. To account for the differences in local conditions from the average sea level conditions Equation (7.6.10) is modified by a parameter called Clearness Number, Cn, introduced by Threlkeld and Jordan (1958):

$$I_{\mathrm{bN}} = \mathrm{Cn} Ie^{-\tau \sec \theta_z} \tag{7.6.11}$$

values of Cn vary between 0.85 and 1.15.

Solar Radiation on a Horizontal Surface

Total incident solar radiation on a horizontal surface is given by

$$I_{t,\mathrm{Horizontal}} = I_{\mathrm{bN}} \cos \theta_z + CI_{\mathrm{bN}} \tag{7.6.12}$$

$$= I_{\mathrm{bN}} \sin \beta + CI_{\mathrm{bN}} \tag{7.6.13}$$

where θ_z is called the solar zenith angle and C is called the sky diffuse factor, as given in Table 7.6.1.

Solar Radiation on a Tilted Surface

For a surface of any orientation and tilt as shown in Figure 7.6.4, the angle of incidence, θ, of the direct solar radiation is given by

$$\cos \theta = \cos \alpha \cos \gamma \sin \beta + \sin \alpha \cos \beta \tag{7.6.14}$$

where γ is the angle between horizontal projections of the rays of the sun and the normal to the surface. β is the tilt angle of the surface from the horizontal.

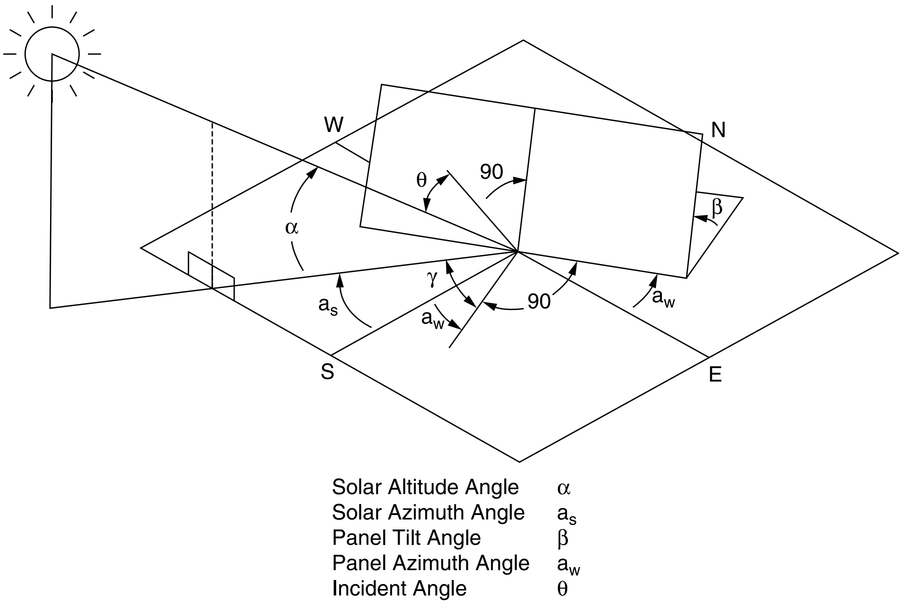

FIGURE 7.6.4 Definitions of solar angles for a tilted surface.

For a tilted surface with angle of incidence θ, the total incident solar radiation is given by

$$I_b = I_{\mathrm{bN}} \cos\theta + I_{\mathrm{diffuse}} + I_{\mathrm{reflected}} \tag{7.6.15}$$

where

$$I_{\mathrm{diffuse}} = CI_{\mathrm{bN}}\left(1+\cos\beta\right)/2 \tag{7.6.16}$$

and

$$I_{\mathrm{reflected}} = \rho I_{\mathrm{bN}}\left(C+\sin\alpha\right)\left(1-\cos\beta\right)/2 \tag{7.6.17}$$

where ρ is the reflectivity of the surroundings. For ordinary ground or grass, ρ is approximately 0.2 while for ground covered with snow it is approximately 0.8.

Solar Radiation Measurements

Two basic types of instruments are used in measurements of solar radiation. These are (see Figure 7.6.5):

1. *Pyranometer:* An instrument used to measure global (direct and diffuse) solar radiation on a surface. This instrument can also be used to measure the diffuse radiation by blocking out the direct radiation with a shadow band.
2. *Pyrheliometer:* This instrument is used to measure only the direct solar radiation on a surface normal to the incident beam. It is generally used with a tracking mount to keep it aligned with the sun.

More-detailed discussions about these and other solar radiation measuring instruments can be found in Zerlaut (1989).

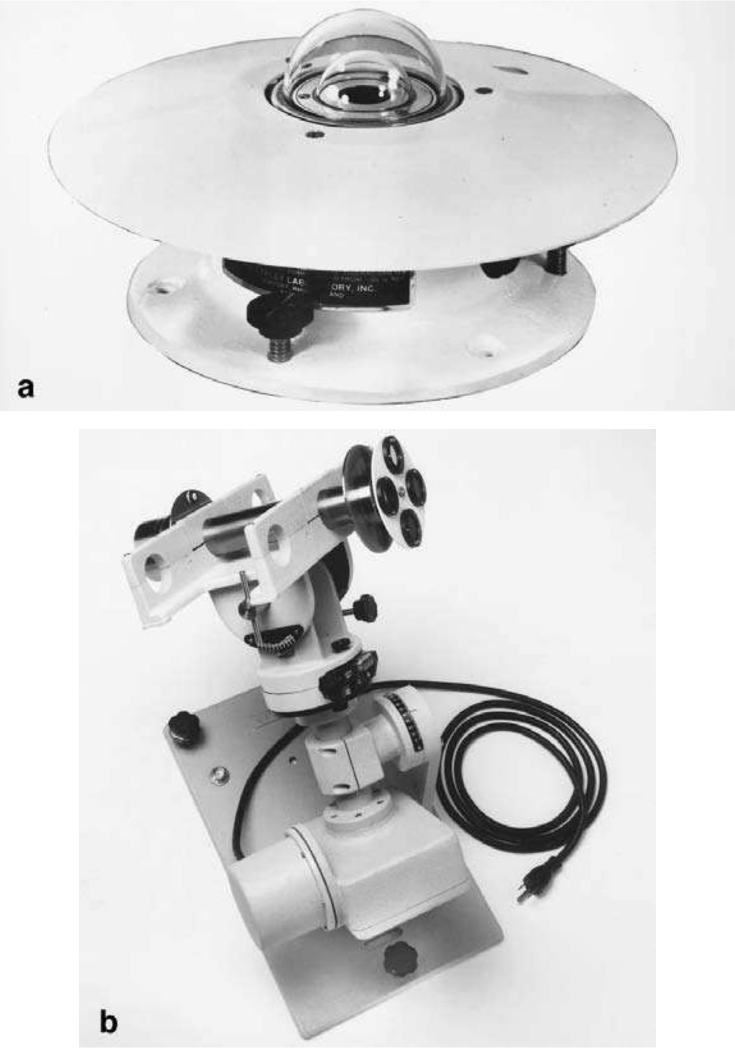

FIGURE 7.6.5 Two basic instruments for solar radiation: (a) pyranometer; (b) pyrheliometer.

Solar Radiation Data

Measured values of solar radiation data for locations in the United States are available from the National Climatic Center in Asheville, NC. A number of states have further presented solar radiation data for locations in those states in readily usable form. Weather services and energy offices in almost all the countries have available some form of solar radiation data or climatic data that can be used to derive solar radiation data for locations in those countries. Table 7.6.2 to Table 7.6.4 give solar radiation data for clear days for south-facing surfaces in the Northern Hemisphere (and northern-facing surfaces in the Southern Hemisphere) tilted at 0°, 15°, 30°, 45°, 60°, 75°, and vertical, for latitudes 0°, 30°, and 60°. The actual average solar radiation data at a location is less than the values given in these tables because of the cloudy and partly cloudy days in addition to the clear days. The actual data can be obtained either from long-term measurements or from modeling based on some climatic parameters, such as percent sunshine.

Worldwide solar radiation data is available from the World Radiation Data Center (WRDC). WRDC has been archiving data from over 500 stations and operates a website in collaboration with NREL (wrdc-mgo.nrel.gov).

TABLE 7.6.2 Average Daily Total Solar Radiation on South-Facing Surfaces in Northern Hemisphere; Latitude = 0°N

Defining Terms

Diffuse radiation: Scattered solar radiation coming from the sky.

Direct or beam normal radiation: Part of solar radiation coming from the direction of the sun on a surface normal to the sun's rays.

Equation of time: Correction factor in minutes, to account for the irregularity of the Earth's motion around the sun.

Extraterrestrial solar radiation: Solar radiation outside Earth's atmosphere.

Insolation: Incident solar radiation measured as W/m^2 or Btu/hr-ft^2.

Solar altitude angle: Angle between the solar rays and the horizontal plane.

Solar azimuth angle: Angle between the true south horizontal line and the horizontal projection of the sun's rays.

Solar constant: Extraterrestrial solar radiation at the mean Earth-sun distance.

Solar declination: Angle between the Earth-sun line and a plane through the equator.

7.7 Wind Energy Resources[2]

Dale E. Berg

Wind Origins

The primary causes of atmospheric air motion, or wind, are uneven heating of the Earth by solar radiation and the Earth's rotation. Differences in solar radiation absorption at the surface of the Earth and transference back to the atmosphere create differences in atmospheric temperature, density, and pressure,

---

[2] This work was supported by the United States Department of Energy under Contract DE-AC04-94AL85000.

which in turn create forces that move air from one place to another. For example, land and water along a coastline absorb radiation differently, and this is the dominant cause of the light winds or breezes normally found along a coast. The Earth's rotation gives rise to semipermanent global wind patterns such as trade winds, westerlies, easterlies, and subtropical and polar jets.

Wind Power

The available power in the wind with air density ρ, passing through an area A, perpendicular to the wind, at a velocity U, is given by

$$\text{Power} = \tfrac{1}{2}\rho A U^3 \tag{7.7.1}$$

Air density decreases with increasing temperature and increasing altitude above sea level. The effect of temperature on density is relatively weak and is normally ignored because these variations tend to average out over the period of a year. The density difference due to altitude, however, is significant; it does not average out and cannot be ignored. For example, the air density at Denver, Colorado (elevation 1600 m, or 5300 ft, above sea level), is approximately 14% lower than at sea level, so wind at Denver contains 14% less power than wind of the same velocity at sea level.

From Equation (7.7.1), it is obvious that the most important factor in the available wind power is the velocity of the wind — an increase in wind velocity of only 20%, e.g., from 5 to 6 m/s (11.2 to 13.4 mph), yields a 73% increase in available wind power.

Wind Shear

Wind moving across the Earth's surface is slowed by trees, buildings, grass, rocks, and other obstructions in its path. The result is a wind velocity that varies with height above the Earth's surface — a phenomena known as **wind shear**. For most situations, wind shear is positive (wind speed increases with height), but situations in which the wind shear is negative or inverse are not unusual. In the absence of actual data for a specific site, a commonly used approximation for wind shear in an open area is:

$$U/U_o = (h/h_o)^{\alpha} \tag{7.7.2}$$

where

U = the velocity at a height h
U_o = the measured velocity at height h_o
α = the wind shear exponent

The wind shear exponent, α, varies with terrain characteristics, but usually falls between 0.10 and 0.25. Wind over a body of open water is normally well modeled by a value of α of about 0.10; wind over a smooth, level, grass-covered terrain such as the U.S. Great Plains by an α of about 0.14; wind over row crops or low bushes with a few scattered trees by an α of 0.20; and wind over a heavy stand of trees, several buildings, or hilly or mountainous terrain by an α of about 0.25. Short-term shear factors as large as 1.25 have been documented in rare, isolated cases.

The available wind power at a site can vary dramatically with height due to wind shear. For example, for $\alpha = 0.20$, Equation (7.7.1) and Equation (7.7.2) reveal that the available wind power at a height of 50 m is approximately $\{(50/10)^{0.2}\}^3 = 2.63$ times the available wind power at a height of 10 m.

Wind Energy Resource

The amount of energy available in the wind (the **wind energy resource**) is the average amount of power available in the wind over a specified period of time — commonly 1 year. If the wind speed is 20 m/s,

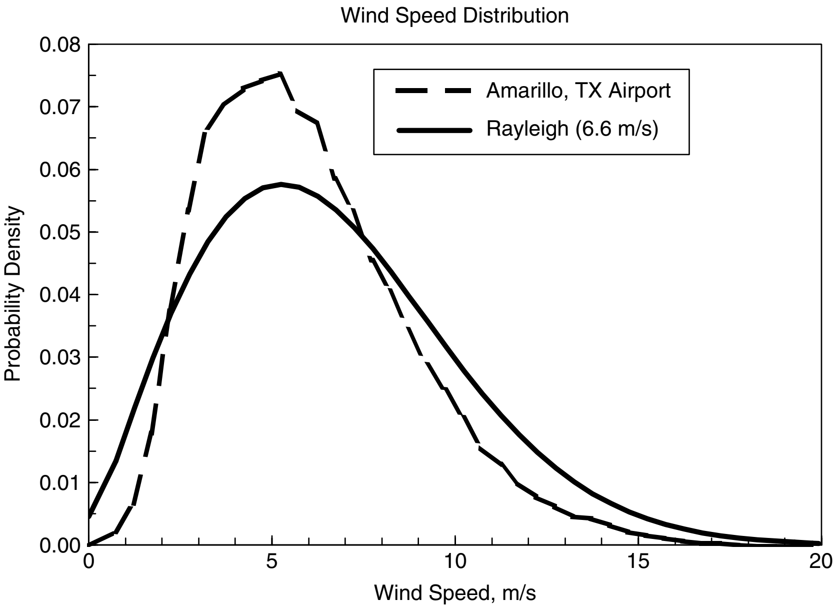

FIGURE 7.7.1 Rayleigh and measured wind speed distributions.

the available power is very large at that instant, but if it only blows at that speed for 10 h per year and the rest of the time the wind speed is near zero, the resource for the year is small. Therefore, the site **wind speed distribution**, or the relative frequency of occurrence for each wind speed, is very important in determining the resource. This distribution is often presented as a probability density function, such as the one shown in Figure 7.7.1. The probability that the wind occurs in any given wind speed range is given by the area under the density function for that wind speed range. If the actual wind speed probability density distribution is not available, it is commonly approximated with the Rayleigh distribution, given by:

$$f(U) = \frac{\pi}{4}\frac{U}{\overline{U}}\exp\left[-\frac{\pi}{4}\frac{U^2}{\overline{U}^2}\right] \tag{7.7.3}$$

where

$f(U)$ = the frequency of occurrence of wind speed U

$\overline{U}$ = the yearly average wind speed

The measured wind speed distribution at the Amarillo, Texas, airport (yearly average wind speed of 6.6 m/s) is plotted in Figure 7.7.1, together with the Rayleigh distribution for that wind speed. It is obvious that the Rayleigh distribution is not a good representation for the Amarillo airport.

How large is the wind energy resource? Even though wind energy is very diffuse, the total resource is very, very large. In the U.S. and many other countries around the world, the resource is large enough to supply the entire current energy consumption of the country, potentially. In 1987, scientists at Batelle Pacific Northwest Laboratory (PNL) in the U.S. carefully analyzed and interpreted the available long-term wind data for the U.S. and summarized their estimate of the wind energy resources in the *Wind Energy Resource Atlas of the United States* (Elliott et al., 1987). Their summary for the entire U.S. is reproduced in Figure 7.7.2. The results are presented in terms of wind power classes based on the annual average power available per square meter of intercepted area (see the legend on Figure 7.7.2).

Scientists at Denmark's Risø National Laboratory have produced a European wind atlas (Troen and Petersen, 1989) that estimates the wind resources of the European Community countries and summarizes the resource available at a 50 m height for five different topographic conditions. A summary of these results is reproduced in Figure 7.7.3. The estimates presented in Figure 7.7.2 and Figure 7.7.3 are quite crude and have been superceded in recent years by much higher resolution maps, made possible by improvements in wind resource computer modeling programs and increases in computer speed.

Many countries around the world have recently embarked on high-resolution mapping efforts to quantify their wind resources and identify those areas of highest resource accurately. The resultant resource maps are frequently available to the public, but in some cases a payment is required to obtain them. High-resolution wind resource maps of the individual states in the U.S. may be found on the Web at www.eere.energy.gov/windpoweringamerica/wind_resources.html. Similar maps for some other countries may be found at www.rsvp.nrel.gov/wind_resources.html, and information on where to find maps and/or data for other countries may be found at www.windatlas.dk/index.htm.

Remember that even the highest resolution resource estimates are just that — estimates. The actual wind resources in any specific area can vary dramatically from those estimates and should be determined with long-term, site-specific measurements.

Wind Characterization

Wind speed, direction, distribution, and shear can vary significantly over fairly short distances in the horizontal or vertical directions, so in order to get the best possible estimate of the wind energy resource at a particular location, it is important to measure the wind resource at the specific site and height of interest. However, a comprehensive site characterization normally requires measuring the wind for at least 12 months, according to meteorologists at PNL (Wegley et al., 1980). This is a very time-consuming and potentially expensive effort. Long-term data from the nearest airport or weather recording station can help determine whether the data obtained at a site are representative of normal winds for the site or of higher or lower than average winds. Wegley et al. (1980) and Gipe (1993) give suggestions on methods of using available data from nearby sites to estimate site wind speed with minimal on-site data.

Sites of wind power class 4 or above (at least 200 W/m^2 at 10 m height or 400 W/m^2 at 50 m height) are often considered economic for utility-scale wind power development with available wind technology. Sites of wind power class 3 (150 to 200 W/m^2 at 10 m height or 300 to 400 W/m^2 at 50 m height) are not considered economic for utility development today but are likely to become economic with near-term wind technology advances. Sites of wind power class 2 or lower (less than 150 W/m^2 at 10 m height or 300 W/m^2 at 50 m height) are usually considered economic only for remote or hybrid wind power systems.

Wind Energy Potential

With a wind speed distribution and a turbine power curve (the electrical power generated by the turbine at each wind speed) properly adjusted for the local air density, the **wind energy potential**, or gross annual wind energy production, for a specific site can be estimated as:

$$\text{Energy} = 0.85\left[8760\sum_{i=1}^{n} f(U_i)\,\Delta U_i\;P(U_i)\right] \tag{7.7.4}$$

where

8760 = the number of hours in a year
n = the number of wind speeds considered
$f(U_i)\Delta U_i$ = the probability of a wind speed occurring in the wind-speed range ΔU_i
$P(U_i)$ = the electrical power produced by the turbine at wind speed U_i, the center of the range ΔU_i

The leading 0.85 factor assumes 15% in losses (10% due to power transfer to the grid, control system losses, and decreased performance due to dirty blades; 5% due to operation within an array of wind turbines). If the turbine is not inside an array, replace 0.85 with 0.90. Wind energy potential is typically 20 to 35% of the wind energy resource.

1. The resources refer to the power present in the wind. A wind turbine can utilize between 20 and 30% of the available resource. The resources are calculated for an air density of 1.23 kg m^{-3}, corresponding to standard sea level pressure and a temperature of 15°C. Air density decreases with height but up to 1000 m a.s.l. the resulting reduction of the power densities is less than 10%.
2. Urban districts, forest and farm land with many windbreaks (roughness class 3).
3. Open landscapes with few windbreaks (roughness class 1). In general, the most favourable inland sites on level land are found here.
4. The classes pertain to a straight coastline, a uniform wind rose and a land surface with few windbreaks (roughness class 1). Resources will be higher, and closer to open sea values, if winds from the sea occur more frequently, i.e. the wind rose is not uniform and/or the land protrudes into the sea. Conversely, resources will generally be smaller, and closer to land values, if winds from land occur more frequently.
5. More than 10 km offshore (roughness class 0).
6. The classes correspond to 50% overspeeding and were calculated for a site on the summit of a single axisymmetric hill with a height of 400 metres and a base diameter of 4 km. The overspeeding depends on the height, length and specific setting of the hill.

FIGURE 7.7.3 Map of European wind energy resources. Reproduced from Troen and Petersen, 1989. *European Wind Atlas*. (Courtesy of Risø National Laboratory, Roskilde, Denmark.)

Defining Terms

Wind energy potential: total amount of energy that can actually be extracted from the wind, taking into account the efficiency of the wind turbine.

Wind energy resource: total amount of energy present in the wind.

Wind shear: change in wind velocity with increasing height above the ground.

Wind speed distribution: probability density of occurrence of each wind speed over the course of a year for the site in question

7.8 Geothermal Energy

Joel L. Renner and Marshall J. Reed

The word *Geothermal* comes from the combination of the Greek words *gê*, meaning Earth, and *thérm*, meaning heat. Quite literally, geothermal energy is the heat of the Earth. Geothermal resources are concentrations of the Earth's heat, or geothermal energy, that can be extracted and used economically now or in the reasonable future. Currently, only concentrations of heat associated with water in permeable rocks can be exploited. Heat, fluid, and permeability are the three necessary components of all exploited geothermal fields. This section of Energy Resources will discuss the mechanisms for concentrating heat near the surface, the types of geothermal systems, and the environmental aspects of geothermal production.

Heat Flow

Temperature within the Earth increases with depth at an average of about 25°C/km. Spatial variations of the thermal energy within the deep crust and mantle of the Earth give rise to concentrations of thermal energy near the surface of the Earth that can be used as an energy resource. Heat is transferred from the deeper portions of the Earth by conduction of heat through rocks, by the movement of hot, deep rock toward the surface, and by deep circulation of water. Most high-temperature geothermal resources are associated with concentrations of heat caused by the movement of magma (melted rock) to near-surface positions where the heat is stored.

In older areas of continents, such as much of North America east of the Rocky Mountains, heat flow is generally 40 to 60 mWm^{-2} (milliwatts per square meter). This heat flow coupled with the thermal conductivity of rock in the upper 4 km of the crust yields subsurface temperatures of 90 to 110°C at 4 km depth in the Eastern United States. Heat flow within the Basin and Range (west of the Rocky Mountains) is generally 70 to 90 mWm^{-2}, and temperatures are generally greater than 110°C at 4 km. There are large variations in the Western United States, with areas of heat flow greater than 100 mWm^{-2} and areas which have generally lower heat flow such as the Cascade and Sierra Nevada Mountains and the West Coast. A more detailed discussion of heat flow in the United States is available in Blackwell et al. (1991).

Types of Geothermal Systems

Geothermal resources are hydrothermal systems containing water in pores and fractures. Most hydrothermal resources contain liquid water, but higher temperatures or lower pressures can create conditions where steam and water or only steam are the continuous phases (White et al., 1971; Truesdell and White, 1973). All commercial geothermal production is expected to be restricted to hydrothermal systems for many years because of the cost of artificial addition of water. Successful, sustainable geothermal energy usage depends on reinjection of the maximum quantity of produced fluid to augment natural recharge of hydrothermal systems.

Other geothermal systems that have been investigated for energy production are (1) geopressured-geothermal systems containing water with somewhat elevated temperatures (above normal gradient) and with pressures well above hydrostatic for their depth; (2) magmatic systems, with temperature from 600 to 1400°C; and (3) hot dry rock geothermal systems, with temperatures from 200 to 350°C, that are subsurface zones with low initial permeability and little water. These types of geothermal systems cannot be used for economic production of energy at this time.

Geothermal Energy Potential

The most recent report (Huttrer, 1995) shows that 6800 MW_e (megawatts electric) of geothermal electric generating capacity is on-line in 21 countries (Table 7.8.1). The expected capacity in the year 2000 is 9960 MW_e. Table 7.8.2 lists the electrical capacity of U.S. geothermal fields. Additional details of the U.S. generating capacity are available in DiPippo (1995) and McClarty and Reed (1992). Geothermal resources also provide energy for agricultural uses, heating, industrial uses, and bathing. Freeston (1995) reports that 27 countries had a total of 8228 MW_t (megawatts thermal) of direct use capacity. The total energy used is estimated to be 105,710 TJ/year (terajoules per year). The thermal energy used by the ten countries using the most geothermal resource for direct use is listed in Table 7.8.3.

The U.S. Geological Survey has prepared assessments of the geothermal resources of the U.S. Muffler(1979) estimated that the identified hydrothermal resource, that part of the **identified accessible base** that could be extracted and utilized at some reasonable future time, is 23,000 MW_e for 30 years. This resource would operate power plants with an aggregate capacity of 23,000 MW_e for 30 years. The undiscovered U.S. resource (inferred from knowledge of Earth science) is estimated to be 95,000 to 150,000 MW_e for 30 years.

Geothermal Applications

In 1991, geothermal electrical production in the United States was 15,738 GWh (gigawatt hours), and the largest in the world (McLarty and Reed, 1992).

Most geothermal fields are water dominated, where liquid water at high temperature, but also under high (hydrostatic) pressure, is the pressure-controlling medium filling the fractured and porous rocks of the reservoir. In water-dominated geothermal systems used for electricity, water comes into the wells from the reservoir, and the pressure decreases as the water moves toward the surface, allowing part of the water to boil. Since the wells produce a mixture of flashed steam and water, a separator is installed between the wells and the power plant to separate the two phases. The flashed steam goes into the turbine to drive the generator, and the water is injected back into the reservoir.

Many water-dominated reservoirs below 175°C used for electricity are pumped to prevent the water from boiling as it is circulated through heat exchangers to heat a secondary liquid that then drives a turbine to produce electricity. **Binary geothermal plants** have no emissions because the entire amount of produced geothermal water is injected back into the underground reservoir. The identified reserves of lower-temperature geothermal fluids are many times greater than the reserves of high-temperature fluids, providing an economic incentive to develop more-efficient power plants.

Warm water, at temperatures above 20°C, can be used directly for a host of processes requiring thermal energy. Thermal energy for swimming pools, space heating, and domestic hot water are the most widespread uses, but industrial processes and agricultural drying are growing applications of geothermal use. In 1995, the United States was using over 500 TJ/year of energy from geothermal sources for direct use (Lienau, et al., 1995). The cities of Boise, ID; Elko, NV; Klamath Falls, OR; and San Bernardino and Susanville, CA have geothermal district-heating systems where a number of commercial and residential buildings are connected to distribution pipelines circulating water at 54 to 93°C from the production wells (Rafferty, 1992).

The use of geothermal energy through ground-coupled heat pump technology has almost no impact on the environment and has a beneficial effect in reducing the demand for electricity. Geothermal heat pumps use the reservoir of constant temperature, shallow groundwater and moist soil as the heat source during winter heating and as the heat sink during summer cooling. The energy efficiency of geothermal heat pumps is about 30% better than that of air-coupled heat pumps and 50% better than electric-resistance heating. Depending on climate, advanced geothermal heat pump use in the United States reduces energy consumption and, correspondingly, power-plant emissions by 23 to 44% compared to advanced air-coupled heat pumps, and by 63 to 72% compared with electric-resistance heating and standard air conditioners (L'Ecuyer et al., 1993).

Environmental Constraints

Geothermal energy is one of the cleaner forms of energy now available in commercial quantities. Geothermal energy use avoids the problems of acid rain, and it greatly reduces greenhouse gas emissions and other forms of air pollution. Potentially hazardous elements produced in geothermal brines are removed from the fluid and injected back into the producing reservoir. Land use for geothermal wells, pipelines, and power plants is small compared with land use for other extractive energy sources such as oil, gas, coal, and nuclear. Geothermal development projects often coexist with agricultural land uses, including crop production or grazing. The average geothermal plant occupies only 400 m^2 for the production of each gigawatt hour over 30 years (Flavin and Lenssen, 1991). The low life-cycle land use of geothermal energy is many times less than the energy sources based on mining, such as coal and nuclear, which require enormous areas for the ore and processing before fuel reaches the power plant. Low-temperature applications usually are no more intrusive than a normal water well. Geothermal development will serve the growing need for energy sources with low atmospheric emissions and proven environmental safety.

All known geothermal systems contain aqueous carbon dioxide species in solution, and when a steam phase separates from boiling water, CO_2 is the dominant (over 90% by weight) **noncondensible gas.** In most geothermal systems, noncondensible gases make up less than 5% by weight of the steam phase. Thus, for each megawatt-hour of electricity produced in 1991, the average emission of carbon dioxide by plant type in the United States was 990 kg from coal, 839 kg from petroleum, 540 kg from natural gas, and 0.48 kg from geothermal flashed-steam (Colligan, 1993). Hydrogen sulfide can reach moderate concentrations of up to 2% by weight in the separated steam phase from some geothermal fields.

At The Geysers geothermal field in California, either the Stretford process or the incineration and injection process is used in geothermal power plants to keep H_2S emissions below 1 ppb (part per billion). Use of the Stretford process in many of the power plants at The Geysers results in the production and disposal of about 13,600 kg of sulfur per megawatt of electrical generation per year. Figure 7.8.1, shows a typical system used in the Stretford process at The Geysers (Henderson and Dorighi, 1989).

The incineration process burns the gas removed from the steam to convert H_2S to SO_2, the gases are absorbed in water to form SO_3^{-2} and SO_4^{-2} in solution, and iron chelate is used to form $S_2O_3^{-2}$ (Bedell and Hammond, 1987). Figure 7.8.2 shows an incineration abatement system (Bedell and Hammond, 1987). The major product from the incineration process is a soluble thiosulfate which is injected into the reservoir with the condensed water used for the reservoir pressure-maintenance program. Sulfur emissions for each megawatt-hour of electricity produced in 1991, as SO_2 by plant type in the United States was 9.23 kg from coal, 4.95 kg from petroleum, and 0.03 kg from geothermal flashed-steam (Colligan, 1993). Geothermal power plants have none of the nitrogen oxide emissions that are common from fossil fuel plants.

The waters in geothermal reservoirs range in composition from 0.1 to over 25 wt% dissolved solutes. The geochemistry of several representative geothermal fields is listed in Table 7.8.4. Temperatures up to 380°C have been recorded in geothermal reservoirs in the United States, and many chemical species have a significant solubility at high temperature. For example, all of the geothermal waters are saturated in silica with respect to quartz. As the water is produced, silica becomes supersaturated, and, if steam is flashed, the silica becomes highly supersaturated. Upon cooling, amorphous silica precipitates from the supersaturated solution. The high flow rates of steam and water from geothermal wells usually prevent silica from precipitating in the wells, but careful control of fluid conditions and residence time is needed to prevent precipitation in surface equipment. Silica precipitation is delayed in the flow stream until the water reaches a crystallizer or settling pond. There the silica is allowed to settle from the water, and the water is then pumped to an injection well.

Operating Conditions

For electrical generation, typical geothermal wells in the United States have production casing pipe in the reservoir with an inside diameter of 29.5 cm, and flow rates usually range between 150,000 and

350,000 kg/hr of total fluid (Mefferd, 1991). The geothermal fields contain water, or water and steam, in the reservoir, and production rates depend on the amount of boiling in the reservoir and the well on the way to the surface. The Geysers geothermal field in California has only steam filling fractures in the reservoir, and, in 1987 (approximately 30 years after production began), the average well flow had decreased to 33,000 kg/hr of dry steam (Mefferd, 1991) supplying the maximum field output of 2000 MW_2. Continued pressure decline has decreased the production.

In the Coso geothermal field near Ridgecrest, CA initial reservoir conditions formed a steam cap at 400 to 500 m depth, a two-phase (steam and water) zone at intermediate depth, and a liquid water zone at greater depth. Enthalpy of the fluid produced from individual wells ranges from 840 to 2760 kJ/kg (Hirtz et al., 1993), reservoir temperatures range from 200 to 340°C, and the fluid composition flowing from the reservoir into the different wells ranges from 100% liquid to almost 100% steam. Production wells have a wide range of flow rates, but the average production flow rate is 135,000 kg/hr (Mefferd, 1991). Much of the produced fluid is evaporated to the atmosphere in the cooling towers of the power plant, and only about 65% of the produced mass is available for injection into the reservoir at an average rate of 321,000 kg/hr (Mefferd, 1991).

The Salton Sea geothermal system in the Imperial Valley of southern California has presented some of the most difficult problems in brine handling. Water is produced from the reservoir at temperatures between 300 and 350°C and total dissolved solid concentrations between 20 and 25% by weight at an average rate of 270,000 kg/hr (Mefferd, 1991). When up to 20% of the mass of brine boils during production, the salts are concentrated in the brine causing supersaturation with respect to several solid phases. Crystallizers and clarifier and thickener tanks are needed to remove solids from the injection water. Figure 7.8.3 shows the flow stream for removal of solids from the vapor and brine (Signorotti and Hunter, 1992). Other power plants use the addition of acid to lower the pH and keep the solutes in solution (Signorotti and Hunter, 1992). The output from the crystallizers and clarifiers is a slurry of brine and amorphous silica. The methods used to dewater the salt and silica slurry from operations in the Salton Sea geothermal system are described by Benesi (1992). Approximately 80% of the produced water is injected into the reservoir at an average rate of 310,000 kg/hr.

Defining Terms

Binary geothermal plant: A geothermal electric generating plant that uses the geothermal fluid to heat a secondary fluid that is then expanded through a turbine.

Identified accessible base: That part of the thermal energy of the Earth that is shallow enough to be reached by production drilling in the foreseeable future. *Identifed* refers to concentrations of heat that have been characterized by drilling or Earth science evidence. Additional discussion of this and other resource terms can be found in Muffler (1979).

Noncondensible gases: Gases exhausted from the turbine into the condenser that do not condense into the liquid phase.

8.1 Steam Power Plant

John Kern

Introduction

This section provides an overview of the steam power cycle. There are noteworthy omissions in the section: site selection; fuel handling; activities related to civil engineering (such as foundations); controls; and nuclear power. Thermal power cycles take many forms, but the majority are fossil steam, nuclear, simple-cycle gas turbine, and combined cycle. Of those listed, conventional coal-fired steam is the predominant power producer — especially in developing countries that have indigenous coal or can import coal inexpensively. A typical steam power plant is shown in Figure 8.1.1.

Because the Rankine cycle is the overwhelmingly preferred process for steam power generation, it is discussed first. Topping and bottoming cycles, with one exception, are rare and mentioned only for completeness. The exception is the combined cycle, in which the steam turbine cycle is a bottoming cycle. Developed countries have been moving to the combined cycle because of relatively low capital costs when compared with coal-fired plants; its high thermal efficiency, which approaches 60%, and low emissions.

The core components of a steam power plant are boiler; turbine; condenser and feedwater pump; and generator. These are covered in successive subsections. The final subsection is an example of the layout and contents of a modern steam power plant.

As a frame of reference, the following efficiencies are typical for modern, subcritical, fossil fuel steam power plants. The specific example chosen has steam conditions of 2400 psia; 1000°F main steam temperature; and 1000°F reheat steam temperature: boiler thermal 92; turbine/generator thermal 44; turbine isentropic 89; generator 98.5; boiler feedwater pump and turbine combined isentropic 82; condenser 85; plant overall 34 (Carnot 64). Supercritical steam plants operate with main steam above the "critical" pressure for water where water and steam have the same density and no longer exist as separate phase states. They are generally used when higher efficiency is desired. Modern supercritical coal plants with main steam conditions of 3600 psia at 1050°F and 1050°F for reheat steam can exceed 40% in overall net plant efficiency.

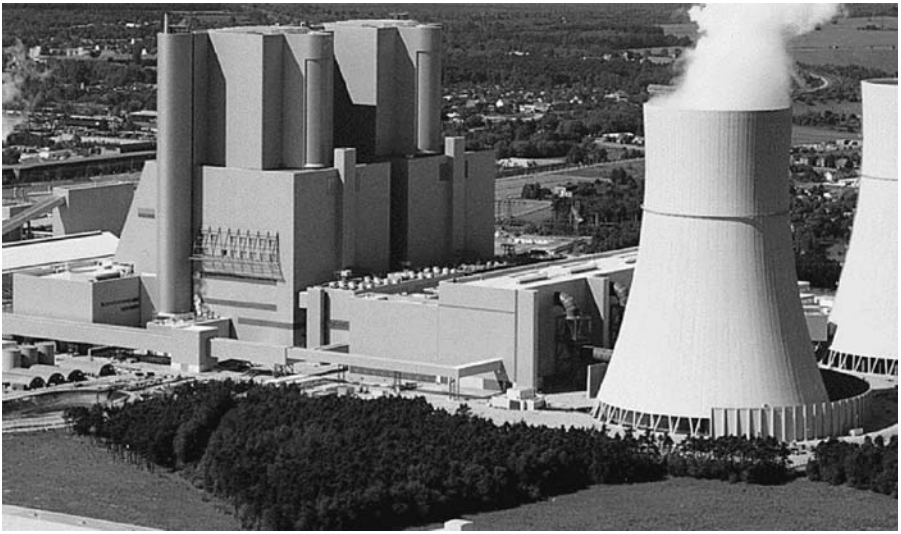

FIGURE 8.1.1 Modern steam power plant.

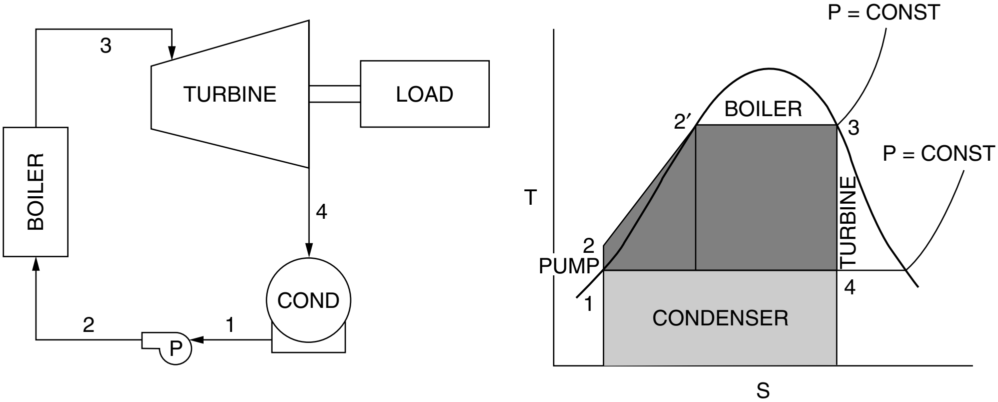

FIGURE 8.1.2 Basic Rankine cycle.

Nuclear power stations are so unique that they are worthy of a few closing comments. Modern stations are all large, varying from 600 to 1500 MW. The steam is low temperature and low pressure (~600°F and ~1000 psia), compared with fossil applications, and hovers around saturation conditions. Therefore, the boilers, superheater equivalent (actually a combined moisture separator and reheater), and turbines are unique to this cycle. The turbine generator thermal efficiency is around 36%.

Rankine Cycle Analysis

Modern steam power generation is based on the Rankine cycle and thermodynamics govern the ultimate performance of the cycle whether used in a coal-fired steam plant or the bottoming cycle of a combined-cycle plant. The basic, ideal Rankine cycle is shown in Figure 8.1.2. The ideal cycle comprises the processes from state 1:

1–2: Saturated liquid from the condenser at state 1 is pumped isentropically (i.e., $S_1 = S_2$) to state 2 and into the boiler.

2–3: Liquid is heated at constant pressure in the boiler to state 3 (saturated steam).

3–4: Steam expands isentropically (i.e., $S_3 = S_4$) through the turbine to state 4, where it enters the condenser as a wet vapor.

4–1: Constant-pressure transfer of heat in the condenser takes place to return the steam to state 1 (saturated liquid).

If changes in kinetic and potential energy are neglected, the total heat added to the Rankine cycle can be represented by the shaded area on the *T–S* diagram in Figure 8.1.2; the work done by this cycle can be represented by the crosshatching within the shaded area. The thermal efficiency of the cycle (η) is defined as the work (W_{NET}) divided by the heat input to the cycle (Q_H).

The Rankine cycle is preferred over the Carnot cycle for the following reasons:

- The heat transfer process in the boiler must be at constant temperature for the Carnot cycle, whereas in the Rankine cycle it is superheated at constant pressure. Superheating the steam can be achieved in the Carnot cycle during heat addition, but the pressure must drop to maintain constant temperature. This means the steam is expanding in the boiler while heat is being added, which is not a practical method.
- The Carnot cycle requires that the working fluid be compressed at constant entropy to boiler pressure. This would require taking wet steam from point 1′ in Figure 8.1.2 and compressing it to saturated liquid condition at 2′. A pump required to compress a mixture of liquid and vapor isentropically is difficult to design and operate. In comparison, the Rankine cycle takes the saturated liquid and compresses it to boiler pressure. This is more practical and requires much less work.

The efficiency of the Rankine cycle can be increased by utilizing a number of variations to the basic cycle. One such variation is superheating the steam in the boiler. The additional work done by the cycle is shown in the crosshatched area in Figure 8.1.3.

The efficiency of the Rankine cycle can also be increased by increasing the pressure in the boiler. However, increasing the steam generator pressure at a constant temperature will result in the excess moisture content of the steam exiting the turbine. To take advantage of higher steam generator pressures and keep turbine exhaust moistures at acceptably low values, the steam is expanded to some intermediate pressure in the turbine and then reheated in the boiler. Following reheat, the steam is expanded to the cycle exhaust pressure. The reheat cycle is shown in Figure 8.1.4.

Another variation of the Rankine cycle is the regenerative cycle, which involves the use of feedwater heaters. The regenerative cycle regains some of the irreversible heat lost when condensed liquid is pumped

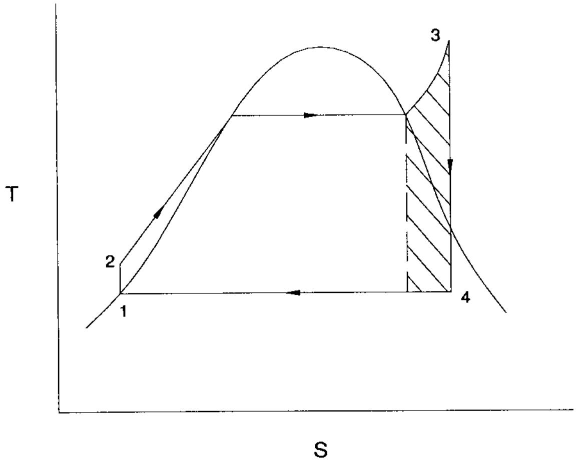

FIGURE 8.1.3 Rankine cycle with superheat.

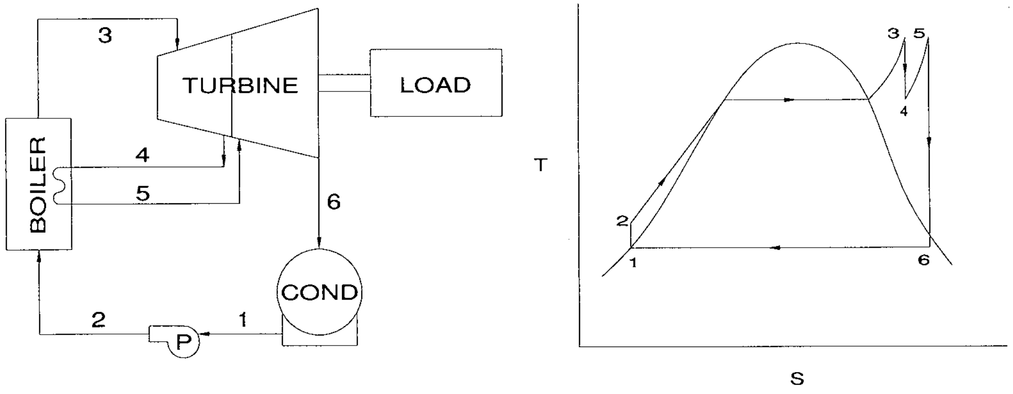

FIGURE 8.1.4 Rankine cycle with reheat.

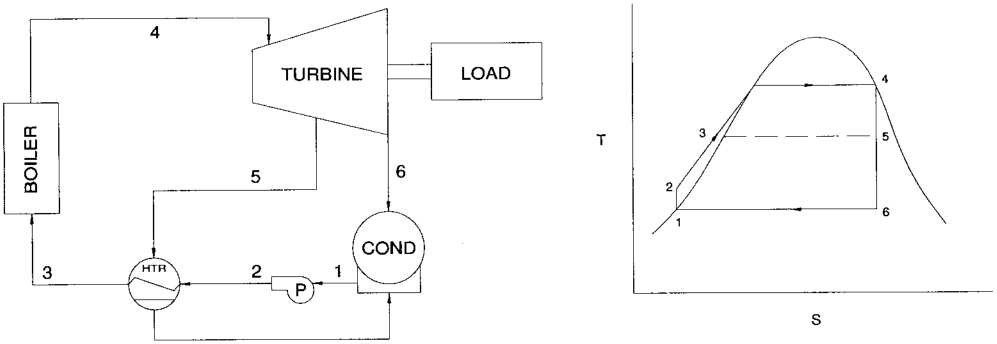

FIGURE 8.1.5 Rankine cycle with regeneration.

directly into the boiler by extracting steam from various points in the turbine and heating the condensed liquid with this steam in feedwater heaters. Figure 8.1.5 shows the Rankine cycle with regeneration.

The actual Rankine cycle is far from ideal because losses are associated with the cycle. They include piping losses due to friction and heat transfer; turbine losses associated with steam flow; pump losses due to friction; and condenser losses when condensate is subcooled. The losses in the compression (pump) and expansion process (turbine) result in an increase in entropy. Also, energy is lost in heat addition (boiler) and rejection (condenser) processes as they occur over a finite temperature difference.

Most modern power plants employ some variation of the basic Rankine cycle in order to improve thermal efficiency. For larger power plants, economies of scale will dictate the use of one or all of these variations to improve thermal efficiency. In most cases, power plants in excess of 200,000 kW will have 300°F superheated steam leaving the boiler reheat and seven to eight stages of feedwater heating.

Topping and Bottoming Cycles

Steam Rankine cycles can be combined with topping and/or bottoming cycles to form binary thermodynamic cycles. These topping and bottoming cycles use working fluids other than water. Topping cycles change the basic steam Rankine cycle into a binary cycle that better resembles the Carnot cycle and improves efficiency. For conventional steam cycles, state-of-the-art materials allow peak working fluid temperatures higher than the supercritical temperature for water. Much of the energy delivered into the cycle goes into superheating the steam, which is not a constant-temperature process. Therefore, a significant portion of the heat supply to the steam cycle occurs substantially below the peak cycle temperature.

Adding a cycle that uses a working fluid with a boiling point higher than water allows more of the heat supply to the thermodynamic cycle to be near the peak cycle temperature, thus improving efficiency. Heat rejected from the topping cycle is channeled into the lower-temperature steam cycle. Thermal energy not converted to work by the binary cycle is rejected to the ambient-temperature reservoir. Metallic substances are the working fluids for topping cycles. For example, mercury has been used as the topping cycle fluid in a plant that operated for a period of time but has since been dismantled. Significant research and testing has also been performed over the years toward the eventual goal of using other substances, such as potassium, sodium, or cesium, as a topping-cycle fluid, but none has proven to be commercially successful.

Steam power plants in a cold, dry environment cannot take full advantage of the low heat rejection temperature available. The very low pressure to which the steam would be expanded to take advantage of the low heat sink temperature would increase the size of the low-pressure (LP) turbine to such an extent that it is impractical or at least inefficient. A bottoming cycle that uses a working fluid with a vapor pressure higher than water at ambient temperatures (such as ammonia or an organic fluid) would enable smaller LP turbines to function efficiently. Thus, a steam cycle combined with a bottoming cycle may yield better performance and be more cost effective than a stand-alone Rankine steam cycle. However, again, these techniques are not at present commercially viable and are not being broadly pursued.

Steam Boilers

A boiler, also referred to as a steam generator, is a major component in the plant cycle. It is a closed vessel that efficiently uses heat produced from the combustion of fuel to convert water to steam. Efficiency is the most important characteristic of a boiler because it has a direct bearing on electricity production. Boilers are classified as drum-type or once-through (Figure 8.1.6). Major components of boilers include an economizer, superheaters, reheaters, and spray attemperators.

Drum-Type Boilers

Drum-type boilers depend on constant recirculation of water through some of the components of the steam–water circuit to generate steam and keep the components from overheating. These boilers circulate water by natural or controlled circulation.

Natural Circulation Boilers. Natural circulation boilers use the density differential between water in the downcomers and steam in the waterwall tubes for circulation.

Controlled Circulation Boilers. Controlled circulation boilers use boiler-water-circulating pumps to circulate water through the steam–water circuit.

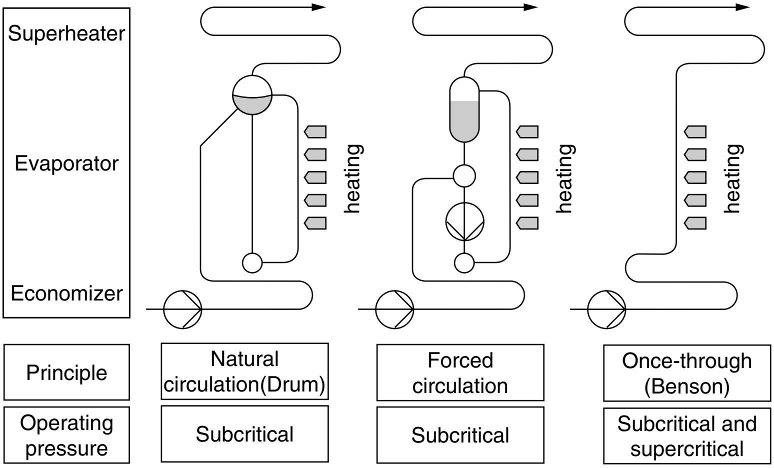

FIGURE 8.1.6 Boiler principles.

Once-Through Boilers

Once-through boilers convert water to steam in one pass through the system rather than re-circulating through the drum. Current designs for once-through boilers use a spiral-wound furnace to assure even heat distribution across the tubes.

Major Boiler Components

- *Economizer.* The economizer is the section of the boiler tubes in which feedwater is first introduced into the boiler and flue gas is used to raise the temperature of the water.
- *Steam drum (drum units only).* The steam drum separates steam from the steam–water mixture and keeps the separated steam dry.
- *Superheaters.* Superheaters are bundles of boiler tubing located in the flow path of the hot gases created by the combustion of fuel in the boiler furnace. Heat is transferred from the combustion gases to the steam in the superheater tubes. Superheaters are classified as primary and secondary. Steam passes first through the primary superheater (located in a relatively cool section of the boiler) after leaving the steam drum. There the steam receives a fraction of its final superheat and then passes through the secondary superheater for the remainder.
- *Reheaters.* Reheaters are bundles of boiler tubes that are exposed to the combustion gases in the same manner as superheaters.
- *Spray attemperators.* Attemperators, also known as desuperheaters, are spray nozzles in the boiler tubes between the two superheaters. These spray nozzles supply a fine mist of pure water into the flow path of the steam to prevent tube damage from overheating. Attemperators are provided for the superheater and the reheater.

Worldwide, the current trend is to use higher temperatures and pressures to improve plant efficiency, which in turn reduces emissions. Improvements in high-temperature materials such as T-91 tubing provide high-temperature strength and improved corrosion resistance permitting reliable operation in advanced steam cycles. In addition, the development of reliable once-through Benson type boilers has resolved most of the operational problems experienced with first- and second-generation supercritical plants.

Steam plant boilers burning coal require advanced exhaust gas clean-up systems to meet today's strict environmental emissions limits. A typical plant burning high-sulfur eastern coal will have an SCR (selective catalytic reduction) for NO_x control, a precipitator for particulate control, and a wet limestone scrubber to reduce SO_x. A typical plant burning low-sulfur western coal might include an SCR, a baghouse filter for particulate control, and a dry scrubber for SO_x reduction.

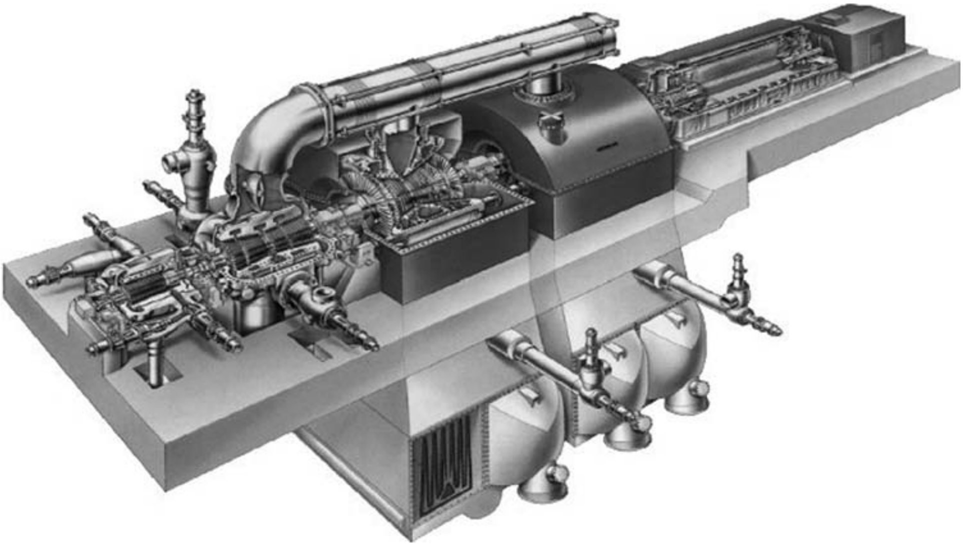

FIGURE 8.1.7 Modern steam turbine generator for a coal-fired steam plant.

Steam Turbines

General

Each turbine manufacturer has unique features in its designs that affect efficiency, reliability, and cost. However, the designs appear similar to a non-steam-turbine engineer. Figure 8.1.7 shows a modern steam turbine generator as used in a coal-fired steam power plant. Steam turbines for power plants differ from most prime movers in at least three ways:

- All are extremely high powered, varying from about 70,000 to 2 million hp, and require a correspondingly large capital investment, which puts a premium on reliability.
- Turbine life is normally between 30 and 40 years with minimal maintenance.
- Turbines spend the bulk of their lives at constant speed, normally 3600 or 1800 rpm for 60-Hz operation.

These three points dominate the design of the entire power station, particularly of the steam turbine arrangement and materials. Figure 8.1.8 shows the dramatic increase of steam turbine power output for one manufacturer over the past 50 years. This is reasonably typical of the industry.

In an earlier subsection it was shown that high steam-supply temperatures make for more efficient turbines. In Europe and Japan, the trend is to use increasingly higher steam-supply temperatures to reduce fuel cost and emissions.

Blading

The most highly stressed component in steam turbines is the blades. Blades are loaded by centrifugal and steam-bending forces and also harmonic excitation (from nonuniform circumferential disturbances in the blade path). All blades are loaded by centrifugal and steam-bending loads, and smaller blades are designed to run when the harmonic excitation is resonant with the natural modes of the blade. If harmonic excitation is permitted on very long blades, however, the blades become impractically large. Fortunately, because the turbine runs at constant speed, the blade modes can be tuned away from resonant conditions so that the harmonic loads are significantly reduced. This forms a split in blade design, commonly referred to as tuned and untuned blading.

Blades guide steam throughout the turbine in as smooth and collision-free a path as possible. Collisions with blades (incidence) and sudden expansions reduce the energy available for doing work. Until recently,

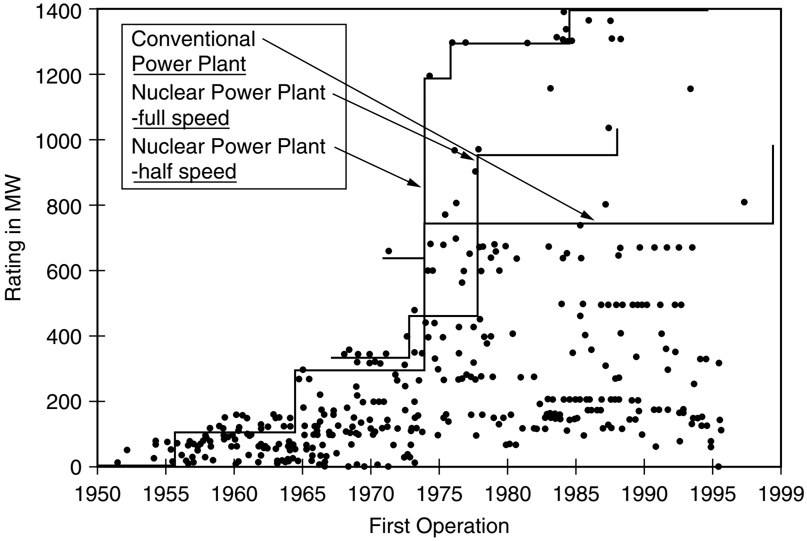

FIGURE 8.1.8 Increase of steam turbine power.

designers would match flow conditions with radially straight blades (called parallel-sided blades). Turbine physics does not recognize this convenience for several reasons. The most visually obvious is the difference in tangential velocity between blade hub and tip. The latest blades address the full three-dimensional nature of the flow by curving in three dimensions (bowed blades). Three dimensional design techniques allow for better matching of the flow (and area) conditions and now, with the use of numerical control machine tools to make it more cost competitive, three-dimensional blading is used extensively in many modern turbines. Examples of three-dimensional and parallel-sided blades are shown in Figure 8.1.9.

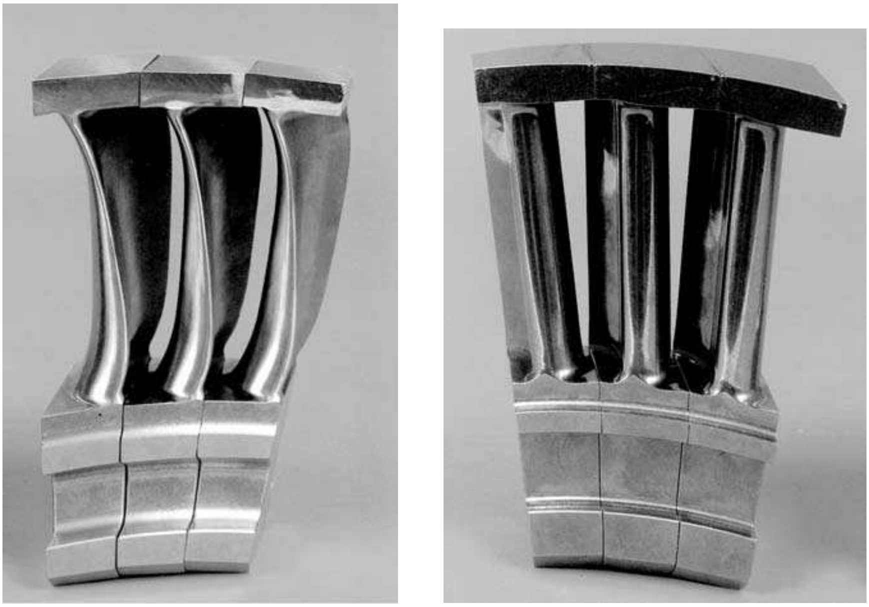

FIGURE 8.1.9 Typical steam turbine blades.

Rotors

After blades, steam turbine rotors are the second most critical component in the machine. Rotor design must take into account

- The large high-strength alloy steel rotor forging that must have uniform chemistry and material properties
- Centrifugal force from the rotor body and the increased centrifugal pull from the attached blades
- The need to have high resistance to brittle fracture, which could occur when the machine is at high speed and the material is still not up to operating temperature
- Creep deformation of the high-pressure (HP) and intermediate-pressure (IP) rotors under steady load while at high temperature

The life cycle is further complicated by transient fatigue loads that occur during power changes and start-up. Two further events are considered in rotor design: torsional and lateral vibrations caused by harmonic steam and electrical loads. As with tuned blades, this is normally addressed by tuning the primary modes away from resonance at full running speed.

Choosing the Turbine Arrangement

Because the turbine shaft would be too long and flexible if it were built in one piece with all the blades in sequence, the rotor is separated into supportable sections. The "cuts" in the shaft result in HP (high pressure), IP (intermediate pressure), and LP (low pressure) cylinders. Manufacturers address the grouping of cylinders in many different ways, depending upon steam conditions. It is common practice to combine HPs and IPs into one cylinder for subcritical units in the power range of about 250 to 600 MW. One manufacturer's grouping, shown in Figure 8.1.10, is fairly representative of the industry.

So far, the text has discussed the steam flow as though it expanded monotonically through the turbine. This is usually not the case for two reasons. First, the most common steam conditions would cause steam exiting the last row of blades to be very wet, creating excessive erosion. Second, thermal efficiency can be raised by removing the steam from the turbine, reheating, and then returning it to the blade path; this increases the "average" heat supply temperature and reduces moisture levels in the turbine exhaust. The turbine position for reheat is normally between the HP and IP turbines.

Type	Basic Configuration	Power
HP-IP-LP (with reheat)		200–1200 MW
HP/IP-LP (with reheat)		160–700 MW
HP-IP/LP (with reheat)		120–260 MW
Single Case (without reheat)		50–300 MW

FIGURE 8.1.10 Steam turbine product combinations.

There is one further geometric arrangement. Cylinders need not be all on one shaft with a single generator at the end. A cross-compound arrangement exists in which the steam path is split into two separate parallel paths with a generator on each path. Commonly, the split will be with paths of HP–LP generator and IP–LP generator. Torsional and lateral vibrations are more easily analyzed with shorter trains, which make the foundation more compact. The primary shortcoming is the need for two generators, two control systems, and a larger power house — all of which increase overall plant cost.

Historically, steam turbines have been split into two classes, reaction and impulse, as explained in Basic Power Cycles. This difference in design makes an observable difference between machines. Impulse turbines have fewer, wider stages than reaction machines. As designs have been refined, the efficiencies and lengths of the machines are now about the same. For a variety of reasons, the longer blades in the LP ends are normally reaction designs. Because each stage may now be designed and fabricated separately, the line between impulse and reaction turbines is diminishing with most manufacturers supplying blading that has characteristics of both technologies. Turbine blading is broadly split between machines as shown in the following table.

	Cylinder			
			LP	
	HP	IP	Short Blades	End Blade(s)
Reaction turbines	Reaction	Reaction	Reaction	Reaction
Impulse turbines	Impulse	Impulse	Impulse	Reaction

Materials

Materials are among the most variable of all turbine parts, with each manufacturer striving to improve performance by using alloying and heat-treatment techniques. It follows that accurate generalizations are difficult. Even so, the following table is reasonably representative for steam turbines with 1000 to 1050°F inlet temperatures:

Item	Common Material Description								
High-temperature HP and IP blades	Moderate- and cold-temperature stator blades	Moderate-temperature rotating blades	Cold LP rotating blades	High-temperature rotors	Low-temperature rotors	Hot	LP	High-temperature bolting	Cold bolting
Mod'd SS403	SS304	SS403	SS403 or 17/4 PH	1CrMoV, occasionally 10Cr	3.5 NiCrMoV	1.25Cr or 2.25Cr	Carbon, steel	SS422	B16

Cylinders and Bolting

These items are relatively straightforward, except for the very large sizes and precision required for the castings and fabrications. In a large HP–IP cylinder, the temperature and pressure loads split between an inner and outer cylinder. In this case, finding space and requisite strength for the bolting presents a challenge for the designer.

Valves

The turbine requires many valves for speed control, emergency control, drains, hydraulics, bypasses, and other functions. Of these, four valves are distinguished by their size and duty: throttle or stop; governor or control; reheat stop; and reheat interceptor. The throttle, reheat stop, and reheat interceptor valves normally operate fully open, except in some control and emergency conditions. Their numbers and design are selected for the appropriate combination of redundancy and rapidity of action. The continuous control of the turbine is accomplished by throttling the steam through the governor valve. This irreversible process detracts from cycle efficiency. In more modern units, the efficiency loss is reduced by reducing the boiler pressure (normally called sliding pressure) rather than throttling across the valves when reducing output.

Heat Exchangers, Pumps, and Other Cycle Components

Heat Exchangers

Heaters. The two classifications of condensate and feedwater heaters are the open or direct contact heater and the closed or shell-and-tube heater.

Open Heaters. In an open heater, the extraction or heating steam comes in direct contact with the water to be heated. Although open heaters are more efficient than closed heaters, each requires a pump to feed the outlet water ahead in the cycle. This adds cost and maintenance and increases the risk of water induction to the turbine, making the closed heater the preferred heater for power plant applications.

Closed Heaters. These heaters employ tubes within a shell to separate the water from the heating steam (see Figure 8.1.11). They can have three separate sections in which the heating of the feedwater occurs.

First is the drain cooler section where the feedwater is heated by the condensed heating steam before cascading back to the next-lower-pressure heater. The effectiveness of the drain cooler is expressed as the drain cooler approach (DCA), which is the difference between the temperature of the water entering the heater and the temperature of the condensed heating steam draining from the heater shell. In the second section (condensing section), the temperature of the water is increased by the heating steam condensing around the tubes. In the third section (desuperheating section), the feedwater reaches its final exit temperature by desuperheating the extraction steam. Performance of the condensing and superheating sections of a heater is expressed as the terminal temperature difference (TTD). This is the difference between the saturation temperature of the extraction steam and the temperature of the feedwater exiting the heater. Desuperheating and drain cooler sections are optional depending on the location of the heater in the cycle (for example, desuperheating is not necessary in wet extraction zones) and economic considerations.

The one exception is the deaerator (DA), which is an open heater used to remove oxygen and other gases that are insoluble in boiling water. The DA is physically located in the turbine building above all other heaters, and the gravity drain from the DA provides the prime for the boiler feed pump (BFP).

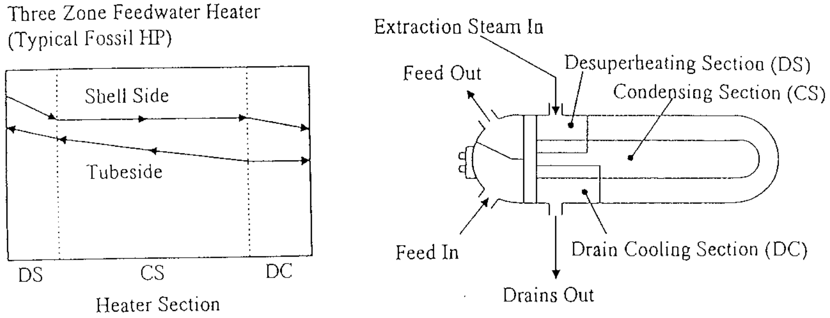

FIGURE 8.1.11 Shell-and-tube feedwater heater.

Two other critical factors considered in heater design and selection are (1) venting the heater shell to remove any noncondensable gases; and (2) the protection of the turbine caused by malfunction of the heater system. Venting the shell is required to avoid air-binding a heater, which reduces its performance. Emergency drains to the condenser open when high water levels are present within the shell to prevent back-flow of water to the turbine, which can cause serious damage. Check valves on the heating steam line are also used with a water-detection monitor to alert operators to take prompt action when water is present.

Condenser. Steam turbines generally employ surface-type condensers comprising large shell-and-tube heat exchangers operating under vacuum. The condenser (1) reduces the exhaust pressure at the last-stage blade exit to extract more work from the turbine; and (2) collects the condensed steam and returns it to the feedwater-heating system. Cooling water circulates from the cooling source to the condenser tubes by large motor-driven pumps. Multiple pumps, each rated less than 100% of required pumping power, operate more efficiently at part load and are often used to allow for operation if one or more pumps are out of service. Cooling water is supplied from a large heat sink water source, such as a river, or from cooling towers. The cooling in the cooling tower is assisted by evaporation of 3 to 6% of the cooling water. Airflow is natural draft (hyperbolic towers) or forced draft. Noncondensable gases are removed from the condenser with a motor-driven vacuum pump or, more frequently, steam jet air ejectors, which have no moving parts.

When adequate cooling water is not available, a dry condenser can be used. This device uses large motor-driven fans to move air across a large radiator-like heat exchanger to condense the steam at ambient temperature. Air condensers are significantly more expensive than wet condensers and generally decrease overall plant efficiency, so they are used only when necessary.

Pumps

Condensate Pump. Condensate is removed from the hot well of the condenser and passed through the LP heater string via the condensate pump. Typically, two or more vertical (larger units) or horizontal (medium and small units) motor-driven centrifugal pumps are located near the condenser hot well outlet. Depending on the size of the cycle, condensate booster pumps may be used to increase the pressure of the condensate on its way to the DA.

Feedwater Booster Pump. The DA outlet supplies the feedwater booster pump, which is typically a motor-driven centrifugal pump. This pump supplies the required suction head for the BFP (boiler feed pump).

Boiler Feed Pump. These pumps are multiple-stage centrifugal pumps that, depending on the cycle, can be turbine or motor driven. BFP turbines (BFPT; Figure 8.1.12), are single-case units that draw extraction steam from the main turbine cycle and exhaust to the main condenser. Typical feed pump turbines require 0.5% of the main unit power at full-load operation. Multiple pumps rated at 50 to 100% each are typically used to allow the plant to operate with one pump out of service.

With the increasing reliability of large electric motors, many plant designers are now using motors to drive the feed pumps for plants up to about 800 MW. Although the cycle is not quite as efficient as using a turbine drive, the overall plant capital cost is significantly less when motor BFP drives are used.

Generators

The electric generator converts rotating shaft mechanical power of the steam turbine to three-phase electrical power at voltages between 11.5 and 27 kV, depending upon the power rating. The generator

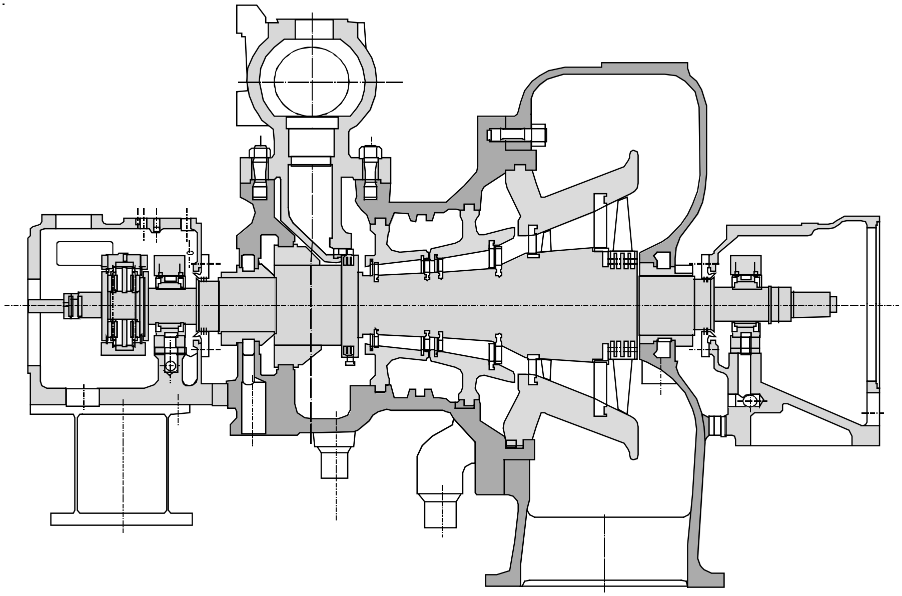

FIGURE 8.1.12 Boiler feed pump turbine.

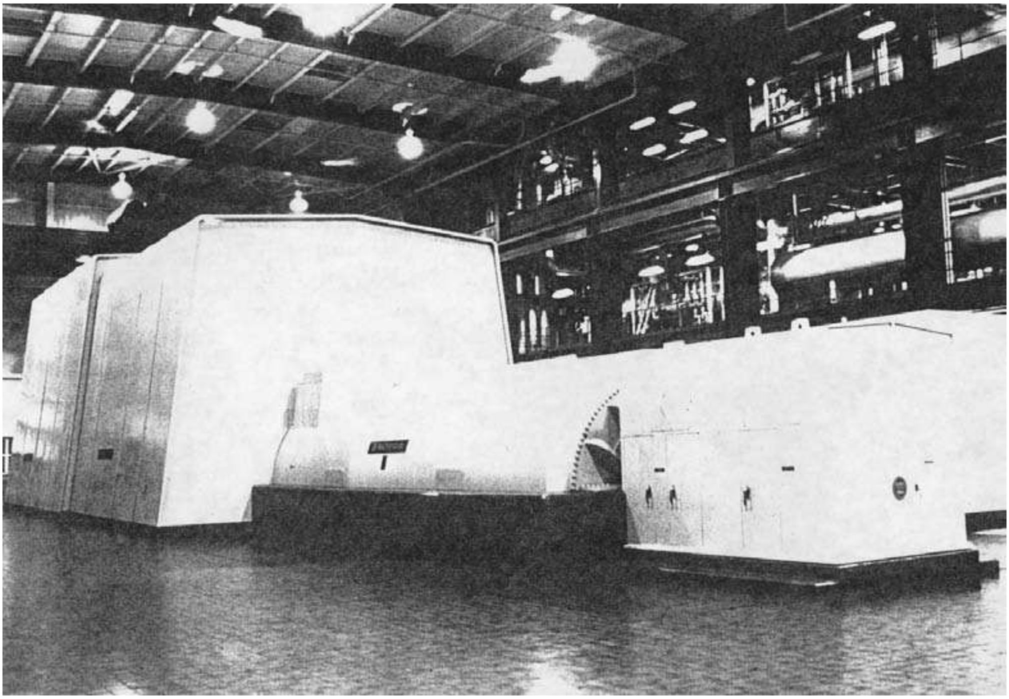

FIGURE 8.1.13 Generator and exciter.

comprises a system of ventilation, auxiliaries, and an exciter. Figure 8.1.13 shows an installed hydrogen-cooled generator and brushless exciter of about 400 MW. Large generators greater than 25 MW usually have a solid, high-strength steel rotor with a DC field winding embedded in radial slots machined into the rotor. The rotor assembly then becomes a rotating electromagnet that induces voltage in stationary conductors embedded in slots in a laminated steel stator core surrounding the rotor (see Figure 8.1.14).

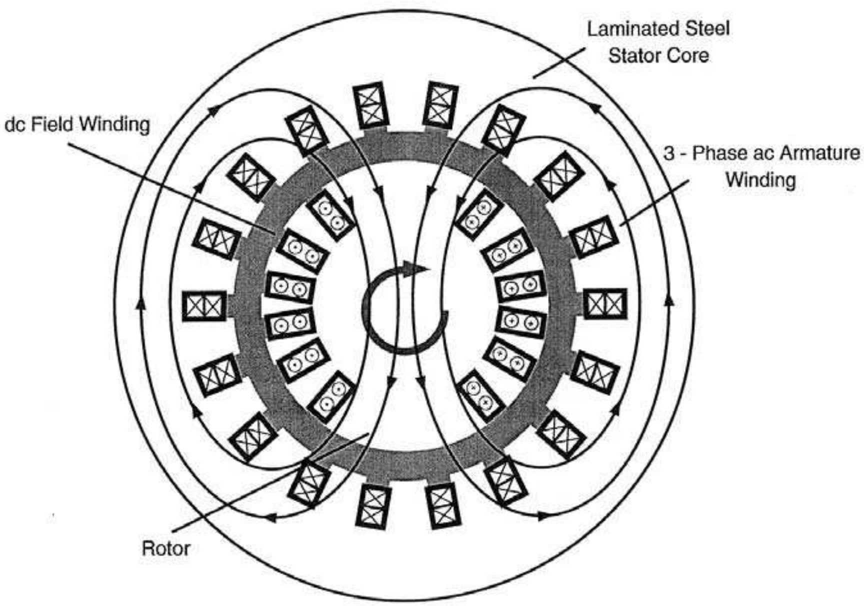

FIGURE 8.1.14 Generator magnetic paths.

The stator conductors are connected to form a three-phase AC armature winding. The winding is connected to the power system, usually through a step-up transformer. Most steam turbines driven by fossil-fired steam use a two-pole generator and rotate at 3600 rpm in 60-Hz countries and 3000 rpm in 50-Hz countries. Most large steam turbines driven by nuclear steam supplies use a four-pole generator and rotate at 1800 or 1500 rpm for 60 and 50 Hz, respectively.

Generator Ventilation

Cooling the active parts of the generator is of such importance that generators are usually classified by the type of ventilation they use. Air-cooled generators are used commonly up to 300 MW. Some use ambient air, drawing air through filters, and others recirculate air through air-to-water heat exchangers. Above 250 MW, most manufacturers offer hydrogen for overall cooling. Hydrogen has 14 times the specific heat of air and is 14 times less dense. This contributes to much better cooling and much lower windage and blower loss. The frame must be designed to withstand the remote circumstance of a hydrogen explosion and requires shaft seals. Hydrogen is noncombustible with purities greater than 70%. Generator purities are usually maintained well above 90%. Depending upon the manufacturer, generators with ratings above 500 MW generally have water-cooled stator winding; the remaining components are cooled with hydrogen.

Generator Auxiliaries

Large generators must have a lubrication oil system for the shaft journal bearings. Major components of this system are pumps, coolers, and a reservoir. In most cases, the turbine and generator use a combined system. For hydrogen-cooled generators, a shaft seal system and hydrogen supply system are needed. The shaft seal system usually uses oil pumped to a journal seal ring at a pressure somewhat higher than the hydrogen pressure. Its major components are pumps, coolers, and reservoir, similar to the lubrication system. The hydrogen supply system consists of a gas supply and regulators. A CO_2 supply is used to purge the generator when going from air to hydrogen or vice versa to avoid a combustible hydrogen–air mixture. The stator winding water supply again uses pumps, coolers, and a reservoir. It requires demineralizers to keep the water nonconducting because the water flow provides a path between the high-voltage conductors and ground. Depending upon the design approach, it may also include chemistry or oxygen content control to avoid corrosion in the winding cooling passages.

Excitation

The rotor field winding must have a DC source. Many generators use rotating "collector" rings with stationary carbon brushes to transfer DC current from a stationary source, such as a thyristor-controlled "static" excitation system, to the rotor winding. A rotating exciter, known as a brushless exciter, is used for many applications. It is essentially a small generator with a rotating rectifier and transfers DC current through the coupling into the rotor winding without the need for collectors and brushes.

Modern Steam Power Plant — an Example

The purpose of a power plant is to generate electric power. It does so by converting chemical energy contained in fuel into thermal energy in steam; thermal energy in steam into mechanical energy in the turbine/generator; and mechanical energy in the turbine/generator into electrical energy. Operating efficiency of a typical modern steam plant is about 35 to 45%. The primary losses result from (1) heat sink losses in the condenser; (2) boiler losses; and (3) electrical losses. Steam plant capacities range from 50 to 1600 MW; however, modern plants are being designed for more than 250 MW due to energy demands, system load requirements, and economies of scale in the larger centralized stations.

Major Steam Plant Components

Steam plants comprise three major components (1) boiler; (2) turbine; and (3) main steam condenser. The boiler and turbine have been covered in earlier subsections and neither will be repeated here. A graphic of the entire fluid or work cycle is shown in Figure 8.1.15.

Condenser. The condenser (also discussed earlier) is a large heat exchanger that takes the LP turbine exhaust steam and converts it back to water. The steam passes over a bundle of tubes located in the condenser and is cooled by the circulating water that passes through the tubes. The steam is condensed into water drops and collected in the condenser hot well. The condensate is delivered from the condenser hot well through the condensate and feedwater systems and back to the boiler, where it becomes steam again.

Fuels. Coal, oil, and gas are used to fuel fossil plants. Although coal possesses the highest carbon content, it also possesses the highest sulfur, nitrogen, and ash content, thereby requiring air pollution-control equipment. Controlling these pollutants requires:

- Installation of scrubbers for sulfur control
- Overfire air or gas recirculation for in-furnace nitrous oxides (NO_x) control
- Selective catalytic reduction (SCR) for postcombustion NO_x control
- Electrostatic precipitators (ESP) or baghouse for fly ash control
- Pneumatic, hydraulic, or mechanical ash-handling systems for bottom ash removal

Fuel oil and natural gas are chiefly composed of compounds of hydrogen and carbon (hydrocarbons) with very low percentages of sulfur, nitrogen, and ash; they do not require pollution-control equipment.

Power Plant System

Power plants comprise the following main systems: fuel handling; air handling; gas handling; main steam; reheat steam; auxiliary steam; extraction steam; condensate; feedwater; circulating water; and air removal.

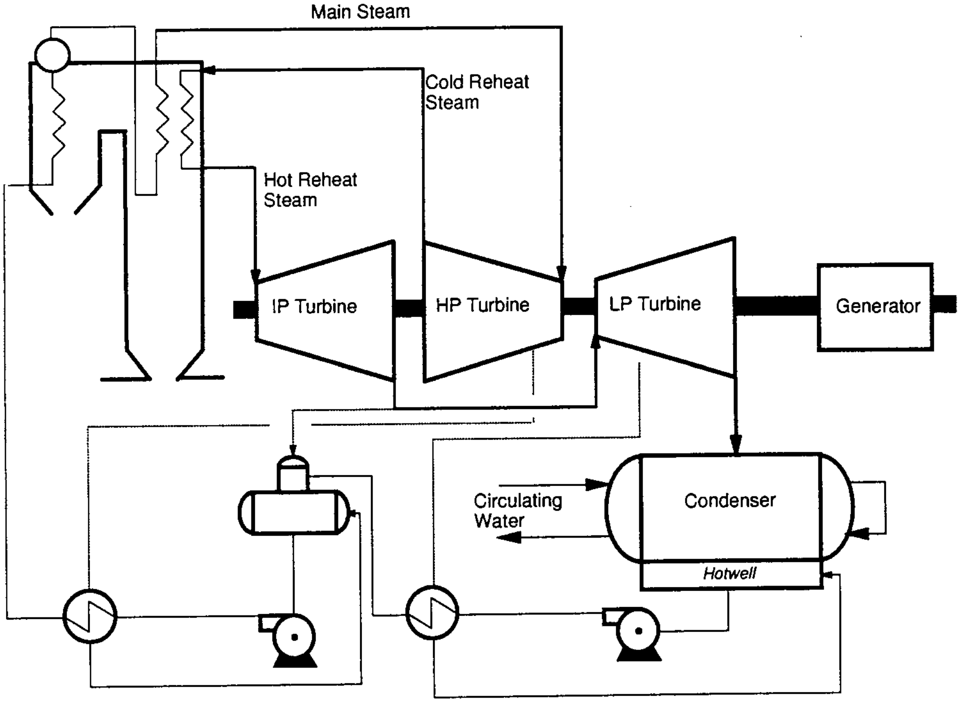

FIGURE 8.1.15 Steam power plant schematic.

Fuel-Handling System. The fuel-handling system consists of delivery, transfer, and processing. Fuel is delivered to the plant from the fuel source by truck, boat, rail (coal and oil), or pipeline (oil and gas). Once delivered, the fuel is transferred from the delivery point to various locations throughout the fuel-handling system. For coal and oil, the fuel is transferred to storage or sent directly to the boiler. For gas, the fuel is directly transferred to the boiler without any storage. Prior to delivery to the boiler for burning, the fuel must be processed so that it will readily mix with air and burn completely. Coal must be broken down into smaller pieces by crushers and then reduced to a fine powder in pulverizers. Oil requires steam, air, or mechanical atomization. Gas requires no processing.

Air/gas-Handling Systems. Steam plants are classified as pressurized or balance draft. Pressurized systems include forced-draft fans to provide the necessary air for fuel; an air heater to transfer heat from the exit gas to the inlet air; and a wind box in which the air is stored and then directed to the individual burner ports. A balanced draft system includes all of the components of the pressurized systems and induced-draft fans to exhaust the combustion products from the boiler, thus maintaining the furnace under slightly negative pressure. Balanced draft is the preferred method because it is better suited to the major exhaust gas clean-up systems now required on all new steam plants.

Main Steam System. The main steam system controls and regulates the flow of high-temperature, HP steam generated in the boiler furnace as it moves from the boiler to the turbine. The components in this system include main steam piping, safety valves, main steam stop valve, and turbine control valve.

Reheat Steam System. The reheat steam system improves overall plant efficiency by increasing the energy of steam that has been exhausted from the HP turbine. Steam from the hot reheat steam system is delivered to the IP turbine. The components of the reheat steam system are cold reheat piping; the reheater section of the boiler; hot reheat piping; safety relief valves; reheat stop valves; reheater desuperheater; and intercept valves.

Auxiliary Steam System. The auxiliary steam system directs and regulates auxiliary steam from the cold reheat line to the auxiliary steam users. The auxiliary steam system users are typically steam/air preheating coils; outdoor freeze protection/heat tracing; turbine seals; and plant heating.

Extraction Steam System. The extraction steam system directs and regulates the flow of the extraction steam from the turbine to the feedwater heaters, turbine driven BFP, and auxiliary steam system. The extraction steam heats the feedwater that flows through the heaters, thus improving overall plant efficiency. In large steam plants, seven or eight stages of feedwater heating are typical.

Condensate System. The condensate system consists of condensate pumps, LP feedwater heaters, and DA. The condensate pumps remove condensate from the main condenser hot well, increase condensate pressure, and deliver it through the LP heaters to the DA. During this process, the condensate is heated, deaerated, and chemically treated.

Feedwater System. The feedwater system consists of BFPs, HP feedwater heaters, piping, and valves. The boiler feedwater pumps deliver water from the DA storage tank, through the HP heaters, and into the boiler. Feedwater is supplied at sufficient quantities and pressure to satisfy unit demands during start-ups, shutdowns, and normal operation. The BFP is also the primary source of spray water for the superheater and reheater desuperheaters for control of the main and reheat steam temperatures. BFPs can be turbine or motor driven. Booster pumps may be required to provide additional net positive suction head (NPSH) to the main and start-up BFPs for plants designed with a low DA setting.

Circulating Water System. The circulating water system pumps cooling water through the condenser tubes at sufficient capacity, temperature, and pressure to absorb the latent heat in the LP exhaust steam. Circulating water systems are classified as once-through systems, when a large water source is available, or recirculating systems employing cooling towers. In once-through systems, circulating water pumps deliver water from the plant water supply (river, lake, or ocean) through the condenser tubes to absorb latent heat in the exhaust steam. Water flows through the system once and is returned to its source. The major parts of this system are screens, pumps, expansion valves, and piping. In recirculating systems, the cooling tower cools the heated circulating water from the main condenser by exposing it to air. The cooled water is stored in a basin located below the tower and is then circulated back through the system by the circulating water pumps.

Air Evacuation System. The air evacuation system removes air and noncondensable gases in the main steam condenser and helps maintain the vacuum created by the volume reduction of the condensing steam during normal operation. The system also establishes a normal vacuum in the condenser prior to turbine start-up.

8.2 Gas Turbines

Steven I. Freedman

Overview

Gas turbines are steady-flow power machines in which a gas (usually air) is compressed, heated, and expanded for the purpose of generating power. The term *turbine* is the component which delivers power from the gas as it expands; it is also called an expander. The term *gas turbine* refers to a complete power machine. The term gas turbine is often shortened to simply turbine, which can lead to confusion with the term for an expander.

The basic thermodynamic cycle on which the gas turbine is based is known as the Brayton cycle. Gas turbines may deliver their power in the form of torque or one of several manifestations of pneumatic power, such as the thrust produced by the high-velocity jet of an aircraft propulsion gas turbine engine.

Gas turbines vary in size from large, 250,000-hp utility machines, to small 5 hp, automobile and motorcycle turbochargers. Microturbines, 25 to 250 kW, recuperated gas turbines are now being sold.

Gas turbines are used in electric power generation, propulsion, and compressor and pump drives. The most efficient power generation systems in commercial service are gas turbine combined cycle plants with power-to-fuel energy efficiencies of more than 54% (higher heating value basis) or 59% (lower heating value basis). Systems five points higher in efficiency are now under development and are being offered commercially, and systems of even higher efficiency are considered feasible.

History

The fourth quarter of the 19th century was one of great innovation in power machinery. Along with the spark-ignited gasoline engine, the compression-ignited diesel engine, and the steam turbine, engineers applied their skills to several hot-air engines. Charles Curtis received the first U.S. patent for a complete gas turbine on June 24, 1895. Aegidius Elling built the first gas turbine in 1903, which produced 11 hp.

The first commercial stationary gas turbine engineered for power generation was a 4000-kW machine built by the Brown Boverei Company in Switzerland in 1939.

Aviation provided the impetus for gas turbine development in the 1930s. In Germany, Hans von Ohain's first engine ran in March 1937. Frank Whittle's first engine ran in England in April 1937. The first airplane flight powered by a gas turbine jet engine was in Germany on August 27, 1939. The first British airplane powered by a gas turbine flew on May 15, 1941.

A Swiss railway locomotive using a gas turbine was first run in 1941. The first automobile powered by a gas turbine was a British Rover, which ran in 1950. And, in 1956, a gas turbine-powered Plymouth car drove over 3000 miles on a coast-to-coast exhibition trip in the United States.

Fuels and Firing

The first heat engines were external combustion steam engines. The combustion products never came in contact with the working fluid, so ash, corrosive impurities, and contaminants in the fuel or exhaust did not affect the internal operation of the engine. Later, internal combustion (piston) engines were developed. In these engines, a mixture of air and fuel burned in the space enclosed by the piston and cylinder walls, thereby heating the air. The air and combustion products formed the working fluid, and contacted internal engine parts.

Most gas turbines in use today are internal combustion engines and consequently require clean fuels to avoid corrosion and erosion of critical turbine components. Efforts were made to develop gas turbines rugged enough to burn residual or crude oil. However, due to the higher efficiencies obtainable by burning extremely clean fuel at higher temperatures, there is little current interest in using fuel other than clean gas and distillate oil in gas turbines. Interest in the use of coal and residual oil is now centered on gasifying and cleaning these fuels prior to use.

A few external combustion gas turbines have been built for use with heavy oil, coal, nuclear reactor, radioisotope, and solar heat sources. However, none of these has become commercial. The added cost and pressure drop in the fired heater make externally fired gas turbines expensive. Because the working fluid temperature cannot be greater than that of the walls of the fired heater, externally fired gas turbines are substantially less efficient than modern internal combustion gas turbines with internally cooled blades.

The only internal combustion coal-fired gas turbine of current interest is the pressurized fluidized bed (PFB) combustion system. In the PFB, air discharged from the compressor of the turbine is used to fluidize a bed of limestone or dolomite in which coal is burned. The bed is maintained at modest temperature so that the ash in the coal does not form sticky agglomerates. Fortuitously, this temperature range also minimizes NO_x formation and allows capture of sulfur dioxide (SO_2) in the bed. Bed temperature is maintained in the desired range by immersed boiler tubes. Carryover fly ash is separated from gaseous combustion products by several stages of cyclone inertial separators and, in some cases, ceramic filters. The power turbine is modified to accommodate the combustion products, which after mechanical cleanup may still contain particles as large as 3 to 5 μm.

The most common gas turbine fuels today are natural gas and distillate oil. To avoid hot corrosion by alkali metal sulfates, the total sodium and potassium content of the fuel is typically limited to less than 5 ppm. Liquid fuels may also contain vanadium, which also causes corrosion. Fuels must be ash-free because particles larger than 3 to 5 μm rapidly erode blades and vanes.

Efficiency

The term *efficiency* is applied not only to complete power generation machines but also to the individual compression, expansion, and combustion processes that make up the gas turbine operating cycle. Different definitions of efficiency apply in each case. In an **expansion process**, the **turbine efficiency** is the ratio of the actual power obtained to the maximum power that could have been obtained by expanding the gas reversibly and adiabatically between the same initial and final pressures.

Gas turbines typically involve high-speed gas flows, so appreciable differences exist between the static pressure and temperature and the total (or stagnation) pressure and temperature. Care must be taken in interpreting data to be sure that the pressure condition — static or stagnation — at each component interface is properly used.

Irreversible losses in one stage of an expansion process show up as heat (increased temperature) in later stages and add to the power delivered by such stages. Hence, a distinction exists between the polytropic efficiency (used to describe the efficiency of a process of differential pressure change) and the adiabatic (complete pressure change) efficiency. The efficiency of compressors and turbines based on their inlet and outlet pressures is called the isentropic or adiabatic efficiency. Unfortunately, both terms are reported in the literature, and confusion can exist regarding the meaning of the term *efficiency.*

Combustion efficiency in well-engineered and well-built internal combustion gas turbines is almost always close to 100%. The combustion losses appear as carbon monoxide, unburned hydrocarbons, and soot, which are typically below 50 ppm, with clean fuels.

The **gas turbine or engine efficiency** is the ratio of the net power produced to the energy in the fuel consumed. The principal gas turbine fuels are liquid and gaseous hydrocarbons (distillate oil and natural gas) which have high hydrogen content. Consequently, the term *engine efficiency* needs to be qualified as to whether it is based on the higher or the lower heat content of the fuel (the difference between the two being the latent heat of condensation of the water vapor in the products of combustion). Utility fuel transactions are traditionally based on higher heating values, and most engine publications presume the lower heating value of the fuel as the efficiency basis. In the case of natural gas fuel, the higher heating value (HHV) efficiency is greater than the lower heating value (LHV) efficiency by 10% of the value of the HHV efficiency.

Engineers analyze gas turbine machines to evaluate improvements in component performance, in higher temperature and pressure ratio designs, and in innovative cycles. Ideal case cycle calculations generally assume the following:

- Air (with either constant or temperature-dependent specific heats) is the working fluid in both turbine and compressor (with equal mass flows);
- Air is the working fluid in both turbine and compressor but with the turbine mass flow greater by the amount of fuel used.

Components are modeled with or without frictional pressure drops, and heat transfer effectiveness may be ideal (unity) or actual, depending on the purpose of the analysis. Use of compressor air for cooling of high-temperature structure, nozzles, and blades are modeled in varying degrees of complexity. Two-dimensional temperature profiles or pattern factors exist. Component inlet and exit total pressure losses should be included in cycle analyses.

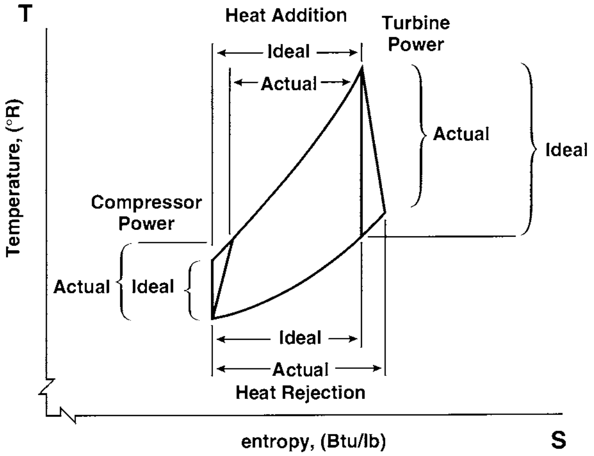

FIGURE 8.2.1 T-S diagram for a simple cycle illustrating the differences in compressor and turbine power for ideal (100% efficient) and actual components.

Gas Turbine Cycles

Gas turbine cycles are usually plotted on temperature-entropy (T-S) coordinates. Readers unfamiliar with entropy are referred to the chapter on thermodynamics. The T-S plot is useful in depicting cycles because in an adiabatic process — as is the case for turbines and compressors — the power produced or consumed is the product of the mass flow and the enthalpy change through the process. Thus, temperature difference, which is found on a T-S plot, is proportional to the power involved. Additionally, the heat exchange in a process involving zero power — such as a combustor or heat exchanger — is the product of the absolute temperature and the entropy change. On a T-S chart, the area under a process line for a combustor or heat exchanger is the heat exchanged.

The slope of a constant-pressure line on a T-S diagram is proportional to the absolute temperature. Consequently, lines of constant pressure become steeper, and diverge as the temperature increases. This illustrates that more work is obtained expanding a gas between fixed pressures at higher temperatures than at lower temperatures. Figure 8.2.1 shows a comparison of the process of an ideal and an actual simple cycle gas turbine on a T-S diagram. The increased compressor power consumption and the decreased turbine power generation in the actual cycle are shown to provide an understanding of the differences that component efficiencies make on machine performance.

The incremental amount of power produced per differential pressure change in the gas is given by

$$d(\text{Power/mass flow}) = -RT\, dp/p$$

Two phenomena are illustrated by this equation. First, power is proportional to the absolute temperature of the gas. Second, power is proportional to the percent change in pressure. This latter point is important in understanding the effect of pressure losses in cycle components. In heat exchangers, the proper measure of power lost is the percent pressure drop.

Cycle Configurations

The basic Brayton cycle consists of a compressor, a combustor or burner, and an expander. This configuration is known as the simple cycle. In idealizing the actual cycle, combustion is replaced by constant-pressure heat addition, and the cycle is completed by the assumption that the exhaust to ambient pressure could be followed by a zero-pressure-loss cooling to inlet conditions.

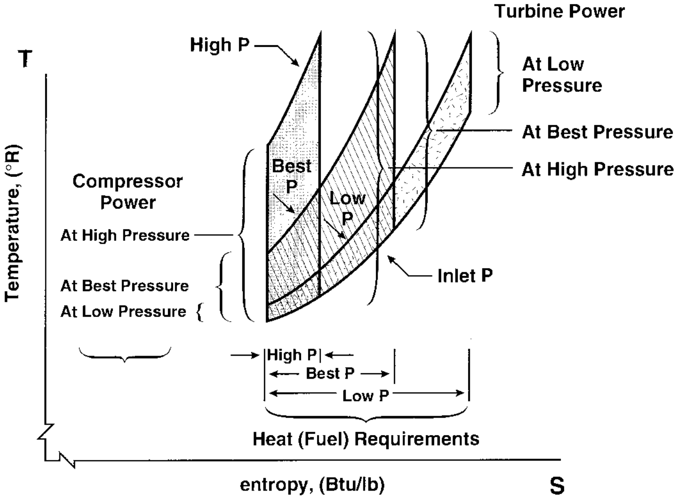

FIGURE 8.2.2 T-S diagram illustrating the power and heat (fuel) requirements at low, best, and high cycle pressures.

A T-S diagram of the simple cycle gas turbine with an upper temperature limit set by metallurgical conditions is illustrated in Figure 8.2.2 for cycles of low, medium, and high pressure ratios. The heat addition is only by fuel combustion, simplified here to be without mass addition or change in specific heat of the working fluid.

It is seen that the low-pressure-ratio cycle requires a large heat addition, which leads to a low efficiency, and the high-pressure-ratio cycle has turbine power output barely greater than the compressor power requirement, thereby leading to low net output and low efficiency. At intermediate pressure ratios, the turbine power output is substantially higher than the compressor power requirement, and the heat addition is modest in comparison with the difference between the turbine and compressor powers. There is an optimum pressure ratio for maximum efficiency, which is a function mainly of the maximum gas temperature in the machine, and to a lesser extent, by the component efficiencies, internal pressure losses, and the isentropic exponent. There is another optimum pressure ratio for maximum specific power (power per unit mass flow).

As the achievable turbine inlet temperature increases, the optimum pressure ratios (for both maximum efficiency and maximum specific power) also increase. The optimum pressure ratio for maximum specific power is at a lower pressure level than that for maximum efficiency for all cycles not employing a recuperator. For cycles with a recuperator, the reverse is true: maximum efficiency occurs at a lower pressure ratio than maximum specific power. Heavy-duty utility and industrial gas turbines are typically designed to operate near the point of maximum specific power, which approximates lowest equipment cost, while aeroderivative gas turbines are designed to operate near the point of maximum efficiency, approximating highest thrust. Figure 8.2.3 shows a performance map (efficiency as a function of power per unit of air flow) for a simple cycle gas turbine for two turbine inlet temperatures. It is seen that at higher temperature, both the efficiency and specific power increase, as well as the optimum pressure ratios for both the maximum efficiency and maximum specific power conditions.

Aircraft gas turbines operate at temperatures above the limit of turbine materials by using blades and vanes with complex internal cooling passages. The added cost is economically justified because these machines can command high prices in the aircraft propulsion marketplace. Aeroderivative engines have higher pressure ratios, higher efficiencies, and lower exhaust temperatures than heavy-duty machines. The stationary power markets served by aeroderlvative gas turbines are principally pipeline compressor stations and oil/gas production wells. Aeroderivative gas turbines also are economically advantageous for intermediate-duty electric power generation applications.

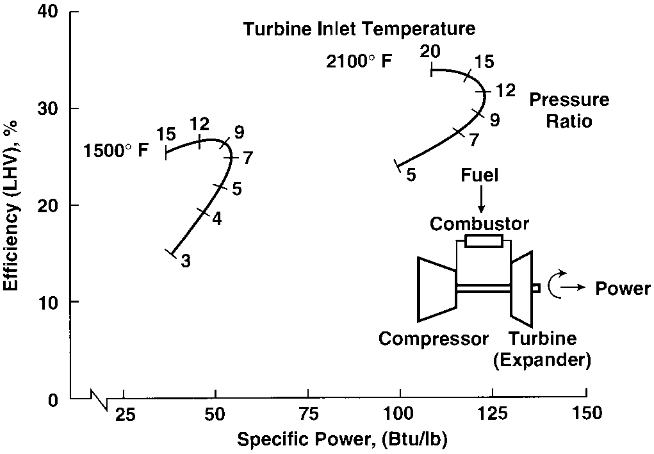

FIGURE 8.2.3 Performance map of a simple cycle gas turbine.

Components Used in Complex Cycles

Recuperators and **regenerators** recover heat from the turbine exhaust and use it to preheat the air from the compressor before it enters the combustor, thereby saving fuel. This heat transfer is shown in Figure 8.2.4. While recuperators and regenerators are quite similar thermodynamically, they are totally different in design. Recuperators are conventional heat exchangers in which hot and cold gases flow steadily on opposite sides of a solid (usually metal) wall.

Regenerators are periodic-flow devices. Fluid streams flow in opposite directions through passages in a wheel with heat storage walls. The wheel rotates, transferring heat from one stream to the other. Regenerators usually use a nest of very small parallel passages oriented axially on a wheel which rotates between hot and cold gas manifolds. Such regenerators are sometimes used in industrial processes for furnace heat recovery, where they are referred to as heat wheels. Because regenerators are usually more compact than recuperators, they were used in experimental automotive gas turbines. The difficulty in

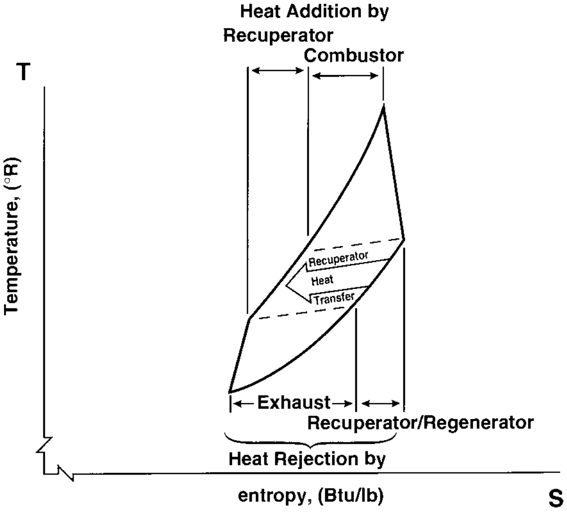

FIGURE 8.2.4 T-S diagram illustrating the heat transfer from the turbine exhaust to the compressor discharge accomplished by a recuperator/regenerator.

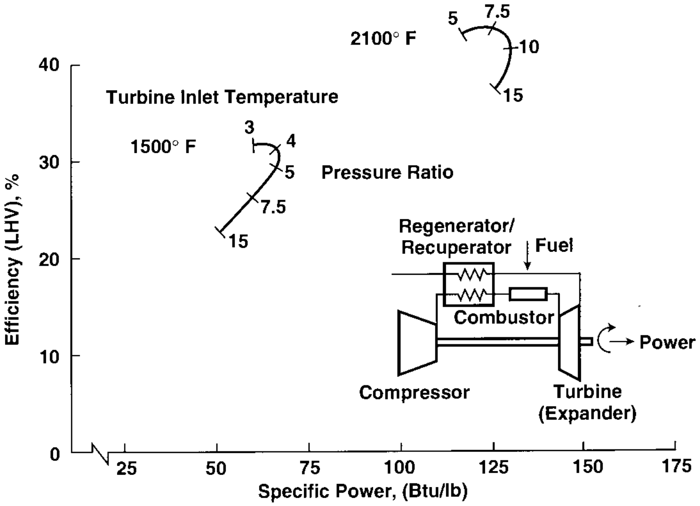

FIGURE 8.2.5 Performance map of a regenerative cycle gas turbine.

using regenerators on gas turbines intended for long life is that the two gas streams are at very different pressures. Consequently, the seals between the manifolds and the wheel must not leak excessively over the maintenance overhaul interval of the engine. If they do, the power loss due to seal leakage will compromise engine power and efficiency. Figure 8.2.5 shows a performance map for the regenerative gas turbine cycle for two temperatures. It is seen that as the temperature increases, the efficiency, specific power, and optimum pressure ratio all increase.

Current research on the recovery of gas turbine exhaust heat includes examination of thermochemical recuperation, where exhaust heat is used to effect a chemical reaction (reforming) of the fuel with steam, thereby increasing the heating value of the fuel. Although this process is feasible, research is underway to determine if it is practical and economic.

Industrial process compressors frequently use **intercoolers** to reduce compressor power when the compressor has a high pressure ratio and operates for a large number of hours per year. When analyzing cycles with intercoolers, the added pressure drops in the compressor interstage entrance and exit diffuser and scroll and the pressure drop in the intercooler itself should be included.

In a similar manner, turbine reheat can be used to increase the power output of a large-pressure-ratio turbine. This is the thermodynamic principle in turbojet afterburner firing. Turbine reheat increases power, but decreases efficiency unless the turbine exhaust heat is used for additional power generation, as is the case with a combined cycle, or is used with a recuperator to preheat combustor inlet air.

Intercoolers and reheat burners increase the temperature difference between the compressor and turbine discharges, thereby increasing the opportunity to use a recuperator to preheat the burner air with exhaust heat. An intercooled recuperated (ICR) machine is at present in development. The efficiency decrease at part load of an ICR gas turbine is much less than of conventional simple cycle machines.

Small gas turbines have uncooled turbine blades as a result of the difficulty in manufacturing extremely small cooling passages in small blades. This results in low efficiencies, making it difficult for such turbines to compete with high-volume production (low-cost) reciprocating (piston) engines. The low-pressure-ratio recuperated cycle has greater efficiency, although at higher cost. The recuperated cycle is finding favor in programs for small (under 300-kW) gas turbines used for stationary power.

Because of their compact size, low emissions, and light weight, gas turbines are also being considered for hybrid engine-battery vehicles. Proponents are pursuing the low-pressure-ratio recuperated gas turbine as the way to obtain high efficiency and low emissions in a compact power plant.

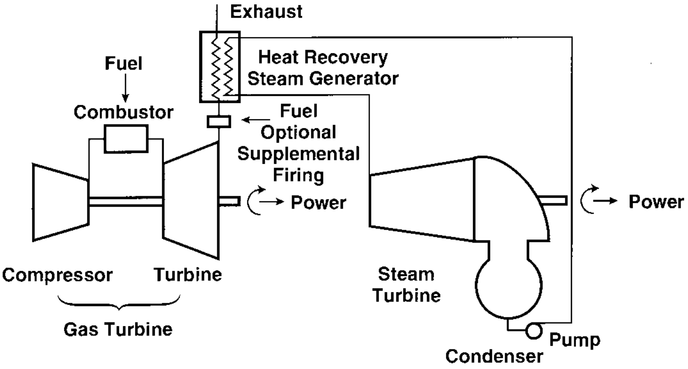

FIGURE 8.2.6 Combined (Brayton-Rankine) cycle.

An ingenious gas turbine cycle is the closed cycle in which the working fluid is sealed in the system. Heat is added to the fluid with an externally fired heater and extracted from the fluid through heat exchangers. The working fluid may be any gas, and the density of the gas may be varied — to vary the power delivered by the machine — by using a gas storage cylinder connected to the compressor discharge and inlet. The gas storage system is at an intermediate pressure so that it can discharge gas into the lowest pressure point in the cycle and receive gas from the highest pressure point in the cycle. About ten such units were built between 1938 and 1968; however, in spite of its sophistication, the added cost and low efficiency inherent in external combustion systems prevented this system from becoming economic.

The exhaust from a gas turbine is quite hot and can be used to raise steam, which can then be used to generate additional power with a steam turbine. Such a compound gas turbine-steam turbine system is referred to as a **combined cycle.** Figure 8.2.6 shows a schematic diagram of the equipment in a combined cycle. Because the exhaust of heavy-duty machines is hotter than that of aeroderivative machines, the gain in combined cycle system efficiency through use of the steam bottoming cycle described above is greater for heavy-duty machines than for aeroderivatives. Indeed, heavy-duty machines are designed with two criteria in mind: achieving lowest cost for peaking (based on the simple cycle configuration) and achieving highest efficiency in combined cycle configuration for baseload use. The optimum pressure ratios for these two system configurations are very close. Steam bottoming cycles used in combined cycles usually use steam at multiple pressure levels to increase efficiency.

Another system in which the power and efficiency of a gas turbine is increased through the use of steam is the **steam-injected gas turbine**. Figure 8.2.7 shows a schematic diagram of a steam-injected gas turbine cycle. Here the turbine exhaust flows into a heat recovery steam generator (HRSG) operating at a pressure somewhat higher than the compressor discharge pressure. The steam is introduced into the gas turbine at the combustor. The steam-air mixture then passes into the turbine, where the augmented mass flow increases the power produced by the turbine. Additional fuel is required by the combustor because the steam must be heated from the HRSG delivery temperature to the combustor discharge temperature. Typical turbines can accommodate only a limited additional mass flow — from 5 to 15%, depending on the design of the original gas turbine. Steam-injected gas turbines enable the host to use the steam for industrial purposes, space heating, or for the generation of additional power.

A group of cycles under consideration for development involve the use of **adiabatic saturators** to provide steam at compressor discharge pressure to augment greatly the mass flow through the turbine, and consequently increase cycle power and efficiency. In the adiabatic saturator, water flows in a counter-current path to the compressor discharge air in a mass transfer tower. Such equipment is often used in the chemical processing industries. The saturated air is preheated in a turbine exhaust heat recuperator. This cycle is called the **humid air turbine**, or HAT, cycle. The HAT cycle is particularly useful in using

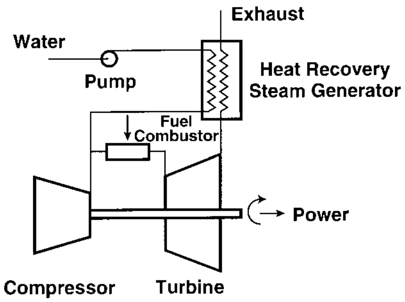

FIGURE 8.2.7 Steam-injected gas turbine.

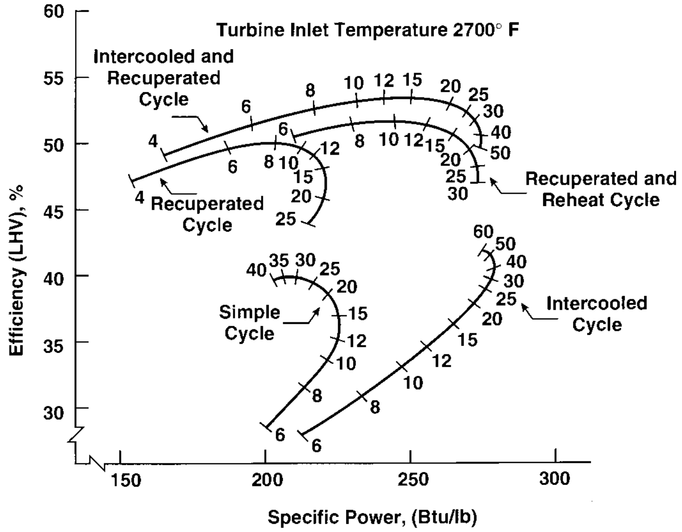

FIGURE 8.2.8 Specific power (Btu/lb).

the low-temperature heat generated in coal-gasification-fueled gas turbine power plants. As the mass flow through the turbine is significantly augmented, engineers can no longer use the expansion turbine which was matched to the compressor in a conventional simple cycle gas turbine.

Figure 8.2.8 shows performance maps for the gas turbine cycles of major interest for a turbine inlet temperature typical of new products. Intercooling increases the specific power appreciably when compared with a simple cycle; however, such improvement requires an increase in pressure ratio. Recuperated cycles have considerably higher efficiency than similar cycles without recuperation. The effect of pressure ratio on the performance of recuperated cycles is opposite to that of similar cycles without recuperation. For recuperated cycles, the pressure ratio for maximum efficiency is considerably lower than for maximum specific power. Performance maps such as these are used in screening cycle alternatives for improved performance. Individual curves are generated for specific component performance values for use as a guide in developing new or improved machines.

Upper Temperature Limit

Classically, gas turbine engineers often spoke of a metallurgical limit in reference to maximum turbine inlet temperature. Later, turbine vane and blade cooling became standard on large machines. This situation creates a temperature difference between the combustion products flowing through the turbine and the turbine blade wall. Thus, because heat can be removed from the blades, the turbine can be operated with a combustion gas temperature higher than the metallurgical limit of the blade material. As a rule, the blades and vanes in new large gas turbines contain complex internal passages, through which up to 20% of compressor discharge air is directed. The cooling air first flows through internal convective cooling passages, then through impingement passages, where the air is directed at the blade and vane walls, and finally through small holes in the blade, where it is used to provide a low-temperature film over the blade surface. This film cooling of the surface reduces heat transfer to the blade.

The design of blade and vane cooling passages is an extremely competitive endeavor because greater cooling enables use of higher combustion temperatures without exceeding the metallurgical limit of the blade material. However, a balance between air flow for cooling and air flow for power must be achieved; the cooling air flowing within a blade drops in pressure without producing any power within that stage (although it is available for power in later stages). In the newest gas turbines, blade cooling, the difference between turbine inlet gas temperature and blade metal temperature, is around 1000°F.

Some of the latest large gas turbines being introduced to the market in the 2005 period are being offered for combined cycle application with closed-circuit **steam cooling** of selected hot section parts. Steam cooling reduces the need for air cooling, so that more of the compressor discharge air can be used for NO_x reduction in the combustor and for power generation. The heat transferred to the steam increases the efficiency of the bottoming cycle. The additional combustion products which flow through the high-pressure portions of the turbine generate substantially more power, thereby increasing both the power output and the efficiency of the machine. With more air for combustion, the fuel can be burned as a leaner mixture, with either less NO_x produced, or, as is preferred, with higher-temperature gases going to the turbine and the same NO_x (or a combination of these benefits).

Materials

The high-technology parts of a gas turbine are its hot section parts: blades, vanes, combustors and transition pieces. Gas turbine power, efficiency, and economics increase with the temperature of the gas flowing through the turbine blade passages. It is in the fabrication of these hot section parts that manufacturers are most competitive. Materials are selected to survive in serviceable condition for over 50,000 hr and associated numbers of thermal cycles. Ceramic coatings protect materials from oxidation and corrosion and provide thermal insulation, permitting higher gas temperatures.

Gas turbine alloys are frequently referred to as superalloys because of their extremely high strength at high temperatures. These superalloys are nickel based (such as IN 738), cobalt based (such as FSX-414), or with a nickel-iron base such as Inconel 718. Nickel resists oxidation and is creep resistant, but is subject to corrosive sulfidation. Alloy and manufacturing advancements have been led by the needs of military aircraft engines. Coating developments for corrosion resistance have been led by the needs of stationary power for overhaul intervals as large as 50,000 hr. The developmental needs of automotive gas turbines have led to significant advances in strength and reliability of high-temperature ceramic components, including radial inflow turbines. Ceramic materials, principally silicon nitride, are of interest to the developer of service soon in small gas turbines.

Combustion

Gas turbine combustors appear to be simple in design, yet they solve several difficult engineering challenges. Until relatively recently, gas turbine combustors employed a (turbulent) diffusion flame design approach, which created the most compact flame. European heavy-duty gas turbine manufacturers — with substantial interest in burning heavy fuel oils — preferred large, off-engine combustors, often called silo combustors because of their appearance, in order to obtain lower flame velocities and longer residence times. American heavy-duty gas turbine manufacturers use compact on-engine combustors and design for gaseous and clean (distillate) liquid fuels. Aeropropulsion gas turbines require the smallest possible frontal area and use only clean liquid fuels; hence, they use on-engine combustors.

Recently, stationary engines have been required to reduce NO_x emissions to the greatest extent possible, and combustors on stationary gas turbines first modified their diffusion flame combustors and employed water and steam injection to quench flame hot spots. Most recently, designs changed to the lean-premixed process. With the improved blade cooling, materials, and coatings now in use, the material limits on turbine inlet temperature and the NO_x emission limits on combustor temperature appear to be converging on a combustion-temperature asymptote around 2700°F (1482°C). This may be increased if catalytic combustors prove practical.

Mechanical Product Features

In view of the need to achieve all the performance features described above, one must keep in mind that a gas turbine is a high-speed dynamic machine with numerous machine design, materials, and fabrication features to consider. Major issues include the following: critical shaft speed considerations, bearing rotational stability, rotor balancing, thrust bearing design, bearing power loss, oil lubrication system, oil selection, air filter design and minimization of inlet and exhaust diffuser pressure drops, instrumentation, controls, diagnostic systems, scheduled service and inspection, overhaul, and repair. All of these topics must be addressed to produce a cost-effective, reliable, long-lived, practical gas turbine product that will satisfy users while also returning to investors sufficient profit for them to continue to offer better power generation products of still higher performance.

Defining Terms

Adiabatic saturator: A combined heat-and-mass-exchanger whereby a hot gas and a volatile liquid pass through a series of passages such that the liquid is heated and evaporates into the gas stream.

Combined cycle: An arrangement of a gas turbine and a stream turbine whereby the heat in the exhaust from the gas turbine is used to generate steam in a heat recovery boiler which then flows through a steam turbine, thereby generating additional power from the gas turbine fuel.

Combustion efficiency: Ratio of rate of heat delivered in a device which burns fuel to the rate of energy supplied in the fuel.

Expansion process: Process of power generation whereby a gas passes through a machine while going from a condition of high pressure to one of low pressure, usually the machine produces power.

Gas turbine or engine efficiency: The ratio of the net power delivered (turboexpander power minus compressor and auxiliary power) to the rate of energy supplied to the gas turbine or engine in the form of fuel, or, in certain cases such as solar power, heat.

Humid air turbine: A gas turbine in which the flow through the expander is augmented by large amounts of steam generated by use of an adiabatic saturator.

Intercooler: A heat exchanger used to cool the flow between sections of a compressor such that the high pressure section acts on a stream of reduced volumetric flow rate, thereby requiring less overall power to compress the stream to the final pressure.

Recuperator: A heat exchanger in which the hot and cold streams pass on opposite sides of a wall through which heat is conducted.

Regenerator: A heat exchanger in which the hot and cold streams alternately heat and cool a wall whose temperature rises and falls, thereby transferring heat between the streams.

Steam cooling: A process in which steam is used as the heat transfer fluid to cool a hot component.

Steam-injected gas turbine: A system in which the gas turbine flow is augmented by steam, thereby generating additional power.

Turbine efficiency: Ratio of the power delivered in an expansion process employing a turbine as the expander to the maximum power which could be produced by expanding the gas in a reversible adiabatic (isentropic) process from its initial pressure and temperature to its final pressure to the actual power.

Cycle efficiency:

$$\eta = \frac{\dot{m}_t \Delta h_t - \dot{m}_c \Delta h_c}{\dot{m}_f HV}$$

where HV = heating value of fuel.

For specific heat independent of temperature and small mass flow of fuel in comparison to air:

$$\eta = \frac{\Delta T_t - \Delta T_c}{\Delta T_b}$$

Isentropic efficiency (finite pressure ratio):

$$\eta_t = \Delta T \text{ actual}/\Delta T \text{ isentropic}$$

$$\eta_t = \frac{1 - T_e/T_i}{1 - r^{(\gamma-1)/\gamma}}$$

or

$$\eta_t = \frac{1 - r^{(n-1)/n}}{1 - r^{(\gamma-1)/\gamma}}$$

and

$$\eta_c = \Delta T \text{ isentropic}/\Delta T \text{ actual}$$

$$\eta_c = \frac{r^{(\gamma-1)/\gamma} - 1}{T_e/T_i - 1}$$

or

$$\eta_c = \frac{r^{(\gamma-1)/\gamma} - 1}{r^{(\eta-1)/\eta} - 1}$$

Polytropic efficiency (differential pressure ratio):

$$\eta_t = \frac{(n-1)/n}{(\gamma-1)/\gamma}$$

and

$$\eta_c = \frac{(\gamma-1)/\gamma}{(n-1)/n}$$

Relationships between isentropic and polytropic efficencies:

$$\eta_{s,c} = \frac{r^{(\gamma-1)/\gamma} - 1}{r^{(\gamma-1)/\gamma\eta_{pc}} - 1}$$

$$\eta_{s,t} = \frac{1 - r^{(\gamma-1)/\gamma\eta_{p,t}}}{1 - r^{(\gamma-1)/\gamma}}$$

$$\eta_{p,c} = \frac{\ln r^{(\gamma-1)/\gamma}}{\ln\left[\dfrac{r^{(\gamma-1)/\gamma} - 1}{\eta_{s,c}} + 1\right]}$$

$$\eta_{p,t} = \frac{\ln\left[1 - \eta_{s,t}\left(1 - r^{(\gamma-1)/\gamma}\right)\right]}{\ln r^{(\gamma-1)/\gamma}}$$

8.3 Internal Combustion Engines

David E. Klett and Elsayed M. Afify

Introduction

This section discusses the two most common reciprocating internal combustion (IC) engine types in current use: the **spark ignition** (SI) and the **compression ignition** (CI or diesel) **engines**. The Stirling engine (technically, an external combustion engine) and the gas turbine engine are covered in other sections of this chapter. Space limitations do not permit detailed coverage of the very broad field of IC engines. For a more detailed treatment of SI and CI engines and for information on variations, such as the Wankel rotary engine and the Miller cycle engine (a variation on the reciprocating four-stroke SI engine introduced in production by Mazda in 1993), several excellent textbooks on the subject, technical papers, and other sources are included in the list of references and the section on further information.

Basic SI and CI engines have not fundamentally changed since the early 1900s with the possible exception of the introduction of the Wankel rotary SI engine in the 1960s (Norbye, 1971). However, major advances in the areas of materials, manufacturing processes, electronic controls, and computer-aided design have led to significant improvements in dependability, longevity, thermal efficiency, and emissions during the past decade. Electronic controls, in particular, have played a major role in efficiency gains in SI automotive engines through improved control of the fuel injection and ignition systems that control the combustion process. Electronic control of diesel fuel injection systems is also now quite common and is producing improvements in diesel emissions and fuel economy.

This section presents the fundamental theoretical background of IC engine function and performance, including **four-stroke** and **two-stroke** SI and CI **engines**. Sections on combustion, emissions, fuels, and intake pressurization (**turbocharging** and **supercharging**) are also included.

Engine Types and Basic Operation

IC engines may be classified by a wide variety of characteristics; the primary ones are SI vs. CI; four stroke vs. two stroke; and reciprocating vs. rotary. Other possible categories of classification include intake type (naturally aspirated vs. turbocharged or supercharged); number of cylinders; cylinder arrangement (in-line, vee, opposed); cooling method (air vs. water); fueling system (injected vs. carbureted); valve gear arrangement (overhead cam vs. pushrod); type of **scavenging** for two-stroke engines (cross, loop, or uniflow); and type of injection for diesel engines (direct vs. indirect).

Four-Stroke SI Engine

Figure 8.3.1 is a cross-section schematic of a four-stroke SI engine. The SI engine relies on a spark plug to ignite a volatile air–fuel mixture as the piston approaches **top dead center** (**TDC**) on the compression stroke. This mixture may be supplied from a carburetor, a single throttle-body fuel injector, or by individual fuel injectors mounted above the intake port of each cylinder. One combustion cycle involves two revolutions of the crankshaft and thus four strokes of the piston, referred to as the intake, compression, power, and exhaust strokes. Intake and exhaust valves control the flow of mixture and exhaust gases into and out of the cylinder, and an ignition system supplies a spark-inducing high voltage to the spark plug at the proper time in the cycle to initiate combustion.

On the intake stroke, the intake valve opens and the descending piston draws a fresh combustible charge into the cylinder. During the compression stroke, the intake valve closes and the fuel–air mixture is compressed by the upward piston movement. The mixture is ignited by the spark plug, typically before TDC. The rapid, **premixed, homogeneous combustion** process causes a sharp increase in cylinder

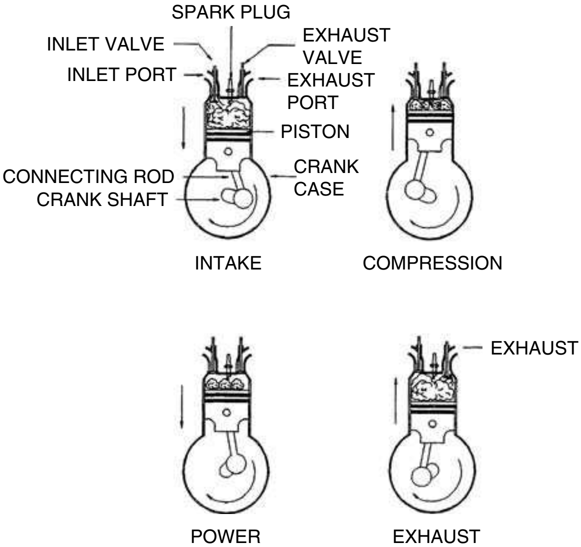

FIGURE 8.3.1 Schematic diagram of four-stroke SI engine.

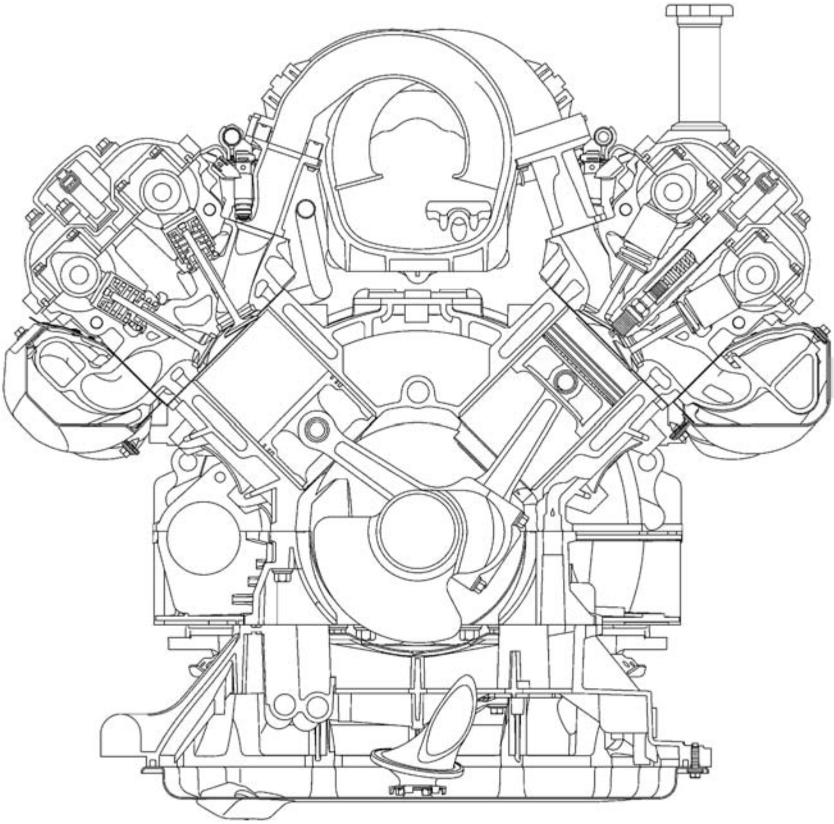

FIGURE 8.3.2 Ford 4.6-L aluminum V-8 SI engine. (Courtesy of Ford Motor Company.)

temperature and pressure that forces the piston down for the power stroke. Near **bottom dead center** (BDC), the exhaust valve opens and the cylinder pressure drops rapidly to near atmospheric. The piston then returns to TDC, expelling the exhaust products. At TDC, the exhaust valve closes and the intake valve opens to repeat the cycle again. Figure 8.3.2 is a cutaway drawing of a modern high-performance automotive SI engine. This is a fuel-injected normally aspirated aluminum alloy V-8 engine of 3.9 L displacement with dual overhead cams for each cylinder bank and four valves per cylinder. Peak power output is 188 kw at 6100 rpm and peak torque is 354 N-m at 4300 rpm.

Two-Stroke SI Engine

The two-stroke SI engine completes a combustion cycle for every revolution of the crankshaft by essentially overlapping the power and exhaust functions in one downward stroke and the intake and compression processes in one upward stroke. A single-cylinder, crankcase-scavenged, two-stroke SI engine is illustrated schematically in Figure 8.3.3. The operation is as follows.

On the upward stroke, the piston first covers the transfer port and then the exhaust port. Beyond this point, the fresh charge is compressed and ignited near TDC. During the upward stroke, the negative pressure created in the crankcase below the piston draws in a fresh charge of fuel–air mixture through a one-way valve. On the downward power stroke, the mixture in the crankcase is pressurized. The piston uncovers the exhaust port and the high-pressure exhaust gases exit. Near BDC, the transfer port is uncovered and the pressurized mixture flows from the crankcase into the cylinder and the cycle repeats. Because the crankcase is part of the induction system, it does not contain oil, and lubrication is accomplished by mixing oil with the fuel. With the cross-flow scavenging configuration illustrated in Figure 8.3.3, there will be a certain degree of mixing of the fresh charge with the combustion products remaining in the cylinder and some loss of fresh charge out the exhaust port.

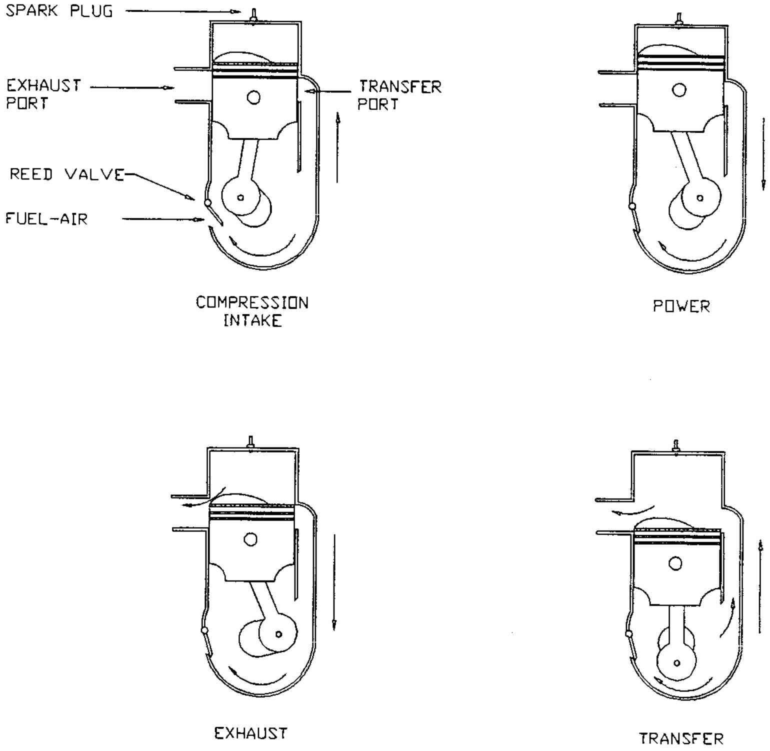

FIGURE 8.3.3 Schematic drawing of two-stroke SI engine.

Because two-stroke engines produce twice the power impulses of four-stroke engines for the same rpm, a two-stroke engine has a higher **power density** and is thus smaller and lighter than a four-stroke engine of equal output. The disadvantages of the two-stroke engine have historically been lower fuel efficiency and higher exhaust emissions because of overlapping intake and exhaust processes and the loss of some fresh intake mixture with the exhaust products. For this reason, two-stroke SI engines have largely been confined to small-displacement applications, such as small motorcycles, outboard marine engines, and small equipment. Several manufacturers have addressed these shortcomings in recent years and have achieved significant improvements in two-stroke engine fuel economy and emissions (Blair, 1988).

The Orbital combustion process (OCP), as illustrated in Figure 8.3.4, applies air-assisted direct injection of the fuel into the cylinder of a two-stroke engine and, in conjunction with a high turbulence combustion chamber design, achieves very favorable fuel economy and significantly reduced levels of hydrocarbon emissions. This system, in use today on single-cylinder scooters and on 2-, 3-, and 6-cylinder marine two-stroke engine applications, is also applicable to four-stroke engines.

Compression Ignition Engine

The basic valve and piston motions are the same for the CI, or diesel, engine as discussed earlier for the SI engine. The CI engine relies on the high temperature and pressure of the cylinder air resulting from the compression process to cause **autoignition** of the fuel, which is injected directly into the combustion chamber of **direct injection** (**DI**) engines or into the prechamber of **indirect injection** (**IDI**) engines, when the piston approaches TDC on the compression stroke. Compression ratios are typically much higher for CI than for SI engines to achieve the high air temperatures required for autoignition, and the fuels used must have favorable autoignition qualities.

The time period between the start of fuel injection and the occurrence of autoignition is called the **ignition delay period**. Long ignition delay periods allow more time for fuel vaporization and fuel–air

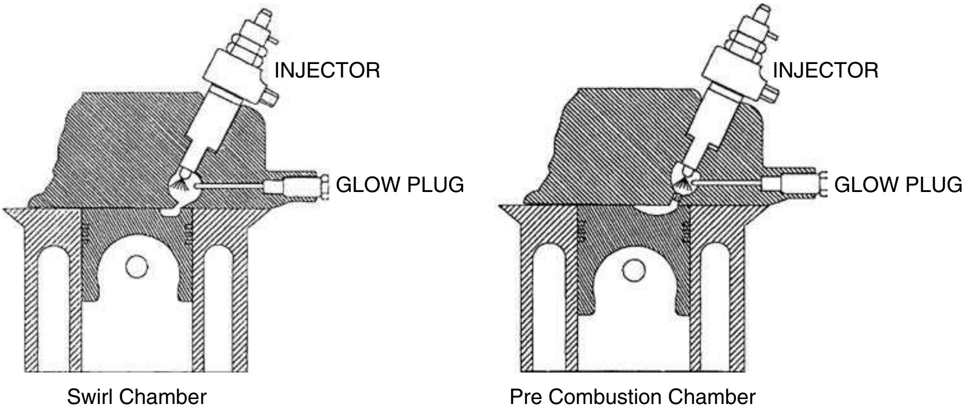
Quiescent Bowl **Toroidal Bowl**

FIGURE 8.3.5 Examples of DI diesel combustion chamber design.

mixing and result in objectionable diesel knock when this larger premixed charge autoignites. Combustion chambers and fuel injection systems must be designed to avoid extended ignition delay periods. Diesel engines may be classified as DI or IDI. In DI engines, the combustion chamber consists of a bowl formed in the top of the piston; the fuel is injected into this volume. The injector tip generally has from four to eight holes to form multiple spray cones.

Two variations are illustrated in Figure 8.3.5. The quiescent chamber engine utilizes a large-diameter shallow bowl shape that produces low **swirl** and low turbulence of the air during compression. Fuel is injected at high pressure through a multihole nozzle; mixing of the fuel and air relies primarily on the energy of the injected fuel to cause air entrainment in the spray cone and diffusion of vaporized fuel into the air. This system is suited to large slow-speed engines that are operated with significant excess air.



Swirl Chamber

Pre Combustion Chamber

FIGURE 8.3.6 Two examples of IDI combustion chambers.

The toroidal bowl combustion chamber is used in conjunction with intake ports and/or valve shrouds designed to produce air swirl to enhance fuel–air mixing. The **swirl ratio** is defined by swirl ratio = swirl speed (rpm)/engine speed (rpm). The swirl velocity component is normal to the fuel spray direction and tends to promote mixing in the regions between the individual spray cones. This system makes better use of the available air and is utilized extensively in moderate-speed engines such as over-the-road truck engines. DI does not lend well to high-speed operation because less time is available for proper mixing and combustion. Diesel engines for passenger car applications are generally designed for higher speed operation to produce higher specific output. They typically utilize IDI combustion systems, two of which are illustrated in Figure 8.3.6.

IDI systems make use of small prechambers incorporated in the cylinder head to promote rapid mixing of fuel and air and shorten the ignition delay period. Swirl chambers are designed to produce a strong vortex in the prechamber during compression. The fuel is sprayed into the chamber through a single-hole nozzle and the high vorticity promotes rapid mixing and short ignition delay periods. Precombustion chambers do not attempt to generate an orderly vortex motion within the chamber; instead, to promote mixing, they rely on a high level of turbulence created by the rush of air into the chamber during compression. Both types of prechambers generally include a lining of low-conductivity material (ceramic) to increase the surface temperature to promote fuel evaporation. Prechambers can be used in small-displacement diesel engines to achieve operating speeds up to 5000 rpm.

Disadvantages of the IDI system include poor cold-start characteristics due to high heat-transfer rates from the compressed air to the chamber wall that result from the high velocities and turbulence levels in the chamber. **Glow plugs** are often installed in each prechamber to heat the air to improve cold starting. Higher compression ratios are also used for IDI engines to improve cold starting. The compression ratios, typically 18 to 24, are higher than the optimum for fuel efficiency (due to decreased mechanical efficiency resulting from higher friction forces), and IDI engines are typically less efficient than larger, slower, DI engines. The use of IDI is generally restricted to high-speed automotive engines, with displacements in the range of 0.3 to 0.8 l per cylinder, and some degree of fuel economy is sacrificed in the interest of improved driveability.

CI engines are produced in two-stroke and four-stroke versions. Because the fuel is injected directly into the combustion chamber of CI engines just prior to TDC, two-stroke CI engines do not suffer the same emission and efficiency shortcomings as do older crankcase-scavenged two-stroke SI engines. Thus, they are available in much larger displacements for high-power-requirement applications such as locomotive and ship propulsion and electric power generation systems. Two-stroke CI engines are generally of the DI type because the use of IDI in a two-stroke engine would lead to aggravated cold-start problems due to lower compression ratios.

Air Standard Power Cycles

The actual operation of IC engines is idealized at a very basic level by the air standard power cycles (ideal thermodynamic models for converting heat into work on a continuous basis). The following simplifying assumptions are common to the air standard cycles: (1) the working substance is air, (2) the air is assumed to behave as an ideal gas with constant specific heats, (3) heat is added to the cycle from an external source, and (4) expansion and compression processes not involving heat transfer occur isentropically. The air standard cycles, while grossly oversimplified in terms of the complex processes occurring within actual engines, are nevertheless useful in understanding some fundamental principles of SI and CI engines. The simplified models also lend insight into important design parameters, e.g., **compression ratio**, that govern theoretical maximum cycle thermal efficiencies.

Constant-Volume Heat Addition — Ideal Otto Cycle

The theory of operation of the SI engine is idealized by the Otto cycle, which assumes that heat is added to the system at constant volume. Constant-volume heat addition is approximated in the SI engine by virtue of the combustion process taking place rapidly when the piston is near TDC. A P-V diagram for the Otto cycle is illustrated in Figure 8.3.7. The cycle consists of the following processes: 1 → 2 isentropic compression; 2 → 3 constant-volume heat addition; 3 → 4 isentropic expansion; and 4 → 1 constant-volume heat rejection. The constant-volume heat rejection process is approximated in SI engines by the exhaust valve opening near BDC and the rapid blow-down of exhaust gases.

Thermal efficiency for a power cycle is defined as the ratio of work output to heat input per cycle,

$$\eta = \frac{W_{\text{out}}}{Q_{\text{in}}} \tag{8.3.1}$$

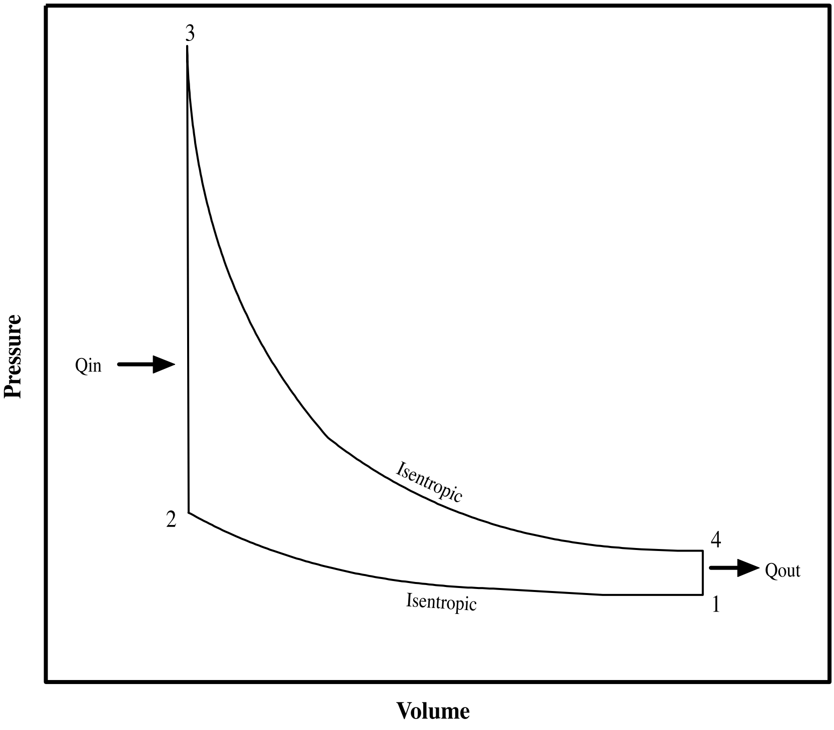


FIGURE 8.3.7 Schematic pressure-volume diagram for the ideal Otto cycle.

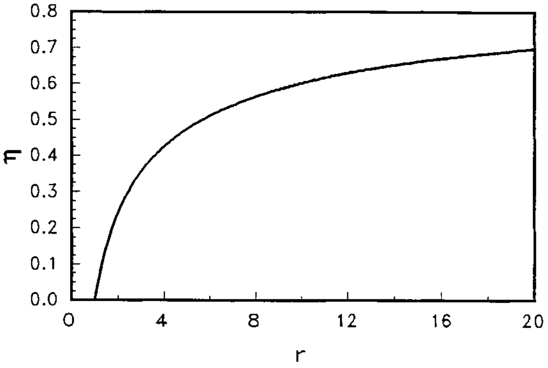

FIGURE 8.3.8 Efficiency of the ideal Otto cycle.

For the Otto cycle, the basic efficiency expression can be manipulated into the form

$$\eta = 1 - \frac{1}{r^{\gamma-1}} \tag{8.3.2}$$

where γ is the ratio of specific heats ($\gamma = C_p/C_v$) and r is the compression ratio, or ratio of the maximum to minimum cycle volumes ($r = V_1/V_2$).

In actual IC engines, the minimum cycle volume is referred to as the **clearance volume** and the maximum cycle volume is the **cylinder volume**. The ideal Otto cycle efficiency for air, with $\gamma = 1.4$, is shown plotted in Figure 8.3.8. The theoretical efficiency of the constant volume heat addition cycle increases rapidly with compression ratio, up to about $r = 8$. Further increases in compression ratio bring moderate gains in efficiency. Compression ratios in practical SI engines are limited because of autoignition (knock) and high NO_x emission problems that accompany high compression ratios. Production SI automotive engines typically have compression ratios in the range of 8 to 10, whereas high-performance normally aspirated racing engines may have compression ratios as high as 14, but require the use of special fuels to avoid autoignition.

Constant-Pressure Heat Addition — Ideal Diesel Cycle

The air standard diesel cycle is the idealized cycle underlying the operation of CI or diesel engines. The diesel cycle, illustrated by the *P-V* diagram in Figure 8.3.9, consists of the following processes: $1 \rightarrow 2$ isentropic compression from the maximum to the minimum cycle volume; $2 \rightarrow 3$ constant-pressure heat addition during an accompanying increase in volume to V_3; $3 \rightarrow 4$ isentropic expansion to the maximum cycle volume; and $4 \rightarrow 1$ constant-volume heat rejection.

Actual diesel engines approximate constant-volume heat addition by injecting fuel for a finite duration that continues to burn and release heat at a rate that tends to maintain the pressure in the cylinder over a period of time during the expansion stroke. The efficiency of the ideal diesel cycle is given by

$$\eta = 1 - \frac{1}{r^{\gamma-1}} \left[\frac{r_c^{\gamma} - 1}{\gamma (r_c - 1)} \right] \tag{8.3.3}$$

The efficiency of the ideal diesel cycle depends not only on the compression ratio, r, but also on the **cut-off ratio**, $r_c = V_3/V_2$, the ratio of the volume when heat addition ends to the volume when it begins. Equation (8.3.3) is shown plotted in Figure 8.3.10 for several values of r_c and for $\gamma = 1.4$. An r_c value of 1 is equivalent to constant-volume heat addition — i.e., the Otto cycle. The efficiency of the ideal Diesel cycle is less than the efficiency of the ideal Otto cycle for any given compression ratio and any value of the cut-off ratio greater than 1. The fact that CI engines, by design, operate at much higher compression

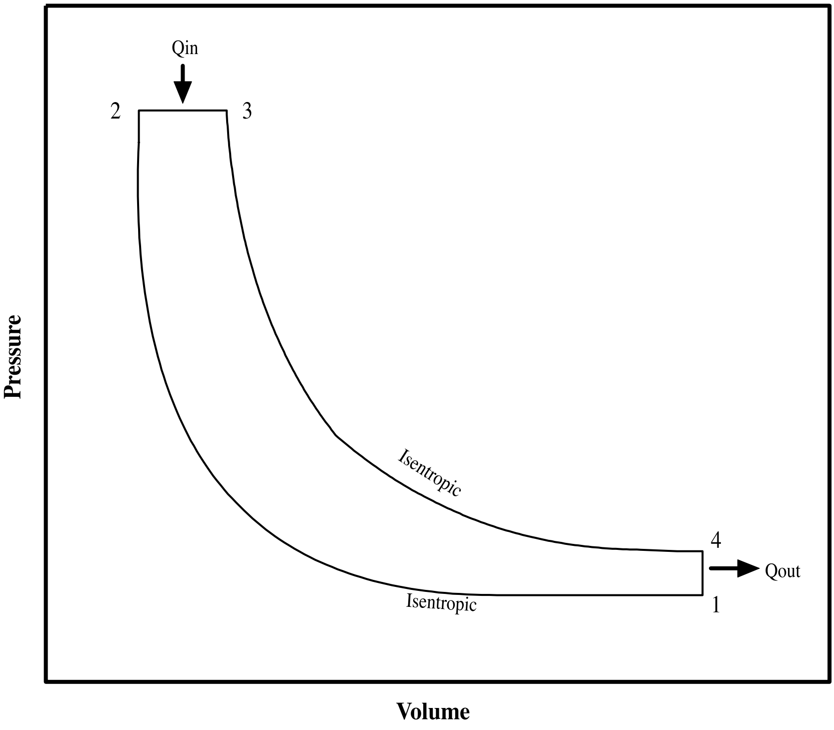

FIGURE 8.3.9 Schematic pressure-volume diagram of ideal diesel cycle.

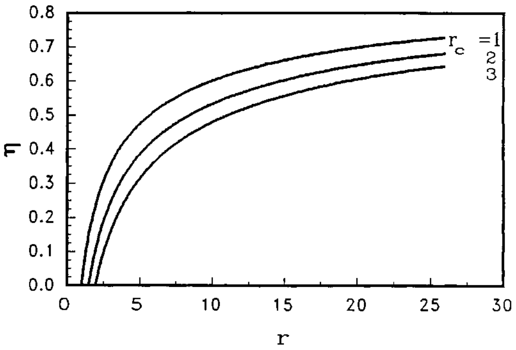

FIGURE 8.3.10 Efficiency of the ideal diesel cycle.

ratios than SI engines (generally between 12 and 24) accounts for their typically higher operating efficiencies relative to SI engines.

Actual Cycles

IC engines do not operate on closed thermodynamic cycles, such as the air standard power cycles, but rather on open mechanical cycles; heat addition occurs neither at constant volume nor at constant pressure. Figure 8.3.11 is a schematic representation of an **indicator diagram** (pressure-volume history) of a four-stroke IC engine; it could be SI or CI. The pressure changes during the intake and exhaust strokes are exaggerated in the diagram. The **indicated work** performed per cycle can be calculated by taking the integral of *PdV* for the complete cycle. The **indicated mean effective pressure, imep**, is defined as the ratio of the net indicated work output to the **displacement volume**:

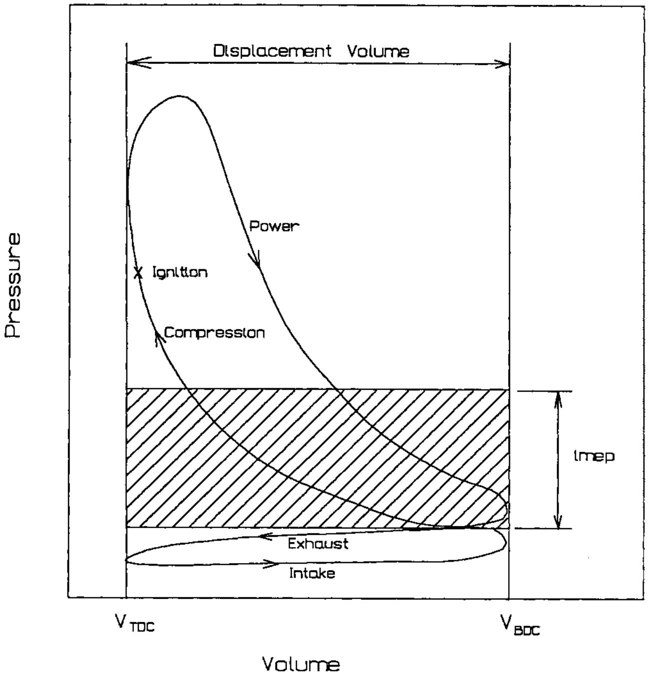

FIGURE 8.3.11 Schematic indicator diagram.

$$\text{imep} = \frac{\text{indicated work output per cycle}}{\text{displacement volume}} \tag{8.3.4}$$

The shaded area in Figure 8.3.11 thus represents the net indicated work output per cycle. During the intake and exhaust processes of a normally aspirated engine, the negative work performed represents pumping losses and acts to decrease the net work output of the engine. The magnitude of the pumping losses depends on the flow characteristics of the intake and exhaust systems, including the valves, ports, manifolds, piping, mufflers, etc. The more restrictive these passages are, the higher the pumping losses will be.

SI engines control power output by throttling the intake air. Thus, under partial-load conditions, the pressure drop resulting from the air throttling represents a significant increase in pumping loss with a corresponding decrease in operating efficiency. SI engines are therefore less efficient at partial-load operation than at full load. The power level of CI engines, on the other hand, is controlled by varying the amount of fuel injected, as opposed to throttling the intake air, making them significantly more efficient than SI engines under partial-load conditions.

Brake work (or power) is the actual work (or power) produced at the output shaft of an engine, as measured by a dynamometer. The brake work will be less than the indicated work due to friction losses and any parasitic power requirements for oil pumps, water pumps, etc. The **brake mean effective pressure, bmep**, is defined as

$$\text{bmep} = \frac{\text{brake work output per cycle}}{\text{displacement volume}} \tag{8.3.5}$$

The mechanical efficiency can then be defined as

$$\eta_m = \frac{\text{brake work (power)}}{\text{indicated work (power)}} = \frac{\text{bmep}}{\text{imep}} \tag{8.3.6}$$

Engine thermal efficiency can be determined from the ratio of power output to rate of fuel energy input, or

$$\eta_t = \frac{\text{Power}}{m_f Q_c} \tag{8.3.7}$$

where m_f is the rate of fuel consumption per unit time and Q_c is the heat of combustion per unit mass of fuel. The thermal efficiency in Equation (8.3.7) could be indicated or brake depending on the nature of the power used in the calculation. Uncertainty associated with variations of energy content of fuels may present a practical difficulty with determining engine thermal efficiency. In lieu of thermal efficiency, **brake-specific fuel consumption (bsfc)** is often used as an efficiency index.

$$\text{bsfc} = \frac{\text{fuel consumption rate } (\text{kg/hr})}{\text{brake power } (\text{kW})} \tag{8.3.8}$$

The efficiency of engines operating on the same fuel may be directly compared by their bsfc.

Volumetric efficiency, η_v, is an important performance parameter for four-stroke engines defined as

$$\eta_v = \frac{m_{\text{actual}}}{m_d} \tag{8.3.9}$$

where m_{actual} is the mass of intake mixture per cycle and m_d is the mass of mixture contained in the displacement volume at inlet conditions (pressure and temperature near the inlet port).

For SI engines, the mixture mass includes air and fuel; for CI engines only air is present during intake. With the intake mixture density determined at inlet conditions, η_v accounts for pressure losses and charge heating associated with the intake ports, valves, and cylinder. Sometimes, for convenience, the mixture density is taken at ambient conditions. In this case, η_v is called the overall volumetric efficiency and includes the flow performance of the entire intake system.

Because a certain minimum amount of air is required for complete combustion of a given amount of fuel, it follows that the maximum power output of an engine is directly proportional to its air-flow capacity. Therefore, although not affecting the thermal efficiency of the engine in any way, the volumetric efficiency directly affects the maximum power output for a given displacement and thus can affect the efficiency of the overall system in which the engine is installed because of the effect on system size and weight. Volumetric efficiency is affected primarily by intake and exhaust valve geometry; valve lift and timing; intake port and manifold design; mixing of intake charge with residual exhaust gases; engine speed; ratio of inlet pressure to exhaust back pressure; and heat transfer to the intake mixture from warmer flow passages and combustion chamber surfaces. For further information on the fundamentals of IC engine design and operation, see Taylor (1985); Ferguson and Kirkpatrick (2001); Heywood (1988); and Stone (1993).

Combustion in IC Engines

Combustion in Spark Ignition Engines

Background. In SI engines, combustion of the fuel–air mixture is initiated by a spark generated between the electrodes of a spark plug. The intake and compression strokes are designed to prepare the mixture for combustion by completely vaporizing the fuel and heating the mixture to just below its autoignition temperature. This is one reason, in addition to controlling emissions, for the current practice of limiting the maximum compression ratio of nonracing SI engines to about 10:1. Near the end of compression, the mixture is well conditioned for combustion and the spark is discharged to initiate the combustion process. For best fuel economy, the combustion process must be completed as close as possible to TDC.

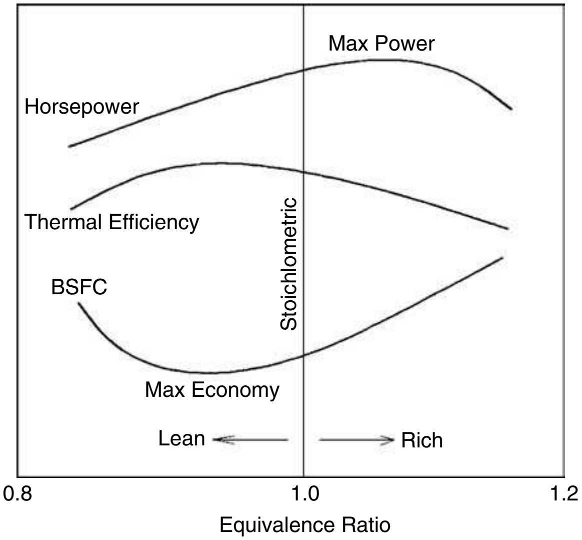

FIGURE 8.3.12 Effect of fuel–air mixture on indicated performance of an SI engine.

This requires that the spark timing be controlled for varying operating speed and load conditions of the engine. Fuel metering and control, according to the engine load requirements and with minimum variation from cylinder to cylinder and cycle to cycle, are essential for good fuel economy, power output, and emission control of the engine.

Carburetors and fuel injection systems are used for fuel-metering control. Because of the superior control capabilities of fuel injection systems, they are nearly universally used today in production automotive applications. Carburetors are used for applications with less-stringent emission requirements, e.g., small engines for lawn and garden equipment.

Figure 8.3.12 illustrates the effect of **fuel–air ratio** on the indicated performance of an SI engine. The **equivalence ratio** (ϕ) is defined by the ratio fuel–air$_{\text{actual}}$/fuel–air$_{\text{stoichiometric}}$. Rich mixtures have fuel–air ratios greater than stoichiometric ($\phi > 1$) and lean mixtures have fuel–air ratios less than stoichiometric ($\phi < 1$). Optimum fuel economy, coinciding with maximum thermal efficiency, is obtained at part throttle with a lean mixture as a result of the fact that the heat release from lean mixtures suffers minimal losses from dissociation and variation of specific heat effects when compared with stoichiometric and rich fuel–air ratios.

Maximum power is obtained at full throttle with a slightly rich mixture — an indication of the full utilization of the air within the cylinders. Idling with a nearly closed throttle requires a rich mixture due to the high percentage of residual exhaust gas that remains in the cylinders. The fuel–air mixture requirement under transient operation, such as acceleration, requires a rich mixture to compensate for the reduced evaporation caused by the sudden opening of the throttle. Cold starting also requires a rich mixture to ensure the vaporization of sufficient amounts of the highly volatile components in the fuel to achieve proper ignition.

Normal Combustion Process. The combustion processes in SI engines can be divided into two categories: normal and abnormal. The normal combustion process occurs in three stages: initiation of combustion; flame propagation; and termination of combustion. Combustion normally starts within the spark plug gap when the spark is discharged. The fuel molecules in and around the spark discharge zone are ignited and a small amount of energy is released. The important criterion for the initial reaction to be self-sustaining is that the rate of heat release from the initial combustion be larger than the rate of heat transfer to the surroundings. The factors that play an important role in making the initial reaction self-sustaining, and thereby establishing a flame kernel, are the ignition energy level; the spark plug gap; the fuel–air ratio; the initial turbulence; and the condition of the spark plug electrodes.

After a flame kernel is established, a thin spherical flame front advances from the spark plug region progressively into the unburned mixture zone. Flame propagation is supported and accelerated by two processes. First, the combined effect of the heat transfer from the high-temperature flame region and the migration of active radicals from the flame front into the adjacent unburned zone raise the temperature and accelerate the reactivity of the unburned mixture region directly ahead of the flame front. This helps to condition and prepare this zone for combustion.

Second, the increase in the temperature and pressure of the burned gases behind the flame front will cause it to expand and progressively create thermal compression of the remaining unburned mixture ahead of the flame front. The flame speed will be slow at the start of combustion, then reach a maximum at about half the flame travel, and finally decrease near the end of combustion. Overall, the flame speed is strongly influenced by the level of turbulence in the combustion chamber; the shape of the combustion chamber; the mixture strength; the type of fuel; and the engine speed.

When the flame front approaches the walls of the combustion chamber, the high rate of heat transfer to the walls slows down the flame propagation and, finally, the combustion process terminates close to the walls because of surface quenching. This leaves a thin layer of unburned fuel close to the combustion chamber walls that shows up in the exhaust as unburned hydrocarbons.

Abnormal Combustion. Abnormal combustion may occur in SI engines associated with two combustion phenomena: **knock** and **surface ignition**. Knock occurs near the end of the combustion process if the end portion of the unburned mixture, which is progressively subjected to thermal compression and seeding by active radicals, autoignites prematurely before the flame front reaches it. As a result of the sudden energy release, a violent pressure wave propagates back and forth across the combustion chamber, causing the walls or other parts of the engine to vibrate, producing a sharp metallic noise called knock. If knock persists for a period of time, the high rate of heat transfer caused by the traveling high pressure and temperature wave may overheat the spark plug electrode or ignite carbon deposits that may be present in the combustion chamber, causing uncontrolled combustion and surface ignition. As a result, loss of power and serious engine damage may occur.

Knock is sensitive to factors that increase the temperature and pressure of the end portion of the unburned mixture, as well as to fuel composition and other time factors. Factors that increase the probability of knock include: (1) increasing the temperature of the mixture by increasing the charge intake temperature, increasing the compression ratio, or turbo/supercharging; (2) increasing the density of the mixture by turbo/supercharging or increasing the load; (3) advancing the spark timing; (4) increasing the time of exposure of the end portion of the unburned mixture to autoignition conditions by increasing the length of flame travel or decreasing the engine speed and turbulence; and (5) using low-octane fuel and/or maximum power fuel–air ratios

Other engine design factors that affect knock in SI engines include the shape of the combustion chamber and the location of the spark plug and inlet and exhaust valves relative to the location of the end portion of the unburned mixture. Modern computerized engine management systems that incorporate a knock sensor can automatically retard the ignition timing at the onset of knock, greatly reducing the possibility of engine damage due to knock.

Surface ignition is the ignition of the unburned mixture by any source in the combustion chamber other than the normal spark. Such sources could include overheated exhaust valves or spark plug electrodes, glowing carbon deposits, or other hot spots. Surface ignition will create secondary flame fronts, which cause high rates of pressure rise resulting in a low-pitched, thudding noise accompanied by engine roughness. Severe surface ignition, especially when it occurs before spark ignition, may cause serious structural and/or component damage to the engine.

Combustion in Compression Ignition Engines

Unlike the SI engine, in which the charge is prepared for combustion as a homogeneous mixture during the intake and compression strokes, fuel preparation for combustion in CI engines occurs in a very short period of time called the ignition delay period, which lasts from the beginning of fuel injection until the

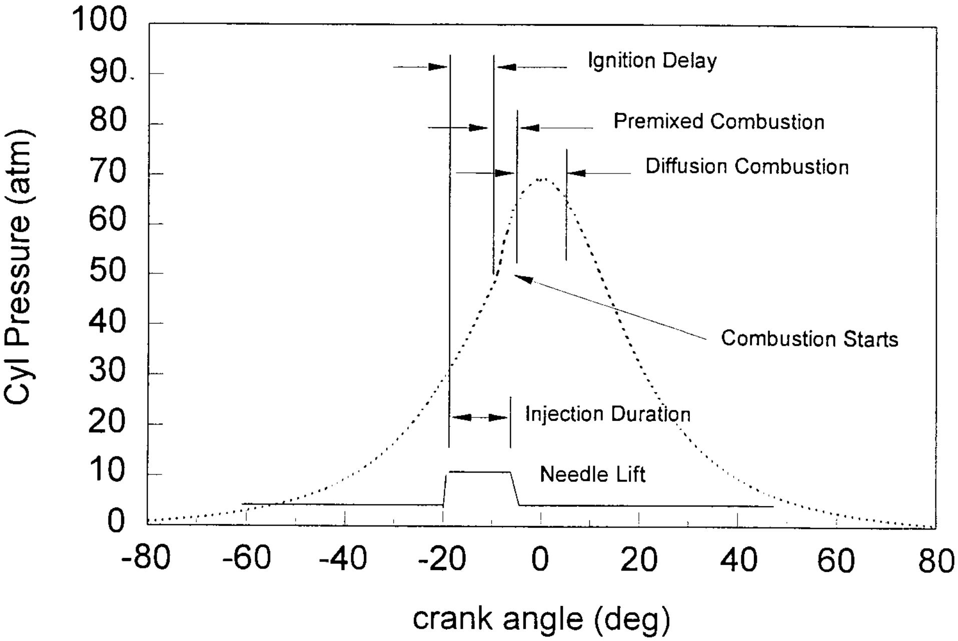

FIGURE 8.3.13 Combustion process in a CI engine.

moment of autoignition. During this period, the fuel injected into the high-temperature air near the end of the compression stroke undergoes two phases of transformation. A physical delay period, during which the fuel is vaporized, mixed with the air, and raised in temperature, is followed by a chemical delay period during which fuel cracking and decomposition occur; this leads to autoignition and combustion of the fuel.

The combustion process is **heterogeneous** and involves two modes, usually identified as premixed combustion and diffusion combustion. Premixed combustion occurs early in the process when the fuel that has evaporated and mixed with air during the ignition delay period autoignites. This mode is characterized by uncontrolled combustion and is the source of combustion noise because it is accompanied by a high rate of heat release, which produces a high rate of pressure rise. When the premixed fuel–air mixture is depleted, diffusion combustion takes over, characterized by a lower rate of heat release and producing controlled combustion during the remainder of the process. Figure 8.3.13 depicts the different stages of the combustion process in CI engines.

The ignition delay period plays a key role in controlling the time duration of the two modes of combustion. Prolonging the ignition delay, through engine design factors or variations in operating conditions, will generate a larger portion of premixed fuel–air mixture and thus tend to increase the premixed combustion mode duration and decrease the diffusion mode duration. This may lead to higher peak cylinder pressure and temperature; this may improve thermal efficiency and reduce CO and **unburned hydrocarbon** (**UHC**) emissions at the expense of increased emissions of oxides of nitrogen (**NO$_x$**).

Large increases in the ignition delay period will cause high rates of pressure rise during premixed combustion and may lead to objectionable diesel knock. Reducing the ignition delay period causes the premixed combustion duration to decrease while increasing the diffusion combustion duration. A large reduction in ignition delay may lead to loss of power, decrease in thermal efficiency, and possible deterioration of exhaust emissions. Several factors related to the fuel–air mixture temperature and density, engine speed, combustion chamber turbulence, injection pressure, rate of injection, and fuel composition influence the duration of the ignition delay period.

Knock in CI Engines. Because the combustion process in CI engines is triggered by autoignition of the fuel injected during the ignition delay period, factors that prolong the ignition delay period will increase the premixed combustion duration, causing very high rates of energy release and thus high rates of pressure rise. As a result, diesel knock may occur. The phenomenon is similar to knock in SI engines except that it occurs at the beginning of the combustion process rather than near the end, as observed in SI combustion. Factors that reduce the ignition delay period will reduce the possibility of knock in diesel engines. Among them are increasing the compression ratio; supercharging; increasing combustion chamber turbulence; increasing injection pressure; and using high-**cetane-number (CN)** fuel. For a more detailed discussion of the combustion process in IC engines, see Henein (1972); Lenz (1992); and Keating (1993).

Exhaust Emissions

Harmful Constituents

The products of combustion from IC engines contain several constituents that are considered hazardous to human health, including CO, UHCs NO_x, and **particulates** (from diesel engines). These emission products are discussed briefly next, followed by a description of the principal schemes for their reduction.

Carbon Monoxide. CO is a colorless, odorless, and tasteless gas that is highly toxic to humans. Breathing air with a small volumetric concentration (0.3%) of CO in an enclosed space can cause death in a short period of time. CO results from the incomplete combustion of hydrocarbon fuels. One of the main sources of CO production in SI engines is the incomplete combustion of the rich fuel mixture that is present during idling and maximum power steady-state conditions and during such transient conditions as cold starting, warm-up, and acceleration. Fuel maldistribution, poor condition of the ignition system, and slow CO reaction kinetics also contribute to increased CO production in SI engines. CO production is not as significant in CI engines because these engines are always operated with significant excess air.

Unburned Hydrocarbons. When UHCs combine with NO_x (see following) in the presence of sunlight, ozone and photochemical oxidants form that can adversely affect human health. Certain UHCs are also considered to be carcinogenic. The principal cause of UHC in SI engines is incomplete combustion of the fuel–air charge, resulting in part from flame quenching of the combustion process at the combustion chamber walls and engine misfiring. Additional sources in four-stroke engines may include fuel mixture trapped in crevices of the top ring land of the piston and outgassed fuel during the expansion (power) stroke that was absorbed into the lubricating oil film during intake. In two-stroke SI engines, the scavenging process often results in a portion of the fresh mixture exiting the exhaust port before it closes, resulting in high UHC emissions.

The presence of UHC in CI engines is related to the heterogeneous nature of the fuel–air mixture. Under certain conditions, fuel–air mixtures that lie outside the flammability limits at the lean and rich extremes can exist in portions of the combustion chamber and escape combustion, thus contributing significantly to UHC in the exhaust. Fuel injected near the end of the combustion process and fuel remaining in the nozzle **sac volume** at the end of injection contribute to UHC emission in CI engines. Engine variables that affect UHC emissions include the fuel–air ratio; intake air temperature; and cooling water temperature.

Oxides of Nitrogen. Nitric oxide (NO) is formed from the combination of nitrogen and oxygen present in the intake air under the high-temperature conditions that result from the combustion process. As the gas temperature drops during the expansion stroke, the reaction is frozen, and levels of NO persist in the exhaust products far in excess of the equilibrium level at the exhaust temperature. In the presence of additional oxygen in the air, some NO transforms to nitrogen dioxide (NO_2), a toxic gas.

The combined NO and NO_2 are referred to as oxides of nitrogen or NO_x. The production of NO_x is in general aggravated by conditions that increase the peak combustion temperature. In SI engines, the most important variables that affect NO_x production are the air/fuel ratio; spark timing; intake air temperature; and amount of residual combustion products remaining in the cylinder after exhaust. In CI engines, ignition delay, which affects the degree of premixed combustion, plays a key role in NO_x formation. A larger premixed combustion fraction will produce higher combustion temperatures and higher levels of NO_x.

Particulates. Particulates are a troublesome constituent in the exhaust from CI engines. They are defined by the U.S. Environmental Protection Agency (EPA) as any exhaust substance (other than water) that can be trapped on a filter at temperatures of 325 K or below. Particulates trapped on a filter may be classified as soot plus an organic fraction of hydrocarbons and their partial oxidation products. Soot consists of agglomerates of solid uncombusted carbon particles. Particulates are of concern because their small size permits inhalation and entrapment in the lung walls, making them potential lung carcinogens.

Soot is formed in CI engines under conditions of heavy load when the gas temperature is high and the concentration of oxygen is low. Smoke production is affected by such parameters as fuel CN; rate of fuel injection; inlet air temperature; and the presence of secondary injection.

Control of Emissions from IC Engines

Figure 8.3.14 depicts the relative concentrations of CO, NO_x, and UHC in the exhaust products of an SI engine as a function of the fuel–air mixture. Lean mixture combustion, which promotes good thermal efficiency, also results in low UHC and CO production but causes high levels of NO_x emission. Increasing the fuel/air ratio to reduce NO_x results in increased CO and UHC emission. Approaches to reduce total emissions fall under two categories: (1) engine design and fuel modifications; and (2) treatment of exhaust gases after they leave the engine.

In SI engines, the first approach focuses on addressing engine variables and design modifications, which improve in-cylinder mixing and combustion in an effort to reduce CO and UHC emissions. To reduce NO_x, attention is focused on factors that reduce peak combustion temperature and reduce the oxygen available in the flame front. Design and operating parameters implemented or modified for decreased emissions include compression ratio reduction, increased coolant temperature, modification of the combustion chamber shape to minimize surface-to-volume ratio and increase turbulence, improvement of intake manifold design for better charge distribution, use of fuel injection instead of carburetors for better mixture control, use of exhaust gas recirculation to reduce NO_x by lowering combustion temperatures, positive crankcase ventilation to reduce UHC, and increased aromatic content in gasoline.

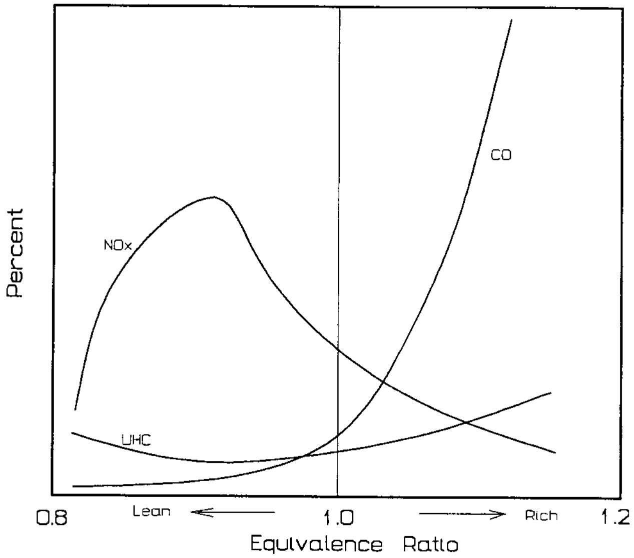

FIGURE 8.3.14 Emission levels from an SI engine vs. fuel–air mixture.

Engine modifications that have been implemented to reduce emissions from CI engines include modifications to the combustion chamber shape to match the air swirl pattern and fuel spray pattern for better mixing and complete combustion; use of exhaust gas recirculation to limit NO_x production; use of higher injection pressure for better atomization to reduce soot and UHC; and the use of precise injection timing with electronic control.

In the second approach, several devices have been developed for after treatment of exhaust products. A thermal reactor may be used to oxidize UHC and CO. These typically consist of a well-insulated volume placed close to the exhaust manifold, with internal baffles to increase the gas residence time and an air pump to supply fresh oxygen for the oxidation reactions. Thermal reactors are ineffective for NO_x reduction and thus have limited application.

Catalytic converters utilize a catalyst, typically a noble metal such as platinum, rhodium, or palladium, deposited on a ceramic substrate to promote reactions at lower temperatures. Two types are in use: oxidation converters and reduction converters. Oxidation catalytic converters use the excess air available in lean mixtures (or supplied from an external air pump) to oxidize CO and UHC emissions. Reduction catalytic converters operate with low levels of oxygen to cause reduction of NO_x. Sometimes, dual catalytic converters are employed to treat all three pollutants with a reducing converter, to reduce NO_x, placed upstream of an oxidation converter for treating CO and UHC. This arrangement requires that the engine be operated with a rich mixture, which decreases fuel economy.

Three-way catalytic converters are a recent development that permits treatment of NO_x, CO, and UHC in a single device, thus reducing size and weight of the exhaust system. Proper operation of a three-way catalyst requires very nearly stoichiometric combustion. If the combustion is too lean, NO_x is not adequately reduced, and if it is too rich, UHC and CO are not adequately oxidized. Within a narrow band for equivalence ratio (from about 0.999 to 1.007), conversion efficiency is 80% or better for all three pollutants (Kummer, 1980). Maintaining engine operation within this narrow mixture band requires a closed-loop fuel-metering system that utilizes an oxygen sensor placed in the exhaust system to monitor excess oxygen and control the fuel injection to maintain near stoichiometric combustion.

Reduction catalytic converters cannot be used with CI engines to reduce NO_x because they normally run lean with significant amounts of excess oxygen in the exhaust. Thus, engine design factors must be relied on to keep NO_x as low as possible. Soot emission may be reduced by after treatment using a device called a trap oxidizer. A trap oxidizer filters particulate matter from the exhaust stream and oxidizes it, usually with the aid of a catalyst for reducing the oxidation temperature. These have been used on small, high-speed automotive diesel engines, but their application to larger, slower speed engines is limited because of the higher level of particulate production and the lower exhaust temperature. For additional information on emissions, see Henein (1972); Obert (1973); and *SAE Surface Vehicle Emissions Standards Manual* (1993).

Fuels for SI and CI Engines

Background

The primary distinguishing factor between SI and CI engines is the fundamental difference in the combustion process. SI engines rely on homogeneous, spark-ignited, premixed combustion, while CI engines are designed for heterogeneous combustion with an autoignited premixed combustion period followed by a diffusion combustion period. The differences in the combustion process call for quite different qualities in the fuels to achieve optimum performance.

By far the most common fuel for SI engines is gasoline, although other fuels can be used in special circumstances, including alcohol, natural gas, and propane. Even such low-grade fuels as wood gas and coal gas have been used to fuel SI engines during wartime when conventional fuels were in short supply. Diesel fuel is the predominant fuel for CI engines, but they too can be designed to operate on a variety of other fuels, such as natural gas, bio-gas, and even coal slurries. This discussion is confined to gasoline and diesel fuel, both of which are distilled from crude oil.

Crude oil is composed of several thousand different hydrocarbon compounds that, upon heating, are vaporized at different temperatures. In the distillation process, different "fractions" of the original crude are separated according to the temperatures at which they vaporize. The more volatile fraction, naphtha, is followed in order of increasing temperature of vaporization by fractions called distillate, gas oil, reduced crude, and residual oil. These fractions may be further subdivided into light, middle, and heavy classifications. Light virgin naphtha can be used directly as gasoline, although it has relatively poor antiknock quality. The heavier fractions can be chemically processed through coking and catalytic cracking to produce additional gasoline. Diesel fuel is derived from the light to heavy virgin gas oil fraction and from further chemical processing of reduced crude.

Gasoline

Gasoline fuels are mixtures of hydrocarbon compounds with boiling points in the range of 32 to 215°C. The two most important properties of gasoline for SI engine performance are volatility and octane rating. Adequate volatility is required to ensure complete vaporization, as required for homogeneous combustion, and to avoid cold-start problems. If the volatility is too high, however, vapor locking in the fuel delivery system may become a problem. Volatility may be specified by the distillation curve (the distillation temperatures at which various percentages of the original sample have evaporated). Higher volatility fuels will be characterized by lower temperatures for given fixed percentages of evaporated sample or, conversely, by higher percentages evaporated at or below a given temperature. Producers generally vary the volatility of gasoline to suit the season, increasing the volatility in winter to improve cold-start characteristics and decreasing it in summer to reduce vapor locking.

The octane rating of a fuel is a measure of its resistance to autoignition or knocking; higher octane fuels are less prone to autoignition. The octane rating system assigns the value of 100 to iso-octane (C_8H_{18}, a fuel that is highly resistant to knock) and the value 0 to *n*-heptane (C_7H_{16}, a fuel that is prone to knock). Two standardized methods are employed to determine the octane rating of fuel test samples: the research method and the motor method; see ASTM Standards Part 47 — Test Methods for Rating Motor, Diesel and Aviation Fuels (ASTM, 1995).

Both methods involve testing the fuel in a special variable compression-ratio engine (cooperative fuels research or CFR engine). The test engine is operated on the fuel sample and the compression ratio is gradually increased to obtain a standard knock intensity reading from a knock meter. The octane rating is obtained from the volumetric percentage of iso-octane in a blend of iso-octane and *n*-heptane that produces the same knock intensity at the same compression ratio.

The principal differences between the research method and the motor method are the higher operating speed, higher mixture temperature, and greater spark advance employed in the motor method. Ratings obtained by the research method are referred to as the **research octane number** (RON); those obtained with the motor method are called the motor octane number (MON). MON ratings are lower than RON ratings because of the more stringent conditions, i.e., higher thermal loading of the fuel. The octane rating commonly advertised on gasoline pumps is the **antiknock index**, $(R + M)/2$, which is the average of the values obtained by the two methods. The typical range of antiknock index for automotive gasolines currently available at the pump is 87 to 93. In general, higher compression SI engines require higher octane fuels to avoid autoignition and to realize full engine performance potential from engines equipped with electronic control systems incorporating a knock sensor.

Straight-run gasoline (naphtha) has a poor octane rating on the order of 40 to 50 RON. Higher octane fuels are created at the refinery by blending with higher octane components produced through alkylation wherein light olefin gases are reacted with isobutane in the presence of a catalyst. Iso-octane, for example, is formed by reacting isobutane with butene. Aromatics with double carbon bonds shared between more than one ring, such as naphthalene and anthracene, serve to increase octane rating because the molecules are particularly difficult to break.

Additives are also used to increase octane ratings. In the past, a common octane booster added to automotive fuels was lead alkyls — tetraethyl or tetramethyl lead. For environmental reasons, lead has been removed from automotive fuels in most countries. It is, however, still used in aviation fuel. Low-lead fuel has a concentration of about 0.5 g/L, which boosts octane rating by about five points. The use of leaded fuel in an engine equipped with a catalytic converter to reduce exhaust emissions will rapidly deactivate the catalyst (typically a noble metal such as platinum or rhodium), quickly destroying the utility of the catalytic converter. Octane-boosting additives in current use include the oxygenators methanol, ethanol, and methyl tertiary butyl ether (MTBE).

RON values of special-purpose, high-octane fuels for racing and aviation purposes can exceed 100 and are arrived at through an extrapolation procedure based on the knock-limited indicated mean effective pressure (klimep). The klimep is determined by increasing the engine intake pressure until knock occurs. The ratio of the klimep of the test fuel to that for iso-octane is used to extrapolate the octane rating above 100.

Diesel Fuels

Diesel fuels are blends of hydrocarbon compounds with boiling points in the range of 180 to 360°C. Properties of primary importance for CI fuels include the density, viscosity, cloud point, and ignition quality (CN). Diesel fuel exhibits a much wider range of variation in properties than does gasoline. The density of diesel fuels tends to vary according to the percentages of various fractions used in the blend. Fractions with higher distillation temperatures tend to increase the density. Variations in density result in variations in volumetric energy content and thus fuel economy, because fuel is sold by volume measure. Higher density fuel will also result in increased soot emission.

Viscosity is important to proper fuel pump lubrication. Low-viscosity fuel will tend to cause premature wear in injection pumps. Too high viscosity, on the other hand, may create flow problems in the fuel delivery system. Cloud point is the temperature at which a cloud of wax crystals begins to form in the fuel. This property is critical for cold-temperature operation because wax crystals will clog the filtration system. ASTM does not specify maximum cloud point temperatures, but rather recommends that cloud points be no more than 6°C above the 10th percentile minimum ambient temperature for the region for which the fuel is intended; see ASTM D 975 (ASTM, 1995).

CN provides a measure of the autoignition quality of the fuel and is the most important property for CI engine fuels. The CN of a fuel sample is obtained through the use of a CI CFR engine in a manner analogous to the determination of octane rating. The test method for CN determination is specified in standard ASTM D 613. *n*-Cetane (same as hexadecane, $C_{16}H_{34}$) has good autoignition characteristics and is assigned the cetane value of 100. The bottom of the cetane scale was originally defined in terms of α-methyl naphthalene ($C_{11}H_{10}$), which has poor autoignition characteristics and was assigned the value 0. In 1962, for reasons of availability and storability, the poor ignition quality standard fuel used to establish the low end of the cetane scale was changed to heptamethylnonane (HMN), with an assigned CN of 15. The CN of a fuel sample is determined from the relative volumetric percentages of cetane and HMN in a mixture that exhibits the same ignition delay characteristics as the test sample using the relation

$$\text{CN} = \%\ n\text{-cetane} + 0.15\left(\%\ \text{HMN}\right) \tag{8.3.10}$$

ASTM standard D 976 (ASTM, 1995) provides the following empirical correlation for calculating the **cetane index** of straight petroleum distillate fuels (no additives) as an approximation to the measured CN:

$$\text{Cetane index} = 454.74 - 1641.416D + 774.74D^2 - 0.554B + 97.803\ (\log B)^2 \tag{8.3.11}$$

where D = density at 15°C (g/mL) and B = mid-boiling temperature (°C).

ASTM standard D 975 (ASTM, 1995) establishes three classification grades for diesel fuels (No. 1-D, No. 2-D, and No. 4-D) and specifies minimum property standards for these grades. No. 1-D is a volatile distillate fuel for engines that must operate with frequent changes in speed and load. No. 2-D is a lower volatility distillate fuel for industrial and heavy mobile service engines. No. 4-D is a heavy fuel oil for low- and medium-speed engines. Nos. 1-D and 2-D are principally transportation fuels, while No. 4-D is for stationary applications. The ASTM minimum CN for No. 1-D and No. 2-D is 40, and for No. 4-D the minimum is 30. Typical CNs for transportation fuels lie in the range of 40 to 55. Use of a low-cetane fuel aggravates diesel knock because of the longer ignition delay period, which creates a higher fraction of premixed combustion.

Antiknock quality (octane number) and ignition quality (CN) are opposing properties of distillate fuels. The CN increases with decreasing octane rating of various fuels. Gasoline, with good antiknock quality, has a CN of approximately 10, while a diesel fuel with a CN of 50 will have an octane number of about 20. Thus, gasoline is not a suitable fuel for CI engines because of its poor autoignition quality, and diesel fuel is inappropriate for use in SI engines as a result of its poor antiknock quality. For additional information on fuels for IC engines see Owen and Coley (1995) and the *SAE Fuels and Lubricants Standards Manual* (1993).

Intake Pressurization — Supercharging and Turbocharging

Backround

Pressurizing the intake air (or mixture) by means of a compressor may be used to boost the specific power output of SI and CI engines. Supercharging generally refers to the use of compressors that are mechanically driven from the engine crankshaft, while turbocharging refers to compressors powered by a turbine, which extracts energy from the exhaust stream. Increasing the intake pressure increases the density and thus the mass flow rate of the intake mixture; this allows an increase in the fueling rate, thereby producing additional power.

The mere process of increasing the cylinder pressure results in increased work output per cycle, as illustrated in the *P-V* diagram in Figure 8.3.15, which compares supercharged and naturally aspirated, air standard Otto cycles having the same compression ratio. The work done for the compressed intake cycle (Area 1,2,3,4,1 and Area 5,6,7,1,5) is greater than that for the naturally aspirated cycle (Area 1′,2′,3′,4′,1′) due to the boost of the intake pressure. Positive-displacement superchargers are capable of producing higher boost pressures than turbochargers, which are nearly always centrifugal-type fans. From a practical standpoint, the maximum useful boost pressure from either system is limited by the onset of autoignition in SI engines and by the permissible mechanical and thermal stresses in CI engines.

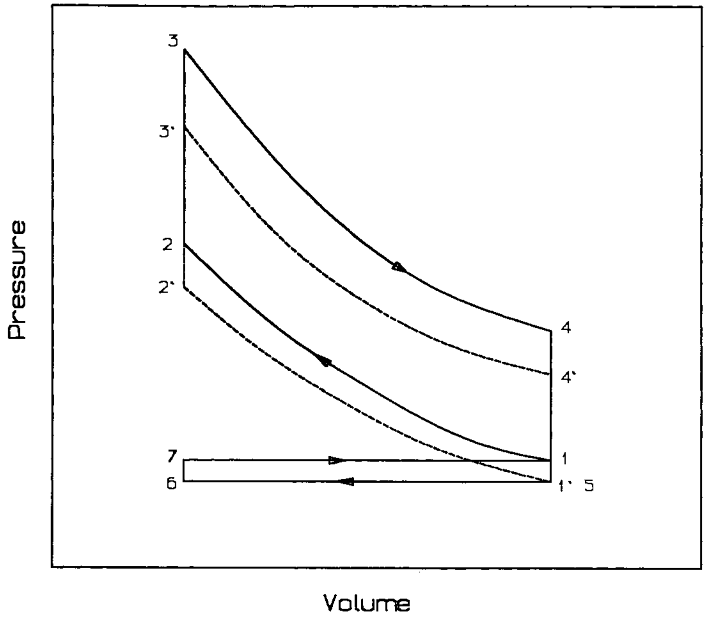

FIGURE 8.3.15 Comparison of supercharged and naturally aspirated Otto cycle.

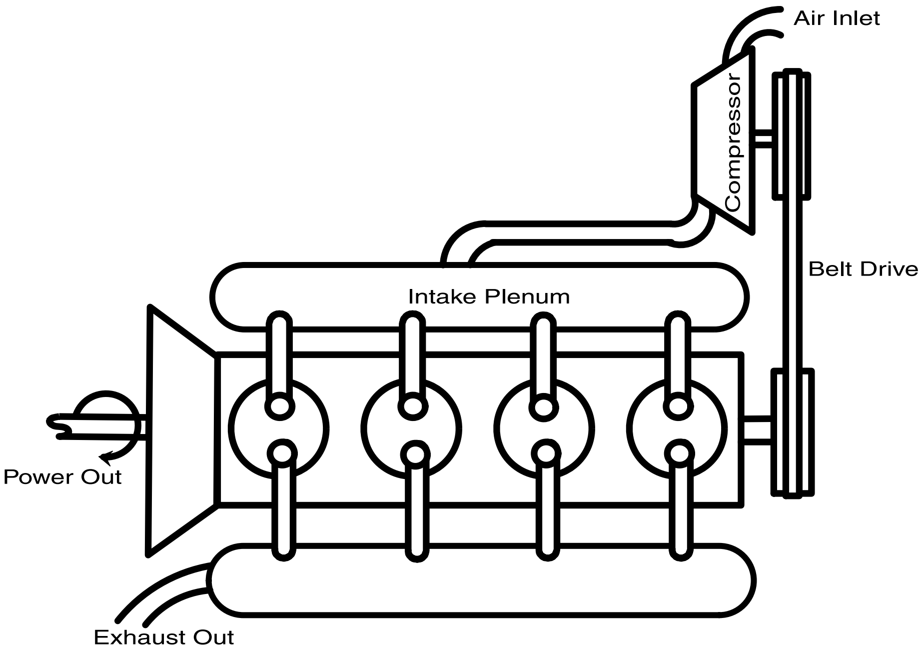

FIGURE 8.3.16 Schematic diagram of supercharged engine.

Supercharging

The principal applications of supercharging SI engines are in high-output drag-racing engines and in large aircraft piston engines to provide high specific output at takeoff and to improve power output at high altitudes. A few high-performance production automobiles also use a supercharger in lieu of the more common turbocharger to achieve their increased performance. For diesel applications, supercharging is used mainly in marine and land-transportation applications. It is common to use supercharging or turbocharging to improve the scavenging process in two-stroke diesel engines. Figure 8.3.16 is a schematic of an engine with a mechanically driven supercharger. Superchargers may be belt, chain, or gear driven from the engine crankshaft.

Two types of superchargers are in use: the positive displacement type (Roots blower) and the centrifugal type. Roots blowers may be classified as: (1) straight double lobe; (2) straight triple lobe; and (3) helix triple lobe (twisted 60%). The helix triple-lobe type runs more quietly than the others and is generally recommended, especially for diesel engines operating under high torque at various speed conditions. Because of its high capacity and small weight and size, the centrifugal type is best suited for applications in which power and volumetric efficiency improvement are required at high engine speed, e.g., with aircraft engines. A centrifugal blower will also survive a backfire more readily than a Roots blower in SI applications. Because superchargers are directly driven from the engine output shaft, no inherent lag in the rate of pressure increase with engine speed is present, as is typically the case with turbochargers.

Turbocharging

Turbochargers utilize a centrifugal compressor directly connected to a turbine that extracts energy from the exhaust gases of the engine and converts it to the shaft work necessary to drive the compressor. Turbocharging is widely used to increase power output in automotive and truck applications of four-stroke SI and CI engines and to improve scavenging of two-stroke CI engines.

There are three methods of turbocharging: the constant pressure; the pulse; and the pulse converter. In the constant-pressure method, as illustrated in Figure 8.3.17, the exhaust pressure is maintained at a nearly constant level above atmospheric. To accomplish this, the exhaust manifold must be large enough to damp out the pressure fluctuations caused by the unsteady flow characteristic of the engine exhaust

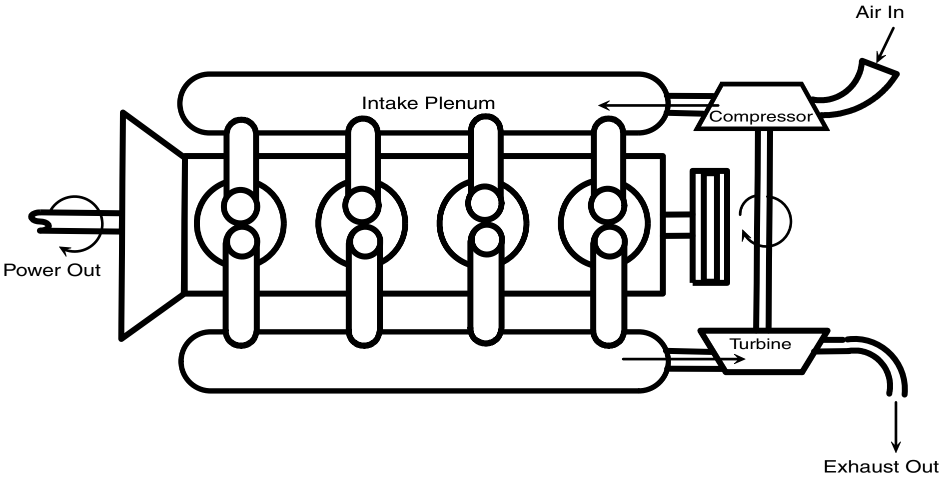

FIGURE 8.3.17 Schematic diagram of a constant-pressure turbocharger.

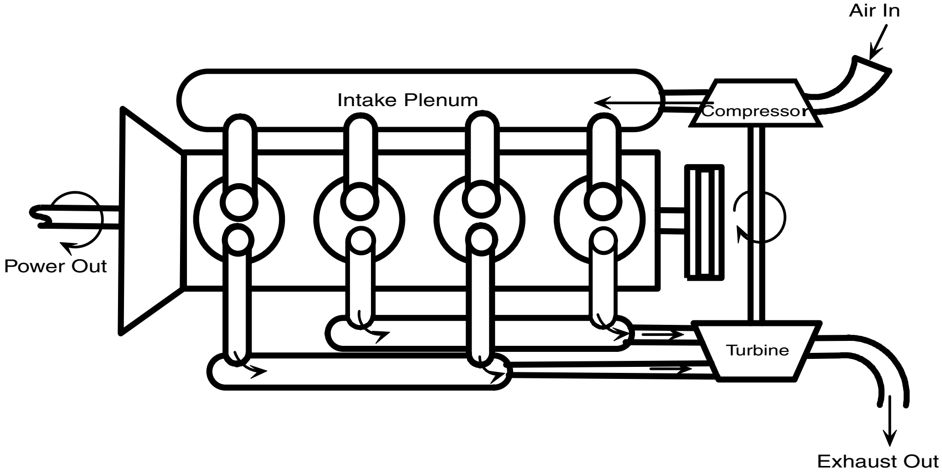

FIGURE 8.3.18 Schematic diagram of a pulse turbocharger.

process. In this method, the turbine operates efficiently under steady-flow conditions; however, some engine power is lost because of the increased backpressure in the exhaust manifold.

The pulse turbocharger, as illustrated in Figure 8.3.18, utilizes the kinetic energy generated by the exhaust blow-down process in each cylinder. This is accomplished by using small exhaust lines grouped together in a common manifold to receive the exhaust from the cylinders, which are blowing down sequentially. In this method, the pressure at the turbine inlet tends to fluctuate; this is not conducive to good turbine efficiency. This is offset to a large degree, however, by improved engine performance as a result of the lower exhaust backpressure relative to the constant-pressure method. The pulse converter method represents a compromise between the previous two techniques. In principle, this is accomplished by converting the kinetic energy in the blow-down process into a pressure rise at the turbine by utilizing one or more diffusers. Details of the different methods of turbocharging may be found in Watson and Janota (1982).

Recent advances in turbocharging technology have focused mainly on (1) improving turbine transient response (turbo-lag); (2) improving torque-speed characteristics of the engine; and (3) increasing the power output by increasing the boost pressure and using charge cooling (intercooling). The use of ceramic materials in fabricating turbine rotors improves the turbine transient response because they are lighter in weight and have less rotational inertia. Ceramic rotors also have greater thermal operating range because of their lower thermal expansion. The use of variable-geometry turbochargers can improve the low-speed torque characteristics of the engine and help reduce the transient response time. This is due to the ability of the variable-geometry turbocharger to change its internal geometry to accommodate low flow rates at low engine speeds and higher volume flow rates at high engine speeds.

However, because the geometry of the turbine rotor remains unchanged while the internal geometry varies, the turbine efficiency will be reduced for all internal geometries other than the optimum design geometry. In response to increased demand for diesel engines with high boost pressure and with size constraints, advances in the aerothermodynamics of axial/radial flow and of two-stage turbochargers, as well as in the design of compressor and turbine blades, have allowed high boost pressure at improved overall turbocharger efficiency.

Charge cooling by means of a heat exchanger (intercooler) between the compressor and the intake ports is effective in reducing NO_x emissions and improving the power output of turbocharged diesel engines and in reducing the probability of knock in SI engines. Two types of charge cooling are in use: air–air and air–water. Air-to-water cooling is used in marine applications, in which a source of cool water is available; air-to-air intercoolers are used for automotive and truck applications.

Defining Terms

Antiknock index: The average of the two octane numbers obtained by the research method and the motor method.

Autoignition: The ability of a fuel–air mixture to ignite spontaneously under conditions of high temperature and pressure.

Bottom dead center (BDC): Piston located at its lowest position in the cylinder. Cylinder volume is maximum at BDC.

Brake mean effective pressure (bmep): Ratio of brake work output per cycle to the displacement volume.

Brake specific fuel consumption (bsfc): The ratio of fuel consumption rate in kilograms per hour to the engine output in kilowatts.

Brake work: Work produced at the output shaft of an IC engine as measured by a dynamometer.

Cetane index: An approximation to the measured cetane number determined from an empirical relationship specified in ASTM D 976.

Cetane number: A measure of the autoignition quality of a fuel important for proper performance of CI engines determined experimentally through use of a CI CFR test engine.

Clearance volume: Combustion chamber volume remaining above the piston at TDC.

Compression ignition (CI) engine: Air alone is compressed in the cylinder and fuel is injected near TDC. Combustion results from autoignition of the fuel–air mixture due to the high temperature of the air.

Compression ratio: The ratio of the cylinder volume at BDC to the volume at TDC.

Cut-off ratio: Ratio of cylinder volume at the end of heat addition to the volume at the start of heat addition in the ideal diesel cycle.

Cylinder volume: Volume above piston at BDC; equals displacement volume plus clearance volume.

Direct injection (DI): Method of fuel injection in low- and medium-speed CI engines wherein fuel is injected into the main combustion chamber formed by a bowl in the top of the piston.

Displacement volume: Difference in cylinder volume between TDC and BDC.

Equivalence ratio: Actual fuel–air ratio divided by stoichiometric fuel–air ratio.

Four-stroke engine: Entire cycle completed in two revolutions of the crankshaft and four strokes of the piston.

Fuel–air ratio: Ratio of mass of fuel to mass of air in the cylinder prior to combustion.

Glow plug: Electric heater installed in prechamber of an IDI diesel engine to aid cold starting.

Heterogeneous combustion: Refers to the mixture of liquid fuel droplets and evaporated fuel vapor and air mixture present in CI engine combustion chambers prior to ignition.

Ignition delay period: Period between start of injection and onset of autoignition in a CI engine.

Indicated mean effective pressure (imep): Ratio of net indicated work output of an IC engine to the displacement volume.

Indicated work: Work output of an IC engine cycle determined by an area calculation from an indicator diagram.

Indicator diagram: Pressure-volume trace for an IC engine cycle; area enclosed by diagram represents work.

Indirect injection (IDI): Method of fuel injection used in high-speed CI engines wherein the fuel is injected into a precombustion chamber to promote fuel–air mixing and reduce ignition delay.

Knock: In SI engines: the noise that accompanies autoignition of the end portion of the uncombusted mixture prior to the arrival of the flame front. In CI engines: The noise that accompanies autoignition of large premixed fractions generated during prolonged ignition delay periods. Knock is detrimental to either type of engine.

NO_x: Harmful oxides of nitrogen (NO and NO_2) appearing in the exhaust products of IC engines.

Octane number: Antiknock rating for fuels important for prevention of autoignition in SI engines.

Particulates: Any exhaust substance, other than water, that can be collected on a filter. Harmful exhaust product from CI engines.

Power density: Power produced per unit of engine mass.

Premixed homogeneous combustion: Fuel and air are mixed in an appropriate combustible ratio prior to ignition process. This is the combustion mode for SI engines and for the initial combustion phase in CI engines.

Sac volume: Volume of nozzles below the needle of a diesel fuel injector that provides a source of UHC emissions in CI engines.

Scavenging: The process of expelling exhaust gases and filling the cylinder with fresh charge in two-stroke engines. This is often accomplished in SI engines by pressurizing the fresh mixture in the crankcase volume beneath the piston and in CI engines by using a supercharger or turbocharger.

Spark ignition (SI) engine: Homogeneous charge of air–fuel mixture is compressed and ignited by a spark.

Stroke: Length of piston movement from TDC to BDC; equal to twice the crankshaft throw.

Supercharging: Pressurizing the intake of an IC engine using a compressor that is mechanically driven from the crankshaft.

Surface ignition: A source of autoignition in SI engines caused by surface hot spots.

Swirl: Circular in-cylinder air motion designed into CI engines to promote fuel–air mixing.

Swirl ratio: Ratio of rotational speed of in-cylinder air (rpm) to engine speed (rpm).

Top dead center (TDC): Piston located at its uppermost position in the cylinder. Cylinder volume (above the piston) is minimum at TDC.

Turbocharging: Pressurizing the intake of an IC engine with a compressor driven by a turbine that extracts energy from the exhaust gas stream.

Two-stroke engine: Entire cycle completed in one revolution of the crankshaft and two strokes of the piston.

Unburned hydrocarbons (UHC): Harmful emission product from IC engines consisting of hydrocarbon compounds that remain uncombusted.

Volumetric efficiency: Ratio of the actual mass of air intake per cycle to the displacement volume mass determined at inlet temperature and pressure.

8.4 Hydraulic Turbines

Roger E.A. Arndt

A hydraulic turbine is a mechanical device that converts the potential energy associated with a difference in water elevation (**head**) into useful work. Modern hydraulic turbines are the result of many years of gradual development. Economic incentives have resulted in the development of very large units (exceeding 800 MW in capacity) with efficiencies that are sometimes in excess of 95%.

The emphasis on the design and manufacture of very large turbines is shifting to the production of smaller units, especially in developed nations, where much of the potential for developing large base-load plants has been realized. At the same time, the escalation in the cost of energy has made many smaller sites economically feasible and has greatly expanded the market for smaller turbines. The increased value of energy also justifies the cost of refurbishment and increasing the capacity of older facilities. Thus, a new market area is developing for updating older turbines with modern replacement runners that have higher efficiency and greater capacity. The introduction of modern computational tools in the last decade has had considerable influence on turbine design.

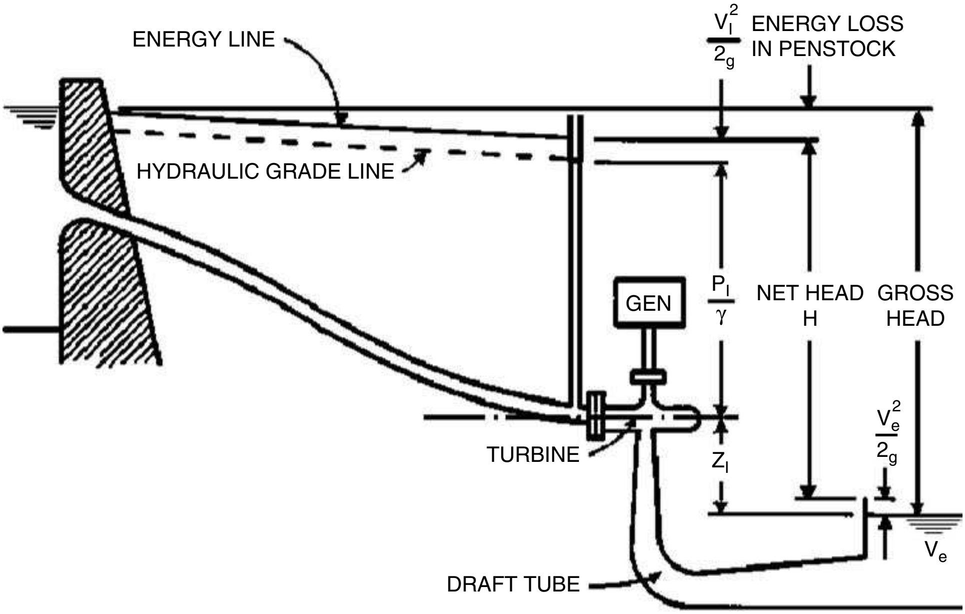

FIGURE 8.4.1 Schematic of a hydropower installation.

General Description

Typical Hydropower Installation

As shown schematically in Figure 8.4.1, the hydraulic components of a hydropower installation consist of an intake, penstock, guide vanes or distributor, turbine, and **draft tube**. Trash racks are commonly provided to prevent ingestion of debris into the turbine. Intakes usually require some type of shape transition to match the passageway to the turbine and also incorporate a gate or some other means of stopping the flow in case of an emergency or turbine maintenance. Some types of turbines are set in an open flume; others are attached to a closed-conduit penstock.

Turbine Classification

The two types of turbines are denoted as impulse and reaction. In an *impulse turbine*, the available head is converted to kinetic energy before entering the **runner**; the power available is extracted from the flow at approximately atmospheric pressure. In a *reaction turbine*, the runner is completely submerged and the pressure and the velocity decrease from inlet to outlet. The velocity head in the inlet to the turbine runner is typically less than 50% of the total head available.

Impulse Turbines. Modern impulse units are generally of the Pelton type and are restricted to relatively high head applications (Figure 8.4.2). One or more jets of water impinge on a wheel containing many curved buckets. The jet stream is directed inwardly, sideways, and outwardly, thereby producing a force on the bucket, which in turn results in a torque on the shaft. All kinetic energy leaving the runner is "lost." A draft tube is generally not used because the runner operates under approximately atmospheric pressure and the head represented by the elevation of the unit above tailwater cannot be utilized. (In principle, a draft tube could be used; this requires the runner to operate in air under reduced pressure. Attempts at operating an impulse turbine with a draft tube have not met with much success.) Because this is a high-head device, this loss in available head is relatively unimportant. As will be shown later, the Pelton wheel is a **low specific speed** device. Specific speed can be increased by the addition of extra nozzles — the specific speed increasing by the square root of the number of nozzles. Specific speed can

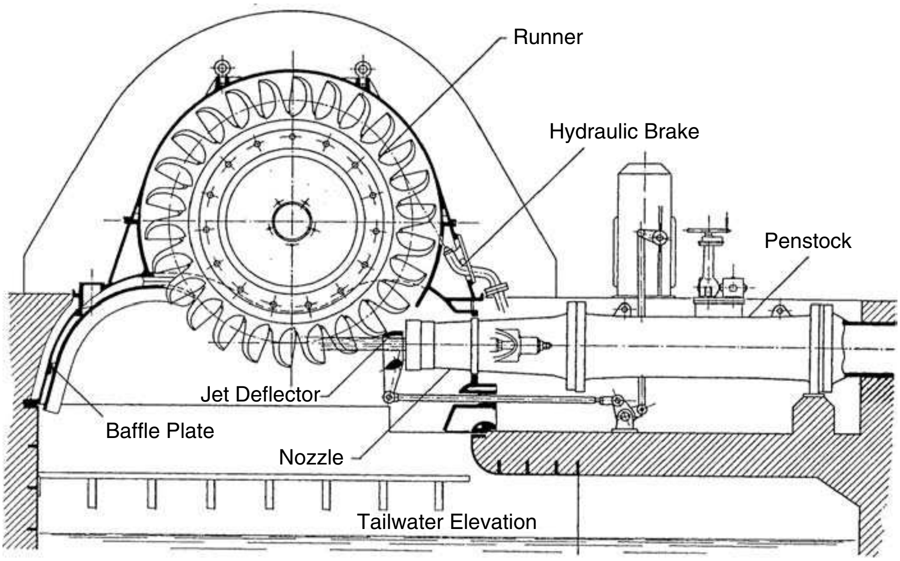

FIGURE 8.4.2 Cross section of a single-wheel, single-jet Pelton turbine. This is the third highest head Pelton turbine in the world, $H = 1447$ m; $n = 500$ rpm; $P = 35.2$ MW; $N_s \sim 0.038$. (Courtesy of Vevey Charmilles Engineering Works. Adapted from Raabe, J. 1985. *Hydro Power: The Design, Use, and Function of Hydromechanical, Hydraulic, and Electrical Equipment.* VDI Verlag, Dusseldorf, Germany.)

also be increased by a change in the manner of inflow and outflow. Special designs such as the Turgo or crossflow turbines are examples of relatively high specific speed impulse units (Arndt, 1991).

Most Pelton wheels are mounted on a horizontal axis, although newer vertical-axis units have been developed. Because of physical constraints on orderly outflow from the unit, the number of nozzles is generally limited to six or less. Whereas **wicket gates** control the power of a reaction turbine, the power of the Pelton wheel is controlled by varying the nozzle discharge by means of an automatically adjusted needle, as illustrated in Figure 8.4.2. Jet deflectors or auxiliary nozzles are provided for emergency unloading of the wheel. Additional power can be obtained by connecting two wheels to a single generator or by using multiple nozzles. Because the needle valve can throttle the flow while maintaining essentially constant jet velocity, the relative velocities at entrance and exit remain unchanged, producing nearly constant efficiency over a wide range of power output.

Reaction Turbines. Reaction turbines are classified according to the variation in flow direction through the runner. In radial- and mixed-flow runners, the flow exits at a radius different from the radius at the inlet. If the flow enters the runner with only radial and tangential components, it is a radial-flow machine. The flow enters a mixed-flow runner with radial as well as axial components. Francis turbines are of the radial- and mixed-flow type, depending on the design specific speed. A Francis turbine is illustrated in Figure 8.4.3.

Axial-flow propeller turbines are generally of the fixed-blade or Kaplan (adjustable-blade) variety. The “classical” propeller turbine, illustrated in Figure 8.4.4, is a vertical-axis machine with a scroll case and a radial wicket gate configuration that is very similar to the flow inlet for a Francis turbine. The flow enters radially inward and makes a right-angle turn before entering the runner in an axial direction. The Kaplan turbine has adjustable runner blades and adjustable wicket gates. The control system is designed so that the variation in blade angle is coupled with the wicket gate setting in a manner that achieves best overall efficiency over a wide range of flow rates.

Some modern designs take full advantage of the axial-flow runner; these include the tube, bulb, and Straflo types illustrated in Figure 8.4.5. The flow enters and exits the turbine with minor changes in direction. A wide variation in civil works design is also permissible. The tubular type can be fixed-

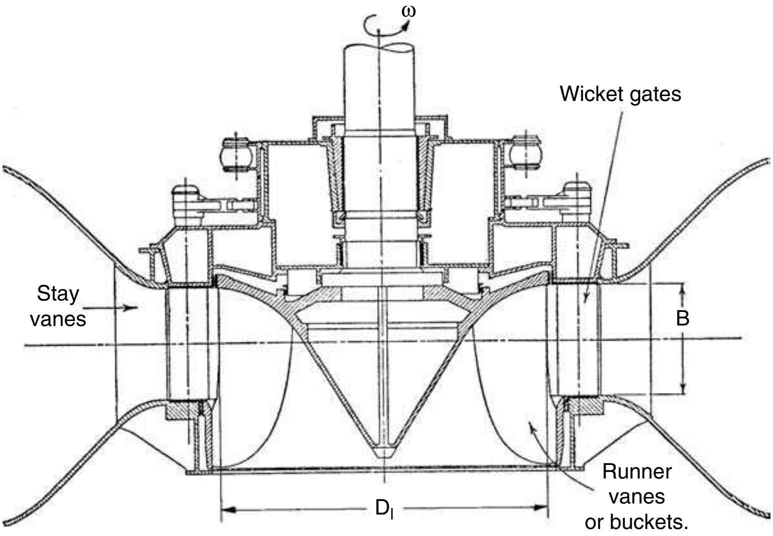

FIGURE 8.4.3 Francis turbine, $N_s \sim 0.66$. (Adapted from Daily, J.W. 1950. In *Engineering Hydraulics,* Ed., H. Rouse. Wiley, New York. Reprinted with permission.)

propeller, semi-Kaplan, or fully adjustable. An externally mounted generator is driven by a shaft that extends through the flow passage upstream or downstream of the runner. The bulb turbine was originally designed as a high-output, low-head unit. In large units, the generator is housed within the bulb and is driven by a variable-pitch propeller at the trailing end of the bulb. Pit turbines are similar in principle to bulb turbines, except that the generator is not enclosed in a fully submerged compartment (the bulb). Instead, the generator is in a compartment that extends above water level. This improves access to the generator for maintenance.

Principles of Operation

Power Available, Efficiency

The power that can be developed by a turbine is a function of the head and flow available:

$$P = \eta \rho g Q H \tag{8.4.1}$$

where η is the turbine efficiency; ρ is the density of water (kg/m^3); g is the acceleration due to gravity (m/s^2); Q is the flow rate (m^3/s); and H is the net head in meters. *Net head* is defined as the difference between the *total head* at the inlet and the tailrace, as illustrated in Figure 8.4.1. Various definitions of net head are used in practice; these depend on the value of the exit velocity head, $V_e^2/2g$, that is used in the calculation. The International Electrotechnical Test Code uses the velocity head at the draft tube exit.

The efficiency depends on the actual head and flow utilized by the turbine runner; flow losses in the draft tube; and the frictional resistance of mechanical components.

Similitude and Scaling Formulae

Under a given head, a turbine can operate at various combinations of speed and flow depending on the inlet settings. For reaction turbines the flow into the turbine is controlled by the wicket gate angle, α. The nozzle opening in impulse units typically controls the flow. Turbine performance can be described in terms of nondimensional variables,

$$\psi = \frac{2gH}{\omega^2 D^2} \tag{8.4.2}$$

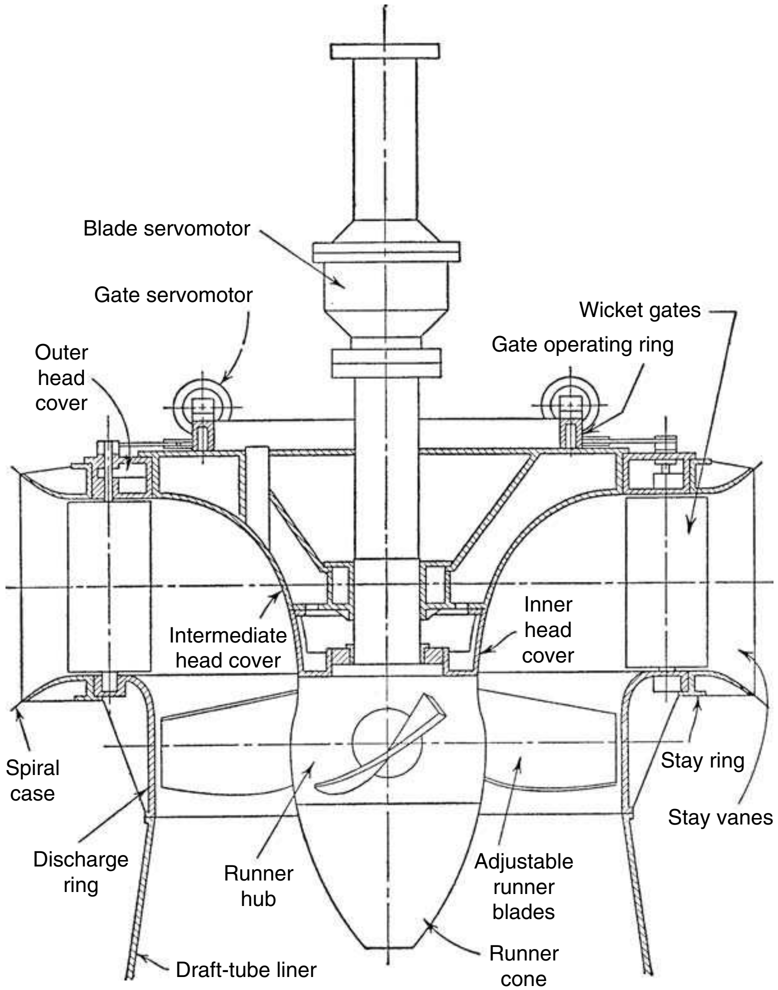

FIGURE 8.4.4 Smith–Kaplan axial-flow turbine with adjustable-pitch runner blades, $N_S \sim 2.0$. (From Daily, J.W. 1950. In *Engineering Hydraulics,* Ed., H. Rouse. Wiley, New York. Reprinted with permission.)

$$\phi = \frac{Q}{\sqrt{2gHD^2}} \tag{8.4.3}$$

where ω is the rotational speed of the turbine in radians per second and D is the diameter of the turbine.

The hydraulic efficiency of the runner alone is given by

$$\eta_h = \frac{\phi}{\sqrt{\psi}}\left(C_1 \cos\alpha_1 - C_2 \cos\alpha_2\right) \tag{8.4.4}$$

where C_1 and C_2 are constants that depend on the specific turbine configuration, and α_1 and α_2 are the inlet and outlet angles that the absolute velocity vectors make with the tangential direction. The value of cos α_2 is approximately zero at peak efficiency. The terms ϕ, ψ_2, α_1, and α_2 are interrelated. Using model test data, isocontours of efficiency can be mapped in the $\phi\psi$ plane. This is typically referred to as a *hill diagram*, as shown in Figure 8.4.6.

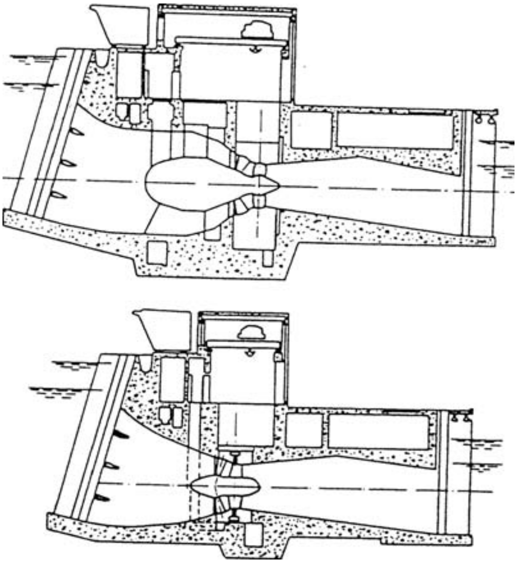

FIGURE 8.4.5 Comparison between bulb (upper) and Straflo (lower) turbines. (Courtesy U.S. Dept. of Energy.)

The **specific speed** is defined as

$$N_s = \frac{\omega\sqrt{Q}}{(2gH)^{3/4}} = \sqrt{\frac{\phi}{\psi}} \tag{8.4.5}$$

A given specific speed describes a specific combination of operating conditions that ensures similar flow patterns and the same efficiency in geometrically similar machines regardless of the size and rotational speed of the machine. It is customary to define the design specific speed in terms of the value at the design head and flow where peak efficiency occurs. The value of specific speed so defined permits a classification of different turbine types.

The specific speed defined here is dimensionless. Many other forms of specific speed exist are dimensional and have distinct numerical values depending on the system of units used (Arndt, 1991). (The literature also contains two other minor variations of the dimensionless form. One differs by a factor of $1/\pi^{1/2}$ and the other by $2^{3/4}$.) The similarity arguments used to arrive at the concept of specific speed indicate that a given machine of diameter D operating under a head H will discharge a flow Q and produce a torque T and power P at a rotational speed ω given by

$$Q = \phi D^2 \sqrt{2gH} \tag{8.4.6}$$

$$T = T_{11}\rho D^3 2gH \tag{8.4.7}$$

$$P = P_{11}\rho D^2 (2gH)^{3/2} \tag{8.4.8}$$

$$\omega = \frac{2u_1}{D} = \omega_{11}\frac{\sqrt{2gH}}{D}, \quad \left[\omega_{11} = \frac{1}{\sqrt{\psi}}\right] \tag{8.4.9}$$

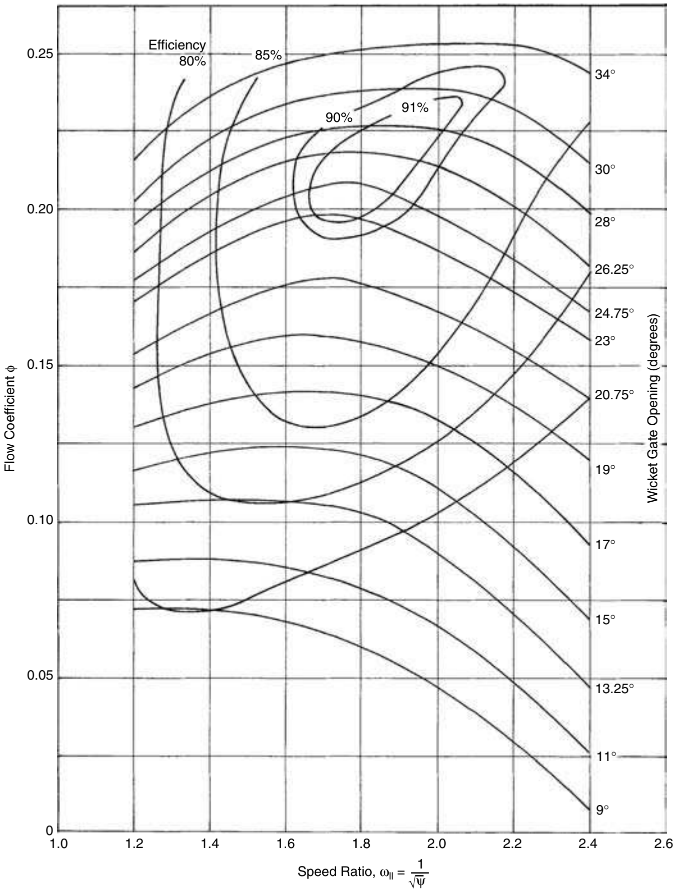

FIGURE 8.4.6 Typical hill diagram. Information of this type is obtained in turbine test stand (see Figure 8.4.9). (Adapted from Wahl, T.L. 1994. Draft tube surging times two: the twin vortex problem. *Hydro Rev.* 13(1):60–69, 1994. With permission.)

with

$$P_{11} = T_{11}\omega_{11} \tag{8.4.10}$$

where T_{11}, P_{11}, and ω_{11} are also nondimensional. (The reader is cautioned that many texts, especially in the American literature, contain dimensional forms of T_{11}, P_{11}, and ω_{11}.) In theory, these coefficients are fixed for a machine operating at a fixed value of specific speed, independent of the size of the machine. Equation (8.4.6) through Equation (8.4.10) can be used to predict the performance of a large machine using the measured characteristics of a smaller machine or model.

Factors Involved in Selecting a Turbine

Performance Characteristics

Impulse and reaction turbines are the two basic types of turbines. They tend to operate at peak efficiency over different ranges of specific speed, due to geometric and operational differences.

Impulse Turbines. Of the head available at the nozzle inlet, a small portion is lost to friction in the nozzle and to friction on the buckets. The rest is available to drive the wheel. The actual utilization of this head depends on the velocity head of the flow leaving the turbine and the setting above tailwater. Optimum conditions, corresponding to maximum utilization of the head available, dictate that the flow leaves at

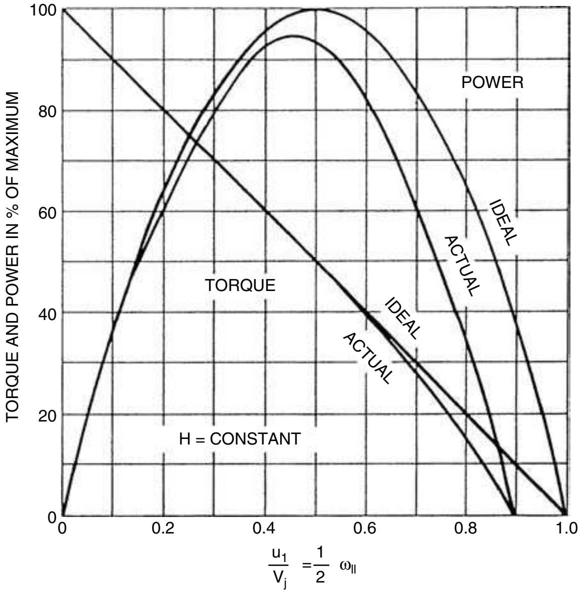

FIGURE 8.4.7 Ideal and actual variable-speed performance for an impulse turbine. (Adapted from Daily, J.W. 1950. In *Engineering Hydraulics*, Ed., H. Rouse. Wiley, New York. With permission.)

essentially zero velocity. Under ideal conditions, this occurs when the peripheral speed of the wheel is one half the jet velocity. In practice, optimum power occurs at a speed coefficient, ω_{11}, somewhat less than 1.0 (illustrated in Figure 8.4.7). Because the maximum efficiency occurs at fixed speed for fixed H, V_j must remain constant under varying flow conditions. Thus, the flow rate Q is regulated with an adjustable nozzle. However, maximum efficiency occurs at slightly lower values of ω_{11} under partial power settings. Present nozzle technology is such that the discharge can be regulated over a wide range at high efficiency.

A given head and penstock configuration establishes the optimum jet velocity and diameter. The size of the wheel determines the speed of the machine. The design specific speed is approximately

$$N_S = 0.77 \frac{d_j}{D} \text{ (Pelton turbines)} \tag{8.4.11}$$

Practical values of d_j/D for Pelton wheels to ensure good efficiency are in the range 0.04 to 0.1, corresponding to N_s values in the range 0.03 to 0.08. Higher specific speeds are possible with multiple nozzle designs. The increase is proportional to the square root of the number of nozzles. In considering an impulse unit, one must remember that efficiency is based on net head; the net head for an impulse unit is generally less than the net head for a reaction turbine at the same gross head because of the lack of a draft tube.

Reaction Turbines. The main difference between impulse units and reaction turbines is that a pressure drop takes place in the rotating passages of the reaction turbine. This implies that the entire flow passage from the turbine inlet to the discharge at the tailwater must be completely filled. A major factor in the overall design of modern reaction turbines is the draft tube. It is usually desirable to reduce the overall equipment and civil construction costs by using high specific speed runners. Under these circumstances, the draft tube is extremely critical for flow stability and efficiency. (This should be kept in mind when retrofitting on older, low specific speed turbine with a new runner of higher capacity.) At higher specific speed, a substantial percentage of the available total energy is in the form of kinetic energy leaving the runner. To recover this efficiently, considerable emphasis should be placed on the draft tube design.

The practical specific speed range for reaction turbines is much broader than for impulse wheels. This is due to the wider range of variables that control the basic operation of the turbine. The pivoted guide vanes allow for control of the magnitude and direction of the inlet flow. Because of a fixed relationship among blade angle, inlet velocity, and peripheral speed for shock-free entry, this requirement cannot be completely satisfied at partial flow without the ability to vary blade angle. This is the distinction between the efficiency of fixed-propeller and Francis types at partial loads and the fully adjustable Kaplan design.

In Equation (8.4.4), optimum hydraulic efficiency of the runner would occur when α_2 is equal to 90°. However, the overall efficiency of the turbine is dependent on the optimum performance of the draft tube as well, which occurs with a little swirl in the flow. Thus, the best overall efficiency occurs with $\alpha_2 \approx 75°$ for high specific speed turbines.

The determination of optimum specific speed in a reaction turbine is more complicated than for an impulse unit because there are more variables. For a radial-flow machine, an approximate expression is

$$N_S = 1.64\left[C_V \sin\alpha_1 \frac{B}{D_1}\right]^{1/2} \omega_{11} \quad \text{(Francis turbines)} \tag{8.4.12}$$

where C_v is the fraction of net head that is in the form of inlet velocity head and B is the height of the inlet flow passage (see Figure 8.4.3). N_s for Francis units is normally found to be in the range 0.3 to 2.5.

Standardized axial-flow machines are available in the smaller size range. These units are made up of standard components, such as shafts and blades. For such cases,

$$N_S \sim \frac{\sqrt{\tan\beta}}{n_B^{3/4}} \quad \text{(Propeller turbines)} \tag{8.4.13}$$

where β is the blade pitch angle and n_B is the number of blades. The advantage of controllable pitch is also obvious from this formula; the best specific speed is simply a function of pitch angle.

It should be further noted that ω_{11} is approximately constant for Francis units and N_S is proportional to $(B/D_1)^{1/2}$. It can also be shown that velocity component based on the peripheral speed at the throat, ω_{11e}, is proportional to N_S. In the case of axial-flow machinery, ω_{11} is also proportional to N_S. For minimum cost, peripheral speed should be as high as possible — consistent with cavitation-free performance. Under these circumstances N_S would vary inversely with the square root of head (H is given in meters):

$$N_S = \frac{C}{\sqrt{H}} \tag{8.4.14}$$

where the range of C is 8 to 11 for fixed-propeller units and Kaplan units and 6 to 9 for Francis units.

Performance Comparison. The physical characteristics of various runner configurations are summarized in Figure 8.4.8. It is obvious that the configuration changes with speed and head. Impulse turbines are efficient over a relatively narrow range of specific speed, whereas Francis and propeller turbines have a wider useful range. An important consideration is whether a turbine is required to operate over a wide range of load. Pelton wheels tend to operate efficiently over a wide range of power loading because of their nozzle design. In the case of reaction machines that have fixed geometry, such as Francis and propeller turbines, efficiency can vary widely with load. However, Kaplan and Deriaz (an adjustable-blade mixed-flow turbine; see Arndt, 1991) turbines can maintain high efficiency over a wide range of operating conditions. The decision of whether to select a simple configuration with a relatively "peaky" efficiency curve or incur the added expense of installing a more complex machine with a broad efficiency curve will depend on the expected operation of the plant and other economic factors.

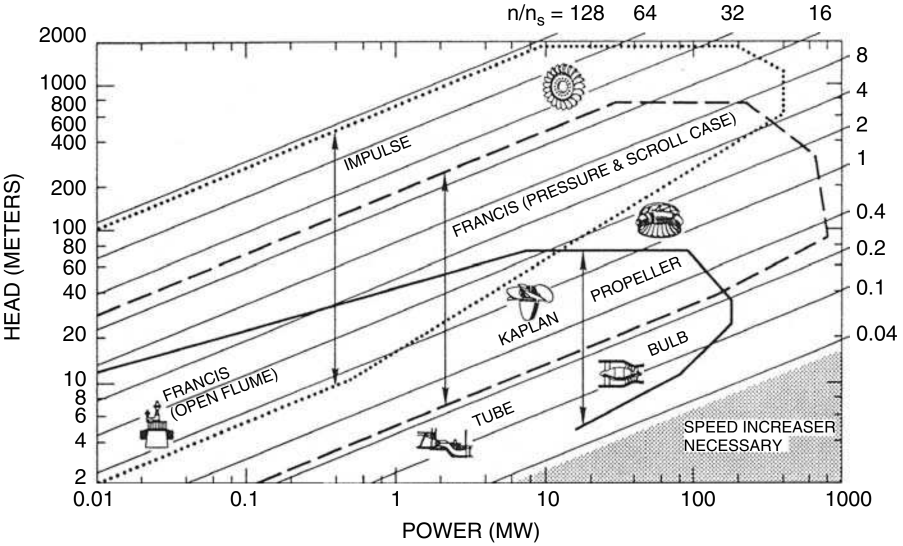

FIGURE 8.4.8 Application chart for various turbine types (n/n_S is the ratio of turbine speed in rpm, n, to specific speed defined in the metric system, $n_S = nP^{1/2}/H^{5/4}$, with P in kilowatts). (From Arndt, R.E.A. 1991. In *Hydropower Engineering Handbook*, Eds., J.S. Gulliver and R.E.A. Arndt, 4.1–4.67. McGraw–Hill, New York. With permission.)

Note that in Figure 8.4.8 an overlap in the range of application of various types of equipment is shown. This means that either type of unit can be designed for good efficiency in this range, but other factors, such as generator speed and cavitation, may dictate the final selection.

Speed Regulation

The speed regulation of a turbine is an important and complicated problem. The magnitude of the problem varies with size; type of machine and installation; type of electrical load; and whether the plant is tied into an electrical grid. It should also be kept in mind that runaway or no-load speed can be higher than the design speed by factors as high as 2.6. This is an important design consideration for all rotating parts, including the generator.

The speed of a turbine must be controlled to a value that matches the generator characteristics and the grid frequency:

$$n = \frac{120f}{N_P} \tag{8.4.15}$$

where n is turbine speed in rpm; f is the required grid frequency in Hertz; and N_P is the number of poles in the generator. Typically, N_p is in multiples of 4. There is a tendency to select higher speed generators to minimize weight and cost. However, consideration must be given to speed regulation.

It is beyond the scope of this section to discuss the question of speed regulation in detail. Regulation of speed is normally accomplished through flow control. Adequate control requires sufficient rotational inertia of the rotating parts. When load is rejected, power is absorbed, accelerating the flywheel; when load is applied, some additional power is available from deceleration of the flywheel. Response time of the governor must be carefully selected, because rapid closing time can lead to excessive pressures in the penstock.

Opening and closing the wicket gates, which vary the flow of water according to the load, control a Francis turbine. The actuator components of a governor are required to overcome the hydraulic and frictional forces and to maintain the wicket gates in fixed position under steady load. For this reason, most governors have hydraulic actuators. On the other hand, impulse turbines are more easily controlled because the jet can be deflected or an auxiliary jet can bypass flow from the power-producing jet without changing the flow rate in the penstock. This permits long delay times for adjusting the flow rate to the new power conditions. The spear on needle valve controlling the flow rate can close quite slowly, e.g., in 30 to 60 seconds, thereby minimizing any pressure rise in the penstock.

Several types of governors are available that vary with the work capacity desired and the degree of sophistication of control. These vary from pure mechanical to mechanical–hydraulic and electrohydraulic. Electrohydraulic units are sophisticated pieces of equipment and would not be suitable for remote regions. The precision of governing necessary will depend on whether the electrical generator is synchronous or asynchronous (induction type). The induction type of generator has its advantages. It is less complex and therefore less expensive, but typically has slightly lower efficiency. Its frequency is controlled by the frequency of the grid into which it feeds, thereby eliminating the need for an expensive conventional governor. It cannot operate independently but can only feed into a network and does so with lagging power factor, which may be a disadvantage, depending on the nature of the load. Long transmission lines, for example, have a high capacitance and, in this case, the lagging power factor may be an advantage.

Speed regulation is a function of the flywheel effect of the rotating components and the inertia of the water column of the system. The start-up time of the rotating system is given by

$$t_s = \frac{I\omega^2}{P} \tag{8.4.16}$$

where I = moment of inertia of the generator and turbine, kg · m^2 (Bureau of Reclamation, 1966).

The start-up time of the water column is given by

$$t_p = \frac{\sum LV}{gH} \tag{8.4.17}$$

where L = the length of water column and V = the velocity in each component of the water column.

For good speed regulation, it is desirable to keep $t_s/tp > 4$. Lower values can also be used, although special precautions are necessary in the control equipment. It can readily be seen that higher ratios of t_s/t_p can be obtained by increasing I or decreasing t_p. Increasing I implies a larger generator, which also results in higher costs. The start-up time of the water column can be reduced by reducing the length of the flow system, using lower velocities, or by adding surge tanks, which essentially reduce the effective length of the conduit. A detailed analysis should be made for each installation because, for a given length, head, and discharge, the flow area must be increased to reduce t_p, which leads to associated higher construction costs.

Cavitation and Turbine Setting

Another factor that must be considered prior to equipment selection is the evaluation of the turbine with respect to tailwater elevations. Hydraulic turbines are subject to pitting, loss in efficiency, and unstable operation due to cavitation (Arndt, 1981, 1991, Arndt et al., 2000). For a given head, a smaller, lower cost, high-speed runner must be set lower (i.e., closer to tailwater or even below tailwater) than a larger, higher cost, low-speed turbine runner. Also, atmospheric pressure or plant elevation above sea level is a factor, as are tailwater elevation variations and operating requirements. This is a complex subject that can only be accurately resolved by model tests. Every runner design will have different cavitation characteristics. Therefore, the anticipated turbine location or setting with respect to tailwater elevations is an important consideration in turbine selection.

Cavitation is not normally a problem with impulse wheels. However, by the very nature of their operation, cavitation is an important factor in reaction turbine installations. The susceptibility for cavitation to occur is a function of the installation and the turbine design. This can be expressed conveniently in terms of Thoma's sigma, defined as

$$\sigma_T = \frac{H_a - H_v - z}{H} \tag{8.4.18}$$

where H_a is the atmospheric pressure head; H is the vapor pressure head (generally negligible); and z is the elevation of a turbine reference plane above the tailwater (see Figure 8.4.1). Draft tube losses and the exit velocity head have been neglected.

The term σ_T must be above a certain value to avoid cavitation problems. The critical value of σ_T is a function of specific speed (Arndt, 1991). The Bureau of Reclamation (1966) suggests that cavitation problems can be avoided when

$$\sigma_T > 0.26 N_s^{1.64} \tag{8.4.19}$$

Equation (8.4.19) does not guarantee total elimination of cavitation, only that cavitation is within acceptable limits. Cavitation can be totally avoided only if the value of σ_T at an installation is much greater than the limiting value given in Equation (8.4.19). The value of σ_T for a given installation is known as the plant sigma, σ_P Equation (8.4.19) should only be considered a guide in selecting σ_P, which is normally determined by a model test in the manufacturer's laboratory. For a turbine operating under a given head, the only variable controlling σ_P is the turbine setting z. The required value of σ_P then controls the allowable setting above tailwater:

$$z_{\text{allow}} = H_a - H_v - \sigma_P H \tag{8.4.20}$$

It must be borne in mind that H_a varies with elevation. As a rule of thumb, H_a decreases from the sea-level value of 10.3 m by 1.1 m for every 1000 m above sea level.

Performance Evaluation

Model Tests

Model testing is an important element in the design and development phases of turbine manufacture. Manufacturers own most laboratories equipped with model turbine test stands. Major hydro projects have traditionally had proof-of-performance tests in model scale (at an independent laboratory or the manufacturer's laboratory) as part of the contract. In addition, it has been shown that competitive model testing at an independent laboratory can lead to large savings at a major project because of improved efficiency.

Recently, turbine design procedures have been dramatically improved through the use of sophisticated numerical analysis of the flow characteristics. These analysis techniques, linked with design programs, provide the turbine designer with powerful tools for achieving highly efficient turbine designs. In spite of this progress, computational methods require fine-tuning with model tests. In addition, model testing is necessary for determining performance over a range of operating conditions and for determining quasitransitory characteristics. Model testing can also be used to eliminate or mitigate problems associated with vibration, cavitation, hydraulic thrust, and pressure pulsation (Fisher and Beyer, 1985).

A typical turbine test loop is shown in Figure 8.4.9. All test loops perform basically the same function. A model turbine is driven by high-pressure water from a head tank and discharges into a tail tank, as shown. The flow is recirculated by a pump, usually positioned well below the elevation of the model to ensure cavitation-free performance of the pump while performing cavitation testing with the turbine model. One important advantage of a recirculating turbine test loop is that cavitation testing can be done over a wide range of cavitation indices at constant head and flow.

The extrapolation of model test data to prototype values has been a subject of considerable debate for many years. Equation 8.4.6 through Equation 8.4.10 can be used to predict prototype values of flow, speed, power, etc. from model tests. Unfortunately, many factors lead to scale effects, i.e., the prototype

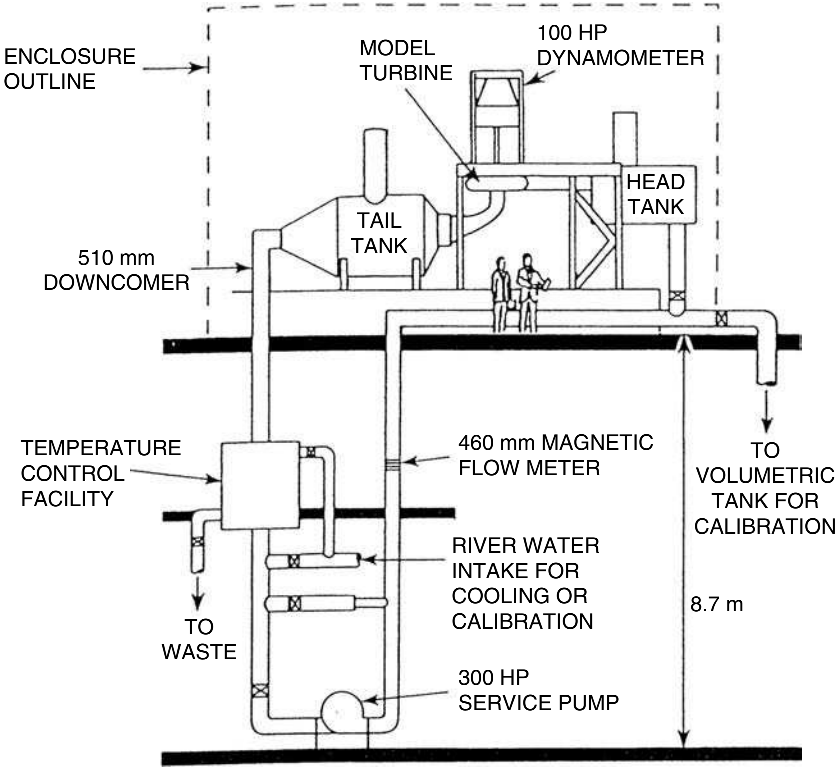

FIGURE 8.4.9 Schematic of the SAFL Independent Turbine Test Facility. *(*Courtesy of the St. Anthony Falls Laboratory, University of Minnesota.)

efficiency and model efficiency are not identical at a fixed value of specific speed. The cited scale-up formulae are based on inviscid flow. Several sources of energy loss lead to an efficiency that is less than ideal. All of these losses follow different scaling laws and, in principle, perfect similitude can only be achieved by testing the prototype. Several attempts at rationalizing the process of scaling up model test data have been made. The International Electrotechnical Test Code and various ASME publications outline in detail the differences in efficiency between model and prototype. It should also be pointed out that other losses, such as those in the draft tube and "shock" losses at the runner inlet, might not be independent of Reynolds number.

Numerical Simulation[1]

Until very recently, the analysis of turbines and other components of hydropower facilities was largely dependent on approximate models such as the Euler equation and Reynolds averaged Navier–Stokes (RANS) models because the complete Navier–Stokes equations were considered to be too difficult to be solved for hydropower components (see Chapter 3). The Euler equation model has been applied with reasonable success for turbine runner simulation, but energy losses and the efficiency could not be calculated. RANS models have been applied for the spiral case and the draft tube simulations with limited success. Goede et al. (1991) contains a good summary of experiences with the application of these computational methods to various hydropower components. Very recently, reliable commercial codes

---

have become available and are used with increasing frequency. Many of the current commercial codes rely on variants of RANS models although rapid progress is being made in adapting LES.

The large eddy simulation method (LES) is a step forward in the application of CFD Song et al. (1995). This technique is able to capture the effects of turbulent flow in a turbine more accurately than previous techniques. At the present time, it requires a supercomputer to achieve sufficient resolution and good accuracy for final design purposes. Parallel processing with desktop computers shows promise and can presently be used for relatively simple geometry or for preliminary evaluation purposes. However, progress in its application is very rapid and it is anticipated that an entire computation may be carried out on a high-end desktop computer in the near future.

The components that require simulation include the spiral case, wicket gates, the runner, and the draft tube. Often the spiral case, including stay vanes and wicket gates, is modeled as a unit. This is necessary because the stay vanes and wicket gates are so close to each other that their mutual interactions cannot be ignored; each stay vane may be of slightly different shape and orientation and cannot be modeled separately. A typical spiral case contains more than 20 stay vanes and an equal number of wicket gates, requiring extensive computational resources for a complete simulation. A sample calculation is shown in Figure 8.4.10. In this example, the calculated energy loss through this device is 2.62% of the net available energy for this particular case. This is significant and justifies additional computational effort to minimize the losses.

The runner is the most extensively studied component of a turbine. Because all the blades in a runner are of the same geometrical shape, only one- or two-flow passage models are commonly used for runner simulation. A complete model is required if vibration or cavitation due to nonsymmetrical modes of interactions between blades and vortices are to be studied. An important application of computer simulation is in the design of runners for units used for pumped storage.

Pumped-storage schemes are becoming a very popular for smoothing out the difference between energy demand and supply. Special care is required in the design because a runner must be designed to act efficiently as a turbine and a pump. Because of viscous effects, a runner optimized under the turbine mode may have poor efficiency in the pump mode. Flow in the pumping mode can be unstable and more difficult to calculate. An LES-based analysis greatly facilitates the optimum design of this type of

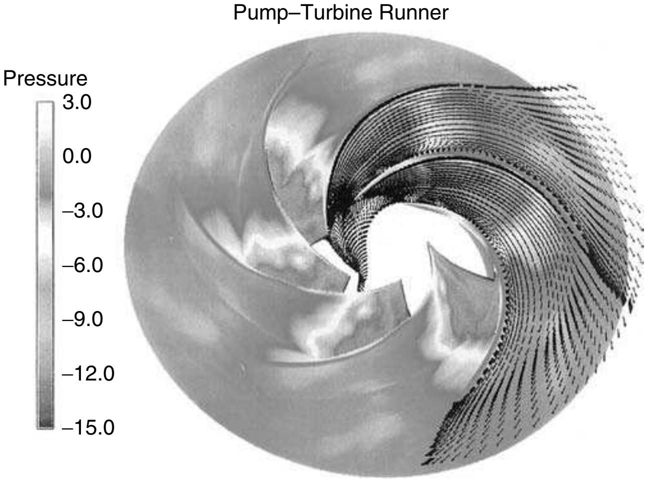

FIGURE 8.4.11 Simulation of the velocity and pressure distribution in a pump turbine runner operating in the pumping mode. (Adapted from Song et al. *Hydro Rev.* XIV(4), 104–111. With permission.)

runner. Figure 8.4.11 is an example of the calculated flow in the pump mode. A small flow separation near the entrance can be observed. This kind of information is very useful to determine how the blade geometry can be modified to improve performance.

Draft tube design is an important factor in the efficiency and stability of operation of a turbine. Although a typical draft tube geometry is somewhat simpler than that of a runner, it takes much more advanced computational techniques to simulate its performance accurately. This is because the diffuser-like flow produces secondary currents, three-dimensional vortex shedding, and horseshoe vortices that are very important contributors to energy loss. Current RANS models are ineffective for this flow; at the present time only the LES model can fulfill the requirements for draft tube simulation.

Figure 8.4.12 illustrates the complexity of the problem. The instantaneous pressure distribution on the walls of an elbow-type draft tube with a divider wall is compared with the same draft tube with the divider wall removed. A dramatic change in the flow pattern and pressure distribution occurs when the divider wall is removed. By removing the wall, the draft tube becomes a diffuser of large angle with very unstable flow. Clearly, the divider wall stabilizes the flow and reduces the energy loss due to vortex shedding. These types of simulations are invaluable in evaluating draft tube performance. This is underscored by the fact that many projects involve refurbishing existing units. Typically, only the runner is replaced, usually with increased design flow. On many occasions, the existing draft tube is unable to operate efficiently at higher flow rates, thus canceling out any improvements that a new runner can provide.

Field Tests

Model tests and numerical simulations are only valid when geometric similitude is adhered to, i.e., the prototype machine is not guaranteed to be an accurate reproduction of the design. In addition, approach flow conditions, intake head losses, the effect of operating other adjacent units, etc. are not simulated in model tests. For these reasons, field performance tests are often performed. The several different types of field tests serve different purposes. The *absolute* efficiency is measured for acceptance or performance tests. *Relative* efficiency is often measured when operating information or fine-tuning of turbine performance is desired. Field tests are also carried out for commissioning a site and for various problem-solving activities. Basic procedures are covered by codes of the American Society of Mechanical Engineering (1992) and the International Electrotechnical Commission (1991).

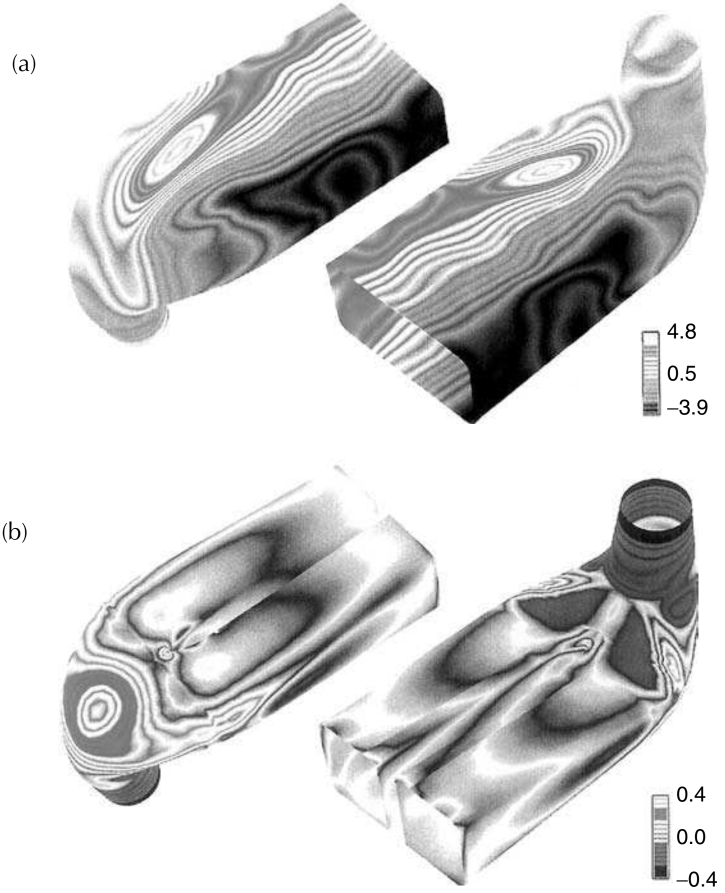

FIGURE 8.4.12 Simulation showing a comparison of the flow in a draft tube with and without a dividing wall. (a) The pressure patterns on the walls indicate a very asymmetrical flow pattern without a divider wall. (b) With a wall in place, a very uniform flow pattern is evident. (Adapted from Song et al. *Hydro Rev.* XIV(4), 104–111. With permission.)

The major difference between an "absolute" and a relative or index test is in the measurement of flow rate. Net head is evaluated in the same manner for each procedure. A variety of methods for measuring flow are code accepted. These include the pressure-time technique; tracer methods (salt velocity, dye dilution); area velocity (Pitot tubes or current meters); volumetric (usually on captive pumped storage sites); Venturi meters; and weirs. The thermodynamic method is actually a direct measure of efficiency. Flow is not measured. In addition to the code-accepted methods, it has been demonstrated that acoustic meters can measure flow in the field with comparable accuracy.

The *pressure-time technique* relies on measuring the change in pressure necessary to decelerate a given mass of fluid in a closed conduit. The method requires the measurement of the piezometric head at two cross sections spaced a distance *L* apart. A downstream valve or gate is necessary for this procedure. This technique requires load rejection for each test point and the need to estimate or measure any leakage. An adequate length of conduit is required and the conduit geometry must be accurately measured (Hecker and Nystrom, 1987).

The *salt velocity method* is based on measuring the transit time, between two sensors, of an injected cloud of concentrated salt solution. Given the volume of the conduit between sensors, the flow rate may be calculated from the average transit time. Electrodes that measure the change in conductivity of the liquid detect the passage of the salt cloud at a given location.

The *dye-dilution method* is based on conservation of a tracer continuously injected into the flow. A sufficient length for complete mixing is necessary for accurate results. The data required are the initial concentration and injection flow rate of the tracer and the measured concentration of the fully mixed tracer at a downstream location. The method is quite simple, but care is necessary to achieve precise results.

In principle, *area-velocity measurements* are also quite simple. Pitot tubes or propeller-type current meters are used to measure point velocities that are integrated over the flow cross section. The method is applicable to closed conduits or open channels. A relatively uniform velocity distribution is necessary for accurate results. A single unit can be traversed across the conduit or a fixed or movable array of instruments can be used to reduce the time for data collection.

The *thermodynamic method* is a direct indication of turbine efficiency. Flow rate is not measured. In its simplest form, the method assumes adiabatic conditions, i.e., no heat transfer from the flow to its surroundings. Under these conditions, the portion of available energy not utilized in the machine to produce useful work results in increased internal energy of the fluid, which is sensed as an increase in temperature.

Acoustic flow meters have been developed that produce results with a precision equal to or greater than the code-accepted methods. Flow velocity is determined by comparing acoustic travel times for paths diagonally upstream and downstream between pairs of transducers. The speed of sound is assumed constant. The difference in travel time is related to the component of flow velocity along the acoustic path (increased travel time upstream, decreased travel time downstream). An extensive evaluation and comparison of this method has been reported (Sullivan, 1983).

Index tests circumvent the problem of accurate flow measurement by measuring relative flow detected by the differential pressure between two points in the water passages leading to the runner. Often the differential pressure is measured with Winter–Kennedy taps positioned at the inner and outer radii of the spiral case of a turbine. Calibration of properly placed Winter–Kennedy taps shows that flow rate is very closely proportional to the square root of the pressure difference. Index testing is useful for calibration of relative power output vs. gate opening and for optimizing the various combinations of gate opening and blade setting in Kaplan units. The use of index testing to optimize cam settings in Kaplan turbines has resulted in substantial increases in weighted efficiency (i.e., a flatter efficiency curve over the full range of operation).

Defining Terms

Draft tube: the outlet conduit from a turbine that normally acts as a diffuser. This is normally considered an integral part of the unit.

Forebay: the hydraulic structure used to withdraw water from a reservoir or river. This can be positioned a considerable distance upstream from the turbine inlet.

Head: the specific energy per unit weight of water. *Gross head* is the difference in water surface elevation between the forebay and tailrace. *Net head* is the difference between *total head* (the sum of velocity head, $V^2/2g$, pressure head, $p/\rho g$, and elevation head, z), at the inlet and outlet of a turbine. Some European texts use specific energy per unit mass, for example, specific kinetic energy is $V^2/2$.

Pumped storage: a scheme in which water is pumped to an upper reservoir during off-peak hours and used to generate electricity during peak hours.

Runner: the rotating component of a turbine in which energy conversion takes place.

Specific speed: a universal number for a given machine design.

Spiral case: the inlet to a reaction turbine.

Surge tank: a hydraulic structure used to diminish overpressures in high-head facilities due to water hammer resulting from the sudden stoppage of a turbine.

Wicket gates: pivoted, streamlined guide vanes that control the flow of water to the turbine.

8.5 Stirling Engines

William B. Stine

Introduction

The Stirling engine was patented in 1816 by Rev. Robert Stirling, a Scottish minister (Figure 8.5.1). Early Stirling engines were coal-burning, low-pressure air engines built to compete with saturated steam engines for providing auxiliary power for manufacturing and mining. In 1987, John Ericsson built an enormous marine Stirling engine with four 4.2-m-diameter pistons. Beginning in the 1930s, the Stirling engine was brought to a high state of technology development by Philips Research Laboratory in Eindhoven, The Netherlands with the goal of producing small, quiet electrical generator sets to be used with high-power-consuming vacuum tube electronic devices. Recently, interest in Stirling engines has resurfaced, with solar electric power generation (Stine and Diver, 1994) and hybrid automotive applications in the forefront.

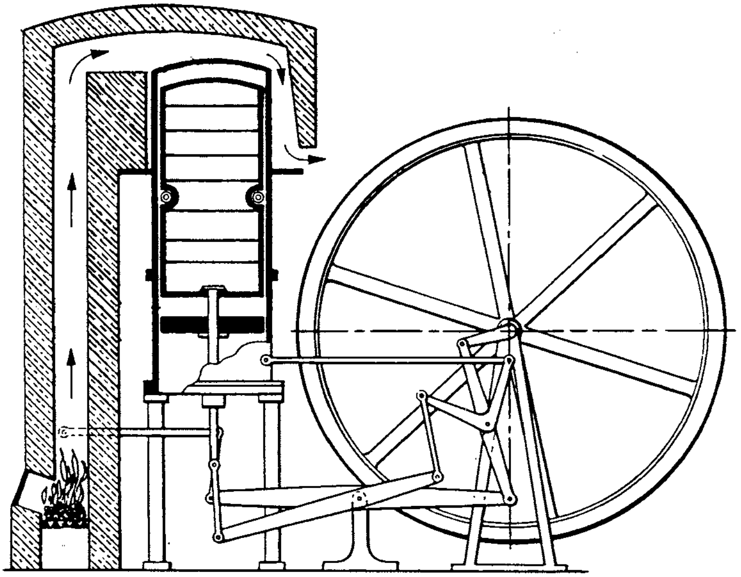

FIGURE 8.5.1 The original patent Stirling engine of Rev. Robert Stirling.

In theory, the **Stirling cycle** engine can be the most efficient device for converting heat into mechanical work with high efficiencies requiring high-temperatures. In fact, with regeneration, the efficiency of the Stirling cycle equals that of the Carnot cycle, the most efficient of all ideal thermodynamic cycles. (See West, 1986 for further discussion of the thermodynamics of Stirling cycle machines.)

Since their invention, prototype Stirling engines have been developed for automotive purposes; they have also been designed and tested for service in trucks, buses, and boats (Walker, 1973). The Stirling engine has been proposed as a propulsion engine in yachts, passenger ships, and road vehicles such as city buses (Meijer, 1992). The Stirling engine has also been developed as an underwater power unit for submarines, and the feasibility of using the Stirling for high-power space-borne systems has been explored by NASA (West, 1986). The Stirling engine is considered ideal for solar heating, and the first solar application of record was by John Ericsson, the famous British-American inventor, in 1872 (Stine and Diver, 1994).

Stirling engines are generally externally heated engines. Therefore, most sources of heat can be used to drive them, including combustion of just about anything, radioisotopes, solar energy, and exothermic chemical reactions. High-performance Stirling engines operate at the thermal limits of the materials used for their construction. Typical temperatures range fiom 650 to 800°C (1200 to 1470°F), resulting in engine conversion efficiencies of around 30 to 40%. Engine speeds of 2000 to 4000 rpm are common

Thermodynamic Implementation of the Stirling Cycle

In the ideal Stirling cycle, a **working gas** is alternately heated and cooled as it is compressed and expanded. Gases such as helium and hydrogen, which permit rapid heat transfer and do not change phase, are typically used in the high-performance Stirling engines. The ideal Stirling cycle combines four processes, two constant-temperature heat-exchange processes and two constant-volume heat-exchange processes. Because more work is done by expanding high-temperature, high-pressure gas than is required to compress low-temperature, low-pressure gas, the Stirling cycle produces net work, which can drive an electric alternator or other mechanical devices.

Working Gases

In the Stirling cycle, the working gas is alternately heated and cooled in constant-temperature and constant-volume processes. The traditional gas for Stirling engines has been air at atmospheric pressure. At this pressure, air has a reasonably high density and therefore can be used directly in the cycle with loss of working gas through seals a minor problem. However, internal component temperatures are limited because of the oxygen in air which can degrade materials rapidly.

Because of their high heat-transfer capabilities, hydrogen and helium are used for high-speed, high-performance Stirling engines. To compensate for the low density of these gases, the mean pressure of the working gas is raised by charging the gas spaces in the engine to high pressures. Compression and expansion vary above and below this **charge pressure**. Hydrogen, thermodynamically a better choice, generally results in more-efficient engines than does helium (Walker, 1980). Helium, on the other hand, has fewer material-compatibility problems and is safer to work with. To maximize power, high-performance engines typically operate at high pressure, in the range of 5 to 20 MPa (725 to 2900 psi). Operation at these high gas pressures makes sealing difficult, and seals between the high-pressure region of the engine and those parts at ambient pressure have been problematic in some engines. New designs to reduce or eliminate this problem are currently being developed.

Heat Exchange

The working gas is heated and cooled by heat exchangers that add heat from an external source, or reject heat to the surroundings. Further, in most engines, an internal heat storage unit stores and rejects heat during each cycle.

The **heater** of a Stirling engine is usually made of many small-bore tubes that are heated externally with the working gas passing through the inside. External heat transfer by direct impingement of combustion products or direct adsorption of solar irradiation is common. A trade-off between high heat-transfer rate using many small-bore tubes with resulting pumping losses, and fewer large-bore tubes and lower pumping losses drives the design. A third criterion is that the volume of gas trapped within these heat exchangers should be minimal to enhance engine performance. In an attempt to provide more uniform and constant-temperature heat transfer to the heater tubes, **reflux** heaters are being developed (Stine and Diver, 1994). Typically, by using sodium as the heat-transfer medium, liquid is evaporated at the heat source and is then condensed on the outside surfaces of the engine heater tubes.

The **cooler** is usually a tube-and-shell heat exchanger. Working gas is passed through the tubes, and cooling water is circulated around the outside. The cooling water is then cooled in an external heat exchanger. Because all of the heat rejected from the power cycle comes from the cooler, the Stirling engine is considered ideal for cogeneration applications.

Most Stirling engines incorporate an efficiency-enhancing **regenerator** that captures heat from the working gas during constant-volume cooling and replaces it when the gas is heated at constant volume. Heating and cooling of the regenerator occurs at over 60 times a second during high-speed engine operation. In the ideal cycle, all of the heat-transferred during the constant volume heating and cooling processes occurs in the regenerator, permitting the external heat addition and rejection to be efficient constant-temperature heat-transfer processes. Regenerators are typically chambers packed with fine-mesh screen wire or porous metal structures. There is enough thermal mass in the packing material to store all of the heat necessary to raise the temperature of the working gas from its low to its high temperature. The amount of heat stored by the regenerator is generally many times greater than the amount added by the heater.

Power Control

Rapid control of the output power of a Stirling engine is highly desirable for some applications such as automotive and solar electric applications. In most Stirling engine designs, rapid power control is implemented by varying the density (i.e., the mean pressure) of the working gas by bleeding gas from the cycle when less power is desired. To return to a higher power level, high-pressure gas must be

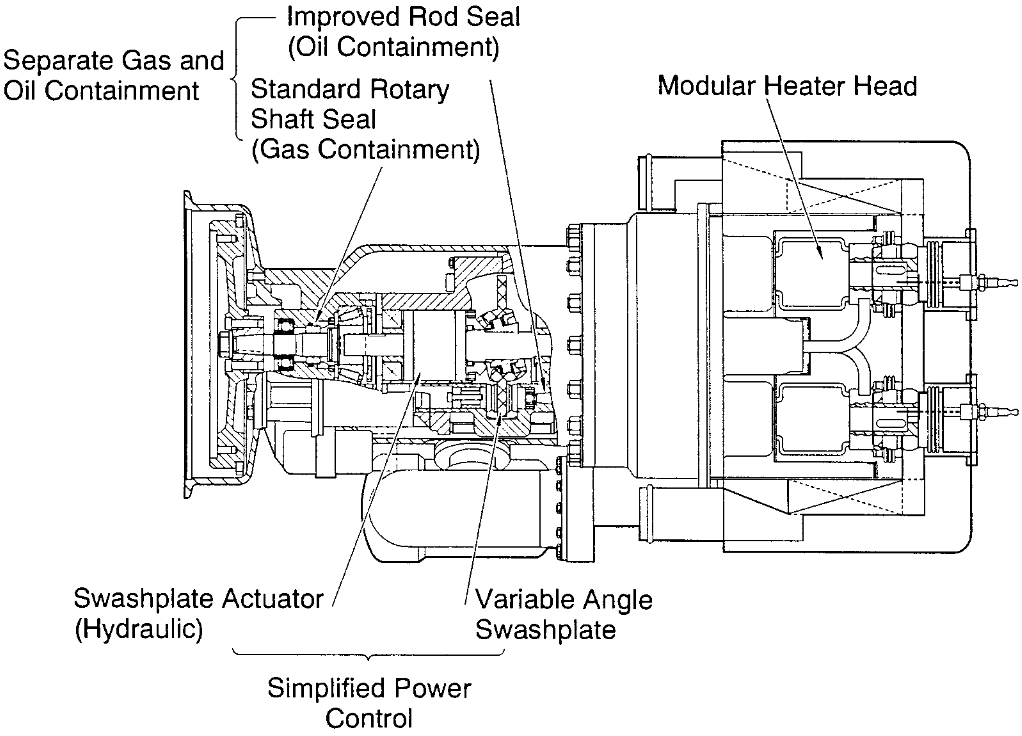

FIGURE 8.5.2 Stirling Thermal Motors 4-120 variable swash plate Rinia configuration engine. (Courtesy Stirling Thermal Motors, Ann Arbor, Michigan.)

reintroduced into the cycle. To accomplish this quickly and without loss of working gas, a complex system of valves, a temporary storage tank, and a compressor are used.

A novel method of controlling the power output is to change the length of stroke of the power piston. This can be accomplished using a variable-angle swash plate drive as described below. Stirling Thermal Motors, Inc., uses this method on their STM 4-120 Stirling engine (Figure 8.5.2).

Mechanical Implementation of the Stirling Cycle

Piston/Displacer Configurations

To implement the Stirling cycle, different combinations of machine components have been designed to provide for the constant-volume movement of the working gas between the high- and low-temperature regions of the engine, and compression and expansion during the constant-temperature heating and cooling. The compression and expansion part of the cycle generally take place in a cylinder with a piston. Movement of the working gas back and forth through the heater, regenerator, and cooler at constant volume is often implemented by a **displacer**. A displacer in this sense is a hollow plug that, when moved to the cold region, displaces the working gas from the cold region causing it to flow to the hot region and vice versa. Only a small pressure difference exists between either end of the displacer, and, therefore, sealing requirements and the force required to move it are minimal.

Three different design configurations are generally used (Figure 8.5.3). Called the alpha-, beta-, and gamma-configurations. Each has its distinct mechanical design characteristics, but the thermodynamic cycle is the same. The **alpha-configuration** uses two pistons on either side of the heater, regenerator, and the cooler. These pistons first move uniformly in the same direction to provide constant-volume processes to heat or cool the gas. When all of the gas has been moved into one cylinder, one piston remains fixed and the other moves to compress or expand the gas. Compression work is done by the **cold piston** and

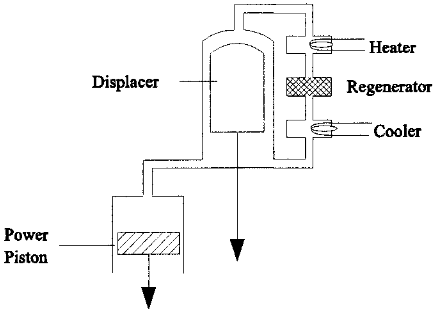
The Beta-Configuration



The Gamma-Configuration

FIGURE 8.5.3 Three fundamental mechanical configurations for Stirling Engines.

expansion work done on the **hot piston** The alpha-configuration does not use a displacer. The Stirling Power Systems V-160 engine (Figure 8.5.4) is an example of this configuration.

A variation on using two separate pistons to implement the alpha-configuration is to use the front and back side of a single piston called a **double-acting piston**. The volume at the front side of one piston is connected, through the heater, regenerator, and cooler, to the volume at the back side of another piston. With four such double-acting pistons, each 90° out of phase with the next, the result is a four-cylinder alpha-configuration engine. This design is called the *Rinia* or *Siemens configuration* and the United Stirling 4-95 (Figure 8.5.5) and the Stirling Thermal Motors STM 4-120 (Figure 8.5.2) are current examples.

The **beta-configuration** is a design incorporating a displacer and a power piston in the same cylinder. The displacer shuttles gas between the hot end and the cold end of the cylinder through the heater, regenerator, and cooler. The power piston, usually located at the cool end of the cylinder, compresses the working gas when the gas is in the cool end and expands the working gas when the gas has been moved to the hot end. The original patent engine by Robert Stirling and most free-piston Stirling engines discussed below are of the beta-configuration.

The third configuration, using separate cylinders for the displacer and the power piston, is called the **gamma-configuration.** Here, the displacer shuttles gas between the hot end and the cold end of a cylinder through the heater, regenerator, and cooler, just as with the beta-configuration. However, the power piston is in a separate cylinder, pneumatically connected to the displacer cylinder.

Piston/Displacer Drives

Most Stirling engine designs dynamically approximate the Stirling cycle by moving the piston and displacer with **simple harmonic motion**, either through a crankshaft, or bouncing as a spring/mass

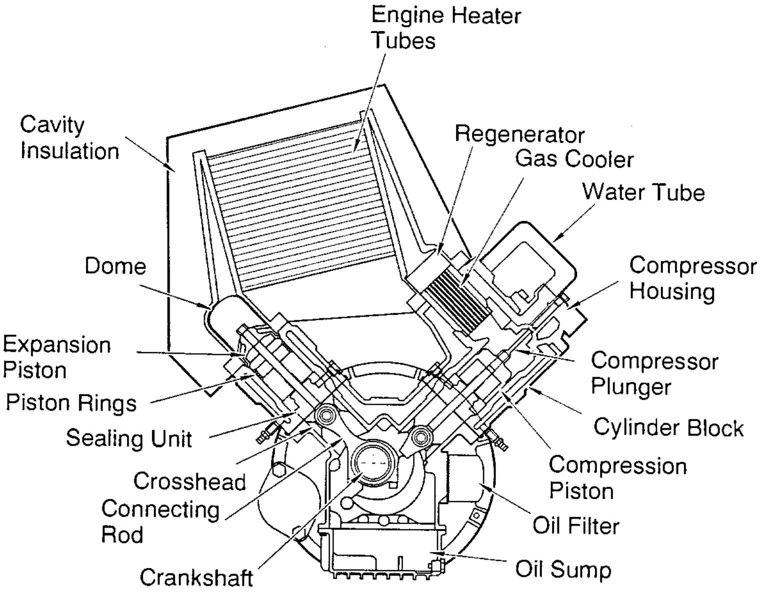


FIGURE 8.5.4 Stirling Power Systems/Solo Kleinmotoren V-160 alpha-configuration Stirling engine.

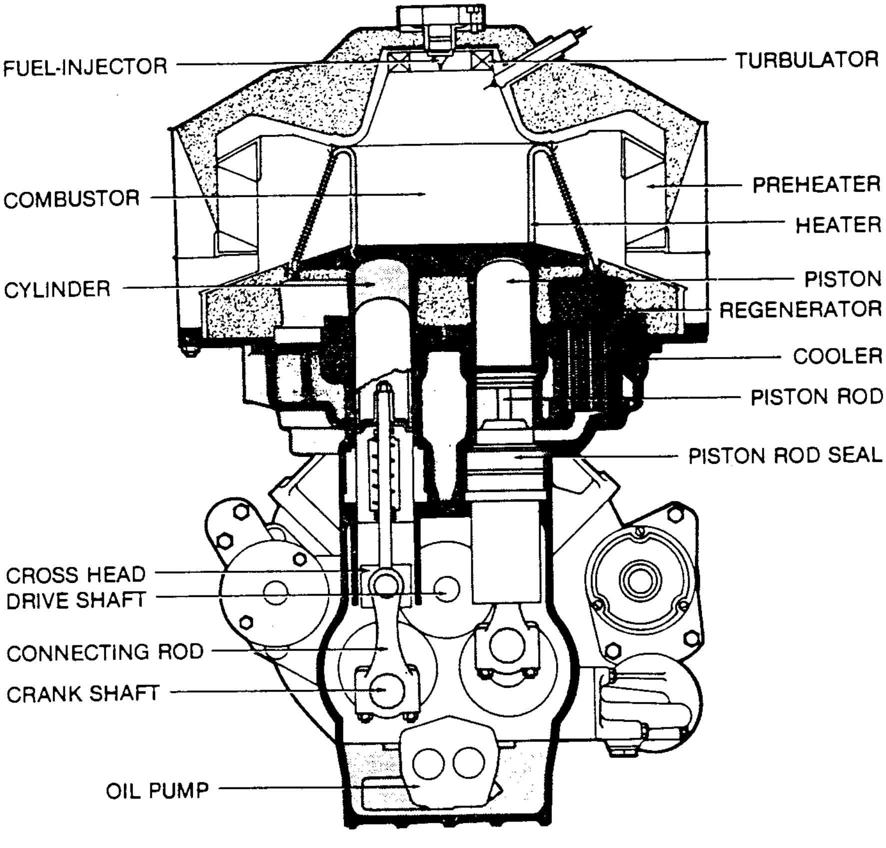

FIGURE 8.5.5 The 4-95 high-performance Siemens configuration Rinia engine by United Stirling (Malmo, Sweden).

second-order mechanical system. For both, a performance penalty comes from the inability of simple harmonic motion to perfectly follow the desired thermodynamic processes. A more desirable dynamic from the cycle point of view, called overdriven or **bang-bang motion**, has been implemented in some designs, most notably the **Ringbom configuration** and engines designed by Ivo Kolin (West, 1986).

Kinematic Engines. Stirling engine designs are usually categorized as either kinematic or free-piston. The power piston of a **kinematic Stirling engine** is mechanically connected to a rotating output shaft. In typical configurations, the power piston is connected to the crankshaft with a connecting rod. In order to eliminate side forces against the cylinder wall, a **cross-head** is often incorporated, where the connecting rod connects to the cross-head, which is laterally restrained so that it can only move linearly in the same direction as the piston. The power piston is connected to the cross-head and therefore experiences no lateral forces. The critical sealing between the high-pressure and low-pressure regions of the engine can now be created using a simple **linear seal** on the shaft between the cross-head and the piston. This design also keeps lubricated bearing surfaces in the low-pressure region of the engine, reducing the possibility of fouling heat-exchange surfaces in the high-pressure region of the engine. If there is a separate displacer piston as in the beta- and gamma configurations, it is also mechanically connected to the output shaft.

A variation on crankshaft/cross-head drives is the **swash plate** or **wobble-plate drive**, used with success in some Stirling engine designs. Here, a drive surface affixed to the drive shaft at an angle, pushes fixed piston **push rods** up and down as the slanted surface rotates beneath. The length of stroke for the piston depends on the angle of the plate relative to the axis of rotation. The STM 4-120 engine (Figure 8.5.2) currently being commercialized by Stirling Thermal Motors incorporates a **variable-angle swash plate drive** that permits variation in the length of stroke of the pistons.

Free-Piston Engine/Converters. An innovative way of accomplishing the Stirling cycle is employed in the free-piston engine. In this configuration, the power piston is not mechanically connected to an output shaft. It bounces alternately between the space containing the working gas and a spring (usually a gas spring). In many designs, the displacer is also free to bounce on **gas springs** or mechanical springs (Figure 8.5.6). This configuration is called the Beale free-piston Stirling engine after its inventor, William Beale. Piston stroke, frequency, and the timing between the two pistons are established by the dynamics of the spring/mass system coupled with the variations in cycle pressure. To extract power, a magnet can be attached to the power piston and electric power generated as it moves past stationary coils. These Stirling engine/alternator units are called **free-piston Stirling converters**. Other schemes for extracting power from free-piston engines, such as driving a hydraulic pump, have also been considered.

Free-piston Stirling engines have only two moving parts, and therefore the potential advantages of simplicity, low cost, and ultra-reliability. Because electricity is generated internally, there are no dynamic seals between the high-pressure region of the engine and ambient, and no oil lubrication is required.

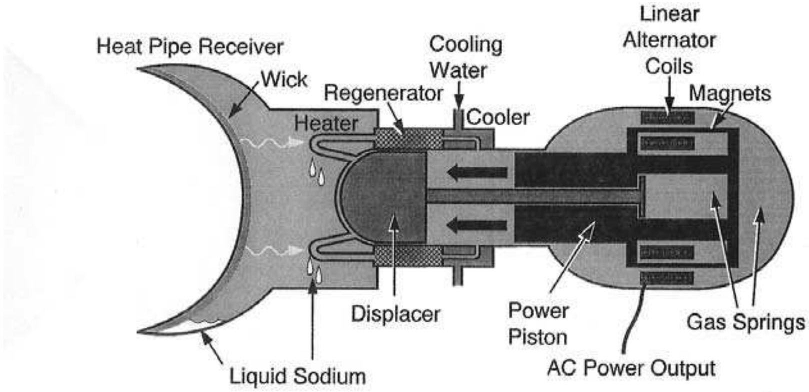

FIGURE 8.5.6 Basic components of a Beale free-piston Stirling converter incorporating a sodium heat pipe receiver for heating with concentrated solar energy.

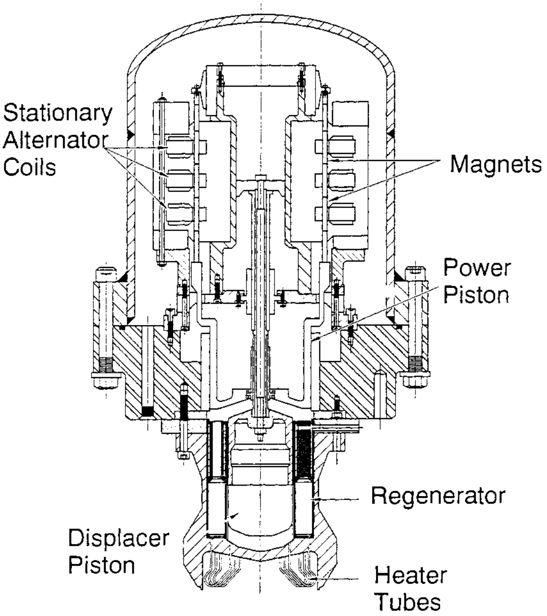

FIGURE 8.5.7 The Sunpower 9-kWe free-piston beta-configuration Stirling engine.

This design promises long lifetimes with minimal maintenance. A number of companies are currently developing free-piston engines including Sunpower, Inc. (Figure 8.5.7), and Stirling Technology Company.

Seals and Bearings

Many proposed applications for Stirling engine systems require long-life designs. To make systems economical, a system lifetime of at least 20 years with minimum maintenance is generally required. Desired engine lifetimes for electric power production are 40,000 to 60,000 hr — approximately ten times longer than that of a typical automotive internal combustion engine. Major overhaul of engines, including replacement of seals and bearings, may be necessary within the 40,000- to 60,000-hr lifetime, which adds to the operating cost. A major challenge, therefore, in the design of Stirling engines is to reduce the potential for wear in critical components or to create novel ways for them to perform their tasks.

Piston seals differ from those used in internal combustion engines in a number of ways. Sealing of the power piston is critical since **blow-by loss** of the hydrogen or helium working gas must be captured and recompressed, or replaced from a high-pressure cylinder. Displacer sealing is less critical and only necessary to force most of the working gas through the heater, regenerator, and cooler. Oil for friction reduction or sealing cannot be used because of the danger of it getting into the working gas and fouling the heat-exchange surfaces. This leads to two choices for sealing of pistons, using **polymer sealing rings** or **gas bearings** (simply close tolerance fitting between piston and wall).

Free-piston engines with gas springs have special internal sealing problems. Small leakage can change the force-position characteristics of the "spring" and rapidly upset the phase and displacement dynamics designed into the engine. In order to prevent this, *centering ports* are used to ensure that the piston stays at a certain location; however, these represent a loss of potential work from the engine.

Materials

Materials used in Stirling engines are generally normal steels with a few exceptions. Materials that can withstand continuous operation at the cycle high temperature are required for the heater, regenerator, and the hot side of the displacement volume. Because most engines operate at high pressure, thick walls are often required. In the hot regions of the engine, this can lead to *thermal creep* due to successive heating and cooling. In the cool regions, large spaces for mechanical linkages can require heavy, thick walls to contain the gas pressure. Use of composite structure technology or reducing the size of the pressurized space can eliminate these problems.

Future of the Stirling Engine

The principal advantages of the Stirling engine, external heating and high efficiency, make this the engine of the future, replacing many applications currently using internal combustion engines and providing access to the sun as an inexpensive source of energy (Figure 8.5.6). For hybrid-electric automotive applications, the Stirling engine is not only almost twice as efficient as modern spark-ignition engines, but because of the continuous combustion process, it burns fuel more cleanly and is not sensitive to the quality or type of fuel. Because of the simplicity of its design, the Stirling engine can be manufactured as an inexpensive power source for electricity generation using biomass and other fuels available in developing nations.

Most importantly, the Stirling engine will provide access to inexpensive solar energy. Because it can receive its heat from a resource 93 million miles away using concentrating solar collectors, and because its manufacture is quite similar to the gasoline or diesel engine, and because economies of scale are certain when producing thousands of units per year, the Stirling engine is considered to be the least expensive alternative for solar energy electric generation applications in the range from 1 kWe to 100 MWe.

Defining Terms

Alpha-configuration: Design of a Stirling engine where two pistons moving out of phase, and cause the working gas between them to go through the four processes of the Stirling cycle.

Beale free-piston Stirling engine: Stirling engine configuration where the power piston and displacer in a single cylinder are free to bounce back and forth along a single axis, causing the enclosed working gas to go through the four processes of the Stirling cycle. Restoration forces are provided by the varying pressure of the working gas, springs (gas or mechanical), and the external load which can be a linear alternator or a fluid pump.

Beta-configuration: Design of a Stirling engine where the displacer and power piston are located in the same cylinder and cause the enclosed working gas to go through the four processes of the Stirling cycle.

Blow-by: The gas that leaks past a seal, especially a piston-to-cylinder seal.

Charge pressure: Initial pressure of the working gas.

Cooler: Heat exchanger that removes heat from the working fluid and transfers it out of the cycle.

Cross-head: A linear sliding bearing surface connected to a crankshaft by a connecting rod. It is purpose is to provide linear reciprocating motion along a single line of action.

Displacer: Closed volume ‘plug’ that forces the working fluid to move from one region of the engine to another by displacing it.

Double-acting piston: A piston in an enclosed cylinder where pressure can be varied on both sides of the piston, resulting a total amount of work being the sum of that done on or by both sides.

Dynamic seals: Seals that permit transfer of motion without permitting gas or oil leakage. These can be either *linear seals* permitting a shaft to move between two regions (i.e., the piston rod seals in a Stirling engine), or *rotating seals* that permit rotating motion to be transmitted from one region to another (i.e., the output shaft of a Stirling engine).

Free-piston Stirling converters: A name given to a hermetically sealed free-piston Stirling engine incorporating an internal alternator or pump.

Gamma-configuration: A design of a Stirling engine where the displacer and power piston are located in separate, connected cylinders and cause the enclosed working gas to go through the four processes of the Stirling cycle.

Gas bearing: A method of implementing the sliding seal between a piston and cylinder as opposed to using piston rings. Uses a precision-fitting piston that depends on the small clearance and long path for sealing and on the viscosity of the gas for lubrication.

Gas spring: A piston that compresses gas in a closed cylinder where the restoration force is linearly proportional to the piston displacement. This is a concept used in the design of free-piston Stirling engines.

Heater: A heat exchanger which adds heat to the working fluid from an external source.

Kinematic stirling engine: Stirling engine design that employ physical connections between the power piston, displacer, and a mechanical output shaft.

Linear seal: see **dynamic seals**.

Overdriven (bang-bang) motion: Linear motion varying with time as a square-wave function. An alternative to simple harmonic motion and considered a better motion for the displacer of a Stirling engine but difficult to implement.

Phase angle: The angle difference between displacer and power piston harmonic motion with a complete cycle representing 360°. In most Stirling engines, the harmonic motion of the power piston follows (lags) the motion of the displacer by approximately 90°.

Push rod: A thin rod connected to the back of the piston that transfers linear motion through a dynamic linear seal, between the low- and high-pressure regions of an engine.

Reflux: A constant-temperature heat-exchange process where a liquid is evaporated by heat addition and then condensed as a result of cooling.

Regenerator: A heat-transfer device that stores heat from the working gas during part of a thermodynamic cycle and returns it during another part of the cycle. In the Stirling cycle the regenerator stores heat from one constant-volume process and returns it in the other constant-volume process.

Ringbom configuration: A Stirling engine configuration where the power piston is kinematically connected to a power shaft, and the displacer is a free piston that is powered by the difference in pressure between the internal gas and atmospheric pressure.

Simple harmonic motion: Linear motion varying with time as a sine function. Approximated by a piston connected to a crankshaft or a bouncing of a spring mass system.

Stirling cycle: A thermodynamic power cycle with two constant-volume heat addition and rejection processes and two constant-temperature heat-addition and rejection processes.

Swash plate drive: A disk on a shaft, where the plane of the disk is tilted away from the axis of rotation of the shaft. Piston push rods that move parallel to the axis of rotation but are displaced from the axis of rotation, slide on the surface of the rotating swash plate and therefore move up and down.

Variable-angle swash plate drive: A swash plate drive where the tilt angle between the drive shaft and the plate can be varied, resulting in a change in the displacement of the push rods.

Wobble plate drive: Another name for a swash plate drive.

Working gas: Gas within the engine that exhibits pressure and temperature change as it is heated or cooled and/or compressed or expanded.

8.6 Advanced Fossil Fuel Power Systems

Anthony F. Armor

Introduction

The generation of electric power from fossil fuels has seen continuing, and in some cases dramatic, technical advances over the last 20 to 30 years. Technology improvements in fossil fuel combustion have been driven largely by the need to reduce emissions and conserve fossil fuel resources, as well as by the economics of the competitive marketplace. The importance of fossil fuel-fired electric generation to the world is undeniable — more than 70% of all power in the U.S. is fossil fuel-based; worldwide the percentage is higher, and growing. Today, although most large power plants worldwide burn coal, generating companies increasingly are turning to natural gas, particularly when the cost of gas-fired generation and the long-term supply of gas appear favorable. This section reviews the current status and likely future deployment of competing generation technologies based on fossil fuels.

It is likely, particularly in the developed world, that gas turbine-based plants will continue to dominate the new generation market in the immediate future. The most advanced combustion turbines now achieve more than 40% **lower heating value** (LHV) efficiency in simple cycle mode and greater than 50% efficiency in **combined cycle** mode. In addition, combustion turbine/combined cycle (CT/CC) plants offer siting flexibility, swift construction schedules, and capital costs between $400 and $800/kW. These advantages, coupled with adequate natural gas supplies (though new wells and pipelines will be needed in the U.S.) and the assurance, in the longer term, of **coal gasification** back-up, make this technology currently the prime choice for green field and repowered plants in the U.S. and Europe.

However, the developing world, particularly China and India, have good reasons why the coal-fired power plant may still be the primary choice for many generation companies. Fuel is plentiful and inexpensive, and sulfur dioxide scrubbers have proved to be more reliable and effective than early plants indicated. In fact, up to 99% SO_2 removal efficiency is now possible. Removal of nitrogen oxides is also well advanced with over 95% removal possible using selective catalytic reduction (SCR). Ways to remove

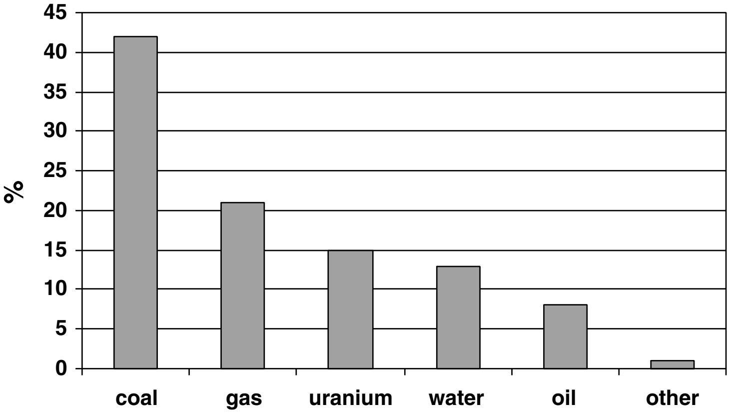

FIGURE 8.6.1 U.S. installed capacity by fuel percentage.

mercury are currently under study, and the issue of carbon dioxide control and sequestration from fossil plants is receiving renewed attention as ways to control global warming are pursued.

Combustion of coal can occur in three basic forms: direct combustion of pulverized coal; combustion of coal in a suspended bed of coal and inert matter; and coal gasification. The pulverized coal (PC) plant, the most common form of coal combustion, has the capability for much improved efficiency even with full **flue gas desulfurization** because ferritic materials technology has now advanced to the point at which higher steam pressures and temperatures are possible. Advanced supercritical PC plants are moving ahead commercially, particularly in Japan and Europe. Even higher steam conditions for PC plants, perhaps using nickel-based superalloys, are under study.

Worldwide, the application of atmospheric fluidized bed combustion (AFBC) plants has increased; these plants offer reductions in SO_2 and NO_x while permitting the efficient combustion of vast deposits of low-rank fuels such as lignites. Since the early 1990s, AFBC boiler technology power — with its advantage of in-furnace SO_2 capture with limestone — has become established worldwide as a mature, reliable technology for the generation of steam and electricity. In fact, the major impetus in the widespread deployment of this relatively new boiler technology since the mid-1980s has been its resemblance to a conventional boiler with the added capability for *in-situ* SO_2 capture, which could eliminate or reduce the need for flue gas desulfurization.

Coal gasification power plants are operating at the 250- to 300-MW level. Much of the impetus came from the U.S. DOE clean coal program where two gasification projects are in successful commercial service. Large gasification plants for power are also in operation in Europe. Gasification with combined cycle operation not only leads to minimum atmospheric (SO_2 and NO_x) and solid emissions, but also provides an opportunity to take advantage of new gas turbine advances. With the rapid advances now being introduced in combustion turbine technology, the coal gasification option is seen as a leading candidate for new plant construction within the first half of the 21st century.

Fuels for Electric Power Generation in the U.S.

The Energy Information Administration listed 498 GW of fossil-steam generating facilities in the U.S. in 1999. This included 407 GW at utilities and 91 GW at nonutilities. Coal-fired units dominated with 1393 units capable of generating 305 GW. All told, fossil-steam plants generate more than 70% of all electric energy in the country (Figure 8.6.1); these aging units (on average more than 30 years old) will remain the foundation of the power industry for the immediate future.

The U.S. electric power industry burns about $30 billion worth of fossil fuels each year, accounting for 70 to 80% of the operating costs of fossil-fired plants. Coal dominates and recent changes to the fuel mixes include:

- A mix of eastern high-sulfur coal with low-sulfur, low-cost western coals, often from Powder River Basin (PRB) deposits in Montana and Wyoming. Compared with eastern bituminous coals, PRB coals have lower heating value, sulfur and ash, but higher moisture content and finer size.
- A mix of 10 to 20% gas with coal in a boiler designed for coal firing.
- Orimulsion, a bitumen-in-water emulsion produced only from the Orinoco Basin in Venezuela. This fuel is relatively high in sulfur and vanadium. Power plants that use it need to add scrubbers.
- A mix of coal with petroleum coke, a by-product of refining, whose cost is currently low but whose sulfur content is high.

Coal as a Fuel for Electric Power (World Coal Institute, 2000)

Coal is the altered remains of prehistoric vegetation that originally accumulated as plant material in swamps and peat bogs. The accumulation of silt and other sediments, together with movements in the Earth's crust (tectonic movements), buried these swamps and peat bogs, often to great depth.

With burial, the plant material was subjected to elevated temperatures and pressures, which caused physical and chemical changes in the vegetation, transforming it into coal. Initially, peat, the precursor of coal, was converted into **lignite** or **brown coal** — coal-types with low organic maturity. Over time, the continuing effects of temperature and pressure produced additional changes in the lignite, progressively increasing its maturity and transforming it into what is known as **sub-bituminous coals**. As this process continued, further chemical and physical changes occurred until these coals became harder and more mature; at this point they are classified as **bituminous** coals. Under the right conditions, the progressive increase in the organic maturity continued, ultimately forming **anthracite**.

The degree of metamorphism or coalification undergone by a coal as it matures from peat to anthracite has an important bearing on its physical and chemical properties, and is referred to as the "rank" of the coal. Low-rank coals, such as lignite and sub-bituminous coals, are typically softer, friable materials with a dull, earthy appearance; they are characterized by high moisture levels and low carbon content, and thus a low energy content. Higher rank coals are typically harder and stronger and often have a black vitreous luster. Increasing rank is accompanied by a rise in the carbon and energy contents and a decrease in the moisture content of the coal. Anthracite is at the top of the rank scale and has a correspondingly higher carbon and energy content and a lower level of moisture.

Large coal deposits only formed after the evolution of land plants in the Devonian period, some 400 million years ago. Significant accumulations of coal occurred during the Carboniferous period (280 to 350 million years ago) in the Northern Hemisphere; the Carboniferous/Permian period (225 to 350 million years ago) in the Southern Hemisphere; and, more recently, the late Cretaceous period to early Tertiary era (approximately 15 to 100 million years ago) in areas as diverse as the U.S., South America, Indonesia, and New Zealand. Of all the fossil fuels, coal is the most plentiful in the world. It is geographically dispersed, spread over 100 countries and all continents (led by Asia with 137 million tons; Eastern Europe and the former Soviet Union with 113 million tons; and North America with 117 million tons).

Current coal reserve/production rations confirm over 200 years of resource availability. The percent of the world reserves categorized by type and use is shown in Figure 8.6.2. Almost one half (48%) of the world's coal reserves are lignite and sub-bituminous coals, which are used primarily for power generation.

Clean Coal Technology Development

At an increasing rate in the last few years, innovations have been developed and tested aimed at reducing emissions through improved combustion and environmental control in the near term, and in the longer term by fundamental changes in the way coal is preprocessed before converting its chemical energy to electricity. Such technologies are referred to as "clean coal technologies" and described by a family of precombustion, combustion–conversion, and postcombustion technologies. They are designed to provide the coal user with added technical capabilities and flexibility and the world with an opportunity to exploit its most abundant fossil source. They can be categorized as:

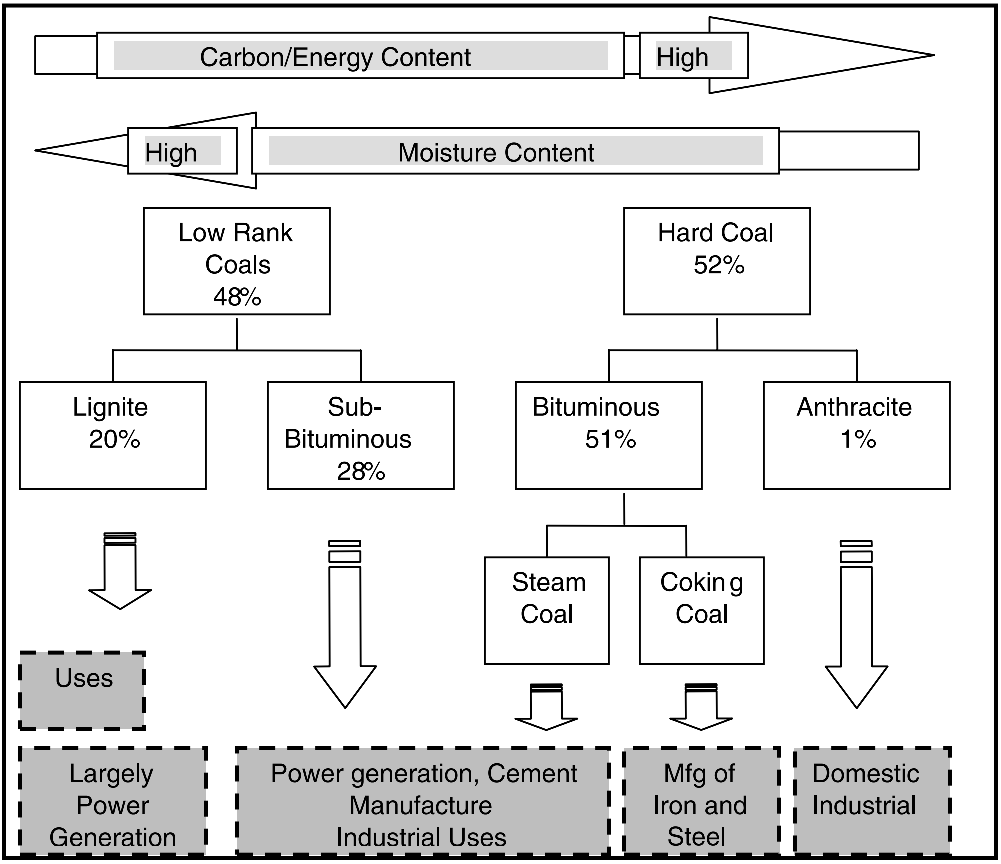

FIGURE 8.6.2 Coals cover a spectrum from lignites (high-moisture, lower-carbon content) to bituminous and anthracite coals (lower moisture, higher carbon content). All the coals can be burned to generate electricity.

- *Precombustion:* sulfur and other impurities are removed from the fuel before it is burned.
- *Combustion:* techniques to prevent pollutant emissions are applied in the boiler while the coal burns.
- *Postcombustion:* the flue gas released from the boiler is treated to reduce its content of pollutants.
- *Conversion:* coal, rather than being burned, is changed into a gas or liquid that can be cleaned and used as a fuel.

Coal Cleaning

Cleaning of coal to remove sulfur and ash is well established in the U.S., with more than 400 operating plants, mostly at mines. Coal cleaning removes primarily pyritic sulfur (up to 70% SO_2 reduction is possible) and in the process increases the heating value of the coal, typically about 10% but occasionally 30% or higher. The removal of organic sulfur, chemically part of the coal matrix, is more difficult, but may be possible using micro-organisms or through chemical methods; research is underway (Couch, 1991). Heavy metal trace elements can be removed also; conventional cleaning can remove (typically) 30 to 80% of arsenic, mercury, lead, nickel, antimony, selenium, and chromium.

Pulverized-Coal Plants

In the late 1950s the first units operating at supercritical pressures were introduced, initially in the U.S. and Germany. American Electric Power put the Philo supercritical unit in service in 1957 and Philadelphia

Electric soon followed with Eddystone 1, a unit still in active service. Today, 159 supercritical units operate in the U.S., and worldwide more than 500 supercritical units are operating with ratings from 200 to 1300 MW. Steam pressures for these units are typically 240 Bar (3500 psi), most of them single reheat designs. Steam temperatures are usually limited to about 594°C (1100°F), in order to utilize all-ferritic materials for thick wall components. A few (for example, Eddystone 1) utilize higher steam temperatures. The increased pressures and temperatures provide significant efficiency improvements over subcritical units, with attendant reductions in environmental emissions: SO_x, NO_x, CO_2, and particulates.

The greatest concentration of installed supercritical units is in the countries of the former USSR where the 232 units in operation provide 40% of all electric power. These units are designed at specific sizes of 300, 500, 800, or 1200 MW, and have steam conditions typically 24 MPa/565°C/565°C. The former USSR has also manufactured 18 supercritical units of 300- and 500-MW output, with shaft speeds of 3000 rpm, for China and Cuba (Oliker and Armor, 1992).

In Japan more than 60 supercritical plants are in operation; 25 are coal fired with another 9 due to start up in the next 2 years. Until the early 1990s, these plants had steam conditions of 24.6 MPa/538°C/566°C but, starting in 1993, the steam temperatures of the newer plants have climbed to the ultrasupercritical range, approaching 600°C.

There are about 60 supercritical units in Western Europe, largely in Germany, Italy (mostly oil fired), and Denmark. In the U.S., it is notable that the original Eddystone 1 unit, constructed in 1960, is still operating with the highest steam pressures and temperatures in the world, 4800 psi, 1150°F (322 Bar, 610°C), more than 35 years after commissioning. After the first supercritical units were installed in the late 1950s, early problems with these first-generation units began to surface. The majority of the problems were related to specific designs, changes in operating conditions, or plant malfunctions unrelated to higher pressure and temperature levels. Nevertheless, a few areas needed improvement, as noted later, to push the envelope of operating conditions as well as to improve the reliability and availability of these plants.

The design and material improvements that have been achieved now offset any deleterious effect of higher steam conditions on the cyclic fatigue life of components. The net result is that current designs do not push design margins on materials beyond the traditional margin of safety used for subcritical units; thus, new units based on their designs should have the same, if not better, availability.

Materials Advances

Higher steam temperatures (to 1150°F) and **supercritical steam pressures** are an important aspect of the modern pulverized coal plant. They are possible now because of advances in ferritic materials technology that extend life, provide greater creep and fatigue strength, and offer resistance to **temper embrittlement** and, in the boiler, to coal ash corrosion (Armor et al., 1999). Of particular note in those units operating today are:

- **Coextruded tubing** or monotubing for superheaters and reheaters, resistant to coal ash corrosion
- Improved 9-chrome steel (P91) for steam piping, valves, headers, and casings
- Improved creep-resistant 12-chrome forgings for HP/IP turbines
- "Superclean" 3.5 NiCrMoV rotors for LP turbines that are resistant to temper embrittlement

Because of the severe temperatures and stresses that exist throughout the boiler and turbine, alloys have been developed that mitigate creep and creep-fatigue problems. Particularly in the headers, steam lines, and HP and IP rotors, the impact of start–stop cycling is a concern as steam temperatures advance. To date, it is reasonable to view 1100°F (593°C) as a steam temperature for which ferritic steels for boilers and turbines are well established using P91 steels. It is likely that 1150°F (620°C) will be possible with improved ferritic steels in the near future, and perhaps even 1200°F (650°C) with the addition of tungsten as an alloying agent of steels such as P92 and P122 (Armor et al., 2003).

Additional long-term creep data may be necessary for these advanced steels. Beyond 1200°F (650°C), it is anticipated that superalloys will replace the traditional ferritic steels for HP and IP rotors. Nickel-based superalloys will be required for turbine forgings, as well as for superheater tubes, boiler outlet headers, steam piping, valve bodies, and turbine casings (Dalton et al., 2001). Because of the increased thermal expansion coefficients of these materials over ferritic steels, forging and casting thermal stresses become an important issue in start-ups and load cycling. For this reason, it is thought that such high temperature designs might be more suitable for base load duty in which thermal stress-caused fatigue damage is limited, rather than for on–off or load-change operation.

Cycle Selection

The selection of a supercritical vs. a subcritical cycle is dependent on many site-specific factors, including fuel cost; emissions regulations; capital cost; load factor; duty; local labor rates; and perceived reliability and availability. As to the reliability and availability of the supercritical cycle, it can match or better the subcritical cycle for base-loaded operation because early problems in first- and second-generation supercritical boilers and steam turbines have been overcome.

In fact, the use of subcritical cycles for the limited number of plants built in the U.S. in the last 20 years has been mainly due to relatively low fuel costs, which eliminated the cost justification for the somewhat higher capital costs of the higher efficiency cycles. However, in some international markets in which fuel cost is a higher fraction of the total cost, the higher efficiency cycles offer a favorable cost-of-electricity comparison and provide lower emissions compared to a subcritical plant. This is true in Europe and Japan.

For future plants though, the issue on cycle selection is likely to be decided based on efficiency considerations. The reduction of CO_2 emissions due to the supercritical cycle could be a deciding factor as ways are sought to reduce global warming concerns.

Supercriticals

Designs in U.S.

A survey of 159 supercritical units operating in the U.S. (EPRI, 1986) showed significant efficiency advantages (up to 3%), compared to typical subcritical units, and outage rates comparable to drum units after an initial learning period. Further studies were carried out in the early 1980s on the optimum steam pressures and temperatures for supercritical cycles (EPRI, 1982) and on the materials of choice for boiler and turbine components. As noted earlier, better materials have now been adopted worldwide for new supercritical units and include the use of P91 (super 9 chrome) for thick wall headers, steam lines, valves, and turbine casings.

The optimum design for a new supercritical cycle was recommended (EPRI, 1985) as a 700-MW double-reheat unit with steam conditions of 309 Bar/594/594/594°C (4500 psi, 1100/1100/1100°F). Such units have been constructed or are in planning in Japan and Denmark. As mentioned, it is notable that the original Eddystone 1 unit, constructed in 1960, is still operating with the highest steam pressures and temperatures in the world (322 Bar, 610°C), more than 35 years after commissioning. Table 8.6.1 notes other double-reheat units operating in the U.S.

Designs in Japan

In Japan more than 60 supercritical plants are in operation; 25 are coal fired with another 9 due to start up by 2004. Until the early 1990s, these plants had steam conditions of 24.6 MPa/538°C/566°C (3500 psi/960°F/1000°F); however, starting in 1993, the steam temperatures of the newer plants have climbed to the ultrasupercritical range, approaching 600°C (1100°F). The more recent of the large-scale, coal-fired supercritical plants to come on line and those planned for commissioning by 2004 are shown in Table 8.6.2 and Table 8.6.3 respectively. It is notable that new USC plants such as Tachibana will use advanced ferritic steels NF616 (P92) and HCM 12A (P122).

With few natural resources, Japan depends on efficient fossil generation plants burning coal, LNG, and heavy oil (as well as nuclear). Efficiency has always been a key issue for resource use minimization as well as environmental control. The Japanese supercriticals have adopted the best in European and U.S. technologies for their plants, including the European spiral-wound boiler and the U.S. partial arc admission turbine. Japanese steel-making is among the best in the world and the original EPRI advanced plant studies involved the leading Japanese steel makers. The first superclean low-pressure turbine steels (an EPRI innovation to avoid temper embrittlement) were first deployed in units at the Chubu Kawagoe station. Material advances for ferritic steels beyond P91 have been stimulated by formulations using tungsten as an alloying element (P92, for example).

TABLE 8.6.1 Advanced Supercritical Cycles at U.S. Locations with Double Reheat

Unit Name and Company	Steam Conditions (MPa/°C/°C/°C)	Design Capacity (MW)

Maizuni #2	Kansai	900	24.1/593/593	2003

Note: Noticeably, these are all single reheat units; double reheat is reserved for the more expensive oil- and gas-fired units.

TABLE 8.6.4 Recent European Supercritical Units with Advanced Steam Conditions

Power Plant	Fuel	Output (MW)	Steam Conditions (MPa/°C/°C/°C)	Start-Up Date
Skaerbaek 3	Gas	411	29/582/580/580	1997
Nordjyllands 3	Coal	411	29/582/580/580	1998
Avedore	Oil, biomass	530	30/580/600	2000
Schopau A,B	Lignite	450	28.5/545/560	1995–1996
Schwarze Pumpe A,B	Lignite	800	26.8/545/560	1997–1998
Boxberg Q,R	Lignite	818	26.8/545/583	1999–2000
Lippendorf R,S	Lignite	900	26.8/554/583	1999–2000
Bexbach II	Coal	750	25/575/595	1999
Niederaussem K	Lignite	1000	26.5/576/599	2002

Note: The trend in Europe appears to be in the direction of larger unit sizes.

It is noticeable in the tables that the units are of large size — sometimes a deterrent to cycling operation because of the thermal stresses involved. However, careful adaptation of automated start-up systems and the use of turbine by-pass systems have essentially solved today's start-up and cycling problems. The next generation, however, with the likely use of austenitic steels or of nickel-based superalloys will present new design challenges.

Designs in Europe

There are more than 100 supercritical units in Europe, largely in Germany, Italy (mostly oil fired), Holland, and Denmark. The most recent European coal-fired units with advanced supercritical steam conditions are listed in Table 8.6.4. Pioneering work on supercritical machines was carried out in Germany in the late 1950s and early 1960s, parallel with the U.S. advances. Particularly of note was the development of the spiral-wound boiler that permitted the pressure to slide up and down without concerns related to any departure from nucleate boiling, a situation that would severely damage boiler tubing. These boilers are now routinely used in Japan and Europe for full sliding pressure supercritical operation.

It is also significant that supercritical units in Germany, with double reheat, were built in unit sizes down to 220 MW — a size that would have appeal in the U.S., where smaller sizes are often sought by generating companies. Unit sizes are climbing in Germany, particularly as shown by the big lignite units at Schwarze Pumpe, Lippendorf, and Niederaussem. Lignite is a major resource in Germany and in several other European counties, such as Greece, where a lignite-fired, supercritical, district heating plant is in construction at Florina. New advanced plants for steam conditions are seen in Denmark, where the 411-MW, double-reheat supercritical units at Skaerbeck and Nordjyllands have steam temperatures of 580°C (1050°F), and at Avedore, a single-reheat design, 600°C (1110°F).

Emissions Controls for Pulverized Coal Plants (Armor and Wolk, 2002)

Today, worldwide, about 40% of electricity is generated from coal and the total installed coal-fired generating capacity is more than 1000 GW, largely made up of 340 GW in North America; 220 GW in Western Europe, Japan, and Australia; 250 GW in Eastern Europe and the former USSR; and 200 GW in China and India. More than 200 GW of new coal capacity has been added since 1990. Thus, together with the potential impact of carbon dioxide emissions contributing to global warming, the control of particulates, sulfur dioxides and nitrogen oxides from those plants is one of the most pressing needs of today and the future. To combat these concerns, a worldwide move toward environmental retrofitting of older fossil-fired power plants is underway, focused largely on sulfur dioxide scrubbers and combustion or postcombustion optimization for nitrogen oxides. Carbon dioxide control and sequestration options are now under study worldwide.

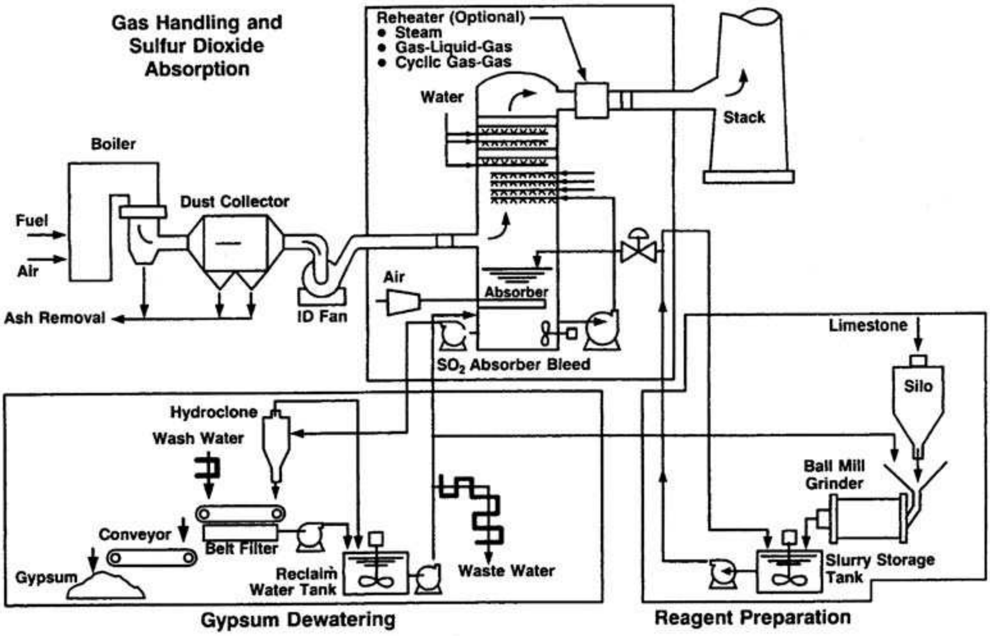

FIGURE 8.6.3 The conventional lime/limestone wet scrubber is the dominant system in operation in the U.S. With recent refinements, this system can be 98-99% effective in removing SO_2.

Conventional Lime/Limestone Wet Scrubber

The dominant SO_2 scrubbing system is the wet limestone design because limestone costs one quarter that of lime as a reagent. In this system (Figure 8.6.3), the limestone is ground and mixed with water in a reagent preparation area. It is then conveyed to a spray tower, called an absorber, as a slurry of 90% water and 10% solids, and sprayed into the flue gas stream. The SO_2 in the flue gas is absorbed in the slurry and collected in a reaction tank where it combines with the limestone to produce water and calcium sulfate or calcium sulfate crystals. A portion of the slurry is then pumped to a thickener where these solids/crystals settle out before going to a filter for final dewatering. Mist eliminators installed in the system ductwork at the spray tower outlet collect slurry/moisture entrained in the flue gas stream. Calcium sulfate is typically mixed with flyash (1:1) and lime (5%) and disposed of in a landfill.

Various improvements can be made to this basic process, including the use of additives for performance enhancement and the use of a hydrocyclone for dewatering, replacing the thickener and leading to a saleable gypsum byproduct. The Chiyoda-121 process (Figure 8.6.4) reverses the classical spray scrubber and bubbles the gas through the liquid. This eliminates the need for spray pumps, nozzle headers, separate oxidation towers, and thickeners. The Chiyoda process was demonstrated in a DOE Clean Coal Technology project on a 100-MW unit at the Yates plant of Georgia Power Company.

Spray Drying

Spray drying (Figure 8.6.5) is the most advanced form of dry SO_2 control technology. Such systems tend to be less expensive than wet FGD but remove typically a smaller percentage of the sulfur (90% compared with 98%). They are usually used when burning low-sulfur coals and utilize fabric filters for particle collection, although recent tests have shown applicability to high-sulfur coals also.

Spray driers use a calcium oxide reagent (quicklime) that, when mixed with water, produces a calcium hydroxide slurry. This slurry is injected into the spray drier where it is dried by the hot flue gas. As the drying occurs, the slurry reacts to collect SO_2. The dry product is collected at the bottom of the spray tower and in the downstream particulate removal device where further SO_2 removal may take place. It may then be recycled to the spray drier to improve SO_2 removal and alkali utilization.

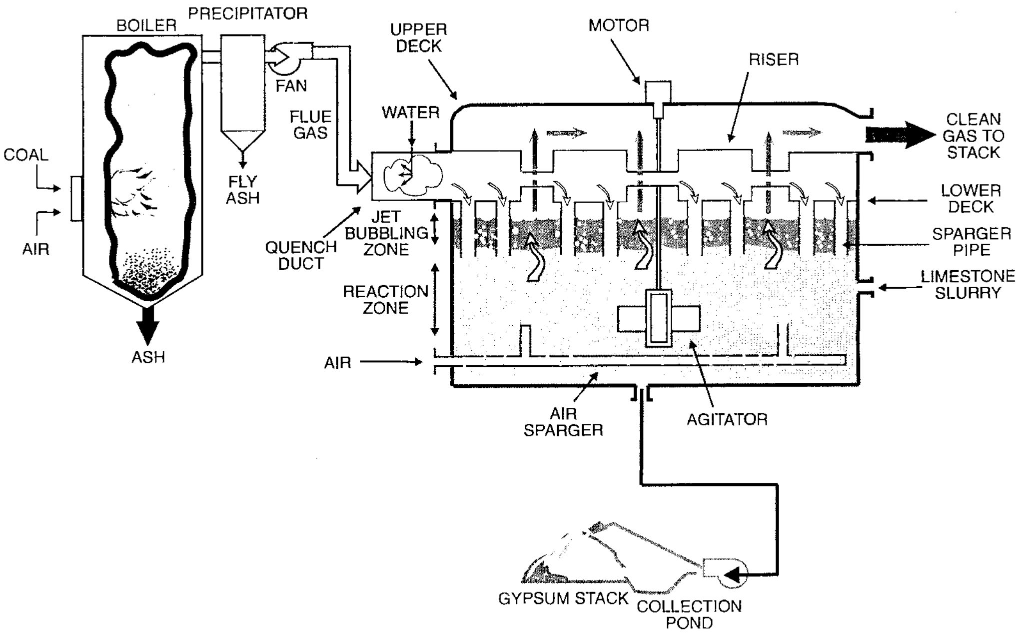

FIGURE 8.6.4 The Chioda-121 scrubber simplifies the process by bubbling the flue gas through the liquid, eliminating some equipment needs.

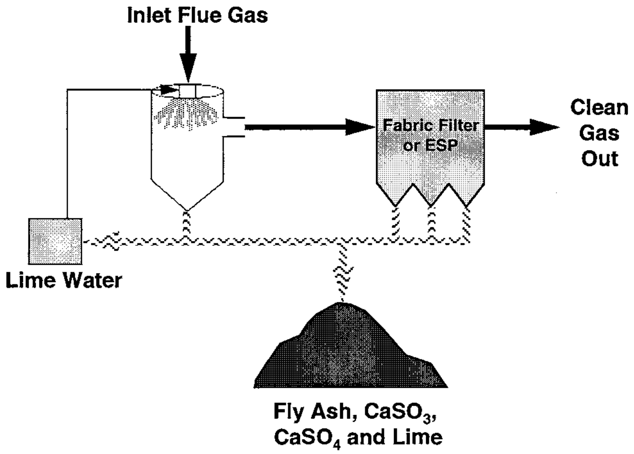

FIGURE 8.6.5 Spray driers use a calcium oxide reagent mixed with water, which is dried by the flue gas. A dry product is collected in a fabric filter.

For small, older power plants with existing **electrostatic precipitators** (ESPs), the most cost effective retrofit spray dry configuration locates the spray dryer and fabric filter downstream of the ESP, separating in this manner the spray dryer and fly ash waste streams. The fly ash can then be sold commercially.

Control of Nitrogen Oxides

Nitrogen oxides can be removed during or after coal combustion. The least expensive option, and the one generating the most attention in the U.S., is combustion control, first through adjustment of the fuel–air mixture, and second through combustion hardware modifications. Postcombustion processes seek to convert NO_x to nitrogen and water vapor through reactions with amines such as ammonia and

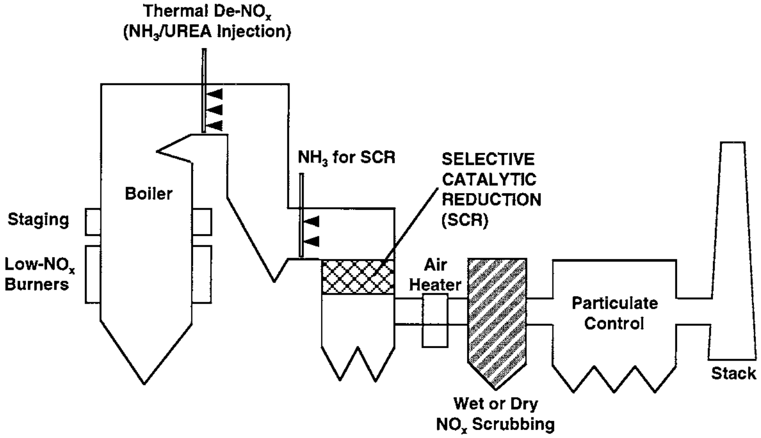

FIGURE 8.6.6 Control options for NO_x include operational, hardware, and postcombustion modifications.

urea. Selective catalytic reduction (SCR) injects ammonia in the presence of a catalyst for greater effectiveness. The options (Figure 8.6.6) can be summarized as:

- *Operational changes:* reduced excess air, and biased firing, including taking burners out of service
- *Hardware combustion modifications:* low NO_x burners, air staging, and fuel staging (reburning)
- *Postcombustion modifications:* injection of ammonia or urea into the convection pass, selective catalytic reduction (SCR), and wet or dry NO_x scrubbing (usually together with SO_2 scrubbing)

Low NO_x burners can reduce NO_x by 50% and SCR by 80%, but the low NO_x burner option is much more cost effective in terms of cost per ton of NO_x removed. Reburning is intermediate in cost per removed ton and can reduce NO_x 50%, or 75% in conjunction with low NO_x burners.

Postcombustion Options

Selective catalytic reduction is used widely in Europe (especially in Germany, where it is installed on more than 30,000 MW of coal-fired boilers) and in Japan, but sparingly to date in the U.S., although applications of SCR are increasing. In an SCR, ammonia is injected into the boiler exhaust gases before the catalyst bank (at about 550 to 750°F). NO_x and NH_3 then react to produce nitrogen and water; the chemical reactions are:

$$4NO + 4NH_3 + O_2 \rightarrow 4N_2 + 6H_2O$$

$$6NO_2 + 8NH_3 \rightarrow 7N_2 + 12H_2O$$

$$2NO_2\ 4NH_3 + O_2 \rightarrow 3N_2 + 6H_2O$$

The reaction can result in a potential NO_x removal capability of more than 90%, though practical limitations include ineffective mixing of NO_x and NH_3; velocity and temperature variations; NH_3 slip; and gradual loss of catalyst activity. Retrofit installation of an SCR system can require considerable space, although the reactor can be placed inside the original ductwork if NO_x reduction levels are modest. This would be difficult for coal-fired systems due to the high gas velocities. A separate reactor allows more flexibility in design.

In general, SCR has been successful in current installations, although impacts on the boiler system have included air heater deposition and plugging due to the formation of ammonium sulfate and bisulfate; ammonia contamination of fly ash; and ammonia slip. SCR systems operate at significantly lower temperatures than SNCR and are much more flexible in achieving the desired degree of NO_x reduction. These systems utilize catalyst coated metal plates to react flue gas. Inlet temperatures to the catalyst panels are controlled by bypassing flue gas around the catalyst zone to meet the required level of NO_x removal. Clearly, an option with relatively high operational cost, it remains an effective proven method for NO_x reductions.

Selective noncatalytic combustion (SNCR) is a promising lower capital cost alternative to SCR ($10/kW vs. more than $50/kW), but with lower performance (20 to 35% reduction compared with 50 to as high as 80% for SCR). In SNCR, the injection of a reagent like urea or ammonia into the upper part of the furnace converts NO_x from combustion into nitrogen; this conversion is a direct function of furnace temperature and reagent injection rate. Usual practice is to inject the reagent into a region of the boiler or convective pass where the temperature is in the range of 1600 to 2100°F (871 to 1149°C). NO_x reductions can range from 20 to as high as 50%, as previously stated, but are typically in the range of 20 to 35%. The level of reduction varies with the amount of nitrogen-containing chemical injected.

One major operating issue is that the system is not very flexible because the temperature of the flue gas at the point of ammonia injection is a function of boiler load. Additional operating issues of concern are the amount of unreacted ammonia (or slip) that exits the reaction zone; air heater fouling by sulfate compounds formed by reaction between SO_3 and excess ammonia; plume formation; and ammonia content of flyash. The operating cost is significant, although reagent consumption can be controlled.

Control of Mercury (EPRI, 2000)

Trace amounts of mercury are present in coal. Consequently, whenever it is combusted, such as in the generation of electricity, some of this mercury is emitted into the air along with exhaust gases. Power plant emissions account for about one third of the mercury emitted to the air from industrial sources in the U.S., but this is only about 2 to 3% of total global mercury emissions. After power plants release mercury, it becomes part of a global cycle.

The behavior of mercury in this cycle depends on its chemical form. Oxidized mercury (also called ionic mercury) may fall or wash out of the air and return to the Earth relatively near its source. Elemental mercury becomes part of the global inventory of mercury in the atmosphere, where it may remain for months to years. Eventually, it too returns to the Earth. This deposited mercury may enter bodies of water, directly or via runoff from surrounding soils, and enter the food chain. The ultimate environmental concern is humans' and animals' ingestion of fish containing elevated levels of mercury. Significant uncertainty and controversy remain about the contribution of individual sources to local or regional water bodies, as well as what constitutes safe levels of mercury in fish.

The removal of mercury from coal-fired units can be accomplished in several ways (Figure 8.6.7). Coal cleaning before combustion can remove some mercury and other heavy metals. After combustion, the injection of a sorbent such as an activated carbon can be very effective. Existing precipitators and SO_2

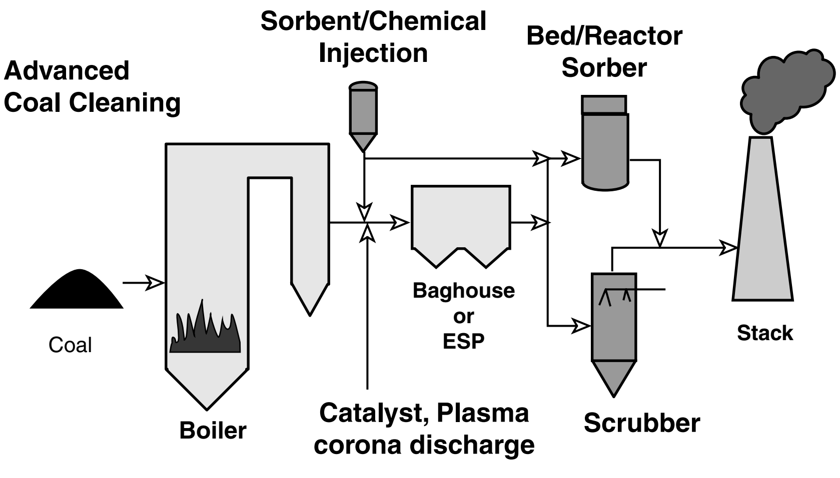

FIGURE 8.6.7 Options for the removal of mercury.

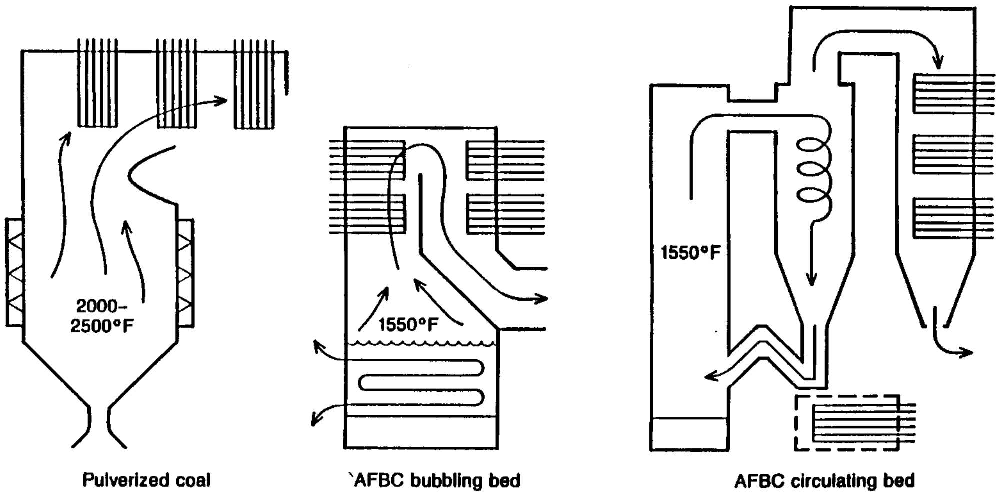

FIGURE 8.6.8 An illustration of the distinguishing features of pulverized coal and fluidized bed boilers. Noticeable in this diagram are the in-bed tubes characteristic of bubbling beds, and the cyclone separator of the circulating bed.

scrubbers can capture from 20 to 60% of mercury. Catalysts and certain chemicals can be injected that oxidize elemental mercury to enhance scrubber capture. Fixed beds, coated with materials such as gold, can form amalgams with mercury.

Fluidized Bed Plants

Introduced nearly 30 years ago, the **fluidized bed combustion** (FBC) boiler has found growing application for power generation. From the first FBC boiler, which generated 5000 lb/h of steam in 1967, the technology has matured to the 350-MW size units available today. In North America, more than 160 units now generate in excess of 9000 MW (EPRI, 2002). Burning coal in a suspended bed with limestone or dolomite permits effective capture of sulfur and fuel flexibility allows a broad range of opportunity fuels. These fuels might include coal wastes (culm from anthracite, gob from bituminous coal), peat, petroleum coke, and a wide range of coals from bituminous to lignite. A low (1500°F) combustion temperature leads to low NO_x formation. The salient features of atmospheric fluidized bed boilers, compared with a pulverized coal boiler, are shown in Figure 8.6.8.

Utility size demonstration projects at the Tennessee Valley Authority in 1989 (Manaker, 1992) (Shawnee, 160 MW) and Northern States Power in 1986 (Hinrichsen, 1989) (Black Dog, 133 MW) are examples of successful atmospheric bubbling-bed units. The Black Dog unit has been dispatched in a daily cycling mode and has successfully fired a blend of coal and petroleum coke. However, the focus of AFBC in the U.S. is now on the circulating fluid bed (CFB). In fact, more than 70% of operating fluid bed boilers in the U.S. are of the circulating type. The CFB unit at Nucla (Tri-State G&T Association) (Blunden, 1989) has been successful in demonstrating the technology at the 110-MW level and commercial CFB plants have now reached 250 MW in size. Most fluidized bed units for electricity generation are installed by independent power producers in the 50- to 100-MW size range; here, the inherent SO_2 and NO_x advantages over the unscrubbed PC plant have encouraged installations even in such traditional noncoal arenas as California (Melvin and Friedman, 1994). Worldwide, the AFBC boiler is employed largely for steam heat; hundreds of them operate in Russia and India, and thousands in China.

Atmospheric Fluidized Bed Combustion (AFBC)

In the bubbling bed version of the AFBC, the fuel and inert matter, together with limestone or dolomite for SO_2 capture, is suspended through the action of fluidizing air, which flows at a velocity of 3 to 8 ft/s in essentially a one-pass system. Circulating fluid beds (CFB) differ from bubbling beds in that much of

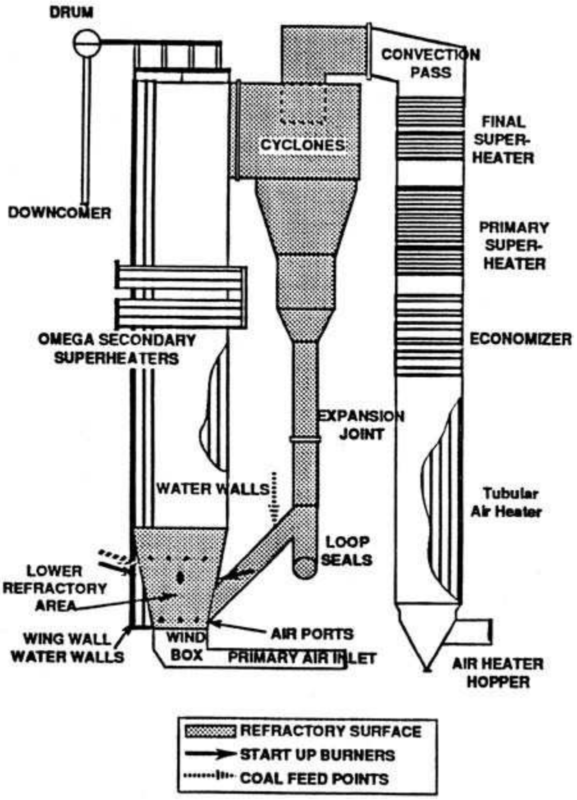

FIGURE 8.6.9 A circulating fluid bed boiler installed at the ACE Cogeneration Company at Trona, California. This 108-MW unit burns low-sulfur, western bituminous coal with limestone in a bed, which circulates back to the boiler after passing through a cyclone separator.

the bed material passes through a cyclone separator before being circulated back to the boiler (Figure 8.6.9). In-bed tubes are generally not used for CFB units permitting a much higher fluidizing velocity of 16 to 26 ft/s. Since the early AFBC designs, attention has been directed toward increasing unit efficiency, and reheat designs are now usual in large units. When SO_2 capture is important, a key parameter is the ratio of calcium in the limestone to sulfur in coal. Typical calcium–sulfur ratios for 90% SO_2 reduction are in the range of 3.0 to 3.5 for bubbling beds and 2.0 to 2.5 for circulating beds. This depends on the fuel, however, and the 200-MW CFB plant at the NISCO cogeneration plant, which burns 100% **petroleum coke** (4.5% S), has a Ca–S ratio of below 1.7 for more than 90% sulfur capture. NO_x levels in AFBCs are inherently low and nominally less than 0.2 lb/MMBtu.

It is important to note that for CFBs, boiler efficiencies can be as high as a pulverized coal unit (Table 8.6.5). In fact, designs now exist for AFBCs with supercritical steam conditions, with prospects for cycles up to 4500 psia, 1100°F with **double reheat** (Skowyra et al., 1995). Large CFB units in the Americas are shown in Table 8.6.6.

Pressurized Fluidized Bed Combustion (PFBC)

In a PFBC combined cycle unit (Figure 8.6.10), coal in a fluid bed is burned with dolomite or limestone in a pressurized steel chamber, raising steam for a steam turbine generator. The pressurized flue gases are expanded through a gas turbine. Commercial plants at about the 80-MW level in Sweden, the U.S., and Spain have demonstrated that bubbling-bed PFBC plants, with a calcium–sulfur molar ratio of about 1.5, offer sulfur capture up to 95%, together with inherently low NO_x emissions due to low combustion temperatures. Cleanup of the flue gas before entry to the gas turbines is a key technical objective, and

first-generation units have used cyclones together with gas turbines ruggedized with special blade coatings. For more advanced, higher efficiency PFBC systems, hot-gas cleanup technology, where the gas is directed through large ceramic filter units, will likely be needed.

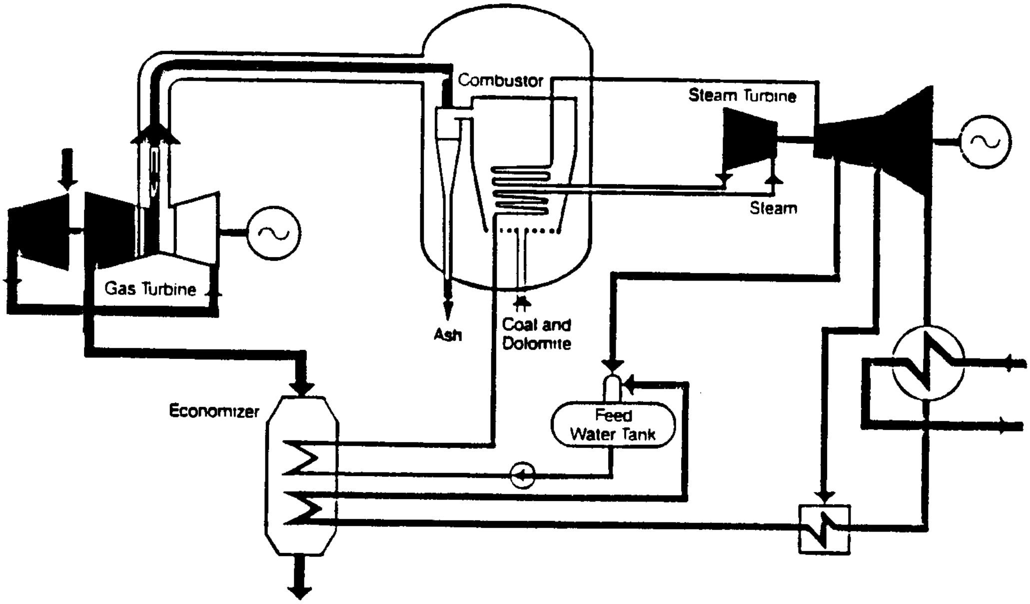

FIGURE 8.6.10 Pressurized, fluidized-bed combustor with combined cycle. This 70-MW system has operated at the Tidd plant of American Electric Power.

Early designs included the 80-MW units at Vaertan (Sweden) and Escatron (Spain) and the 70-MW unit at Tidd (AEP), which operated satisfactorily. The modular aspect of the PFBC unit is a particularly attractive feature, leading to short construction cycles and low-cost power. One promising use for PFBC units is for small, in-city cogeneration plants in which the inherent size advantages, high efficiencies, and effective coal gas cleanup approach permits compact plants to be retrofitted in place of heating boilers; the small steam turbines can be easily be adapted to electricity and hot water supply (Olesen, 1985).

A 250-MW subcritical unit based on the Hitachi bubbling bed technology was built at Osaka for Chugoku Electric and started commercial operation in late 2000. Steam conditions are 16.7 MPa/566°C/593°C (386psig/1050°F/1100°F). A 360-MW supercritical unit based on the ABB technology was constructed in Japan at Karita for Kyushu Electric Power Company. The boiler is designed for steam conditions of 24.1 MPa/565°C/593°C (3500 psig/1050°F/1100°F). The plant started up in late 1999.

In early 2000, ABB decided that it would no longer market PFBC but would confine its role to that of supplying the gas turbine. Alstom subsequently acquired ABB's power business. Thus, it appears that the future of PFBC will depend on the market in Japan However, in the Japanese market, PFBC faces strong competition from the several 800- to 1000-MW ultrasupercritical (USC) PC plants that have entered service. These have been performing very well, so the economies of scale represented by these large USC PC plants will make it very difficult for PFBC to compete. At this time (2003), commercialization of PFBC in the U.S is not currently actively progressing (Courtright et al., 2003).

Gasification Plants

One option of growing interest to coal-burning utilities is that of coal gasification. After the EPRI Cool Water demonstration in 1984 at the 100-MW level, the technology has moved ahead in the U.S. largely through demonstrations under the Clean Coal Technology (CCT) program (U.S. DOE, 2002).

Gasification-based plants have among the lowest emissions of pollutants of any central station fossil technology. Using the efficiency advantages of combined cycles, CO_2 emissions are also low. Fuel flexibility is an additional benefit because the gasifier can accommodate a wide range of coals, plus petroleum coke. Integrated gasification combined cycle (IGCC) plants permit a hedge against long-term increases in

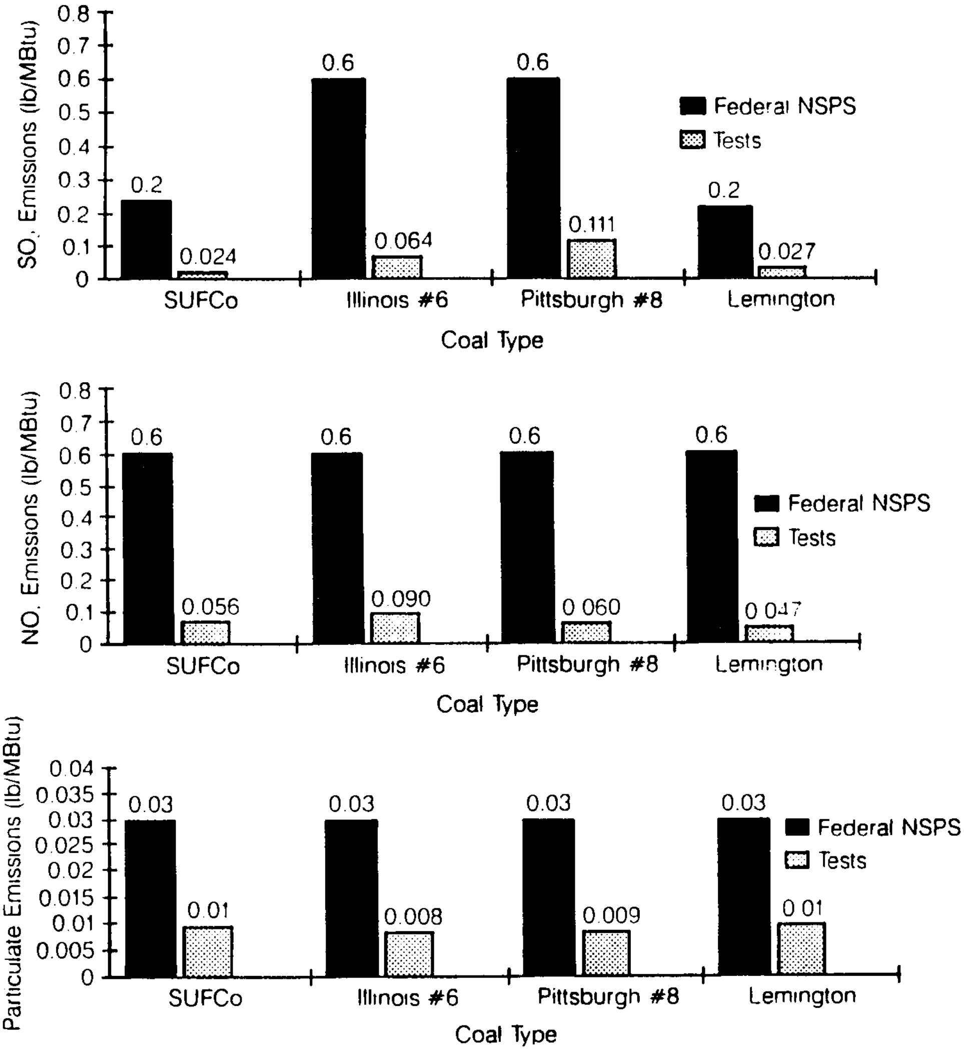

FIGURE 8.6.11 Tests at Cool Water on four coals show emissions of SO_2, NO_X, and particulates substantially below the federal New Source Performance Standards.

natural gas prices because natural gas-fired combustion turbines can be installed initially, and gasifiers at a later time, when a switch to coal becomes prudent (Douglas, 1986).

The pioneering Cool Water plant, the first of its kind in the world, operated for more than 4 years, gasifying 1.1 million tons of coal and producing 2.8 million MWh of electricity. The project was a collaborative effort of the industry involving the utility (Southern California edition); equipment manufacturers (Texaco, General Electric); and consultants/research consortia (Bechtel, EPRI, and others). Particularly notable was the achievement of exceptionally low levels of emissions of SO_2, NO_X, and particulates, as shown in Figure 8.6.11.

Basically, IGCC plants replace the traditional coal combustor with a gasifier and gas turbine. Ultralow emissions are realized; over 99% of the coal's sulfur is removed before the gas is burned in the gas turbine. A gasification cycle can take advantage of all the technology advances made in combustion turbines and steam turbines, so as to enhance overall cycle efficiency

There are currently two coal-based IGCC commercial sized demonstration plants operating in the U.S. and two in Europe (Table 8.6.7). The U.S. projects were all supported under the U.S. Department

TABLE 8.6.7 Coal-Based Commercial Size IGCC Plants

Operating IGCC Plants	Gasification Technology	Plant Size (MW)	Start-Up Date
Wabash River, Indiana	Destec	262	October 1995
Tampa Electric, Florida	Texaco	250	September 1996
SEP/Demkolec, Buggenum, The Netherlands	Shell	253	Early 1994

of Energy's (DOE) Clean Coal Technology (CCT) demonstration program. The 262-MW Wabash River IGCC repowering project in Indiana started up in October 1995 and uses the E-GAS™ (formerly Destec) gasification technology. The 250-MW Tampa Electric Company (TEC) IGCC project in Florida started up in September 1996 and is based on the Texaco gasification technology.The first of the European IGCC plants, the SEP/Demkolec project at Buggenum, the Netherlands, uses the Shell gasification technology and started operations in early 1994. The second European project, the ELCOGAS project in Puertollano, Spain, which uses the Prenflo gasification technology, started coal-based operations in December 1997.

Polk County IGCC

Texaco's pressurized, oxygen-blown, entrained-flow gasifier is used at the Tampa Electric Polk County plant to produce a medium-Btu fuel gas (Figure 8.6.12). Coal/water slurry and oxygen are combined at high temperature and pressure to produce a high-temperature syngas. Molten coal ash flows out of the bottom of the vessel and into a water-filled quench tank where it is turned into a solid slag. The syngas from the gasifier moves to a high-temperature heat-recovery unit, which cools the gases.

The cooled gases flow to a particulate-removal section before entering gas-cleanup trains. A portion of the syngas is passed through a moving bed of metal oxide absorbent to remove sulfur. The remaining

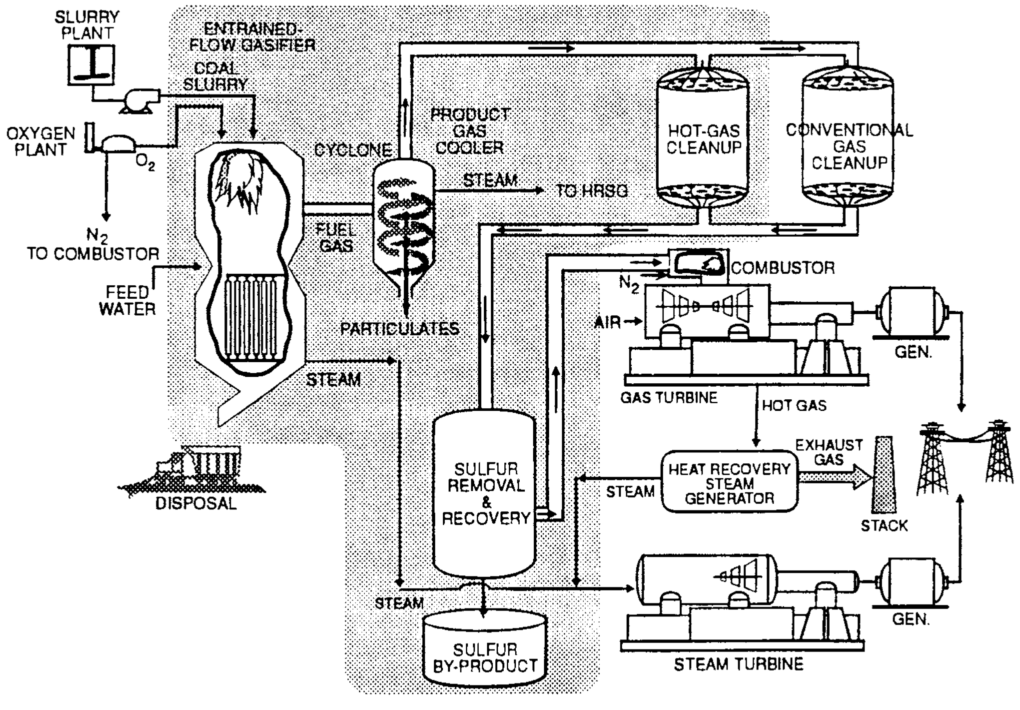

FIGURE 8.6.12 Integrated gasification, combined cycle at Tampa Electric, Polk County plant. A Texaco oxygen-blown gasifier is used. Total net generation is 250 MW.

syngas is further cooled through a series of heat exchangers before entering a conventional gas-cleanup train where sulfur is removed by an acid-gas removal system. These cleanup systems combined are expected to maintain sulfur levels below 0.21 lb/million Btu (96% capture). The cleaned gases are then routed to a combined-cycle system for power generation. A gas turbine generates about 192 MW. Thermally generated NO_x is controlled to below 0.27 lb/MM Btu by injecting nitrogen as a dilutent in the turbine's combustion section. A heat-recovery steam generator uses heat from the gas-turbine exhaust to reduce high-pressure steam. This steam, along with the steam generated in the gasification process, is routed to the steam turbine to generate an additional 120 MW. The IGCC heat rate for this demonstration is approximately 8600 Btu/kWh (40% efficient). Coals used in the demonstration are Illinois 6 and Pittsburgh 8 bituminous coals with sulfur contents ranging from 2.5 to 3.5%.

By-products from the process — sulfuric acid and slag — can be sold commercially, sulfuric acid by-products as a raw material to make agricultural fertilizer and the nonleachable slag for use in roofing shingles and asphalt roads and as a structural fill in construction projects.

Buggenum IGCC

Tests are in progress on the 250-MW IGCC plant in Buggenum, Netherlands. After successful operations running on natural gas, a switch was made to coal gas using Columbia coals. Buggenum comprises a 2000 ton/day single reactor coal gasification unit and an air separation plant able to produce 1700 ton/day of 95% pure oxygen. Syngas drives a Siemens combined cycle power unit, including a 156-MW, V94.2 gas turbine and a 128-MW steam turbine. The gasifier, operating at 28-bar pressure and 2700°F is designed to produce syngas containing 42% nitrogen, 25% carbon monoxide, and 12% hydrogen, with a combustion value of 4.3 MJ/kg. The environmental constraints are defined by permit requirements fixing upper limits of SO_2 at 0.22g/kWh, NO_x at 0.62 g/kWh, and particulates at 0.007 g/kWh.

Key steps for limiting emissions include:

- Removing fly ash with cyclone and candle filters after gas cooling
- Removing halogens and other soluble pollutants with water scrubbing
- Desulfurizing gas by catalytic and chemical processes; sulfur is fixed in sulfinol-*M* solvent, which is further treated to produce elemental sulfur
- Desulfurized gas is mixed with nitrogen from the air separation units and saturated with water vapor to reduce its lower heating value from about 11,000 to 4300 kJ/kg, thus greatly reducing NO_x production

Combustion Turbine Plants

Combustion turbine (CT)-based plants comprise the fastest growing technology in power generation. Almost all of these CT and CC plants will be gas fired, leading to a major expansion of gas for electricity generation. It is likely that combustion turbines and combined cycles will grow steadily more important in all generation regimes — peaking, mid-range and base load. The present 2300°F firing temperature machines operate reliably and durably and CT and CC plants are beginning to replace older steam plants. Combustion turbine plants will be a competitive choice for new fossil generation, and advanced CT cycles, with intercooling, reheat, and possibly chemical recuperation and humidification; they will spear-head the drive to higher efficiencies and lower capital costs. Gasification, which guarantees a secure bridge to coal in the near term, will come into its own as natural gas prices rise under demand pressure.

Modern gas turbines for power generation are mostly heavy-frame machines, with 60 HZ ratings in a simple cycle configuration around 170 to 190 MW for the high firing temperatures (~2300°F) of the **"F-class" machines**. Efficiencies (lower heating value) are 36 to 38% in simple cycles. In combined cycles, the units are 260 to 380 MW in size and 53 to 56% efficient. The next generation of CTs, with efficiencies from 57 to 60% is now emerging (Table 8.6.8). Smaller scale aeroderivative machines have benefited from turbofan engines designed for wide-body aircraft and today are available in ratings of 35 to 65 MW and with efficiencies of 40% or more for turbine inlet temperatures around 2250°F.

Advanced Combustion Turbines

Under the Department of Energy Advanced Turbine System (ATS) program (DOE, 2001), development work was carried out with two manufacturers to enhance the efficiency and environmental performance of utility-scale gas turbines. The goals were to achieve 60% efficiency or more in a combined-cycle mode; NO_x emission levels less than 9 ppm; and a 10% reduction in the cost of electricity. To achieve the efficiency objective required significantly higher turbine inlet temperatures. These higher temperatures required advancements in materials, cooling systems, and low-NO_x combustion techniques.

The focus of General Electric work for DOE was the "H" series gas turbine. To accommodate turbine inlet temperatures of 2800°F, General Electric is employing closed loop steam cooling for the first and second stages to reduce the differential between combustion (2800°F) and firing (2600°F) temperatures; the company is also developing new single-crystal (nickel superalloy) turbine blades with better thermal fatigue and creep characteristics. Thermal barrier coatings protect the metal substrate from the combustion gases using a ceramic top coat for thermal resistance and a metal bond coat for oxidation resistance. An MS9001H unit is being deployed in the U.K., and an MS7001H in Scriba, New York, in 2004.

Siemens–Westinghouse used its 501G turbine as a test bed for the ATS design. Computer modeling has allowed design refinements contributing to capital cost reduction and efficiency enhancement. These include a piloted ring combustor, which uses a lean, premixed multistage design to produce ultralow pollutant emissions and stable turbine operation. Siemens–Westinghouse has also developed brush and abradable coating seals to reduce internal leakage and new thermal barrier coatings for turbine blades to permit higher temperatures. These ATS developments will be incorporated into the commercial 501G turbine at the Lakeland Electric McIntosh station in Florida and demonstrated in 2005. A comparison of the "F" and "H" class machines for GE is shown in Table 8.6.9.

Humidified Air Power Plants (Cohn, 1994)

A new class of combustion turbines has been designed based on humidifying the combustion air. In these combustion turbine cycles, the compressor exit air is highly humidified prior to combustion. This reduces the mass of dry air needed and the energy required to compress it, thus raising plant efficiency.

The continuous plant cycle for this concept is termed the **humid air turbine** (HAT). This cycle has been calculated to have a heat rate for natural gas about 5% better than current high-technology combined cycles. The HAT cycle is adaptable to coal gasification — leading to the low-emissions and high-efficiency

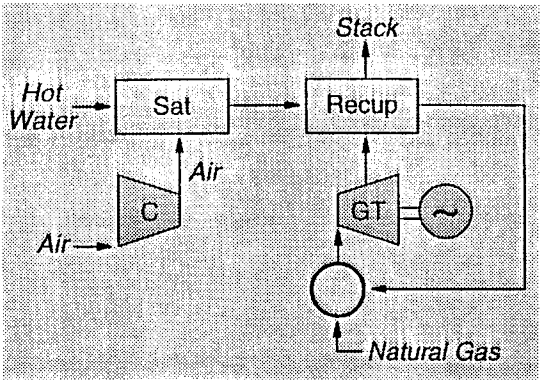

FIGURE 8.6.13 The humid air turbine (HAT) cycle adds moisture to the compressor exit air, reducing the air mass flow needed and increasing cycle efficiency.

characteristics of gasification combined cycle plants — but at a low capital cost because the steam turbine bottoming cycle is eliminated. A simple humidified air turbine cycle is shown in Figure 8.6.13. The addition of moisture means that perhaps 25% more mass flow goes through the turbine than through the compressor. This suggests the use of separate spools for the turbine and compressor. Using today's 2350°F firing temperatures, it is reasonable to expect a HAT heat rate of about 6100 Btu/kWh from this cycle.

The ideal natural-gas-fired HAT plant has been calculated to have higher efficiency (about 2 points higher) than a combined cycle for the same turbine cooling technology. Thus, it would provide the lowest heat rate for a natural-gas-fired thermal plant and would be utilized in baseload or long intermediate dispatch. The capital cost of this power plant has been calculated to be only slightly higher than that of a combined cycle. However, the anticipated development cost for the ideal turbo machinery has been estimated to be very high, in excess of $250 million.

In contrast, the CHAT (cascaded humid air turbine) plant utilizes turbine components, which are now available, with few exceptions, in a cascade arrangement that allows them to match together. The development cost of the CHAT equipment is currently estimated to be only in the $5 to 10 million range, making its development much more practical.

The HAT and CHAT cycles can be integrated with gasification. Because these cycles directly incorporate humidification, they can make direct use of hot water generated in the gasification plant, but cannot readily utilize steam. Thus, they match well with the lower capital cost, but lower-efficiency, quench types of gasifier. This provides an overall power plant with efficiency about the same as an IGCC. Moreover, the capital cost of the IGHAT plant has been calculated to be about $150/kW less than an IGCC plant. These humidification cycles have yet to be offered commercially. The main obstacle is the need to demonstrate low-emission, high-efficiency, full-scale combustors utilizing very humid air experimentally.

Other Combustion Turbine Cycle Enhancements (Lukas, 1986)

Several variants of the combustion turbine-based Brayton cycle increase plant efficiency and capacity. **Regenerative cycles** use storage type heat exchangers, where porous or honeycomb wall structures store energy from the hot gases. This is released later to the cold gases. A **recuperative cycle** uses a heat exchanger where the hot and cold streams are separated by walls through which heat transfer occurs. This is the approach commonly used in combustion turbines, allowing gains in efficiency and reduced fuel consumption, but no specific output increase.

Intercooling between compressor stages increases useful output by about 30% for a given air mass flow, by reducing the volume flow and increasing available energy to the power turbine. It has minimal effect on efficiency because heat removed must be added back in the combustion chamber, but it is commonly used in conjunction with recuperation. In a reheat cycle the fuel is introduced at two locations, increasing the total energy available to produce work. A combination of intercooling, reheat, and recuperation is shown in Figure 8.6.14.

Steam injection, in which the steam is injected directly into the combustion chamber, increases the mass flow through the turbine and results in increased output power. Steam-injected gas turbine (SIGT)

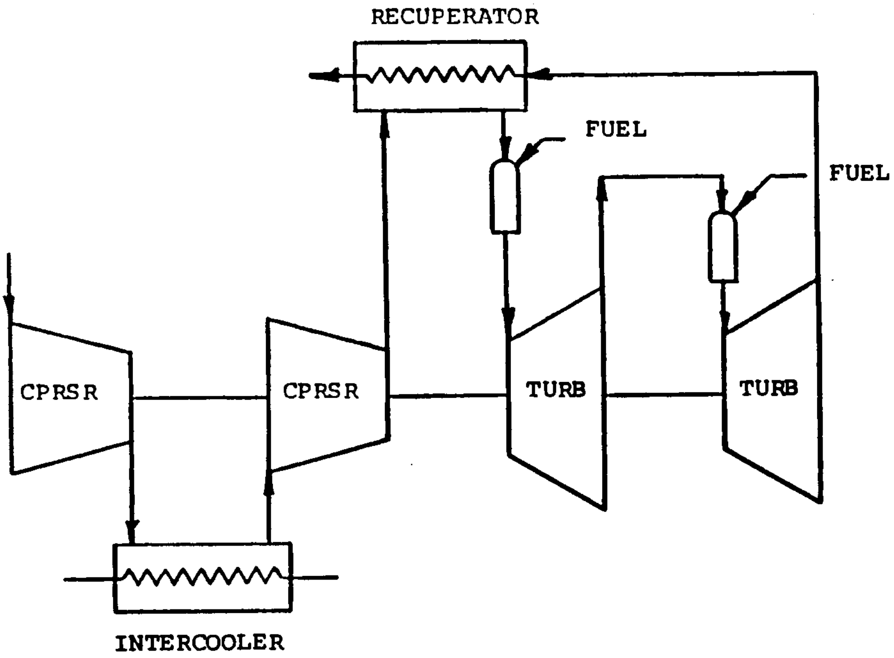

FIGURE 8.6.14 Improvement in combustion turbine performance is illustrated in this schematic, which combines an intercooler for the compressor with a recuperator using combustion turbine exhaust heat, and a reheat cycle for the turbine to improve efficiency.

cycles have been compared from the viewpoints of efficiency, power generation, capital and operating costs, and environmental impacts with combined cycle systems (Esposito, 1989). Above 50-MW size, it was found that combined cycle plants were more economical and achieved significantly better heat rates, although cooling tower fog, visible plumes, and drift deposition favored SIGT plants for a flat site

Central Station Options for New Generation

Coal and gas fuels are expected to continue to dominate U.S. central stations in the next decade, with gas-fired combined cycles supplanting several older fossil steam stations. This process is already underway, and by the end of 1999, 118 gas-fired combined cycles were in planning, totaling 56 GW of new power.

The U.S. central station generation options for fossil fuels may be described as follows:

- *Coal, oil, and gas-fired plants of conventional design with typical plant efficiencies of 35% (coal and oil) and 33% (gas); mostly Rankine cycles.* These represent the majority of plants currently in operation. On average, they are 30 years old, many (more than 70,000 MW) equipped with SO_2 scrubbers; most are facing NO_x control additions and perhaps other environmental upgrades. Yet they provide for the bulk of electricity needs; are extremely reliable; and are increasingly in demand as evidenced by an average capacity factor at an all-time high of nearly 70%.
- *Repowered plants, based on gas-firing and combined cycle operation, with efficiencies up to 45%.* Many of the gas-fired steam plants are now targeted for repowering, i.e., combustion turbines will be added to provide exhaust heat for producing steam for the existing steam turbines. This combination of gas and steam turbine cycles adds megawatts, reduces emissions, and improves efficiencies 5% or more.
- *New combined cycles based on gas-firing (about 45% efficiency with today's gas turbines and 50% with advanced gas turbines), and on coal-firing with gasification, utilizing advanced gas and steam turbine technology (50% efficiency).* Gas-fired combined cycles are currently the new plants of choice. Although relatively few are in operation today, more than 50 GW are planned. The massive deployment of these plants in the future raises questions of gas and gas pipeline availability, gas prices, and a potential retreat from coal that could have serious future energy consequences. Coal plants, whether pulverized or gasified, also lend themselves to combined cycles, although none are planned domestically outside the DOE Clean Coal demonstrations.
- *Coal-fired Rankine cycles with advanced steam conditions and up to 50% plant efficiency.* Advancing steam temperatures and pressures in pulverized coal steam plants greatly improve overall efficiency. Such ultrasupercritical cycles are already in operation outside the U.S. Advancing steam temperatures to 750°C from current levels of about 590°C permits plants to rival the best gas combined cycles. When used in coal combined cycles and with temperatures increased to 850°C or beyond, a coal plant approaching 60% efficiency is attained. Significant challenges still exist in materials technology.
- *Integrated coal gasification fuel cells, perhaps combined with gas turbines with efficiencies of 60% or more.* The fuel cell is an exciting advance that will change the energy picture in the long term. Shorter term, and in small sizes, great advances are being made in mobile as well as stationary applications. If the fuel cell can be used as a combuster for a gas turbine, efficiencies can be raised above 60%. Clearly, this is a power source of great promise for the second half of this century

Overall Plant Performance and Cost Estimates

As shown in Figure 8.6.15, mature versions of IGCC plants are expected to have capital costs slightly higher than the capital costs for PC plants, while the capital costs for PFBC plants are expected to be slightly lower than for PC plants. More advanced coal plants, when they become commercially available, are expected to have capital costs that are 20 to 25% lower than today's PC plants (Booras, 1999). These calculations include all engineering and construction costs. They assume a mature technology in which the plant achieves rated performance as designed. (Figure 8.6.16).

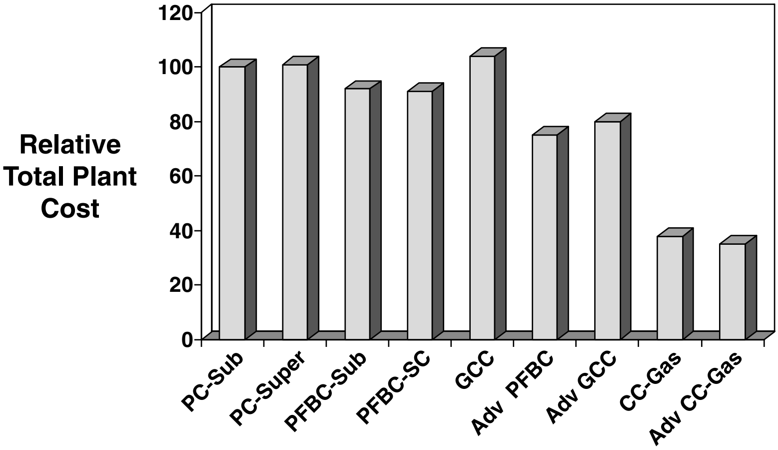

FIGURE 8.6.15 Capital costs for coal and gas-fired central stations. These costs assume mature technologies and fully functional equipment manufacturing lines for the newer technologies.

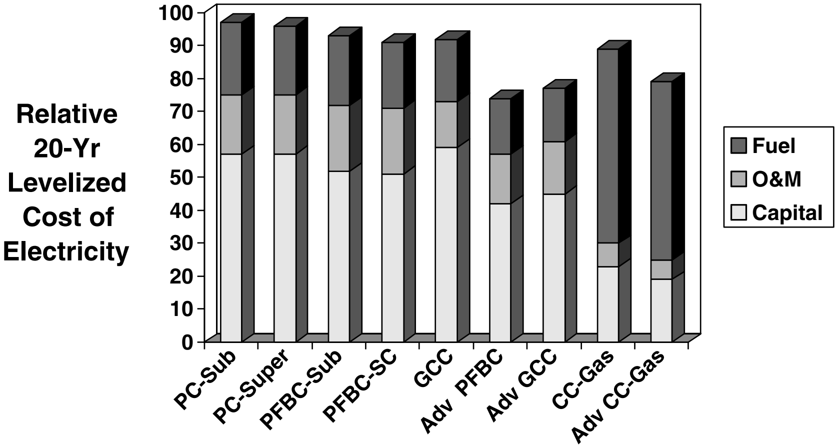

FIGURE 8.6.16 Levelized cost of electricity comparisons based on mean fuel prices for the U.S. and a 2010 start-up date. Coal is assumed at \$1.06/MMBtu and gas at \$3.08/MMBtu, a price differential about 40% greater than in 2000.

Summary

The preceding section has described how the future for electric power generation will increasingly be dominated by environmental control needs, putting an emphasis on the base efficiency of new generation, and on heat rate recovery for existing units. The pulverized coal-fired power plant with flue gas desulfurization will remain a focus of most near-term activity related to upgrades and retrofits. However, new technology, based on coal gasification, is under development and being tested in a growing number of demonstration plants that promise extremely low emissions.

The future for many nations will be based on exploiting the opportunities offered by clean and efficient use of coal. This implies access to the range of new technologies now being tested at large scale in the U.S. and other developed nations. This strategy is timely and prudent on a global basis as the world increasingly voices concerns related to carbon combustion.

New, base-load, central generation plants will largely be focused in the immediate future on the rapidly developing areas of the world: Asia (particularly China and India) and Latin America. In these areas, the fuel of choice will likely be coal, particularly in Asia, and the generating unit most often will be a conventional pulverized coal unit; such units will increasingly deploy supercritical steam at temperatures of 1100°F and above. In North America, Europe, and Japan, gas-fired central plants using combustion turbines, often in a combined cycle, will continue to be built through 2010 due to the short construction time and lower carbon dioxide emissions (compared with conventional PC plants).

As the cost of natural gas, relative to coal, increases, this will then encourage the installation of coal gasification units enabling the enormous world coal reserves to be utilized fully. Then, as the 21st century progresses, smaller distributed generating sources will begin to emerge, based on gas-fired fuel cells, small combustion turbines, or possibly photovoltaics. As the economics for the distributed option become favorable, these smaller generating units will encourage broad electrification of the developing countries of the world, avoiding the immediate need for large high-voltage transmission systems. Such distributed generation plants will also be added at strategic locations in the developed world as ways are sought to relieve the growing congestion on transmission networks.

Defining Terms

Lower heating value: Fuels containing hydrogen produce water vapor as a product of combustion. Fuel heating value is said to be "lower" if the combustion process leaves all products in the gaseous state, but "higher" if the fuel heating value includes the latent heat of vaporization. Practice in the U.S. is to use the higher value.

Combined cycle: Power stations that employ combustion turbines (Brayton cycle) and condensing steam turbines (Rankine cycle) where the waste heat from the CTs generate steam for the STs are called "combined" cycle plants. Overall plant efficiency improves.

Coal gasification: Coal can be converted into a mixture of carbon monoxide and hydrogen by burning it with a controlled deficiency of oxygen. Use of pure oxygen produces a medium calorific value gas, and air a low calorific value gas. This "syngas" can then be used to power a combustion turbine.

Flue gas desulfurization: Removal of sulfur dioxide, SO_2, from combustion gases is accomplished in a number of flue gas desulfurization methods. Most of these involve wet "scrubbing" of the gas using lime or limestone, and result in a calcium sulfate waste product. A 95% removal efficiency, or higher, is possible.

Slagging and fouling: The mineral matter in coal can attach itself following combustion to the boiler walls and heat exchanger surfaces. Oxides of silicon, aluminum, iron, calcium, and magnesium can foul all boiler surfaces, requiring soot blowers for cleaning. Hot ash can melt, becoming sticky and sometimes coalescing in the furnace to cause slagging problems.

On–off cycling capability: Generating units are often not required on a 24-h basis. Some are shut down during low demand times and started up perhaps hours later. This form of "on–off cycling" imposes thermal stresses on the equipment, leading to premature equipment failure unless special measures are taken to deal with this.

Temper embrittlement: Tempering of steel in the manufacturing process removes some of the brittleness and is carried out by a heating and cooling process. During operation, though, it is possible that ductility can worsen close to specific "tempering temperatures." The material is then said to be temper embrittled and premature cracking may follow.

Coextruded tubing: Tubing for superheaters and reheaters must be strong enough to withstand the pressures and temperatures expected, and also corrosion resistant to depositions of fly ash. By making tubing with a strong inner layer and corrosion-resistant outer layer through an extrusion process, both concerns can be dealt with.

Spray drying: Spray dryers, for desulfurization, used typically when burning lower sulfur coals, use a spray of quicklime, which is dried by the hot flue gas and results in a dry solid product. A 90% removal efficiency is typical.

Electrostatic precipitators: Flue gas particles, when electrically charged in an ionized gas flow, collect on electrodes in the presence of a strong electrostatic field. Collected dust is discharged by rapping into hoppers. A collection efficiency above 99% is possible.

Fluidized bed: A process of burning solid fuels, particularly coal, by combustion suspending the fuel within a column of air supplied from below the furnace. This method permits effective combustion of poor-quality fuels; lowers NO_x emissions due to low combustion temperatures; and captures sulfur in the bed by mixing limestone or dolomite in with the fuel.

Petroleum coke: Petroleum coke is a residual product of the oil refining process, and in its fuel grade form is an almost pure carbon by-product. About 19 million tons of fuel grade pet coke is produced each year in the U.S. It is inexpensive, although it may have high sulfur and vanadium content.

Double reheat: Modern designs of fossil steam-generating units remove a portion of the steam before full expansion through the turbine and reheat it in the boiler before returning it to the turbine. This enhances the thermal efficiency of the cycle by up to 5%. For supercritical cycles, two stages of reheat can be justified — double reheat.

Cogeneration: Cogeneration refers to the production of multiple products from a power plant. Typically, process steam, or hot water for heating, are produced in addition to electricity. This approach leads to high plant utilization, the "effective" heat rate being 70% or more.

Ash-softening temperature: The tendency for fly ash to adhere to tube banks is increased as the ash softens and melts. The point at which the ash begins to soften is dependent on the type of coal and is difficult to predict, depending on the many coal constituents. Slagging and fouling of tubes can lead to severe tube corrosion.

Fuel cell: Fuel cells convert gaseous or liquid fuels directly to electricity without any combustion process. Like a continuous battery, the fuel cell has electrodes in a electrolyte medium. Typically, hydrogen and air are supplied and DC electricity, water, and carbon dioxide are produced.They are currently high-cost, low-size devices, but with minimum environmental emissions.

Hot gas cleanup: Cycles that use gas from the combustion of coal, typically pressurized fluidized bed or gasification cycles, need to clean up the ash particles before passing them through a gas turbine. This prevents severe erosion of the turbine blades and other components. Hot gas cleanup can involve the application of hanging particulate traps, using ceramic filters.

F-class machines: Recent designs of combustion turbines have increased efficiencies resulting from increased firing temperatures. The first generation of these machines has firing temperatures of about 2300°F. They have been termed "F class" machines (for example the GE 7F). Even higher temperatures have now been incorporated into "G-class" turbines. Aeroderivative turbine: in the 1960s, gas turbines derived from military jet engines formed a source of utility peaking capacity. Now modern airline fan jets are being converted to utility service. These lighter combustion turbines are highly efficient and can have low NO_x emissions, high pressure ratios, and low capital cost.

Humid air turbine: A new type of combustion turbine uses humidified compressor exit air for the combustor. The mass of dry air needed is thus lessened for a given mass flow, and turbine efficiency increases. Several applications of this "HAT" appear attractive in gasification and compressed air storage cycles.

Regenerative cycles: Combustion turbine cycles using heat exchangers to store and transfer heat from hot gases to cold gases are termed regenerative cycles.

Recuperative cycle: Recuperative cycles for combustion turbines use walls between the hot and cold streams through which heat is transferred. This improves efficiency and reduces fuel consumption.

Intercooling: Increased output from a combustion turbine can be obtained by cooling the air between compressor stages. This reduces volume flow and increases energy to the power turbine.

Steam injection: Injecting steam directly into the combustion chamber of a combustion turbine increases turbine mass flow and thus increases the output power.

8.7 Energy Storage

Chand K. Jotshi and D. Yogi Goswami

Introduction

Energy storage is very important for utility load leveling, electrical vehicles, solar energy systems, uninterrupted power supply, and energy systems at remote locations. Two important parameters for energy storage are duration of storage and **specific energy** or **energy density**. Duration of energy storage may vary from many years to a fraction of a second. In a nuclear power plant, nuclear fuel is stored within a reactor for a year. Coal piles, gas and oil storage tanks, or pumped hydro are kept by power utilities for several days use, depending upon the need. Similarly for a solar energy system, requirement of energy storage may be on an hourly, daily, or weekly basis. Specific energy or energy density is a critical factor for the size of a storage system.

Energy can be stored as mechanical, thermal, chemical, electrical, or magnetic energy. In this section, storage of thermal, mechanical, and electrical energy are described.

Thermal Energy Storage (TES)

Thermal energy can be stored as sensible heat, latent heat, or as the heat of chemical reaction (thermochemical).

Sensible heat, Q, is stored in a material of mass m and specific heat C_p by raising the temperature of the storage material and is expressed by Equation (8.7.1):

$$Q = mc_p \Delta T \tag{8.7.1}$$

Most common sensible heat storage materials are water, organic oils, rocks, ceramics, and molten salts. Some of these materials along with their physical properties are listed in Table 8.7.1. Water has the highest specific heat value of 4190 J/kg · C.

Thermal energy, Q, can be stored as latent heat in a material of mass, m, that undergoes phase transformation as given by Equation (8.7.2):

$$Q = m\lambda \tag{8.7.2}$$

where λ = heat of phase transformation.

TABLE 8.7.1 Physical Properties of Some Sensible Heat Storage Materials

Storage Medium	Temperature Range, °C	Density (ρ), kg/m^3	Specific Heat (C), J/kg K	Energy Density(ρC) kWhr/m^3 K	Thermal Conductivity (W/m K)
Water	0–100	1000	4190	1.16	0.63 at 38°C

Steric acid	70	203	—	2.35	941	847	48	0.172ℓ

[a] Composition in percent by weight.
Note: ℓ = liquid.

Four types of phase transformations useful for latent heat storage are: solid $\rightleftarrows$ liquid, liquid $\rightleftarrows$ vapor, solid $\rightleftarrows$ vapor, and solid $\rightleftarrows$ solid. Since phase transformation is an isothermal process, thermal energy is stored and retrieved at a fixed temperature known as the transition temperature. Some common phase change materials (PCMs) used for thermal storage are paraffin waxes, nonparaffins, inorganic salts (both anhydrous and hydrated), and eutectics of organic and/or inorganic compounds. Table 8.7.2 lists some PCMs with their physical properties.

Thermochemical energy can be stored as heat of reaction in reversible chemical reactions. In this mode of storage, the reaction in the forward direction is endothermic (storage of heat), while the reverse reaction is exothermic (release of heat). For example,

TABLE 8.7.3 Properties of thermochemical storage media

	Condition of Reaction						
Reaction	Pressure, kPa	Temperature, °C	Component (Phase)	Pressure, kPa	Temperature, °C	Density, kg/m^3	Volumetric Storage Density, kWhr/m^3
$MgCO_3$ (s) + 1200 kJ/kg =	100	427–327	$MgCO_3$(s)	100	20	1500	
MgO (s) + CO_2(g)			$CO_2(\ell)$	7400	31	465	
							187
$Ca(OH)_2$(s) + 1415 kJ/kg =	100	572–402	$Ca(OH)_2$(s)	100	20	1115	
CaO(s) + H_2O(g)			$H_2O(\ell)$	100	20	1000	345
SO_3(g) + 1235 kJ/kg =	100	520–960	$SO_3(\ell)$	100	45	1900	
SO_2(g) + ½O_2(g)			$SO_2(\ell)$	630	40	1320	
			O_2(g)	10000	20	130	280

Note: s = solid, ℓ = liquid, g =gas.

$$A + \Delta H \rightleftarrows B + C \tag{8.7.3}$$

The amount of heat Q stored in a chemical reaction depends on the heat of reaction and the extent of conversion as given by Equation (8.7.4):

$$Q = a_r m \Delta H \tag{8.7.4}$$

where a_r = fraction reacted, ΔH = heat of reaction per unit mass, and m = mass.

Chemical reaction is generally a highly energetic process. Therefore, a large amount of heat can be stored in a small quantity of a material. Another advantage of thermochemical storage is that the products of reaction can be stored at room temperature and need not be insulated. For sensible and latent heat storage materials, insulation is very important. Examples of reactions include decomposition of metal hydrides, oxides, peroxides, ammoniated salts, carbonates, sulfur trioxide, etc. Some useful chemical reactions are reported in Table 8.7.3.

Applications and Examples

Cool Storage has major applications in space cooling of buildings, food and medicine preservation, and transportation of items that need to be stored at low temperatures. A major application of cool storage is in the use of off-peak electricity for air-conditioning during peak hours. During off-peak hours electricity can be used to make ice or chilled water, which can be used later for air-conditioning of buildings during the peak hours. The advantage of using ice as a storage medium over chilled water is that a much larger amount of coolness can be stored in ice; 1 kg of ice stores 335 kJ, whereas 1 kg of water stores only 42 kJ for a temperature swing of 10°C. The disadvantage of ice is its lower thermal conductivity, which is responsible for lower heat-transfer rates.

Cool storage systems have been used in several buildings in the United States and Canada. The Merchandise Mart of Chicago boasts the largest ice storage system in the world: each day more than 1 million kg of ice are made and melted. For long-term cool storage, aquifers have been used for chilled water storage. Examples include cooling of buildings at the University of Alabama and the United States Postal Service in Long Island, NY, using chilled water stored in aquifers (Tomlinson and Kannberg, 1990). Other materials which have been found to have cool storage potential are PCMs like $LiClO_3 \cdot 3H_2O$, a eutectic of Glauber's salt, paraffins and their mixtures, and some gas hydrates or clatherates.

Heat Storage has major applications in space heating, crop drying, cooking, electric power generation, industrial process heat (air and steam), waste heat utilization, and solar energy utilization, etc. Heat storage in water is the most economical and well-developed technology. Epoxy-lined steel, fiberglass-reinforced polymer, concrete with plastic liner, and wood tanks are suitable containment materials for systems using water as the storage material. The storage tanks may be located above or below ground.

In North America and China, aquifers have been used for long-term storage of hot water and chilled water. Pressurized water tanks are used to store heat from off-peak electricity (ASHRAE, 1995). For example, water is heated to maximum temperatures of about 138°C in a tank at a pressure of 50 psig.

Molten nitrate salt (50 wt% $NaNO_3$/50 wt% KNO_3) also known as Draw salt, which has a melting point of 222°C, has been used as a storage and a heat-transfer fluid in an experiment in Sandia National Labs, Albuquerque, NM. It was the first commercial demonstration of generating power from storage (Delameter and Bergen, 1986). Solar Two, a 10-MW solar thermal power demonstration project in Barstow, CA, is also designed to use this molten salt to store solar energy (Chavez et al., 1995). Another molten nitrate salt is 40 wt% $NaNO_2$/7 wt% $NaNO_3$/53 wt% KNO_3, known as HTS (heat-transfer salt) with a melting point of 142°C. This salt has been widely used in the chemical industry.

For applications in heating and cooling of buildings the containment of PCM can become an integral part of the building. It may be part of the ceiling, wall, or floor of the building and may serve a structural or a nonstructural function. Tubes, trays, rods, panels, balls, canisters, and tiles containing PCMs have been studied in the 1970s and 1980s for space-heating applications (Moses and Lane, 1983). The PCMs used were mostly salt hydrates such as Glauber's salt ($Na_2SO_4 \cdot 10H_2O$), Hypo ($Na_2S_2O_3 \cdot 5H_2O$), $NaCH_3COO \cdot 3H_2O$, $Na_2HPO_4 \cdot 12H_2O$, $Ba(OH)_2 \cdot 8H_2O$, $MgCl_2 \cdot 6H_2O$, and $Mg(NO_3)_2 \cdot 6H_2O$. Paraffin mixtures have been used for thermal storage in wall boards. Some PCMs, such as salt hydrates, exhibit supercooling and phase segregation problems during heat removal. Low thermal conductivity and complex mechanism of heat transfer during melting and freezing introduce complexities in the design of their containment systems.

Mechanical Energy Storage

Mechanical energy may be stored as potential or kinetic energy.

Kinetic Energy

Kinetic energy can be stored in the rotating mass of a wheel, commonly known as a flywheel. Kinetic energy of a rotating body is given by Equation (8.7.5):

$$KE = \frac{1}{2} I \omega^2 \tag{8.7.5}$$

where I = moment of inertia, and ω = angular velocity.

The maximum specific energy of a flywheel is expressed by the following equation (Jensen, 1980):

$$\frac{KE_{\max}}{m} = A \frac{\rho_{\max}}{\rho} \tag{8.7.6}$$

where A = shape factor, and its value depends on the geometry of flywheel; A = 1.0 for a constant stress disk and 0.5 for a thin-rimmed flywheel. This equation shows that high tensile strength and low density are the key parameters to store maximum energy. Tensile strength, density, and specific energy of some materials are given in Table 8.7.4.

Storing energy in a flywheel is one of the oldest techniques used in ancient potteries. Present-day flywheels are much more advanced as a result of superstrong/ultralight composite materials and frictionless high-performance magnetic bearings.

Potential Energy

If a body of mass m is elevated against the gravitational force g to a height Δh, the potential energy stored is given by

$$\mathrm{PE} = mg\Delta h \tag{8.7.7}$$

TABLE 8.7.4 Flywheel Rotor Materials

Material	Design Stress, MN/m^2	Density, kg/m^3	Specific Energy, Whr/kg
Composite fiber[a]/epoxy	750	1550	51.5
E-glass fiber[a]/epoxy	250	1990	14.0
S-glass fiber[a]/epoxy	350	1900	19.6
Kevlar fiber[a]/epoxy	1000	1400	76.2
Maraging steel	900	8000	24.2
Titanium alloy	650	4500	30.8

[a] 60% fiber.

From Equation (8.7.7), 1 Wh of energy can be stored in 1 kg mass of a body by raising it to a height of 367 m.

Potential energy is also stored in a spring, either by compressing or expanding. Here, energy stored is given by

$$\mathrm{PE} = (1/2)kx^2 \tag{8.7.8}$$

where k = spring constant and x is the distance to which the spring is compressed or expanded. Springs have been widely used to power toys and watches mainly because of very low values of energy density.

Pumped Hydro

Water may be pumped from a lower reservoir to a higher reservoir using electricity during off-peak hours, which may be used to generate electricity using hydraulic turbines during peak hours. Advantages of pumped hydro units include simple operation, high reliability, low maintenance, long life, quick start from standstill, and economic generation of peaking electrical energy. In the United States a large number of such systems are in operation. Power-generating capacities of these systems vary between 5 and 2000 MW (Makansi, 1994). The overall efficiencies of these power plants vary between 65 and 90%, which includes the efficiencies of pumps, hydraulic turbines, generators, and losses from the upper reservoir. In spite of the technical and economic viability of pumped hydro, the requirement of a specific type of topography and some environmental concerns limit its application.

Electrical Energy Storage

Electrochemical energy storage, more commonly known as battery storage, stores electrical energy as chemical energy. Batteries are classified as primary and secondary batteries. Only secondary batteries are rechargeable and are therefore suitable for energy storage applications. Lead-acid and nickel-cadmium are well-known rechargeable batteries that are most commonly used. Lead-acid batteries have been used for over a century and are still the most popular batteries.

Electrochemical operation of a cell during discharge and charge is shown in Figure 8.7.1a and Figure 8.7.1b. During discharge when a cell is connected to a load, electrons flow from the anode to the cathode. In this operation oxidation, or loss of electrons, takes place at the anode, and reduction, or gain of electrons, occurs at the cathode. The cell chemistry of a lead-acid battery is as follows: the anode is lead (Pb) and the cathode is lead oxide (PbO_2); the electrolyte is H_2SO_4. The cell reaction is

$$2H_2SO_4 \rightarrow 4H^+ + 2SO_4^-$$

$$\text{Anodic reaction:} \quad Pb + SO_4^{2-} = PbSO_4 + 2e^- \tag{8.7.9}$$

$$\text{Cathodic reaction:} \quad PbO_2 + SO_4^{2-} + 4H^+ + 2e^- = PbSO_4 + 2H_2O \tag{8.7.10}$$

Theoretical voltages and capacities of some known batteries are reported in Table 8.7.5.

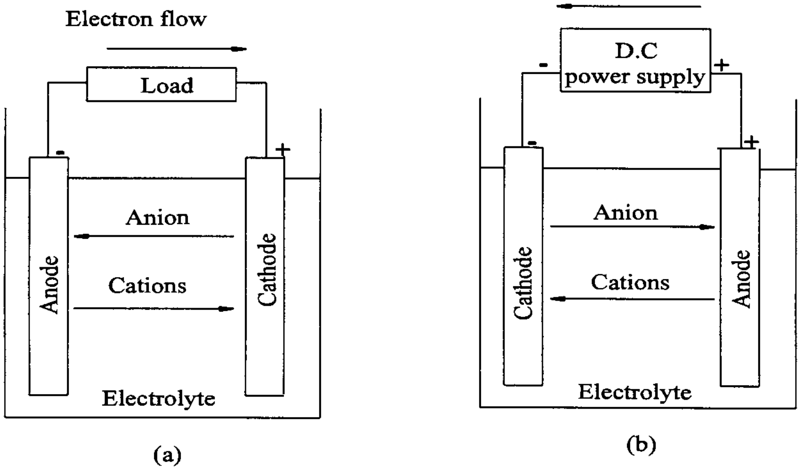

FIGURE 8.7.1 Electrochemical operation of a cell: (a) discharge; (b) charge.

TABLE 8.7.5 Properties of Some Rechargeable Batteries

No.	System	Electrolyte	Temp. °C	O.C.V. (V)	Energy Density (Theoretical), Whr/kg	Energy Density (Achievable), Whr/kg	In/Out Electrical Effciency	Cycle Life
1	Lead-Acid	H_2SO_4	20–30	2.05	171	50	75	1000
2	Nickel-Iron	KOH	20–30	1.37	267	60	55	2000

Note: O.C.V. = open cell voltage.

Applications

Battery storage is used in a wide range of applications. Currently, the main emphasis of research is on applications in vehicles and load leveling.

Electric Vehicles. For electric vehicles, the specific energy and specific power are two important parameters. The greater the specific energy, the farther a vehicle can travel. If specific power is high, a vehicle can accelerate more quickly and have a higher top speed. Other important requirements are the ability to charge and discharge a large number of times, to retain charge over an extended period of time, and to charge and discharge over a wide range of temperatures. Table 8.7.5 provides information about some rechargeable batteries.

Power Plants. Recent start-up of a commercial unit for the Puerto Rico Electric Power Authority (PREPA) is the latest development in large-scale application of lead-acid batteries. The facility stores 20 MW for 20 min, both for peaking requirement and voltage and frequency control. Maximum discharge is limited to 10 MW (Makansi, 1994).

Defining Terms

Cool storage: The storage of thermal energy at temperatures below the nominal temperature required by the space or process.

Heat storage: The storage of thermal energy at temperatures above the nominal temperature required by the space or process.

Energy density: Amount of energy stored per unit volume, kJ/m^3 or kWh/m^3.
Specific energy: Amount of energy stored per unit mass, kJ/kg or kWh/kg.

8.8 Nuclear Power

Roberto Pagano and James S. Tulenko

Nuclear power refers to power generated through reactions involving atomic nuclei (i.e., nuclear reactions). These reactions fall into three broad categories — fusion reactions, fission reactions, and radioisotopes. In fusion, two light nuclei (most commonly isotopes of hydrogen) combine to form a heavier nucleus (usually helium), with energy being released in the process. Nuclear fusion is the source of energy generated in the stars (our sun). In artificial applications, the technology to induce fusion reactions has been available for several decades, but such reactions have been essentially uncontrolled (the hydrogen bomb). Once initiated, fusion reactions generate huge amounts of energy, which is subsequently released explosively. Means to produce and release energy from fusion in a sustained, controlled manner are still being developed. Extensive research is ongoing, both in the United States and abroad, on the development of nuclear fusion as a controlled source of power.

Nuclear fission, in contrast, is the basis of a mature technology applied to the generation of power. Fission is the fragmentation of a heavy nucleus into two, sometimes three, lighter nuclei. Certain nuclides found in nature fission spontaneously, that is, with no external intervention. However, spontaneous fission in naturally occurring nuclides takes place at a very slow rate. Fission can be induced through a nuclear reaction. Of primary interest here is the fissioning of several specific nuclei through interactions with neutrons. Again, the fissioning of a nucleus is accompanied by the release of energy.

At present, the element of primary importance with respect to nuclear fission power is uranium. Naturally occurring uranium consists of three isotopes — ^{238}U, ^{235}U, and ^{234}U. In a mixture of isotopes of an element, the abundance of any one is usually expressed as the number of atoms of that isotope present per 100 atoms of the mixture, abbreviated as atom percent a/o or weight percent w/o. Natural uranium consists of 99.2745 a/o ^{238}U, 0.7200 a/o ^{235}U, and 0.0055 a/o ^{234}U.

Radioisotope power is the third form of nuclear energy. When radioisotopes decay, high-energy electrons (beta particles), helium atoms (alpha particles), and gamma rays (photons) are emitted. When the energy of these radiations is stopped and converted to heat, a power source is created. Radioisotopes decay energies range from 0.01 to 10 MeV. Radioisotopes are generally separated from radioactive wastes produced from nuclear power plants. The most common radioisotopes are polonium-210 (alpha emitter of 5.3 MeV), plutonium-238 (alpha emitter of 5.46 MeV), cesium-144 (beta emitter of 1.25 MeV), and strontium-90 (beta emitter of 1.10 MeV).

The Fission Process

Consider first the fission of a nucleus of ^{235}U caused by an interaction with a neutron. A compound nucleus of ^{236}U is initially formed. If fission occurs, it does so within a very short time. Normally with thermal reaction, 85% of the interaction leads to fission. Alternatively, the compound nucleus dissipates energy by emitting a gamma photon, no fission occurs and the nucleus remains as ^{236}U. This latter process occurs in 20% of the interaction of ^{235}U with a neutron.

The fissioning of a nucleus produces fission fragments called fission products, a number of neutrons and gamma photons. Most frequently, the number of neutrons is 2 or 3, ranging in extreme cases from 0 to 8. In the fissioning of ^{235}U, the average number of neutrons released, designated by υ, has a value of 2.42. This value applies strictly if the fission is induced by a neutron of relatively low kinetic energy, called a thermal neutron.

In a nuclear reactor, which is a special material medium in which ^{235}U is dispersed for the reactor to work, one of the neutrons liberated in the fissioning of a nucleus must go on to induce a fission in another nucleus. This leads to the idea of a self-sustaining chain reaction or, more specifically, a **critical configuration** in which a self-sustaining chain reaction can be maintained indefinitely. To this end, an adequate supply of ^{235}U must be on hand and replenished as needed. Further, the configuration must be such that the likelihood that any particular neutron ultimately induces a fission is adequately high to ensure that on average one neutron will induce a fission.

The energy liberated in fission results from Einstein's equation $E = Mc^2$, which says that mass and energy are equivalent. A summation of the masses of the fission fragments and the neutrons resulting from fission shows that the combined mass of the products of a fission is less than the mass of the compound nucleus before fission occurs. It is found that the energy released is equal to $E = \Delta Mc^2$ when ΔM is the difference in the masses. This nuclear energy is traditionally expressed in units of electron volts (eV), with the equivalence of $1 \text{ eV} = 1.602 \times 10^{-19}$ J. The single fission of a single uranium atom releases approximately 200×10^6 eV, or 200 MeV, of energy. When one realizes that the combusion of a single carbon atom ($C + O_2 \rightarrow CO_2$) releases 4 eV, a quantity 50 million times smaller, one gets a true appreciation of the concentrated power of nuclear energy.

Most of the energy liberated in a fission appears as the kinetic energy of the fission fragments (168 MeV, or 84%) and the kinetic energy of the neutrons (5 MeV, or 2.5%). The remainder is distributed among the gamma photons appearing instantaneously with the fission and the energy associated with the radioactive decay of the fission fragments. These fragments are readily stopped in the reactor. Their range is of the order of 0.01 to 0.001 mm. Thus, the major portion of the energy from a fission is deposited within a very short distance from the site of the fission.

In the largest power reactors in operation in the United States today, heat is generated at the rate of 3800 MW. At 200 MeV per fission, fissioning in such reactors must occur at the rate of 1.2×10^{20} fissions/sec to produce the power. In terms of ^{235}U, this requires the fissioning of all the nuclei contained in 0.047 g of ^{235}U, or the fissioning of approximately 4 kg per day. Thus, as a rule of thumb, the fissioning of all the nuclei present in 1 g of ^{235}U is sufficient to generate 1 MW day of thermal energy. In contrast, the generation of the same amount of energy from coal requires the combustion of 4 tons of coal of typical heating value. With the combustion of coal there is the associated release of a large quantity of carbon dioxide (~14 tons) to the atmosphere with its effects on global warming.

Cross Sections

A measure of the probability of a particular nuclide to interact with a neutron is provided by a quantity known as a **cross section**. Numerical values of cross sections are determined experimentally and are expressed in units of barns (b), with 1 b defined as 10^{-24} cm^2, or 10^{-28} m^2.

As a quantity, a cross section may be interpreted as a target area — the larger the cross section, the more likely the interaction of the nucleus with a neutron in its vicinity. For example, the cross section for fission of ^{235}U, denoted by σ_f^{235}, has a value of 582 b if the interacting neutron is traveling at the velocity associated with thermal energy (2200 m/sec). If the neutron is traveling at high energy, the cross section may drop to a value of approximately 2 b. With respect to the radiative capture of a neutron in ^{235}U leading to the formation of ^{236}U, the cross section is given by $\sigma_c^{235} = 99$ b, if the neutron is thermal. In summary, a cross section is a property specific to a given nuclide, but it is a property whose value depends on the energy of the interacting neutron.

Cross sections are additive. Thus, the cross section for the absorption of a thermal neutron in ^{235}U — whether the absorption gives rise to a fission or a radiative capture — is given by $\alpha_a = \alpha_f + \alpha_{\mathrm{c}} = 582$ b + 99 b = 681 b. Further, the probability of a fission occurring as a result of a thermal neutron being absorbed in ^{235}U is given by α_f/α_a = 582 b/681 b = 0.85. Fission is, therefore, the more likely outcome of an interaction between a ^{235}U nuclide and a thermal neutron.

On average, the neutrons arising from the fissioning of ^{235}U have a kinetic energy of 2 MeV, corresponding to a speed of 2×10^7 m/sec. These neutrons are four orders of magnitude greater than the speed at which a neutron is considered to be thermal (2200 m/sec).

Categories of Nuclear Reactors

A prerequisite for a self-sustaining chain reaction is that sufficient ^{235}U be present in the medium to ensure that the absorption of a neutron in a nucleus of ^{235}U is a likely occurrence. If the population of neutrons present in the medium at any instant consists predominantly of slow neutrons, a far lesser amount of ^{235}U is needed to ensure criticality than would be the case if the population were to consist of fast neutrons. This comes about because of the difference in the values of the cross sections mentioned previously.

There is, from this particular standpoint, an incentive to slow down the neutrons originating in fission in order to reduce the inventory of ^{235}U needed to maintain criticality. In the power reactors operating today, means are provided to slow down the neutrons. The slowing down is effected through multiple elastic scatterings of the neutrons with the nuclei of light elements deliberately present in the medium acting as so-called **moderators**. Notable among such elements are hydrogen present in water, deuterium in heavy water, and carbon in the form of graphite.

All of the reactors in which substantive moderation of the neutrons occurs are categorized as **thermal reactors**. This term stems from the distinguishing feature that the neutron population is in, or near, thermal equilibrium with the nuclei of the moderator. As a consequence, there is no net exchange of energy between the neutron population and its surroundings. The neutrons are then referred to as thermal neturons.

In a population of **thermal neutrons**, the distribution of the speeds of the neutrons is characterized, adequately in many cases, by the Maxwell-Boltzmann distribution, originally formulated to apply to the molecules of an ideal gas. According to this distribution, the most probable speed of the neutrons at the reference temperature of 20°C is 2200 m/sec and the kinetic energy corresponding to the most probable speed is 0.025 eV.

Reactors that are not thermal reactors fall in the category of **fast reactors**. In these reactors, the moderation of neutrons is much reduced for reasons discussed later.

Nuclear Fuel

In light-water reactors (LWR), the type of power reactors most commonly in service today, the nuclear fuel is uranium with a content of 2 to 4% of ^{235}U. This fuel is produced by enriching natural uranium in ^{235}U by one of several technologies, principally gaseous diffusion and gaseous centrifugation (Benedict et al., 1981). Neutrons of all energies, down to and including thermal energies, can induce fission in ^{235}U. For this reason, ^{235}U is said to be fissile.

In contrast, ^{238}U, present to the extent of 96 to 98% in the fuel, can be fissioned to a significant extent by neutrons with energies in excess of a threshold of roughly 2 MeV. Fissions of ^{238}U, referred to as fast fissions, play only a slight role in the chain reaction in an LWR. However, ^{238}U absorbs neutrons radiatively to yield ^{239}U. This nuclide is radioactive and decays to ^{239}Np which, in turn, decays to ^{239}Pu, a **fissile nuclide**. Thus, in LWR fuel ^{239}Pu, produced from ^{238}U, is available for fissioning by neutrons of all energies and contributes to the chain reaction. Because of its ability to form fissile ^{239}Pu, ^{238}U is termed a **fertile nuclide**.

Conversion and Breeding

To characterize the unique capability of nuclear fuel simultaneously to produce and consume fissile material, a figure of merit known as the **conversion ratio** (CR) is informative. It is defined by the relation:

$$\mathrm{CR} = \frac{\text{number of fissile nuclei produced from fertile nuclei}}{\text{number of fissile nuclei consumed}}$$

In fuel irradiated in an LWR, the conversion ratio typically has a value of 0.5. If the appropriate combination of materials, design, and operating parameters could be found to raise the conversion ratio to a value greater than unity, a reactor would become a breeder reactor, that is, one that produces more fissile material than it consumes in its operation.

To illustrate the possibility of breeding, consider a parameter known as the reproduction factor and given by

$$\eta = \nu \frac{\text{number of neutrons causing fission in fuel}}{\text{total number of neutrons absorbed in fuel}} = \nu \frac{\sigma_f^{\text{fuel}}}{\sigma_a^{\text{fuel}}}$$

In the case of ^{235}U and thermal neutrons, the value of η is given by $\eta_{235} = 2.42 \times 582/(589 + 99) = 2.42 \times 0.85 = 2.07$.

If a chain reaction is to be self-sustaining in a reactor, the condition $\eta > 1$ must apply. To achieve breeding requires that $\eta > 2$. In other words, one neutron from fission would be available to sustain the chain reaction and another to produce a fissile nucleus from a fertile nucleus. Practical considerations indicate that the value of η must be substantially greater than 2, since neutrons will be lost by absorption in structural materials, heat removal medium, fission fragments, the moderator, if present, and by escaping from the physical confines of the reactor.

As shown, ^{235}U has a value of η slightly above 2 with neutrons at thermal energies. Breeding or near-breeding conditions could arise, in principle, if very judicious choices of materials and parameters prevail. A more attractive fuel from the standpoint of breeding is ^{233}U. This isotope of uranium is produced artificially by placing the naturally occurring nuclide ^{232}Th in a reactor. A radiative capture of a neutron in ^{232}Th leads to the formation of the radioactive nuclide ^{233}Th. Two successive radioactive decays yield ^{233}U. In a thermal reactor, the value of η with ^{233}U is 2.29, approaching the level where breeding might be contemplated. Intermediate between the two fissile isotopes of uranium is ^{239}Pu, which at thermal energies yields a value of η of 2.15.

Figure 8.8.1 shows the behavior of η as the energy of the neutrons inducing fission increases. A little above thermal energies the value of η for ^{239}Pu and ^{235}U drops below 2, indicating that breeding is impossible at such energies. As energy increases, the values of η for both reache the threshold of 2 and continue to increase steadily, with ^{239}Pu clearly the more attractive fuel from the standpoint of breeding. The value of ^{239}Pu for ^{235}U is relatively insensitive to increases in energy and remains continuously above 2. Again, at higher energies, η is the more attractive fuel.

Research on the development of **breeder reactors** has focused on the ^{239}Pu fuel cycle, both in the U.S. and abroad. Representative of these reactors is the liquid metal fast breeder reactor (LMFBR) in which

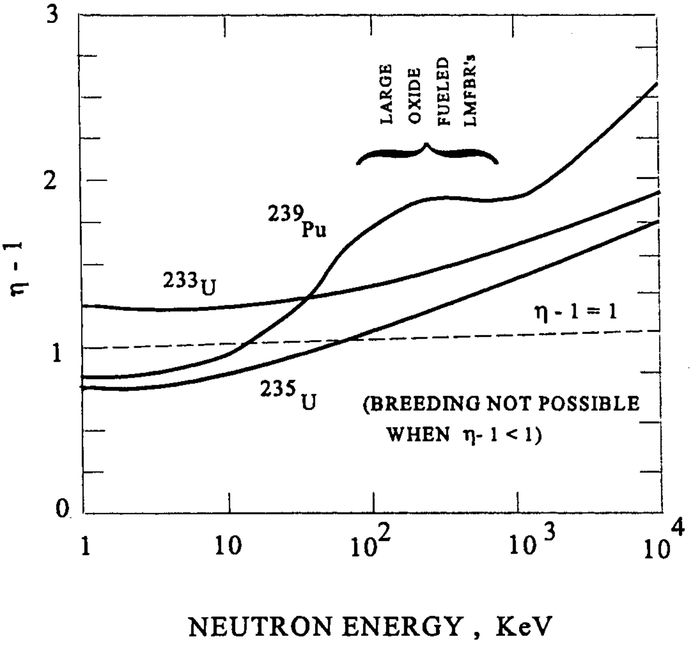

FIGURE 8.8.1 Dependence of reproduction factor of neutron energy.

liquid sodium is the heat-removal fluid and provides the small amount of moderation needed. Breeder reactors with ^{233}U as fuel, represented by an adaptation of the high-temperature gas-cooled reactor (HTGCR), in which the heat-removal fluid is helium and the moderator is graphite, although less attractive, in principle, as breeders, might with further research and development prove to be viable alternatives to the LMFBR.

LWR Fuel

Nuclear fuel in light water is in the form of small cylindrical pellets of the ceramic UO_2, with the uranium enriched to 2 to 4% in ^{235}U, as mentioned previously. These pellets are stacked vertically in tubes and the ends of the tubes are sealed off. The dimensions and further details given here apply strictly to the more common type of LWR, known as the pressurized water reactor (PWR), but may be taken as generally representative of LWRs.

The tubes containing the fuel pellets are referred to as fuel rods. They are 4.3 to 4.7 m in length and 0.0095 m in outside diameter. An array typically of 17 × 17 rods constitutes a fuel assembly, as shown in Figure 8.8.2. Certain fuel rods within the assembly are replaced by guide sheaths in which absorber rods can be moved vertically. These rods absorb neutrons, thus providing one of the means of controlling the chain reaction as the rods are inserted or withdrawn. Within the fuel assembly the fuel rods are placed on a pitch of 0.0127 m, leaving vertical passages through which water can flow. A total of approximately 200 fuel assemblies, juxtaposed to form a roughly cylindrical configuration constitute the core of the reactor. Water is circulated through the core where the water serves both to moderate the neutrons and to remove the heat generated by fissions in the nuclear fuel.

Light-Water Reactors

LWRs currently make up the largest portion of the installed nuclear generating capacity throughout the world. Among these, the PWRs are more numerous. By operating at a sufficiently high pressure, bulk boiling of the reactor coolant is suppressed in a PWR. In contrast, the coolant is allowed to boil in a boiling water reactor (BWR) and a portion of the coolant is converted to steam as it circulates through the core.

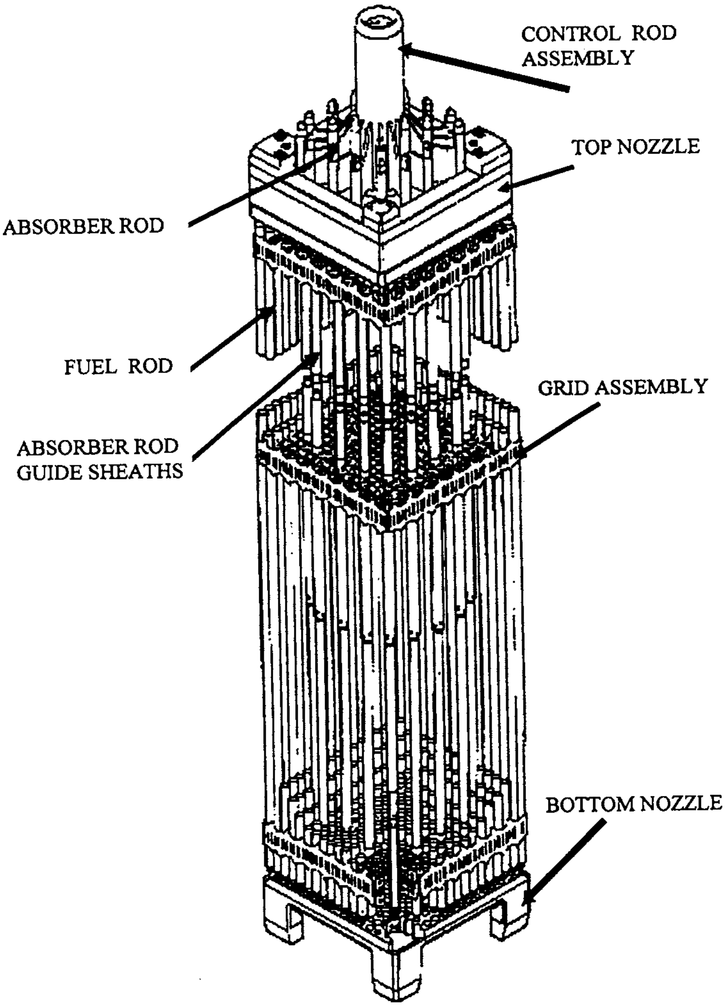

FIGURE 8.8.2 PWR fuel assembly.

Pressurized Water Reactors

A schematic of a PWR system is shown in Figure 8.8.3. At the heart of the system is the core made up of fuel assemblies and associated control rods. The core is contained in a reactor vessel, or pressure vessel, designed to operate at a pressure typically of 15.5 mPa. Water is circulated through the core where it acts as a moderator and also removes the heat generated through fission. Typical operating temperatures at full power are 295°C at the inlet and 330°C at the outlet, an increase of 35°C as a result of the water passing through the core.

From the reactor vessel, the coolant is circulated to steam generators and returned to the reactor vessel to complete the so-called primary loop. This loop constitutes the nuclear steam supply (NSS). Steam emerging from the steam generators is directed toward the secondary loop, or balance of plant, consisting of turbine generator, condenser, and feedwater pumps. Extremely small quantities of radioactive contaminants may be present in the steam generated in PWRs, and all releases to the environment from the secondary side of the plant are carefully monitored and controlled. Otherwise, steam from the NSS differs from steam generated in fossil fueled plants only inasmuch as its grade is inferior.

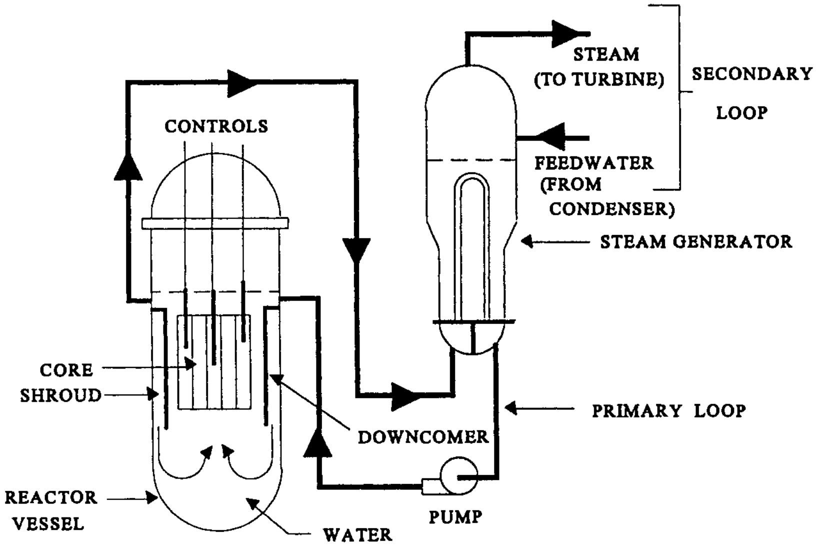

FIGURE 8.8.3 Schematic of a pressurized water reactor.

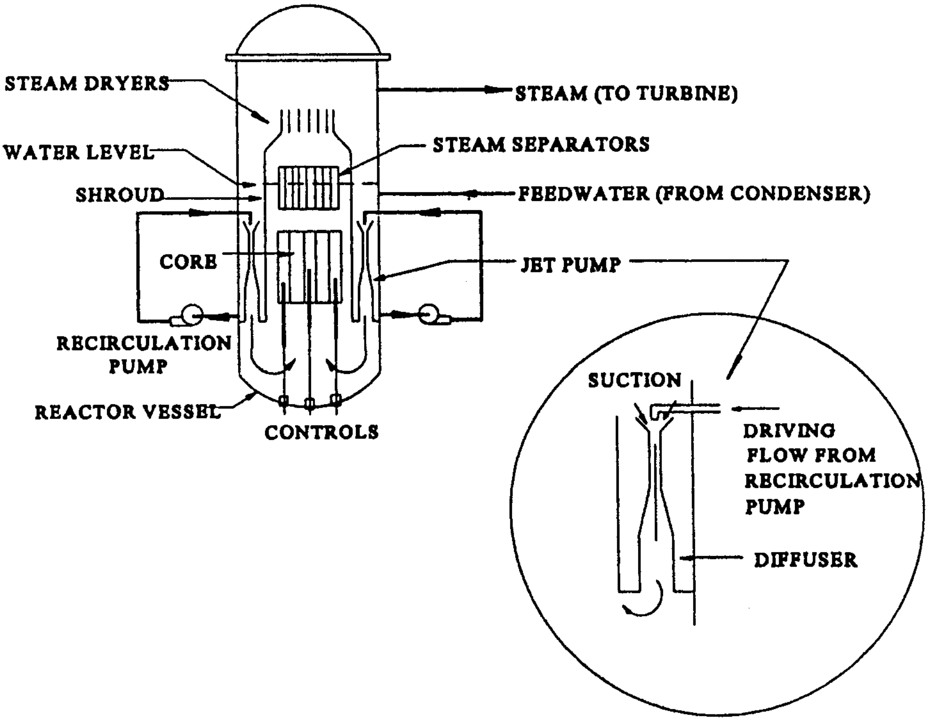

FIGURE 8.8.4 Schematic of a boiling water reactor.

Boiling Water Reactors

Figure 8.8.4 is a schematic of a BWR system. A reduced operating pressure of 7.2 MPa causes a portion of the coolant to flash to steam. Steam separators and driers allow dry steam to emerge from the reactor vessel, thus eliminating the need for separate steam generators and a secondary loop. Steam from the reactor vessel flows through a turbine generator and condenser, from which circulating pumps return the condensate to the reactor. Large quantities of radioactive contamination may be present in the steam produced by a BWR because of the direct cycle, so releases must be carefully monitored. A distinguishing feature of the BWR are the jet pumps, typically 24 in number, placed along the periphery of the core. These pumps augment the flow of coolant through the core.

Defining Terms

Breeder reactors: Reactors in which the conversion ratio is greater than unity.
Conversion ratio: The ratio of the number of fissile nuclei produced in a reactor to the number of fissile of nuclei consumed.
Critical configuration: A medium containing nuclear fuel in which a self-sustaining chain reaction can be maintained.
Cross section: A numerical quantity, determined experimentally, related to the probability that a specific nuclide will undergo a given nuclear reaction.
Fast reactors: Reactors in which little moderation of the neutrons occurs and the neutron populations consist of neutrons of relatively high speeds.
Fertile nuclide: A nuclide that, through the absorption of a neutron and subsequent radioactive decays, can produce a fissile nuclide.
Fissile nuclide: A nuclide that can be fissioned by neutrons of all energies, down to and including thermal energies.
Moderator: A component of a reactor present expressly to slow down neutrons and produce a population of thermal neutrons.
Thermal neutrons: A population of neutrons in, or near, thermal equilibrium with the nuclei of a medium in which the populations exists.
Thermal reactors: Reactors in which the neutron populations consist predominantly of thermal neutrons.

8.9 Nuclear Fusion

Thomas E. Shannon

Introduction

Nuclear fusion holds the promise of providing almost unlimited power for future generations. If the process can be commercialized as envisioned by reactor design studies (Najmabadi et al., 1994), many of the problems associated with central electric power stations could be eliminated. Fusion power plants would not produce the pollution caused by the burning of fossil fuel and would eliminate the concern for meltdown associated with nuclear fission. The amount of radioactive waste material produced by a fusion reactor will be much less than that of a fission reactor since there is essentially no radioactive ash from the fusion reaction. If **low activation advanced materials** such as silicon carbide composites can be developed for the reactor structural material, the problem of disposal of activated components can also be eliminated.

Fusion Fuel

Although a number of different atomic nuclei can combine to release net energy from fusion, the reaction of **deuterium and tritium** (D-T) is the basis of planning for the first generation of fusion reactors. This choice is based on considerations of reactor economy. The D-T reaction occurs at the lowest temperature, has the highest probability for reaction, and provides the greatest output of power per unit of cost (Shannon, 1989). The disadvantages of D-T as a fusion fuel are twofold. Tritium does not occur naturally in nature and must be bred in the fusion reactor or elsewhere. Second, tritium is a radioactive isotope of hydrogen with a relatively long **half-life** of 12.3 years. Since tritium can readily combine with air and water, special safety procedures will be required to handle the inventory necessary for a fusion reactor. There is hope that a less reactive fuel, such as deuterium alone (D-D) will eventually prove to be an economically acceptable alternative (Shannon, 1989).

Confinement Concepts

Magnetic fusion, based on the tokamak concept, has received the majority of research funding for fusion energy development. However, other magnetic fusion concepts, such as the stellarator, the spherical torus, reversed-field pinch, and field-reversed configurations, are being developed as possible alternatives to the tokamak (Sheffield, 1994). It may also be possible to develop fusion power reactors by inertial confinement concepts (Waganer et al., 1992). Research on these concepts has been done primarily in support of weapons development; therefore, the level of scientific understanding for power reactor applications is significantly less than that of magnetic fusion. The remainder of this discussion on reactor development, fusion energy conversion, and transport will consider only the tokamak magnetic fusion concept.

Tokamak Reactor Development

The tokamak device has proved to be the most effective means of producing the conditions necessary for magnetic fusion energy production. In 1994, researchers at the Princeton Plasma Physics Laboratory achieved in excess of 10 MW of D-T fusion power in a research tokamak, the Tokamak Fusion Test Reactor (TFTR). This accomplishment, coupled with worldwide progress in 40 years of magnetic fusion research, has established the scientific feasibility of the tokamak concept. The next major step, the International Thermonuclear Experimental Reactor (ITER) is being carried out under an international agreement among Europe, Japan, Russia, and the United States (Conn et al., 1992). A drawing of the ITER tokamak is shown in Figure 8.9.1. If the project is approved for construction, it will be in operation around 2005. The ITER is being designed to produce a fusion power in excess of 1000 MW. This will be a significant step on the path to commercial fusion power.

The U.S. Department of Energy has proposed a strategy, shown in Figure 8.9.2, which will lead to a demonstration power reactor by the year 2025. Supporting research and development programs necessary to achieve this goal are shown in this figure.

Fusion Energy Conversion and Transport

The energy from fusion is created in the form of charged particles and neutrons. The D-T reaction produces a neutron with an energy of 14.1 MeV and an alpha particle (helium) with an energy of 3.5 MeV in the reaction

$$\mathrm{D} + \mathrm{T} \rightarrow \mathrm{He}^4\ (3.5\ \mathrm{MeV}) + \mathrm{n}(14.1\ \mathrm{MeV})$$

In the tokamak device, the reaction will take place in the toroidal vacuum vessel as previously shown in the ITER drawing, Figure 8.9.1. The D-T fuel, in the form of a **plasma**, will absorb energy from the positively charged alpha particles to sustain the temperature necessary for the reaction to continue. The neutron, having no charge, will escape from the plasma and pass through the wall of the vessel and

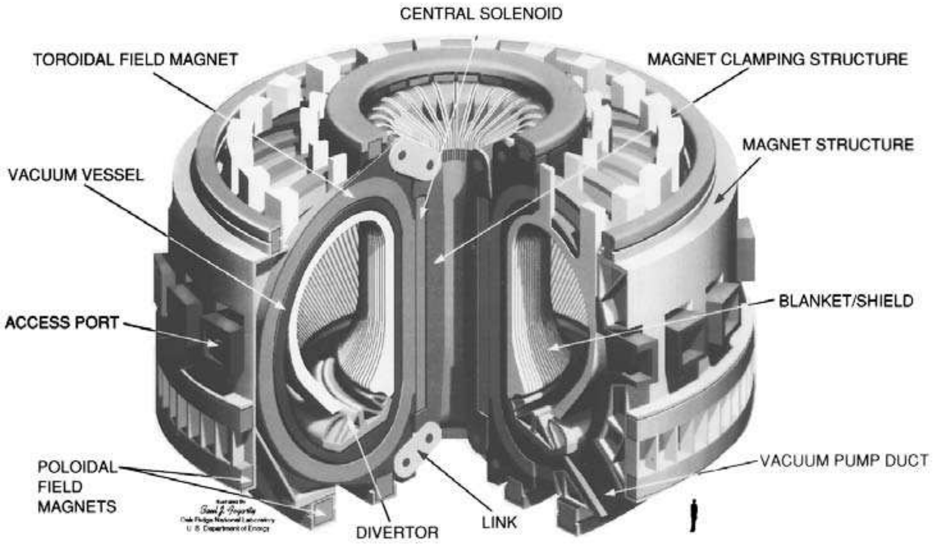

FIGURE 8.9.1 The International Thermonuclear Experimental Reactor (ITER).

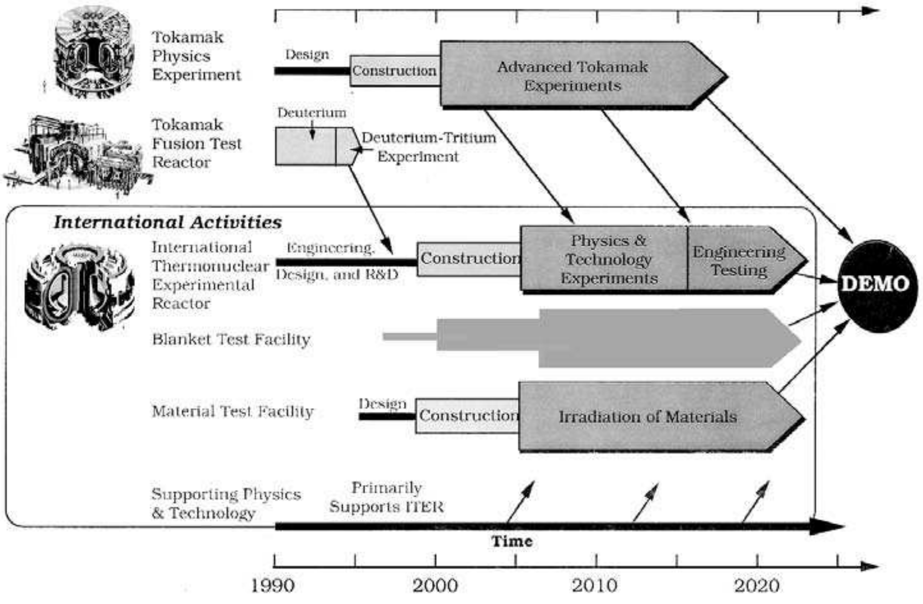

FIGURE 8.9.2 The U.S. Department of Energy magnetic fusion energy strategy.

penetrate into the surrounding blanket/shield structure. The kinetic energy of the alpha particles from the fusion reaction is eventually deposited on the wall of the vacuum vessel by radiation and conduction heat transfer from the plasma while the neutron deposits most of its energy within the cross section of the blanket/shield. The resulting thermal energy is transferred by a coolant such as water to a steam generator where a conventional steam to electric generator system may be used to produce electricity. An overall schematic diagram of the energy conversion and heat-transport system is shown in Figure 8.9.3.

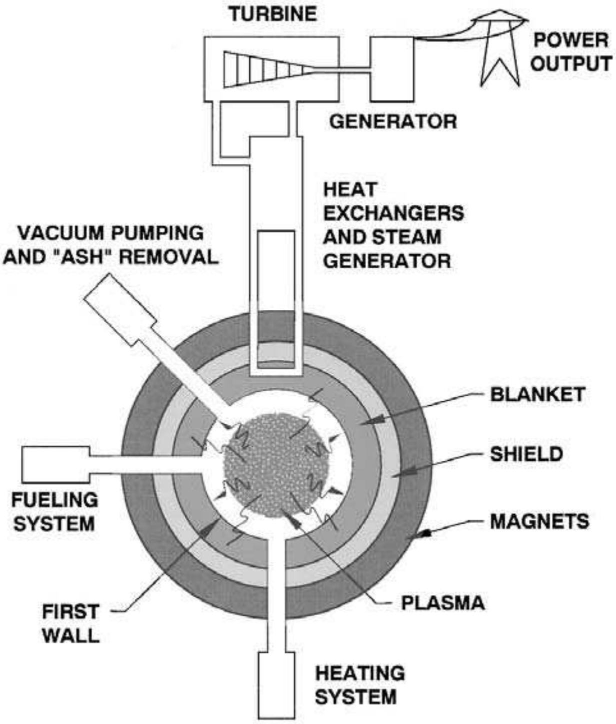

FIGURE 8.9.3 Schematic Diagram of a Magnetic Fusion Reactor Power Plant.

Defining Terms

Deuterium and tritium: Isotopes of hydrogen as the fuel for fusion reactors.

Half-life: The time required for half of the radioactive material to disintegrate.

Low activation advanced materials: Structural materials that significantly reduce the radioactivity induced by exposure to fusion neutrons.

Plasma: A gas such as a mixture of deuterium and tritium raised to a very high temperature at which the electrons and the nuclei of the atoms separate. The plasma, consisting of electrons and ions, can conduct electricity and react to magnetic fields.

8.10 Solar Thermal Energy Conversion

D. Yogi Goswami

Introduction

Solar thermal energy applications such as space and water heating have been known for a long time. Researchers over the past few decades have developed a number of additional solar thermal applications, such as industrial process heat, refrigeration and air-conditioning, drying and curing of agricultural products, and electric power production by solar thermal conversion. This section will cover solar thermal energy conversion including solar thermal collectors and conversion systems.

Solar Thermal Collectors

A simple **solar thermal collector** consists of (1) an absorber surface (usually a dark, thermally conducting surface), (2) some insulation behind the absorber to reduce heat loss, (3) a trap for thermal reradiation from the surface such as glass, which transmits the shorter-wavelength solar radiation but blocks the longer-wavelength radiation from the absorber, and (4) a heat-transfer medium such as air, water, etc. High-temperature collectors require reflectors of sunlight that concentrate solar radiation on the absorber. The technology of solar collectors is developed to achieve temperatures as high as 1000°C or even higher. The design of a solar collector and the choice of working fluids depend on the desired temperature and the economics of the application. Table 8.10.1 lists the types of solar thermal collectors based on their temperature range.

Flat Plate Collectors

Flat plate collectors may be designed to use liquids (water, oil, etc.) or air as the heat-transfer fluid. Figure 8.10.1 shows a typical liquid-type flat plate collector. The choice of materials for glazing and absorber needs special attention.

Glazing. The purpose of **glazing** is to (1) transmit the shorter-wavelength solar radiation, but block the longer-wavelength reradiation from the absorber plate, and (2) reduce heat loss by convection from the top of the absorber plate. Glass is the most widely used glazing material. Transmittance of low iron glass in the visible and near infrared wavelength range can be as much as 91%, while for the longer-wavelength radiation (>3 μm) its transmittance is almost zero. Other materials that can be used as glazings include certain plastic sheets such as polycarbonates (Lexan® and Tuffac® — transmittance ~75%), acrylics (Plexiglass® and Lucite® — transmittance ~92%), and thin plastic films such as polyethylene. A major advantage of the plastics is that they are shatterproof; however, they scratch easily and lose transparency over time.

Absorbers. Copper is the most common material used for absorber plates and tubes because of its high thermal conductivity and high corrosion resistance. For low-temperature applications such as swimming pool heating, a plastic material called ethylene propylene polymer (trade names EPDM, HCP, etc.) can be used to provide inexpensive absorber material. To compensate for low thermal conductivity of these

TABLE 8.10.1 Types of Solar Collectors and Their Typical Temperature Range

Type of Collector	Concentration Ratio	Typical Working Temperature Range (°C)
Flat plate collector	1	≤70
High-efficiency flat plate collector	1	60–120
Fixed concentrator	2–5	100–150
Parabolic trough collector	10–50	150–350
Parabolic dish collector	200–2000	250–700
Central receiver tower	200–2000	400–1000

TABLE 8.10.2 Absorptivity and Emissivity of Common Selective Surfaces

Surface	Absorbtivity	Emissivity
Black chrome	0.95	0.1
Black nickel	0.9	0.08
Copper oxide	0.9	0.17
Lead sulfide	0.89	0.2
Flat black paint	0.98	0.98

Source: Compiled from Goswami, D.Y., Kreith, F., and Kreider, J., *Principles of Solar Engineering,* Taylor and Francis, Washington, D.C., 2000.

materials, a large surface area is provided for heat transfer. In order to increase the absorption of solar radiation and to reduce the emission from the absorber, the metallic absorber surfaces are painted or coated with flat black paint or some selective coating. Absorptivities and emissivities of some common **selective surfaces** are given in Table 8.10.2.

Evacuated Tube Collectors. Evacuated tube collectors have essentially a vacuum between the absorber and the glazing tube. This eliminates most of the heat loss by conduction and convection. Therefore, these collectors give a very high efficiency at higher temperatures. Evacuated tube collectors are typically used in the temperature range of 80 to 140°C

Concentrating Collectors. Concentrating collectors use reflectors or lenses to focus solar radiation from a large area onto a small area, thereby creating higher temperatures. Such collectors are usually used for temperatures higher than 100°C. Figure 8.10.2 shows schematics of some of the concentrating collectors.

Nontracking Concentrators. The simplest concentrating collector can be made by using flat wall reflectors to concentrate the solar radiation on a flat plate collector. Concentration ratios of two to three can be achieved this way. For slightly higher concentration ratios, a novel design, developed by Roland Winston, called a “compound parabolic concentrator” (CPC) can be used (Winston, 1974).

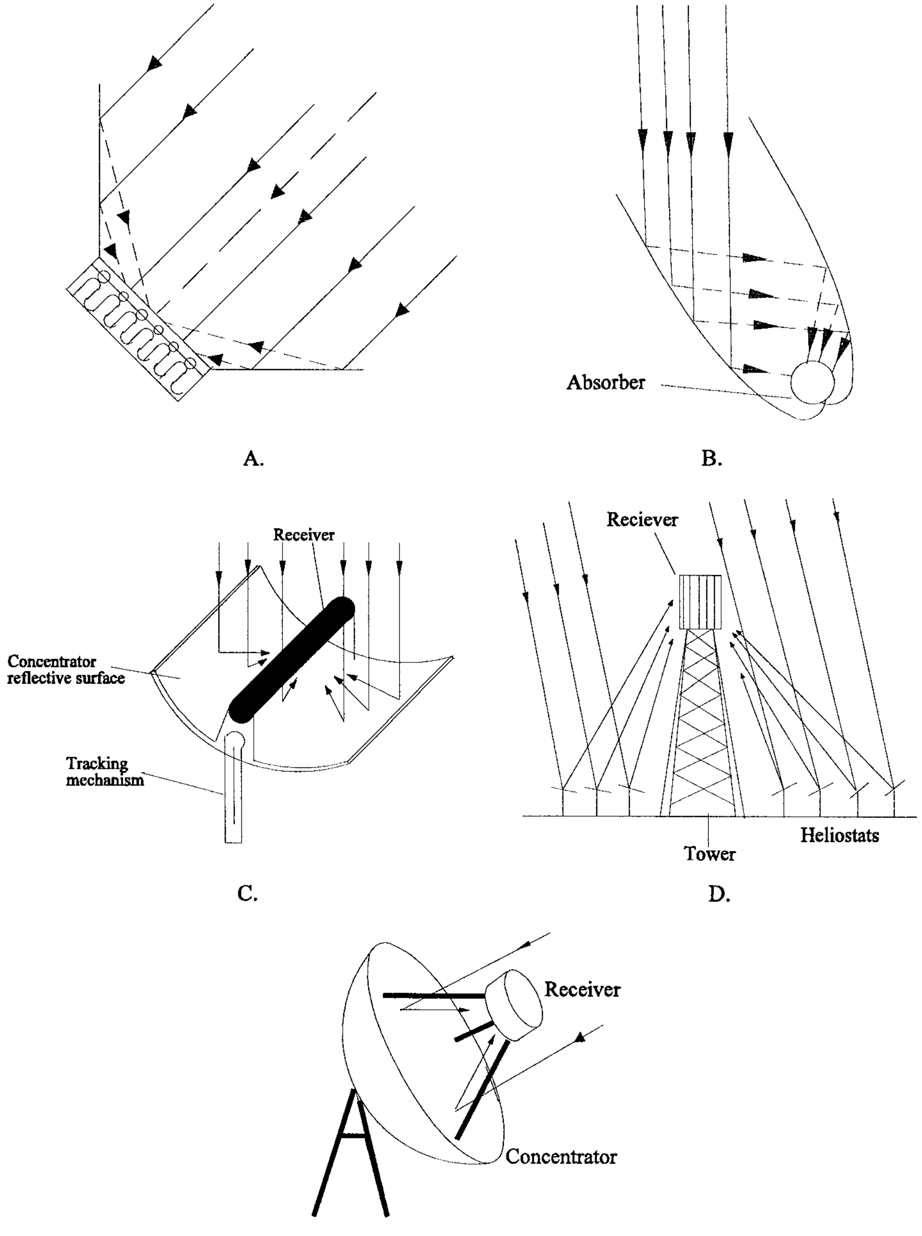

FIGURE 8.10.2 Types of concentrating collectors. (A) Flat plate collector with reflective wings; (B) Compound parabolic concentrator; (C) parabolic trough; (D) central receiver; (E) parabolic dish.

Tracking Concentrators. For temperatures up to 350°C, cylindrical parabolic trough collectors are used. These collectors focus solar radiation on a line focus where the absorber is located. These collectors usually require tracking on one axis only with seasonal adjustment on the other axis. A reflecting spherical or paraboloidal bowl is used when temperatures of the order of 250 to 500°C are needed. These collectors require two-axis tracking. In some cases, the dish is kept stationary while the receiver is moved to track the focus of the reflected solar radiation. Finally, for extremely high temperatures (500 to 1000°C) needed for large-scale thermal power generation, a large field of tracking flat mirrors (called heliostats) is used to concentrate solar radiation on a receiver that is located on top of a central tower.

Collector Thermal Performance

The instantaneous efficiency of a collector is given by

$$\eta = \frac{\text{Useful energy collected}}{\text{Incident solar energy}} = \frac{Q_u/A}{I} \tag{8.10.1}$$

where

$$Q_u = \dot{m}C_p\left(T_o - T_i\right) \tag{8.10.2}$$

and A = area of the collector, I = incident solar energy per unit area, $\dot{m}$, C_p, T_i, and T_o are the mass flow rate, specific heat, and inlet and outlet temperatures of the heat-transfer fluid.

The efficiency of a flat plate solar collector can also be written by the Hottel–Whillier–Bliss equation:

$$\eta = F_R(\tau\alpha)_e - F_R U_L \frac{\left(T_i - T_{\text{amb}}\right)}{I} \tag{8.10.3}$$

where F_R, called the collector heat-removal factor, is a convenient parameter that gives the ratio of the actual useful energy gain of a flat plate collector to the useful gain if the whole collector surface were at the inlet fluid temperature; $(\tau\alpha)_e$ = effective transmittance absorptance product; and U_L = collector heat-loss coefficient.

Equation 8.10.2 suggests that if the efficiency, η, is plotted against $(T_i - T_{\text{amb}})/I$, the resulting curve will have a y intercept equal to F_R $(\tau\alpha)_e$ and a slope of $F_R U_L$. A linear curve usually gives an adequate approximation. Figure 8.10.3 shows an example of a performance curve for a water-heating flat plate collector, which is a linear least square curve fit to the actual test data.

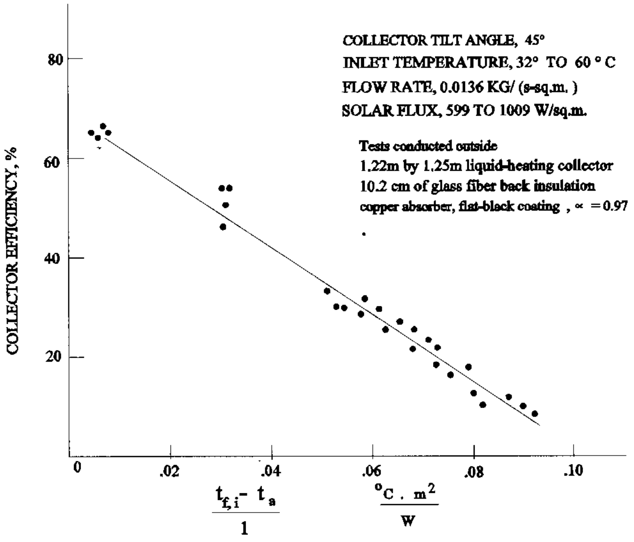

FIGURE 8.10.3 Thermal efficiency curve for a double-glazed flat plate liquid-type of solar collector. FIGURE 8.10.4 Schematic of a salt gradient solar pond.

Solar Ponds

A solar pond combines collector and energy storage in one unit. Solar radiation that enters the pond travels some distance through the water before being totally absorbed, thus increasing the temperature of the water at that depth. The heat thus collected can be stored in the pond by creating a stagnant, transparent, insulating layer in the top part of the pond. The most common method is by the addition of a salt into the pond to increase the density of water in the lower section of the pond. This type of pond is called a **salt gradient solar pond**. Reid (1987) reviewed the progress in the design and applications of salt gradient solar ponds. Figure 8.10.4 shows a schematic of a salt gradient pond along with a density profile in the pond.

The theory of salt gradient solar ponds has been described by Tabor (1981). The most important aspect of such ponds is the creation and maintenance of the salt gradient. Theory shows that the condition for maintaining stability is

$$\frac{\partial S}{\partial Z} > -1.14 \frac{\partial \rho}{\partial T} \frac{\partial T}{\partial Z} \frac{\partial \rho}{\partial S} \tag{8.10.4}$$

where S is the salt concentration in kilograms per cubic meter, Z is the depth from the surface in meters, ρ is the density in kilograms per cubic meter, and T is the temperature in Kelvin. The two most common salts considered for solar pond applications are NaCl and $MgCl_2$. According to the above criteria, there is no difficulty in obtaining stability with $MgCl_2$ and it is somewhat difficult but possible to get stability with NaCl.

Solar Water-Heating Systems

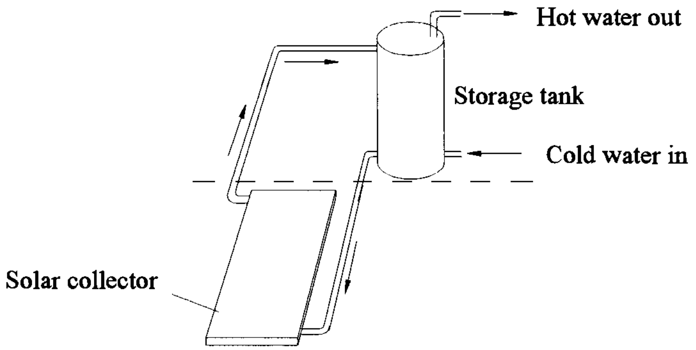
Solar water-heating systems represent the most common application of solar energy at the present time. Small systems are used for domestic hot water applications while larger systems are used in industrial process heat applications. There are basically two types of water-heating systems: **natural circulation or passive solar system** (thermosyphon) and **forced circulation or active solar system**.

Natural Circulation

Figure 8.10.5 shows a schematic of a natural circulation solar water-heating system. It is also called a thermosyphon or passive solar water heater because it does not require a pump to circulate water. The storage tank is located above the collector. When the water in the collector gets heated, it rises into the tank, because of density change, setting up a circulation loop.

Forced Circulation

Figure 8.10.6 shows three configurations of forced circulation systems: (1) open loop, (2) closed loop, and (3) closed loop with drainback. In an open loop system, the collectors are empty when they are not providing useful heat and the storage tank is at atmospheric pressure. A disadvantage of this system is the high pumping power required to pump the water to the collectors every time the collectors get hot.



FIGURES 8.10.5 Schematic of a thermosyphon solar water-heating system.

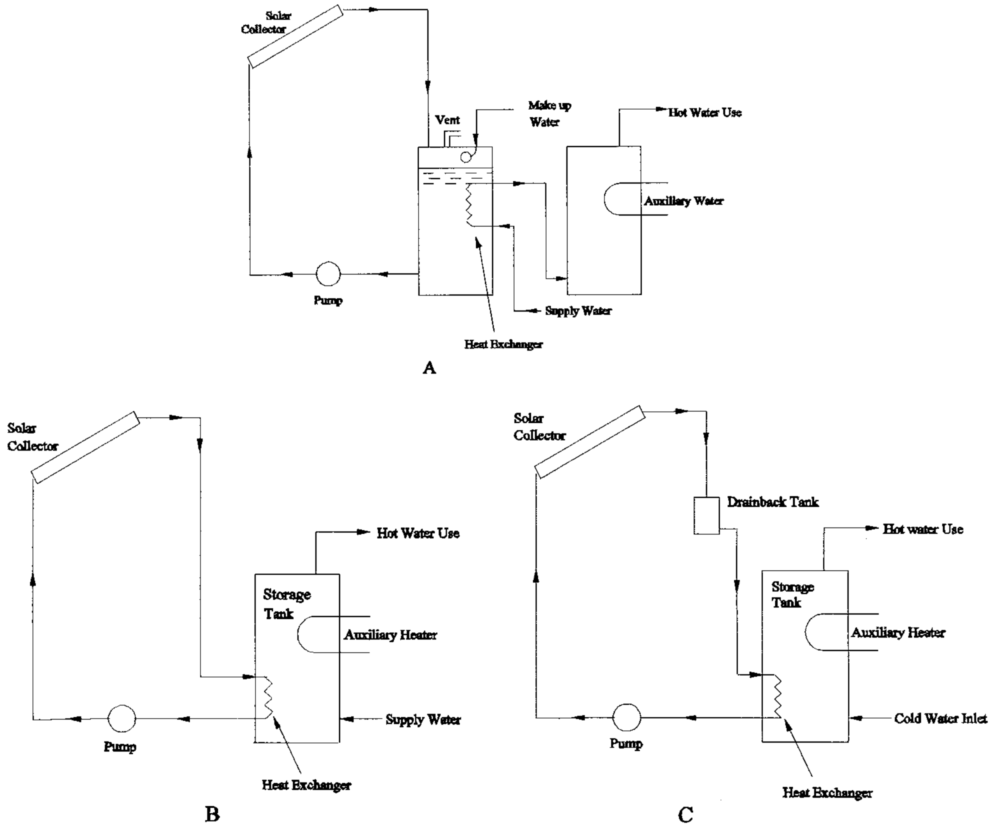


FIGURE 8.10.6 Typical configurations of solar water-heating systems: (A) open loop system, (B) closed loop system, (C) closed loop drainback system. (Adapted from Goswami, D.Y., *Alternative Energy in Agriculture,* Vol. 1, CRC Press, Boca Raton, FL, 1986.)

This disadvantage is overcome in the pressurized closed loop system (Figure 8.10.6B) since the pump has to overcome only the resistance of the pipes. Because water always stays in the collectors of this system, antifreeze (propylene glycol or ethylene glycol) is required for locations where freezing conditions can occur. During stagnation conditions (in summer), the temperature in the collector can become very high, causing the pressure in the loop to increase. This can cause leaks in the loop unless some fluid is allowed to escape through a pressure-relief valve. In both cases, air enters the loop causing the pump to

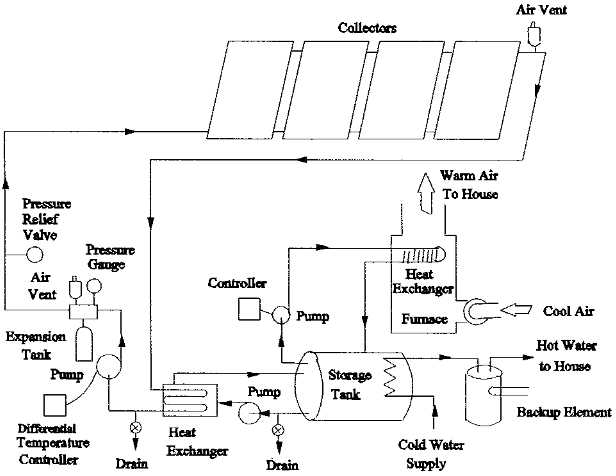

FIGURE 8.10.7 Schematic of an active solar space-heating system.

run dry. This disadvantage can be overcome in a closed loop drainback system (Figure 8.10.6C). In this system, when the pump shuts off, the water in the collectors drains back into a small holding tank, which can be located where freezing does not occur. The holding tank can be located at a high level to reduce pumping power.

Industrial Process Heat Systems

For temperatures of up to about 100°C, required for many industrial process heat applications, forced circulation water-heating systems described above can be used. The systems, however, will require a large collector area, storage and pumps, etc. For higher temperatures, evacuated tube collectors or concentrating collectors must be used.

Space-Heating Systems

Solar space-heating systems can be classified as active or passive depending on the method utilized for heat transfer. A system that uses pumps and/or blowers for fluid flow in order to transfer heat is called an *active system*. On the other hand, a system that utilizes natural phenomena for fluid flow and heat transfer is called a *passive system*. Examples of passive solar space-heating systems include direct gain, attached greenhouse, and storage wall (also called Trombe wall).

Active space-heating systems store solar collected heat in water or rocks. Heat from water storage can be transferred to the space by convertors or by fan-coil units. A system using a fan-coil unit can be integrated with a conventional air system as shown in Figure 8.10.7. Heat from rock storage can be transferred to air by simply blowing air over the rocks.

Solar Thermal Power

Solar thermal energy can be used to produce electrical power using conventional thermodynamic power cycles such as Rankine, Stirling, and Brayton cycles. The choice of power cycle and the working fluids depends on the temperature obtainable in the solar system, which depends on the type of solar collectors used. At present, developed solar thermal power systems include

Parabolic trough systems
Central receiver systems
Parabolic dish-Stirling engine system

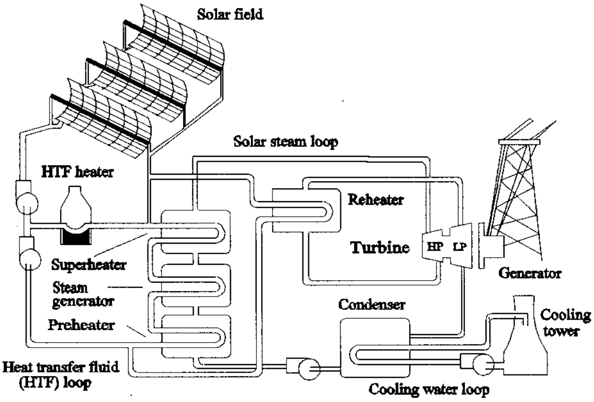

FIGURE 8.10.8 Schematic of SEGS IX power plant.

TABLE 8.10.3 Plant Characteristics — SEG IX

Power Block		Solar Field	
Gross power	88 MWe	Number of collectors	888
Net power	80 MWe	Aperature area	483,960 m^2
Steam inlet pressure	100 bar	Inlet temperature	293°C
Steam inlet temperature	371°C	Outlet temperature	390°C
Reheat pressure	17.2 bar	Annual thermal efficiency	50%
Reheat temperature	371°C	Peak optical efficiency	80%
Conversion efficiency	37.6%	Heat-transfer fluid (HTF)	Oil (VP-1)
Annual gas use	25.2×10^9 m^3	HTF volume	1289 m^3

Parabolic Trough Systems

Parabolic trough systems are simple in concept and, therefore, the most developed commercially. In 1984, Luz Company installed a Solar Electric Generating System (SEGS I) of 14 MW$_e$ capacity in Southern California, utilizing parabolic trough solar collectors and natural gas fuel for superheat and backup. From 1984 to 1991, Luz Company installed eight additional plants, SEGS II to SEGS IX, with the total capacity of the nine plants being 354 MW$_e$. With each successive SEGS plant the technology was improved and the cost reduced. The cost of electricity was reduced from about 30¢/kWhr for the first plant to about 8¢/kWhr for the last plant. A schematic of the SEGS IX is shown in Figure 8.10.8, and some important data for the system are given in Table 8.10.3.

It has been recognized that this design does not utilize the energy of the natural gas efficiently. It has been suggested that energy of natural gas can be better utilized by combining the solar system with a natural gas turbine combined-cycle power plant (DeLaquil et al., 1993; Washom et al., 1994). Such a hybrid system would use the exhaust of a natural gas turbine for superheating and preheating of water, while the solar field would be used for steam generation. Such a hybrid system can achieve conversion efficiency as high as 60%. A schematic of a **solar hybrid combined cycle** is shown in Figure 8.10.9.

Central Receiver System

A central receiver system can potentially operate at very high temperature and therefore can have much higher efficiency than parabolic trough systems. However, the system can be economical only at larger capacities, such as 100 MW and above. The central receiver absorber can heat the working fluid or an intermediate fluid to a temperature as high as 600 to 1000°C which can be used to drive a Rankine cycle or Brayton cycle.

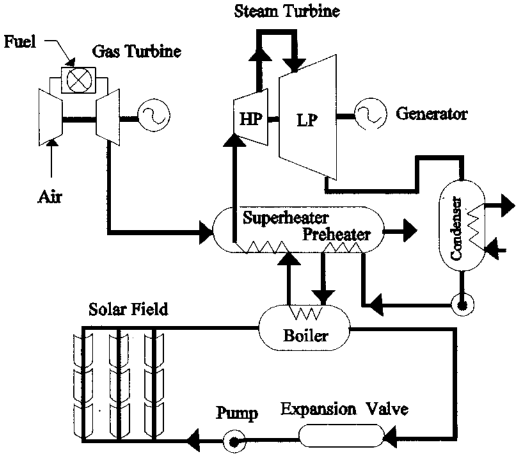

FIGURE 8.10.9 Solar hybrid combined cycle. (Adapted from Washom, B. et al., paper preesnted at the 1994 ASES Annual Conference, San Jose, CA, 1994.)

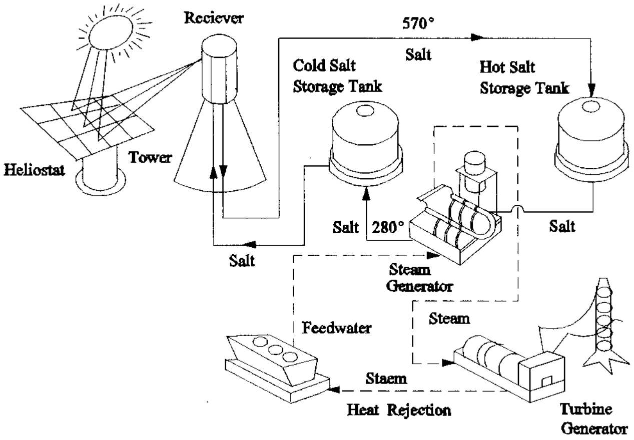

FIGURE 8.10.10 Schematic of Solar Two.

Solar One, a 10-MW$_e$ central receiver power plant started operating in 1982 in Barstow, California. This plant generated superheated steam at 510°C and 10.3 MPa in the receiver absorber, which was used to drive a simple steam Rankine power cycle. The plant operated successfully for 6 years and provided a good learning experience. The plant was redesigned as Solar Two in which molten sodium nitrate is used as the heat-transfer fluid as well as for storage. Use of molten salt allows operation of the receiver absorber at much lower pressures The constraint is that the salt must always be above its melting point (220°C). Figure 8.10.10 shows a schematic of the Solar Two power plant.

Parabolic Dish Systems

Parabolic dish systems can achieve very high temperatures. The high temperatures produced by parabolic dishes can be used to drive Rankine, Stirling, and Brayton power cycles. So far, Rankine and Stirling cycles have been successfully demonstrated with parabolic dishes for electrical power production.

Early versions of parabolic dishes were made from die-stamped aluminum petals made reflective using a metallized polymer film. Later designs used simpler flat mirror facets fixed on a structure in such a way as to approximate a parabolic dish. The latest designs use a polymer film stretched on a circular frame (Mancini, 1994). The film is given a slight concave curvature by providing a vacuum behind it. These stretched polymer films are fixed on a structure to approximate a parabolic dish. Because of the low weight of the polymer film, the dish structure can be made out of light tubular members, thereby reducing the cost of the dish considerably. Parabolic dishes require two-axis tracking.

McDonnell Douglas Corporation successfully demonstrated a 25-KW$_e$ parabolic dish system using a Stirling engine and a generator assembly fixed at the focal point of the dish in 1985 (Gupta, 1987). The concept is very attractive because it provides a modular design of stand-alone power plants for small communities and independent power applications. Present development is based on stretched polymer film facets for a parabolic dish, a heat pipe receiver absorber, a free-piston Stirling engine, and a linear alternator, resulting in a very compact power generation system. A detailed discussion of Stirling engines is given in Section 8.5.

Nomenclature

A = area of collector
C_p = specific heat
m = mass flow rate
T = temperature
I = incident solar radiation
Qn = useful heat collected
F_R = collector heat-removal factor
U_L = collector heat-loss coefficient
S = salt concentration
Z = depth

Greek Symbols

α = absorptance
τ = transmittance
η = efficiency
ρ = density

Subscripts

i = inlet
o = outlet
amb = ambient
e = effective

Defining Terms

Forced circulation or active solar system: A solar thermal system that uses active means, such as pumps, for fluid flow and heat transfer.

Glazing: A material used in a solar collector that transmits short-wavelength solar radiation and blocks longer-wavelength reradiation from the absorber plate.

Natural circulation passive solar system: A solar thermal system that uses natural means, such as the thermosyphon effect, for fluid flow and heat transfer.

Salt gradient solar pond: A solar pond that uses high salt concentration in the lowest layer and a concentration gradient in the middle layer to make those layers nonconvective.

Selective surface: A surface that has high absorptance in short wavelengths and low emittance in longer wavelengths.

Solar hybrid combined cycle: A hybrid of solar and natural gas turbine combined cycle.

Solar thermal collector: A solar collector that absorbs sunlight and converts it to heat.

8.11 Wind Energy Conversion[2]

Dale E. Berg

Introduction

Wind energy is the most rapidly expanding source of energy in the world today. Over the past decade, the world-wide installed capacity of wind energy has grown at an average rate of over 28% per year, leading to an installed nameplate capacity at the end of 2002 of over 31,000 MW — enough to power 7.5 million average American homes or 16 million average European homes. As of January, 2003, Germany was the world leader in wind energy installations, with 12,001 MW installed, followed by Spain (4830); the U.S. (4685); Denmark (2880); India (1702); Italy (785); the Netherlands (688); the U.K. (552); China (468); and Japan (415). Although wind power only supplies about 0.4% of the world's electricity demand today, the size of that contribution is growing rapidly. In Germany, the contribution of wind power to electricity consumption is over 5%, and in Denmark it is approximately 25%. The cost to generate wind energy has decreased dramatically from about $0.38 per kilowatt-hour (kWh) in the early 1980s to the $0.03 to $0.06/kWh range in 2003, and it continues to decrease.

---

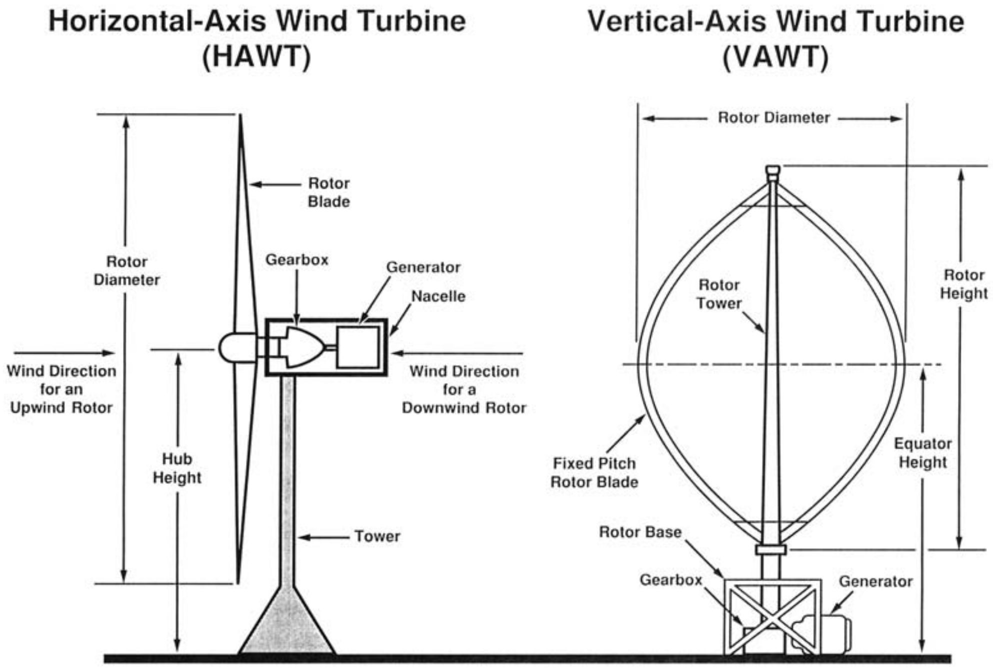

FIGURE 8.11.1 Wind turbine configurations.

The first wind machines were built over 2000 years ago. The wind turbines of today may look much different from those first machines, but the basic idea remains the same: use the power in the wind to generate useful energy. Modern wind machines, called wind turbines, tend to have a small number of airfoil-shaped blades, in contrast to the older windmills that usually had several flat or slightly curved blades. (Dutch windmills, with four blades, obviously do not fit this stereotype.) The reasons for this difference in blade number will be examined a little later.

Although many different configurations of wind turbines exist, most of them can be classified as horizontal-axis wind turbines (HAWTs), which have blades that rotate about a horizontal axis parallel to the wind, or vertical-axis wind turbines (VAWTs), with blades that rotate about a vertical axis. Figure 8.11.1 illustrates the main features of HAWTs and VAWTs.

As shown in Figure 8.11.1, HAWTs and VAWTs have very different configurations, each with its own set of strengths and weaknesses. HAWTs usually have all of their drive train (the transmission, generator, and any shaft brake) equipment located in a nacelle or enclosure mounted on a tower; their blades are subjected to cyclic stresses due to gravity as they rotate and their rotors must be oriented (yawed) so that the blades are properly aligned with respect to the wind. HAWTs may readily be placed on tall towers to access the stronger winds typically found at greater heights. The most common type of modern HAWT is the propeller-type machine; these machines are generally classified according to the rotor orientation (upwind or downwind of the tower); blade attachment to the main shaft (rigid or hinged); maximum power control method (full or partial-span blade pitch or blade stall); and number of blades (generally two or three blades).

VAWTs, on the other hand, usually have most of their drive train on the ground; their blades do not experience cyclic gravitational stresses and do not require orientation with respect to the wind. However, VAWT blades are subject to severe alternating aerodynamic loading due to rotation, and VAWTs cannot readily be placed on tall towers to exploit the stronger winds at greater heights. The most common types of modern VAWTs are the Darrieus turbines, with curved, fixed-pitch blades, and the “H” or “box” turbines with straight fixed-pitch blades. All of these turbines rely on blade stall for maximum power control.

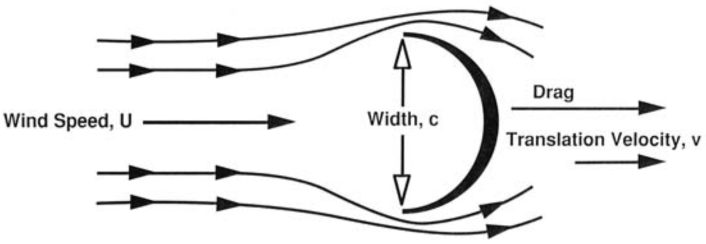

FIGURE 8.11.2 Schematic of translating drag device.

Although there are a few manufacturers of VAWTs in the world today, the overwhelming majority of wind turbine manufacturers have elected to devote their efforts to developing improved (and usually bigger) HAWTs.

Because the fuel for wind turbines is free, the initial cost of a wind turbine is a very large contributor to the cost of energy (COE) for the energy generated by that turbine. In order to minimize that COE, wind turbine designs must be optimized for the particular site or wind environment in which they will operate. Trial and error methods become very expensive and time-consuming when applied to optimizing and/or developing turbines, especially larger ones. An optimized wind turbine can be developed at a reasonable cost only if the designers can accurately predict the performance of conceptual machines and investigate the effects of design alternatives. In the past two decades, numerous techniques have been developed to predict the aerodynamic and structural dynamic performance of wind turbines accurately; these analytical models are not, in general, amenable to simple approximations, but must be solved with the use of computer codes of varying complexity. These models are summarized in the following paragraphs.

Wind Turbine Aerodynamics

Items exposed to the wind are subjected to forces in the drag direction (parallel to the air flow) and the lift direction (perpendicular to the air flow). The earliest wind machines, known as windmills, used the drag on the blades to produce power, but many windmill designs over the last few centuries did make limited use of lift to increase their performance. Because large numbers of blades resulted in higher drag and produced more power, predominantly drag machines tended to have many blades. The Dutch windmills utilized lift, and because lift devices must be widely separated to generate the maximum possible amount of lift, those machines evolved with a small number of blades.

The high-lift, low-drag shapes, referred to as airfoils, developed for airplane wings and propellers in the early part of the 20th century were quickly incorporated into wind machines to produce the first modern wind machines, usually known as wind turbines. Wind turbines use the lift generated by the blades to produce power. As mentioned earlier, the blades must be widely separated to generate the maximum amount of lift, so lift-type machines tend to have a small number of blades. The following paragraphs contrast the characteristics of drag- and lift-type machines.

Figure 8.11.2 illustrates the flow field about a moving drag device. The drag results from the relative velocity between the wind and the device. The power generated by the device (the product of the drag force and the translation velocity) may be expressed as

$$P = Dlv = \left[0.5\rho(U - v)^2\right]C_D clv \tag{8.11.1}$$

where

P = power extracted from the wind
D = drag force per unit length in the span direction (into the page)
l = length of device in the span direction (into the page)
v = translation velocity

ρ = air density
U = steady free-stream wind velocity
C_D = drag coefficient (function of device geometry)
c = device width (perpendicular to the wind, in the plane of the page)

The translation velocity of the device must always be less than the wind velocity or no drag is generated and no power produced. The power extraction efficiency of the device may be expressed as the ratio of the power extracted by the device to the power available in the area occupied by the device ($\frac{1}{2}\rho U^3 A = \frac{1}{2}\rho U^3 cl$), a ratio known as the **power coefficient** or C_p. For a drag machine, this ratio is

$$C_P = \frac{P}{\frac{1}{2}\rho U^3 cl} = \frac{v}{U}\left[1-\frac{v}{U}\right]^2 C_D \tag{8.11.2}$$

Now consider a device that utilizes lift to extract power from the wind, i.e., an airfoil. Figure 8.11.3 illustrates an airfoil moving at some angle relative to the wind that is subject to lift and drag forces. The relative wind across the airfoil is the vector sum of the wind velocity, U, and the blade velocity, v. The angle between the direction of the relative wind and the airfoil chord (the straight line from the leading edge to the trailing edge of the airfoil) is termed the angle of attack, α. The power extracted by this device may be expressed as

$$P = \frac{1}{2}\rho U^3 cl \frac{v}{U}\left[C_L - C_D\frac{v}{U}\right]\sqrt{1+\left(\frac{v}{U}\right)^2} \tag{8.11.3}$$

where

c = chord length
C_L, C_D = lift and drag coefficients, respectively (functions of airfoil shape and α)

The other quantities are as defined for Equation (8.11.1).

The power coefficient then is

$$C_P = \frac{v}{U}\left[C_L - C_D\frac{v}{U}\right]\sqrt{1+\left(\frac{v}{U}\right)^2} \tag{8.11.4}$$

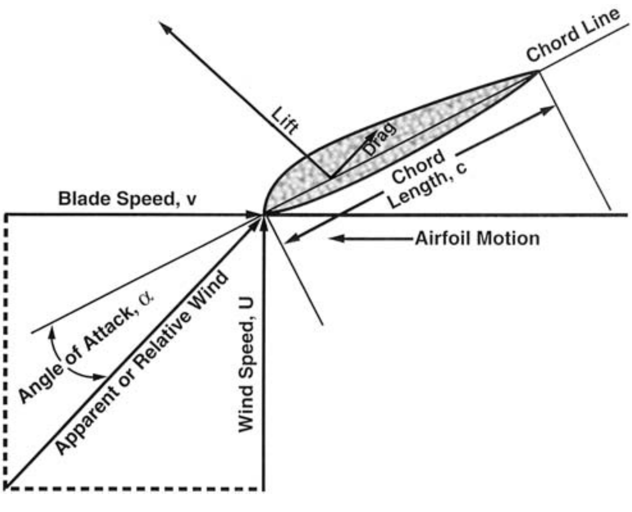

FIGURE 8.11.3 Schematic of translating lift device.

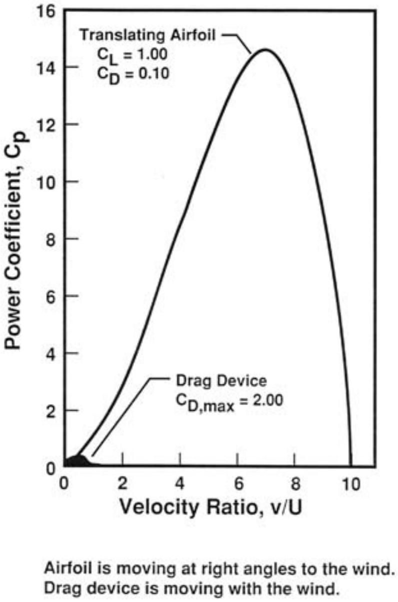

FIGURE 8.11.4 Comparison of power coefficients for a translating airfoil and a translating drag device.

Keep in mind that Equation 8.11.2 and Equation 8.11.4 express the performance coefficients of these devices in terms of the device surface area. Figure 8.11.4 compares Equation 8.11.2 and Equation 8.11.4 using $C_L = 1.0$ and $C_D = 0.10$ for the airfoil (reasonable values for modern airfoils), and a drag coefficient of 2.0 (the maximum possible) for the drag device. The airfoil has a maximum power coefficient of about 15, compared with 0.3 for the drag device; it extracts 50 times more power per unit of device surface area. Of course, the airfoil must be translated across the wind to produce power, but this is easily achieved with rotating machines such as wind turbines.

As mentioned earlier, lift-type machines tend to have only a few blades, while drag-type machines tend to have many. Thus, the difference in performance of actual machines is much less than might be expected from the preceding analysis; a well-designed lift-type machine may achieve a peak power coefficient (based on the area covered by the rotating turbine blades) of 0.5 to 0.59, while a pure drag-type machine will achieve a peak power coefficient of no more than 0.2. Some of the multibladed drag-type windmills actually utilize a blade shape that creates some lift, and they may achieve power coefficients as high as 0.3. However, experience has shown that lift-type machines can produce electricity at a significantly lower COE than can drag-type machines can. Only lift-type machines will be considered in the remainder of this discussion.

Aerodynamic Models

The aerodynamic analysis of a wind turbine has two primary objectives: 1) to predict the aerodynamic performance or power production of the turbine; and 2) to predict the detailed distribution of aerodynamic loads acting on the turbine rotor blades. In general, the same models are used to accomplish both objectives. Accurate prediction of turbine aerodynamic performance does not guarantee accurate prediction of the loading distribution. The performance predictions result from the integration of aerodynamic lift and drag over the entire turbine, and significant errors may be present in the detailed lift and drag predictions but balance out in the performance predictions.

Although a considerable body of data shows good agreement of predicted performance with measured performance, very few data are available against which to compare detailed load-distribution predictions. The aerodynamics of wind turbines are far too complex to model with simple formulas that can be solved with hand-held calculators; computer-based models ranging from very simple to very complex are required. Several commonly used aerodynamic models are described next.

Momentum Models

The simplest aerodynamic model of a wind turbine is the actuator disk or **momentum model** in which the turbine rotor is modeled as a single porous disk. This analysis was originally adapted for wind turbine use by Betz (1920) from the propeller theory developed by Froude (1889) and Lanchester (1915). In this model, the axial force acting on the rotor is equated to the time rate of change of the momentum of the air stream passing through the rotor. Utilizing conservation of mass, conservation of axial momentum, the Bernoulli equation, and the first law of thermodynamics, and assuming isothermal flow, the power produced by the turbine (the product of the axial force and the air velocity at the rotor) may be expressed as

$$P = 2\rho A U^3 a(1-a)^2 \tag{8.11.5}$$

where

$a = (U - v)/U$
v = wind velocity at the disk

The power coefficient for the turbine becomes

$$C_P = 4a(1-a)^2 \tag{8.11.6}$$

This is maximized for $a = 1/3$, yielding $C_{P,\max} = 16/27 = 0.593$ as the maximum possible performance coefficient for a lift-type machine, a maximum often referred to as the **Betz limit**. Expressed in slightly different terms, this result states that no lift-type turbine can extract more than 59.3% of the available energy in the wind passing through the rotor.

The typical performance of various types of wind machines is compared to the Betz limit in Figure 8.11.5, in which the variations of the turbine power coefficients with the **tip-speed ratio** (the ratio of the speed of the blade tip to the free-stream wind speed) are presented. Even though the maximum performance of modern HAWTs and VAWTs is well above that of the older, drag-type machines, it is still well below the Betz limit.

For horizontal-axis wind turbines, the momentum model can be expanded to the widely used **blade element momentum (BEM) model** in which the blades are divided into small radial elements and local flow conditions at each element are used to determine blade forces and loads on those elements. To obtain accurate predictions, this theory typically incorporates numerous modifications to account for blade and turbine wake effects; the three-dimensional flow near blade tips; the thick blade sections near the root; and blade stall at high wind speeds. Additional information on these models may be found in Hansen and Butterfield (1993), Wilson (1994), and Snel (1998).

The momentum model for vertical-axis wind turbines may be expanded into the multiple streamtube and the double-multiple steamtube models that are the VAWT equivalent of the HAWT blade element model. Additional information on these models may be found in Touryan et al. (1987), Wilson (1994), and Paraschivoiu (2002).

Momentum-based models are extremely popular with wind turbine designers because they are simple, fast, and fairly accurate for performance prediction. However, they are approximate because they are based upon the assumptions of steady flow and stream tubes that are fixed in time and space. They cannot predict the effects of yawed flow, unsteady aerodynamics, and other complex flows present on wind turbines — all of which can have large impacts on turbine performance and loads. In some cases, specialized codes based on experimental results are used to model some of these effects, but these codes are limited to specific turbine sizes and geometries. In other cases, more realistic models such as vortex-based models, hybrid models, and full computational fluid dynamics (CFD) models have been used to estimate these effects.

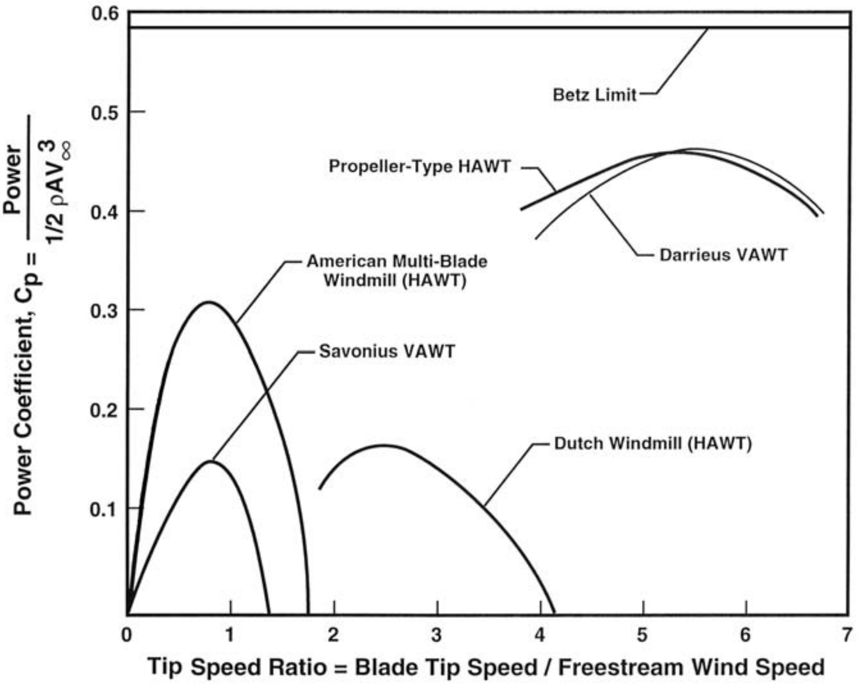

FIGURE 8.11.5 Typical performance of various types of wind turbines.

Vortex Models

Vortex models are usually more properly referred to as lifting line or lifting surface models, depending on whether a lifting line or a lifting surface formulation is used to model the blades. In the lifting line method, each rotor blade is modeled as a segmented "bound vortex line" located at the blade one-quarter chord line. Vortex strengths, defined by the blade lift at each radial location, are associated with the line segments at those radial locations. The lifting surface method represents the blade in more detail, as a distribution of vortex elements over the blade surface.

Either of these models will generate trailing vorticity (perpendicular to the span of the blade), due to the differences in vortex strength along the blade span, and shed vorticity (parallel to the span of the blade), due to time-dependent changes in vortex strength, which is shed into the wake. These vortex methods lend themselves to the modeling of unsteady problems because the shed vorticity models the time-dependent changes in the blade bound vortex strength. Solutions are achieved by placing the rotating turbine into a uniform flow field and allowing the flow field to develop until it reaches a steady state or periodic condition.

The manner in which the transport of the vorticity is modeled in the wake depends on whether a free wake or a fixed (or prescribed) wake model is used. In the free-wake model, the vorticity is allowed to convect, stretch, and rotate as it is transported through the wake. However, the movement of each element of vorticity (whether a line element or particle) is influenced by the presence of all of the other elements of vorticity, including those on the blade. As the computation progresses in time, the number of elements that must be followed, as well as the time required to calculate the element interactions, grow very quickly.

In order to minimize the need for large computer resources, the fixed or prescribed wake models have been developed. In these models, the geometry of the wake is either fixed or described by only a few parameters, and the vortex interactions in the wake are no longer modeled. The result is a much faster execution time, but the accuracy of the predicted power generation and blade loads depends very heavily upon the fidelity with which the specified wake approximates the actual physical wake. The three-dimensional, lifting-surface, free-wake formulation is the most physically realistic of the vortex models, but a computer program implementing such a model will require a large amount of computer resources and time. Experience has shown that the dramatic increase in computer resources required by such a model does not yield significantly more accurate predictions than what can be obtained with a three-dimensional, lifting-line, free-wake model.

A major problem with vortex codes is finding a good balance among model simplification (and the associated limitations on fidelity), computation time, and desired accuracy. Vortex models are not widely used in the wind industry today. Additional information on vortex models may be found in Strickland et al. (1981), Kocurek (1987), and Snel (1998), among others.

Limitations Common to the Momentum and Vortex Models

Momentum-based and vortex models normally utilize airfoil performance characteristic tables (lift and drag coefficients as functions of angle of attack and air velocity) to determine the blade lift and drag. These tables are generated from static two-dimensional wind tunnel test results or two-dimensional static airfoil design code predictions. The table contents are modified with empirical, semiempirical, or analytic methods and used to estimate blade loads under the three-dimensional, dynamic conditions actually experienced by the turbine blades. The greatest difficulty in obtaining accurate load distribution predictions with either type of model is determination of the appropriate airfoil performance characteristics.

Computational Fluid Dynamics Models

In a broad sense, computational fluid dynamics (CFD) is the solution of the partial differential equations describing the flow field by approximating these equations with algebraic expressions (discretizing them), and then solving those expressions numerically with the aid of a computer. Within the wind-energy community, the term CFD normally refers to the numerical solution of the unsteady Navier–Stokes equations, usually restricted to four partial differential equations (one conservation of mass equation and conservation of momentum equations in three orthogonal directions) that describe general ideal, incompressible, nonreacting fluid flow.

Arguably, the most detailed and physically realistic method of modeling the performance of and loads on a wind turbine is to utilize CFD to model the airflow around the turbine and through the rotor. The flow field in the vicinity of the wind turbine is approximated as a computational grid of variable density, and the discretized Navier–Stokes equations are applied to each element of that grid. The computational grid close to the turbine blades must be very, very dense in order to capture the details of the airflow around the blades; it becomes less dense as the distance from the turbine becomes greater and the effect of the blades on the airflow decreases. The resulting set of simultaneous equations must be solved, frequently in a time-marching manner, to determine the time-dependent nature of the entire flow field.

Duque et al. (2003) describe a fairly recent CFD investigation of a wind turbine in which they utilized a complex grid with 11.5 million points to model the flow around a 10-m diameter HAWT rotor and tower combination. A steady-flow solution for that model at a single wind speed, utilizing eight PC processors, each operating at 1.4 GHz in a parallel processor computer configuration, required approximately 26 h. An unsteady-flow solution with the same computing resources required over 48 h for each rotor revolution. Sørensen et al. (2002) and Johansen et al. (2003) report other recent CFD modeling efforts. At this point, CFD is suitable for research use or final design verification only — it is far too slow and requires far too many computer resources to be considered for use as a routine design tool.

Hybrid Models

The hybrid model approach typically approximates the airflow close to the turbine with the descretized Navier–Stokes equations, similar to the procedure used by the CFD models. However, away from the turbine, the model uses nonviscous or potential flow equations that are much less complex and can be solved much faster than the Navier–Stokes equations. The two solutions must be merged at the boundary between the two regions. The result is a code with the accuracy of the CFD model, but one that requires an order of magnitude less computing resources to solve. Xu and Sankar (2002) describe recent work on such a code. Even this model requires a large amount of computer resources and is too slow and expensive to be considered a practical design tool.

None of these models is capable of accurately predicting the performance of and detailed loads on an arbitrary wind turbine operating at a variety of wind speeds. In order to have high confidence in the code predictions for a turbine design, the code must be calibrated against the measured performance and loads obtained from turbines of similar size and shape. Simms et al. (2001) report on the ability of 19 codes based on the preceding models to predict the distributed loads on and performance of an upwind HAWT with a 10-m diameter rotor that was tested in the NASA/Ames 80 ft × 120 ft wind tunnel. Although the rotor was small compared to the 80-m diameter and larger commercial turbines built today, a panel of experts from around the world concluded that it was large enough to yield results representative of what would be observed on the larger turbines.

The comparisons of the code predictions and the experimental results were not especially encouraging: turbine power predictions ranged from 30 to 275% of measured and blade-bending moment predictions ranged from 85 to 150% of measured for what is considered to be the most easy-to-predict conditions of no yaw, steady state, and no stall. Many aerodynamic code developers have spent considerable effort over the past 2 years attempting to identify the sources of the discrepancies and improving the accuracy of their various codes.

Additional information and references on wind turbine aerodynamics models may be found in Hansen and Butterfield (1993), Wilson (1994), and Snel (1998) for HAWTs and in Touryan et al. (1987) and Wilson (1994) for VAWTs.

Wind Turbine Loads

The wind is **stochastic** in nature, with significant short-term variations or turbulence in direction and in velocity. Wind turbine aerodynamic loads may be regarded as falling into one of two broad categories: (1) the deterministic loads occurring in narrow frequency bands resulting from the mean steady atmospheric wind, wind shear, rotor rotation, and other deterministic effects; and (2) the random loads occurring over all frequencies resulting from the wind turbulence. As recently as 10 years ago, the deterministic loads were frequently predicted with an aerodynamics code, such as those described in the previous parts of this section, utilizing a uniform wind input, and the random loads were estimated with empirical relations. However, turbine designers now recognize that this approach may lead to serious underprediction of the maximum blade loads, resulting in costly short-term component failures. Most analysts today utilize an aerodynamics performance code with a wind model that includes a good representation of the turbulence of the wind in all three dimensions to predict long-term wind turbine loads. The appropriate method of determining the wind-induced extreme events that limit the lifetime of a turbine remains the subject of ongoing research.

Wind Turbine Structural Dynamics

Horizontal Axis Turbines

Small horizontal axis turbine designs usually use fairly rigid, high-aspect-ratio blades, cantilevered from a rigid hub and main shaft. As turbine size increases, the flexibility of the components tends to increase, even if the relative scales remain the same; thus, the blades on larger turbines tend to be quite flexible, and the hub and main shaft tend to be far less rigid than the components on the small turbines. The entire drive-train assembly is mounted on and yaws about a tower that may also be flexible.

These structures have many natural vibration modes and some of them may be excited by the wind or the blade rotation frequency to cause a **resonance** condition in which the vibrations are amplified and cause large stresses in one or more components. Operating at a resonance condition would quickly destroy a turbine. Careful structural analysis during the turbine design can ensure that the turbine will not experience a resonance condition, but ignoring the analysis altogether or failing to conduct parts of it properly may result in a turbine that will experience one or more resonance conditions leading to early failure. Although the relatively rigid small turbines are not too likely to experience these resonance problems, the very flexible, highly dynamic larger turbines are quite likely to experience resonance problems unless they are very carefully designed and controlled.

The large relative motion between the rotor and the tower precludes the use of standard commercial finite element analysis codes and requires the use of a model constructed specifically for analysis of wind turbines. Development of such a model can be a rather daunting task because it requires the formulation and solution of the full nonlinear governing equations of motion. The model must incorporate

- Yaw motion of the nacelle
- Pitch control of the blades
- Any motion and control associated with hinged blades
- Interaction between the rotor and the supporting tower
- Starting and braking sequences, etc.

If the full equations of motion are developed with finite-element or multibody dynamics formulations, the resultant models contain moderate numbers of elements and potential motions (or degrees of freedom, DOF), and significant computer resources are required to solve the problem. On the other hand, a modal formulation utilizing limited DOF may yield an accurate representation of the wind turbine, resulting in models that do not require large computing resources. The development of the modal equations of motion does require considerably more effort than do the finite-element or multibody equations.

The modal degrees of freedom must include blade bending in two directions, blade motion relative to the main shaft, drive train torsion, tower bending in two directions, and nacelle yaw. Blade torsional bending is not normally included in current models, but it will become more important as the turbine sizes continue to increase and the blades become more flexible. The accuracy of the modal formulation is typically limited by its inability to model the nonlinear variation of airfoil lift with angle of attack that occurs as a result of aerodynamic stall. The modal formulation is the most widely used analysis tool today; however, as computer resources become more readily available and cheaper, the finite element and multibody dynamic codes will gain in popularity.

The resultant equations of motion, whether finite-element, multibody, or modal, can be solved in the frequency domain or in the time domain. The frequency domain calculations are fast, but they are unable to account for nonlinear structural dynamics due to large component deflections and nonlinear control system dynamics. In spite of these limitations, frequency-domain solutions of the modal formulation are frequently used in the preliminary design of a wind turbine, when quick analysis of many configurations is required. Regardless of the methods used in preliminary design, the state of the art in wind turbine design today is to use finite-element-based equations of motion, coupled with time-accurate solutions to analyze the turbine behavior for the detailed final design calculations.

Malcolm and Wright (1994) provide a list of some of the available HAWT dynamics codes that have been developed, together with their limitations. Buhl et al. (2000) compare some of the HAWT dynamics codes that have been extensively verified and are widely used today, and Quarton (1998) provides a good history of the development of HAWT wind-turbine analysis codes.

Vertical Axis Turbines

Darrieus turbine designs normally use relatively slender, high-aspect-ratio structural elements for the blades and supporting tower. As with large HAWTs, the result is a very flexible, highly dynamic structure, with many natural modes of vibration that, again, must be carefully analyzed to ensure that the turbine will avoid structural resonance conditions under all operating environments. The guy cables and turbine support structure can typically be analyzed with commercial or conventional finite element codes, but the tower and blades require a more refined analysis, usually requiring the use of a finite element code possessing options for analyzing rotating systems. With such a code, the blades and tower of a VAWT are modeled in a rotating coordinate frame resulting in time-independent interaction coefficients. The equations of motion must incorporate the effects of the steady centrifugal and gravitational forces, the aerodynamic forces due to the turbulent wind, and the forces arising from rotating coordinate system effects. Detailed information on finite-element modeling of VAWTs may be found in Lobitz and Sullivan (1983).

Wind Turbine Electrical Generators

Once a wind turbine has converted the kinetic energy in the wind into rotational mechanical energy, it is usually converted into electricity that can be readily transported wherever it is needed. Although some wind turbines utilize permanent magnet alternators to generate electricity, most grid-connected turbines today utilize synchronous or induction generators. Induction generators are cheaper and easier to control than synchronous generators and provide some power-train damping; however, they tend to create adverse effects upon the power carried by the grid to which they are connected. These adverse effects can usually be solved fairly quickly and at low cost with modern power electronics.

Permanent magnet generators tend to achieve higher efficiency at low power ratings than induction or synchronous generators do, leading to increased energy capture, but the technology is less mature than it is for the others and the cost is somewhat higher.

Although most older turbines operate at a single fixed rotational speed, most newer turbines, and especially the larger ones, are variable speed, operating within a fixed range of rotational speeds. Variable-speed turbine operation offers the following major advantages over fixed-speed operation:

- The aerodynamic efficiency of the rotor at low to moderate wind speeds may be improved by changing the rotational speed to keep the turbine operating close to the optimum tip-speed ratio, maximizing the power coefficient. At higher wind speeds, the blades are in stall or are pitched to limit peak power and it is not necessary to operate at the optimum tip-speed ratio.
- System dynamic loads may be attenuated by the inertia of the rotor as it speeds up and slows down in response to wind gusts.
- The turbine may be operated in a variety of modes, including operation at maximum efficiency for lower wind speeds to maximize energy capture or operation to minimize fatigue damage

In variable-speed operation, certain rotational speeds within the operating-speed range will likely excite turbine vibration modes, causing structural resonance and increased rates of fatigue damage. These rotational speeds must be avoided during operation, leading to complex control schemes.

Variable-speed operation, in general, generates variable-frequency power. Most applications include interfacing with power grids, requiring high-quality power at a reference frequency. Several methods have been developed for accomplishing this with sophisticated power electronics (Smith, 1989), but research to develop improved methods with higher efficiencies continues.

In general, generator efficiency drops off rapidly as the generated power falls below the rated generator capacity, and single-generator systems tend to be very inefficient at low wind speeds. Some turbine designs address this deficiency by having multiple smaller generators. At low wind speed, only one generator might be attached to the drive train, with more added as the wind speed increases. The net result is that each generator operates close to its rated power much of the time, increasing the overall generator efficiency. Similar results can be obtained with a single generator utilizing pole switching or multiple windings.

Wind Turbine Controls

All wind turbines include auxiliary systems to control turbine performance and protect the turbine from excessive loads. The more common systems include the following.

Yaw Systems

The rotor of a HAWT must be oriented so that the rotor axis is parallel to the wind direction for peak power production. Most upwind HAWTs and a few downwind HAWTs incorporate active yaw control systems, using a wind direction sensor and a drive motor to orient the rotor with respect to the wind direction. Some downwind HAWTs are designed to utilize the wind to orient the rotor automatically. Active yaw systems tended to be extremely problematical in early turbines, basically because the loads acting on them were not well understood. Because yaw loads are much better understood today, these systems are no longer a major problem area. VAWTs do not require yaw systems.

Peak Power Regulation System

All turbines incorporate some method of regulating or limiting the peak power produced. Because the entire turbine must be sized to handle the loads associated with peak power production, the entire system would be tremendously overdesigned and the generator and transmission would be very inefficient at normal wind speeds if such a capability were absent. Regulating the peak power enables the designer to size the generator so that it will operate near its design power rating, where it is most efficient, at normal operating wind speeds (between the rated wind speed and the shut-down wind speed). The additional energy captured due to the increase in generator efficiency over the lower wind speeds is usually many times greater than that lost due to limiting the peak power at the infrequent high wind speeds. Most large horizontal-axis turbines use blade pitch control, but some use blade stall control. Small turbines frequently incorporate features that turn the rotor so that the axis is at an angle to the wind in order to achieve peak power regulation.

With full-span blade pitch control, the blade is rotated about its longitudinal axis to decrease the effective angle of attack as the wind speed increases, causing decreased blade lift to regulate the peak power. Although pitch control results in decreased drag loads at high winds, a major disadvantage is poor peak-power control during high-wind stochastic conditions; power excursions can exceed twice the rated power levels before the high-inertia blade pitch system can respond. With blade stall control, the blades are designed to encounter **stall** at high wind speeds, resulting in decreased blade lift and increased blade drag to regulate the peak power. Major disadvantages of stall control include increasing blade drag loads as the wind speed increases (even after stall) and possible large dynamic loads due to wind turbulence. A major advantage of stall control is the lower cost compared to that of the active pitch control. Sample power curves for stall- and pitch-regulated 500-kW turbines are shown in Figure 8.11.6.

Partial-span control surfaces typically regulate the peak power by decreasing the lift and increasing the drag of a portion of the blade. These control surfaces are usually much smaller than the full blade, so they can respond to wind changes much faster than can the full-span blade. However, partial span

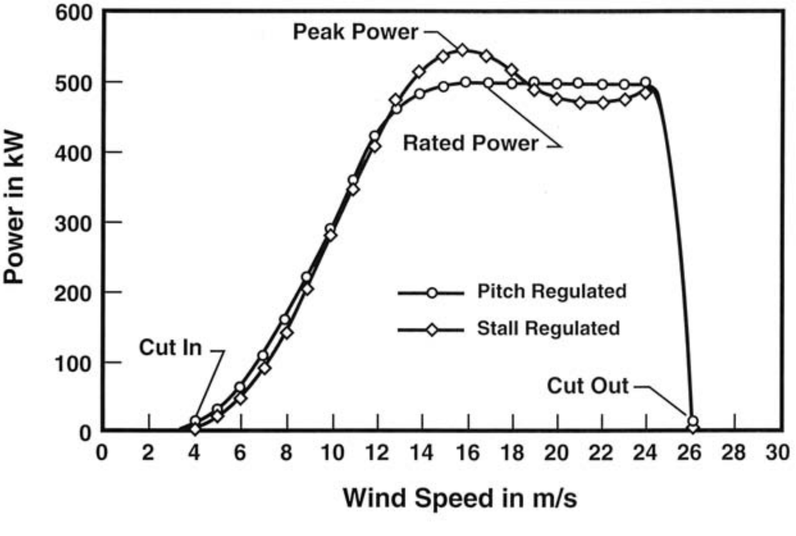

FIGURE 8.11.6 Sample power curves for stall-regulated and pitch-regulated wind turbines.

devices are very difficult to integrate into a blade and they tend to create noise. Recent work has focused on very small load control devices that can generate large changes in lift and drag while experiencing small loads. Dimensions of these devices are typically on the order of 1% of the blade chord and they can therefore be activated very quickly to alleviate excess loads. Their small size helps to limit noise creation.

Several other methods of pitch control have also been used, but on a limited basis. Passive pitch-control techniques automatically adjust the blade pitch angle by using cams activated by centrifugal loads or by using tailored blade materials that permit the blade to twist under high loads. These devices are very carefully tailored to maintain peak performance at lower wind speeds; however, they limit the peak power and blade loads at high wind speed.

Virtually all vertical-axis wind turbines utilize stall regulation with fixed-pitch blades to control peak power.

High Wind Speed Protection System

In general, wind turbines are designed to operate when the incident wind is high enough to generate electricity and to cease operation when the wind speeds exceed 25 to 30 m/s, where high loads threaten to damage the operating wind turbine. In spite of the tremendous amount of power present in high winds, these winds are normally present only for short periods of time, and the additional energy that can be captured is usually more than offset by the increased cost of a turbine that is designed to withstand the attendant high loads.

Controller System

Every wind turbine contains a controller, usually a microprocessor-based system, to control turbine operations. The basic turbine controller will start and stop the machine, connect or disconnect the generator output to the power grid, as needed; control the operation of the yaw and pitch systems (if present); perform diagnostics to monitor the operation of the machine; and perform normal or emergency shutdown of the turbine as required. For older turbines, the controller was frequently a fairly generic device with a minimum of machine-specific features that was simply added to an existing turbine.

For newer turbines, especially large, variable-speed machines, controllers incorporate much more intelligence than the old, generic type; they may be designed to

- Utilize the pitch system to limit peak power and/or torque
- Control the rotor speed
- Maximize energy capture
- Trade off energy capture and loads mitigation
- Reduce power fluctuations
- Control power quality
- Actively control some turbine dynamics

Controllers with any or all of these capabilities should be included in the models of system dynamics and must be designed from scratch as an integral component of the wind turbine.

Wind Turbine Materials

Most of the materials used in the construction of wind turbines are typical of materials used in other rotating machinery and towers — relatively common structural materials such as metal, wood, concrete, and glass-fiber reinforced plastic (GFRP) composites. However, wind turbine blades are fatigue critical structures (their design is driven by consideration of the fatigue loads they must endure), and the number of fatigue cycles they experience in a 30-year design life is three orders of magnitude beyond the 10^6 cycles that are the common limit of fatigue data for these materials. Over the past 15 years, high-cycle fatigue databases for many potential blade materials have been developed specifically for wind turbine applications. The blade material of choice today is GFRP composites due to the high strength and stiffness that can be obtained; the ease of tailoring them to the loads; and their relatively low cost (Sutherland, 2000).

However, the trend to larger and larger turbines, with the resultant increase in blade weight and flexibility, has created intense interest in utilizing some carbon fiber in the blades to decrease weight and add stiffness. Carbon fiber, even in the cheapest form available today, remains relatively expensive, and the challenge to turbine designers is to incorporate it into blades in a cost-effective manner.

Defining Terms

Betz limit: Maximum portion of available wind energy that can be extracted by a wind turbine, according to momentum theory.

Blade element momentum (BEM) model: An enhanced version of the momentum model that is the primary model used to compute aerodynamic performance and structural loading for HAWTs.

Horizontal-axis wind turbine (HAWT): A turbine in which the blades rotate about a horizontal axis.

Momentum model: A method of estimating the performance of a turbine by equating the time rate of change of air momentum through the turbine to the force acting on turbine blades.

Power coefficient: The ratio of captured energy to the energy available in the reference area.

Resonance: A vibration of large amplitude caused by a relatively small excitation at or near a system natural frequency.

Stall: An operating condition in which an airfoil experiences a decrease in lift and a large increase in drag as the angle of attack increases.

Stochastic: Containing variations from a smooth, uniform flow.

Tip-speed ratio: The ratio of the speed of the blade tip to the free-stream wind speed.

Vertical-axis wind turbine (VAWT): A turbine in which the blades rotate about a vertical axis.

8.12 Energy Conversion of the Geothermal Resource

Carl J. Bliem and Gregory L. Mines

This section discusses the uses of the geothermal resource. The primary use of the energy from geothermal resources to date has been in the production of electrical energy. Other applications, such as process heat and space conditioning, have also been made and will be discussed under the topic of direct use. This section begins with a discussion of the geothermal resource as it applies to the use of the energy. Then discussion of the three types of electrical generating facilities presently in use: — the **direct steam system**, the **flashed steam system**, and the **binary system** — is given. Finally, some discussion of direct-use applications is given.

Geothermal Resource Characteristics Applicable to Energy Conversion

Geothermal energy as defined here applies to hot fluids under pressure found at a reasonable depth (1 to 2 km) in the earth's crust. If one disregards the complex geological details relating to the formation of such naturally occurring reservoirs of hot fluids, Figure 8.12.1 and Figure 8.12.2 present schematic representations of these reservoirs. High-temperature fluid (200 to 300°C) is created by the convection of water through the porous rock. As the water circulates, it dissolves various amounts of minerals containing sodium, potassium, calcium, silica, carbonates, and chlorides and gases such as nitrogen and carbon dioxide. In **geopressured resources** of the Gulf of Mexico, high pressures and significant amounts of dissolved methane are seen.

The convective cells operate over large horizontal distances of as much as 30 km. The time in which the transfer of energy from the magma to the water takes place is of the order of 10^5 to 10^6 years. At the present time, it is difficult to say whether or not the resource can be considered "renewable." If natural circulation or the injection of spent geothermal liquid into the reservoir can make up for the liquid extracted during the energy conversion process, the reservoir can be considered at least of a very long life. (Individual wells generally have a life of about 10 years.)

The resources considered in this section are said to be **hydrothermal**. (Work is being done on creating artificial reservoirs by injecting water into hot dry rock, but this development is in its early stages and will not be considered here. The geopressured resource will not be considered either.)

As the geofluid is extracted from a reservoir, it flows to a region of lower static pressure. If this pressure falls below the saturation pressure for the temperature of the geofluid (close to but not equal to the saturation pressure of pure water because of the presence of the dissolved solids and gases), the geofluid will flash into steam. Therefore, the person using this energy source may have a number of different physical forms to consider:

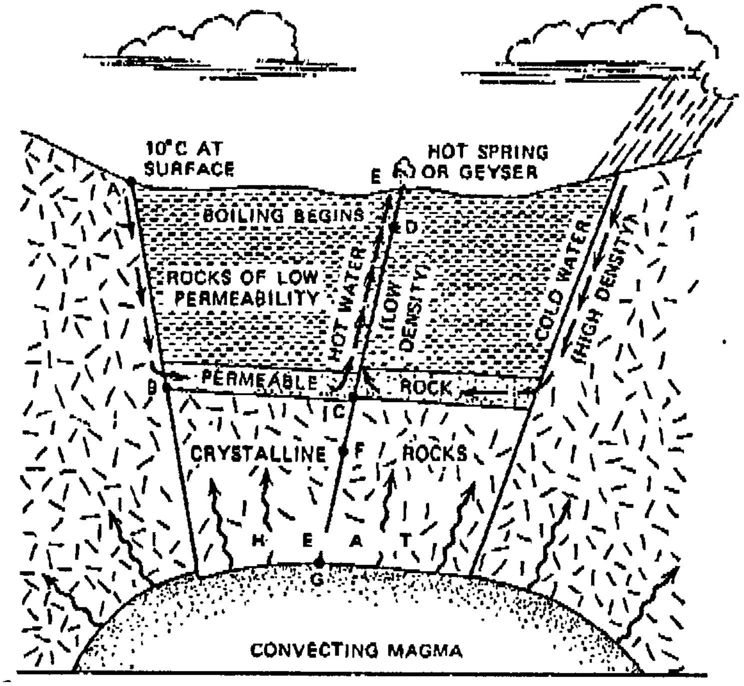

FIGURE 8.12.2 Schematic diagram of a characteristic geothermal reservoir. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

1. Wet steam from a *vapor-dominated resource*;
2. Superheated or saturated steam from a vapor-dominated resource;
3. Liquid at a pressure above the saturation pressure from a *liquid-dominated resource*;
4. A mixture of liquid and vapor at a relatively low quality from a liquid-dominated resource.

Electrical Energy Generation from Geothermal Resources

The type of energy conversion system used to produce electrical power depends on the type and quality (temperature) of the geothermal resource. Vapor-dominated resources use systems where steam is expanded directly through a turbine, similar to conventional fossil fuel steam plants. Liquid-dominated resources use flash steam systems and binary systems, with binary systems predominantly used for the lower-quality resources. The term **binary system** is used to describe a power cycle where the geothermal fluid provides the source of thermal energy for a closed-loop Rankine cycle using a secondary working fluid. In this closed loop, the working fluid is vaporized using the energy in the geofluid, expanded through a turbine, condensed, and pumped back to the heater completing the closed loop.

Hydrothermal resources typically contain varying amounts of numerous dissolved minerals and dissolved gases. In power cycles where steam is extracted from the geothermal resource directly (vapor dominated) or indirectly (flashing liquid dominated) and expanded through a condensing turbine, the design and operation of the power cycle must account for the removal of the noncondensable gases. If the gases are not removed from the condenser, they will accumulate in the condenser, raising the turbine back pressure and decreasing the power output. In systems where the liquid geofluid is handled (binary cycle heat exchangers and piping and flash steam flash tanks and piping), measures must be taken to prevent the precipitation of the dissolved solids and/or to provide a means of removal of the resulting scale.

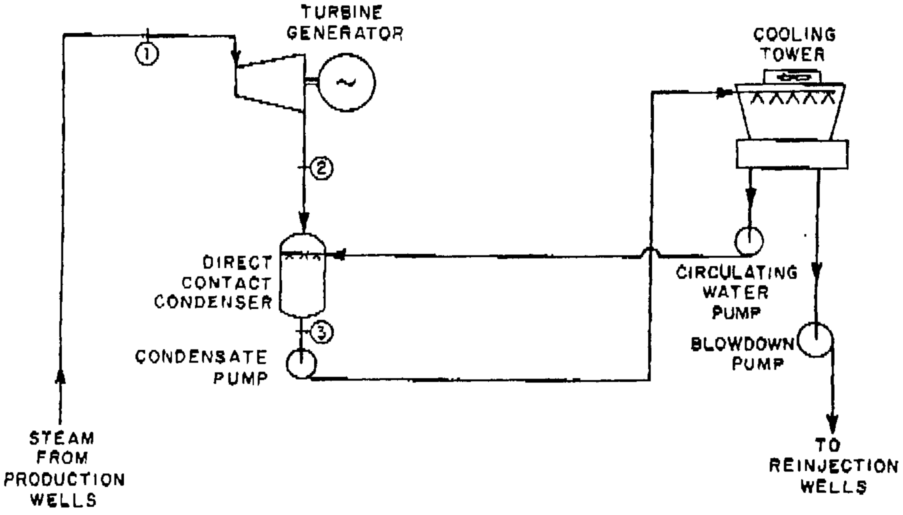

FIGURE 8.12.3 Schematic diagram of a direct dry-steam plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

Direct Steam Systems — Vapor-Dominated Resources

For a geothermal resource producing a superheated or saturated vapor steam (Case 2), the vapor from the geothermal production well is sent to a conventional steam turbine as shown in Figure 8.12.3. (This is done after appropriate removal of rocks and debris and possibly after scrubbing with water to remove corrosive substances.) Normally, the turbine is a condensing type, as shown in the figure, although in some applications a back-pressure turbine is used, exhausting the steam to the atmosphere. The back-pressure turbine is typically used for small systems with the possible later addition of another turbine and a condenser to increase the power generated by the geofluid flow from the wells.

Figure 8.12.3 shows a system with a direct-contact condenser and a wet cooling tower. In this type of system, the condensate from the condenser is more than enough to make up the evaporation and blowdown from the cooling tower. Therefore, the figure shows some of the condensate being injected into the reservoir. In many cases, direct-contact condensers are not feasible because of the hydrogen sulfide in the steam which would be released in the cooling tower exhaust. When hydrogen sulfide is in the steam, the majority of it appears as noncondensable and the noncondensable gas from the condensers must be treated. For these systems, surface condensers are normally used in conjunction with wet cooling towers. The actual hardware configuration is dictated by the process for removal of the sulfur. Again, some of the condensate can be used for cooling tower makeup if the sulfur is removed from the process. A number of processes have been developed to remove sulfur from the process.

Figure 8.12.4 depicts a system which is similar to the one described above, but one which receives wet steam (Case 1). Here, the liquid is separated from the vapor prior to the entry of the vapor into the turbine. Otherwise, the system is the same as the one in Figure 8.12.3 and the same comments apply.

Flash Steam Systems — Liquid Dominated Resources

When the geofluid is flashed before it leaves the well, flash steam systems are generally used. This indicates that the resource is at a relatively high temperature. Figure 8.12.5 and Figure 8.12.6 depict single- and dual-flash systems schematically. The single-flash system in Figure 8.12.5 is quite similar to the system in Figure 8.12.4. The only difference is that the geofluid pressure is dropped further before the steam is separated and sent to the turbine. An optimum flash pressure exists because the lower the flash pressure, the more steam which is evolved. However, the work done per unit mass of steam flowing through the turbine will also decrease with the lower flash pressure. For a given set of geofluid conditions entering the plant, a flash pressure exists that will maximize the energy produced per unit mass of geofluid and

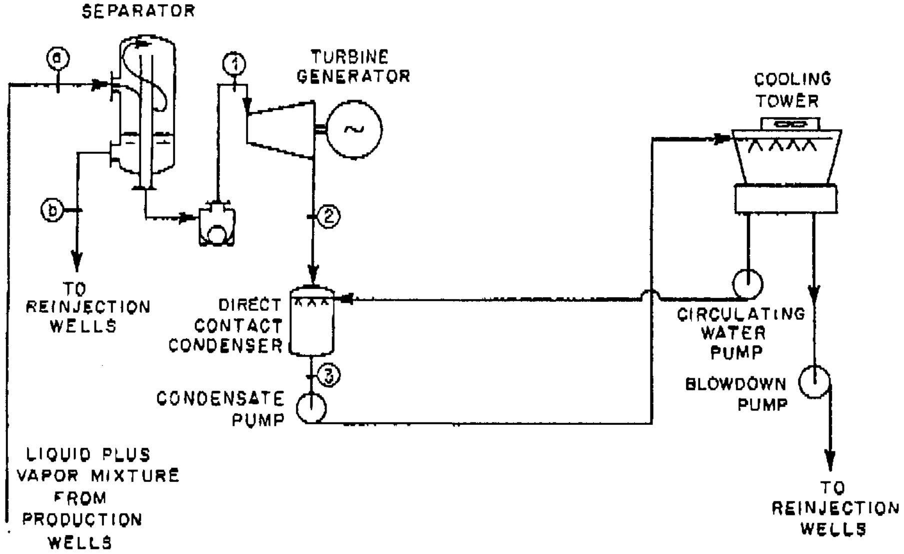

FIGURE 8.12.4 Schematic diagram of a plant using a two-phase resource. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

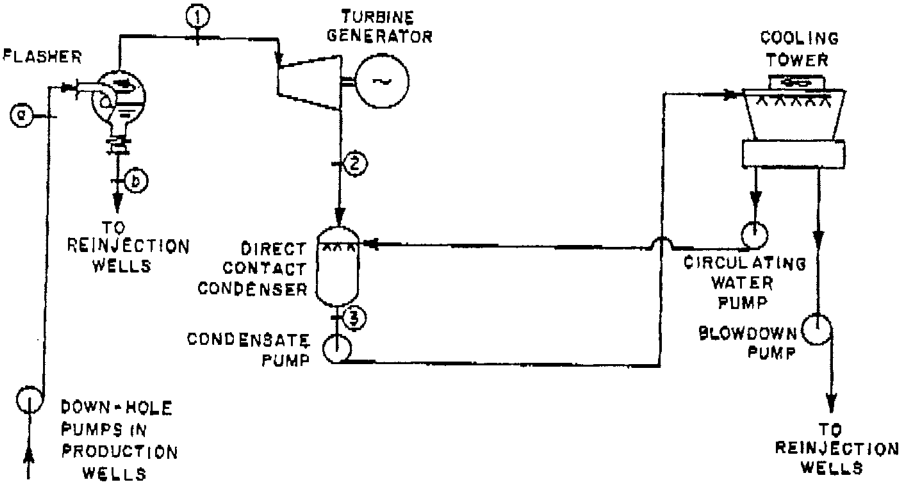

FIGURE 8.12.5 Schematic diagram of a single-flash plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

also minimize the levelized energy cost (LEC). The performance and cost optima will be near, but not generally at the same pressure.

The flash steam system can also be utilized in applications where the fluid enters the plant as a liquid (single phase). In these systems, the geothermal fluid is throttled with an expansion valve to the desired flash pressure. This flashing process can be considered adiabatic, where the amount of steam evolved can be determined from energy and mass balances of a simple throttling calculation.

Most successful flash systems are dual flash. The first flash is generally near the well-head pressure and the second flash near atmospheric pressure. The low-pressure flash is normally kept above atmospheric

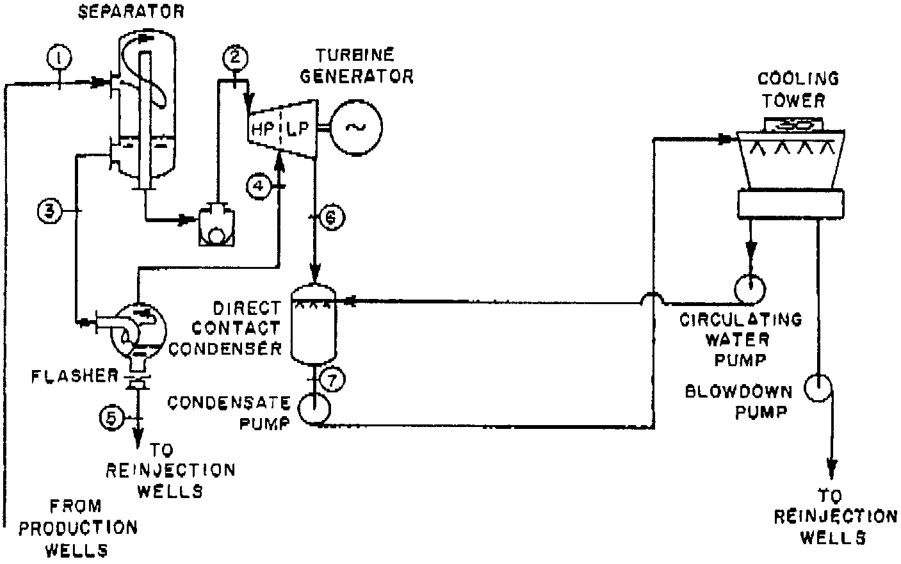

FIGURE 8.12.6 Schematic diagram of a dual-flash plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

pressure to prohibit leakage of air into the system in the flasher. Some recent studies have indicated that for low-temperature resources, a subatmospheric second flash would produce a cost-effective system. Again, optimization of the two flash pressures is necessary to minimize the LEC. In cases in which the geofluid has a high dissolved solid content, flash crystallizers are used to remove the precipitated dissolved solids. The flashing process releases carbon dioxide dissolved in lowering the geofluid pH, which causes the precipitation of insoluble carbonates. The solubility of silica is temperature dependent; lowering the geofluid temperature causes the precipitation of silica.

None of the steam cycles depicted provides for the removal of the noncondensable gases from the condenser. This removal is typically accomplished with steam ejectors or compressors which continuously remove the small stream of vapor from the condenser. Some steam is lost in this process of removing the noncondensable gases.

Binary Systems — Liquid-Dominated Resources

Recent studies have shown that for resources below 200°C, current technology binary systems have lower LEC than flash steam plants for liquid-dominated resources. Figure 8.12.7 shows a typical binary system with an evaporative heat-rejection system. This type of heat-rejection system has been replaced by air-cooled condensers in most applications. In the areas where the geothermal resource exists, there is little excess water for makeup in the cooling tower, as shown in Figure 8.12.7. All of the cooled geofluid in a binary system is typically injected back into the reservoir. This provides an environmentally acceptable means of disposal of the fluid and, more important, provides a recharge of the reservoir to maintain the reservoir productivity.

The binary cycle is an attempt to reduce the scaling potential of the geofluid. Carbonates are precipitated when the pressure of the geofluid is reduced and carbon dioxide comes out of solution as the geofluid flashes. With downhole pumps in the wells, this can be eliminated by keeping the fluid pressurized. Some resources do not require pumps to maintain the flow and pressure necessary to eliminate flashing (artesian flow). Similarly, if the exit temperature of the geofluid remains above some minimum value, silica will not be precipitated. These two operational strategies limit the scaling in a binary plant. Any constraint imposed on the geofluid exit temperature will impact the design of the binary plant, affecting the selection of turbine inlet conditions as well as the possible choice of working fluid.

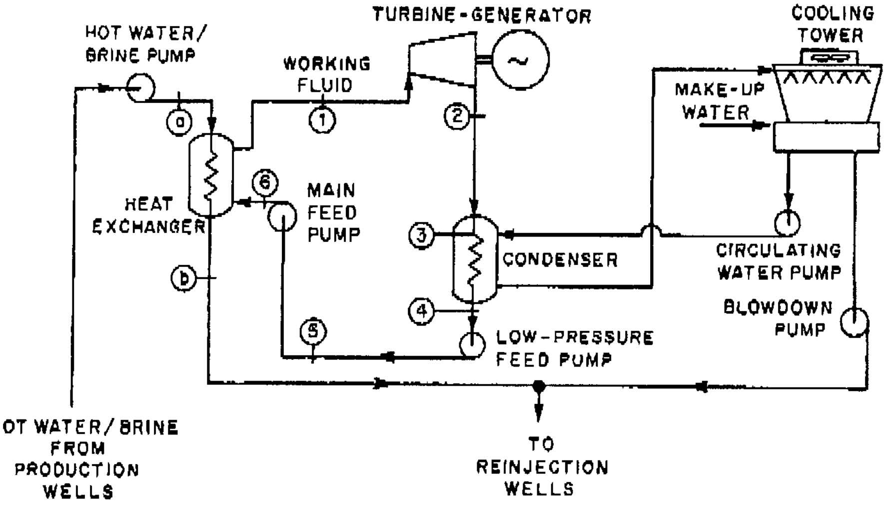

FIGURE 8.12.7 Schematic diagram of a binary plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

The binary cycle consists of a closed loop of a working fluid normally performing a Rankine cycle. Most existing binary cycles use isobutane, pentane, or isopentane as working fluids. Studies have indicated that mixtures of hydrocarbons, e.g., 96% isobutane/4% hexane, will produce better utilization of a 180°C resource and in some instances lower LEC.

The performance of the binary system depends on a number of factors. Some plant designs incorporate multiple or staged boiling cycles, where the working fluid flow is split and boiling occurs at multiple pressures. In these cycles, multiple or staged turbines are required. The advantage of these cycles is the fact that the working fluid heat-addition process more closely matches the sensible cooling of the liquid geofluid (as shown on the T-Q or T-h diagram). This lowers temperature differences through the cycle, reducing cycle irreversibilities and increasing performance. The same effect can be achieved by heating the working fluid at supercritical pressures (pressures above the critical pressure). While the supercritical cycle will have higher component, material, and pumping costs because of higher operating pressures, they have fewer components because they are less complex than multiple boiling cycles. (In many cases, the maximum pressure can be kept below 600 psi with hydrocarbons such as isobutane.) Lowering the mean temperature difference in heat exchangers tends to require larger units so that capital costs are increased. In general, the LEC is reduced because the effects of increased performance more than outweigh the increase in capital cost.

The choice of the working fluid for the power cycle will also impact the cycle performance. In general, as resource temperature decreases, the more volatile fluids will produce more power per unit mass of geofluid. Power cycles using the more volatile fluids typically operate at higher pressures and have higher associated material and equipment cost. These higher costs may offset the gains in performance and produce higher LECs in some cases.

Working fluid mixtures have been shown to provide superior performance to the single component or pure working fluids. This performance improvement is due to the nonisothermal phase changes of this type of fluid at constant-pressure (both boiling and condensing), which allows the working fluid to match more closely the sensible cooling of the geofluid. More importantly in the reduction of irreversibilities, the desuperheating and condensing process more closely matches the sensible heating of cooling water or air in the heat-rejection process.

One additional type of binary cycle that has been proposed uses an ammonia-water mixture for the working fluid. A great deal of recuperative preheat of the working fluid is accomplished by splitting the duty of the geofluid, turbine exhaust, and preheated liquid flows through a more complex heat-transfer train than is shown in Figure 8.12.7. These systems are known as **Kalina systems**. In general, these systems do not change the composition of the mixture in the cycle as the Kalina cycle for applications such as is the case for gas turbine bottoming.

There is some consideration of using a binary cycle as a bottoming cycle for a flash steam or direct steam system. Similarly, a binary cycle could be used to bottom another binary system, perhaps with a different working fluid.

Design Considerations

The selection of the working fluid in binary cycles imposes safety considerations to be considered in the design of the power plant. Equipment and facility designs must take into account the flammable characteristic of the hydrocarbon working fluids.

The selection of materials of construction for the piping and components exposed to the geofluid will be resource specific. Typically, carbon steel is used for piping and pressure vessels. Turbines that use the steam directly may have stainless steel components, although the use of stainless may be limited by the presence of chlorides and the potential for stress cracking. The standard design for heat exchangers in binary cycles is for the geofluid to be on the tube side. This facilitates the cleaning of the exchanger if scaling or fouling occurs on the surfaces exposed to the geofluid. If the geofluid has a high scaling potential, components and piping should be designed to allow for periodic cleaning.

Direct Use of the Geothermal Resource

A number of direct-use applications of the heat in a geothermal resource have been successfully implemented. These include

1. Space conditioning (heating with the resource or a secondary fluid and cooling with heat pumps);
2. Heating of greenhouses;
3. Aquaculture;
4. Process heating (drying vegetable products);
5. Ground coupled heat pumps.

Although the United States is one of the world leaders for the production of electrical power from geothermal energy, other nations take the lead for the direct use of this energy source. In Iceland, over 85% of the buildings are supplied with heat and domestic hot water from geothermal systems (Ragnorson, 1995).

Typical direct-use applications are either closed systems with produced fluids being injected back into the geothermal reservoir or systems where the produced water is pure enough for beneficial use or disposal to surface waterways. Experience has shown that it is usually worthwhile to inject as much of the cooled fluid as possible back into the reservoir to maintain pressure and production rates.

Defining Terms

Binary system: A binary system that uses thermal energy from the geofluid to vaporize a secondary working fluid in a Rankine cycle.

Direct steam system: A geothermal energy conversion system that utilizes steam directly from a geothermal well.

Flashed steam system: A geothermal energy conversion system that utilizes steam flashed from the liquid geofluid.

Geopressurized resource: Naturally occurring reservoirs of hot pressurized fluid created by convection of water through hot porous rock.

Hydrothermal resource: Artificial reservoirs created by injecting water into hot dry rock in the earth's core.

Kalina system: A binary system using a mixture of ammonia and water as the working fluid in the power cycle.

8.13 Direct Energy Conversion

Solar Photovoltaic Cells

Kitt C. Reinhardt

Introduction

Solar photovoltaic cells convert sunlight directly into electrical energy via the collection of solar photon-generated semiconductor charge carriers. The collection of charge carriers within the cell produces a voltage across the terminals of the cell, called the **photovoltaic effect**, that can drive an external electrical circuit or charge a storage battery. Photovoltaic cells are useful in both space and terrestrial power applications. Silicon, Si, photovoltaic cells have provided the main source of electrical power to virtually all Earth-bound satellites since the advent of the space program in the late 1950s. In the early 1970s, photovoltaics generated a significant amount of interest for use in terrestrial power systems when oil supplies to the industrial world were disrupted. Today, while photovoltaic power remains the primary energy source for most communication and surveillance satellites, issues concerning system efficiency, reliability, and cost currently prevent its widespread use in residential and power utility applications. For example, in the United States the average price for conventional utility electricity is 6¢/kWhr, compared with ~35¢/kWhr for terrestrial photovoltaic electricity (Zweibel, 1995). Thus, the cost of photovoltaic power must be reduced by a factor of ~6 for it to become economically viable. At present, photovoltaic power is generally only cost-competitive for use in remotely located systems where conventional power is cost-prohibitive, such as in remote water-pumping and communications stations, signal and emergency lighting, and for village power. Factors that influence photovoltaic system energy costs include cell panel efficiency, total system lifetime, and cost per unit area. The present discussion will focus on issues concerning photovoltaic cells and panels. Detailed literature on power conditioning electronics and energy storage systems can be found elsewhere. A large number of different photovoltaic cell designs have been demonstrated by researchers over the years. However, the most common and practical cell designs are fabricated using single-crystal Si. Consequently, Si will be used to describe basic principles of semiconductors and photovoltaic cell operation.

Introduction to Semiconductors

We begin with a description of the concept of covalent bonding, valence electrons, and energy bands, which relates to conduction in semiconductors (Sze, 1981). The crystalline structure of Si is diamond, where each Si atom in the lattice is covalently bonded to four equidistant nearest neighbors that lie at the corners of a tetrahedron. Each Si atom has four electrons in its outer orbit, called valence electrons, and each atom shares these electrons with its four neighbors to form four covalent bonds. The atomic configuration of the 14 electrons of Si is $1s^2 2s^2 2p^6 3s^2 3p^2$. At practical temperatures, only the $3s^2 3p^2$ valence electrons contribute to the electrical conductivity; the $1s^22s2^2p^6$ core electrons are too tightly bounded to the nucleus to participate. In a simplified model, as N Si atoms are brought together at 0 K to form a crystal, two distinct and nearly continuous bands of electronic energy levels form that are separated by an energy gap called the semiconductor **band gap, E_g**. The resulting upper **conduction band** contains 4N states, as does the lower **valence band**. The 4N electrons that come from the Si $3s^23p^2$ states completely fill the 4N states in the valence band at 0 K, and the conduction band states are completely empty. Since there are no unoccupied states in the valence band for electrons to move and the conduction band is empty, Si is a perfect insulator at 0 K.

As the temperature of the crystal increases, electrons in the valence band gain sufficient thermal energy ($>E_g$) to be excited across the band gap into the conduction band, leaving holes (missing electrons) behind in the valence band. When current conduction in a semiconductor is dominated by thermally generated electrons and holes, it is called intrinsic. In this case, the resulting number of electrons per unit volume in the conduction band, n, equals the number of holes per volume in the valence band, p, that is $n = p = n_i$, where n_i is called the intrinsic carrier concentration. In the presence of an electric field, intrinsic electrons and holes gain kinetic energy and conduct electricity. However, since at room temperature n_i for Si is only 1.45×10^{10} cm^{-3}, compared with a free-electron density of more than 10^{22} cm^{-3} in metals, Si behaves as a very good insulator, i.e., electrical conductivity, σ, is given by $\sigma = q(n\mu_n + p\mu_p)$, where q is the electronic charge and μ is the respective carrier mobility.

In order to increase the conductivity to values useful for solid-state devices, the level of n and p can be increased by purposely adding impurity atoms into the crystal, called doping, that liberate extra electrons or holes. In the case of Si, which is in column IV of the periodic table, and hence has four valence electrons for bonding, doping is achieved using either column III elements (boron, aluminum, gallium, or indium), which have three valence electrons, or column V elements (phosphorus, arsenic, or antimony), which have five valence electrons. When an arsenic atom with five valence electrons replaces (substitutes) an Si atom, four of its electrons are used to form covalent bonds with the four neighboring Si atoms. The fifth electron is loosely bound to the arsenic nucleus, and at room temperature is ionized and "donated" to the conduction band. Arsenic is therefore called a donor, and Si becomes an n-type (mostly electrons) semiconductor. Similarly, when a boron atom with three valence electrons substitutes for an Si atom, one of the boron four covalent bonds becomes deficient of one electron. Boron can then accept one electron from the valence band to satisfy the bond requirement, which creates a positively charged hole in the valence band. Boron is therefore called an acceptor, and Si becomes a p-type (mostly holes) semiconductor. In this way the electrical conductivity of semiconductors can be precisely controlled by varying the concentration of donor and acceptor impurities. In practical solid-state devices, typical values of n and p range between 10^{15} and 10^{19} cm^{-3}.

The p-n Junction Diode

The p-n junction is a basic structure used for solid-state device rectification, amplification, and switching, as well as for photocarrier collection in photovoltaic cells. A p-n junction is formed when a p-type semiconductor is metallurgically joined with an n-type semiconductor (Streetman, 1980). Before they are joined, the p-material has a large concentration of holes and very few electrons, whereas the converse is true for the n-material. Upon joining the two materials, holes instantaneously diffuse from the p-side into the n-side and electrons diffuse from the n-side into the p-side. The transport of these carriers constitutes a "diffusion" current from the p-side to n-side; electron current is opposite in direction to electron flow by convention. As shown in Figure 8.13.1, negative acceptor ions are left behind as holes leave the p-side of the junction, creating a negative space-charge region (SCR), and positive donor ions are left behind as electrons leave the n-side of the junction, creating a positive SCR. Consequently, an electric field directed from the positive SCR to the negative SCR results that opposes the further diffusion of electrons and holes; i.e., the electric field creates a drift component of current from the n-side to p-side that opposes the diffusion component. In the absence of any external fields a condition of equilibrium is established, and the net current flow across the junction is zero. As will be discussed, the p-n junction electric field is also responsible for separating and collecting photon-generated carriers in photovoltaic cells.

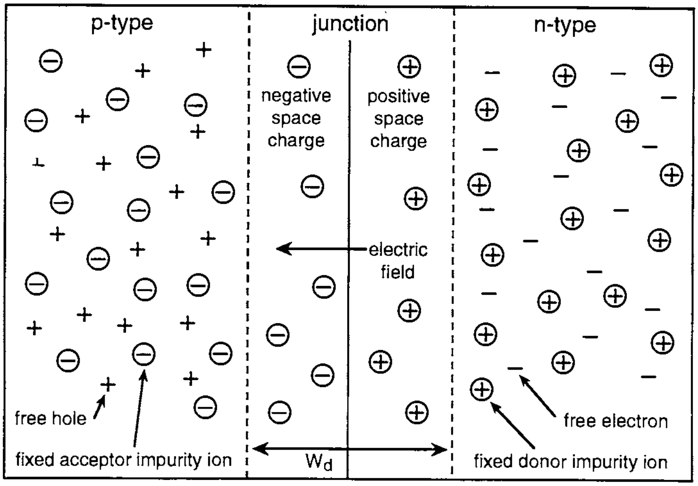

FIGURE 8.13.1 Schematic diagram illustrating an abrupt p-n junction with a uniform concentration of donor impurities in the n-region and acceptor impurities in the p-region.

When a voltage is applied across a p-n junction, the balance between the electron and hole drift and diffusion currents is disturbed and a net current results. Under forward bias, a positive voltage is applied to the p-side relative to the n-side, and the electric field across the junction is reduced; i.e., the electric field associated with the applied voltage subtracts from the zero-bias field. The reduced field enhances hole diffusion from the p-side to the n-side and electron diffusion from the n-side to the p-side, thereby increasing the "positive" current; the transport of current from the p-side to the n-side is positive by convention. Conversely, under reverse bias a negative voltage is applied to the p-side relative to the n-side, and the electric field across the junction increases. Consequently, the diffusion component of current decreases relative to the drift component, and a net "negative" current results across the junction.

The dark current-voltage (I-V) characteristics for an Si p-n junction are generally well described by the ideal Shockley diode equation (Sze, 1981),

$$I_D = I_o\left[\exp\left(qV/nkT\right) - 1\right] \tag{8.13.1}$$

where I_D is the junction dark current, I_o is the reverse saturation current, V is the forward-bias voltage, n is the diode ideality factor, and T is the absolute temperature. The value of n is ~1.0 when the current is dominated by carrier diffusion, but increases and approaches values of ~2 or greater when other current mechanisms become important, such as carrier recombination or tunneling. In high-quality Si p-n junction photovoltaic cells, the value of n is ~1.0 near the relevant operating voltage. The parameter I_o varies with T and E_g according to

$$I_o = qA\left[D_n n_p / L_n + D_p p_n / L_p\right] \propto T^3 \exp\left(-E_g/kT\right) \tag{8.13.2}$$

where A is the junction area and D_n and D_p, n_p and p_n, and L_n and L_p are the diffusion coefficients, minority carrier densities, and diffusion lengths for electrons and holes, respectively. The value of I_o decreases strongly as E_g increases, which, as will be shown, increases the photovoltage obtainable from a photovoltaic cell.

Cell Operation and Efficiency

Cell Operation. Photovoltaic energy conversion in a p-n junction is a two-step process where free electrons and holes (photocarriers) are generated in the semiconductor via the absorption of solar energy and then

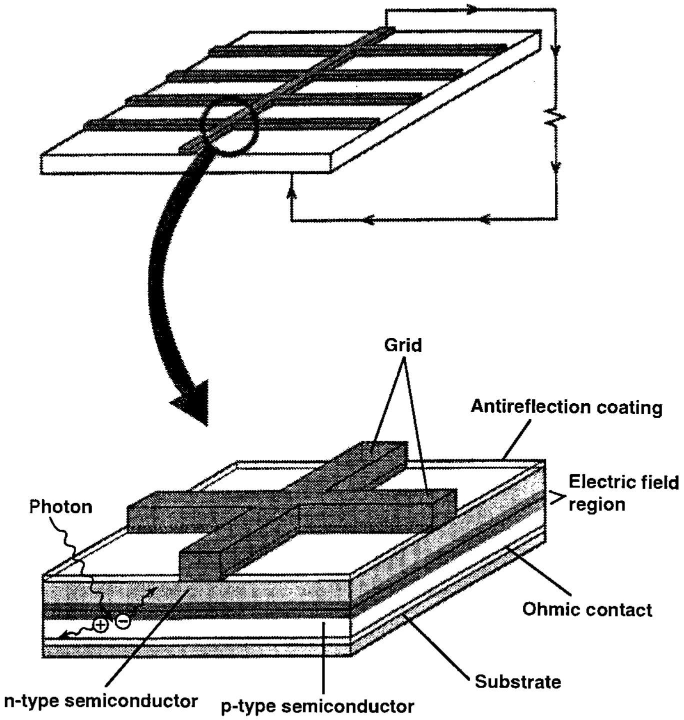

FIGURE 8.13.2 Schematic diagram of a typical p-n junction photovoltaic cell. (From Stone, J.L. *Phys. Today*, September 24, 1993. With permission.)

simultaneously collected across the junction (Fahrenbruch and Bube, 1983). Consider the schematic of a typical photovoltaic cell shown in Figure 8.13.2 which consists of a p-n junction formed very close to the top surface of the cell. Front metal ohmic contact grid fingers allow solar energy to pass into the absorber layers. The entire top surface is covered with an antireflection coating to minimize reflective losses, and the entire back surface is covered with an ohmic contact. The ohmic contacts form n and p region terminals that transfer (conduct) current from the semiconductor to the external circuit with a negligible amount of voltage drop.

When the photovoltaic cell is exposed to solar radiation, photons with energies greater than E_g (super-band-gap photons) are absorbed in the n and p layers, and free electrons and holes are generated via the breaking of covalent bonds. These electron-hole pairs, or **photocarriers**, are shown in Figure 8.13.1. The energy of the free photocarriers is converted directly into a current and voltage via photocarrier collection by the junction. The absorbed photons effectively contribute an energy E_g to the cell output, and energy greater than E_g is lost as heat. Photons with energies less than E_g (sub-band-gap photons) are transmitted through the cell. After generation, minority photocarriers, that is, holes on the n-side and electrons on the p-side, diffuse toward the edges of the junction due to a gradient of carriers that exists there. If the minority carriers are generated within a diffusion length, L, of the junction, they will reach it and be swept across it by the electric field of the junction. Hence, electrons are swept from the p-side to the n-side and holes from the n-side to the p-side, and thus they are separated. The minority carrier gradient present at the edges of the junction is due to the depletion of minority carriers that results from their transfer across the junction. The diffusion flux of minority carriers toward and across the junction constitutes a light-generated current, I_L, or photocurrent, that is directed from the n-side to the p-side of the cell. The build-up of positive holes on the p-side and negative electrons on the n-side gives rise to a **photovoltage** across the junction. The polarity of both the photovoltage and photocurrent is identical to that of a battery, and power is delivered from the junction to the external circuit.

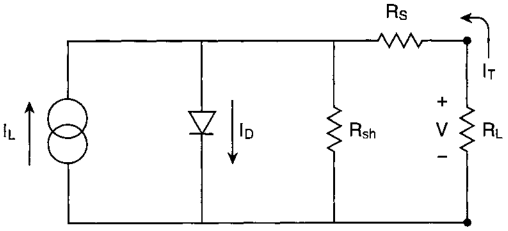

FIGURE 8.13.3 Schematic of equivalent circuit model for a p-n photovoltaic cell.

Cell Efficiency. In order to derive the solar conversion efficiency, it is convenient to model the photovoltaic cell as an ideal p-n diode in parallel with a **light-generated** (constant) **current** source, $\boldsymbol{I_L}$, as shown in the equivalent circuit of Figure 8.13.3. Parasitic series and shunt resistance losses, R_s and R_{sh}, respectively, are also shown, where R_s is due to ohmic contact and semiconductor resistances, and R_{sh} is due to defect-related carrier recombination and/or tunneling phenomena (Stirn, 1972). A qualitative expression for I_L is given by Tada et al. (1982):

$$I_L = qAG\left(L_n + W_d + L_p\right) \tag{8.13.3}$$

where G is the photocarrier generation rate in carriers/cm^3-sec due to solar photon absorption, which depends on E_g and the photon energy (wavelength) and intensity (concentration), and W_d is the sum of the negative and positive SCR widths. As mentioned, I_L is directed from the n-side to the p-side. In contrast, the dark diode current given by Equation (8.13.1) is directed oppositely from the p-side to the n-side. The **dark current** is due to the forward-bias photovoltage that appears across the cell p-n junction when it is illuminated. Thus, the dark current opposes the light current. In the ideal case, that is, when $R_s = 0$ and $R_{\text{sh}} = \infty$, the total forward current, I_T, is given by

$$I_T = I_D - I_L = I_o\left[\exp\left(qV/nkT\right) - 1\right] - I_L \tag{8.13.4}$$

A plot of dark and light current-voltage (I-V) curves resulting from Equation (8.13.1) and Equation (8.13.4), respectively, is shown in Figure 8.13.4 for a typical p-n solar cell. Under illumination, the forward-bias dark I-V curve is displaced downward into the fourth quadrant by the **photocurrent,** $\boldsymbol{I_L}$. It is noted from Figure 8.13.3 that the voltage drop across the load resistance, R_L, is $V = -I_T R_L$. Under short-circuit conditions, that is, when the n and p terminals are tied to each other, R_L is negligible. The resulting voltage drop across the p-n junction will also be negligible, and from Equation (8.13.1), $I_D \approx 0$. As shown in Figure 8.13.4, the resultant current is termed the **short-circuit current,** $\boldsymbol{I_{\text{sc}}}$, or $I_T = -I_{\text{sc}} = -I_L$. As the value of R_L increases, a voltage appears across the junction, $V = -I_T R_L$, called the **photovoltage**, and I_D increases in accordance with Equation 8.13.1. Under this condition the cell is operating in the fourth quadrant of the I-V characteristic (i.e., the junction voltage is positive and the current is negative), and, consequently, the cell delivers power (product of the current and voltage) to R_L. As the value of R_L continues to increase, so too does V and I_D. When the value of R_L approaches infinity, that is, under open-circuit conditions, I_D approaches I_L and I_T goes to zero. The resulting **open-circuit voltage,** $\boldsymbol{V_{\text{oc}}}$, is shown in Figure 8.13.4. V_{oc} can be obtained by setting $I_T = 0$ in Equation (8.13.4) and solving for V. For $V \gg \text{kT/q}$,

$$V_{oc} = nkT/q \ln\left[I_L/I_o\right] \tag{8.13.5}$$

Thus, the operating point on the I-V curve in the fourth quadrant can be swept from (I_{sc}, 0) to (0, V_{oc}) by varying the value of R_L. When the optimum load is chosen (i.e., $R_L \approx V_{\text{oc}}/I_{\text{sc}}$), approximately 80% of the product $I_{\text{sc}}V_{\text{oc}}$ can be extracted as useful power as shown by the shaded maximum-power rectangle

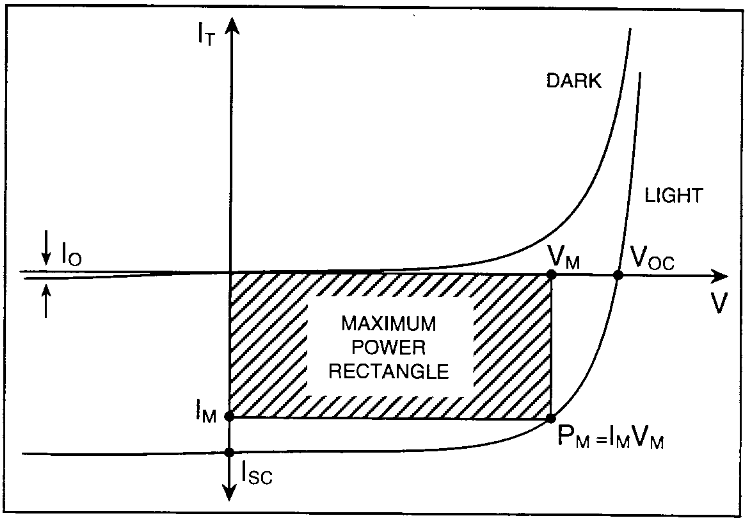

FIGURE 8.13.4 Typical dark and light current-voltage characteristics for a p-n photovoltaic cell.

in Figure 8.13.4. Also shown in Figure 8.13.4 are the parameters I_m and V_m, which correspond to values of current and voltage, respectively, that yield the maximum cell power, P_m, where $P_m = I_m V_m$. The knee that appears at P_m is due to the parasitic effects of R_s and R_{sh}. The curvature of the knee at P_m is described by the **fill factor**, **FF**, where

$$\mathrm{FF} = I_m V_m / I_{sc} V_{oc} \tag{8.13.6}$$

The photovoltaic cell **conversion efficiency**, **η**, is defined as

$$\eta = I_m V_m / P_{\mathrm{in}} A$$

or

$$\eta = FF\, I_{sc} V_{oc} / P_{\mathrm{in}} \tag{8.13.7}$$

where P_{in} is the incident power in W/m^2 equal to the sum in energy of the incident photons per time per area. Values for V_{oc}, I_{sc}, FF, and η can be obtained in the laboratory under various air mass conditions from light *I-V* curves measured using a carefully controlled (calibrated) light source to illuminate the cell.

Cell Material vs. Efficiency

The optimum value of material E_g for solar photovoltaic conversion is ~1.0 to 1.5 eV. To understand how the choice of cell material affects conversion efficiency, an ideal expression can be derived using Equation 8.13.4 for the theoretical conversion efficiency. The output power can be expressed as (Henry, 1980)

$$P = IV = I_o V\left[\exp\left(qV/nkT\right) - 1\right] - I_L V \tag{8.13.8}$$

The maximum output power is obtained when $dP/dV = 0$, and an expression for I_m and V_m can be obtained from Equation (8.13.8) and multiplied to give P_m, where

$$P_m = I_m V_m \approx I_L\left[V_{oc} - kT/q \ln\left(qV_m/kT + 1\right) - kT/q\right] \tag{8.13.9}$$

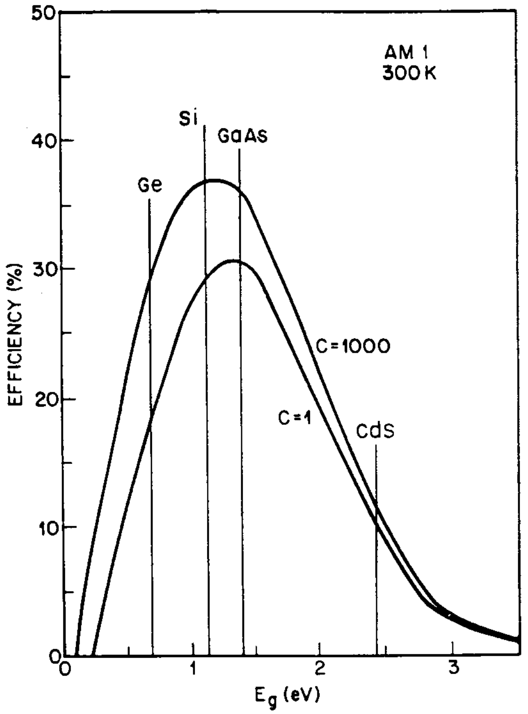

FIGURE 8.13.5 Theoretical AM1 efficiency vs. semiconductor band gap E_g for an ideal photovoltaic cell under 1 sun and 1000 suns concentrations. (From Henry, C.H., *J. Appl. Phys.*, 51, 4494, 1980. With permission.)

In practical cells, values for V_m and V_{oc} are typically $\frac{1}{2}E_g/q$ to $\frac{2}{3}E_g/q$. Thus, for materials with $E_g \sim 1 - 2$ eV, the quantity in the large brackets of Equation (8.13.9) becomes $\sim V_{oc}$, and the factors that determine I_L and V_{oc} also determine P_m. From Equation (8.13.2) and Equation (8.13.5), it is clear that V_{oc} increases with E_g through the reduction in I_o. In contrast, as E_g increases, I_L decreases because a smaller portion of the solar spectrum is energetic enough to be absorbed; i.e., I_L is the product of q and the number of available photons with energy greater than E_g. Hence, for a given solar spectrum there is an optimum value of E_g that maximizes the product of V_{oc} and I_L. A plot of ideal AM1 conversion efficiency vs. E_g is shown in Figure 8.13.5 for "one sun" (925 W/m^2) and "1000 suns" (925 kW/m^2) concentrations (Henry, 1980). The efficiency curves were obtained using Equation (8.13.1) through Equation (8.13.7) at 300 K. A maximum in efficiency occurs for $E_g \sim 1.0 - 1.5$ eV.

Manufacture of Cells and Panels

There are basically five important solar cell design concepts, and each offers a trade-off between efficiency and cost: (1) Large-area single-crystal planar cells, typically 1 × 1 cm^2 to 6 × 6 cm^2, yield high efficiencies under normal light conditions, 2) single-crystal small-area concentrator cells, typically less than 1 × 1 cm^2, are potentially less costly and yield higher efficiencies under concentrated light, i.e., concentration ratios of 20 to 1000 are typical; (3) more-complex single-crystal multijunction cells yield the highest efficiencies measured to date, but are substantially more expensive; (4) cells made from polycrystalline materials are less expensive than single-crystalline cells, but are less efficient; and (5) cells made from thin film amorphous materials provide the lowest-cost approach yet, but are generally less efficient than polycrystalline cells.

A typical 15% 4 × 4 cm^2 photovoltaic cell produces only ~0.25 W under AM1.5 conditions. Therefore, individual cells must be electrically wired together to form larger submodules or panels to increase the total output power. The cells can be connected in series to increase the total voltage or in parallel to increase the current. The modular nature of photovoltaic power allows the design of systems that can deliver electrical power from a few watts to many megawatts. In terrestrial applications the cells are typically supported and held in place with a rigid substrate, i.e., typically aluminum, Plexiglas, fiberglass, or glass, and are encapsulated with glass or a polymeric material; in space applications the support structure may be rigid or flexible, and the cells are protected from the space environment with quartz cover slides. The electrical power generated by the cells is conducted to an electrical load or storage battery. Metal interconnects soldered to the ohmic contacts of the cells conduct electrical current from one cell to the next. Current is then conducted from the network of series- and parallel-connected cells by wires to a distribution terminal "bus" that transfers the power to either the load or battery.

Single-Crystal Cells. The p-n photovoltaic cells made from **single-crystal** Si dominate in space and terrestrial applications because of their high efficiency and reliability. The formation of single-crystal p-type Si results from the selective cooling of pure molten Si to form large cylindrical crystal ingots, called boules, from which thin wafers are sliced and polished. The p-type impurities, usually boron, are added to the melt, to give the desired impurity concentration. A large-area p-n junction is then formed by diffusion of n-type impurity atoms, usually phosphorus. Front and back metal ohmic contacts and an antireflection coating are then formed using standard photolithography thermal evaporation or sputtering techniques (Sze, 1985). The resulting cell structure is shown in Figure 8.13.2, and typical cell areas range from 1 to 36 cm^2. Different semiconductors absorb sunlight more efficiently than others, described by a factor called the absorption coefficient. Si has a relatively small absorption coefficient compared with other materials, such as InP, GaAs, and amorphous-Si, and consequently requires an absorption layer thickness of ~100 μm to maximize conversion efficiency. Conventional Si cells have a thickness on the order of 250 μm, but can be chemically or mechanically polished to a thickness of 100 μm.

Single-crystal III-V photovoltaic cells, such as InP and GaAs, are made from elements in the III and V columns of the periodic table. The band gaps of these cells, 1.35 and 1.42 eV, respectively, are close to the optimum value. These materials involve the growth of single-crystal semiconductor layers upon a single-crystal semiconductor substrate. This technique is called epitaxy and it provides a method to produce both n-type and p-type layers to form the p-n junction. Epitaxial growth of n and p layers is required for InP and GaAs because diffusion of impurities at high temperatures is confounded by the high vapor pressure of the material. The formation of ohmic contacts and antireflection coating employ the same techniques as used for Si cells. The required absorption layer thickness for these cells is only a few microns because of their large absorption coefficients. However, issues concerning yield and mechanical strength limit their minimum thickness to ~100 μm The best reported efficiencies for single-crystal Si, GaAs, and InP cells under AM1.5 conditions are 24, 25, and 22%, respectively (Green et al., 1995).

Polycrystalline Cells. In the case of **polycrystalline** Si cells, molten Si is directly deposited into either cylindrical or rectangular ingots. As the material solidifies, individual crystalline regions form that are separated by grain boundaries which contain large numbers of structural defects. When the cell is illuminated, these defects capture a portion of the light-generated electron-hole pairs through recombination processes before they can reach the junction and be collected. Thus, the grain boundaries diminish the light-generated current and overall efficiency of the cell. However, polycrystalline silicon cells are sufficiently inexpensive to be commercially viable (Stone, 1993). An area that requires improvement is the slicing of polycrystalline ingots, where yields as low as 50% are common. An approach that eliminates the expense of sawing and polishing altogether is the growth of polycrystalline Si directly into the form of thin ribbons using a technique called edge-defined film-fed growth (EFG) (Fahrenbruch and Bube, 1983). In this approach, a carbon die with a slot-shaped aperture is immersed in a crucible of molten Si. The liquid Si wets the die and flows through the slot where it cools and is pulled to form a thin ribbon. This material also has high crystalline defect densities, but has good overall yields. An additional approach involves the growth of films of nearly single-crystal quality, where two parallel supporting dendrites form the boundaries of a web or ribbon pulled from a supercooled melt of Si. The best efficiency for polycrystalline Si cells under AM1.5 conditions is ~18%; that for Si cells grown by the EFG technique is 14%; and that for Si dendritic web cells is 15.5% (Stone, 1993). It is important to note that although these lower-cost films yield lower cell efficiencies compared with single-crystal cells, the cost of cells depends on the cost of the starting material and the cost per watt is more important than efficiency (Zweibel, 1995).

Thin Film Cells. Thin films cells provide an even lower-cost (and lower-efficiency) approach because they require a very small amount of semiconductor. An excellent review on thin film photovoltaic technologies, particularity on present and future cost issues, is given by Zweibel (1995). The general approach involves depositing only a few microns of material on a low-cost substrate using various vacuum deposition techniques, although a multitude of other deposition techniques have also been demonstrated. The top thin film cell candidates are amorphous Si, a-Si, cadmium telluride, CdTe, and copper indium diselenide, CIS (and related alloys). The highest reported thin film AM1.5 efficiencies are 17% for CIS, followed by 15.8% for CdTe, and ~11% for a-Si (Zweibel, 1995). However, the relative level of maturity of each design for commercial application must be put into perspective. While the best CIS cell efficiency is quite high, the best CIS square foot panel efficiency reported back in 1988 was, and still is today, only 11%. Significant manufacturing problems have plagued the CIS cell, and currently it is still not commercially available. CdTe is believed to be the easiest of the thin film cells to fabricate, and probably represents the closest to large-scale commercialization. Two U.S. companies have publicly announced CdTe manufacturing plants, and commercial efficiencies are likely to be in the range of 6 to 8% in the first plants. The future of a-Si cells is currently believed to be limited if it cannot overcome a 10% efficiency at the module level. Development problems include electrochemical instability to light that results in a 20 to 40% degradation. However, it appears that the use of multijunction thin film a-Si layers may solve the problem, and modules of 7 to 9% are expected in the near term.

Concentrator Cells. Photovoltaic modules are typically either of the flat plate or concentrator configuration. Flat plate modules can be fixed with respect to the sun or mounted to track the sun in one or two axis. Concentrator modules use large-area mirrors or lenses to concentrate sunlight onto smaller-area cells. Concentrator cells operate at higher efficiencies. However, concentrator modules require one- or two-axis tracking which adds system complexity and cost that generally offsets the module efficiency and lower area cost benefits. The increase in conversion efficiency with illumination intensity is shown in the 1000-sun concentration curve of Figure 8.13.5. Values for I_L increase linearly with concentration through the factor G in Equation (8.13.3) and V_{oc} increases logarithmically with concentration through I_L in Equation (8.13.5). Under solar concentration of "20 suns" or greater, a significant amount of cell heating can occur. While J_{sc} increases slightly with increasing temperature, values of V_{oc} and FF drop strongly. Thus, on adequate heat sink or active cooling is required at high concentrations. The reported AM1.5 efficiency for Si cells increases from 24 to 26.5% under a concentration of 255; and that for GaAs cells increases from 25 to 27.6% under a concentration of 140 (Green et al., 1995).

Multijunction Cells. Another approach to increase photovoltaic cell efficiency is through the use of multijunction tandem solar cells. A multijunction solar cell consists of a stack of three or four layers of light-sensitive semiconductor material, successively grown atop one another, that optimally converts the sun's light energy into electricity. Each layer in the stack absorbs a different portion of the solar spectrum, which is determined by its electronic bandgap, E_g. Generally, the top layer absorbs the ultraviolet light, the middle layer absorbs the visible, and the bottom layer(s) absorb the infrared. The trick to maximizing multijunction solar cell conversion efficiency is finding the optimum combination of semiconductor layers that have the right bandgap and can be grown atop each other. Current practice multijunction solar cells utilize a three-junction, two-terminal device configuration, where three p-n junctions are epitaxially grown atop each other on an inactive substrate as shown in Figure 8.13.6. The top p-n junction has the highest seminconductor bandgap, E_{g1}, in the stack and absorbs photons with energies $\geq E_{g1}$. The middle p-n junction has a bandgap of E_{g2}, and absorbs photons with energies E, where $E_{g1} < E < E_{g2}$. The bottom p-n junction has a bandgap of E_{g3}, and absorbs photons with energies $E_{g2} < E < E_{g3}$. The values for semiconductor E_{g1}, E_{g2}, and E_{g3} must be chosen to achieve both maximum solar absorption and current mathcing; i.e., the three p-n junctions must generate equal electrical currents when illuminated. The current state-of-practice triple junction solar cell consists of a $GaInP_2/GaAs/Ge$ design, having

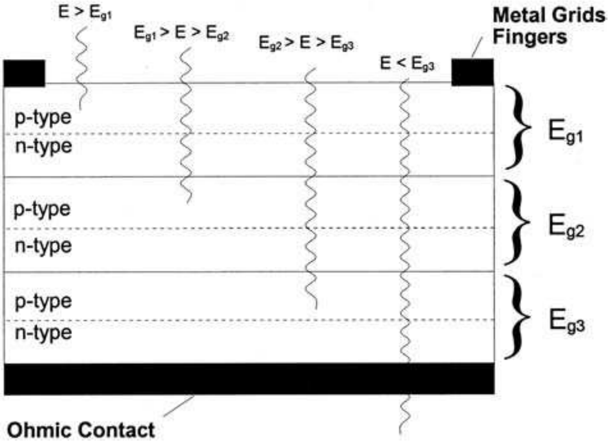

FIGURE 8.13.6 Schematic diagram of a triple junction solar photovoltaic cell under illumination.

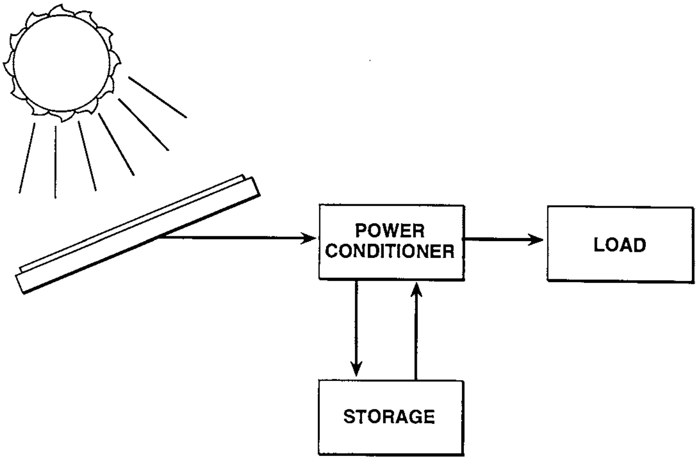

FIGURE 8.13.7 Schematic diagram depicting the basic components of a typical photovoltaic power system.

the bandgap combination of $E_{g1} = 1.9$ eV ($GaInP_2$), $E_{g2} = 1.4$ eV (GaAs) and $E_{g3} = 0.7$ eV (Ge). Large area (30 cm^2) $GaInP_2$/GaAs/Ge solar cell conversion efficiencies range from 26 to 28% in space (AM0 spectrum) and 31% on the ground (AM1.5 spectrum). Today, the primary use for multijunction solar cells is in space power applications, due to their relatively high cost compared to lower cost, lower efficiency silicon solar cells that dominate in terrestrial applications.

Design of a Photovoltaic Generating System

A schematic diagram depicting the basic components of a typical photovoltaic power generation system is shown in Figure 8.13.7 (Pulfrey, 1978). The system includes a photovoltaic array that consists of many smaller submodules, each containing many hundreds or thousands of photovoltaic cells. The DC output power from the array is controlled by a power conditioning unit that contains an inverter for developing AC power and an input power tracking device to maintain the optimal array load to achieve maximum output power. Power is directly fed to the electrical load and/or storage system by the conditioning unit. The storage system is needed to save energy when power is generated in excess of the immediate demand, or when the load demand exceeds the immediate generation level. Total photovoltaic power system efficiency is the product of the efficiencies of the individual components. Typical efficiencies for the power conditioning unit (determined by the inverter) and energy storage system are about 95% and

50-80%, respectively. Thus, an array efficiency of 10% would result in a total system efficiency of about 5 to 8%, and a total system efficiency of 10% would require an array efficiency in excess of 13%.

Defining Terms

Band gap (E_g): The difference in energy between the energy level of the bottom of the conduction band and the energy level of the top of the valence band.

Conduction band: A range of allowable energy states in a solid in which electrons can move freely.

Conversion efficiency (η): The ratio of the available power output photovoltaic cell to the total incident radiant power.

Dark current: Any current that flows through the p-n junction in the absence of external irradiation.

Fill factor (ff): The ratio of the maximum photovoltaic cell output power to the product of the open-circuit voltage and short-circuit current.

Light-generated current (I_L): The electrical current obtained from an illuminated p-n junction resulting from the collection of photocarriers across the junction.

Open-circuit voltage (V_{oc}): The voltage obtained across the terminals of an illuminated p-n photovoltaic cell under open-circuit conditions.

Photocarriers: Electrons and holes generated within a semiconductor via the absorption of photon energy.

Photocurrent: Synonymous with light-generated current.

Photovoltaic effect: The production of a voltage difference across a p-n junction resulting from the absorption of photon energy.

Photovoltage: The voltage resulting from the photovoltaic effect.

Polycrystalline: A material characterized by an array or agglomerate of small single-crystal sections of various crystal orientations separated from one another by grain boundaries, which are localized regions of very severe lattice disruptions and dislocations.

Short-circuit current (I_{sc}): The electrical current measured through the terminals of an illuminated p-n photovoltaic cell under short-circuit conditions.

Single crystal: A material characterized by a perfect periodicity of atomic structure; the basic arrangement of atoms is repeated throughout the entire solid.

Valence band: A range of allowable energy states in a solid crystal in which lie the energies of the valence electrons that bind the crystal together.

Further Information

An excellent presentation of the basic theory of the various photovoltaic cell designs is given in *Fundamentals of Solar Cells: Photovoltaic Solar Energy Conversion*, by Alan L. Fahrenbruch and Richard H. Bube. This text covers the basics of solar insolation, semiconductors, p-n junctions, and single-crystal, polycrystalline, thin film, and concentrator photovoltaic cells.

An excellent review of the progress achieved in terrestrial and space photovoltaics can be traced in the *Proceedings of the IEEE (Institute of Electrical and Electronics Engineers) Photovoltaics Specialists Conference* (PVSC) that dates back to 1961. These proceedings include thousands of papers that address nearly every aspect of photovoltaic cell development: basic theory, design, fabrication, and application.

The monthly journal *Solar Energy Materials and Solar Cells* covers many aspects of improving device efficiency, reducing costs, and testing and applications.

The monthly journal *Progress in Photovoltaics* documents recent results of research work conducted in photovoltaics worldwide. This journal is an excellent source for currently reported cell conversion efficiencies.

Proceedings of the conference *Space Photovoltaics Research and Technology* is an excellent source for the reader interested in the development of photovoltaics for use in space.

Fuel Cells

D. Yogi Goswami

Introduction

A *fuel cell* is an electrochemical device in which a fuel and an oxidant react in such a controlled manner that the chemical energy of reaction is converted directly into electrical energy. Ordinarily, a fuel reacts violently with an oxidant in a combustion reaction resulting in the release of heat of combustion. The heat of combustion can, then, be converted into electrical energy via mechanical work with the constraint of the second law of thermodynamics. The overall efficiency of the series of conversion processes is of the order of 40%. A fuel cell bypasses these processes resulting in potential efficiencies of the order of 80%. As an example, when hydrogen is burned in an atmosphere of oxygen it results in the following reaction:

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O + \Delta H \quad \text{(heat of reaction)} \tag{8.13.10}$$

In this reaction, two hydrogen atoms bond with an oxygen atom by sharing their electrons with the outermost orbit of oxygen, which becomes full, resulting in a stable structure.

The reactants H_2 and O_2 may be combined to form the same product (H_2O) by first stripping the electrons away from the hydrogen atoms and allowing the electrons to pass through an external circuit before combining with oxygen.

$$H_2 \rightarrow 2H^+ + 2e^- \quad \text{(electrons)} \tag{8.13.11}$$

$$2H^+ + O + 2e^- \rightarrow H_2O \tag{8.13.12}$$

Figure 8.13.8 shows a schematic of an arrangement that would allow the above reaction to proceed.

In order for the above reactions to occur according to the schematic of Figure 8.13.8:

1. Electrodes must be porous to let the fuel and electrolyte penetrate.
2. The electrolyte must be permeable to H^+ and $(OH)^-$ ions.
3. Electrode materials must be catalysts for the reaction (Pt, Ni, etc.).

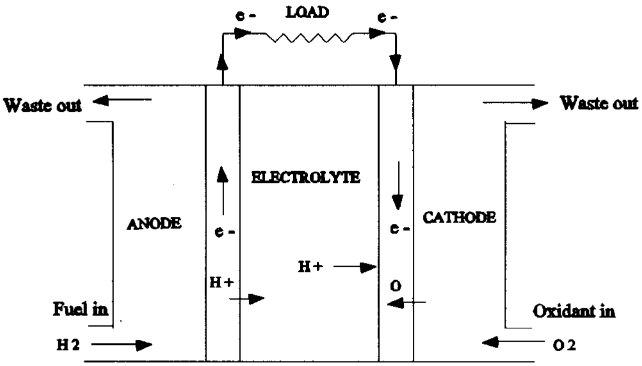

FIGURE 8.13.8 Conceptual schematic of a hydrogen fuel cell.

In 1839, William Grove, an English investigator, constructed a chemical battery in which he noticed that the water-forming reaction of hydrogen and oxygen generated an electrical current. However, it was not until 50 years later that two English chemists, Ludwig Mond and Carl Langer, developed a device they actually called a fuel cell (Angrist, 1982). There has been a strong resurgence in research and development of fuel cells in the last four decades.

Thermodynamic Performance

The energy released or needed in any chemical reaction (ΔH) is equal to the difference between the enthalapy of formation of the products and the reactants.

$$\Delta H = \sum (\Delta H)_{\text{products}} - \sum (\Delta H)_{\text{reactants}} \tag{8.13.13}$$

In an exothermic reaction the change in enthalpy of formation (ΔH) is negative. Table 8.13.1 gives values of ΔH for various compounds at 25°C at 1 atm. All naturally occurring elements have a ΔH value of zero.

In a combustion reaction all of the change in the enthalpy of formation (ΔH) is converted to heat and is, therefore, called the higher heating value (HHV).

$$-(\Delta H)_{\text{reaction}} = \text{HHV of fuel} \tag{8.13.14}$$

For example, for complete combustion of hydrogen according to the following reaction:

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O \quad (\text{liquid}) \tag{8.13.15}$$

TABLE 8.13.1 Enthalty of Formation ΔH^0 and Gibbs Free Energy ΔG^0 of Compounds at 1 atm and 298 K

Compound or Ion	Enthalpy of Formation, ΔH^0, J/kg · mol	Gibbs Free Energy ΔG^0, J/kg · mol
CO	-110.0×10^6	-137.5×10^6
CO_2	-394.0×10^6	-395.0×10^6
CH_4	-74.9×10^6	-50.8×10^6
Water	-286.0×10^6	-237.0×10^6
Steam	-241.0×10^6	-228.0×10^6
C, H_2, O_2	0	0
O(g)	$+249.2 \times 10^6$	$+231.8 \times 10^6$
H(g)	$+218.0 \times 10^6$	$+203.3 \times 10^6$

Source: Adapted from Wark, K., *Thermodynamics*, McGraw–Hill, New York, 1988. With permission.

Change in the enthalpy of formation is

$$\Delta H = \Delta H_{\mathrm{H_2O}} - \Delta H_{\mathrm{H_2}} - \frac{1}{2}\left(\Delta H_{\mathrm{O_2}}\right) = \left(-286 \times 10^{6}\right) - 0 - 0 = -286 \times 10^{6} \text{ J/kg} \cdot \text{mol H}_2 \quad (8.13.16)$$

In a fuel cell, most of ΔH can be converted to electricity directly. The part that cannot be converted to work directly gets converted into heat. The minimum amount that must be converted to heat is represented by reversible heat transfer $\int T\, dS$. If a fuel cell operates isothermally, the maximum amount of electrical work (W_e) produced is given by

$$W_e, \max = \Delta H - T\Delta S \quad (8.13.17)$$

In an irreversible reaction

$$W_e, \max < \Delta H - T\Delta S \quad (8.13.18)$$

Gibbs free energy, G, is given by:

$$G = H - TS \quad (8.13.19)$$

Therefore, in a reversible isothermal process

$$\Delta G = \Delta H - T\Delta S = W_e, \max \quad (8.13.20)$$

The actual electrical work in a fuel cell is given by

$$W_e \le \Delta G \quad \text{(change in Gibbs free energy for the reaction)} \quad (8.13.21)$$

$$\Delta G_{\text{reaction}} = \sum (\Delta G)_{\text{products}} - \sum (\Delta G)_{\text{reactants}} \quad (8.13.22)$$

The electrical work, W_e, is associated with the work of electrons passing through an external resistance. 1 g · mol of electrons is equal to Avogadro's number (6.022×10^{23}) and the charge of these electrons is equal to 96,439 C which is called a **faraday** (F). If n g · mols of electrons are generated and E is the internal reversible cell voltage, then the maximum electrical work is given by

$$W_e, \max = \Delta G = -nFE \quad (8.13.23)$$

denoting values under standard conditions (25°C, 1 atm) by superscript 0, we have

$$\Delta G^0 = -nFE^0 \quad (8.13.24)$$

Values of G^0 for various compounds are given in Table 8.13.1. For fuel cell reactions as below:

$$aA + bB \rightarrow cC + dD \quad (8.13.25)$$

if the reactants (A and B) and the products (C and D) are assumed to be ideal gases with partial pressures P_A, P_B, P_C, and P_D the change in Gibbs free energy ΔG and the internal reversible cell voltage, E, are given by

$$\Delta G = \Delta G^0 + R_u T \ln \frac{(P_C)^c (P_D)^d}{(P_A)^a (P_B)^b} \tag{8.13.26}$$

$$E = E^0 + \frac{R_u T}{nf} \ln \frac{(P_A)^a (P_B)^b}{(P_C)^c (P_D)^d} \tag{8.13.27}$$

where R_u is the universal gas constant. Equation 8.13.27 is also called the Nernst equation.

Table 8.13.2 gives typical electrochemical reactions in fuel cells.

TABLE 8.13.2 Electrochemical Reactions in Fuel Cells

Fuel Cell	Anode Reaction	Cathode Reaction	Overall Reaction
Proton exchange	$H_2 \rightarrow 2H^+ + 2e^-$	$½O_2 + 2H^+ + 2e^- \rightarrow H_2O$	$H_2 + ½O_2 \rightarrow H_2O$
Alkaline	$H_2 + 2(OH)^- \rightarrow 2H_2O + 2e^-$	$½O_2 + H_2O + 2e^- \rightarrow 2(OH)^-$	$H_2 + ½O_2 \rightarrow H_2O$
Phosphoric acid	$H_2 \rightarrow 2H^+ + 2e^-$	$½O_2 + 2H^+ + 2e^- \rightarrow H_2O$	$H_2 + ½O_2 \rightarrow H_2O$
Molten carbonate	$H_2 + CO_3^= \rightarrow H_2O + CO_2 + 2e^-$	$½O_2 + CO_2 + 2e^- \rightarrow CO_3^=$	$H_2 + ½O_2 + CO_2$ (cathode)
	$CO + CO_3^= \rightarrow 2CO_2 + 2e^-$		$\rightarrow H_2O + CO_2$ (anode)
Solid oxide	$H_2 + O^- \rightarrow H_2O + 2e^-$	$½O_2 + 2e^- \rightarrow O^-$	$H_2 + ½O_2 \rightarrow H_2O$
	$CO + O^- \rightarrow CO_2 + 2e^-$		$CO + ½O_2 \rightarrow CO_2$
	$CH_4 + 4O^- \rightarrow 2H_2O + CO_2 + 8e^-$		$CH_4 + 2O_2 \rightarrow H_2O + CO_2$

The maximum conversion efficiency of a fuel cell is given by

$$\eta_{\max} = \frac{W_e, \max}{\Delta H} = \frac{\Delta G}{\Delta H} = 1 - \frac{T\Delta S}{\Delta H} = \frac{-nFE}{\Delta H} \tag{8.13.28}$$

As current is drawn through an external circuit, the actual voltage drop (V) will be less than the internal cell voltage (E). Therefore, the actual conversion efficiency of a fuel cell will be lower than above and may be calculated as

$$\eta_{\text{actual}} = \frac{-nFV}{\Delta H} = \frac{ItV}{\Delta H} \tag{8.13.29}$$

where I is the current drawn through an external circuit for a period of time, t.

Types of Fuel Cells

Fuel cells are primarily classified by type of electrolyte, since many characteristics, particularly operating temperatures, are limited by the electrolyte properties (Hirschenhofer et al., 1994). Major fuel cells under active development at this time are the **phosphoric acid fuel cell** (PAFC), the **molten carbonate fuel cell** (MCFC), the **solid oxide fuel cell** (SOFC), the **polymer electrolyte membrane fuel cell** (PEMFC), and the **alkaline fuel cell** (AFC).

Phosphoric Acid Fuel Cell. PAFC uses concentrated phosphoric acid (H_3PO_4) as the electrolyte, hydrogen as the fuel, and oxygen (from air) as the oxidant. Table 8.13.4 provides information on the electrodes and other materials for PAFC as well as other fuel cells.

The reactions take place at the porous electrodes on highly dispersed electrocatalyst Pt particles supported on carbon black and a polymeric binder, usually polytetrafluoroethylene (PTFE) (about 30 to 50% by weight) (Kinoshita et al., 1988; Hirschenhofer et al., 1994). A porous carbon paper substrate provides structural support for the electrocatalyst and serves as the current collector. A typical carbon paper electrode impregnated with the electrocatalyst has a porosity of about 60%, consisting of micropores of about 34 Å diameter and macropores of 3 to 50 μm diameter.

Dipolar plates (usually graphite) are used to separate the individual cells and electrically connect them in series in a fuel cell stack. In PAFC stacks, provisions are included to remove the waste heat, by liquids (usually water) or gases (usually air) which flow through channels provided in the cell stack.

Molten Carbonate Fuel Cells. MCFCs use as electrolytes mixtures of molten carbonates of lithium (Li_2CO_3), potassium (K_2CO_3), and sodium (Na_2CO_3) in proportions as shown in Table 8.13.4. The operating temperature of the cell (~650°C) is higher than the melting temperature of the carbonate electrolytes. Besides H_2 (fuel) and O_2 (oxidant from air), the cell uses CO_2 which transfers from the cathode to the anode according to the reactions in Table 8.13.2.

According to the reactions, 1 g · mol of CO_2 is transferred along with 2 g · mol of electrons ($2F$). The reversible potential for an MCFC, taking into account the transfer of CO_2, is given by the Nernst equation in Table 8.13.3.

It is usual practice to recycle the CO_2 generated at the anode to the cathode where it is consumed. An early process used to fabricate electrolyte structures involved hot processing mixtures of $LiAlO_2$ and alkali carbonates at temperatures slightly below the melting point of carbonates. These electrolyte structures had problems of void spaces, nonuniformity of microstructure, poor mechanical strength, and high iR drop. To overcome these problems, processes have been developed recently that include tape casting (Maru et al., 1984; Hirschenhofer et al., 1994) and electrophoretic deposition (Baumgartner et al., 1985; Hirschenhofer et al., 1994).

Increasing the operating pressures results in enhanced cell voltages. Increasing the operating temperature above 550°C also enhances the cell performance. However, beyond 650°C the gains are diminished and the electrolyte loss and material corrosion are increased. Therefore, 650°C is about the optimum operating temperature.

Solid Oxide Fuel Cell. SOFCs offer a number of advantages over MCFCs for high-temperature operation, since there is no liquid electrolyte. Solid electrolyte allows flexibility in cell shape design based on application. Cells of several shapes, as shown in Figure 8.13.9, are being developed. Because of the high temperature of operation (~1000°C) carbon monoxide (CO) and hydrocarbons such as methane (CH_4) can be used as fuels. At 1000°C, these fuels can easily produce H_2 that is used at the anode by steam reforming and water-gas reactions as

$$CO + H_2O \rightarrow CO_2 + H_2 \quad \text{(water-gas)} \tag{8.13.30}$$

$$CH_4 + H_2O \rightarrow CO + 3H_2 \quad \text{(steam reforming)} \tag{8.13.31}$$

TABLE 8.13.4 Cell Components for Various Fuel Cells

Component	PAFC	MCFC	SOFC[b]	PEMFC	AFC
Anode	• PTFE-bonded Pt/C • Vulcan XC-72[a] • 0.1 mg Pt/cm^2	• Ni-10 wt% Cr • 3–6 µm pore size • 50–70% initial porosity • 0.5–1.5 mm thickness • 0.1–1 m^2/g	• Ni/ZrO$_2$ cermet[c] (30 mol% Ni) • Deposit slurry • 12.5 × 10^{-6} cm/cm °C • ~150 µm thickness • 20–40% porosity	• 10% Pt thin film	• Dual Porosit Ni • 16 µm max pore on electrolyte side • 30 µm pore on gas side
Cathode	• PTFE-bonded Pt/c • Vulcan XC-72[a] • 0.5 mg Pt/cm^2	• Lithiated NiO • 7–15 µm pore size • 60–65% after lithiation and oxidation • 70–80% initial porosity • 0.5–0.75 mm thickness • 0.5 m^{2}g	• Sr-doped lanthanum manganite (10 mol% Sr) • Deposit slurry, sinter • ~1 mm thickness • 12 × 10^{-6} cm/cm °C expansion from room temperature to 1000°C[d] • 20–40% porosity	• 10% Pt thin film	• Porous lithinated NiO
Electrode support	• Carbon paper	—	—	• Carbon paper with Teflon coating on one side	
Electrolyte support	• PTFE-bonded SiC	• γ-LiAlO$_2$ • 0.1–12m^2/g • 0.5 mm thickness	—	—	—
Electrolyte[a]	• 100% H$_3$PO$_4$	• 62 Li-38 K • 50 Li-50 Na • 50 Li-50 K • Tape cast • 0.5 mm thickness	• Yttria-stabilized ZrO$_2$ (8 mol% Y) • EVD[d] • 10.5 × 10^{-6} cm/cm °C expansion from room temperature to 1000°C[d] • ~40 µm thickness	• Proton conducting membrane of perfluoro sulfonic acid polymer	• KOH (45% to 85%)

[a] Conductive oil furnace black, product of Cabot Corp. Typical properties: 002 d-spacing of 3.6 Å by X-ray diffusion, surface area of 220 m^2/g by nitrogen adsorption, and average particle size of 30 µm by electron microscopy.

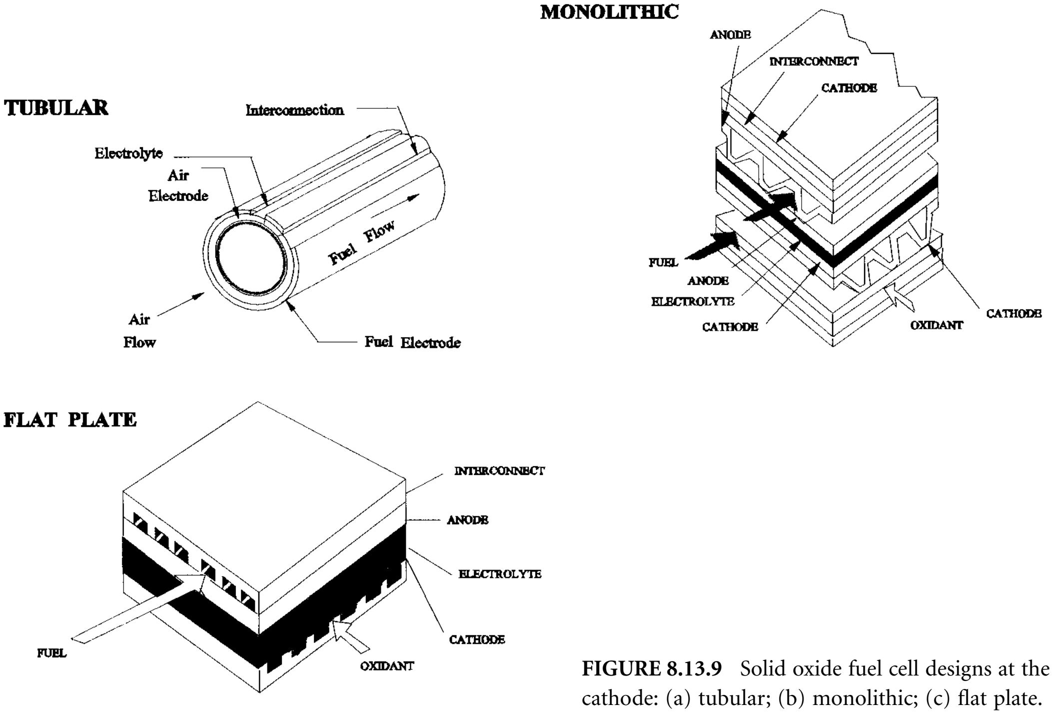

FIGURE 8.13.9 Solid oxide fuel cell designs at the cathode: (a) tubular; (b) monolithic; (c) flat plate.

Because of very high operating temperatures the choice of cell materials is limited by (1) chemical stability in oxidizing and reducing atmosphere; (2) chemical stability of contacting materials; and (3) conductivity and thermomechanical compatibility. A detailed description of the current status is given by Minh (1991; 1993) and Appleby and Foulkes (1989). Present SOFC designs make use of thin film wall concepts where films of electrodes, electrolyte, and interconnect material are deposited on each other and sintered to form cell structure. Electrochemical vapor deposition (EVD) is now used to deposit thin layers.

Increasing pressure and temperature enhances the performance of SOFC.

Polymer Electrolyte Membrane Fuel Cell. The basic cell consists of a proton-conducting membrane such as perfluoro sulfonic acid polymer sandwiched between two Pt-impregnated porous electrodes. The backs of the electrodes are made hydrophobic by coating with Teflon®, which provides a path for gas to diffuse to the catalyst layer.

The electrochemical reactions for PEMFC are similar to PAFC as given in Table 8.13.2.

The protons from the anode diffuse through the membrane with the help of water molecules soaked in the membrane. The cell operates at low temperature (80°C) and can have very high current densities. Therefore, the cell can be made very compact and can have fast start. There are no corrosive fluids (acids or alkalis) in the cell. Because of these attributes the cell is particularly suited for vehicle-power operation. Present research includes investigation of using methanol and natural gas as the fuel for the cell.

Alkaline Fuel Cell. Alkaline electrolytes have faster kinetics, which allows the use of non-noble metal electrocatalysts. However, AFCs suffer a drastic performance loss if CO_2 is present in the fuel or the oxidant, for example, air. Therefore, AFCs are restricted for use where pure H_2 and O_2 can be used. They have been used in the past in the space program.

Fuel Cell Performance

The performance of fuel cells is affected by the operating variables (e.g., temperature, pressure, gas composition, reactant utilization, and current density) and other factors that influence the reversible cell potential (impurities) and the magnitude of the irreversible voltage losses (polarization, contact resistance, exchange current).

The cell voltage (V_{cell}) is given by

$$V_{\text{cell}} = E - iR - \mu_p \tag{8.13.32}$$

where i is the current through the cell, R is the cell resistance, and μ_p is the polarization loss.

Current Density. Current density has a major impact on the cell voltage. Figure 8.13.10 shows how various losses affect the current-voltage characteristics.

Temperature and Pressure. Increase in pressure generally has a beneficial effect on the cell performance. Increased reactant pressure increases gas solubility and mass transfer rates. In addition, electrolyte loss due to evaporation is decreased.

Theoretically, the reversible potential of an H_2/O_2 fuel cell decreases with an increase in temperature. The practical effect of temperature is mixed, as shown in Figure 8.13.11.

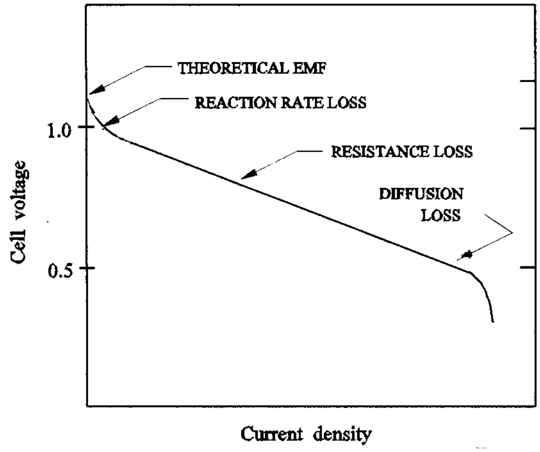

FIGURE 8.13.10 Losses affecting current-voltage characteristics.

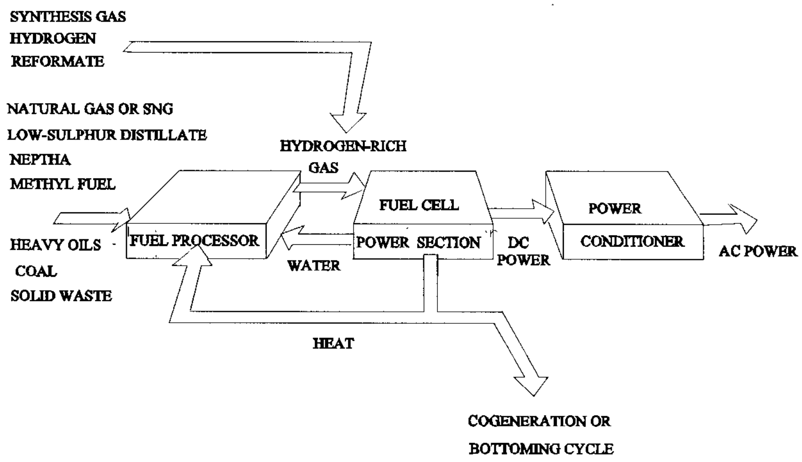

FIGURE 8.13.12 Basic fuel cell power system.

Fuel Cell Power Systems

A general fuel cell power system consists of a fuel processor, fuel cell stack, power conditioner, and possibly a cogeneration or bottoming system to utilize the rejected heat. A schematic of a basic system is shown in Figure 8.13.12.

Fuel Processors. If pure hydrogen is available, no additional fuel processor is needed. However, in most applications hydrogen needs to be generated from other fuels, such as natural gas, methane, methanol, etc.

Natural Gas Processing. Natural gas is mostly methane (CH_4) with small amounts of other hydrocarbons. It can be converted to H_2 and CO in a steam-reforming reactor according to Equation (8.13.31). Fuels are typically steam reformed at temperatures of 760 to 980°C.

Liquid Fuel Processing. Liquid fuels such as distillate, naphtha, diesel oil, and fuel oil can be reformed by noncatalytic partial oxidation of the fuel by oxygen in the presence of steam with flame temperatures of 1300 to 1500°C.

Nomenclature

E = internal cell voltage
F = Faraday, charge of 1 g-mol of electrons
G = Gibbs free energy
H = enthalpy
ΔH = heat of reaction, enthalpy of formation
I = current
n = number of g-mol
P = Pressure
R = gas constant
S = entropy
t = time
T = temperature
V = voltage drop
W_e = electrical work

Superscript

0 = values under standard conditions — 25°C, 1 atm

Defining Terms

Alkaline fuel cell (AFC): A fuel cell using KOH as the electrolyte.
Faraday: Change of 1 g · mol of electrons, which equals 96,439 C.
Molten carbonate fuel cell (MCFC): A fuel cell using molten carbonate as the electrolyte.
Phosphoric acid membrane fuel cell (PAMFC): A fuel cell using phosphoric acid as the electrolyte.
Polymer electrolyte fuel cell (PEFC): A fuel cell using Zerconia as the electrolyte.
Solid oxide fuel cell (SOFC): A fuel cell using potassium as the electrolyte.

Thermionic Energy Conversion

Mysore L. Ramalingam

Introduction

Thermionic energy conversion (TEC) is the process of converting heat directly to useful electrical work by the phenomenon of thermionic electron emission. This fundamental concept can be applied to a cylindrical version of the planar converter, considered the building block for space nuclear power systems (SNPS) at any power level. Space nuclear reactors based on TEC can produce power in the range of 5 kWe to 5 MWe, a spectrum that serves the needs of current users such as National Aeronautics and Space Administration (NASA), United States Air Force (USAF), United States Department of Energy (USDOE), and Ballistic Missile Defense Organization (BMDO). Electrical power in this range is currently being considered for commercial telecommunication satellites, navigation, propulsion, and planetary exploration missions.

The history of thermionic emission dates back to the mid-1700s when Charles Dufay observed that electricity is conducted in the space near a red-hot body. Although Thomas Edison requested a patent in the late 1800s, indicating that he had observed thermionic electron emission while perfecting his electric light system, it was not until the 1960s that the phenomenon of TEC was adequately described

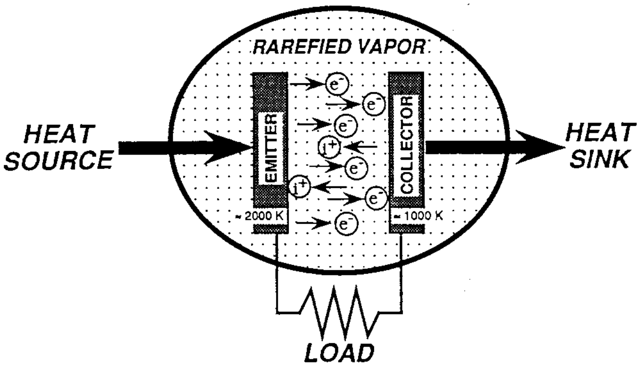

FIGURE 8.13.13 Schematic of an Elementary TEC.

theoretically and experimentally (Hatsopoulos and Gryftopoulos, 1973). These pioneering activities have led to the development of thermionic SNPS that could potentially be augmented by Brayton and Stirling cycle generators to produce additional power from waste heat in NASA manned lunar and martian exploration missions (Ramalingam and Young, 1993).

Principles of Thermionic Energy Conversion

Figure 8.13.13 represents a schematic of the essential components and processes in an elementary thermionic converter (TC). Electrons "boil-off" from the emitter material surface, a refractory metal such as tungsten, when heated to high temperatures (2000 K) by a **heat source**. The electrons then traverse the small interelectrode gap, to a colder (1000 K) collector surface where they condense, producing an output voltage that drives the current through the electrical load and back to the emitter. The flow of electrons through the electrical load is sustained by the temperature difference and the difference in **surface work functions** of the electrodes.

Surface Work Function. In a simple form, the energy required to separate an electron from a metal surface atom and take it to infinity outside the surface is termed the electron work function or the work function of the metal surface. The force experienced by an electron as it crosses an interface between a metal and a rarefied vapor can be represented by the **electron motive, Ψ,** which is defined as a scalar quantity whose negative gradient at any point is a measure of the force exerted on the electron at that point (Langmuir and Kingdon, 1925). At absolute zero the kinetic energy of the **free electrons** would occupy quantum energy levels from zero to some maximum value called the Fermi level. Each energy level contains a limited number of free electrons, similar to the electrons contained in each electron orbit surrounding the nucleus of an atom. Fermi energy, μ, corresponds to the highest energy of all free electrons at absolute zero. At temperatures other than absolute zero some of the free electrons begin to experience energies greater than that at the Fermi level. Thus, the electron work function Φ, would be defined as

$$\Phi = \Psi_T - \mu \tag{8.13.33}$$

where Ψ_T represents the electron motive or energy at some temperature, T, above absolute zero.

Interelectrode Motive Distribution. Figure 8.13.14 provides a schematic representation of the electron motive distribution in the interelectrode space of a thermionic converter. Under ideal conditions of particle transport, the motive varies linearly from Ψ_{EM}, the motive just outside the emitter, to Ψ_{CO}, the motive outside the collector surface. The magnitudes of the Fermi energies of the emitter and collector relative to Ψ_{EM} and Ψ_{CO} are clearly indicated. The internal voltage drop of the converter is defined as;

$$\Delta V = \left(\Psi_{EM} - \Psi_{CO}\right)/e \tag{8.13.34}$$

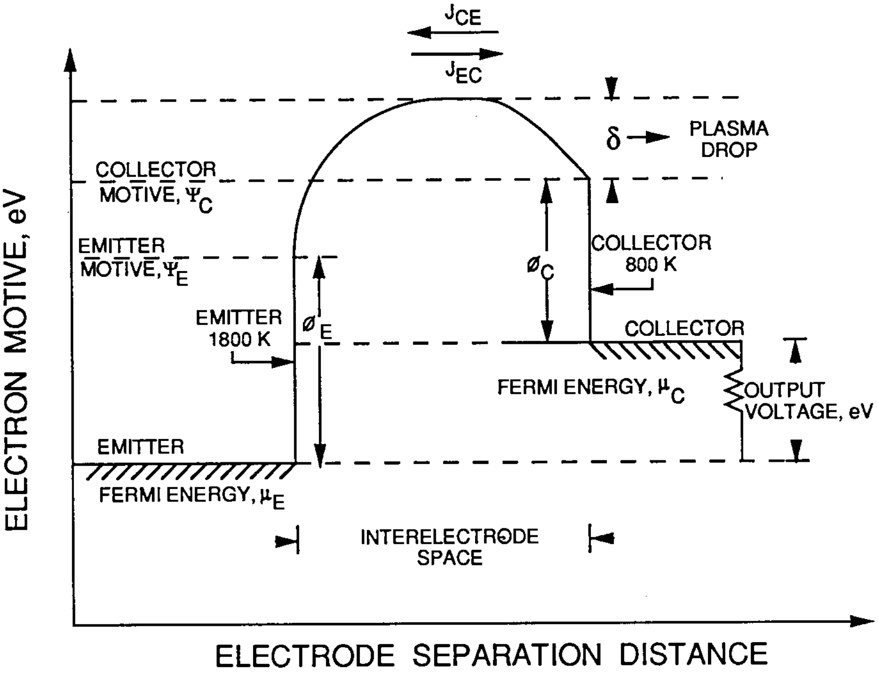

FIGURE 8.13.14 Electron motive distribution in the interelectrode gap.

In a conventional thermionic converter, the emitter and collector are not at the same temperature, but to a good approximation, the output voltage, neglecting **lead losses** and **particle interaction losses**, can be represented by the relationship.

$$V = \left(\mu_{\mathrm{CO}} - \mu_{\mathrm{EM}}\right)/e \tag{8.13.35}$$

Since a real thermionic converter has an ionizing medium to improve its performance, a similar motive distribution can be defined for the ions. It is sufficient to state that the ion interelectrode motive has a slope equal and opposite to the corresponding electron interelectrode motive. The ions are, therefore, decelerated when the electrons are accelerated and vice versa.

Electron Saturation Current. In the absence of a strong influence from an external electrical source, the electron current ejected from a hot metal at the emitter surface into the vacuum ionizing medium is termed the *electron saturation current.* As this quantity depends on the number of free electrons $N(\varepsilon_x)$, Fermi-Dirac statistics provide the means to compute the number of free electrons, $N(\varepsilon_x)\, d\varepsilon_x$, incident on a unit area within the metal in unit time with energies corresponding to the motion normal to the area, between ε_x and $\varepsilon_x + d\varepsilon_x$. For energies greater than the Fermi energy, the functional dependence of $N(\varepsilon_x)$ on ε_x is given by (Fowler, 1955)

$$N\left(\varepsilon_x\right) \approx \left[4\pi m_e kT/h^3\right]\left[\exp\left\{-\varepsilon_x - \mu/kT\right\}\right] \tag{8.13.36}$$

where m_e is the mass of the electron = 9.108×10^{-28} g and h is Planck's constant = 4.140×10^{-15} eV · sec.

The electron saturation current density, J_{sat}, for a uniform surface, is found by integrating $N(\varepsilon_x)$ in the range of ε_x from Ψ_T to infinity for all $\Psi_T - \mu > kT$, which is the case for almost all materials and practical temperatures. The result of the integration yields

$$J_{\mathrm{sat}} = AT^2 \exp\left[-\left(\Psi_T - \mu\right)/kT\right] \tag{8.13.37}$$

or

$$J_{\text{sat}} = AT^2 \exp\left[-(\Phi)/kT\right] \tag{8.13.38}$$

where A is the Richardson constant ≈ 120 A/cm² · K².

Equation (8.13.38), which is the most fundamental and important relationship for the design of a thermionic converter, is called the Richardson-Dushmann equation (Richardson, 1912). On similar lines, the ion saturation current density for a converter with an ionizing medium is given by the relationship (Taylor and Langmuir, 1933):

$$\tilde{J}_{\text{iSat}} = ep_g \Big/ \left[\left(2\pi m_g kT_g\right)^{0.5}\left(1 + 2\exp\left\{\left(V_i - \Phi/kT\right)\right\}\right)\right] \tag{8.13.39}$$

where p_g, T_g, m_g, and V_i are the pressure, temperature, mass, and first ionization energy, respectively, of the ionizing medium.

Types of Thermionic Converters

Thermionic converters can be broadly classified as vacuum thermionic converters and vapor thermionic converters, depending on the presence of an ionizing medium in the interelectrode gap. In vacuum thermionic converters the interelectrode space is evacuated so that the space is free of particles other than electrons and the two electrodes are placed very close together, thereby neutralizing the negative space charge buildup on the electrode surface and reducing the total number of electrons in transit. Due to machining limitations, vacuum converters have been all but completely replaced by vapor-filled thermionic converters. In vapor-filled thermionic converters, the interelectrode space is filled with a rarefied ionizing medium at a vapor pressure generally on the order of 1 to 10 torr. The vapor generally used is cesium as it is the most easily ionized of all stable gases and this can be provided through an external two-phase reservoir or an internal graphite reservoir (Young et al., 1993). The vapor neutralizes the negative space charge effect by producing positive ions at the electrode surfaces and gets adsorbed on the surfaces, thereby altering the work function characteristics.

Converter Output Characteristics

Figure 8.13.15 represents the output current-voltage characteristics for various modes of operation of the vacuum and vapor-filled thermionic converters. Characteristics obtained by not considering particle interactions in the interelectrode gap are generally considered ideal output characteristics. The figure essentially displays three types of converter output current-voltage characteristics, an ideal characteristic, an ignited mode characteristic, and an unignited mode characteristic. For an ideal converter in the interelectrode space the net output current density consists of the electron current density, J_{EMCO} flowing from emitter to collector diminished by the electron current density J_{COEM} flowing from collector to emitter and the ion-current density $\tilde{J}_{i\text{EMCO}}$ flowing from emitter to collector. Thus,

$$J_{\text{net}} = J_{\text{EMCO}} - J_{\text{COEM}} - \tilde{J}_{i\text{EMCO}} \tag{8.13.40}$$

By expressing the individual terms as functions of ϕ, T, and V,

$$\begin{aligned} J_{\text{net}} = {} & AT_{\text{EM}}^2 \exp\left[-\left(\Phi_{\text{EM}}/kT_{\text{EM}}\right)\right] - AT_{\text{CO}}^2 \exp\left[-\left(\Phi_{\text{EM}} - eV\right)/kT_{\text{CO}}\right] \\ & - \tilde{J}_{\text{EMS}} \exp\left[-\left(\Psi_{\text{EM}} - \Psi_{\text{CO}}\right)kT_{\text{EM}}\right] \end{aligned} \tag{8.13.41}$$

$$\text{for} \quad eV < \Phi_{\text{EM}} - \Phi_{\text{CO}}$$

Similar relationships can be generated for various types of thermionic converters.

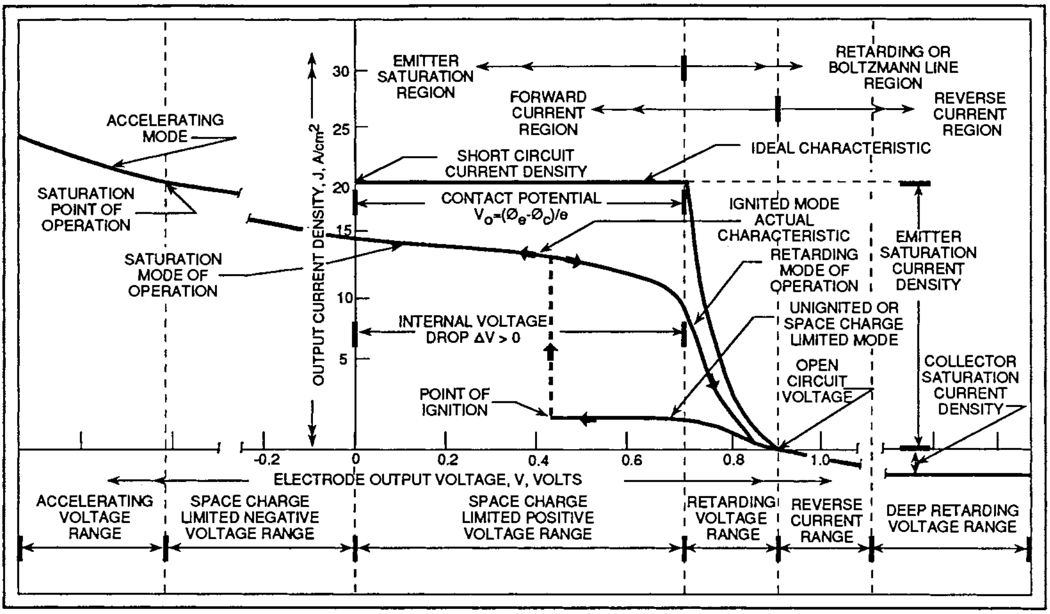

FIGURE 8.13.15 Thermionic diode output current density characteristics and nomenclature.

Thermodynamic Analysis

In thermodynamic terms a thermionic converter is a heat engine that receives heat at high temperature, rejects heat at a lower temperature, and produces useful electrical work while operating in a cycle analogous to a simple vapor cycle engine. Based on the application of the first law of thermodynamics to the control volumes around the emitter (Houston, 1959; Angrist, 1976),

$$\text{Energy In} = \text{Energy Out} \tag{8.13.42}$$

i.e.,

$$q_{\text{CB}} + q_{\text{JH}} + q_{\text{HS}} = q_{\text{EC}} + q_{\text{WB}} + q_{\text{CD}} + q_{\text{RA}} \tag{8.13.43}$$

where, by using the terminology in Figure 8.13.14, each of the terms in Equation (8.13.43) can be elaborated as follows:

(a) Energy supplied by back emission of the collector:

$$q_{\text{CB}} = J_{\text{COEM}}\left[\Phi_{\text{CO}} + \delta + V + \left(2kT_{\text{CO}}/e\right)\right] \tag{8.13.44}$$

(b) Energy supplied by joule heating of lead wires and plasma:

$$q_{\text{JH}} = 0.5\left[J_{\text{EMCO}} - J_{\text{COEM}}\right]^2\left(R_{\text{LW}} + R_{\text{PL}}\right) \tag{8.13.45}$$

(c) Energy dissipated by electron cooling:

$$q_{\text{EC}} = J_{\text{EMCO}}\left[\Phi_{\text{CO}} + \delta + V - \Phi_{\text{EM}} + \left(2kT_{\text{EM}}\right)/e\right] \tag{8.13.46}$$

(d) Energy dissipated due to phase change by electron evaporation:

$$q_{\mathrm{WB}} = J_{\mathrm{EM}}\Phi_{\mathrm{EM}} \tag{8.13.47}$$

(e) Energy dissipated by conduction through the lead wires and plasma:

$$q_{\mathrm{CD}} = \Delta T\left[\left(K_{\mathrm{LW}}A_{\mathrm{LW}}/A_e L_{\mathrm{LW}}\right) + \left(K_{\mathrm{PL}}A_{\mathrm{PL}}/A_e L_{\mathrm{IG}}\right)\right] \tag{8.13.48}$$

Here, K represents thermal conductivity, LW = lead wires, PL = plasma, and IG = interelectrode gap.

(f) Energy dissipated by radiation from emitter to collector:

$$q_{\mathrm{RA}} = 5.67\times 10^{-12}\left(T_{\mathrm{EM}}^{2} - T_{\mathrm{CO}}^{4}\right)\left(\varepsilon_{\mathrm{EM}}^{-1} + \varepsilon_{\mathrm{CO}}^{-1} - 1\right)^{-1} \tag{8.13.49}$$

Substitution for the various terms in Equation (8.13.42) yields q_{Hs}, the energy supplied to the emitter from the heat source.

The thermal efficiency of the thermionic converter is now expressed as

$$\eta_{\mathrm{TH}} = \left[V\left(J_{\mathrm{EMCO}} - J_{\mathrm{COEM}}\right)/q_{\mathrm{HS}}\right] \tag{8.13.50}$$

Design Transition to Space Reactors — Concluding Remarks

All the fundamentals discussed so far for a planar thermionic converter can be applied to a cylindrical version which then becomes the building block for space power systems at any power level. In a thermionic reactor, heat from the nuclear fission process produces the temperatures needed for thermionic emission to occur. The design of a thermionic SNPS is a user-defined compromise between the required output power and the need to operate reliably for a specified lifetime. Based on the type of contact the emitter has with the nuclear fuel, the power systems can be categorized as "in-core" or "out-of-core" power systems. At this stage it suffices to state that the emitter design for in-core systems is extremely complex because of its direct contact with the hot nuclear fuel.

Defining Terms

Electron motive: A scalar quantity whose negative gradient at any point is a measure of the force exerted on an electron at that point.

Free electrons: Electrons available to be extracted from the emitter for thermionic emission.

Heat source: Electron bombardment heating of the emitter.

Lead losses: Voltage drop as a result of the built-in resistance of the leads and joints.

Particle interaction losses: Voltage drop in the interelectrode gap as a result of particle collisions and other interactions.

Surface work function: A measure of the electron-emitting capacity of the surface.

Thermionic energy conversion: Energy conversion from heat energy to useful electrical energy by thermionic electron emission.

Thermoelectric Power Conversion

Jean-Pierre Fleurial

Introduction

The advances in materials science and solid-state physics during the 1940s and 1950s resulted in intensive studies of thermoelectric effects and related applications in the late 1950s and through the mid-1960s (Rowe and Bhandari, 1983). The development of semiconductors with good thermoelectric properties made possible the fabrication of thermoelectric generators and refrigerators. Being solid-state devices, thermoelectric systems offer some unique advantages, such as high reliability, long life, small-size and no-vibrations refrigerators, and can be used in a wide temperature range, from 200 to 1300 K. However, because of their limited conversion efficiencies, these devices have remained confined to specialized applications. As the following sections will emphasize, the performance of those devices is closely associated with the magnitude of the **dimensionless figure of merit**, *ZT*, of the thermoelectric semiconductor.

ZT represents the relative magnitude of electrical and thermal cross-effect transport in materials. State-of-the-art thermoelectric materials, known since the early 1960s, have been extensively developed. Although significant improvements of the thermoelectric properties of these materials have been achieved, a maximum *ZT* value close to 1 is the current approximate limit over the whole 100 to 1500 K temperature range (Figure 8.13.16). To expand the use of thermoelectric devices to a wide range of applications will require improving *ZT* by a factor of two to three. There is no theoretical limitation on the value of *ZT*, and new promising approaches are now focusing on the investigation of totally different materials and the development of novel thin film heterostructure.

Thermoelectric Effects

Thermoelectric devices are based on two transport phenomena: the Seebeck effect for power generation and the Peltier effect for electronic refrigeration. If a steady temperature gradient is applied along a conducting sample, the initially uniform charge carrier distribution is disturbed as the free carriers located at the high-temperature end diffuse to the low-temperature end. This results in the generation of a back emf which opposes any further diffusion current. The open-circuit voltage when no current flows is the

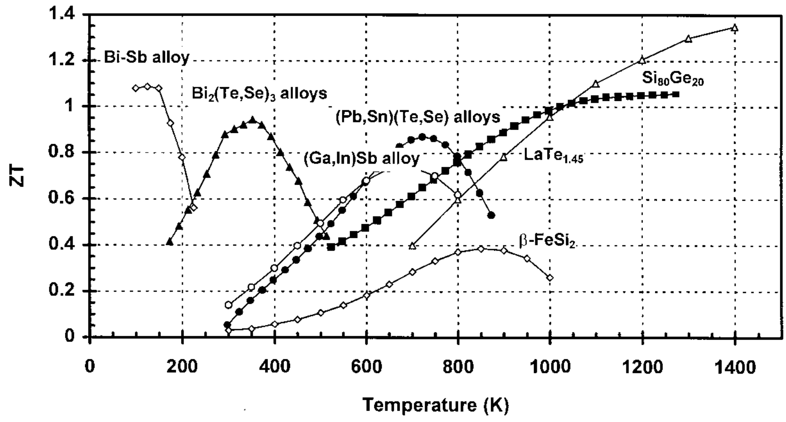

FIGURE 8.13.16 Typical temperature variations of *ZT* of state-of-the-art n-type thermoelectric alloys.

Seebeck voltage. When the junctions of a circuit formed from two dissimilar conductors (n- and p-type semiconductors) connected electrically in series but thermally in parallel are maintained at different temperatures T_1 and T_2, the open-circuit voltage V developed is given by $V = S_{\mathrm{pn}}(T_1 - T_2)$, where S_{pn} is the Seebeck coefficient expressed in $\mu\mathrm{V} \cdot \mathrm{K}^{-1}$.

The complementary Peltier effect arises when an electrical current I passes through the junction. A temperature gradient is then established across the junctions and the corresponding rate of reversible heat absorption $\dot{Q}$ is given by $\dot{Q} = \Pi_{\mathrm{pn}} I$, where Π_{pn} is the Peltier coefficient expressed in $W \cdot A^{-1}$ or V. There is actually a third, less-important phenomenon, the Thomson effect, which is produced when an electrical current passes along a single conducting sample over which a temperature gradient is maintained. The rate of reversible heat absorption is given by $\dot{Q} = \beta I(T_1 - T_2)$, where β is the Thomson coefficient expressed in $\mathrm{V} \cdot \mathrm{K}^{-1}$. The three coefficients are related by the Kelvin relationships:

$$S_{\mathrm{pn}} = \frac{\Pi_{\mathrm{pn}}}{T} \quad \text{and} \quad \frac{dS_{\mathrm{pn}}}{dT} = \frac{\beta_{\mathrm{p}} - \beta_{\mathrm{n}}}{T} \tag{8.13.51}$$

Thermoelectric Applications

The schematic of a thermoelectric device, or module, on Figure 8.13.17, illustrates the three different modes of operation: power generation, cooling, and heating. The *thermoelectric module* is a standardized device consisting of several p- and n-type legs connected electrically in series and thermally in parallel, and bonded to a ceramic plate on each side (typically alumina). The modules are fabricated in a great variety of sizes, shapes, and number of thermoelectric couples and can operate in a wide range of currents, voltages, powers, and efficiencies. Complex, large-scale thermoelectric systems can be easily designed and built by assembling various numbers of these modules connected in series or in parallel depending on the type of applications.

Power Generation. When a temperature gradient is applied across the thermoelectric device, the heat absorbed at the hot junction (Figure 8.13.17, hot side $T_h - T_1$ and cold side, $T_c - T_2$) will generate a current through the circuit and deliver electrical power to the load resistance R_L (Harman and Honig, 1967). The conversion efficiency η of a thermoelectric generator is determined by the ratio of the electrical energy, supplied to the load resistance, to the thermal energy, absorbed at the hot junction, and is given by

$$\eta = \frac{R_L I^2}{S_{\mathrm{pn}} I T_h + K\left(T_h - T_c\right) - \frac{1}{2} R I^2} \tag{8.13.52}$$

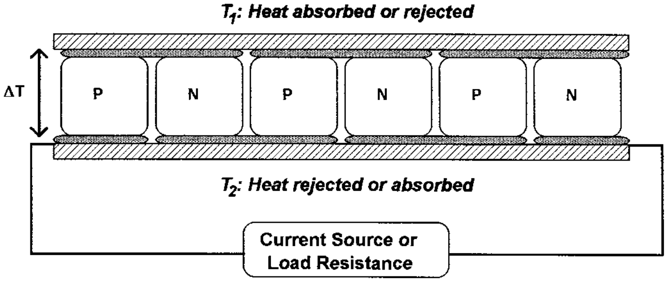

FIGURE 8.13.17 Schematic of a thermoelectric module.

where K is the thermal conductance in parallel and R is the electrical series resistance of one p-n thermoelectric couple. The electrical power P_L generated can be written as

$$P_L = \frac{S_{\mathrm{pn}}\left(T_h - T_c\right)^2 R_L}{\left(R_L + R\right)^2} \tag{8.13.53}$$

The thermoelectric generator can be designed to operate at maximum power output, by matching the load and couple resistances, $R_L = R$. The corresponding conversion efficiency is

$$\eta_P = \frac{T_h - T_c}{\frac{3}{2}T_h + \frac{1}{2}T_c + \frac{1}{4}Z_{\mathrm{pn}}^{-1}} \tag{8.13.54}$$

where Z_{pn} is the figure of merit of the p-n couple given by

$$Z_{\mathrm{pn}} = \frac{S_{\mathrm{pn}}^2}{RK} \tag{8.13.55}$$

The figure of merit can be optimized by adjusting the device geometry and minimizing the RK product. This results in Z_{pn} becoming independent of the dimensions of the **thermoelectric legs**. Moreover, if the p- and n-type legs have similar transport properties, the figure of merit, $Z_{\mathrm{pn}} = Z$, can be directly related to the Seebeck coefficient S, electrical conductivity σ or resistivity ρ, and thermal conductivity λ of the thermoelectric material:

$$Z = \frac{S^2}{\rho\lambda} = \frac{S^2\sigma}{\lambda} \tag{8.13.56}$$

The maximum performance $\eta_{\max}$ of the generator is obtained by optimizing the load-to-couple-resistance ratio, leading to the maximum energy conversion efficiency expressed as

$$\eta_{\max} = \frac{T_h - T_c}{T_h} \frac{\sqrt{1 + Z_{\mathrm{pn}}T_{\mathrm{av}}} - 1}{\sqrt{1 + Z_{\mathrm{pn}}T_{\mathrm{av}}} + \frac{T_c}{T_h}} \tag{8.13.57}$$

It must be noted that the maximum efficiency is thus the product of the Carnot efficiency, less than unity, and of a material-related efficiency, increasing with increasing Z_{pn} values as illustrated in Figure 8.13.18.

Refrigeration. When a current source is used to deliver electrical power to a thermoelectric device, heat can be pumped from T_1 to T_2 and the device thus operates as a refrigerator (Figure 8.13.17, hot side $T_h = T_2$

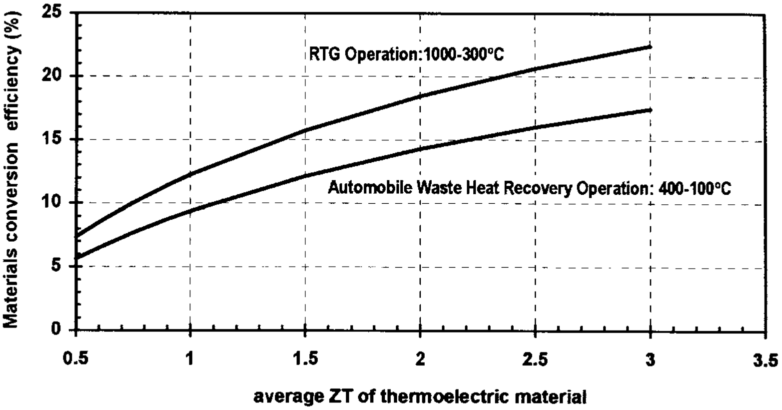

FIGURE 8.13.18 Maximum conversion efficiency $\eta_{\max}$ as a function of the average material figure of merit *ZT*, calculated using Equation (8.13.57) for two systems operating in different temperature ranges: the radioisotope generator (RTG) used for deep space missions and an automobile waste heat recovery generator.

and cold side, $T_c = T_1$). As in the case of a thermoelectric generator the operation of a thermoelectric cooler depends solely upon the properties of the p-n thermocouple materials expressed in terms of the figure of merit Z_{pn} and the two temperatures T_c and T_h (Goldsmid, 1986). The conversion efficiency or coefficient of performance, COP, of a thermoelectric refrigerator is determined by the ratio of the cooling power pumped at the cold junction to the electrical power input from the current source and is given by

$$\text{COP} = \frac{S_{\text{pn}} T_c I - \frac{1}{2} R I^2 - K\left(T_h - T_c\right)}{S_{\text{pn}}\left(T_h - T_c\right) I + R I^2} \tag{8.13.58}$$

There are three different modes of operation which are of interest to thermoelectric coolers. A thermoelectric cooler be designed to operate at maximum cooling power, $Qc_{\max}$, by optimizing the value of the current:

$$I_{Qc_{\max}} = \frac{S_{\text{pn}} T_c}{R} \quad \text{and} \quad Qc_{\max} = \frac{1}{2}\frac{\left(ST_c\right)^2}{R} - K\left(T_h - T_c\right) \tag{8.13.59}$$

Similarly, the conditions required for operating at maximum efficiency, $\text{COP}_{\max}$, across a constant temperature gradient, are determined by differentiating Equation (8.13.58) with respect to *I*, with the solution:

$$I_{\text{COP}_{\max}} = \frac{K\left(T_h - T_c\right)_c}{S_{\text{pn}} T_{\text{av}}}\left(1 + \sqrt{1 + Z_{\text{pn}} T_{\text{av}}}\right) \tag{8.13.60}$$

$$\text{COP}_{\max} = \frac{T_c}{T_h - T_c} \frac{\sqrt{1 + Z_{\text{pn}} T_{\text{av}}} - \frac{T_h}{T_c}}{\sqrt{1 + Z_{\text{pn}} T_{\text{av}}} + 1} \tag{8.13.61}$$

By reversing the input current to the device, the thermoelectric refrigerator can become a heat pump, with T_1 being the hot junction temperature. The expression of the maximum conversion efficiency of the heat pump is very similar to Equation (8.13.61) because of the following relationship:

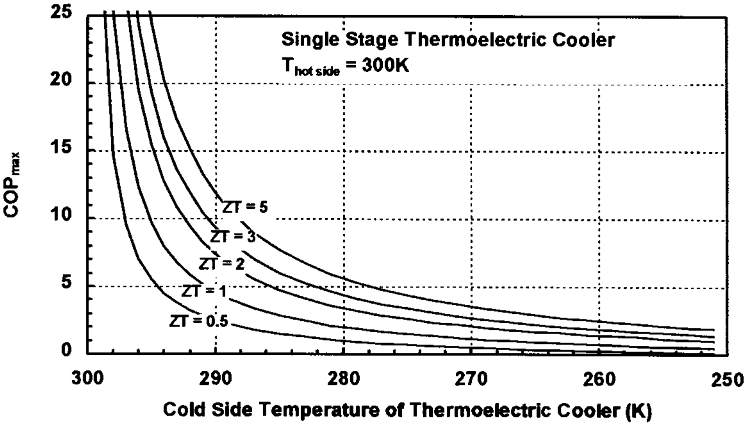

FIGURE 8.13.19 Maximum material coefficient of performance COP$_{\max}$ of a single-stage thermoelectric cooler calculated using Equation (8.13.61) as a function of the cold-side temperature (hot-side temperature of 300 K). Curves corresponding to various values of the average material figure of merit are displayed.

$$\left(\text{COP}_{\max}\right)^{\text{heat pump}} = 1 + \left(\text{COP}_{\max}\right)^{\text{refrigerator}} \tag{8.13.62}$$

The maximum COP expression in Equation (8.13.61) is similar to the one derived for the conversion efficiency η of a thermoelectric generator in Equation (8.13.57). However, there is a major difference between the COP$_{\max}$ and $\eta_{\max}$ parameters. Clearly, $\eta_{\max}$ increases with increasing ΔT values but is limited by the Carnot efficiency (Equation 8.13.54) which is less than 1, while COP$_{\max}$ in Equation (8.13.52) increases with decreasing ΔT values and can reach values much larger than 1. Figure 8.13.19 represents the variations of the COP$_{\max}$ of a thermoelectric cooling device optimized for working voltage and geometry as a function of average ZT values and temperature differences (hot junction temperature at 300 K). The average ZT value for current state-of-the-art commercially available materials (Bi_2Te_3-based alloys) is about 0.8. For example, it can be seen that a COP$_{\max}$ of 4 is obtained for a $(T_h - T_c)$ difference of 10 K, meaning that to pump 8 W of thermal power only 2 W of electrical power needs to be provided to the thermoelectric cooling device. This also means that 10 W of thermal power will be rejected at the hot side of the cooler.

The operation of a thermoelectric refrigerator at maximum cooling power necessitates a substantially higher input current than the operation at maximum efficiency. This is illustrated by calculating the variations of the maximum COP and cooling power with the input current and temperature difference which have been plotted in Figure 8.13.20 and Figure 8.13.21. The calculation was based on the properties of a thermoelectric cooler using state-of-the-art Bi_2Te_3-based alloys, and the arbitrary units are the same for both graphs. It can be seen that $I_{\text{COP}_{\max}}$ increases while $I_{Qc_{\max}}$ decreases with increasing ΔT. Also, it is possible to operate at the same cooling power with two different current values.

Finally, the third problem of interest for thermoelectric coolers is to determine the maximum temperature difference, $\Delta T_{\max}$, that can be achieved across the device. As shown on Figure 8.13.21, by operating at maximum cooling power and extrapolating Equation (8.13.59) to $Qc_{\max} = 0$, $\Delta T_{\max}$ is given by

$$\Delta T_{\max} = \frac{1}{2} Z_{\text{pn}} T_c^2 \quad \text{and} \quad T_{c\,\min} = \frac{\sqrt{1 + 2Z_{\text{pn}} T_h} - 1}{Z_{\text{pn}}} \tag{8.13.63}$$

where $T_{c\,\min}$ corresponds to the lowest cold-side temperature achievable. If the cooler operates at a ΔT close to $\Delta T_{\max}$ or higher, it becomes necessary to consider a cascade arrangement with several **stages.** The

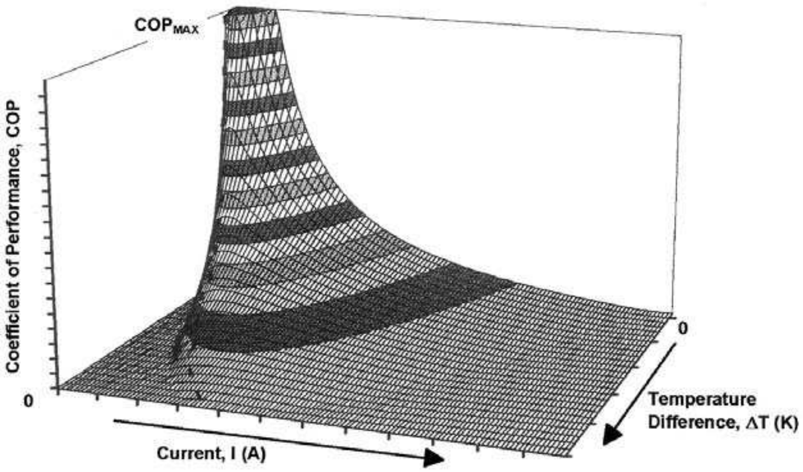

FIGURE 8.13.20 Three-dimensional plot of the variations of the COP of a thermoelectric cooler as a function of the operating current and the temperature difference.

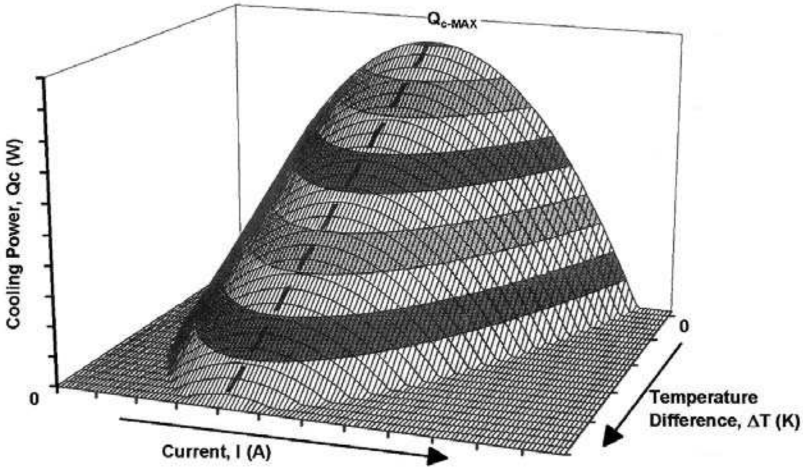

FIGURE 8.13.21 Three-dimensional plot of the variations of the cooling power of a thermoelectric cooler as a function of the operating current and the temperature difference.

COP of an n-stage thermoelectric cooler is optimized if the COP of each stage, COP_i, is the same, which requires $\Delta T_i / T_{i-1}$ to be the same for each stage. The overall maximum COP is then expressed as

$$\mathrm{COP}_{\max} = \frac{1}{\left(\prod_{i=1}^{n}\left(1 + \frac{1}{\mathrm{COP}_i}\right) - 1\right)} \tag{8.13.64}$$

Additional Considerations

When considering the operation of an actual thermoelectric device, several other important parameters must be considered. The thermal and electrical contact resistances can substantially degrade the device performance, in particular for short lengths of the thermoelectric legs. For example, the conversion efficiency of a radioisotope generator system is about 20% lower than the value calculated in Figure 8.13.18

for the thermoelectric materials only. The electrical contact resistance arises from the connection (see Figure 8.13.17) of all the legs in series. Typical values obtained for actual generators and coolers are 10 to 25 $\mu\Omega \cdot \mathrm{cm}^2$. The thermal contact resistance is generated by the heat-transfer characteristics of the ceramic plates and contact layers used to build the thermoelectric module. The heat exchangers and corresponding heat losses should also be taken into account.

In addition, the transport properties of the thermoelectric materials vary with temperature, as illustrated in Figure 8.13.16. When a thermoelectric device is operating across a wide temperature range, these variations should be factored in the calculation of its performance.

Nomenclature

COP	coefficient of performance
$\mathrm{COP}_{\max}$	maximum coefficient of performance
COP_i	coefficient of performance of the *i*th stage of a multistage thermoelectric cooler
I	current intensity
$I_{\mathrm{COP}_{\max}}$	current intensity required to operate a thermoelectric cooler at maximum conversion efficiency
$I_{Qc_{\max}}$	current intensity required to operate a thermoelectric cooler at maximum cooling power
K	thermal conductance
Q	rate of reversible heat absorption
R	electrical resistance
R_L	load resistance
P_L	electrical power delivered to the load resistance
S	Seebeck coefficient
S_{pn}	Seebeck coefficient of a p-n couple of thermoelements
T_1	temperature
T_2	temperature
T_{av}	average temperature across the thermoelectric device
T_c	cold-side temperature of a thermoelectric device
$T_{c\,\min}$	minimum cold-side temperature which can be achieved by a thermoelectric cooler
T_h	hot-side temperature of a thermoelectric device
V	voltage; open-circuit voltage
Z	thermoelectric figure of merit
Z_{pn}	thermoelectric figure of merit of a p-n couple of thermoelements
ZT	dimensionless thermoelectric figure of merit
β	Thomson coefficient
β_p	Thomson coefficient for the p-type thermoelement
β_n	Thomson coefficient for the n-type thermoelement
ΔT	temperature difference across a thermoelectric device
$\Delta T_{\max}$	maximum temperature difference which can be achieved across a thermoelectric cooler
η	thermoelectric conversion efficiency
$\eta_{\max}$	maximum thermoelectric conversion efficiency
λ	thermal conductivity
Π_{pr}	Peltier coefficient
ρ	electrical resistivity

Defining Terms

Coefficient of performance: Electrical to thermal energy conversion efficiency of a thermoelectric refrigerator, determined by the ratio of the cooling power pumped at the cold junction to the electrical power input from the current source.

Dimensionless figure of merit: The performance of a thermoelectric device depends solely upon the properties of the thermoelectric material, expressed in terms of the dimensionless figure of merit

ZT, and the hot-side and cold-side temperatures. *ZT* is calculated as the square of the Seebeck coefficient times the absolute temperature divided by the product of the electrical resistivity to the thermal conductivity. The best *ZT* values are obtained in heavily doped semiconductors, such as Bi_2Te_3 alloys, PbTe alloys, and Si-Ge alloys.

Stage: Multistage thermoelectric coolers are used to achieve larger temperature differences than possible with a single-stage cooler composed of only one module.

Thermoelectric leg: Single thermoelectric element made of n-type or p-type thermoelectric material used in fabricating a thermoelectric couple, the building block of thermoelectric modules. The geometry of the leg (cross-section-to-length ratio) must be optimized to maximize the performance of the device.

Thermoelectric module: Standardized device consisting of several p- and n-type legs connected electrically in series and thermally in parallel, and bonded to a ceramic plate on each. The modules are fabricated in a great variety of sizes, shapes, and number of thermoelectric couples.

Magnetohydrodynamic Power Generation

William D. Jackson

Introduction

The discipline known as magnetohydrodynamics (MHD) deals with the interactions between electrically conducting fluids and electromagnetic fields. First investigated experimentally by Michael Faraday in 1832 during his efforts to establish the principles of electromagnetic induction, application to energy conversion yields a heat engine which has its output in electrical form and, therefore, qualifies as a direct converter. This is generally referred to as an MHD generator, but could be better described as an electromagnetic turbine as it operates on a thermodynamic cycle similar to that of a gas turbine.

The operating principle is elegantly simple, as shown in Figure 8.13.22. A pressurized, electrically conducting fluid flows through a transverse magnetic field in a channel or duct. Electrodes located on the channel walls parallel to the magnetic field and connected through an external circuit enable the motionally induced "Faraday electromotive force" to drive an electric current through the circuit and thus deliver power to a load connected into it. Taking the fluid velocity as **u** and the magnetic flux density as **B**, the intensity of the motionally induced field is $\mathbf{u} \times \mathbf{B}$. The current density, **J**, in the channel for a scalar conductivity σ is then given by Ohm's law for a moving conductor as

$$\mathbf{J} = \sigma[\mathbf{E} + \mathbf{u} \times \mathbf{B}]$$

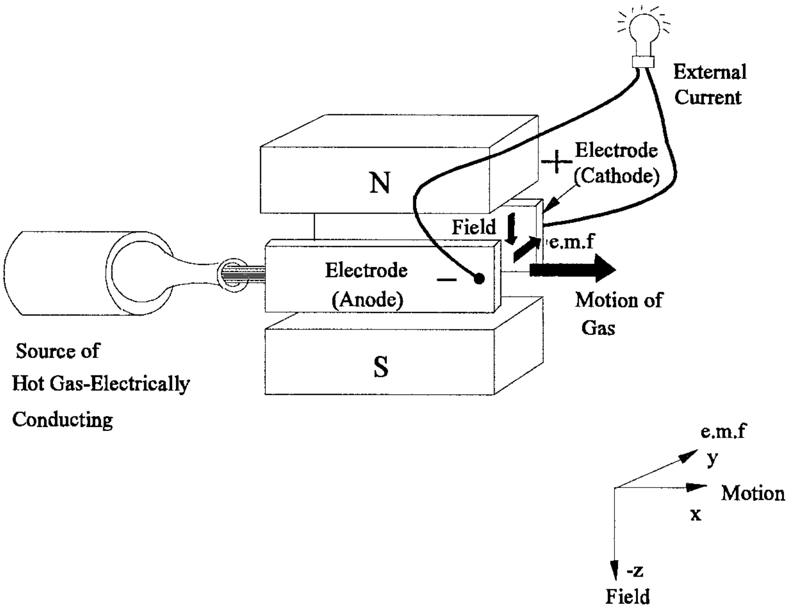

FIGURE 8.13.22 Principle of electromagnetic turbine or MHD generator.

By taking the coordinates of Figure 8.13.22 and assuming that the quantities are constant, the power density flow from the MHD generator is, using **E** · **J**

$$w_e = \sigma u_x^2 B^2 k(1-k)$$

where $k = Ez/u \times B$ is the "loading factor" relating loaded electric field to open circuit induction and is used in the same manner as the regulation of an electrical machine is applied to its terminal voltage.

It is instructive at this point to determine the power density of an MHD generator using values representative of the most commonly considered type of MHD generator. Combustion gas with σ = 10 S/m, a flow velocity of 800 m/sec and an applied field of 5 T for maximum power transfer (k = 0.5) yields w_e as 40 MW/m^3. This value is sufficiently attractive to qualify MHD generators for bulk power applications. An intensive, worldwide development effort to utilize this and other MHD generator properties has been conducted since the late 1950s. However, this has not yet led to any significant application of MHD generators. To understand how this has come about and what still needs to be accomplished to make MHD attractive will now be summarized.

Electrical Conductivity Considerations

Two approaches have been followed to obtain adequate ionization and, therefore, conductivity in the working fluid. What may be termed the mainline approach to achieving electrical conductivity is to add a readily ionizable material to "seed" the working fluid. Alkali metals with ionization potentials around 4 V are obvious candidates, although a lower value would be highly desirable. A potassium salt with an ionization potential of 4.09 eV has been widely used because of low cost but cesium with a 3.89-eV value is the preferred seed material when the running time is short or the working fluid is recycled. There are two methods of ionization:

1. Thermal ionization in which recombination ensures a common temperature for electrons, ions, and neutrals; the mass action law (Saha equation) is followed; and the heat of ionization in electron volts is the ionization potential; and
2. Extrathermal or nonequilibrium ionization where electrons and heavy particles are at different temperatures and the concept of entwined fluids (electron, ion, and neutral gases) is involved.

The former is applicable to diatomic combustion gases while the latter occurs in monatomic (noble) gases but is also observed in hydrogen. Only a small amount of seed material is required and is typically around 1% of the total mass flow for maximum conductivity.

The existence of mutually perpendicular **E** and **B** fields in an MHD generator is of major significance in that the electrons are now subjected to the Hall effect. This causes electrons and, therefore, electric currents to flow at an angle with respect to the **E** field in the collision-dominated environment of the MHD generator. The presence of a significant Hall effect requires that the electrical boundary conditions on the channel be carefully selected and also introduces the possibility of working fluid instabilities driven by force fluctuations of electrical origin. A further source of fluctuations and consequent loss of conductivity occurs when nonequilibrium ionization is employed due to current concentration by Joule heating. This latter effect is controlled by operating only in a regime where, throughout the channel, complete ionization of the seed material is acheived.

Generator Configurations and Loading

The basic consequence of the Hall effect is to set up **E** fields in both transverse and axial directions in the generator channel and these are generally referred to as the Faraday and Hall fields, respectively. The direction of the Faraday field depends on the magnetic field; the Hall field depends on the Hall parameter and is always directed toward the upstream end of the channel. These considerations, in turn, lead to the MHD generator having the characteristics of a gyrator — a two-terminal pair power-producing device in which one terminal pair (Faraday) is a voltage source and the other (Hall) is a current source dependent in this case on the Hall parameter. Electric power can be extracted from either the Faraday or Hall terminals, or both.

This has resulted in several electrical boundary conditions being utilized with the axial flow channel as shown in Figure 8.13.23. These are most readily understood by treating each anode-cathode pair as a generating cell. The segmented Faraday configuration (Figure 8.13.23a) is then simply a parallel operation of cells which leads to the apparently inconvenient requirement of separate loading of individual cells: the Hall connection (Figure 8.13.23b) utilizes a single load by series connection but depends on the Hall parameter for its performance; and the diagonal connection (Figure 8.13.23c) connects the cells in series-parallel and so avoids Hall parameter dependence while retaining the single load feature. In all three linear configurations, the channel walls are electrically segmented to support the Hall field, and experience

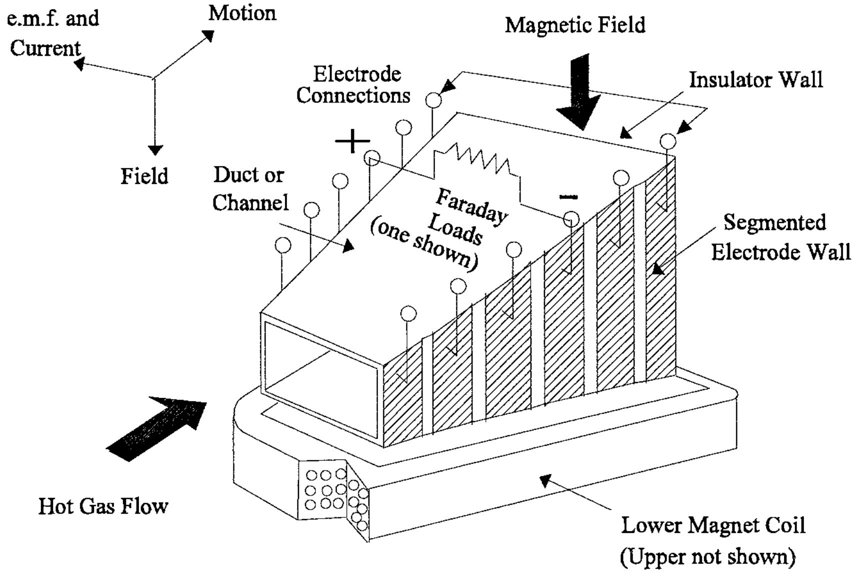

FIGURE 8.13.23 Basic Faraday linear MHD generator.

has shown that this must be sufficiently finely graded so that no more than 50 V is supported by the interelectrode gaps to avoid electrical breakdown.

The MHD generator is a linear version of the homopolar machine originally demonstrated by Faraday and is, as a practical matter, confined to DC generation. Accordingly, some form of DC-AC conversion using power electronics is required for the vast majority of applications. The single load feature loses significance in this situation as the "power conditioning" can readily be arranged to combine (consolidate) the individual cell outputs before conversion to the required AC system conditions. Indeed, to maximize power extraction while limiting interelectrode voltages and controlling electrode currents (to ensure adequate lifetime), the power conditioning is arranged to extract power from both Faraday and Hall terminal pairs.

An alternative geometry is to set up a radial flow (usually but not necessarily outward) with the disk configuration of Figure 8.13.23d. The result is a Hall generator, which is generally favored for nonequilibrium ionization as it avoids the inevitable nonuniformities associated with electrode segmentation with their proclivity for promoting ionization instabilities. A measure of Faraday performance is achievable through the introduction of swirl, and additional ring electrodes enable power conditioning to control (and optimize) the radial electric field.

Components

An MHD generator per se requires several components to make up a complete powertrain. In addition to the power conditioning needed for DC-AC conversion these include a magnet, seed injector, combustor with fuel and oxidizer supply or an input heat exchanger, nozzle, compressor, diffuser, exhaust gas-cleaning system (for once-through systems), and controls. The need to accommodate a channel between the poles of a magnet qualifies the MHD generator as a large-air-gap machine.

Systems

Power systems incorporating MHD generators are either of the once-through (open-cycle) or working fluid recycle (closed-cycle) type, and the complete MHD system described in the previous section can either be stand-alone or incorporated into a more complex configuration such as a binary cycle. In the latter case, the high-temperature operation of the MHD unit makes it a topping cycle candidate and it is in this mode that MHD has received most system consideration. An MHD generator operated directly on ionized combustion gas is usually associated with an open cycle while nonequilibrium ionization with seeded noble gases and LMMHD are invariably considered for closed-cycle operation. An exception is nonequilibrium ionization in cesium-seeded hydrogen which has received some attention for open-cycle operation.

Heat Sources, Applications, and Environmental Considerations

A heat source capable of providing from 1000 K for LMMHD to over 3000 K for open-cycle systems for power production is a candidate. Rocket motor fuels, all fossil fuels, high-temperature nuclear reactors cooled with hydrogen and biomass are suitable for open cycles, while closed cycles can be driven through a heat exchanger by any of these combustion sources. A high-temperature nuclear reactor, probably helium cooled, is also a feasible source for MHD and in the early stages of development of the process received much attention. With the abandonment of efforts to develop commercial reactors to operate at temperatures above 1200 K, attention has focused on high-energy fuels for pulse power (few seconds) operation and coal for utility power generation.

While the debate over the role of fossil energy in the long-term electricity generation scenario continues, it is established that coal is a major resource which must be utilized at maximim efficiency to limit CO_2 production and must be combusted in a manner which reduces SO_2 and NO_x effluents to acceptable levels. The use of MHD generators significantly advances all of these objectives. Briefly, it was first observed that the "electromagnetic turbine" has the major advantage that it cannot only provide the highest efficiency of any known converter from the Carnot viewpoint but that its operation is not adversely affected by coal slag and ash. Indeed, slag provides an excellent renewable coating for the channel walls and increases lifetime.

System calculations have shown that, when coupled as a topping cycle to the best available steam plant technology, a thermal efficiency with coal and full environmental control is 52.5%. When coupled into a ternary cycle with either a gas turbine or fuel cells and a steam turbine, efficiencies upward of 60% are possible.

Technology Status

A pulse-type MHD generator was successfully built and operated by Avco (now Textron Defense Industries) in 1963 and a complete natural gas-fired pilot plant with a nominal 20-MW MHD generator was commissioned in the U.S.S.R. on the northern outskirts of Moscow in 1971. In the decade of the 1980s, development was focused on coal firing as a result of the oil crises of the 1970s and in the U.S. progressed to the point where the technology base was developed for a demonstration plant with a 15-MW MHD generator.

Future Prospects

The two particular attributes of the MHD generator are its rapid start-up to multimegawatt power levels for pulse power applications and its ability to provide a very high overall thermal efficiency for power plants using coal while meeting the most stringent environmental standards. The first has already been utilized in crustal exploration, and the second must surely be utilized when coal is the fuel of choice for electric power production. In the meantime, MHD has been established as a viable technology on which further development work will be conducted for advanced applications such as the conversion system for thermonuclear fusion reactors.

Further Information

The following proceedings series contain a full and complete record of MHD generator and power system development:

1. *Proceedings of the Symposia for the Engineering Aspects of Magnetohydrodynamics*, held annually in the U.S. since 1960 (except for 1971 and 1980).
2. *Proceedings of 11 International Conferences on Magnetohydrodynamic Electrical Power Generation*, held in 1962, 1964, 1966, 1968, 1971 , 1975, 1980, 1983, 1986, 1989, and 1992. The 12th conference will be held in Yokahama, Japan in October 1996.

8.14 Ocean Energy Technology

Desikan Bharathan and Federica Zangrando

The ocean contains a vast renewable energy potential in its waves and tides; in the temperature difference between cold, deep waters and warm surface waters; and in the salinity differences at river mouths (SERI, 1990; WEC, 1993; Cavanagh et al., 1993). Waves offer a power source for which numerous systems have been conceived. Tides are a result of the gravity of the sun, the moon, and the rotation of the Earth working together. The ocean also acts as a gigantic solar collector, capturing the energy of the sun in its surface water as heat. The temperature difference between warm surface waters and cold water from the ocean depths provides a potential source of energy. Other sources of ocean energy include ocean currents, salinity gradients, and ocean-grown biomass.

The following subsections briefly describe the status and potential of the various ocean energy technologies, with emphasis placed on those with a near-term applicability.

Ocean Thermal Energy Conversion

Ocean thermal energy conversion (OTEC) technology is based on the principle that energy can be extracted from two reservoirs at different temperatures (SERI, 1989). A temperature difference of as little as 20°C can yield usable energy. Such temperature differences prevail between ocean waters at the surface and at depths up to 1000 m in tropical and subtropical latitudes between 24° north and south of the equator. Here, surface water temperatures range from 22 to 29°C, while temperatures at a depth of 1000 m range from 4 to 6°C. This constitutes a vast, renewable resource, estimated at 10^{13} W, for potential base load power generation.

Past research has been concentrated on two OTEC power cycles, namely, **closed cycle** and **open cycle**, for converting this thermal energy to electrical energy (Avery and Wu, 1994). Both cycles have been demonstrated, but no commercial system is in operation. In a closed-cycle system, warm seawater is used to vaporize a working fluid such as ammonia flowing through a heat exchanger (evaporator). The vapor expands at moderate pressures and turns a turbine. The vapor is condensed in a condenser using cold seawater pumped from the ocean depths and the condensed fluid is pumped back to the evaporator to repeat the cycle. The working fluid remains in a closed system and is continuously circulated (Figure 8.14.1).

In an open-cycle system, the warm seawater is "flash" evaporated in a vacuum chamber to make steam at an absolute pressure of about 2.4 kPa. This steam expands through a low-pressure turbine coupled to a generator to produce electricity. The steam is then condensed by using cold seawater. If a surface condenser is used, condensed steam is separated as desalinated water (Figure 8.14.2).

Effluent from a closed-cycle or an open-cycle system can be further processed to make more desalinated water through evaporator/condenser systems in subsequent stages. For combined production of power and water, these systems can be competitive with conventional systems in several coastal markets.

Tidal Power

The energy from tides is derived from the kinetic energy of water moving from a higher to a lower elevation, similar to hydroelectric plants. High tide can provide the potential energy for seawater to flow into an enclosed basin or estuary and then be discharged at low tide (Ryan, 1980). Electricity is produced from the gravity-driven inflow or outflow or both through a turbogenerator. The tidal resource is variable but predictable, and there are no technical barriers for deployment of this technology. Because costs are strongly driven by the civil works required to dam the reservoir, only a few sites around the world have the proper conditions of tides and landscape to use this technology. Recent developments in marine and offshore construction have helped reduce construction time and cost; however, the economics of tidal power production remains uncompetitive to conventional energy systems.

The highest tides in the world can reach above 17 m, as in the Bay of Fundy between Maine and Nova Scotia, where it is projected that up to 10,000 MW could be produced by tidal systems in this bay alone. A minimum tidal range (difference between mean high and low tides) of 5 m is required for plants using conventional hydroelectric equipment. More recently, low-head hydroelectric power equipment has proved adaptable to tidal power and new systems for 2-m ranges have been proposed.

A few tidal power stations are operating in France, the former U.S.S.R., China, and Canada. The largest and longest-operating plant is the 240-MW tidal power station on the Rance River estuary in northern France (Banal and Bichon, 1981), which has operated with 95% availability since 1968. The 400-kW tidal plant in Kislaya Bay on the Barents Sea in the former U.S.S.R. has been operating since 1968; at this favorable site, only a 50-m-wide dam was needed to close the reservoir. The 20-MW Canadian plant at Annapolis on the Bay of Fundy has operated reliably since 1984. A number of small turbine generator plants of up to 4 MW are also installed on the China coastline.

Wave Power

Waves contain significant power that can be harnessed by shore-mounted or offshore systems. Offshore installations will have larger incident power on the device but require more costly installations. A myriad of wave-energy converter concepts have been devised, transforming wave energy into other forms of mechanical (rotary, oscillating, or relative motion), potential, or pneumatic energy, and ultimately into electricity; very few have been tested at sea.

The power per unit frontal length of the wave is proportional to wave height squared and to wave period, with their representative values on the order of 2 m and 10 sec. The strong dependence on wave height makes the resource highly variable, even on a seasonal and a yearly average basis. The northeastern Pacific and Atlantic coasts have average yearly incident wave power of about 50 kW/m, while near the tip of South America the average power can reach 100 kW/m. Japan, on the other hand, receives an average of 15 kW/m. Waves during storms can reach 200 kW/m, but large waves are unsafe for operation. Because of their severity, they impose severe constraints and increase system costs. Overall, the amount of power that could be harvested from waves breaking against world coastlines is estimated to be on the order of the current global consumption of energy. However, total installed capacity amounts to less than 1 MW worldwide.

A commonly deployed device is the oscillating water column (OWC), which has so far been mounted on shore but is also proposed for floating plants. It consists of an air chamber in contact with the sea so that the water column in the chamber oscillates with the waves. This motion makes the air flow in and out of the chamber, turning a turbine. A Wells turbine uses symmetrical airfoil blades in a simple rotor to extract power from the airflow in both directions. Flywheels are often used to smooth out fluctuating delivered energy by the waves.

Two of the largest wave-energy power plants were built at Toftestallen, near Bergen, Norway. A Norwegian company, Norwave A.S., built a 350-kW tapered channel (Tapchan) device in 1984, which survived a severe storm in 1989 (the 500 kW multiresonant OWC plant built by Kvaerner Brug A.S. did not). The channel takes advantage of the rocky coastline to funnel waves through a 60-m-wide opening into a coastal reservoir of 5500 m^2, while maintaining civil engineering costs to a minimum. Wave height increases as the channel narrows over its 60-m length, and the rising waves spill over the 3-m-high channel walls, filling the reservoir. Continuous wave action maintains the reservoir level at a relatively constant elevation above sea level, providing potential energy for a low-head hydroelectric Kaplan turbogenerator. Estimates by Norwave to rebuild an identical plant at this site suggested capital costs of $3500/kW installed, and energy costs of 8¢/kWh, at a plant capacity factor of 25% (ASCE, 1992). In recent efforts, the National Institute of Ocean Technology, India, has installed a 150-kW wave-energy conversion device in the southern tip of India.

Concluding Remarks

Among the many ocean energy prospects, OTEC, tides, and tapered channel wave-energy converters offer the most near-term potential and possess applicability for a large variety of sites. To realize their potential, additional research and development is required. Ocean resources can be most suitable to address humanity's future needs for water and hydrogen for fuel cells.

Defining Terms

Ocean thermal energy conversion (OTEC): a system that utilizes the temperature difference between the seawater at the surface and at depths.

Closed-cycle OTEC: uses a working fluid in a closed cycle.

Open-cycle OTEC: uses steam flashed from the warm seawater as the working fluid that is condensed and exhausted.

8.15 Combined-Cycle Power Plants

Alex Lezuo

In the decades since the early 1970s, power plant concepts featuring a combination of gas and steam turbines have been successfully commercialized. These combined-cycle power plants make very efficient use of fuel compared with other power plants. The first combined-cycle power plants in the 1970s achieved net efficiencies of about 40%, while the most recent ones attain net plant efficiencies of more than 58%.

Combined-Cycle Concepts

The considerable amount of energy available in the exhaust of a gas turbine also can be used in a secondary system, increasing overall efficiency considerably. Figure 8.15.1 shows three of the most common types of combined-cycle (CC) concepts.

The *natural-gas-fired CC* power plant, which offers the highest efficiency potential, is the most commonly used system today. However, to attain these high efficiencies, only fuels such as natural gas can be burned in the gas turbine. The use of other fuels results in a higher heat rate. The arrangement is relatively simple and therefore has the lowest specific investment costs among all power generation systems.

The *parallel-powered CC* power plant is mainly used for repowering existing coal-fired power plants. This is an efficient way of reducing the heat rate of older coal-fired power plants with a relatively small investment and short implementation schedules. In addition, this concept provides excellent part-load behavior, thus making it suitable for cycling duty. Instead of generating steam with the combustion turbine exhaust gas, it is also possible simply to heat the feedwater of a coal-fired power plant and thus reduce the amount of extraction steam required from the steam turbine for the feedwater heaters. This can increase the output and efficiency of the coal plant.

When no natural gas is available, the CC can also be used in connection with a coal gasification plant. Integrated systems (*integrated gasification combined cycle, IGCC*) increase system complexity and most likely decrease overall plant availability, but permit the use of lower cost fuels such as coal or petcoke in an environmentally acceptable manner. Several industrial-scale demonstration plants have proven the technical feasibility, but wider application is dependent on the price spread between coal and natural gas.

Other CC developments have been proposed but the natural-gas-fired CC has proven to be the most efficient and most economical under present technical and economical boundary conditions. Therefore, this CC will be described in greater detail.

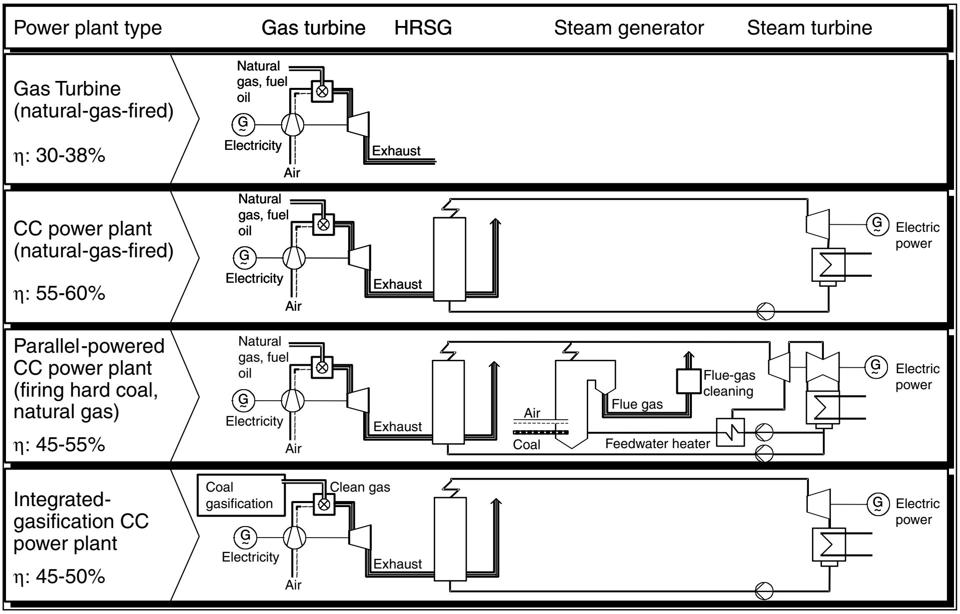

FIGURE 8.15.1 Combined-cycle power plant concepts.

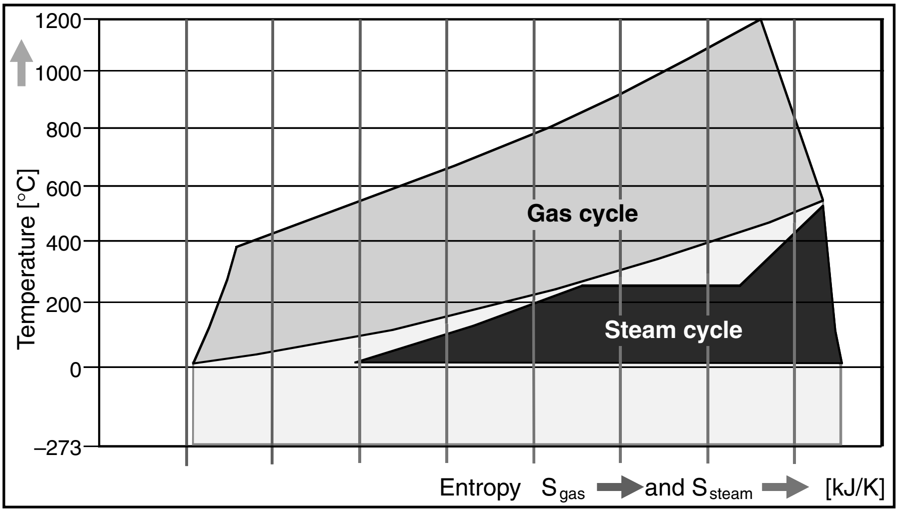

FIGURE 8.15.2 *T–S* diagram of a combined-cycle power plant with single-pressure steam cycle.

Combined-Cycle Thermodynamics

The exhaust gas temperature of today's gas turbines varies between 500°C (932°F) for small and older gas turbines and 600°C (1112°F) for advanced GTs, and the specific exhaust gas stream amounts to 2 to 3 kg/s (4.4 to 6.6 lb/s) per megawatt, where the smaller figure relates to large, advanced gas turbines. By using the heat of this exhaust gas in a water–steam cycle, total cycle efficiency can be raised considerably because a very high total temperature difference can be utilized in the combined cycle (Figure 8.15.2) compared to a simple-cycle gas turbine.

With the improvement of gas turbines and the accompanying increase in exhaust temperature, main steam pressure and temperature of the steam cycle have been raised to as high as 165 bar (2400 psi) and 565°C (1050°F). In addition, multipressure heat-recovery steam generators (HRSGs) with reheat are

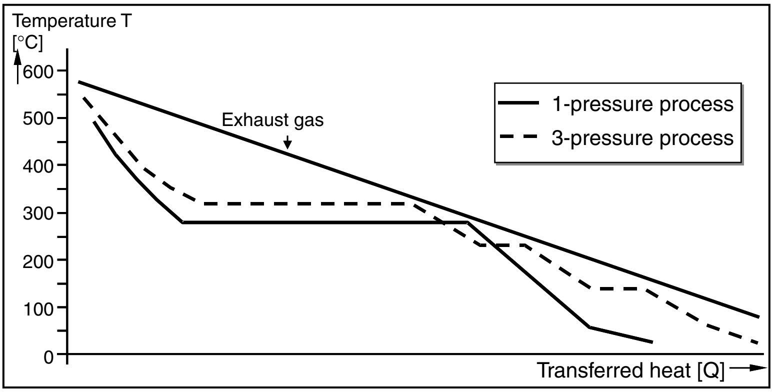

FIGURE 8.15.3 *T*–*Q* diagram for heat-recovery steam generators.

used, which represents another improvement in utilization of the exhaust heat. In this way, the losses can be reduced as shown in Figure 8.15.3, which compares a single-pressure HRSG with a triple-pressure system. The ideal temperature/heat transfer diagram would be one in which the temperature difference in the HRSG between the steam and the exhaust gases is constant.

The exhaust gases leaving the gas turbine enter the HRSG at a temperature between approximately 550 and 600°C (1022 and 1112°F) and leave the HRSG typically between 80 and 100°C (176 and 212°F). The water in the steam cycle portion of the combined cycle enters the HRSG economizer as a subcooled liquid. The temperature of the water is increased in the economizer until the liquid becomes saturated. At this point, the minimum temperature difference between the water in the steam cycle and the exhaust gases occurs and is called the "pinch point." Typical pinch-point values range from 8 to 30°C (46 to 86°F); the smaller the pinch point difference is, the larger the required heat-transfer surface area. After evaporation at constant temperature, the steam is superheated to the final temperature in the superheater section.

Figure 8.15.3 shows the improvement in heat transfer from the single-pressure cycle to the triple-pressure cycle. High-performance plant designs are today equipped with a triple-pressure HRSG with one reheat stage.

Table 8.15.1 lists net plant output and performance values for a selection of CCs from the four main suppliers worldwide. This is just a selection of available gas turbines and possible configurations because manufacturers are developing and improving their engines on a regular basis. Performance data are based on standard designs and configurations at ISO conditions of 15°C (59°F), which provides a normalized basis for comparison.

Combined-Cycle Arrangements

Today, several designs for natural-gas-fired CCs are available. All consist of the following main components (Figure 8.15.4):

- Gas turbine
- Steam turbine
- Generator
- HRSG
- Stack
- Condenser with heat removal system
- Condensate pumps
- Feedwater pumps
- Auxiliary systems for gas and steam turbine
- Main and auxiliary transformers

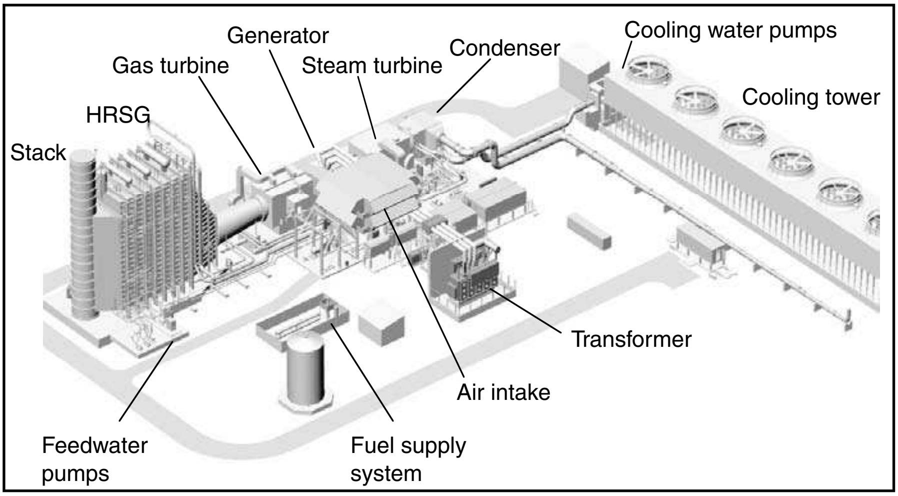

FIGURE 8.15.4 Arrangement and main components of a single-shaft CC plant.

- Fuel supply system
- Electrical equipment
- Instrumentation and control systems

Figure 8.15.5 shows the configuration of a *single-shaft CC* arrangement with the steam turbine at one end, the common generator in the center, and a synchronous self-shifting (SSS) clutch between the

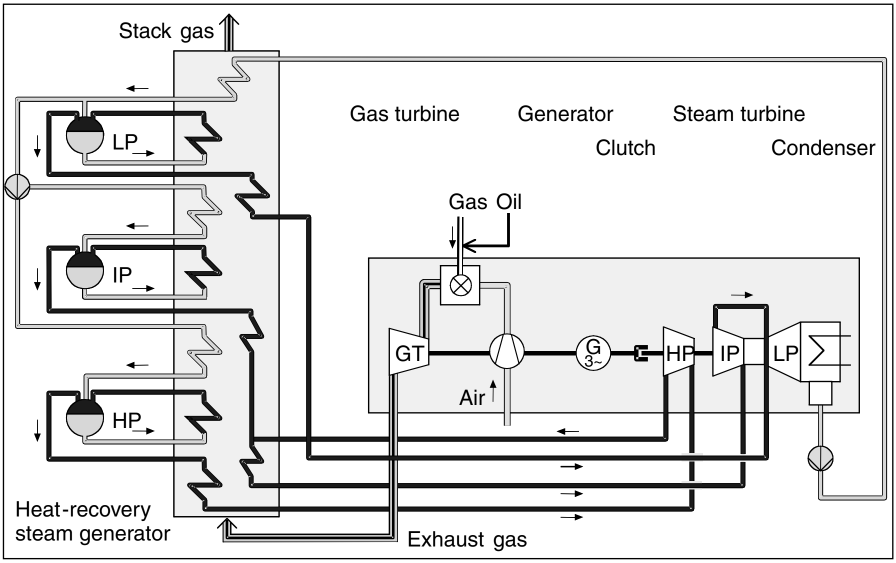

FIGURE 8.15.5 Single-shaft CC plant schematic with triple-pressure reheat.

generator and the steam turbine. The gas turbine can be started independently without any restrictions arising from the actual condition (hot, warm, or cold) of the steam turbine and the cooling system. The clutch acts as a coupling to enable unrestricted axial expansion of the steam turbine shaft relative to the generator. This allows optimized axial clearances for the steam turbine blading, resulting in improved efficiency.

The clutch engages automatically once the steam turbine approaches the operational rotating speed of the generator (3000 or 3600 rpm). It automatically disconnects the steam turbine whenever the steam turbine slows down relative to the generator. The clutch allows the gas turbine to be started and operated independently of the steam turbine. The gas turbine can be started up relatively quickly and the steam turbine can be accelerated at a suitable rate once the gas turbine is loaded. The steam turbine can be shut down at any time, leaving the gas turbine operating in open-cycle mode. In this mode, the steam produced is dumped to the condenser via the bypass station. The single-shaft configuration requires less space and can be built in efficient and independent units.

In the *multishaft CC* arrangement, the gas turbine and the steam turbine are separated; each engine has its own generator and transformer. They are built in 1 + 1 configuration, which means one gas turbine, one HRSG and one steam turbine as the schematic in Figure 8.15.6 shows, or in the very common 2 + 1 configuration (two gas turbines, two HRSGs, and one common steam turbine). Sometimes a 3 + 1 arrangement and even a 4 + 1 arrangement are used.

The multishaft arrangement offers the advantage that the plant can be built in what is known as “phased construction.” The gas turbine with its very fast construction time can be installed first and operated in a simple cycle (of course, with low efficiency); the plant can be extended later by adding an HRSG and steam turbine along with all the other necessary equipment. In this way, the customer gets not only a gradual increase in power output but also a deferment of the necessary investment. In such an unfired configuration, about two thirds of the total power output is generated in the gas turbine and one third in the steam turbine. This is due to the fixed amount of exhaust energy from the gas turbine.

Natural- gas-fired CC plants have relatively small auxiliary systems and do not require major stack gas clean-up systems. Consequently, the parasitic power of CC plants is low compared to steam power plants — amounting to approximately 1.5% of total rated power output.

One way to increase the plant output is to introduce supplementary firing in the exhaust duct between the gas turbine exit and HRSG inlet. This increases temperature and available heat transferred to the steam cycle (Figure 8.15.7).

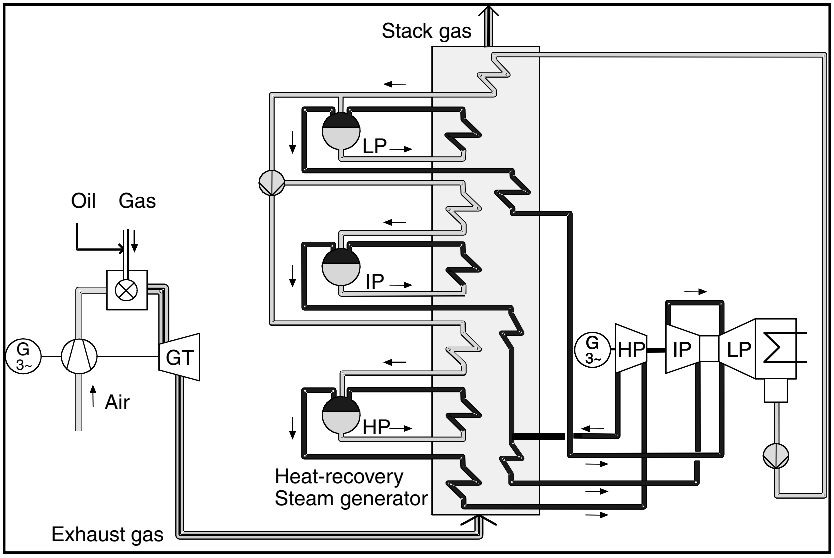

FIGURE 8.15.6 Multishaft CC plant arrangement with triple-pressure reheat.

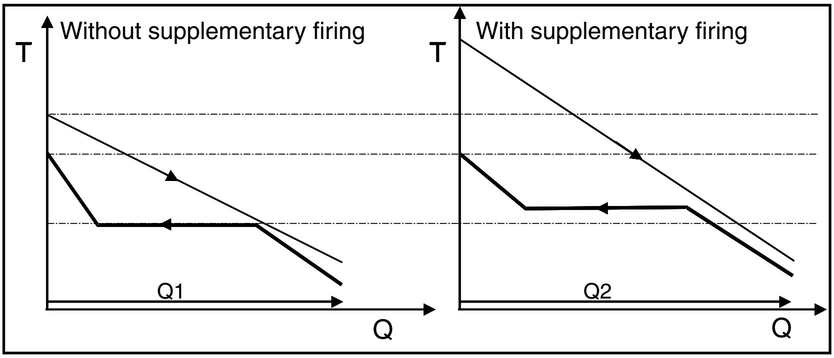

FIGURE 8.15.7 *T*–*Q* diagrams for CC without/with supplementary firing.

The advantages of adding supplementary or duct firing are:

- The total output from the combined cycle will increase with a higher fraction of the output coming from the steam turbine cycle.
- The temperature at the HRSG inlet can be controlled. This is important because the temperature and mass flow rate at the exit from the gas turbine are highly dependent on ambient temperature.
- The implementation of supplementary firing requires relatively low investment.
- Duct firing can be easily turned on or off, making it an excellent choice for peaking capacity.

The disadvantage is that a drop in overall plant efficiency occurs when the duct firing is employed.

Duct firing can be employed in varying amounts, from small firing rates to compensate for high ambient temperature reductions in CT output to firing levels that can double the steam cycle output. For this reason, an economic analysis is recommended before applying this option.

Combined Heat and Power from Combined-Cycle Plants

As in other power plants, not only electricity but also usable heat can be produced in CC plants and thus a fuel utilization factor ($(P_{electricity} + P_{heat})/Q_{fuel}$) up to 90% can be achieved. Depending on specific

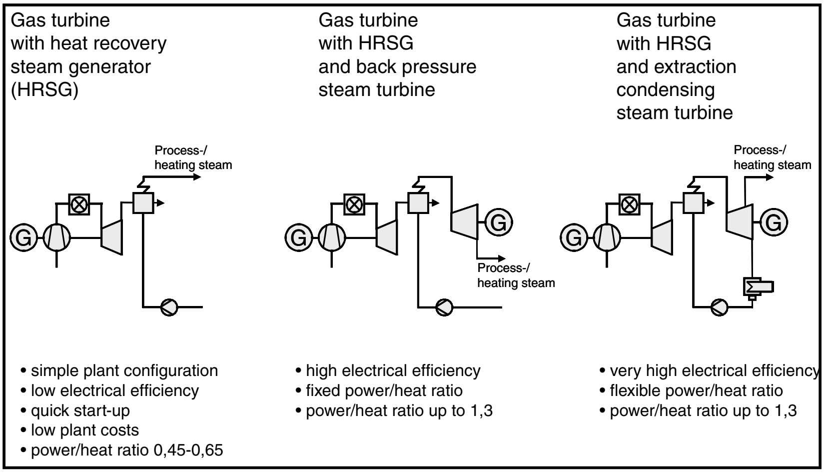

FIGURE 8.15.8 CHP concepts using gas turbines.

requirements, several different gas turbine power plant configurations can be utilized in cogeneration applications (Figure 8.15.8). A plant with a backpressure turbine has a relatively inflexible operation profile, while the use of an extraction condensing turbine makes it possible to vary the electric power-to-heat ratio depending on the demand. The required temperature and amount of heated steam are the primary factors for determining the design concept.

Environmental Aspects

From an environmental perspective, the natural-gas-fired CC is one of the most environmentally benign fossil-fueled power plant designs. As a result of its high efficiency and the use of clean natural gas, emissions of the greenhouse gas carbon dioxide (CO_2) are very low. Depending on plant design, a value of approximately 320 to 380 g/kWh (0.70 and 0.83 lb/kWh) can be obtained. The very high efficiency is also the reason for the relatively small amount of waste heat that must be dumped into the atmosphere.

With the development of dry low-NO_x (DLN) burners, the standard NO_x emissions are today <25 ppmvd with a tendency to even lower values. With the help of selective catalytic reduction (SCR) values of <5 ppmvd can be achieved. CO emissions in the exhaust gas are usually <10 ppmvd in the upper load range. CO catalysts can lower this value to <4 ppmvd.

9.1 Introduction

Shan K. Wang

Air-Conditioning

Air-conditioning is a process that simultaneously conditions air; distributes it combined with ventilation air to the conditioned space; and at the same time controls and maintains the space's temperature, humidity, air movement, air cleanliness, sound level, and pressure differential within predetermined limits for the health and comfort of the occupants, for product processing, or both.

The acronym HVAC&R stands for heating, ventilating, air-conditioning, and refrigerating. The combination of these processes is equivalent to the functions performed by air-conditioning.

Because I-P units are widely used in the HVAC&R industry in the U.S., I-P units are used in this chapter.

Air-Conditioning Systems

An *air-conditioning* or *HVAC&R system* consists of components and equipment arranged in sequential order to heat or cool, humidify or dehumidify, clean and purify, attenuate objectionable equipment noise, transport the conditioned outdoor air and recirculate air to the conditioned space, and control and maintain an indoor or enclosed environment at optimum energy use.

The types of buildings which the air-conditioning system serves can be classified as:

- Institutional buildings, such as hospitals and nursing homes
- Commercial buildings, such as offices, stores, and shopping centers
- Residential buildings, including single-family and multifamily low-rise buildings of three or fewer stories above grade
- Manufacturing buildings, which manufacture and store products

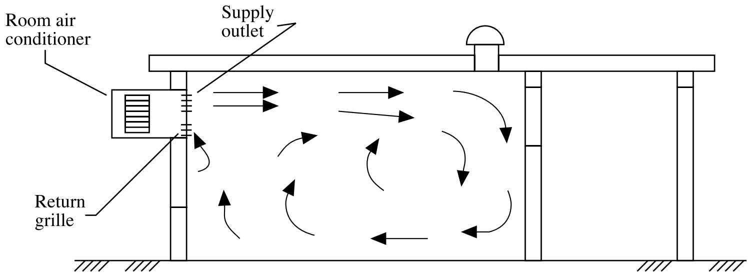

FIGURE 9.1.1 An individual room air-conditioning system.

Types of Air-Conditioning Systems

In institutional, commercial, and residential buildings, air-conditioning systems are mainly for the occupants' health and comfort. They are often called *comfort air-conditioning systems.* In manufacturing buildings, air-conditioning systems are provided for product processing, or for the health and comfort of workers as well as processing, and are called *processing air-conditioning systems.*

Based on their size, construction, and operating characteristics, air-conditioning systems can be classified as the following.

Individual Room or Individual Systems. An individual air-conditioning system normally employs either a single, self-contained, packaged room air conditioner (installed in a window or through a wall) or separate indoor and outdoor units to serve an individual room, as shown in Figure 9.1.1. "Self-contained, packaged" means factory assembled in one package and ready for use.

Space-Conditioning Systems or Space Systems. These systems have their air-conditioning—cooling, heating, and filtration—performed predominantly in or above the conditioned space, as shown in Figure 9.1.2. Outdoor air is supplied by a separate outdoor ventilation system.

Unitary Packaged Systems or Packaged Systems. These systems are installed with either a single self-contained, factory-assembled packaged unit (PU) or two split units: an indoor air handler, normally with ductwork, and an outdoor condensing unit with refrigeration compressor(s) and condenser, as shown in Figure 9.1.3. In a packaged system, air is cooled mainly by direct expansion of refrigerant in coils called DX coils and heated by a gas (or oil) furnace or electric heating. The unit may also function as a reverse cycle and provide heat (heat pump).

Central Hydronic or Central Systems. A central system uses chilled water or heating hot water from a central plant to cool and heat the air at the coils in an air handling unit (AHU) as shown in Figure 9.1.4. For energy transport, the heat capacity of water is about 3400 times greater than that of air. Central systems are built-up systems assembled and installed on the site.

Both central and space-conditioning systems consist of the following.

Air Systems. An air system is also called an air handling system or the air side of an air-conditioning or HVAC&R system. Its function is to condition the air, distribute it, and control the indoor environment according to requirements. The primary equipment in an air system is an AHU or air handling unit; both of these include fan, coils, filters, dampers, humidifiers (optional), supply and return ductwork, supply outlets and return inlets, and controls.

Water Systems. These systems include chilled water, hot water, and condenser water systems. A water system consists of pumps, piping work, and accessories. The water system is sometimes called the water side of a central or space-conditioning system.

Central Plant Refrigeration and Heating Systems. The refrigeration system in the central plant of a central system is usually in the form of a chiller package with an outdoor condensing unit. The refrigeration system is also called the refrigeration side of a central system. A boiler and accessories make up the

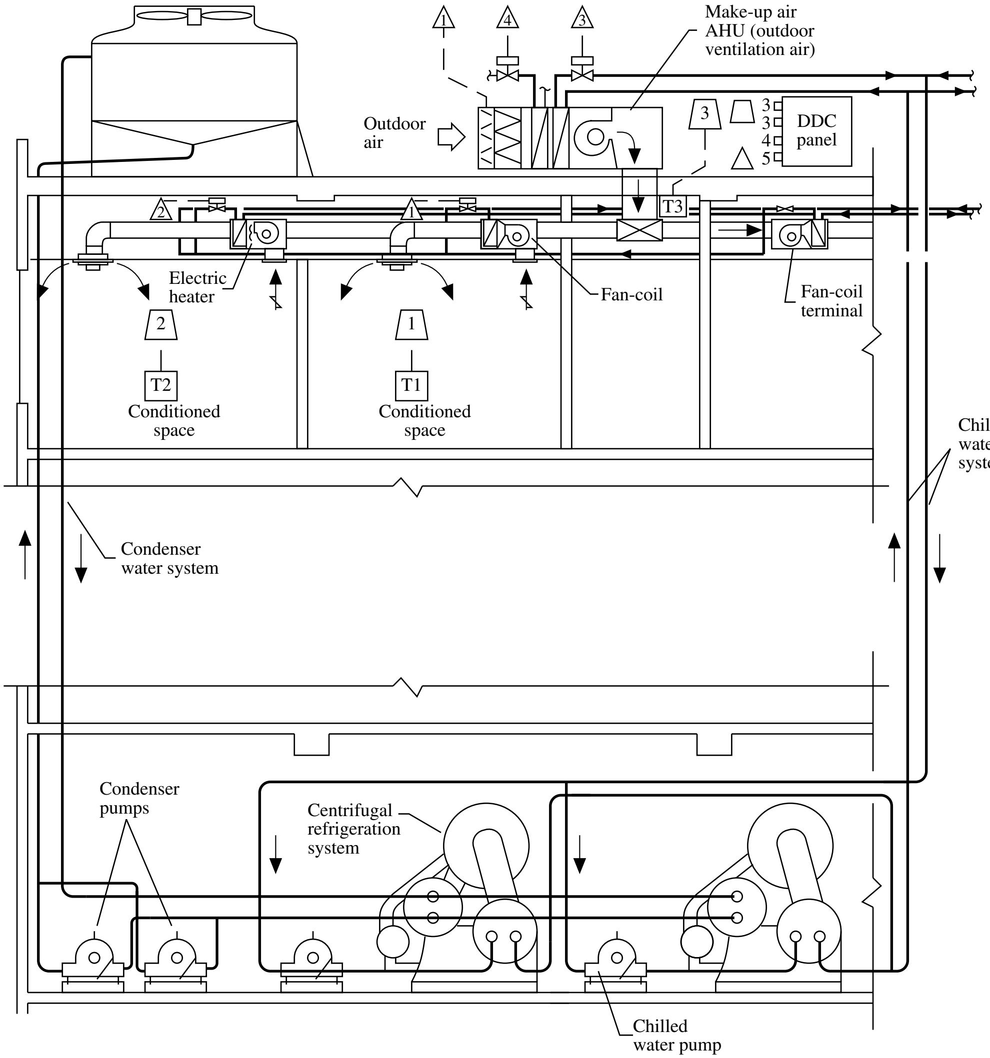

FIGURE 9.1.2 A space-conditioning air-conditioning system (fan-coil system).

heating system in a central plant for a central system, and a direct-fired gas furnace is often the heating system in the air handler of a rooftop packaged system.

Control Systems. Control systems usually consist of sensors, a microprocessor-based direct digital controller (DDC), a control device, control elements, personal computer (PC), and communication network.

Air-Conditioning Project Development and System Design

The goal of an air-conditioning/HVAC&R system is to provide a healthy and comfortable indoor environment with acceptable indoor air quality, while being energy efficient and cost effective.

ASHRAE Standard 62 defines *acceptable indoor air quality* as "air in which there are no known contaminants at harmful concentrations as determined by cognizant authorities and with which a substantial majority (80% or more) of the people exposed do not express dissatisfaction."

The basic steps in the development and use of an air-conditioning project are scope definition design, procurement, installation, commissioning, operation, and maintenance. There are several types of air-conditioning projects: *design-bid, design-build,* and construction management to name a few. A design-bid

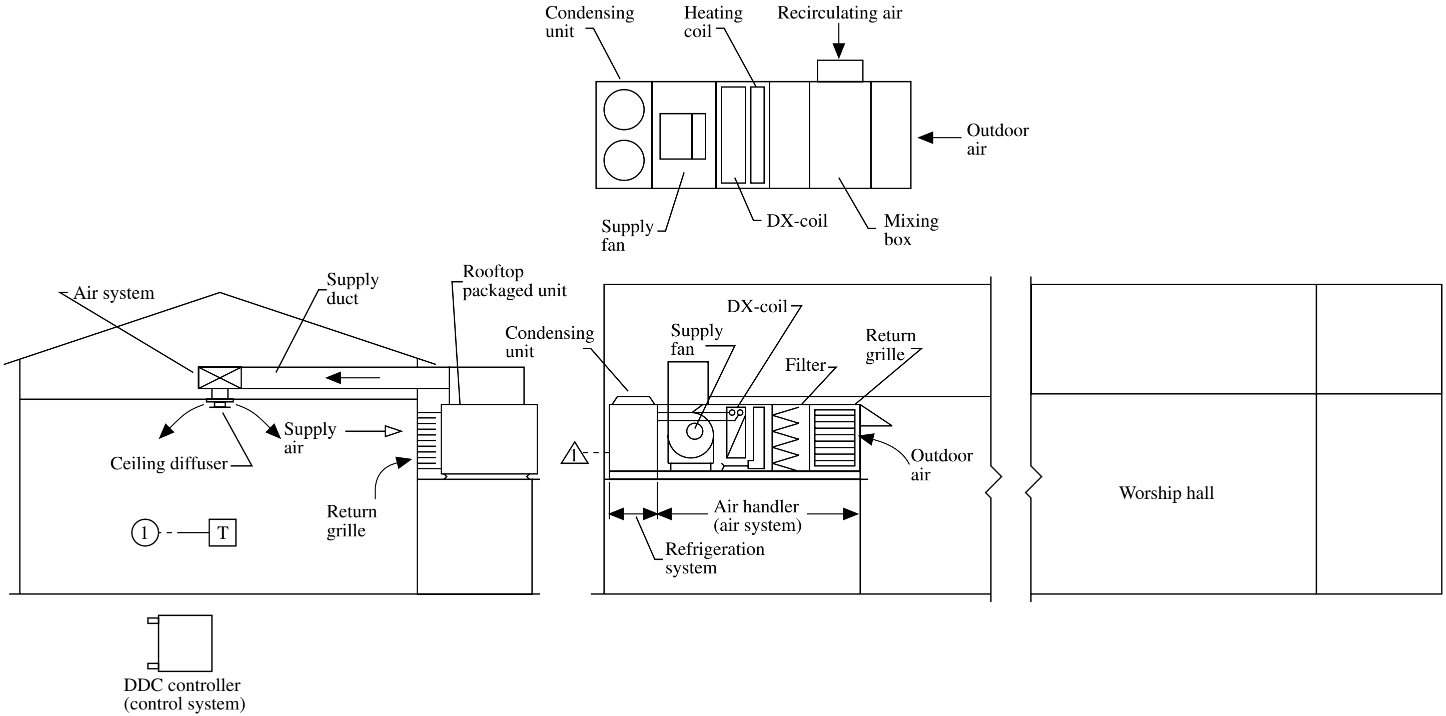

FIGURE 9.1.3 A packaged air-conditioning system.

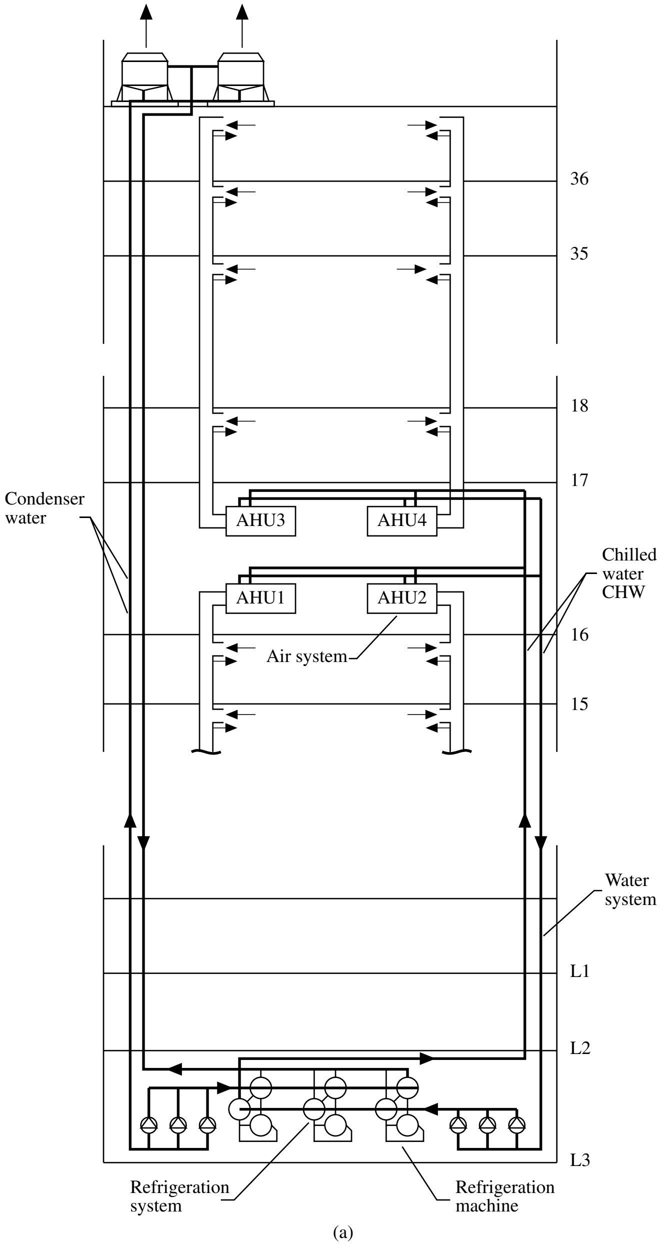

FIGURE 9.1.4a A central air-conditioning system: schematic diagram.

project separates the design (engineering consultant) and installation (contractors) responsibilities. In a design-build project, the design is also done by the installation contractor. A design-build project is usually a small project or a project having insufficient time to go through normal bidding procedures.

In the building construction industry, air-conditioning or HVAC&R is one of the *mechanical services*; these also include plumbing, fire protection, and escalators.

Air-conditioning design is a process of selecting the optimum system, subsystem, equipment, and components from various alternatives and preparing the drawings and specifications. Haines (1994) summarized this process in four phases: gather information, develop alternatives, evaluate alternatives, and sell

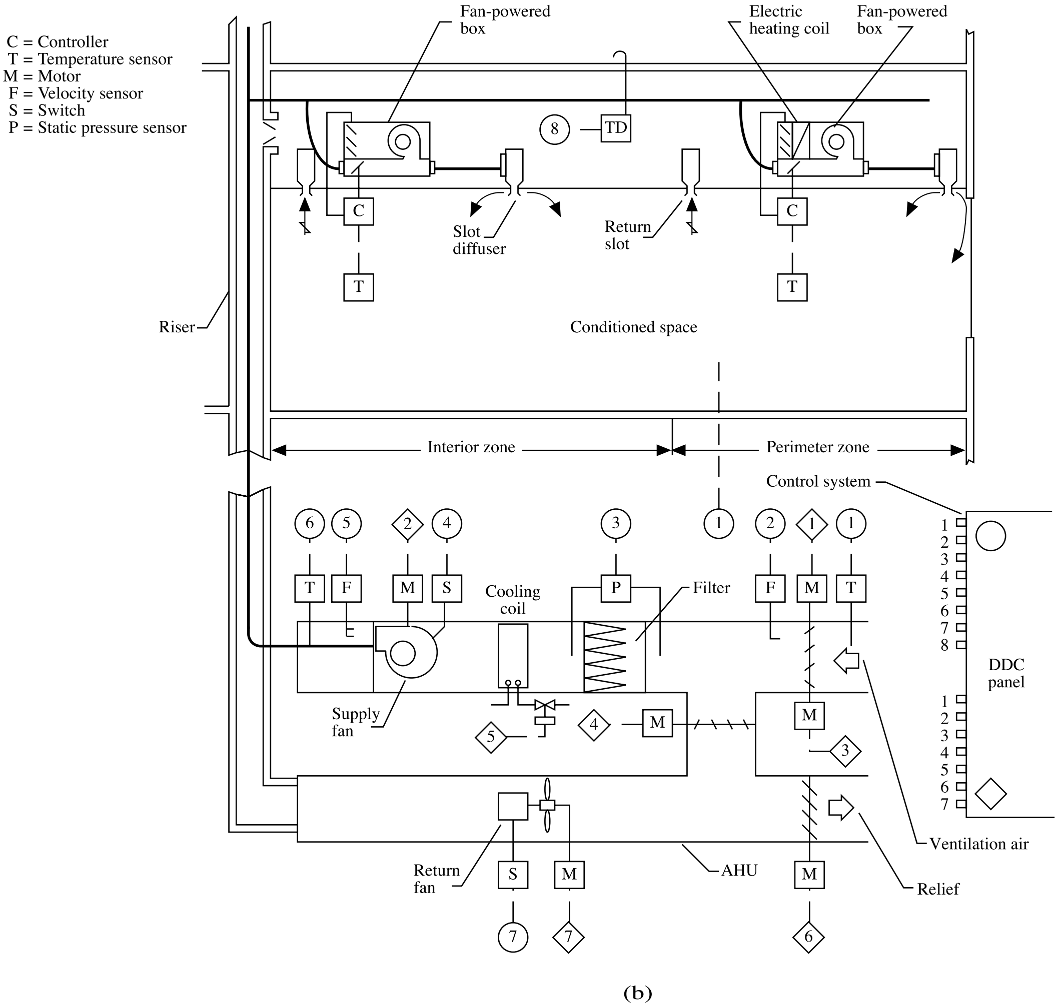

FIGURE 9.1.4b A central air-conditioning system: air and control systems for a typical floor.

the best solution. Design determines the basic operating characteristics of a system. After an air-conditioning system is designed and constructed, it is difficult and expensive to change its basic characteristics.

The foundation of a successful project is teamwork and coordination between designer, contractor, and operator and between mechanical engineer, electrical engineer, facility operator, architect, and structural engineer.

Field experience is helpful to the designer. Before beginning the design process it is advisable to visit similar projects that have operated for more than 2 years and talk with the operator to investigate actual performance.

Mechanical Engineer's Responsibilities

The normal procedure in a design-bid construction project and the mechanical engineer's responsibilities are

1. Initiation of a project by owner or developer
2. Define scope, develop schedule, establish budget
3. Organizing a design team
4. Negotiation of a contract
5. Determining the design criteria and indoor environmental parameters

6. Calculation of cooling and heating loads
7. Selection of systems, subsystems, and their components
8. Preparation of schematic layouts; sizing of piping and ductwork
9. Preparation of contract documents: drawings and specifications
10. Competitive biddings by various contractors; evaluation of bids; negotiations and modifications
11. Advice on awarding of contract
12. Monitoring, supervision, and inspection of installation; reviewing shop drawings
13. Supervision of commissioning
14. Modification of drawings to the as-built condition; preparation of the operation and maintenance manual
15. Handing over to the property management for operation

Design Documents

Drawings and *specifications* are legal documents of a construction contract. The designer conveys the owner's or developer's requirements to the contractor through these documents. Drawings and specifications complement each other.

Drawings should clearly and completely show, define, and present the work. Adequate plan and sectional views should be drawn. More often, isometric drawings are used to show the flow diagrams for water or the supply, return, and exhaust air. Drawings provide information on size, quantity and location and may schedule specific systems by model number and performance.

Specifications include the legal contract between the owner and the contractor, installer, or vendor and the technical specifications, which describe in detail what kind of material and equipment should be used and how they are to be installed.

Most projects now use a format developed by the Construction Specifications Institute (CSI) called the Masterformat for Specifications.

Each section includes general considerations, equipment and material, and field installation. Design criteria and selected indoor environmental parameters that indicate the performance of the HVAC&R system must be clearly specified.

There are two types of specifications: the performance specification, which depends mainly on the required performance criteria, and the or-equal specification, which specifies the wanted vendor. Specifications should be written in simple, direct, and clear language without repetition.

Computer-Aided Design and Drafting

With the wide acceptance of the PC and the availability of numerous types of engineering software, the use of *computer-aided drafting* (CAD) and *computer-aided design and drafting* (CADD) has become common practice in the engineering office.

Drafting software used to reproduce architectural drawings is the foundation of CADD. Automated CAD (AutoCAD) is the leading personal computer-based drafting tool software used in architectural and engineering design firms.

Software for piping system design and analysis can also be integrated with CAD. The software developed at the University of Kentucky, KYCAD/KYPIPE, is intended for the design and diagnosis of large water piping systems, has extensive hydraulic modeling capacities, and is the most widely used. Softdesk AdCADD Piping is relative new software; it is intended for drafting in 2D and 3D, linking to AutoCAD through design information databases.

Currently, software for CADD for air-conditioning and HVAC&R falls into two categories: engineering and product. The engineering category includes CAD (AutoCAD integrated with duct and piping system), load calculations and energy analysis, etc. The most widely used software for load calculations and energy analysis is Department of Energy DOE-2, Trane Company's TRACE 700, and Carrier Corporation's softwares for load calculation, HAP.

Product categories include selection, configuration, performance, price, and maintenance schedule. Product manufacturers provide software including data and CAD drawings for their specific product.

Codes and Standards

Codes are federal, state, or city laws that require the designer to perform the design without violating people's (including occupants and the public) safety and welfare. Federal and local codes must be followed. The designer should be thoroughly familiar with relevant codes. HVAC&R design codes are definitive concerning structural and electrical safety, fire prevention and protection (particularly for gas- or oil-fired systems), environmental concerns, indoor air quality, and energy conservation.

Often standards are referenced by codes and thus become enforceable. Otherwise, conformance with *ASHRAE Standards* is voluntary.

For the purpose of performing an effective, energy-efficient, safe, and cost-effective air-conditioning system design, the following ASHRAE Standards should be referred to from time to time:

- ANSI/ASHRAE/IESNA Standard 90.1-2001, Energy Standard for Buildings Except New Low-Rise Residential Buildings
- ANSI/ASHRAE Standard 62, Ventilation for Acceptable Indoor Air Quality
- ANSI/ASHRAE Standard 55-1992, Thermal Environmental Conditions for Human Occupancy
- ASHRAE Standard 15-2001, Safety Standard for Refrigeration Systems

9.2 Psychrometrics

Shan K. Wang

Moist Air

Above the surface of the earth is a layer of air called the *atmosphere*, or *atmospheric air*. The lower atmosphere, or homosphere, is composed of moist air, that is, a mixture of dry air and water vapor.

Psychrometrics is the science of studying the thermodynamic properties of moist air. It is widely used to illustrate and analyze the change in properties and the thermal characteristics of the air-conditioning process and cycles.

The composition of dry air varies slightly at different geographic locations and from time to time. The approximate composition of dry air by volume is nitrogen, 79.08%; oxygen, 20.95%; argon, 0.93%; carbon dioxide, 0.03%; other gases (e.g., neon, sulfur dioxide), 0.01%.

The amount of water vapor contained in the moist air within the temperature range 0 to 100°F changes from 0.05 to 3% by mass. The variation of water vapor has a critical influence on the characteristics of moist air.

The equation of state for an ideal gas that describes the relationship between its thermodynamic properties covered in Chapter 2 is

$$pv = RT_R \tag{9.2.1}$$

or

$$pV = mRT_R \tag{9.2.2}$$

where

p = pressure of the gas, psf (1 psf = 144 psi)
v = specific volume of the gas, ft^3/lb
R = gas constant, ftlb$_f$/lb$_m$ °R
T_R = absolute temperature of the gas, °R
V = volume of the gas, ft^3
m = mass of the gas, lb

The most exact calculation of the thermodynamic properties of moist air is based on the formulations recommended by Hyland and Wexler (1983) of the U.S. National Bureau of Standards. The psychrometric charts and tables developed by ASHRAE are calculated and plotted from these formulations. According to Nelson et al. (1986), at a temperature between 0 and 100°F, enthalpy and specific volume calculations using ideal gas Equation (9.2.1) and Equation (9.2.2) show a maximum deviation of 0.5% from the results of Hyland and Wexler's exact formulations. Therefore, ideal gas equations are used in the development and calculation of psychrometric formulations in this handbook.

Although air contaminants may seriously affect human health, they have little effect on the thermodynamic properties of moist air. For thermal analysis, moist air may be treated as a binary mixture of dry air and water vapor.

Applying Dalton's law to moist air:

$$p_{\mathrm{at}} = p_{\mathrm{a}} + p_{\mathrm{w}} \tag{9.2.3}$$

where

p_{at} = atmospheric pressure of the moist air, psia
p_{a} = partial pressure of dry air, psia
p_{w} = partial pressure of water vapor, psia

Dalton's law is summarized from the experimental results and is more accurate at low gas pressure. Dalton's law can also be extended, as the Gibbs-Dalton law, to describe the relationship of internal energy, enthalpy, and entropy of the gaseous constituents in a mixture.

Humidity and Enthalpy

The *humidity ratio* of moist air, *w*, in lb/lb is defined as the ratio of the mass of the water vapor, m_{w} to the mass of dry air, m_{a}, or

$$w = m_{\mathrm{w}}/m_{\mathrm{a}} = 0.62198 p_{\mathrm{w}}/\left(p_{\mathrm{at}} - p_{\mathrm{w}}\right) \tag{9.2.4}$$

The *relative humidity* of moist air, φ, or RH, is defined as the ratio of the mole fraction of water vapor, x_{w}, to the mole fraction of saturated moist air at the same temperature and pressure, x_{ws}. Using the ideal gas equations, this relationship can be expressed as:

$$\varphi = x_{\mathrm{w}}/x_{\mathrm{ws}}\big|_{T,p} = p_{\mathrm{w}}/p_{\mathrm{ws}}\big|_{T,p} \tag{9.2.5}$$

and

$$x_{\mathrm{w}} = n_{\mathrm{w}}/\left(n_{\mathrm{a}} + n_{\mathrm{w}}\right); \quad x_{\mathrm{ws}} = n_{\mathrm{ws}}/\left(n_{\mathrm{a}} + n_{\mathrm{ws}}\right)$$

$$x_{\mathrm{a}} + x_{\mathrm{w}} = 1 \tag{9.2.6}$$

where

p_{ws} = pressure of saturated water vapor, psia
T = temperature, °F
n_{a}, n_{w}, n_{ws} = number of moles of dry air, water vapor, and saturated water vapor, mol

Degree of saturation μ is defined as the ratio of the humidity ratio of moist air, *w*, to the humidity ratio of saturated moist air, w_{s}, at the same temperature and pressure:

$$\mu = w/w_{\mathrm{s}}\big|_{T,p} \tag{9.2.7}$$

The difference between φ and μ is small, usually less than 2%.

At constant pressure, the difference in specific enthalpy of an ideal gas, in Btu/lb, is $\Delta h = c_p \Delta T$. Here c_p represents the specific heat at constant pressure, in Btu/lb. For simplicity, the following assumptions are made during the calculation of the *enthalpy* of moist air:

1. At 0°F, the enthalpy of dry air is equal to zero.
2. All water vapor is vaporized at 0°F.
3. The enthalpy of saturated water vapor at 0°F is 1061 Btu/lb.
4. The unit of the enthalpy of the moist air is Btu per pound of dry air and the associated water vapor, or Btu/lb.

Then, within the temperature range 0 to 100°F, the enthalpy of the moist air can be calculated as:

$$\begin{aligned} h &= c_{\text{pd}} T + w\left(h_{\text{g0}} + c_{\text{ps}} T\right) \\ &= 0.240T + w(1061 + 0.444T) \end{aligned} \tag{9.2.8}$$

where

c_{pd}, c_{ps} = specific heat of dry air and water vapor at constant pressure, Btu/lb°F. Their mean values can be taken as 0.240 and 0.444 Btu/lb°F, respectively.

h_{g0} = specific enthalpy of saturated water vapor at 0°F.

Moist Volume, Density, Specific Heat, and Dew Point

The specific *moist volume* v, in ft^3/lb, is defined as the volume of the mixture of dry air and the associated water vapor when the mass of the dry air is exactly 1 lb:

$$v = V/m_{\text{a}} \tag{9.2.9}$$

where V = total volume of the moist air, ft^3. Since moist air, dry air, and water vapor occupy the same volume,

$$v = R_{\text{a}} T_{\text{R}} / p_{\text{at}} (1 + 1.6078w) \tag{9.2.10}$$

where R_{a} = gas constant for dry air.

Moist air density, often called *air density* ρ, in lb/ft^3, is defined as the ratio of the mass of dry air to the total volume of the mixture, or the reciprocal of the moist volume:

$$\rho = m_{\text{a}}/V = 1/v \tag{9.2.11}$$

The *sensible heat of moist air* is the thermal energy associated with the change of air temperature between two state points. In Equation (9.2.8), $(c_{\text{pd}} + wc_{\text{ps}})T$ indicates the sensible heat of moist air, which depends on its temperature T above the datum 0°F. *Latent heat of moist air*, often represented by wh_{fg0}, is the thermal energy associated with the change of state of water vapor. Both of them are in Btu/lb. Within the temperature range 0 to 100°F, if the average humidity ratio w is taken as 0.0075 lb/lb, the *specific heat of moist air* c_{pa} can be calculated as:

$$c_{\text{pa}} = c_{\text{pd}} + wc_{\text{ps}} = 0.240 + 0.0075 \times 0.444 = 0.243 \text{ Btu/lb °F} \tag{9.2.12}$$

The *dew point temperature* T_{dew}, in °F, is the temperature of saturated moist air of the moist air sample having the same humidity ratio at the same atmospheric pressure. Two moist air samples of similar dew points T_{dew} at the same atmospheric pressure have the same humidity ratio w and the same partial pressure of water vapor p_{w}.

Thermodynamic Wet Bulb Temperature and Wet Bulb Temperature

The *thermodynamic wet bulb temperature* of moist air, T^*, is equal to the saturated state of a moist air sample at the end of a constant-pressure, ideal adiabatic saturation process:

$$h_1 + \left(w_s^* - w_1\right)h_w^* = h_s^* \tag{9.2.13}$$

where

h_1, h_s^* = enthalpy of moist air at the initial state and enthalpy of saturated air at the end of the constant-pressure, ideal adiabatic saturation process, Btu/lb

w_1, w_s^* = humidity ratio of moist air at the initial state and humidity ratio of saturated air at the end of the constant-pressure, ideal adiabatic saturation process, lb/lb

h_w^* = enthalpy of water added to the adiabatic saturation process at temperature T^*, Btu/lb

An *ideal adiabatic saturation process* is a hypothetical process in which moist air at initial temperature T_1, humidity ratio w_1, enthalpy h_1, and pressure p flows over a water surface of infinite length through a well-insulated channel. Liquid water is therefore evaporated into water vapor at the expense of the sensible heat of the moist air. The result is an increase of humidity ratio and a drop of temperature until the moist air is saturated at the thermodynamic wet bulb temperature T^* during the end of the ideal adiabatic saturation process.

The thermodynamic wet bulb temperature T^* is a unique fictitious property of moist air that depends only on its initial properties, T_1, w_1, or h_1.

A sling-type *psychrometer*, as shown in Figure 9.2.1, is an instrument that determines the temperature, relative humidity, and thus the state of the moist air by measuring its dry bulb and wet bulb temperatures. It consists of two mercury-in-glass thermometers. The sensing bulb of one of them is dry and is called the dry bulb. Another sensing bulb is wrapped with a piece of cotton wick, one end of which dips into a water tube. This wetted sensing bulb is called the wet bulb and the temperature measured by it is called the *wet bulb temperature* T'.

When unsaturated moist air flows over the surface of the wetted cotton wick, liquid water evaporates from its surface. As it absorbs sensible heat, mainly from the surrounding air, the wet bulb temperature drops. The difference between the dry and wet bulb temperatures is called *wet bulb depression* ($T - T'$). Turning the handle forces the surrounding air to flow over the dry and wet bulbs at an air velocity between 300 to 600 fpm. Distilled water must be used to wet the cotton wick.

At steady state, if heat conduction along the thermometer stems is neglected and the temperature of the wetted cotton wick is equal to the wet bulb temperature of the moist air, as the sensible heat transfer from the surrounding moist air to the cotton wick exactly equals the latent heat required for evaporation, the heat and mass transfer per unit area of the wet bulb surface can be evaluated as:

$$h_c\left(T - T'\right) + h_r\left(T_{ra} - T\right) = h_d\left(w_s' - w_1\right) \tag{9.2.14}$$

where

h_c, h_r = mean conductive and radiative heat transfer coefficient, Btu/hr ft²°F

h_d = mean convective mass transfer coefficient, lb/hr ft²

T = temperature of undisturbed moist air at a distance from the wet bulb, °F

T_{ra} = mean radiant temperature (covered later), °F

w_1, w_s' = humidity ratio of the moist air and the saturated film at the interface of cotton wick and surrounding air, lb/lb

h_{fg}' = latent heat of vaporization at the wet bulb temperature, Btu/lb

The humidity ratio of the moist air is given by:

$$w_1 = w_s' - K'\left(T - T'\right)\left(1 + \left\{h_r\left(T_{ra} - T'\right)/\left[h_c\left(T - T'\right)\right]\right\}\right)$$

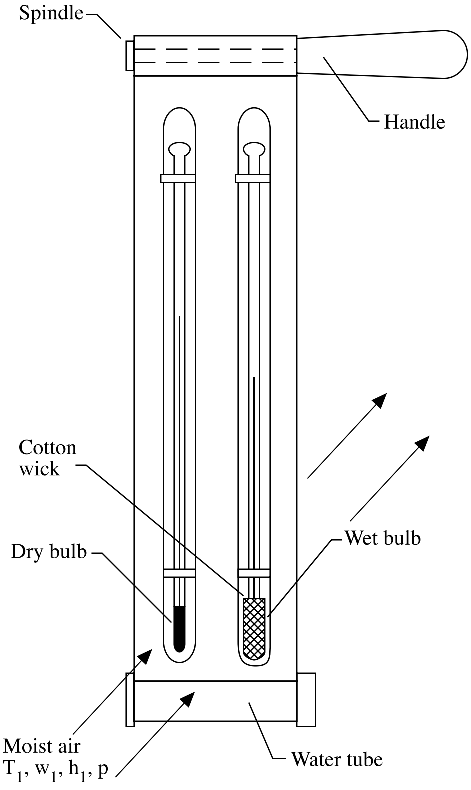

FIGURE 9.2.1 A sling psychrometer.

$$K' = c_{pa} Le^{0.6667} \big/ h'_{fg} \tag{9.2.15}$$

where

K' = wet bulb constant, which for a sling psychrometer = 0.00218 1/°F
Le = Lewis number

The wet bulb temperature T' depends not only on its initial state but also on the rate of heat and mass transfer at the wet bulb. Therefore, the thermodynamic wet bulb temperature is used in ASHRAE psychrometric charts.

Psychrometric Charts

A *psychrometric chart* is a graphical presentation of the thermodynamic properties of moist air and various air-conditioning processes and air-conditioning cycles. A psychrometric chart also helps in calculating and analyzing the work and energy transfer of various air-conditioning processes and cycles.

Psychrometric charts currently use two kinds of basic coordinates:

1. *h-w* charts. In *h-w* charts, enthalpy *h*, representing energy, and humidity ratio *w*, representing mass, are the basic coordinates. Psychrometric charts published by ASHRAE and the Charted Institution of Building Services Engineering (CIBSE) are *h-w* charts.
2. *T-w* charts. In *T-w* charts, temperature *T* and humidity ratio *w* are basic coordinates. Psychrometric charts published by Carrier Corporation, the Trane Company, etc. are *T-w* charts.

Figure 9.2.2 shows an abridged ASHRAE psychrometric chart. In the ASHRAE chart:

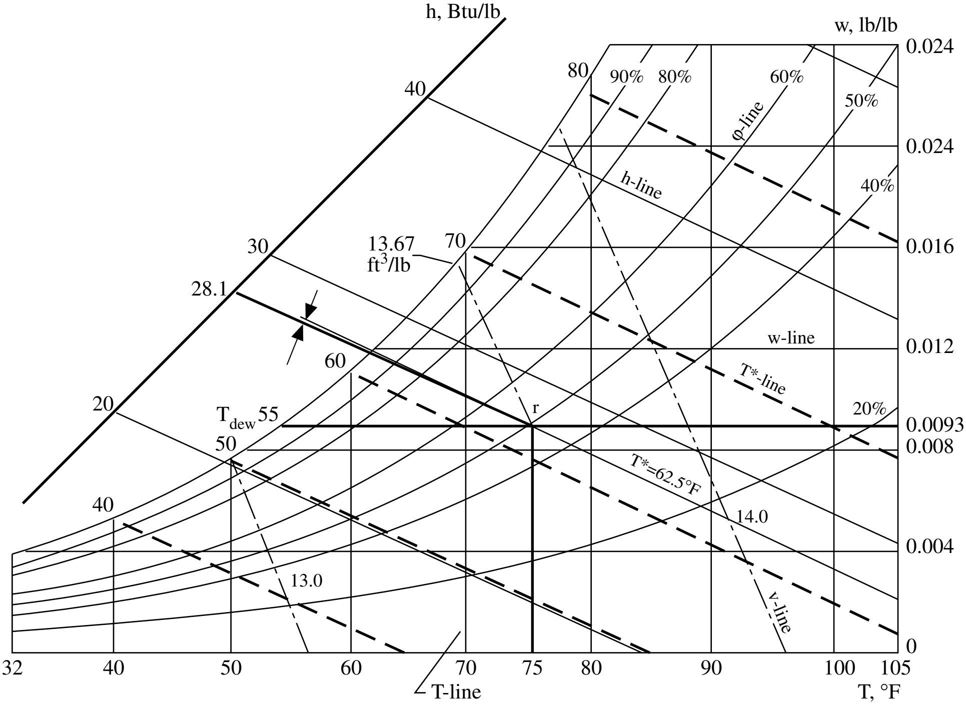

FIGURE 9.2.2 The abridged ASHRAE psychrometric chart and the determination of properties as in Example 9.2.1.

- A normal temperature chart has a temperature range of 32 to 120°F, a high-temperature chart 60 to 250°F, and a low-temperature chart –40 to 50°F. Since enthalpy is the basic coordinate, temperature lines are not parallel to each other. Only the 120°F line is truly vertical.
- Thermodynamic properties of moist air are affected by atmospheric pressure. The standard atmospheric pressure is 29.92 in. Hg at sea level. ASHRAE also published charts for high altitudes of 5000 ft, 24.89 in. Hg, and 7500 ft, 22.65 in. Hg. Both of them are in the normal temperature range.
- Enthalpy h-lines incline downward to the right-hand side (negative slope) at an angle of 23.5° to the horizontal line and have a range of 12 to 54 Btu/lb.
- Humidity ratio w-lines are horizontal lines. They range from 0 to 0.28 lb/lb.
- Relative humidity φ-lines are curves of relative humidity 10%, 20%, … 90% and a saturation curve. A saturation curve is a curve of the locus of state points of saturated moist air, that is, $\varphi = 100\%$. On a saturation curve, temperature T, thermodynamic wet temperature bulb T^*, and dew point temperature T_{dew} have the same value.
- Thermodynamic wet bulb T^*-lines have a negative slope slightly greater than that of the h-lines. A T^*-line meets the T-line of the same magnitude on the saturation curve.
- Moist volume v-lines have a far greater negative slope than h-lines and T^*-lines. The moist volume ranges from 12.5 to 15 ft³/lb.

Moist air has seven independent thermodynamic properties or property groups: h, T, φ, T^*, p_{at}, $\rho - v$, and $w - p_{\text{w}} - T_{\text{dew}}$. When p_{at} is given, any additional two of the independent properties determine the state of moist air on the psychrometric chart and the remaining properties.

Software using AutoCAD to construct the psychrometric chart and calculate the thermodynamic properties of moist air is available. It can also be linked to the load calculation and energy programs to analyze the characteristics of air-conditioning cycles.

Refer to Wang's *Handbook of Air Conditioning and Refrigeration* (1993) and *ASHRAE Handbook, Fundamentals* (2001) for details of psychrometric charts and psychrometric tables that list thermodynamic properties of moist air.

Example 9.2.1

An air-conditioned room at sea level has an indoor design temperature of 75°F and a relative humidity of 50%. Determine the humidity ratio, enthalpy, density, dew point, and thermodynamic wet bulb temperature of the indoor air at design condition.

Solution

1. Since the air-conditioned room is at sea level, a psychrometric chart of standard atmospheric pressure of 14.697 psi should be used to find the required properties.
2. Plot the state point of the room air at design condition r on the psychrometric chart. First, find the room temperature 75°F on the horizontal temperature scale. Draw a line parallel to the 75°F temperature line. This line meets the relative humidity curve of 50% at point r, which denotes the state point of room air as shown in Figure 9.2.2.
3. Draw a horizontal line toward the humidity ratio scale from point r. This line meets the ordinate and thus determines the room air humidity ratio $\varphi_r = 0.0093$ lb/lb.
4. Draw a line from point r parallel to the enthalpy line. This line determines the enthalpy of room air on the enthalpy scale, $h_r = 28.1$ Btu/lb.
5. Draw a line through point r parallel to the moist volume line. The perpendicular scale of this line indicates $v_r = 13.67$ ft^3/lb.
6. Draw a horizontal line to the left from point r. This line meets the saturation curve and determines the dew point temperature, $T_{dew} = 55$°F.
7. Draw a line through point r parallel to the thermodynamic wet bulb line. The perpendicular scale to this line indicates that the thermodynamic wet bulb temperature $T^* = 62.5$°F.

9.3 Air-Conditioning Processes and Cycles

Shan K. Wang

Air-Conditioning Processes

An *air-conditioning process* describes the change in thermodynamic properties of moist air between the initial and final stages of conditioning as well as the corresponding energy and mass transfers between the moist air and a medium, such as water, refrigerant, absorbent or adsorbent, or moist air itself. The energy balance and conservation of mass are the two principles used for the analysis and the calculation of the thermodynamic properties of the moist air.

Generally, for a single air-conditioning process, heat transfer or mass transfer is positive. However, for calculations that involve several air-conditioning processes, heat supplied to the moist air is taken as positive and heat rejected is negative.

The *sensible heat ratio* (SHR) of an air-conditioning process is defined as the ratio of the change in absolute value of sensible heat to the change in absolute value of total heat, both in Btu/hr:

$$\mathrm{SHR} = \left|q_{\mathrm{sen}}\right| / \left|q_{\mathrm{total}}\right| = \left|q_{\mathrm{sen}}\right| / \left(\left|q_{\mathrm{sen}}\right| + \left|q_{1}\right|\right) \tag{9.3.1}$$

For any air-conditioning process, the sensible heat change

$$q_{\mathrm{sen}} = 60 \mathring{V}_{\mathrm{s}} \rho_{\mathrm{s}} c_{\mathrm{pa}} \left(T_2 - T_1\right) = 60 \mathring{m}_{\mathrm{a}} c_{\mathrm{pa}} \left(T_2 - T_1\right) \tag{9.3.2}$$

where

$\overset{\circ}{V}_s$ = volume flow rate of supply air, cfm

ρ_s = density of supply air, lb/ft³

T_2, T_1 = moist air temperature at final and initial states of an air-conditioning process, °F

and the mass flow rate of supply air

$$\overset{\circ}{m}_s = \overset{\circ}{V}_s \rho_s \tag{9.3.3}$$

The latent heat change is

$$q_l \approx 60\overset{\circ}{V}_s \rho_s \left(w_2 - w_1\right) h_{\text{fg.58}} = 1060 \times 60\overset{\circ}{V}_s \rho_s \left(w_2 - w_1\right) \tag{9.3.4}$$

where w_2,w_1 = humidity ratio at final and initial states of an air-conditioning process, lb/lb.

In Equation (9.3.4), $h_{\text{fg58}} \approx 1060$ Btu/lb represents the latent heat of vaporization or condensation of water at an estimated temperature of 58°F, where vaporization or condensation occurs in an air-handling unit or packaged unit. Therefore

$$\text{SHR} = \overset{\circ}{m}_a c_{pa}\left(T_2 - T_1\right) \Big/ \left[\overset{\circ}{m}_a c_{pa}\left(T_2 - T_1\right) + \overset{\circ}{m}_a \left(w_2 - w_1\right) h_{\text{fg.58}}\right] \tag{9.3.5}$$

Space Conditioning, Sensible Cooling, and Sensible Heating Processes

In a *space conditioning process*, heat and moisture are absorbed by the supply air at state *s* and then removed from the conditioned space at the state of space air *r* during summer, as shown by line *sr* in Figure 9.3.1, or heat or moisture is supplied to the space to compensate for the transmission and infiltration losses through the building envelope as shown by line *s′r′*. Both processes are aimed at maintaining a desirable space temperature and relative humidity.

The space cooling load q_{rc}, in Btu/hr, can be calculated as:

$$q_{rc} = 60\overset{\circ}{m}_a\left(h_r - h_s\right) = 60\overset{\circ}{V}_s \rho_s \left(h_r - h_s\right) \tag{9.3.6}$$

where h_r, h_s = enthalpy of space air and supply air, Btu/lb.

The space sensible cooling load q_{rs}, in Btu/hr, can be calculated from Equation (9.3.2) and the space latent load q_{rl}, in Btu/hr, from Equation (9.3.1). In Equation (9.3.4), T_2 should be replaced by T_r and T_1 by T_s. Also in Equation (9.3.1), w_2 should be replaced by w_r and w_1 by w_s. The space heating load q_{rh} is always a sensible load, in Btu/hr, and can be calculated as:

$$q_{rh} = 60\overset{\circ}{m}_a c_{pa}\left(T_s - T_r\right) = 60\overset{\circ}{V}_s \rho_s c_{pa}\left(T_s - T_r\right) \tag{9.3.7}$$

where T_s, T_r = temperature of supply and space air, °F.

A *sensible heating process* adds heat to the moist air in order to increase its temperature; its humidity ratio remains constant, as shown by line 1-2 in Figure 9.3.1. A sensible heating process occurs when moist air flows over a heating coil. Heat is transferred from the hot water inside the tubes to the moist air. The rate of heat transfer from the hot medium to the colder moist air is often called the heating coil load q_{rh}, in Btu/hr, and is calculated from Equation (9.3.2).

A *sensible cooling process* removes heat from the moist air, resulting in a drop of its temperature; its humidity ratio remains constant, as shown by line 1′-2′ in Figure 9.3.1. The sensible cooling process

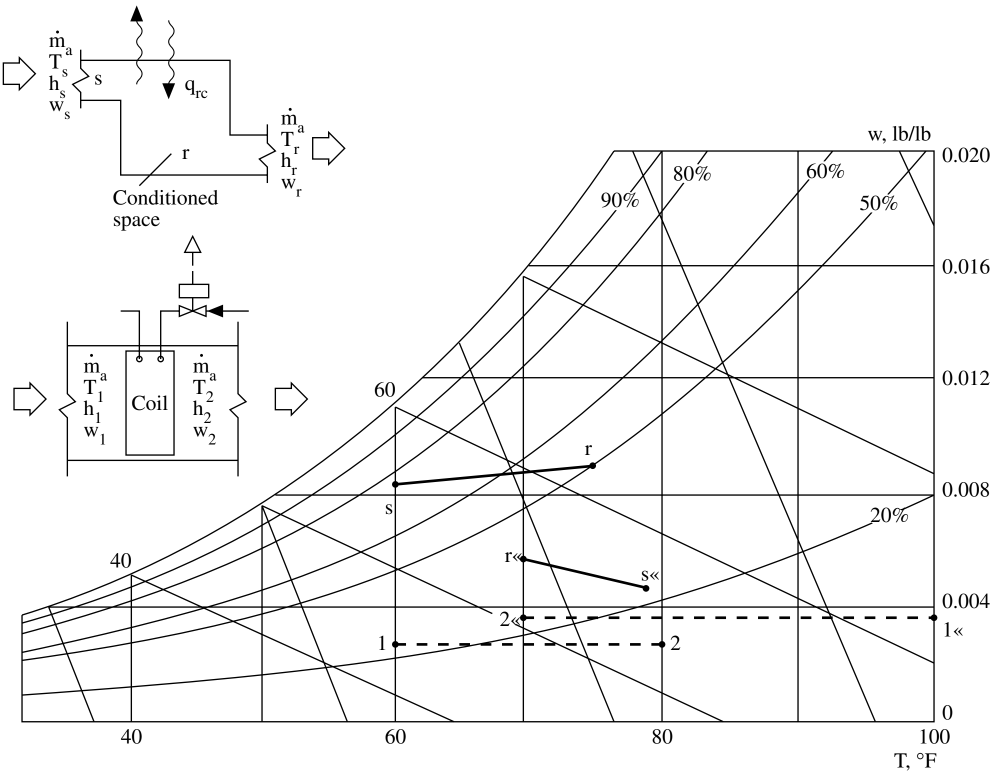

FIGURE 9.3.1 Supply conditioning, sensible heating, and sensible cooling processes.

occurs when moist air flows through a cooling coil containing chilled water at a temperature equal to or greater than the dew point of the entering moist air. The sensible cooling load can also be calculated from Equation (9.3.2). T_2 is replaced by T_1 and T_1 by $T_{2'}$.

Humidifying and Cooling and Dehumidifying Processes

In a *humidifying process*, water vapor is added to moist air and increases the humidity ratio of the moist air leaving the humidifier if the moist air entering is not already saturated. Large-scale humidification of moist air is usually performed by steam injection, evaporation from a water spray, atomizing water, a wetted medium, or by passing a side stream of air over water with submerged heating elements. Dry steam in a steam injection humidifying process is often supplied from the main steam line to a grid-type humidifier and injected into the moist air directly through small holes at a pressure slightly above atmospheric, as shown by line 1-2 in Figure 9.3.2(a) and (b). The humidifying capacity $\mathring{m}_{hu}$, in lb/min, is given by:

$$\mathring{m}_{hu} = \mathring{V}_s \rho_s \left(w_{hl} - w_{he} \right) \tag{9.3.8}$$

where w_{hl}, w_{he} = humidity ratio of moist air leaving and entering the humidifier, lb/lb. The slight inclination at the top of line 1-2 is due to the high temperature of the steam. The increase in temperature of the moist air due to steam injection can be calculated as:

$$\left(T_2 - T_1 \right) = w_{sm} c_{ps} T_s \Big/ \left(c_{pd} + w_{12} c_{ps} \right) \tag{9.3.9}$$

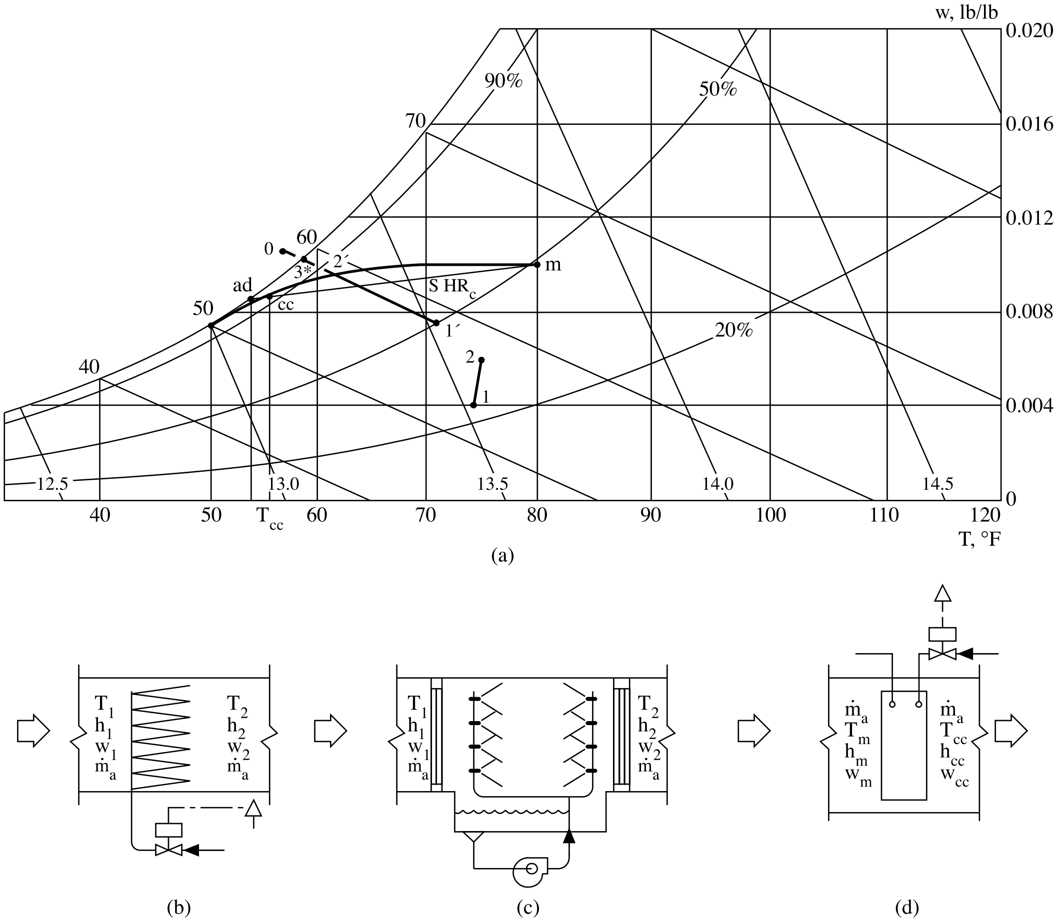

FIGURE 9.3.2 Humidifying and cooling and dehumidifying processes: (a) process on psychrometric chart, (b) steam humidifier, (c) air washer, and (d) chilled water cooling or DX coil.

where

T_2, T_1 = temperature of moist air at initial and final states, °F
w_{sm} = ratio of mass flow rate of injected steam to moist air, $\overset{\circ}{m}_s / \overset{\circ}{m}_a$
T_s = temperature of injected steam, °F
w_{12} = average humidity ratio of moist air, lb/lb

An *air washer* is a device that sprays water into moist air in order to humidify, to cool and dehumidify, and to clean the air, as shown in Figure 9.3.2(c). When moist air flows through an air washer, the moist air is humidified and approaches saturation. This actual adiabatic saturation process approximately follows the thermodynamic wet bulb line on the psychrometric chart as shown by line 1′-2′. The humidity ratio of the moist air is increased while its temperature is reduced. The cooling effect of this adiabatic saturation process is called *evaporative cooling*.

Oversaturation occurs when the amount of water present in the moist air w_{os}, in lb/lb, exceeds the saturated humidity ratio at thermodynamic wet bulb temperature w_s^*, as shown in Figure 9.3.2(a). When moist air leaves the air washer, atomizing humidifier, or centrifugal humidifier after humidification, it often contains unevaporated water droplets at state point 2′, w_w, in lb/lb. Because of the fan power heat gain, duct heat gain, and other heat gains providing the latent heat of vaporization, some evaporation takes place due to the heat transfer to the water drops, and the humidity ratio increases further. Such evaporation of oversaturated drops is often a process with an increase of both humidity ratio and enthalpy of moist air. Oversaturation can be expressed as:

$$w_{os} = w_o - w_s^* = \left(w_{2'} + w_w\right) - w_s^* \tag{9.3.10}$$

where

$w_{2'}$ = humidity ratio at state point 2′, lb/lb
w_o = sum of $w_{2'}$ and w_w, lb/lb

The magnitude of w_w depends mainly on the construction of the humidifier and water eliminator, if any. For an air washer, w_w may vary from 0.0002 to 0.001 lb/lb. For a pulverizing fan without an eliminator, w_w may be up to 0.00135 lb/lb.

Cooling and Dehumidifying Process

In a cooling and dehumidifying process, both the humidity ratio and temperature of moist air decrease. Some water vapor is condensed in the form of liquid water, called *condensate*. This process is shown by curve m-cc on the psychrometric chart in Figure 9.3.2(a). Here m represents the entering mixture of outdoor and recirculating air and cc the conditioned air leaving the cooling coil.

Three types of heat exchangers are used in a cooling and dehumidifying process: (1) chilled water cooling coil as shown in Figure 9.3.2(d); (2) direct expansion DX coil, where refrigerant evaporates directly inside the coil's tubes; and (3) air washer, in which chilled water spraying contacts condition air directly.

The temperature of chilled water entering the cooling coil or air washer T_{we}, in °F, determines whether it is a sensible cooling or a cooling and dehumidifying process. If T_{we} is smaller than the dew point of the entering air T''_{ae} in the air washer, or T_{we} makes the outer surface of the water cooling coil $T_{s.t} < T''_{ae}$, it is a cooling and dehumidifying process. If $T_{we} \geq T''_{ae}$, or $T_{s.t} \geq T''_{ae}$, sensible cooling occurs. The cooling coil's load or the cooling capacity of the air washer q_{cc}, in Btu/hr, is

$$q_{cc} = 60\overset{\circ}{V}_s \rho_s \left(h_{ae} - h_{cc}\right) - 60\overset{\circ}{m}_w h_w \tag{9.3.11a}$$

where

h_{ae}, h_{cc} = enthalpy of moist air entering and leaving the coil or washer, Btu/lb
$\overset{\circ}{m}_w$ = mass flow rate of the condensate, lb/min
h_w = enthalpy of the condensate, Btu/lb

Since the thermal energy of the condensate is small compared with q_{cc}, in practical calculations the term $60\overset{\circ}{m}_w h_w$ is often neglected, and

$$q_{cc} = 60\overset{\circ}{V}_s \rho_s \left(h_{ae} - h_{cc}\right) \tag{9.3.11b}$$

The sensible heat ratio of the cooling and dehumidifying process SHR_c can be calculated from

$$SHR_c = q_{cs}/q_{cc} \tag{9.3.12}$$

where q_{cs} = sensible heat removed during the cooling and dehumidifying process, Btu/hr. SHR_c is shown by the slope of the straight line joining points m and cc.

The relative humidity of moist air leaving the water cooling coil or DX coil depends mainly on the outer surface area of the coil including pipe and fins. For coils with ten or more fins per inch, if the entering moist air is around 80°F dry bulb and 68°F wet bulb, the relative humidity of air leaving the coil (off-coil) may be estimated as:

Four-row coil	90 to 95%
Six-row and eight-row coils	96 to 98%

Two-Stream Mixing Process and Bypass Mixing Process

For a *two-stream adiabatic mixing process*, two moist air streams, 1 and 2, are mixed together adiabatically and a mixture *m* is formed in a mixing chamber as shown by line 1-m1-2 in Figure 9.3.3. Since the AHU or PU is well insulated, the heat transfer between the mixing chamber and ambient air is small and is usually neglected. Based on the principle of heat balance and conservation of mass:

$$\begin{aligned} \mathring{m}_1 h_1 + \mathring{m}_2 h_2 &= \mathring{m}_m h_m \\ \mathring{m}_1 w_1 + \mathring{m}_2 w_2 &= \mathring{m}_m w_m \\ \mathring{m}_1 T_1 + \mathring{m}_2 T_2 &= \mathring{m}_m T_m \end{aligned} \tag{9.3.13}$$

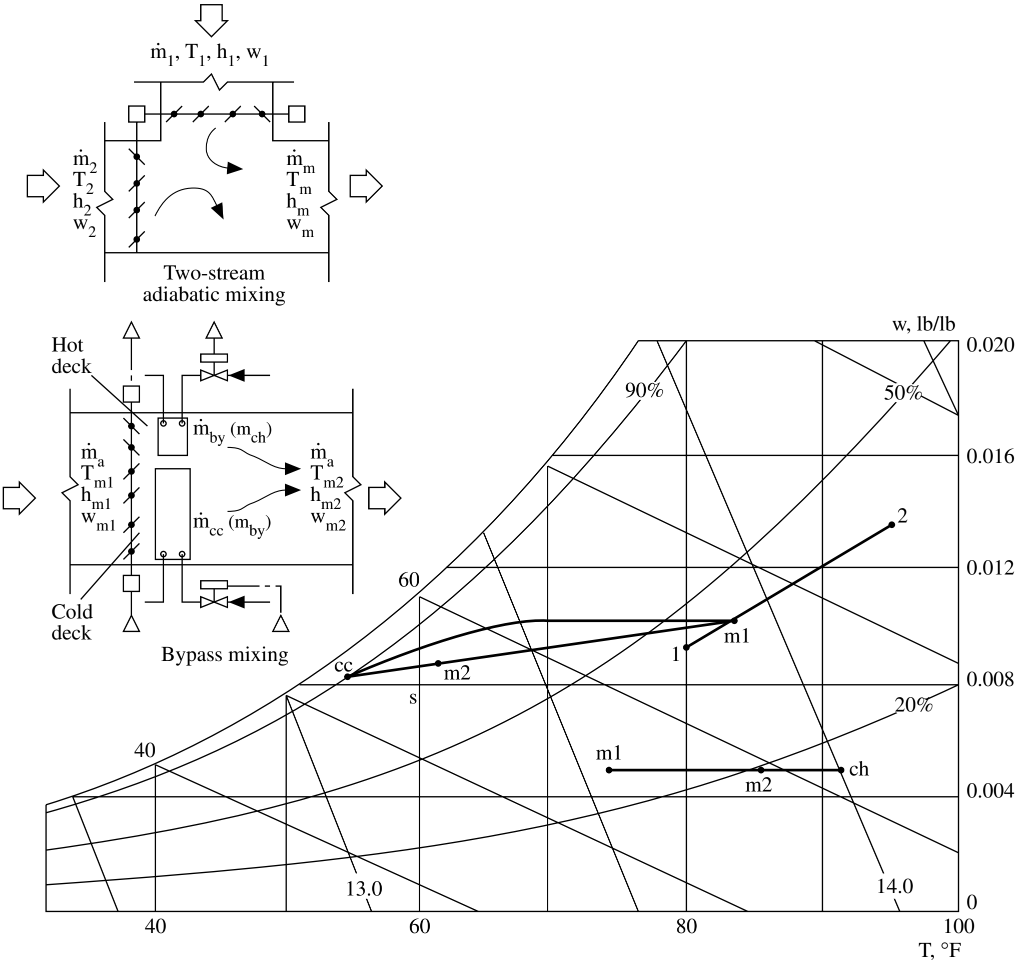

FIGURE 9.3.3 Mixing processes.

In Equation (9.3.13), $\mathring{m}$ represents the mass flow rate of air, lb/min; h the enthalpy, in Btu/lb; w the humidity ratio, in lb/lb; and T the temperature, in °F. Subscripts 1 and 2 indicate air streams 1 and 2 and m the mixture; also,

$$\begin{aligned} \mathring{m}_1/\mathring{m}_{\mathrm{m}} &= \left(h_2 - h_{\mathrm{m}}\right)/\left(h_2 - h_1\right) = \left(w_2 - w_{\mathrm{m}}\right)/\left(w_2 - w_1\right) \\ &= \left(\text{line segment m1 2}\right)/\left(\text{line segment 12}\right) \end{aligned} \tag{9.3.14}$$

Similarly,

$$\begin{aligned} \mathring{m}_2/\mathring{m}_{\mathrm{m}} &= \left(h_{\mathrm{m}} - h_1\right)/\left(h_2 - h_1\right) = \left(w_{\mathrm{m}} - w_1\right)/\left(w_2 - w_1\right) \\ &= \left(\text{line segment 1-ml}\right)/\left(\text{line segment 1-2}\right) \end{aligned} \tag{9.3.15}$$

Mixing point m must lie on the line that joins points 1 and 2 as shown in Figure 9.3.3.

If the differences between the density of air streams 1 and 2 and the density of the mixture are neglected,

$$\begin{aligned} \mathring{V}_1 h_1 + \mathring{V}_2 h_2 &= \mathring{V}_{\mathrm{m}} h_{\mathrm{m}} \\ \mathring{V}_1 w_1 + \mathring{V}_2 w_2 &= \mathring{V}_{\mathrm{m}} w_{\mathrm{m}} \\ \mathring{V}_1 T_1 + \mathring{V}_2 T_2 &= \mathring{V}_{\mathrm{m}} T_{\mathrm{m}} \end{aligned} \tag{9.3.16}$$

$$\mathring{V}_1 + \mathring{V}_2 = \mathring{V}_{\mathrm{m}} \tag{9.3.17}$$

In a *bypass mixing process*, a conditioned air stream is mixed with a bypass air stream that is not conditioned. The cold conditioned air is denoted by subscript "cc", the heated air "ch", and the bypass air "by".

Equation (9.3.14) and Equation (9.3.17) can still be used but subscript 1 should be replaced by cc or ch and subscript 2 by "by" (bypass).

Let $K_{\mathrm{cc}} = \mathring{m}_{\mathrm{cc}}/\mathring{m}_{\mathrm{m}}$ and $K_{\mathrm{ch}} = \mathring{m}_{\mathrm{ch}}/\mathring{m}_{\mathrm{m}}$; then the cooling coil's load q_{cc} and heating coil's load q_{ch}, both in Btu/hr, for a bypass mixing process are

$$\begin{aligned} q_{\mathrm{cc}} &= K_{\mathrm{cc}} \mathring{V}_{\mathrm{s}} \rho_{\mathrm{s}} \left(h_{\mathrm{m}} - h_{\mathrm{cc}}\right) \\ q_{\mathrm{ch}} &= K_{\mathrm{ch}} \mathring{V}_{\mathrm{s}} \rho_{\mathrm{s}} \left(h_2 - h_1\right) \end{aligned} \tag{9.3.18}$$

In Equation (9.3.18), subscript s denotes the supply air and m the mixture air stream.

Air-Conditioning Cycle and Operating Modes

An *air-conditioning cycle* comprises several air-conditioning processes that are connected in a sequential order. An air-conditioning cycle determines the operating performance of the air system in an air-conditioning system. The *working substance* to condition air may be chilled or hot water, refrigerant, desiccant, etc.

Each type of air system has its own air-conditioning cycle. Psychrometric analysis of an air-conditioning cycle is an important tool in determining its operating characteristics and the state of moist air at various system components, including the volume flow rate of supply air, the coil's load, and the humidifying and dehumidifying capacity.

According to the cycle performance, air-conditioning cycles can be grouped into two categories:

- *Open cycle*, in which the moist air at its end state does not resume its original state. An air-conditioning cycle with all outdoor air is an open cycle.
- *Closed cycle*, in which moist air resumes its original state at its end state. An air-conditioning cycle that conditions the mixture of recirculating and outdoor air, supplies it, recirculates part of the return air, and mixes it again with outdoor air is a closed cycle.

Based on the outdoor weather and indoor operating conditions, the operating modes of air-conditioning cycles can be classified as:

- *Summer mode*: when outdoor and indoor operating parameters are in summer conditions.
- *Winter mode*: when outdoor and indoor operating parameters are in winter conditions.
- *Air economizer mode*: when all outdoor air or an amount of outdoor air that exceeds the minimum amount of outdoor air required for the occupants is taken into the AHU or PU for cooling. The air economizer mode saves energy use for refrigeration.

Continuous modes operate 24 hr a day and 7 days a week. Examples are systems that serve hospital wards and refrigerated warehouses. An *intermittently operated mode* usually shuts down once or several times within a 24-hr operating cycle. Such systems serve offices, class rooms, retail stores, etc. The 24-hr day-and-night cycle of an intermittently operated system can again be divided into:

1. *Cool-down or warm-up period.* When the space is not occupied and the space air temperature is higher or lower than the predetermined value, the space air should be cooled down or warmed up before the space is occupied.
2. *Conditioning period.* The air-conditioning system is operated during the occupied period to maintain the required indoor environment.
3. *Nighttime shut-down period.* The air system or terminal is shut down or only partly operating to maintain a set-back temperature.

Summer, winter, air economizer, and continuously operating modes consist of *full-load* (design load) and part-load operations. *Part load* occurs when the system load is less than the design load. The capacity of the equipment is selected to meet summer and winter system design loads as well as system loads in all operating modes.

Basic Air-Conditioning Cycle — Summer Mode

A *basic air-conditioning system* is a packaged system of supply air at a constant volume flow rate, serving a single zone, equipped with only a single supply/return duct. A *single zone* is a conditioned space for which a single controller is used to maintain a unique indoor operating parameter, probably indoor temperature. A *basic air-conditioning cycle* is the operating cycle of a basic air-conditioning system. Figure 9.1.3 shows a basic air-conditioning system. Figure 9.3.4 shows the basic air-conditioning cycle of this system. In summer mode at design load, recirculating air from the conditioned space, a worship hall, enters the packaged unit through the return grill at point ru. It is mixed with the required minimum amount of outdoor air at point o for acceptable indoor air quality and energy saving. The mixture *m* is then cooled and dehumidified to point cc by the DX coil, and the conditioned air is supplied to the hall through the supply fan, supply duct, and ceiling diffuser. Supply air then absorbs the sensible and latent load from the space, becoming the space air r. Recirculating air enters the packaged unit again and forms a closed cycle. *Return air* is the air returned from the space. Part of the return air is exhausted to balance the outdoor air intake and infiltration. The remaining part is the *recirculating air* that enters the PU or AHU.

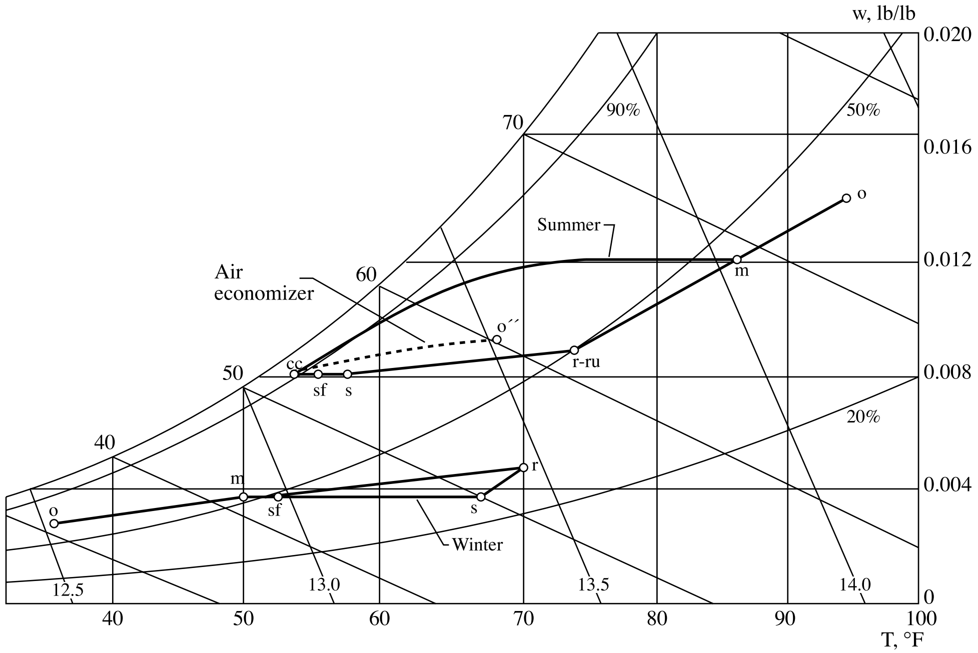

FIGURE 9.3.4 Basic air-conditioning cycle — summer, winter, and air economizer mode.

The summer mode operating cycle consists of the following processes:

1. Sensible heating process, represented by line r-ru, due to the return system gain $q_{r.s}$, in Btu/hr, when recirculating air flows through the return duct, ceiling plenum, and return fan, if any. In this packaged system, the return system heat gain is small and neglected.
2. Adiabatic mixing process of recirculating air at point ru and outdoor air at point o in the mixing box, represented by line ru-m-o.
3. Cooling and dehumidifying process m cc at the DX coil whose coil load determines the cooling capacity of the system calculated from Equation (9.3.11).
4. Sensible heating process related to the supply system heat gain $q_{s.s}$, in Btu/hr, represented by line cc sf s. $q_{s.s}$ consists of the fan power heat gain q_{sf}, line cc sf, and duct heat gain q_{sd}, line sf s, that is:

$$q_{s.s} = q_{sf} + q_{sd} = \mathring{V}_s \rho_s c_{pa} \Delta T_{s.s} \tag{9.3.19}$$

   It is more convenient to use the temperature rise of the supply system $\Delta T_{s.s}$ in psychrometric analysis.
5. Supply conditioning process line s-r.

Design Supply Volume Flow Rate

Design supply volume flow rate and cooling and heating capacities are primary characteristics of an air-conditioning system. Design supply volume flow rate is used to determine the size of fans, grills, outlets, air-handling units, and packaged units. For most comfort systems and many processing air-conditioning systems, *design supply volume flow rate* $\mathring{V}_{s.d}$, in cfm, is calculated on the basis of the capacity to remove the space cooling load at summer design conditions to maintain a required space temperature T_r:

$$\mathring{V}_{s.d} = q_{rc.d} \Big/ \left[60\rho_s \left(h_r - h_s\right)\right] = q_{rs.d} \Big/ \left[60\rho_s c_{pa} \left(T_r - T_s\right)\right] \tag{9.3.20}$$

where $q_{\mathrm{rc.d}}$, $q_{\mathrm{rs.d}}$ = design space cooling load and design sensible cooling load, Btu/hr. In Equation (9.3.20), the greater the $q_{\mathrm{rs.d}}$, the higher $\mathring{V}_{\mathrm{s}}$ will be. Specific heat c_{pa} is usually considered constant. Air density ρ_{s} may vary with the various types of air systems used. A greater ρ_{s} means a smaller $\mathring{V}_{\mathrm{s.d}}$ for a given supply mass flow rate. For a given $q_{\mathrm{rs.d}}$, the supply temperature differential $\Delta T_{\mathrm{s}} = (T_{\mathrm{r}} - T_{\mathrm{s}})$ is an important parameter that affects $\mathring{V}_{\mathrm{s.d}}$. Conventionally, a 15 to 20°F ΔT_{s} is used for comfort air-conditioning systems. Recently, a 28 to 34°F ΔT_{s} has been adopted for cold air distribution in ice-storage central systems. When ΔT_{s} has a nearly twofold increase, there is a considerable reduction in $\mathring{V}_{\mathrm{s}}$ and fan energy use and saving in investment on ducts, terminals, and outlets.

The summer cooling load is often greater than the winter heating load, and this is why q_{rc} or $q_{\mathrm{rs.d}}$ is used to determine $\mathring{V}_{\mathrm{s.d}}$, except in locations where the outdoor climate is very cold.

Sometimes the supply volume flow rate may be determined from the following requirements:

- To dilute the concentration of air contaminants in the conditioned space C_{i}, in mg/m^3, the design supply volume flow rate is

$$\mathring{V}_{\mathrm{s.d}} = 2118\mathring{m}_{\mathrm{par}} \big/ \left(C_1 - C_{\mathrm{s}}\right) \tag{9.3.21}$$

  where
  C_{s} = concentration of air contaminants in supply air, mg/m^3
  $\mathring{m}_{\mathrm{par}}$ = rate of contaminant generation in the space, mg/sec

- To maintain a required space relative humidity φ_{r} and a humidity ratio w_{r} at a specific temperature, the design supply volume flow rate is

$$\mathring{V}_{\mathrm{s.d}} = q_{\mathrm{rl.d}} \Big/ \left[60\rho_{\mathrm{s}}\left(w_{\mathrm{r}} - w_{\mathrm{s}}\right)h_{\mathrm{fg.58}}\right] \tag{9.3.22}$$

  where $q_{\mathrm{rl.d}}$ = design space latent load, Btu/hr.

- To provide a required air velocity v_{r}, in fpm, within the working area of a clean room, the supply volume flow rate is given by

$$\mathring{V}_{\mathrm{s.d}} = A_{\mathrm{r}}v_{\mathrm{r}} \tag{9.3.23a}$$

  where A_{r} = cross-sectional area perpendicular to the air flow in the working area, ft^2.

- To exceed the outdoor air requirement for acceptable air quality for occupants, the supply volume flow rate must be equal to or greater than

$$\mathring{V}_{\mathrm{s}} \ge n\mathring{V}_{\mathrm{oc}} \tag{9.3.23b}$$

  where
  n = number of occupants
  $\mathring{V}_{\mathrm{oc}}$ = outdoor air requirement per person, cfm/person

- To exceed the sum of the volume flow rate of exhaust air $\mathring{V}_{\mathrm{ex}}$ and the exfiltrated or relief air $\mathring{V}_{\mathrm{ef}}$, both in cfm,

$$\mathring{V}_{\mathrm{s}} \ge \mathring{V}_{\mathrm{ex}} + \mathring{V}_{\mathrm{ef}} \tag{9.3.24}$$

The design supply volume flow rate should be the largest of any of the foregoing requirements.

Rated Supply Volume Flow Rate

For an air system at atmospheric pressure, since the required mass flow rate of the supply air is a function of air density and remains constant along the air flow,

$$\begin{aligned}\mathring{m}_{\mathrm{a}} &= \mathring{V}_{\mathrm{cc}}\,\rho_{\mathrm{cc}} = \mathring{V}_{\mathrm{s}}\,\rho_{\mathrm{s}} = \mathring{V}_{\mathrm{sf}}\,\rho_{\mathrm{sf}} \\ \mathring{V}_{\mathrm{sf}} &= \mathring{V}_{\mathrm{s}}\,\rho_{\mathrm{s}}\big/\rho_{\mathrm{sf}}\end{aligned} \tag{9.3.25}$$

where

$\mathring{V}_{\mathrm{sf}}$ = volume flow rate at supply fan outlet, cfm
ρ_{sf} = air density at supply fan outlet, lb/ft^3

A supply fan is rated at *standard air conditions*, that is, dry air at a temperature of 70°F, an atmospheric pressure of 29.92 in. Hg (14.697 psia), and an air density of 0.075 lb/ft^3. However, a fan is a constant-volume machine at a given fan size and speed; that is, $\mathring{V}_{\mathrm{s.f}} = \mathring{V}_{\mathrm{sf.r}}$. Here $\mathring{V}_{\mathrm{sf.r}}$ represents the rated volume flow rate of a fan at standard air conditions. Therefore,

$$\mathring{V}_{\mathrm{sf.r}} = \mathring{V}_{\mathrm{sf}} = q_{\mathrm{rs.d}}\Big/\Big[60\rho_{\mathrm{sf}}c_{\mathrm{pa}}\big(T_{\mathrm{r}} - T_{\mathrm{s}}\big)\Big] \tag{9.3.26}$$

- For conditioned air leaving the cooling coil at T_{cc} = 55°F with a relative humidity of 92% and T_{sf} of 57°F, $\rho_{\mathrm{sf.r}} = 1/v_{\mathrm{sf}} = 1/13.20 = 0.0758$ lb/ft^3. From Equation (9.3.26):

$$\mathring{V}_{\mathrm{sf.r}} = q_{\mathrm{rs.d}}\Big/\Big[60\times 0.0758\times 0.243\big(T_{\mathrm{r}} - T_{\mathrm{s}}\big)\Big] = q_{\mathrm{rs.d}}\Big/\Big[1.1\big(T_{\mathrm{r}} - T_{\mathrm{s}}\big)\Big] \tag{9.3.26a}$$

  Equation (9.3.26a) is widely used in calculating the supply volume flow rate of comfort air-conditioning systems.
- For cold air distribution, T_{cc} = 40°F and φ_{cc} = 98%, if T_{sf} = 42°F, then v_{sf} = 12.80 ft^3/lb, and the rated supply volume flow rate:

$$\mathring{V}_{\mathrm{sf.r}} = 12.80q_{\mathrm{rs.d}}\Big/\Big[60\times 0.243\big(T_{\mathrm{r}} - T_{\mathrm{s}}\big)\Big] = q_{\mathrm{rs.d}}\Big/\Big[1.14\big(T_{\mathrm{r}} - T_{\mathrm{s}}\big)\Big] \tag{9.3.26b}$$

- For a blow-through fan in which the fan is located upstream of the coil, if T_{sf} = 82°F and φ_{sf} = 43%, then v_{sf} = 13.87 ft^3/lb, and the rated supply volume flow rate:

$$\mathring{V}_{\mathrm{sf.r}} = 13.87q_{\mathrm{rs.d}}\Big/\Big[60\times 0.243\big(T_{\mathrm{r}} - T_{\mathrm{s}}\big)\Big] = q_{\mathrm{rs.d}}\Big/\Big[1.05\big(T_{\mathrm{r}} - T_{\mathrm{s}}\big)\Big] \tag{9.3.26c}$$

Effect of the Altitude

The higher the altitude, the lower the atmospheric pressure and the air density. In order to provide the required mass flow rate of supply air, a greater $\mathring{V}_{\mathrm{sf.r}}$ is needed. For an air temperature of 70°F:

$$\mathring{V}_{\mathrm{x.ft}} = \mathring{V}_{\mathrm{sf.r}}\big(p_{\mathrm{sea}}/p_{\mathrm{x.ft}}\big) = \mathring{V}_{\mathrm{sf.r}}\big(\rho_{\mathrm{sea}}/\rho_{\mathrm{x.ft}}\big) \tag{9.3.27}$$

where

$\mathring{V}_{\mathrm{x.ft}}$ = supply volume flow rate at an altitude of *x* ft, cfm
p_{sea}, $p_{\mathrm{x.ft}}$ = atmospheric pressure at sea level and an altitude of *x* ft, psia
ρ_{sea}, $\rho_{\mathrm{x.ft}}$ = air density at sea level and an altitude of *x* ft, psia

Following are the pressure or air density ratios at various altitudes. At 2000 ft above sea level, the rated supply volume flow rate $\mathring{V}_{\mathrm{r.2000}} = \mathring{V}_{\mathrm{sf.r}}\ (p_{\mathrm{sea}}/p_{\mathrm{x.ft}}) = 1.076\ \mathring{V}_{\mathrm{sf.r}}$ cfm instead of $\mathring{V}_{\mathrm{sf.r}}$ cfm at sea level.

Altitude, ft	p_{at}, psia	ρ, lb/ft^3	$(p_{\mathrm{sea}}/p_{\mathrm{x,ft}})$
0	14.697	0.075	1.000
1000	14.19	0.0722	1.039
2000	13.58	0.0697	1.076
3000	13.20	0.0672	1.116
5000	12.23	0.0625	1.200

Off-Coil and Supply Air Temperature

For a given design indoor air temperature T_r, space sensible cooling load q_{rs}, and supply system heat gain $q_{s.s}$, a lower air off-coil temperature T_{cc} as well as supply temperature T_s means a greater supply temperature differential ΔT_s and a lower space relative humidity φ_r and vice versa. A greater ΔT_s decreases the supply volume flow rate $\overset{\circ}{V}_s$ and then the fan and terminal sizes, duct sizes, and fan energy use. The result is a lower investment and energy cost.

A lower T_{cc} and a greater ΔT_s require a lower chilled water temperature entering the coil T_{we}, a lower evaporating temperature T_{ev} in the DX coil or refrigerating plant, and therefore a greater power input to the refrigerating compressors. When an air-conditioning system serves a conditioned space of a single zone, optimum T_{cc}, T_s, and T_{we} can be selected. For a conditioned space of multizones, T_{cc}, T_s, and T_{we} should be selected to satisfy the lowest requirement. In practice, T_s and T_{we} are often determined according to previous experience with similar projects.

In general, the temperature rise due to the supply fan power system heat gain q_{sf} can be taken as 1 to 3°F depending on the fan total pressure. The temperature rise due to the supply duct system heat gain at design flow can be estimated as 1°F/100 ft insulated main duct length based on 1-in. thickness of duct insulation. Note that ANSI/ASHRAE/IESNA Standard 90.1-2001 covers duct insulation energy standards.

Outside Surface Condensation

The outside surface temperature of the ducts, terminals, and supply outlets T_{sur} in the ceiling plenum in contact with the return air should not be lower than the dew point of the space air T_r'', in °F. The temperature rise due to the fan power heat gain is about 2°F. According to Dorgan (1988), the temperature difference between the conditioned air inside the terminal and the outside surface of the terminal with insulation wrap is about 3°F. For a space air temperature of 75°F and a relative humidity of 50%, its dew point temperature is 55°F. If the outside surface temperature $T_s = (T_{cc} + 2 + 3) \leq 55°\text{F}$, condensation may occur on the outside surface of the terminal. Three methods are often used to prevent condensation:

1. Increase the thickness of the insulation layer on the outside surface.
2. Adopt a supply outlet that induces more space air.
3. Equip with a terminal that mixes the supply air with the space air or air from the ceiling plenum.

Example 9.3.1

The worship hall of a church uses a package system with a basic air system. The summer space sensible cooling load is 75,000 Btu/hr with a latent load of 15,000 Btu/hr. Other design data for summer are as follows:

Outdoor summer design temperature: dry bulb 95°F and wet bulb 75°F
Summer indoor temperature: 75°F with a space relative humidity of 50%:
Temperature rise: fan power 2°F
supply duct 2°F
Relative humidity of air leaving cooling coil: 93%
Outdoor air requirement: 1800 cfm

Determine the

1. Temperature of supply air at summer design conditions
2. Rated volume flow rate of the supply fan
3. Cooling coil load
4. Possibility of condensation at the outside surface of the insulated branch duct to the supply outlet

Solution

1. From Equation 9.3.1 the sensible heat ratio of the space conditioning line is

$$\text{SHR}_s = |q_{rs}| / (|q_{rs}| + |q_{rl}|) = 60{,}000/(60{,}000 + 15{,}000) = 0.8$$

On the psychrometric chart, from given $T_r = 75°F$ and $\varphi_r = 50\%$, plot space point r. Draw a space conditioning line sr from point r with $SHR_s = 0.8$.

Since $\Delta T_{s.s} = 2 + 2 = 4°F$, move line segment cc s (4°F) up and down until point s lies on line sr and point cc lies on the $\varphi_{cc} = 93\%$ line. The state points s and cc are then determined as shown in Figure 9.3.4:

$T_s = 57.5°F$, $\varphi_s = 82\%$, and $w_s = 0.0082$ lb/lb

$T_{cc} = 53.5°F$, $\varphi_{cc} = 93\%$, $h_{cc} = 21.8$ Btu/lb, and $w_{cc} = 0.0082$ lb/lb

2. Since $T_{sf} = 53.5 + 2 = 55.5°F$ and $w_{sf} = 0.0082$ lb/lb, $\rho_{sf} = 1/v_{sf} = 1/13.15 = 0.076$ lb/ft^3. From Equation 9.4.2, the required rated supply volume flow rate is

$$\overset{\circ}{V}_{sf.r} = q_{rs.d} \Big/ \left[60 \rho_{sf} c_{pa} \left(T_r - T_s\right)\right]$$

$$= 60{,}000 \big/ \left[60 \times 0.076 \times 0.243 (75 - 57.5)\right] = 3094 \text{ cfm}$$

3. Plot outdoor air state point o on the psychrometric chart from given dry bulb 95°F and wet bulb 75°F. Connect line r-o. Neglect the density differences between points r, m, and o; then

$$\text{r-m/r-o} = 1800/3094 = 0.58$$

From the psychrometric chart, the length of line r-o is 2.438 in. As shown in Figure 9.3.4, point m is then determined as:

$$T_m = 86.7°\text{F}, \qquad h_m = 35 \text{ Btu/lb}$$

From Equation (9.3.11), the cooling coil load is

$$q_{cc} = 60 \overset{\circ}{V}_s \rho_s \left(h_m - h_{cc}\right) = 60 \times 3094 \times 0.076 (35 - 21.8) = 186{,}234 \text{ Btu/lb}$$

4. From the psychrometric chart, since the dew point of the space air $T_r'' = 55°F$ and is equal to that of the plenum air, the outside surface temperature of the branch duct $T_s = 53.5 + 2 + 3 = 58°F$ which is higher than $T_r'' = 55°F$. Condensation will not occur at the outside surface of the branch duct.

Basic Air-Conditioning Cycle — Winter Mode

When the basic air-conditioning systems are operated in winter mode, their air-conditioning cycles can be classified into the following four categories:

Cold Air Supply without Space Humidity Control. In winter, for a fully occupied worship hall, if the heat loss is less than the space sensible cooling load, a cold air supply is required to offset the space sensible cooling load and maintain a desirable indoor environment as shown by the lower cycle in Figure 9.3.4. Usually, a humidifier is not used.

The winter cycle of a cold air supply without humidity control consists of the following air-conditioning processes:

1. Adiabatic mixing process of outdoor air and recirculating air o m r.
2. Sensible heating process due to supply fan power heat gain m sf. Because of the smaller temperature difference between the air in the ceiling plenum and the supply air inside the supply duct, heat transfer through duct wall in winter can be neglected.
3. Supply conditioning line sr.

For a winter-mode basic air-conditioning cycle with a cold air supply without space humidity control, the space relative humidity depends on the space latent load, the humidity ratio of the outdoor air, and the amount of outdoor air intake. In order to determine the space humidity ratio w_r, in lb/lb, and the space relative humidity φ_r, in %, Equation (9.3.15) and Equation (9.3.22) should be used to give the following relationships:

$$\begin{aligned}
&\left(w_r - w_m\right) \big/ \left(w_r - w_o\right) = \mathring{V}_o \big/ \mathring{V}_s \\
&\left(w_r - w_s\right) = q_{rl} \Big/ \left(60 \mathring{V}_s \rho_s h_{fg.58}\right) \\
&w_s = w_m
\end{aligned} \tag{9.3.28}$$

For a cold air supply, if there is a high space sensible cooling load, the amount of outdoor air must be sufficient, and the mixture must be cold enough to satisfy the following relationships:

$$\begin{aligned}
&\left(T_r - T_s\right) = q_{rs} \Big/ \left(60\ \mathring{V}_s \rho_s c_{pa}\right) \\
&\left(T_r - T_s\right) \big/ \left(T_r - T_o\right) = \mathring{V}_o \big/ \mathring{V}_s
\end{aligned} \tag{9.3.29}$$

The heating coil load for heating of the outdoor air can be calculated using Equation (9.3.7).

Example 9.3.2

For the same packaged air-conditioning system using a basic air system to serve the worship hall in a church as in Example 9.3.1, the space heating load at winter design condition is 10,000 Btu/hr and the latent load is 12,000 Btu/hr. Other winter design data are as follows:

Winter outdoor design temperature	35°F
Winter outdoor design humidity ratio	0.00035 lb/lb
Winter indoor design temperature	70°F
Temperature rise due to supply fan heat gain	2°F
Outdoor air requirement	1800 cfm

Determine (1) the space relative humidity at winter design temperature and (2) the heating coil load.

Solution

1. Assume that the supply air density $\rho_{sf} = 1/v_{sf} = 1/13.0 = 0.0769$ lb/ft^3, and the mass flow rate of the supply air is the same as in summer mode. Then from Equation 9.3.28 the humidity ratio difference is

$$\left(w_r - w_s\right) = q_{rl} \Big/ \left(60 \mathring{V}_{sf.r} \rho_{sf} h_{fg.58}\right) = 12{,}000/(60 \times 3094 \times 0.0769 \times 1060) = 0.00079 \text{ lb/lb}$$

From Equation 9.3.29, the supply air temperature differential is

$$\left(T_r - T_s\right) = q_{rs.d} \Big/ \left(60 \mathring{V}_{sf.r} \rho_{sf} c_{pa}\right) = 10{,}000/(60 \times 3094 \times 0.0769 \times 0.243) = 2.88°\text{F}$$

Since $\mathring{V}_o / \mathring{V}_s = 1800/3094 = 0.58$ and $w_s = w_m$,

$$\left(w_r - w_s\right) \big/ \left(w_r - w_o\right) = 0.00079 \big/ \left(w_r - w_o\right) = \mathring{V}_o \big/ \mathring{V}_s = 0.58$$

$$\left(w_r - w_o\right) = 0.00079/0.58 = 0.00136 \text{ lb/lb}$$

And from given information,

$$w_r = 0.00136 + w_o = 0.00136 + 0.0035 = 0.00486 \text{ lb/lb}$$

From the psychrometric chart, for T_r = 70°F and w_r = 0.00486 lb/lb, point r can be plotted, and φ_r is about 32% (see Figure 9.3.4).

2. Since mr/or = 0.58, point m can be determined, and from the psychrometric chart T_m = 50.0°F. As T_s = 70 – 2.88 = 67.12°F and $T_{sf} = T_m + 2 = 50.0 + 2 = 52.0$°F, from Equation 9.3.7 the heating coil's load is

$$q_{ch} = 60 \overset{\circ}{V}_s \rho_s c_{pa} \left(T_s - T_{sf}\right) = 60 \times 3094 \times 0.0769 \times 0.243(67.12 - 52.0) = 52{,}451 \text{ Btu/hr}$$

Warm Air Supply without Space Humidity Control

When the sum of space heat losses is greater than the sum of the internal heat gains in winter, a warm air supply is needed. For many comfort systems such as those in offices and stores, in locations where winter is not very cold, humidification is usually not necessary. The basic air-conditioning cycle for a warm air supply without space humidity control is shown in Figure 9.3.5(a). This cycle is similar to the winter mode cycle of a cold air supply without space humidity control shown in Figure 9.3.4 except that the supply air temperature is higher than space temperature, that is, $T_s > T_r$. To prevent stratification, with the warm supply air staying at a higher level, $(T_s - T_r) > 20$°F is not recommended.

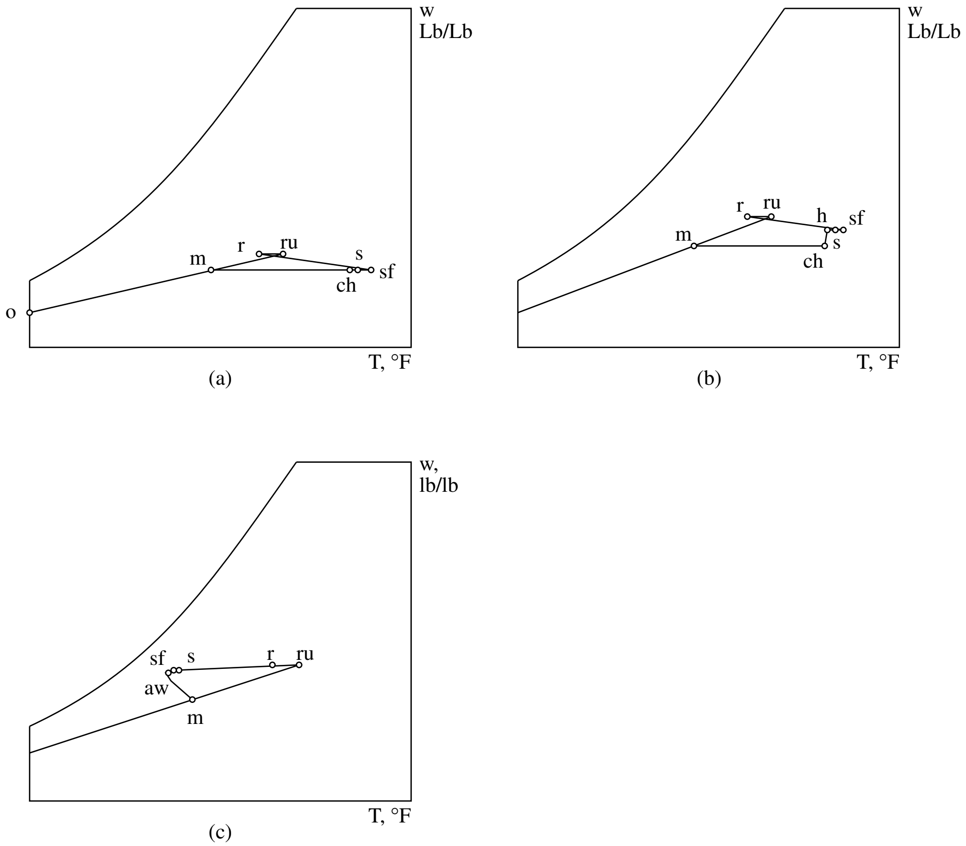

FIGURE 9.3.5 Basic air-conditioning cycle — winter modes: (a) warm air supply without space humidity control, (b) cold air supply without space humidity control, and (c) cold air supply with space humidity control. ch = air leaving heating coil, h = air leaving humidifer, and aw = air leaving air washer.

Warm Air Supply with Space Humidity Control

This operating cycle (see Figure 9.3.5[b]) is often used for hospitals, nurseries, etc. or in locations where winter is very cold. The state point of supply air must be determined first by drawing a space conditioning line with known SHR_s and then from the calculated supply temperature differential ΔT_s. The difference in humidity ratio ($w_s - w_{ch}$) is the water vapor must be added at the humidifier. Humidifying capacity can be calculated from Equation 9.3.8.

Cold Air Supply with Space Humidity Control

This operating cycle (shown in Figure 9.3.5[c]) is widely used in industrial applications such as textile mills where a cold air supply is needed to remove machine load in winter and maintains the space relative humidity required for the manufacturing process. An outdoor air and recirculating air mixture is often used for the required cold air supply. An air washer is adopted for winter humidification.

Air Economizer Mode

In the *air economizer* mode, as shown by the middle dotted line cycle o″-cc-sf-s-r in Figure 9.3.4, all outdoor air or an outdoor air-recirculating air mixture is used to reduce the refrigeration capacity and improve the indoor air quality during spring, fall, or winter.

When all outdoor air is admitted, it is an open cycle. Outdoor air is cooled and often dehumidified to point cc. After absorbing fan and duct heat gains, it is supplied to the conditioned space. Space air is exhausted entirely through openings, relief dampers, or relief/exhaust fans to the outside. An all-outdoor air-operating mode before the space is occupied is often called an *air purge* operation, used to dilute space air contaminants.

Cool-Down and Warm-Up Modes

In summer, when an air system is shut down during an unoccupied period at night, the space temperature and relative humidity often tend to increase because of infiltration of hot and humid air and heat transfer through the building envelope. The air system is usually started before the space is occupied in cool-down mode to cool the space air until the space temperature falls within predetermined limits.

In winter, the air system is also started before the occupied period to warm up the space air to compensate for the nighttime space temperature setback to 55 to 60°F for energy saving or the drop of space temperature due to heat loss and infiltration.

If dilution of indoor air contaminants is not necessary, only recirculating space air is used during cool-down or warm-up periods in order to save energy. Care should be taken in suggesting cool-down or warm-up modes as for some applications after-hour conditions could result in damage to interior surfaces or materials.

9.4 Refrigerants and Refrigeration Cycles

Shan K. Wang

Refrigeration and Refrigeration Systems

Refrigeration is the cooling effect of the process of extracting heat from a lower temperature heat source, a substance or cooling medium, and transferring it to a higher temperature heat sink, probably atmospheric air and surface water, to maintain the temperature of the heat source below that of the surroundings.

A *refrigeration system* is a combination of components, equipment, and piping, connected in a sequential order to produce the refrigeration effect. Refrigeration systems that provide cooling for air-conditioning are classified mainly into the following categories:

1. *Vapor compression systems.* In these systems, a compressor(s) compresses the refrigerant to a higher pressure and temperature from an evaporated vapor at low pressure and temperature. The compressed refrigerant is condensed into liquid form by releasing the latent heat of condensation to the condenser water. Liquid refrigerant is then throttled to a low-pressure, low-temperature vapor,

producing the refrigeration effect during evaporation. Vapor compression is often called *mechanical refrigeration*, that is, refrigeration by mechanical compression.

2. *Absorption systems.* In an absorption system, the refrigeration effect is produced by means of thermal energy input. After liquid refrigerant produces refrigeration during evaporation at very low pressure, the vapor is absorbed by an aqueous absorbent. The solution is heated by a direct-fired gas furnace or waste heat, and the refrigerant is again vaporized and then condensed into liquid form. The liquid refrigerant is throttled to a very low pressure and is ready to produce the refrigeration effect again.
3. *Gas expansion systems.* In an air or other gas expansion system, air or gas is compressed to a high pressure by compressors. It is then cooled by surface water or atmospheric air and expanded to a low pressure. Because the temperature of air or gas decreases during expansion, a refrigeration effect is produced.

Refrigerants, Cooling Mediums, and Absorbents

A *refrigerant* is a primary working fluid used to produce refrigeration in a refrigeration system. All refrigerants extract heat at low temperature and low pressure during evaporation and reject heat at high temperature and pressure during condensation.

A *cooling medium* is a working fluid cooled by the refrigerant during evaporation to transport refrigeration from a central plant to remote cooling equipment and terminals. In a large, centralized air-conditioning system, it is more economical to pump the cooling medium to the remote locations where cooling is required. Chilled water and brine are cooling media. They are often called secondary refrigerants to distinguish them from the primary refrigerants.

A *liquid absorbent* is a working fluid used to absorb the vaporized refrigerant (water) after evaporation in an absorption refrigeration system. The solution that contains the absorbed vapor is then heated. The refrigerant vaporizes, and the solution is restored to its original concentration to absorb water vapor again.

A numbering system for refrigerants was developed for hydrocarbons and halocarbons. According to ANSI/ASHRAE Standard 34-1997, the first digit is the number of unsaturated carbon–carbon bonds in the compound. This digit is omitted if the number is zero. The second digit is the number of carbon atoms minus one. This is also omitted if the number is zero. The third digit denotes the number of hydrogen atoms plus one. The last digit indicates the number of fluorine atoms. For example, the chemical formula for refrigerant R-123 is $CHCl_2CF_3$. In this compound:

No unsaturated carbon–carbon bonds, first digit is	0
There are two carbon atoms, second digit is	$2 - 1 = 1$
There is one hydrogen atom, third digit is	$1 + 1 = 2$
There are three fluorine atoms, last digit is	3

To compare the relative ozone depletion of various refrigerants, an index called the *ozone depletion potential* (ODP) has been introduced. ODP is defined as the ratio of the rate of ozone depletion of 1 lb of any halocarbon to that of 1 lb of refrigerant R-11. For R-11, ODP = 1.

Similar to the ODP, halocarbon global warming potential (HGWP) is an index used to compare the global warming effect of a halocarbon refrigerant with the effect of refrigerant R-11.

Classification of Refrigerants

Nontoxic and nonflammable synthetic chemical compounds called *halogenated hydrocarbons*, or simply *halocarbons*, were used almost exclusively in vapor compression refrigeration systems for comfort air-conditioning until 1986. Because chlorofluorocarbons (CFCs) cause ozone depletion and global warming, they must be replaced. A classification of refrigerants based on ozone depletion follows (see Table 9.4.1):

TABLE 9.4.1 Properties of Commonly Used Refrigerants 40°F Evaporating and 100°F Condensin

		Chemical Formula	Molecular Mass	Ozone Depletion Potential (ODP)	Global Warming Potential (HGWP)	Evaporating Pressure, psia	Condensing Pressure, psia	Compression Ratio	Refrigeration Effect, Btu/lb

Source: Adapted with permission from *ASHRAE Handbooks 1993 Fundamentals.* Also from refrigerant manufacturers.

[a] First classification is that safety classification of the formulated composition. The second is the worst case of fractionation.

Hydrofluorocarbons (HFCs)

HFCs contain only hydrogen, fluorine, and carbon atoms and cause no ozone depletion. HFCs group include R-134a, R-32, R-125, and R-245ca.

HFC's Azeotropic Blends or Simply HFC's Azeotropes

An azeotrope is a mixture of multiple components of volatilities (refrigerants) that evaporate and condense as a single substance and do not change in volumetric composition or saturation temperature when they evaporate or condense at constant pressure. HFC's azeotropes are blends of refrigerant with HFCs. ASHRAE assigned numbers between 500 and 599 for azeotropes. HFC's azeotrope R-507, a blend of R-125/R-143, is the commonly used refrigerant for low-temperature vapor compression refrigeration systems.

HFC's Near Azeotropic

A near azeotrope is a mixture of refrigerants whose characteristics are near those of an azeotrope. Because the change in volumetric composition or saturation temperature is rather small for a near azeotrope, such as, 1 to 2°F, it is thus named. ASHRAE assigned numbers between 400 and 499 for zeotropic. R-404A (R-125/R-134a/R-143a) and R-407B (R-32/R-125/R134a) are HFC's near azeotrope. R-32 is flammable; therefore, its composition is usually less than 30% in the mixture. HFC's near azeotropes are widely used for vapor compression refrigeration systems.

Zeotropes or nonazeotropes, including near azeotropes, show a change in composition due to the difference between liquid and vapor phases, leaks, and the difference between charge and circulation. A shift in composition causes the change in evaporating and condensing temperature/pressure. The difference in dew point and bubble point during evaporation and condensation is called glide, expressed in °F. Near azeotrope has a smaller glide than zeotropes. The midpoint between the dew point and bubble point is often taken as the evaporating and condensing temperature for refrigerant blends.

Hydrochlorofluorocarbons (HCFCs) and Their Zeotropics

HCFCs contain hydrogen, chlorine, fluorine, and carbon atoms and are not fully halogenated. HCFCs have a much shorter lifetime in the atmosphere (in decades) than CFCs and cause far less ozone depletion (ODP 0.02 to 0.1). R-22, R-123, R-124, etc. are HCFCs. HCFCs are the most widely used refrigerants today.

HCFC's near azeotropes and *HCFC's zeotropes* are blends of HCFCs with HFCs. They are transitional or interim refrigerants and are scheduled for a restriction in production starting in 2004.

Inorganic Compounds

These compounds include refrigerants used before 1931, like ammonia R-717, water R-718, and air R-729. They are still in use because they do not deplete the ozone layer. Because ammonia is toxic and flammable, it is used in industrial applications. Inorganic compounds are assigned numbers between 700 and 799 by ASHRAE.

Chlorofluorocarbons, Halons, and Their Azeotropic Blends

CFCs contain only chlorine, fluorine, and carbon atoms. CFCs have an atmospheric lifetime of centuries and cause ozone depletion (ODP from 0.6 to 1). R-11, R-12, R-113, R-114, R-115… are all CFCs.

Halons or BFCs contain bromide, fluorine, and carbon atoms. R-13B1 and R-12B1 are BFCs. They cause very high ozone depletion (ODP for R-13B1 = 10). Until 1995, R-13B1 was used for very low temperature vapor compression refrigeration systems.

Phaseout of CFCs, BFCs, HCFCs, and Their Blends

On September 16, 1987, the European Economic Community and 24 nations, including the United States, signed a document called the Montreal Protocol. It is an agreement to restrict the production and consumption of CFCs and BFCs in the 1990s because of ozone depletion.

The Clean Air Act amendments, signed into law in the United States on November 15, 1990, concern two important issues: the phaseout of CFCs and the prohibition of deliberate venting of CFCs and HCFCs.

In February 1992, President Bush called for an accelerated ban of CFCs in the United States. In late November 1992, representatives of 93 nations meeting in Copenhagen agreed to phase out CFCs beginning January 1, 1996. Restriction on the use of HCFCs will start in 2004, with a complete phaseout by 2030.

In the earlier 1990s, R-11 was widely used for centrifugal chillers, R-12 for small and medium-size vapor compression systems, R-22 for several other vapor compression systems, and CFC/HCFC blend R-502 for low-temperature vapor compression systems. Because of the phaseout of CFCs and BFCs before 1996 and HCFCs in the early years of the next century, alternative refrigerants have been developed to replace them:

- R-123 (an HCFC of ODP = 0.02) to replace R-11 is a short-term replacement that causes a slight reduction in capacity and efficiency. R-245ca (ODP = 0) may be the long-term alternative to R-11.
- R-134a (an HFC with ODP = 0) to replace R-12 in broad applications. R-134a is not miscible with mineral oil; therefore, a synthetic lubricant of polyolester is used.
- R-404A (R-125/R-134a/143a) and R-407C (R-32/R-125/R-134a) are both HFCs near azeotropic of ODP = 0. They are long-term alternatives to R-22. For R-407C, the composition of R-32 in the mixture is usually less than 30% so that the blend will not be flammable. R-407C has a drop of only 1 to 2% in capacity compared with R-22.
- R-507 (R-125/R-143a), an HFC's azeotropic with ODP = 0, is a long-term alternative to R-502. Synthetic polyolester lubricant oil will be used for R-507. There is no major performance difference between R-507 and R-502. R-402A (R-22/R-125/R-290), an HCFC's near azeotropic, is a short-term immediate replacement, and drop-in of R-502 requires minimum change of existing equipment except for reset of a higher condensing pressure.

Required Properties of Refrigerants

A refrigerant should not cause ozone depletion. A low global warming potential is required. Additional considerations for refrigerant selection are

1. *Safety*, including toxicity and flammability. ANSI/ASHRAE Standard 34-1997 classifies the *toxicity* of refrigerants as Class A and Class B. Class A refrigerants are of low toxicity. No toxicity was identified when their time-weighted average concentration was less than or equal to 400 ppm, to which workers can be exposed for an 8-hr workday and 40-hr work week without adverse effect. Class B refrigerants are of higher toxicity and produce evidence of toxicity.

ANSI/ASHRAE Standard 34-1982 classifies the *flammability* of refrigerants as Class 1, no flame propagation; Class 2, lower flammability; and Class 3, higher flammability.

The safety classification of refrigerants is based on the combination of toxicity and flammability: A1, A2, A3, B1, B2, and B3. R-134a and R-22 are in the A1 group, lower toxicity and nonflammable; R-123 in the B1 group, higher toxicity and nonflammable; and R-717 (ammonia) in the B2 group, higher toxicity and lower flammability.

2. *Effectiveness of refrigeration cycle*. High effectiveness is a desired property. The power consumed per ton of refrigeration produced, hp/ton or kW/ton, is an index for this assessment. Table 9.4.1 gives values for an ideal single-stage vapor compression cycle.
3. *Oil miscibility*. Refrigerant should be miscible with mineral lubricant oil because a mixture of refrigerant and oil helps to lubricate pistons and discharge valves, bearings, and other moving parts of a compressor. Oil should also be returned from the condenser and evaporator for continuous lubrication. R-22 is partially miscible. R-134a is hardly miscible with mineral oil; therefore, synthetic lubricant of polyolester will be used.
4. *Compressor displacement*. Compressor displacement per ton of refrigeration produced, in cfm/ton, directly affects the size of the positive displacement compressor and therefore its compactness. Ammonia R-717 requires the lowest compressor displacement (1.70 cfm/ton) and R-22 the second lowest (1.91 cfm/ton).

5. Desired properties:
   - Evaporating pressure p_{ev} should be higher than atmospheric. Then noncondensable gas will not leak into the system.
   - Lower condensing pressure for lighter construction of compressor, condenser, piping, etc.
   - A high thermal conductivity and therefore a high heat transfer coefficient in the evaporator and condenser.
   - Dielectric constant should be compatible with air when the refrigerant is in direct contact with motor windings in hermetic compressors.
   - An inert refrigerant that does not react chemically with material will avoid corrosion, erosion, or damage to system components. Halocarbons are compatible with all containment materials except magnesium alloys. Ammonia, in the presence of moisture, is corrosive to copper and brass.
   - Refrigerant leakage can be easily detected. Halide torch, electronic detector, and bubble detection are often used.

Ideal Single-Stage Vapor Compression Cycle

Refrigeration Process

A refrigeration process shows the change of the thermodynamic properties of the refrigerant and the energy and work transfer between the refrigerant and surroundings.

Energy and work transfer is expressed in British thermal units per hour, or Btu/hr. Another unit in wide use is ton of refrigeration, or ton. A ton = 12,000 Btu/hr of heat removed; i.e., 1 ton of ice melting in 24 hr = 12,000 Btu/hr.

Refrigeration Cycles

When a refrigerant undergoes a series of processes like evaporation, compression, condensation, throttling, and expansion, absorbing heat from a low-temperature source and rejecting it to a higher temperature sink, it is said to have undergone a refrigeration cycle. If its final state is equal to its initial state, it is a *closed cycle*; if the final state does not equal the initial state, it is an *open cycle*. Vapor compression refrigeration cycles can be classified as single stage, multistage, compound, and cascade cycles.

A *pressure-enthalpy diagram* or *p-h* diagram is often used to calculate the energy transfer and to analyze the performance of a refrigeration cycle, as shown in Figure 9.4.1. In a *p-h* diagram, pressure *p*, in psia or psig logarithmic scale, is the ordinate, and enthalpy *h*, in Btu/lb, is the abscissa. The saturated liquid and saturated vapor line encloses a two-phase region in which vapor and liquid coexist. The two-phase region separates the subcooling liquid and superheated vapor regions. The constant-temperature line is nearly vertical in the subcooling region, horizontal in the two-phase region, and curved down sharply in the superheated region.

In the two-phase region, a given saturated pressure determines the saturated temperature and vice versa. The constant-entropy line is curved upward to the right-hand side in the superheated region. Each kind of refrigerant has its own *p-h* diagram.

Refrigeration Processes in an Ideal Single-Stage Cycle

An *ideal cycle* has isentropic compression, and pressure losses in the pipeline, valves, and other components are neglected. All refrigeration cycles covered in this section are ideal. Single stage means a single stage of compression.

There are four refrigeration processes in an ideal single-stage vapor compression cycle, as shown in Figure 9.4.2(a) and (b):

1. Isothermal evaporation process 4–1 — The refrigerant evaporates completely in the evaporator and produces refrigeration effect q_{rf}, in Btu/lb:

$$q_{rf} = \left(h_1 - h_4\right) \tag{9.4.1}$$

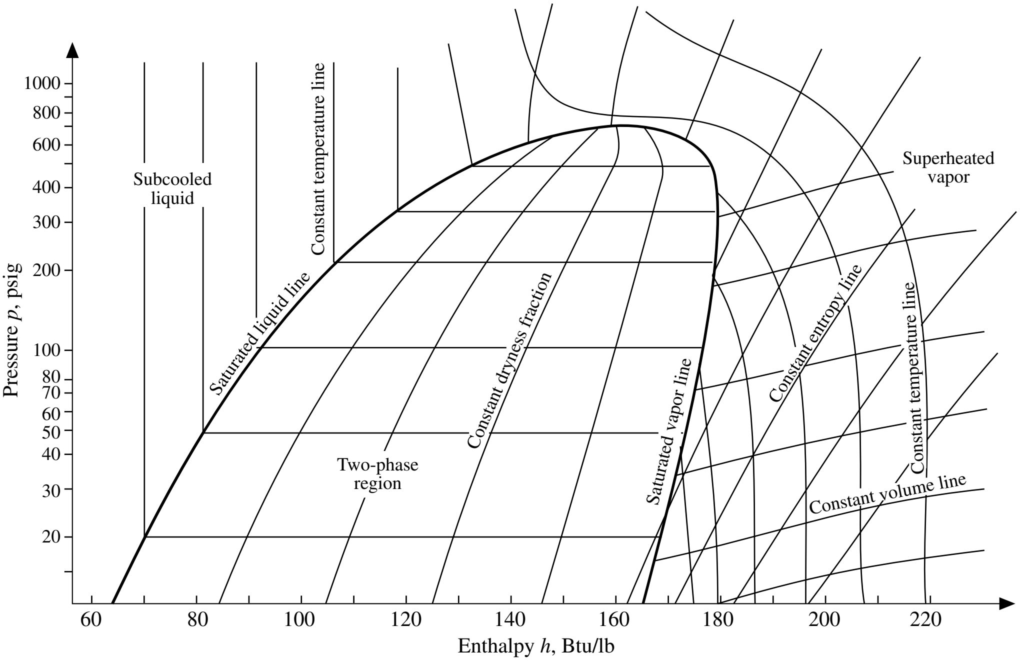

FIGURE 9.4.1 Skeleton of pressure-enthalpy diagram for R-22.

where h_1,h_4 = enthalpy of refrigerant at state points 1 and 4, respectively, Btu/lb.

2. Isentropic compression process 1–2 — Vapor refrigerant is extracted by the compressor and compressed isentropically from point 1 to 2. The work input to the compressor W_{in}, in Btu/lb, is

$$W_{in} = (h_2 - h_1) \tag{9.4.2}$$

where h_2 = enthalpy of refrigerant at state point 2, Btu/lb.

The greater the difference in temperature/pressure between the condensing pressure p_{con} and evaporating pressure p_{ev}, the higher will be the work input to the compressor.

3. Constant pressure condensation process 2–3 — Hot gaseous refrigerant discharged from the compressor is condensed in the condenser into liquid, and the latent heat of condensation is rejected to the condenser water or ambient air. The heat rejection during condensation, q_{2-3}, in Btu/lb, is

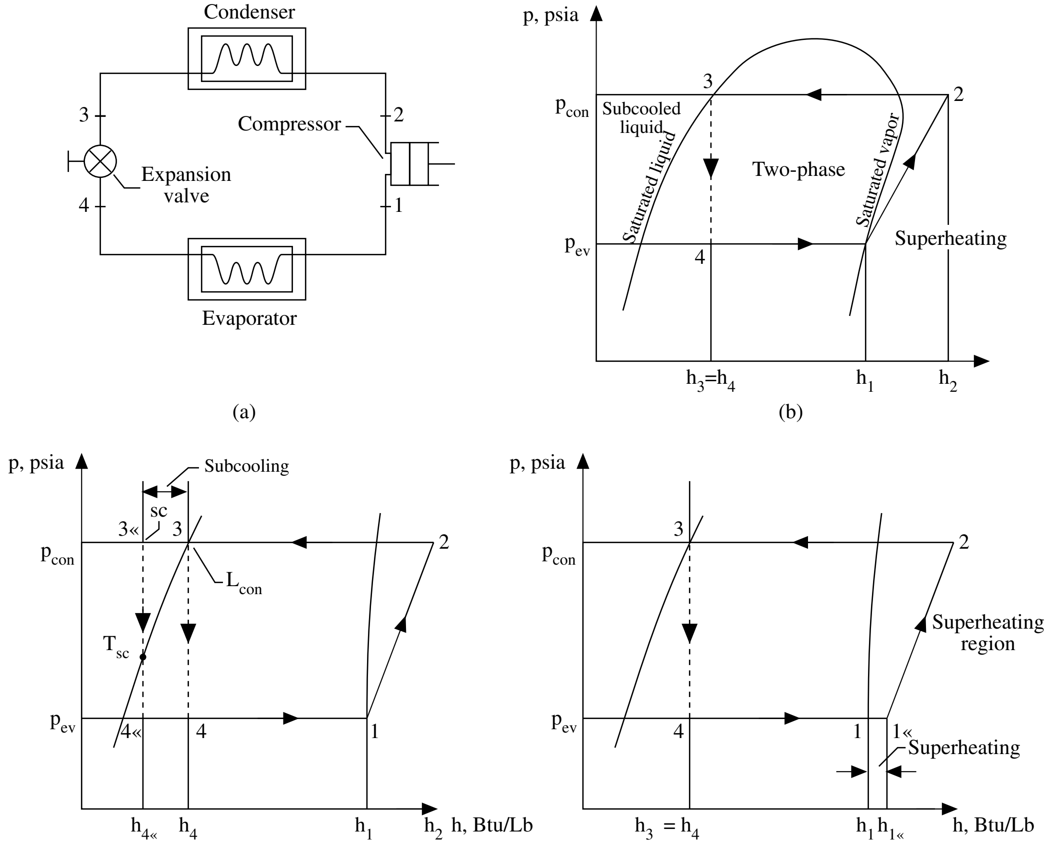
$$-q_{2-3} = (h_2 - h_3) \tag{9.4.3}$$

where h_3 = enthalpy of refrigerant at state point 3, Btu/lb.

4. Throttling process 3–4 — Liquid refrigerant flows through a throttling device (e.g., an expansion valve, a capillary tube, or orifices) and its pressure is reduced to the evaporating pressure. A portion of the liquid flashes into vapor and enters the evaporator. This is the only irreversible process in the ideal cycle, usually represented by a dotted line. For a throttling process, assuming that the heat gain from the surroundings is negligible:

$$h_3 = h_4 \tag{9.4.4}$$

The mass flow rate of refrigerant $\overset{\circ}{m}_r$, in lb/min, is



(a) (b) (c) (d)

FIGURE 9.4.2 A single-stage ideal vapor compression refrigeration cycle: (a) schematic diagram, (b) *p-h* diagram, (c) subcooling, and (d) superheating.

$$\overset{\circ}{m}_{r} = q_{rc}/60q_{rf} \tag{9.4.5}$$

where q_{rc} = refrigeration capacity of the system, Btu/hr.

The ideal single-stage vapor compression refrigeration cycle on a *p-h* diagram is divided into two pressure regions: high pressure (p_{con}) and low pressure (p_{ev}).

Coefficient of Performance of Refrigeration Cycle

The *coefficient of performance* (COP) is a dimensionless index used to indicate the performance of a thermodynamic cycle or thermal system. The magnitude of COP can be greater than 1.

- If a *refrigerator* is used to produce a refrigeration effect, COP_{ref} is

$$\text{COP}_{ref} = q_{rf}/W_{in} \tag{9.4.6}$$

- If a *heat pump* is used to produce a useful heating effect, its performance denoted by COP_{hp} is

$$\text{COP}_{hp} = q_{2-3}/W_{in} \tag{9.4.7}$$

- For a heat recovery system when both refrigeration and heating effects are produced, the COP_{hr} is denoted by the ratio of the sum of the absolute values of q_{rf} and $q_{2\text{-}3}$ to the work input, or

$$\text{COP}_{\text{hr}} = \left(\left|q_{\text{rf}}\right| + \left|q_{2-3}\right|\right) / W_{\text{in}} \tag{9.4.8}$$

Subcooling and Superheating

Condensed liquid is often subcooled to a temperature lower than the saturated temperature corresponding to the condensing pressure p_{con}, in psia or psig, as shown in Figure 9.4.2(c). *Subcooling* increases the refrigeration effect to $q_{\text{rf.sc}}$ as shown in Figure 9.4.2(c):

$$q_{\text{rf.sc}} = \left(h_{4'} - h_1\right) > \left(h_4 - h_1\right) \tag{9.4.9}$$

The enthalpy of subcooled liquid refrigerant h_{sc} approximately equals the enthalpy of the saturated liquid refrigerant at subcooled temperature $h_{\text{s.sc}}$, both in Btu/lb:

$$h_{\text{sc}} = h_{3'} = h_{4'} = h_{1.\text{con}} - c_{pr}\left(T_{\text{con}} - T_{\text{sc}}\right) \approx h_{\text{s.sc}} \tag{9.4.10}$$

where

$h_{3'}$, $h_{4'}$ = enthalpy of liquid refrigerant at state points 3′ and 4′ respectively, Btu/lb
$h_{\text{l.con}}$ = enthalpy of saturated liquid at condensing temperature, Btu/lb
c_{pr} = specific heat of liquid refrigerant at constant pressure, Btu/lb °F
T_{con} = condensing temperature or saturated temperature of liquid refrigerant at condensing pressure, °F
T_{sc} = temperature of subcooled liquid refrigerant, °F

The purpose of *superheating* is to prevent liquid refrigerant flooding back into the compressor and causing slugging damage as shown in Figure 9.4.2(d). The degree of superheating depends mainly on the types of refrigerant feed, construction of the suction line, and type of compressor. The state point of vapor refrigerant after superheating of an ideal system must be at the evaporating pressure with a specific degree of superheat and can be plotted on a *p-h* diagram for various refrigerants.

Refrigeration Cycle of Two-Stage Compound Systems with a Flash Cooler

A *multistage system* employs more than one compression stage. Multistage vapor compression systems are classified as compound systems and cascade systems. A *compound system* consists of two or more compression stages connected in series. It may have one high-stage compressor (higher pressure) and one low-stage compressor (lower pressure), several compressors connected in series, or two or more impellers connected internally in series and driven by the same motor.

The *compression ratio* R_{com} is defined as the ratio of discharge pressure p_{dis} to the suction pressure at the compressor inlet p_{suc}:

$$R_{\text{com}} = p_{\text{dis}} / p_{\text{suc}} \tag{9.4.11}$$

Compared to a single-stage system, a multistage has a smaller compression ratio and higher compression efficiency for each stage of compression, greater refrigeration effect, lower discharge temperature at the high-stage compressor, and greater flexibility. At the same time, a multistage system has a higher initial cost and more complicated construction.

The pressure between the discharge pressure of the high-stage compressor and the suction pressure of the low-stage compressor of a multistage system is called *interstage pressure* p_{i}, in psia. Interstage

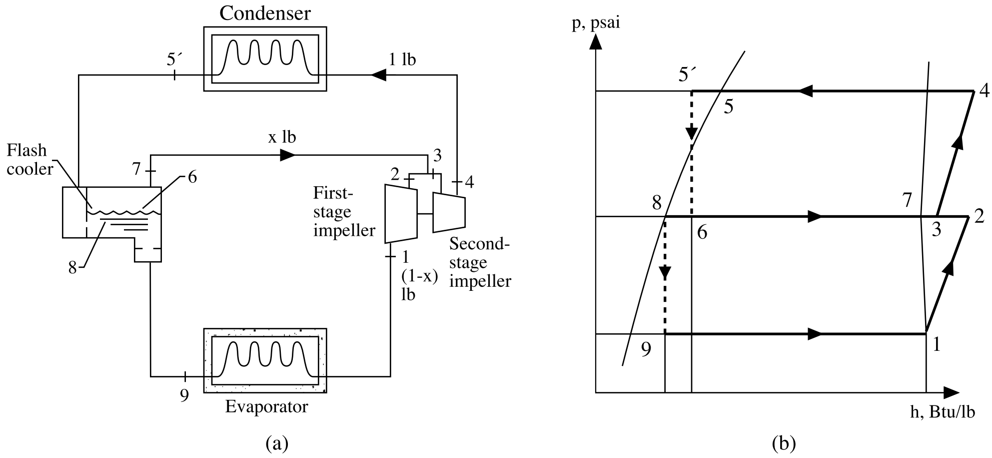


FIGURE 9.4.3 Two-stage compound system with a flash cooler: (a) schematic diagram and (b) refrigeration cycle.

pressure for a two-stage system is usually determined so that the compression ratios are nearly equal between two stages for a higher COP. Then the interstage pressure is

$$p_i = \sqrt{\left(p_{con} p_{ev}\right)} \tag{9.4.12}$$

where p_{con}, p_{ev} = condensing and evaporating pressures, psia.

For a multistage system of *n* stages, then, the compression ratio of each stage is

$$R_{com} = \left(p_{con}/p_{suc}\right)^{1/n} \tag{9.4.13}$$

Figure 9.4.3(a) shows a schematic diagram and Figure 9.4.3(b) the refrigeration cycle of a two-stage compound system with a flash cooler. A *flash cooler*, sometimes called an economizer, is used to subcool the liquid refrigerant to the saturated temperature corresponding to the interstage pressure by vaporizing a portion of the liquid refrigerant in the flash cooler.

Based on the principle of heat balance, the fraction of evaporated refrigerant, *x*, or quality of the mixture in the flash cooler is

$$x = \left(h_{5'} - h_8\right)/\left(h_7 - h_8\right) \tag{9.4.14}$$

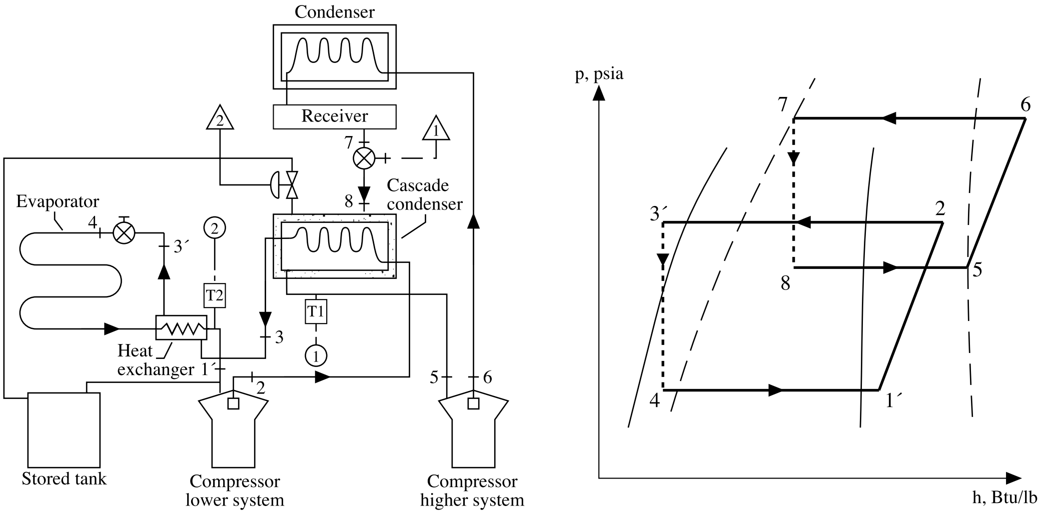
where $h_{5'}$, h_7, h_8 = enthalpy of the refrigerant at state points 5′, 7, and 8, respectively, Btu/lb. The coefficient of performance of the refrigeration cycle of a two-stage compound system with a flash cooler, COP_{ref}, is given as

$$\text{COP}_{ref} = q_{rf}/W_{in} = (1-x)\left(h_1 - h_9\right)/\left[(1-x)\left(h_2 - h_1\right) + \left(h_4 - h_3\right)\right] \tag{9.4.15}$$

where h_1, h_2, h_3, h_4, h_9 = enthalpy of refrigerant at state points 1, 2, 3, 4, and 9, respectively, Btu/lb. The mass flow rate of refrigerant flowing through the condenser, $\overset{\circ}{m}_r$, in lb/min, can be calculated as

$$\overset{\circ}{m}_r = q_{rc}/60q_{rf} \tag{9.4.16}$$

Because a portion of liquid refrigerant is flashed into vapor in the flash cooler and goes directly to the second-stage impeller inlet, less refrigerant is compressed in the first-stage impeller. In addition, the



(a)

(b)

FIGURE 9.4.4 Cascade system: (a) schematic diagram and (b) refrigeration cycle.

liquid refrigerant in the flash cooler is cooled to the saturated temperature corresponding to the interstage temperature before entering the evaporator, which significantly increases the refrigeration effect of this compound system. Two-stage compound systems with flash coolers are widely used in large central air-conditioning systems.

Cascade System Characteristics

A *cascade system* consists of two independently operated single-stage refrigeration systems: a lower system that maintains a lower evaporating temperature and produces a refrigeration effect and a higher system that operates at a higher evaporating temperature as shown in Figure 9.4.4(a) and (b). These two separate systems are connected by a *cascade condenser* in which the heat released by the condenser in the lower system is extracted by the evaporator in the higher system.

A heat exchanger is often used between the liquid refrigerant from the condenser and the vapor refrigerant leaving the evaporator of the lower system. When the system is shut down in summer, a relief valve connected to a stored tank should be used to relieve the higher pressure of refrigerant at the higher storage temperature.

The main advantages of a cascade system compared with a compound system are that different refrigerants, oils, and equipment can be used for the lower and higher systems. Disadvantages are the overlap of the condensing temperature of the lower system and the evaporating temperature of the higher system because of the heat transfer in the cascade condenser and a more complicated system.

The refrigeration effect q_{rf} of the cascade system is

$$q_{\mathrm{rf}} = \left(h_1 - h_4\right) \tag{9.4.17}$$

where h_1, h_4 = enthalpy of the refrigerant leaving and entering the evaporator of the lower system, Btu/lb. The total work input to the compressors in both higher and lower systems W_{in}, in Btu/lb, can be calculated as

$$W_{\mathrm{in}} = \left(h_2 - h_{1'}\right) + \mathring{m}_{\mathrm{h}}\left(h_6 - h_5\right)\Big/\mathring{m}_1 \tag{9.4.18}$$

where

h_2 = enthalpy of refrigerant discharged from the compressor of the lower system
$h_{1'}$ = enthalpy of the vapor refrigerant leaving the heat exchanger
h_6, h_5 = enthalpy of the refrigerant leaving and entering the high-stage compressor
$\mathring{m}_h, \mathring{m}_1$ = mass flow rate of the refrigerant of the higher and lower systems, respectively

The coefficient of performance of a cascade system $\mathrm{COP}_{\mathrm{ref}}$ is

$$\mathrm{COP}_{\mathrm{ref}} = q_{\mathrm{rf}}/W_{\mathrm{in}} = \mathring{m}_1\left(h_1 - h_4\right)\Big/\left[\mathring{m}_1\left(h_2 - h_{1'}\right) + \mathring{m}_h\left(h_6 - h_5\right)\right] \qquad (9.4.19)$$

9.5 Outdoor Design Conditions and Indoor Design Criteria

Shan K. Wang

Outdoor Design Conditions

In principle, the capacity of air-conditioning equipment should be selected to offset or compensate for the space load so that indoor design criteria can be maintained if the outdoor weather does not exceed the design values. Outdoor and indoor design conditions are used to calculate the design space loads. In energy use calculations, hour-by-hour outdoor climate data of a design day should be adopted instead of summer and winter design values.

ASHRAE Handbook 2001 Fundamentals (Chapter 27) and *Wang's Handbook of Air Conditioning and Refrigeration* (Chapter 7) both list tables of climate conditions for the U.S. and Canada based on the data from the National Climate Data Center (NCDC), U.S. Air Force, U.S. Navy, and Canadian Atmospheric Environment Service.

Indoor Design Criteria and Thermal Comfort

Indoor design criteria, such as space temperature, humidity, and air cleanliness, specify the requirements for the indoor environment as well as the quality of an air-conditioning or HVAC&R project.

The human body requires energy for physical and mental activity. This energy comes from the oxidation of food. The rate of heat release from the oxidation process is called the *metabolic rate*, expressed in met (1 met = 18.46 Btu/h.ft^2). The metabolic rate depends mainly on the intensity of the physical activity of the human body. Heat is released from the human body by two means: *sensible heat exchange* and *evaporative heat loss*. Experience and experiments all show that there is thermal comfort only under these conditions:

- Heat transfer from the human body to the surrounding environment causes a steady state of thermal equilibrium; that is, there is no heat storage in the body core and skin surface.
- Evaporative loss or regulatory sweating is maintained at a low level.

The physiological and environmental factors that affect the thermal comfort of the occupants in an air-conditioned space are mainly:

1. Metabolic rate M determines the amount of heat that must be released from the human body.
2. *Indoor air temperature* T_r and *mean radiant temperature* T_{rad}, both in °F. The *operating temperature* T_o is the weighted sum of T_r and T_{rad}. T_{rad} is defined as the temperature of a uniform black enclosure in which the surrounded occupant would have the same radiative heat exchange as in an actual indoor environment. T_r affects both the sensible heat exchange and evaporative losses, and T_{rad} affects only sensible heat exchange. In many indoor environments, $T_{\mathrm{rad}} \approx T_r$.
3. Relative humidity of the indoor air φ_r, in %, which is the primary factor that influences evaporative heat loss.
4. Air velocity of the indoor air v_r, in fpm, which affects the heat transfer coefficients and therefore the sensible heat exchange and evaporative loss.
5. *Clothing insulation* R_{cl}, in clo (1 clo = 0.88 h.ft^2.°F/Btu), affects the sensible heat loss. Clothing insulation for occupants is typically 0.6 clo in summer and 0.8 to 1.2 clo in winter.

Indoor Temperature, Relative Humidity, and Air Velocity

For comfort air-conditioning systems, according to ANSI/ASHRAE Standard 55-1992, the following indoor design temperatures and air velocities apply for conditioned spaces where the occupant's activity level is $\leqslant$1.2 met, mean air speed $\leqslant$ 30 fpm, indoor space relative humidity is 50% (in summer only), and $T_r = T_{rad}$:

	Clothing Insulation (clo)	Indoor Temperature (°F)
Winter	0.9	68–75
Summer	0.5	73–79

Regarding the indoor humidity:

1. Many comfort air-conditioning systems are not equipped with humidifiers. Winter indoor relative humidity should not be specified in such circumstances.
2. When comfort air-conditioning systems are installed with humidifiers, ASHRAE/IES Standard 90.1-2001 provides specific requirements for economy of operation.
3. Indoor relative humidity should not exceed 75% to avoid increasing bacterial and viral populations.
4. For air-conditioning systems that use flow rate control in a chilled water cooling coil, space indoor relative humidity may be substantially higher in part load than at full load.

Therefore, for comfort air-conditioning systems, the recommended indoor relative humidities, in %, are

	Tolerable range	Preferred value
Summer	30–65	40–50
Winter		
With humidifier		25–30
Without humidifier		Not specified

In surgical rooms or similar health care facilities, the indoor relative humidity is often maintained at 40 to 60% year round.

Indoor Air Quality and Outdoor Ventilation Air Requirements

According to the National Institute for Occcupational Safety and Health (NIOSH), 1989, the causes of indoor air quality complaints in buildings are inadequate outdoor ventilation air, 53%; indoor contaminants, 15%; outdoor contaminants, 10%; microbial contaminants, 5%; construction and furnishings, 4%; unknown and others, 13%. For space served by air-conditioning systems using low- and medium-efficiency air filters, according to the U.S. Environmental Protection Agency (EPA) and Consumer Product Safety Commission (CPSC) publication "A Guide to Indoor Air Quality" (1988) and the field investigations reported by Bayer and Black (1988), *indoor air contaminants* may include some of the following:

1. *Total particulate concentration*. This concentration comprises particles from building materials, combustion products, mineral fibers, and synthetic fibers. In February 1989, the EPA specified the allowable indoor concentration of particles of 10 μm and less in diameter (which penetrate deeply into lungs) as:

   50 μg/m^3 (0.000022 grain/ft^3), 1 year

   150 μg/m^3 (0.000066 grain/ft^3), 24 hr

   In these specifications, "1 year" means maximum allowable exposure per day over the course of a year.
2. *Formaldehyde and organic gases*. Formaldehyde is a colorless, pungent-smelling gas. It comes from pressed wood products, building materials, and combustion. Formaldehyde causes eye, nose, and

throat irritation as well as coughing, fatigue, and allergic reactions. Formaldehyde may also cause cancer. Other organic gases come from building materials, carpeting, furnishings, cleaning materials, etc.

3. *Radon*. Radon, a colorless and odorless gas, is released by the decay of uranium from the soil and rock beneath buildings, well water, and building materials. Radon and its decay products travel through pores in soil and rock and infiltrate into buildings along the cracks and other openings in the basement slab and walls. Radon at high levels causes lung cancer. The EPA believes that levels in most homes can be reduced to 4 pCi/l (picocuries per liter) of air. The estimated national average is 1.5 pCi/l, and levels as high as 200 pCi/l have been found in houses.
4. *Biologicals*. These include bacteria, fungi, mold and mildew, viruses, and pollen. They may come from wet and moist walls, carpet furnishings, and poorly maintained dirty air-conditioning systems and may be transmitted by people. Some biological contaminants cause allergic reactions, and some transmit infectious diseases.
5. *Combustion products*. These include environmental tobacco smoke, nitrogen dioxide, and carbon monoxide. *Environmental tobacco* smoke from cigarettes is a discomfort factor to other persons who do not smoke, especially children. Nicotine and other tobacco smoke components cause lung cancer, heart disease, and many other diseases. *Nitrogen dioxide* and *carbon monoxide* are both combustion products from unvented kerosene and gas space heaters, woodstoves, and fireplaces. Nitrogen dioxide (NO_2) causes eye, nose, and throat irritation; may impair lung function; and increases respiratory infections. Carbon monoxide (CO) causes fatigue at low concentrations; impaired vision, headache, and confusion at higher concentrations; and is fatal at very high concentrations. Houses without gas heaters and gas stoves may have CO levels varying from 0.5 to 5 parts per million (ppm).
6. *Human bioeffluents*. These include the emissions from breath including carbon dioxide exhaled from the lungs, body odors from sweating, and gases emitted as flatus.

There are three basic means of reducing the concentration of indoor air contaminants and improving indoor air quality: (1) eliminate or reduce the source of air pollution, (2) enhance the efficiency of air filtration, and (3) increase the ventilation (outdoor) air intake. Dilution of the concentrations of indoor contaminants by outdoor ventilation air is often the simple and cheapest way to improve indoor air quality. The amount of outdoor air required for metabolic oxidation is rather small.

Outdoor air requirements listed in ANSI/ASHRAE Standard 62-1999 can be used in the ventilation procedure method to satisfy indoor air quality requirements. The minimum outside air ventilation per person for any type of space is 15 cfm.

This requirement is based on the analysis of dilution of CO_2 as the representative human bioeffluent to an allowable indoor concentration within 0.07% (700 ppm) of the outdoor concentration. Field measurements of daily maximum CO_2 levels in office buildings reported by Persily (1993) show that most of them were within the range 400 to 820 ppm. The quality of outdoor air must meet the EPA's National Primary and Secondary Ambient Air Quality Standards, some of which is listed below:

	Long-Term Concentration			Short-Term Concentration		
Pollutants	µg/m³	ppm	Exposure	µg/m³	ppm	Exposure
Particulate	75		1 year	260		24 hr
SO_2	80	0.03	1 year	365	0.14	24 hr
CO				40,000	35	1 hr
				10,000	9	8 hr
NO_2	100	0.055	1 year			
Lead	1.5		3 months			

Here exposure means average period of exposure.

If unusual contaminants or unusually strong sources of contaminants are introduced into the space, or recirculated air is to replace part of the outdoor air supply for occupants, then acceptable indoor air quality is achieved by controlling known and specific contaminants. This is called an indoor air quality procedure. Refer to ANSI/ASHRAE Standard 62-1999 for details.

Clean Rooms

Electronic, pharmaceutical, and aerospace industries and operating rooms in hospitals all need strict control of air cleanliness during manufacturing and operations. According to ASHRAE Handbook 1991 HVAC Applications, clean rooms can be classified as follows based on the particle count per ft^3:

Class	Particle Size 0.5 µm and Larger	 5 µm and Larger
	Particle Count per ft^3 Not to Exceed	
1	1	0
10	10	0
100	100	
1000	1000	
10,000	10,000	65
100,000	100,000	700

For clean rooms, space temperature is often maintained at 72 ± 2°F and space humidity at 45 ± 5%. Here, ±2°F and ±5% are allowable tolerances. Federal Standard 209B specifies that the ventilation (outdoor air) rate should be 5 to 20% of the supply air.

Space Pressure Differential

Most air-conditioning systems are designed to maintain a slightly higher pressure than the surroundings, a positive pressure, to prevent or reduce infiltration and untreated air entering the space directly. For laboratories, restrooms, or workshops where toxic, hazardous, or objectional gases or contaminants are produced, a slightly lower pressure than the surroundings, a negative pressure, should be maintained to prevent or reduce the diffusion of these contaminants' exfiltrate to the surrounding area.

For comfort air-conditioning systems, the recommended pressure differential between the indoor and outdoor air is 0.02 to 0.05 in in. WG. WG indicates the pressure at the bottom of a top-opened water column of specific inches of height; 1 in. WG = 0.03612 psig.

For clean rooms, Federal Standard No. 209B, Clean Rooms and Work Stations Requirements (1973), specifies that the minimum positive pressure between the clean room and any adjacent area with lower cleanliness requirements should be 0.05 in. WG with all entryways closed. When the entryways are open, an outward flow of air is to be maintained to prevent migration of contaminants into the clean room. In comfort systems, the space pressure differential is usually not specified in the design documents.

Sound Levels

Noise is any unwanted sound. In air-conditioning systems, noise should be attenuated or masked with another less objectionable sound.

Sound power is the capability to radiate power from a sound source exited by an energy input. The intensity of sound power is the output from a sound source expressed in watts (W). Due to the wide variation of sound output at a range of 10^{20} to 1, it is more convenient to use a logarithmic expression to define a *sound power level* L_w, in dB:

$$L_w = 10 \log\left(w/10^{-12}\ \mathrm{W}\right) \text{ re 1 pW} \tag{9.5.2}$$

where w = sound source power output, W.

The human ear and microphones are sound pressure sensitive. Similarly to the sound power level, the *sound pressure level* L_p, in dB, is defined as:

$$L_p = 20\log\left(p/2\times10^{-5}\ \text{Pa}\right)\ \text{re}\ 20\ \mu\text{Pa} \qquad (9.5.3)$$

where p = sound pressure, Pa.

The sound power level of any sound source is a fixed output. It cannot be measured directly; it can only be calculated from the measured sound pressure level. The sound pressure level at any one point is affected by the distance from the source and the characteristics of the surroundings.

Human ears can hear frequencies from 20 Hz to 20 kHz. For convenience in analysis, sound frequencies are often subdivided into eight octave bands. An *octave* is a frequency band in which the frequency of the upper limit of the octave is double the frequency of the lower limit. An octave band is represented by its center frequency, such as 63, 125, 250, 500, 1000, 2000, 4000, and 8000 Hz. On 1000 Hz the octave band has a higher limit of 1400 Hz and a lower limit of 710 Hz. Human ears do not respond in the same way to low frequencies as to high frequencies.

The object of noise control in an air conditioned space is to provide background sound low enough that it does not interfere with the acoustical requirements of the occupants. The distribution of background sound should be balanced over a broad range of frequencies, that is, without whistle, hum, rumble, and beats.

The most widely used criteria for sound control are the noise criteria NC curves. The shape of NC curves is similar to the equal-loudness contour representing the response of the human ear. NC curves also intend to indicate the permissible sound pressure level of broad-band noise at various octave bands rated by a single NC curve. NC curves are practical and widely used.

Other criteria used are room criteria RC curves and A-weighted sound level, dBA. RC curves are similar to NC curves except that the shape of the RC curves is a close approximation to a balanced, bland-sounding spectrum. The A-weighted sound level is a single value and simulates the response of the human ear to sound at low sound pressure levels.

The following are abridged indoor design criteria, NC or RC range, listed in *ASHRAE Handbook 1987 Systems and Applications*:

Type of Area	Recommended NC or RC Range (dB)
Hotel guest rooms	30–35
Office	
Private	30–35
Conference	25–30
Open	30–35
Computer equipment	40–45
Hospital, private	25–30
Churches	25–30
Movie theaters	30–35

For industrial factories, if the machine noise in a period of 8 hr exceeds a prescribed level given in dBA, Occupational Safety and Health Administration Standard Part 1910.95 requires the occupants to use personal protection equipment. If the period is shorter, the dBA level can be slightly higher. Refer to this standard for details.

9.6 Principles of Load Calculations

Ari Rabl and Peter Curtiss

Design Conditions

Loads are the heat that must be supplied or removed by HVAC equipment to maintain a space at the desired conditions. Loads depend on the indoor conditions that one wants to maintain and on the weather. The latter is not known in advance. If the HVAC equipment is to guarantee comfort at all times, it must be designed for peak conditions. What are the extremes? For most buildings it would not be practical to aim for total protection by choosing the most extreme weather on record and adding a safety margin. Such oversizing of the HVAC equipment would be excessive, not just in initial cost but also in operating cost; most of the time, the equipment would run with poor part-load efficiency. Therefore, compromise — reducing the cost of the HVAC equipment significantly while accepting the risk of slight discomfort under rare extremes of weather — is necessary. The greater the extreme is, the more rarely it occurs.

Wind speed is another weather-dependent variable that has a bearing on loads. Traditionally the ASHRAE (2001) value

$$v_{win} = 15 \text{ mi/h } \left(6.7 \text{ m/s}\right) \tag{9.6.1}$$

has been recommended for heating loads, if extreme conditions (such as an exposed hilltop location) are not implied. For cooling loads, a value half as large is recommended:

$$V_{sum} = 7.5 \text{ mi/s } \left(3.4 \text{ m/s}\right) \tag{9.6.2}$$

because wind tends to be less strong in summer than in winter. Of particular interest is the surface heat transfer coefficient (radiation plus convection) h_o for which ASHRAE (2001) recommends the design values:

$$h_{o,win} = 6.0 \text{ Btu}\Big/\left(\text{h}\cdot\text{ft}^2\cdot{}^\circ\text{F}\right) \;\; 34.0 \text{ W}\Big/\left(\text{m}^2\cdot\text{K}\right) \tag{9.6.3}$$

$$h_{o,sum} = 4.0 \text{ Btu}\Big/\left(\text{h}\cdot\text{ft}^2\cdot{}^\circ\text{F}\right) \;\; 22.7 \text{ W}\Big/\left(\text{m}^2\cdot\text{K}\right) \tag{9.6.4}$$

This coefficient is only one of several components of the calculation of thermal loads, and it enters only through the building heat transmission coefficient defined in the next section. The better a building is insulated and tightened, the less its heat transmission coefficient K_{tot} depends on wind. With current practice for new construction in the United States, typical wind speed variations may change the heat transmission coefficient by about 10% relative to the value at design conditions.

Building Heat Transmission Coefficient

One of the most important terms in the heat balance of a building is the heat flow across the envelope. Heat flow can be assumed to be linear in the temperature difference when the range of temperatures is sufficiently small; this is usually a good approximation for heat flow across the envelope. Thus, one can calculate the heat flow through each component of the building envelope as the product of its area A; its conductance U; and the difference $T_i - T_o$ between the interior and outdoor temperatures.

The total conductive heat flow from interior to exterior is

$$\dot{Q}_{cond} = \sum_k U_k A_k (T_i - T_o), \tag{9.6.5}$$

with the sum running over all parts of the envelope that have a different composition. It is convenient to define a total conductive heat transmission coefficient K_{cond}, or UA value, as

$$K_{cond} = \sum_k U_k A_k \tag{9.6.6}$$

so that the conductive heat flow for the typical case of a single interior temperature T_i can be written as

$$\dot{Q}_{cond} = K_{cond}(T_i - T_o) \tag{9.6.7}$$

In most buildings, the envelope consists of a large number of different parts; the greater the desired accuracy is, the greater the amount of detail to be taken into account.

As a simplification, one can consider a few major groups and use effective values for each. The three main groups are glazing, opaque walls, and roof. The reason for distinguishing the wall and the roof lies in the thickness of the insulation: roofs tend to be better insulated because it is easier and less costly to add extra insulation there than in the walls. With these three groups, one can write

$$K_{\mathrm{cond}} = U_{\mathrm{glaz}} A_{\mathrm{glaz}} + U_{\mathrm{wall}} A_{\mathrm{wall}} + U_{\mathrm{roof}} A_{\mathrm{roof}} \tag{9.6.8}$$

if one takes for each the appropriate effective value. Results for aggregate U values for walls and roofs of typical construction can be found in ASHRAE lookup tables.

In the energy balance of a building, one other term is proportional to $T_i - T_o$. It is the flow of sensible heat [W (Btu/h)] due to air exchange:

$$\dot{Q}_{air} = \rho c_p \dot{V}(T_i - T_o) \tag{9.6.9}$$

where

ρ = density of air
c_p = specific heat of air
$\dot{V}$ = air exchange rate ft³/h (m³/s)

At standard conditions, 14.7 psia (101.3 kPa) and 68°F (20°C), the factor ρc_p has the value

$$\rho c_p = 0.018 \text{ Btu/(ft}^3 \cdot {}^\circ\text{F) } [1.2 \text{ kJ/(m}^3 \cdot \text{K)}] \tag{9.6.10}$$

In USCS units, if $\dot{V}$ is in cubic feet per minute, it must be converted to cubic feet per hour by multiplying by 60 (ft³/h)/(ft³/min). It is convenient to combine the terms proportional to $T_i - T_o$ by defining the total heat transmission coefficient K_{tot} of the building as the sum of conductive and air change terms:

$$K_{\mathrm{tot}} = K_{cond} + \rho c_p \dot{V} \tag{9.6.11}$$

Note that $\dot{V}$ increases with the temperature difference for a number of reasons (see Kreider et al., 2001).

Heat Gains

Heat gains affect heating as well as cooling loads. In addition to solar gains, heat gains occur from occupants, lights, and equipment such as appliances, motors, computers, and copiers. Power densities for lights in office buildings are around 20 to 30 W/m². For lights and for resistive heaters, the nominal power rating (i.e., the rating on the label) is usually close to the power drawn in actual use. However, for office equipment, that would be quite misleading; the actual power has been measured to be much lower, often by a factor of two to four (Norford et al., 1989). Some typical values are indicated in Table 9.6.1. In recent decades, the computer revolution has brought a rapid increase in electronic office equipment, and the impact on loads has become quite important, comparable to that of lighting. The energy consumption for office equipment is uncertain: will the occupants turn off the computers between uses or keep them running nights and weekends?

For special equipment such as laboratories or kitchens, it is advisable to estimate the heat gains by taking a close look at the inventory of the equipment to be installed, paying attention to the possibility that much of the heat may be drawn directly to the outside by exhaust fans.

TABLE 9.6.1 Typical Heat Gain Rates for Several Kinds of Equipment

Equipment	Heat Gain Btu/h	Heat Gain W	Comments
Television set	170–340	50–100	
Refrigerator	340–680	100–200	Recent models more efficient
Personal computer (desktop)	170–680	50–200	Almost independent of use while turned on
Impact printer	34–100	10–30 standby	Increases about twofold during printing
Laser printer	500	150 standby	Increases about twofold during printing
Copier	500–1000	150–300 standby	Increases about twofold during printing

Note: Measured values are often less than half of the nameplate rating.

TABLE 9.6.2 Nominal Heat Gain Values from Occupants

	Total		Sensible		Latent	
Activity	Btu/h	W	Btu/h	W	Btu/h	W
Seated at rest	340	100	240	70	100	30
Seated, light office work	410	120	255	75	150	45
Standing or walking slowly	495	145	255	75	240	70
Light physical work	850	250	310	90	545	160
Heavy physical work	1600	470	630	185	970	285

Source: Based on ASHRAE, 1989, *Handbook of Fundamentals*. American Society of Heating, Refrigerating and Air-Conditioning Engineers, Atlanta.

Heat gain from occupants depends on the level of physical activity. Nominal values are listed in Table 9.6.2. It is instructive to reflect on the origin of this heat gain. The total heat gain must be close to the caloric food intake because most of the energy is dissipated from the body as heat. An average of 100 W corresponds to

$$100 \text{ W} = 0.1 \text{ kJ/s} \times \left(\frac{1\,kcal}{4.186\,kJ}\right) \times (24 \times 3600 \text{ s/day}) = 2064 \text{ kcal/day} \tag{9.6.12}$$

indeed, a reasonable value compared to the typical food intake (note that the dietician's calorie is really a kilocalorie).

The latent heat gain must be equal to the heat of vaporization of water that is exhaled or transpired. Dividing 30 W by the heat of vaporization of water, yields a water quantity of 30 W/(2450 kJ/kg) = 12.2×10^{-6} kg/s, or about 1.1 kg/24 h. That also appears quite reasonable.

The latent heat gain due to the air exchange is

$$\dot{Q}_{air,lat} = \dot{V}\rho h_{fg}(W_o - W_i) \tag{9.6.13}$$

where

$\dot{V}$ = volumetric air exchange rate, ft^3/min (m^3/s or L/s)

ρ = density, lb$_m$/ft^3 (kg/m^3)

$\rho\, h_{fg}$ = 4840 Btu/(h · ft^3/min) [3010 W/(L/s)] at standard conditions

W_i, W_o = humidity ratios of indoor and outdoor air

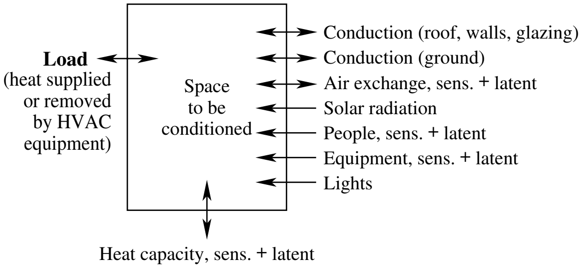

FIGURE 9.6.1 The terms in a load calculation.

Heat Balance

Load calculations are like accounting. One considers all the heat that is generated in the space or flows across the envelope; the total energy, including the thermal energy stored in the space, must be conserved according to the first law of thermodynamics. The principal terms are indicated in Figure 9.6.1. Outdoor air, occupants, and possibly certain kinds of equipment contribute sensible and latent heat terms.

Load calculations are straightforward in the static limit, i.e., if all input is constant. As discussed in the following subsection, that is usually an acceptable approximation for the calculation of peak heating loads. However, for cooling loads, dynamic effects (i.e., heat storage) must be taken into account because some of the heat gains are absorbed by the mass of the building and do not contribute to the loads until several hours later. Dynamic effects are also important whenever the indoor temperature is allowed to float.

Sometimes it is appropriate to distinguish several aspects of the load. If the indoor temperature is not constant, the instantaneous load of the space may differ from the rate at which heat is being supplied or removed by the HVAC equipment. The load for the heating or cooling plant is different from the space load if there are significant losses from the distribution system or if part of the air is exhausted to the outside rather than returned to the heating or cooling coil. It is convenient to classify the terms of the static energy balance according to the following groups. The sensible energy terms are:

- Conduction through building envelope other than ground:

$$\dot{Q}_{cond} = K_{cond}(T_i - T_o) \tag{9.6.14}$$

- Conduction through floor, $\dot{Q}_{floor}$
- Heat due to air exchange (infiltration and/or ventilation), at rate $\dot{V}$:

$$\dot{Q}_{air} = \dot{V}\rho c_p(T_i - T_o) \tag{9.6.15}$$

- Heat gains from solar radiation, lights, equipment (appliances, computers, fans, etc.), and occupants:

$$\dot{Q}_{gain} = \dot{Q}_{sol} + \dot{Q}_{lit} + \dot{Q}_{equ} + \dot{Q}_{occ} \tag{9.6.16}$$

Combining the heat loss terms and subtracting the heat gains, one obtains the total *sensible load*:

$$\dot{Q} = \dot{Q}_{cond} + \dot{Q}_{air} + \dot{Q}_{floor} - \dot{Q}_{gain} \pm \dot{Q}_{stor} \tag{9.6.17}$$

where a term, $\dot{Q}_{stor}$, has been added on the right to account for storage of heat in the heat capacity of the building (the terms *thermal mass* and *thermal inertia* are also used to designate this effect). A dynamic analysis includes this term; a static analysis neglects it.

$\dot{Q}_{floor}$ has been kept as a separate item because it should not be taken proportional to $T_i - T_o$ except in cases like a crawl space, where the floor is in fairly direct contact with outside air. More typical is conduction through massive soil, for which other methods are required. In traditional construction, the floor term has usually been small, and often it has been neglected altogether; however, in superinsulated buildings it can be relatively important.

Using the total heat transmission coefficient K_{tot},

$$K_{tot} = K_{cond} + \dot{V}\rho c_p \tag{9.6.18}$$

one can write the sensible load in the form

$$\dot{Q} = K_{tot}(T_i - T_o) + \dot{Q}_{floor} - \dot{Q}_{gain} \pm \dot{Q}_{stor} \tag{9.6.19}$$

For signs, take the convention that $\dot{Q}$ is positive when there is a heating load and negative when there is a cooling load. Sometimes, however, it will be preferable to have a positive sign for cooling loads. In that case, subscripts c and h will be added with the understanding that

$$\dot{Q}_c = -\dot{Q} \text{ and } \dot{Q}_h = \dot{Q} \tag{9.6.20}$$

The *latent heat gains* are mainly due to air exchange, equipment (such as in the kitchen and bathroom), and occupants. Their sum is

$$\dot{Q}_{lat} = \dot{Q}_{lat,air} + \dot{Q}_{lat,occ} + \dot{Q}_{lat,equ} \tag{9.6.21}$$

The total load is the sum of the sensible and the latent loads.

During the heating season, the latent gain from air exchange is usually negative (with the signs of Equation 9.6.13) because the outdoor air is relatively dry. A negative Q_{lat} implies that the total heating load is greater than the sensible heating load alone, but this is relevant only if humidification can maintain the specified humidity ratio W_i. For buildings without humidification, one has no control over W_i, and it is pointless to calculate the latent contribution to the heating load at a fictitious value of W_i.

Zones

So far the interior has been considered as a single zone at uniform temperature — a fair approximation for simple houses, for certain buildings without windows (such as warehouses), or for buildings dominated by ventilation. In large or complex buildings, however, one must usually calculate the loads separately for a number of different zones, for several reasons. An obvious case is a building in which different rooms are maintained at different temperatures, e.g., a house with an attached sunspace. Here, the heat balance equation is written for each zone, but with an additional term:

$$\dot{Q}_{j-k} = U_{j-k} A_{j-k}(T_j - T_k) \tag{9.6.22}$$

for the heat flow between zones j and k.

However, even when the entire building is kept at the same temperature, multizone analysis becomes necessary if the spatial distribution of heat gains is too nonuniform. Consider, for example, a building with large windows on the north and south sides, during a sunny winter day when the gains just balance the total heat loss. In that case, neither heating nor cooling would be required, according to a one-zone analysis — but how can the heat from the south get to the north?

Heat flow is the product of the heat transfer coefficient and the temperature difference, as in Equation (9.6.22). Temperature differences between occupied zones are small, usually not more than a few Kelvins;

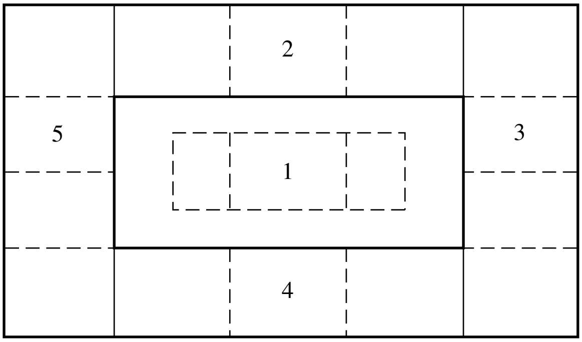

FIGURE 9.6.2 Example of recommended zoning. Thick lines represent zones, labeled 1 through 5. Dashed lines represent subzones.

otherwise there would be complaints about comfort. The heat transfer coefficients between zones are often not sufficiently large for effective redistribution of heat, especially if walls or partitions are part of the space — thus the thermodynamically perverse fact that many large buildings require simultaneous heating and cooling.

The problem of divergent zone loads is one of the prime targets for energy conservation in large buildings. The first step is to reduce the loads through the envelope, by improved insulation and control of solar radiation. The smaller the loads are, the smaller the differences between the loads. Careful attention must be paid to the design of the HVAC system and the choice of its zones. Finally, heat pump may be able to recover and redistribute heat between zones.

The basic criterion for zoning is the ability to control the comfort conditions; the control is limited by the number of zones one is willing to consider. *To guarantee comfort, the HVAC plant and distribution system must be designed with sufficient capacity to meet the load of each zone.* In choosing the zones for a multizone analysis, the designer should try to match the distribution of heat gains and losses. A common and important division is between interior and perimeter zones, because the interior is not exposed to the changing environment. Different facades of the perimeter should be considered separately for cooling load calculations, as suggested in Figure 9.6.2. Corner rooms should be assigned to the facade with which they have the most in common; usually, this will be the facade where a corner room has the largest windows. Corner rooms are often the critical rooms in a zone, requiring more heating or cooling (per unit floor area) than single-facade rooms of the same zone.

Actually, a zoning analysis has different levels, corresponding to different levels of the HVAC system. In an air system, major zones correspond to each air handler. Within each air handler zone, the air ducts, air outlets, and heating or cooling coils must have sufficient capacity and controllability to satisfy the loads of each subzone; the design flow rates for each room are scaled according to the design loads of the room. For best comfort (and if cost were no constraint), each zone should have its own air handler and each room its own thermostat. There is a tradeoff between equipment cost and achievable comfort, and the best choice depends on the circumstances. If temperature control is critical, one installs separate air handlers for each of the five zones in Figure 9.6.2 and separate thermostats for each room. To save equipment cost, one often assigns several zones to one air handler and several rooms to one thermostat; however, the more divergent the loads are, the more problematic the control. For the building of Figure 9.6.2, a single air handler and five thermostats may be adequate if the distribution of heat gains is fairly uniform and if the envelope is well insulated, with good control of solar gains.

Another example is a house in which air distribution system has a single fan (typical of all but the largest houses). Even though there is only one major zone, the detailed design of the distribution system demands some attention to subzones. Within each room, the peak heating capacity should match the peak heat loss. Also, it is advisable to place heat sources close to points with large heat loss, i.e., under windows (unless they are highly insulating).

The choice of zones is not always clear-cut, and the design process may be iterative. Depending on the distribution of gains and losses, one may want to assign several rooms to a zone, one room to a zone, or even several zones to a room (if it is very large). With finer zonal detail, one improves the control of comfort, but at the price of greater calculation effort and higher HVAC system cost. In an open office space, no obvious boundary exists between interior and perimeter; here a good rule is to make the perimeter zone as deep as the penetration depth of direct solar radiation, typically a few meters. Spaces connected by open doors, for example, offices and adjacent hallways, can sometimes be treated as a single zone. Separate zones are advisable for rooms with large computers or energy-intensive equipment. In multistory buildings, one may want to treat the top floor apart from the rest.

The calculation of peak *heating* loads and capacities can often be done without defining different perimeter zones because peak heating loads occur when the sun is not present; with uniform internal gains, the corresponding thermal balance is uniform around the perimeter. Although the calculation can be carried out for a single zone, the operation requires multiple zones because the heating system must allow separate control of different facades to compensate for the variability of solar gains during the day. For *cooling* loads, a multizone analysis is essential, even at the calculation stage, because the loads occur when the sun is shining.

Peak cooling loads require a dynamic analysis whereas peak heating loads can be estimated quite well by static models (at least in the absence of thermostat setback). Compared to heating loads, the calculation of cooling loads of large buildings is thus doubly complicated: It requires multiple zones and dynamic analysis if one wants reasonable accuracy.

A related issue is the coincidence between peak loads of different zones. To determine the capacity of the central plant, one needs to know the peak load of the totality of zones served by the plant. This is usually less than the simple sum of the individual peak loads because of noncoincidence. The term *diversity* is used to designate the ratio of the actual system peak to the sum of the individual peak loads. In practice, one often finds diversity around 0.6 to 0.8 for large buildings or groups of buildings (e.g., university campuses); for better estimates at the design stage, computer simulations are recommended.

Heating Loads

Because the coldest weather is likely to occur during periods without solar radiation, it is advisable not to rely on the benefit of solar heat gains when calculating peak heating loads (unless the building contains long-term storage). If the indoor temperature T_i is constant, a static analysis is sufficient and the calculation of the peak heating load $\dot{Q}_{h,\max}$ is very simple: find the design heat loss coefficient K_{tot}; multiply by the design temperature difference $T_i - T_o$; and subtract the internal heat gains on which one can count during the coldest weather:

$$\dot{Q}_{h,\max} = K_{tot}(T_i - T_o) - \dot{Q}_{gain} \tag{9.6.23}$$

What would happen if the thermostat were set back at night? For a rough indication, consider that a house of lightweight construction typical in the U.S. requires heat input at the rate of 1.2 kW if its temperature is increased by 2 K in 5 h. For setback recovery after winter nights, one might want rates that are several times faster, say, 4 K in 2.5 h. Assuming that the heat input is proportional to the warmup rate,[1] the extra load for setback recovery (also known as the *pickup load*) would be 4 × 1.2 kW = 4.8 kW, comparable to the static design heat load. In this case, the capacity of the heating system would need to be doubled relative to the case without setback.

In a given situation, the required extra capacity depends on the amount of setback $T_i - T_o$, the acceptable recovery time, and building construction. For reasonable accuracy, a dynamic analysis is recommended.

---

[1] Actually, at faster rates the effective heat capacity is smaller (the heat pulse takes longer than 1 h to penetrate the entire mass); thus, the real increment for setback recovery is less. One does not know how much without a detailed dynamic analysis.

Optimizing the capacity of the heating system involves a tradeoff between energy savings and capacity savings, with due attention to part-load efficiency. As a general rule for residences, ASHRAE (1989) recommends oversizing by about 40% for a night setback of 10°F (5.6 K), to be increased to 60% oversizing if additional setback occurs during the day. In any case, some flexibility can be provided by adapting the operation of the building. If the capacity is insufficient, one can reduce the depth and duration of the setback during the coldest periods.

In commercial buildings with mechanical ventilation, the demand for extra capacity during setback recovery is reduced if the outdoor air intake is closed during unoccupied periods. In winter that should always be done for energy conservation (unless air quality problems demand high air exchange at night).

CLTD/SCL/CLF Method for Cooling Loads

Because of thermal inertia, it is advisable to distinguish several heat flow rates. The *heat gain* is the rate at which heat is transferred to or generated in a space. The *cooling load* is the rate at which the cooling equipment would have to remove thermal energy from the air in the space in order to maintain constant temperature and humidity. Finally, the *heat extraction rate* is the rate at which the cooling equipment actually does remove thermal energy from the space.

Conductive heat gains and radiative heat gains do not enter the indoor air directly; rather, they pass through the mass of the building, increasing its temperature relative to the air. Only gradually are they transferred to the air. Thus their contribution to the cooling load is delayed, and there is a difference between heat gain and cooling load. Averaged over time, these rates are, of course, equal, by virtue of the first law of thermodynamics.

The heat extraction rate is equal to the cooling load only if the temperature of the indoor air is constant (as assumed in this section). Otherwise the heat flow to and from the building mass causes the heat extraction rate to differ from the cooling load.

To account for transient effects without resorting to a full-fledged dynamic analysis, a special shorthand method has been developed that uses the *cooling load temperature difference (CLTD)* and *cooling load factor (CLF)*. To explain the principles, note that the cooling load due to conduction across an envelope element of area *A* and conductance *U* would be simply

$$\dot{Q}_{cond} = U\,A\,(T_o - T_i) \tag{9.6.24}$$

under static conditions, i.e., if indoor temperature T_i and outdoor temperature T_o were both constant. When the temperatures vary, this is no longer the case because of thermal inertia. However, if the temperatures follow a periodic pattern, day after day, $\dot{Q}_{c,cond}$ will also follow a periodic pattern. Once $\dot{Q}_{c,cond}$ has been calculated, one can define a CLTD as the temperature difference that gives the same cooling load when multiplied by *UA*. If such temperature differences are tabulated for typical construction and typical temperature patterns, they can be looked up for quick determination of the load. Thus, the conductive cooling load is

$$\dot{Q}_{cond,t} = U\,A\,\mathrm{CLTD}_t \tag{9.6.25}$$

where the subscript *t* indicates the hour *t* of the day.

Likewise, if there is a constant radiative heat gain in a zone, the corresponding cooling load is simply equal to that heat gain. If the heat gain follows a periodic pattern, the cooling load also follows a periodic pattern. The cooling load factor (CLF) is defined such that it yields the cooling load at hour *t* when multiplied by the daily maximum $\dot{Q}_{\max}$ of the heat gain:

$$\dot{Q}_{c,rad,t} = \dot{Q}_{\max}\ \mathrm{CLF}_t \tag{9.6.26}$$

The CLFs account for the fact that radiative gains (solar, lights, etc.) are first absorbed by the mass of the building, becoming a cooling load only as they are transferred to the air. Only convective gains can be counted as cooling load without delay. Some heat gains, for example, from occupants, are partly convective and partly radiative; the corresponding CLFs take care of that.

The CLTDs and CLFs of ASHRAE have been calculated by means of the transfer functions discussed in the next section. To keep the bulk of numerical data within reasonable limits, only a limited set of standard construction types and operating conditions has been considered. Some correction factors are available to extend the applicability, however, without escaping the constraint that the indoor temperature T_i be constant. For a list of these factors, see ASHRAE (2001) or Kreider et al. (2001).

Roof CLTD Value Selection

The CLTD/SCL/CLF method uses 10 types of roofs. The roof types are numbered 1, 2, 3, 4, 5, 8, 9, 10, 13, and 14. The roof type chosen depends on the principal roof material; location of the mass in the roof; overall R value of the roof; and whether the ceiling is suspended.

The tables of new roof CLTD values are calculated based on an indoor temperature of 78°F, maximum and mean outdoor temperatures of 95 and 85°F, respectively, and a daily range of 21°F. Once the 24 CLTD values are selected, they are each adjusted by

$$\text{Corrected CLTD} = \text{CLTD} + (78 - T_i) + (T_{om} - 85) \tag{9.6.27}$$

where T_i is the actual inside design dry bulb temperature and T_{om} is the mean outside design dry bulb temperature,

$$T_{om} = \text{Outside design dry bulb temperature} - \frac{\text{Daily range}}{2} \tag{9.6.28}$$

No adjustments to the CLTD are recommended for color or ventilation. The CLTD charts are usually published for several different latitudes; interpolation between the latitudes for an exact site is acceptable.

Wall CLTD Value Selection

The CLTD/SCL/CLF uses 15 wall types numbered sequentially 1 through 16 with no wall 8. The wall type is chosen based on the principal wall material; secondary wall material; location of the mass in the wall; and overall wall R value. The tables of wall CLTD values are broken down by latitude. The wall CLTDs were calculated using the same conditions as the roof CLTD values and may require adjustments based on the actual inside and ambient conditions. Interpolation between the tables may be necessary to obtain the correct values for a given site.

Once the roof and wall CLTD values have been selected and adjusted as necessary, the conductive heat flow through the roof and walls is calculated for each hour t

$$q(t) = U\,A\,\text{CLTD}(t) \tag{9.6.29}$$

where

U = overall heat transfer coefficient for the surface (Btu/h·ft^2·°F)
A = area of surface
CLTD = cooling load temperature difference

Glass CLTD Value Selection

As with the roof and wall CLTDs, the fenestration CLTD values may need to be corrected. The conductive load calculation from the glass uses the same method as that for the roof and walls.

Solar Cooling Load

The solar cooling load (SCL) is used to calculate the radiative (solar) heat gain through any glass surface in the building. The radiative solar gains are then given by

$$q(t) = A \text{ SC SCL}(t) \tag{9.6.30}$$

where A is the area of the glass surface and SC is the shading coefficient. The shading coefficient is the ratio of the actual solar heat gain to that from the reference window used to calculate the SCL.

Using the SCL value tables requires that one know the number of walls, floor covering, and inside shading, as well as a number of other variables for the zone. The tables are also broken down by building type, with different tables for zones in

- Single-story buildings
- Top floor of multistory buildings
- Middle floors of multistory buildings
- First floor of multistory buildings

The zone types used for determining the SCL are not necessarily the same zone type used for the CLF tables. Once the zone type has been determined, the SCL is found from lookup tables.

Accounting for Adjacent Zones

The CLTD/SCL/CLF method treats the conductive heating load from any adjacent spaces through internal partitions, ceilings, and floors as a simple steady-state energy flow:

$$q(t) = U\,A\,(T_a - T_r) \tag{9.6.31}$$

where T_a is the temperature in the adjacent space and T_r is the temperature of the room in question.

Occupant Loads

People within a space add sensible as well as latent loads to the space. The heating load at any given hour due to the occupants is given as

$$q(t) = N\,F_d\,[q_s \text{ CLF}(t) + q_l] \tag{9.6.32}$$

where

N = the number of people in the space
F_d = the diversity factor
CLF = the cooling load factor for occupants on a given schedule

As implied by Equation (9.6.32), the latent load is assumed to translate immediately into a cooling load on the system while the sensible load is subject to some time delay as dictated by the mass of the room — i.e., its capability to absorb heat and release it at a later time. The diversity factor F_d takes into account the variability of the actual number of occupants in the space.

The CLF values come from tables. To find the CLF, it is first necessary to determine the zone type. This is done in a fashion similar to that for the solar cooling loads. That is, the building type, room location, and floor coverings must be known before the zone type can be found. Note that the zone type for occupants and equipment is not the same as for lighting. The same holds true for the solar cooling load: the zone type for occupants is not the same as the zone type for the SCL.

Once the zone type has been determined, the occupant CLF is found from the lookup tables. Zone type A is for light construction and the zones get progressively more massive for types B, C, and D. Figure 9.6.3 shows the cooling load factors for type A and D zones that are occupied for 12 h. Note that the occupant CLF will be 1.0 for all hours in a building with high occupant density (greater than 1 person per 10 ft^2) such as auditoriums and theaters. The CLF will also be 1.0 in buildings with occupancy 24 h/day.

Lighting Loads

At any given hour the load due to the lighting is approximated as

$$q(t) = \text{watts } F_d\,F_{sa} \text{ CLF}(t) \tag{9.6.33}$$

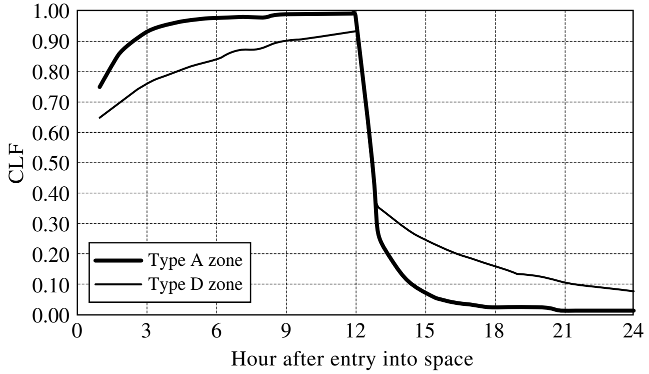

FIGURE 9.6.3 Occupant cooling load factors for type A and type D zones for a space occupied for 12 h.

where

Watts = the total lamp wattage in the space
F_d = the diversity factor
F_{sa} = a ballast special allowance factor
CLF = the cooling load factor for the lights for a given on/off schedule

The diversity factor F_d takes into account the variability of the actual wattage of lights on at any given time.

The lighting CLF values come from tables and are found in a fashion similar to that for the occupants. The zone types for lighting are not necessarily the same zone types for the solar cooling load or the occupants. Note that the lighting CLF will be 1.0 for buildings in which the lights are on 24 h/day or the cooling system is shut off at night or on the weekends. If the calculations are done in inch–pound units, then the result from Equation (9.6.33) is multiplied by 3.41 to convert watts to British thermal units per hour.

Appliance and Equipment Loads

Equipment can add heat through resistive heating or from electrical motors operating in the equipment. The CLTD/SCL/CLF method accounts for both types of equipment heat separately. In addition, the equipment loads are further broken down into sensible or latent components. The latent components are assumed to become immediate loads on the cooling system. The latent loads are found in tables devoted to hospital equipment, restaurant equipment, and office equipment. Latent loads are cited only for the hospital and restaurant equipment. The sensible component of the loads is adjusted by

$$q(t) = q_{sa}\,\mathrm{CLF}(t) \tag{9.6.34}$$

where q_{sa} is the sensible heat gain per appliance as found from the tables. The cooling load factor is found by first determining the zone type and then looking up the CLF in a table appropriate for that zone type, as was done for the occupants and lighting. Although the zone type is similar for occupants and equipment, it may not be the same as that for lighting.

The total cooling load in the space is then found from the sum of the sensible and latent loads. If a cooling load is due to equipment with electrical motors that run equipment in the space, then the space cooling load is incremented by

$$q(t) = 2545\frac{\mathrm{HP}}{\eta}F_l F_u\,\mathrm{CLF}(t) \tag{9.6.35}$$

where

HP = the rated horsepower of the motor
η = the efficiency
F_l = the load factor average (power used divided by rated horsepower, typically around 12)
F_u = the motor use factor (accounting for intermittent use)

The term 2545 converts from horsepower to Britsh thermal units per hour and CLF is the cooling load factor for the equipment on a given schedule. Equation (9.6.32a) assumes that the equipment and the motor are located within the space. If the equipment is in the space but the motor is located outside the space, then this equation is derated by the motor efficiency:

$$q(t) = 2545 \text{ HP } F_l F_u \text{CLF}(t) \tag{9.6.36}$$

Conversely, if the motor is inside the space but it acts on equipment outside the space, the cooling load is incremented by

$$q(t) = 2545 \text{HP} \frac{1-\eta}{\eta} F_l F_u \text{CLF}(t) \tag{9.6.37}$$

As with the lighting, the CLF is always 1.0 when the cooling system does not operate 24 h/day.

Air Infiltration

The infiltrating air is assumed to become a load on the cooling system immediately.

Transfer Functions for Dynamic Load Calculations

Basis of the Method

The *load* $\dot{Q}$ can be considered the response of the building or room to the driving terms $\{T_i, T_o, \dot{Q}_{sol}$, etc.) that act on it. The transfer function method calculates the response of a system by making the following basic assumptions:

- *Discrete time steps*: all functions of time are represented as series of values at regular time steps (hourly in the present case).
- *Linearity*: the response of a system is a linear function of the driving terms and of the state of the system.
- *Causality*: the response at time *t* can depend only on the past, not on the future.

As an example, suppose a single driving term $u(t)$ and the response $y(t)$. To make the expressions more readable, indicate the time dependence as a subscript, in the form $y(t) = y_t$, $u(t) = u_t$, and so on. Then, according to the transfer function model, the relation between the response and the driving term is of the form:

$$y_t = -(a_1 y_{t-1\Delta t} + a_2 y_{t-2\Delta t} + \cdots + a_n y_{t-n\Delta t}) + (b_0 u_t + b_1 u_{t-1\Delta t} + b_2 u_{t-2\Delta t} + \cdots + b_m u_{t-m\Delta t}) \tag{9.6.38}$$

with time step

$$\Delta t = 1 \text{ h} \tag{9.6.39}$$

where a_1 to a_n and b_0 to b_m are coefficients that characterize the system; they are independent of the driving term or response. Equation (9.6.33) is obviously linear. It satisfies causality because y_t depends only on the past values of the response ($y_{t-1\Delta t}$ to $y_{t-n\Delta t}$) and on present and past values of the driving terms (u_t to $u_{t-m\Delta t}$).

The past state of the system enters because of the coefficients a_1 to a_n and b_1 to b_m; this is how thermal inertia is taken into account. The response is instantaneous only if these coefficients are zero. The greater their number and magnitude are, the greater the weight of the past. The accuracy of the model increases as the number of coefficients is enlarged and as the time step is reduced. For most load calculations, hourly time resolution and a handful of coefficients per driving term will suffice. The coefficients are called *transfer function coefficients*.

Incidentally, the relation between *u* and *y* could be written in symmetric form:

$$a_0 y_t + a_1 y_{t-1\Delta t} + a_2 y_{t-2\Delta t} + \cdots + a_n y_{t-n\Delta t} = b_0 u_t + b_1 u_{t-1\Delta t} + b_2 u_{t-2\Delta t} + \cdots + b_m u_{t-m\Delta t} \tag{9.6.40}$$

which is equivalent because one can divide both sides of the equation by a_0. Because the roles of u and y are symmetric, one can use the same model to find, for example, the load (i.e., the heat $\dot{Q}$ to be supplied or removed) as a function of T_i, or T_i as a function of $\dot{Q}$.

Equation (9.6.35) can be readily generalized to the case where there are several driving terms. For instance, if the response T_i is determined by two driving terms, heat input $\dot{Q}$, and outdoor temperature T_o, then one can write the transfer function model in the form

$$\begin{aligned} a_{i,0}T_{i,t} + a_{i,1}T_{i,t-1\Delta t} + \cdots + a_{i,n}T_{i,t-n\Delta t} &= a_{o,0}T_{o,t} + a_{o,1}T_{o,t-1\Delta t} + \cdots + a_{o,m}T_{o,t-m\Delta t} \\ &+ a_{Q,0}\dot{Q}_t + a_{Q,1}\dot{Q}_{t=1\Delta t} + a_{Q,2}\dot{Q}_{t-2\Delta t} + \cdots + a_{Q,r}\dot{Q}_{t-r\Delta t} \end{aligned} \tag{9.6.41}$$

with three sets of transfer function coefficients: $a_{i,0}$ to $a_{i,n}$; $a_{o,0}$ to $a_{o,m}$; and $a_{Q,0}$ to $a_{Q,r}$. This equation can be considered an algorithm for calculating $T_{i,t}$, hour by hour, given the previous values of T_i and the driving terms T_o and $\dot{Q}$. Likewise, if T_i and T_o were given as driving terms, one could calculate $\dot{Q}$ as response.

Any set of response and driving terms can be handled in this manner. Thus, loads can be calculated hour by hour, for any driving terms (meteorological data, building occupancy, heat gain schedules, etc.); in fact, this method is used by the computer simulation program DOE2.1 (Birdsall et al., 1990).

Once the necessary numerical values of the transfer function coefficients have been obtained, the calculation of peak loads is simple enough for a spreadsheet. One specifies the driving terms for the peak day and iterates an equation like Equation (9.6.36) until the result converges to a steady daily pattern. Transfer function coefficients have been calculated and listed for a wide variety of standard construction types (ASHRAE, 1989).

In the remainder of this section, the ASHRAE transfer function method is discussed in detail. The method involves three steps:

- Calculate the conductive heat gain (or loss) for each distinct component of the envelope, by Equation (9.6.37).
- Calculate the load of the room at constant temperature, based on this conductive heat gain (or loss) as well as any other heat source in the room, by Equation (9.6.42).
- Calculate the heat extraction (or addition) rate for the cooling (or heating) device and thermostat setpoints of the room.

Conductive Heat Gain

The conductive heat gain (or loss) $\dot{Q}_{cond,t}$ at time t through the roof and walls is calculated according to the formula:

$$\dot{Q}_{cond,t} = -\sum_{n\geq 1} d_n \dot{Q}_{cond,t-n\Delta t} + A\left(\sum_{n\geq 0} b_n T_{os,t-n\Delta t} - T_i \sum_{n\geq 0} c_n\right) \tag{9.6.42}$$

where

A = area of roof or wall, m^2 (ft^2)
Δt = time step = 1 h
$T_{o,st}$ = sol–air temperature of outside surface at time t
b_n, c_n, d_n = coefficients of conduction transfer function

The indoor temperature T_i is multiplied by the sum of the c_n values, so the individual c_n coefficients are not needed (because T_i is assumed constant at this point). In general, the initial value $\dot{Q}_{\text{cond},t} = O$ is not known; its value does not matter if the calculation is repeated over a sufficient number of time steps until the resulting pattern becomes periodic within the desired accuracy. Usually a few days to a week will be sufficient.

Numerical values of the coefficients of the conduction transfer function are listed in Table 9.6.3: roofs in section (a) of the table and walls in section (b). If the room in question is adjacent to rooms at a different temperature, the heat gain across the partitions is also calculated according to Equation (9.6.37).

It is instructive to establish the connection of the transfer function coefficients with the U value. In the steady-state limit, i.e., when $\dot{Q}_{\text{cond}}$, T_{os}, and T_i are all constant, Equation (9.6.37) becomes

$$\dot{Q}_{cond}\sum_{n\geq 1} d_n = A\left(T_{os}\sum_{n\geq 0} b_n - T_i\sum_{n\geq 0} c_n\right) \tag{9.6.43}$$

where $d_0 = 1$.

Because that limit also contains

$$\dot{Q}_{\text{cond}} = A\ U\ (T_{os} - T_i) \tag{9.6.44}$$

the coefficients of T_{os} and T_i must be equal,

$$\sum_{n\geq 0} b_n = \sum_{n\geq 0} c_n \tag{9.6.45}$$

and the U value is given by

$$U = \frac{\sum\limits_{n\geq 0} c_n}{\sum\limits_{n\geq 0} d_n} \tag{9.6.46}$$

The Load at Constant Temperature

The preceding calculation of the conductive heat gain (or loss) is to be repeated for each portion of the room envelope that has a distinct composition. The relation between these conductive gains and the total load depends on the construction of the entire room. For example, a concrete floor can store a significant fraction of the heat radiated by lights or by a warm ceiling, thus postponing its contribution to the cooling load of the room.

For each heat gain component $\dot{Q}_{\text{gain}}$, the corresponding cooling load $\dot{Q}_c$ (or reduction of the heating load) at constant T_i is calculated by using another set of coefficients: the coefficients v_n and w_n, of the *room transfer function*

$$\begin{aligned}\dot{Q}_{c,t} = v_0\dot{Q}_{\text{gain},t} + v_1\dot{Q}_{\text{gain},t-1\Delta t} + v_2\dot{Q}_{\text{gain},t-2\Delta t} + \cdots \\ -w_1\dot{Q}_{c,t-1\Delta t} - w_2\dot{Q}_{c,t-2\Delta t} - \cdots\end{aligned} \tag{9.6.47}$$

with the subscript t indicating time, as before. The coefficient w_0 of $\dot{Q}_{c,t}$ is not shown because it is set equal to unity.

Equation (9.6.42) must be applied separately to each of the heat gain types and the resulting cooling load components, $\dot{Q}_{c,t}$, are added to obtain the total cooling load of the room at time t. The heat gain types are as follows:

- Solar gain (through glass without interior shade) and the radiative component of heat from occupants and equipment
- Conduction through envelope and solar radiation absorbed by interior shade
- Lights
- Convective gains (from air exchange, occupants, equipment)

For lights the coefficients depend on the arrangement of the lighting fixture and the ventilation system.

Specific numbers vary a great deal with the circumstances; however, the general pattern is common to all peak cooling loads: *thermal inertia attenuates and delays the peak contributions of individual load components*. The total peak is usually less than the result of a steady-state calculation, although it could be more if the time delays act in the sense of making the loads coincide.

In contrast to peak loads, daily average loads can be determined by a static calculation if the average indoor temperature is known; that follows from the first law of thermodynamics. However, if the thermostat allows floating temperatures, the indoor temperature is, in general, not known without a dynamic analysis.

With the transfer functions described so far, one can calculate peak loads when the indoor temperature T_i is constant. That is how the cooling load factors and cooling load temperature differences of the previous section have been determined. Of course, the indoor temperature T_i may vary, not only because of variable thermostat setpoints but also because of limitations of the HVAC equipment (capacity, throttling range, imperfect control). The extension to variable T_i requires one additional transfer function, which is described in ASHRAE (1997) and Kreider et al. (2001).

9.7 Air Handling Units and Packaged Units

Shan K. Wang

Terminals and Air Handling Units

A *terminal unit*, or *terminal*, is a device or equipment installed directly in or above the conditioned space to cool, heat, filter, and mix outdoor air with recirculating air. Fan-coil units, VAV boxes, fan-powered VAV boxes, etc. are all terminals.

An *air handling unit* (AHU) handles and conditions the air, controls it to a required state, and provides motive force to transport it. An AHU is the primary equipment of the air system in a central air-conditioning system. The basic components of an AHU include a supply fan with a fan motor, a water cooling coil, filters, a mixing box except in a makeup AHU unit, dampers, controls, and an outer casing. A return or relief fan, heating coil(s), and humidifier are optional depending on requirements. The supply volume flow rate of AHUs varies from 2000 to about 60,000 cfm.

AHUs are classified into the followings groups according to their structure and location.

Horizontal or Vertical Units

Horizontal AHUs have their fan, coils, and filters installed at the same level as shown in Figure 9.7.1(a). They need more space and are usually for large units. In *vertical units*, as shown in Figure 9.7.1(b), the supply fan is installed at a level higher than coils and filters. They are often comparatively smaller than horizontal units.

Draw-Through or Blow-Through Units

In a *draw-through unit,* as shown in Figure 9.7.1(a), the supply fan is located downstream of the coils. Air is evenly distributed over the coil section, and the fan discharge can easily be connected to a supply duct of nearly the same air velocity. In a *blow-through unit*, as shown in Figure 9.7.1(c), the supply fan is located upstream of the coils. It usually has hot and cold decks with discharge dampers connected to warm and cold ducts, respectively.

Factory-Fabricated and Field Built-Up Units

Factory-fabricated units are standard in construction and layout, low in cost, of higher quality, and fast in installation. *Field built-up units* or *custom-built units* are more flexible in construction, layout, and dimensions than factory-built standardized units.

Rooftop and Indoor Units

A *rooftop AHU*, sometimes called a penthouse unit, is installed on the roof and will be completely weatherproof. An *indoor AHU* is usually located in a fan room or ceiling and hung like small AHU units.

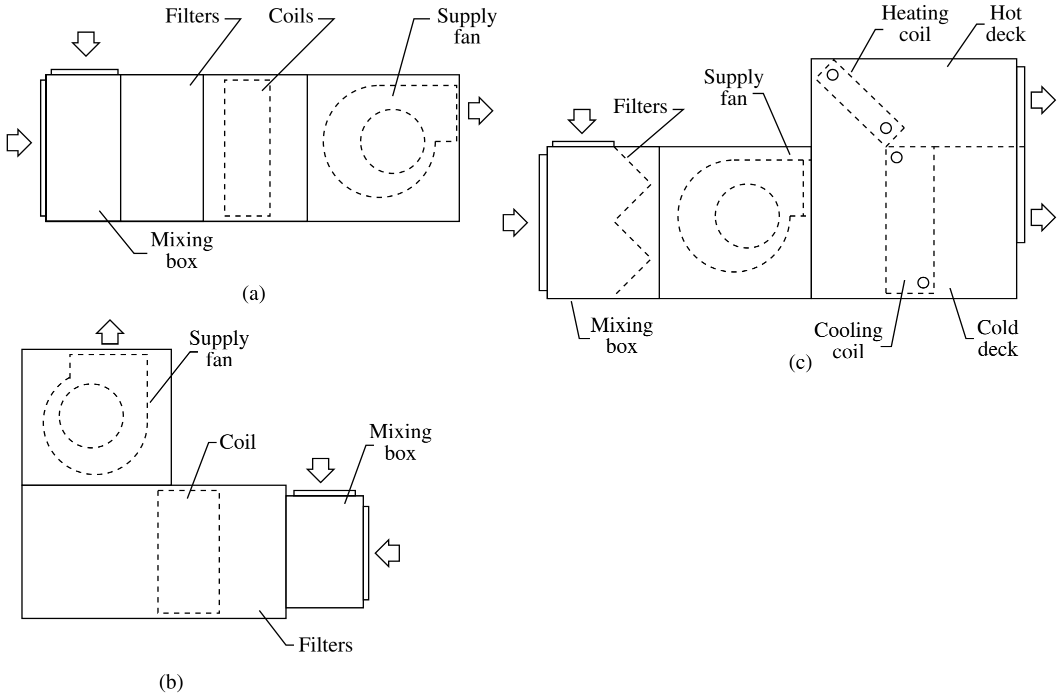

FIGURE 9.7.1 Type of air handling units: (a) horizontal draw-through unit, (b) vertical draw-through unit, and (c) multizone blow-through unit.

Make-Up Air and Recirculating Units

A *make-up AHU*, also called a primary-air unit, is used to condition outdoor air entirely. It is a once-through unit. There is no return air and mixing box. *Recirculating units* can have 100% outdoor air intake or mixing of outdoor air and recirculating air.

Packaged Units

A *packaged unit* (PU) or Packaged Terminal Air Conditioner (PTAC) is a self-contained air conditioner. It conditions the air and provides it with motive force and is equipped with its own heating and cooling sources. The packaged unit is the primary equipment in a packaged air-conditioning system and is always equipped with a DX coil for cooling, unlike an AHU. R-22, R-134a, and others are used as refrigerants in packaged units. The portion that handles air in a packaged unit is called an *air handler* to distinguish it from an AHU. Like an AHU, an indoor air handler has an indoor fan, a DX coil (indoor coil), filters, dampers, and controls. Packaged units can be classified according to their place of installation: rooftop, indoor, and split packaged units.

Rooftop Packaged Units

A *rooftop packaged unit* is mounted on the roof of the conditioned space as shown in Figure 9.7.2. From the types of heating/cooling sources provided, rooftop units can be subdivided into:

- Gas/electric rooftop packaged unit, in which heating is provided by gas furnace and cooling by electric power-driven compressors.
- Electric/electric rooftop packaged unit, in which electric heating and electric power-driven compressors provide heating and cooling.

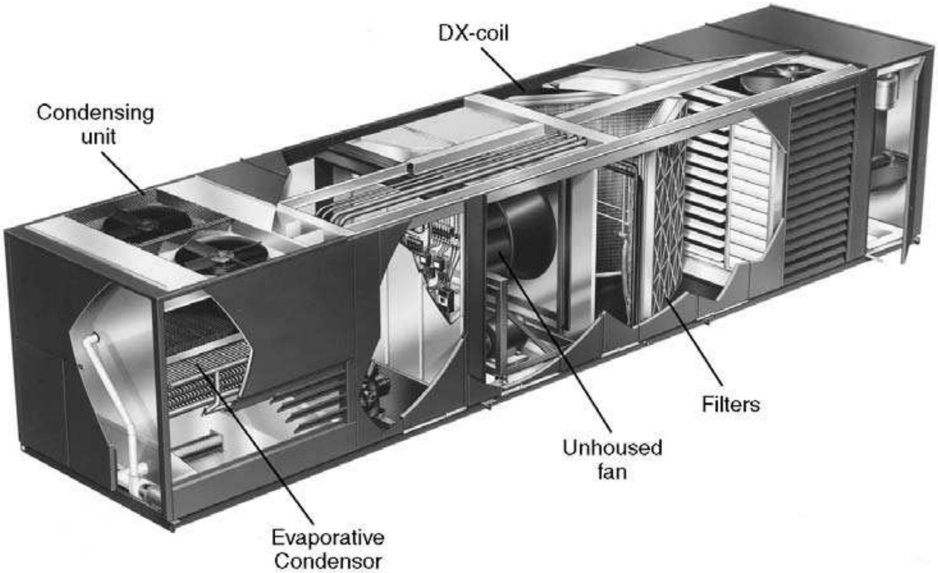

FIGURE 9.7.2 A cut view of a rooftop package unit. (Source: Mammoth, Inc. Reprinted by permission.)

- Rooftop packaged heat pump, in which both heating and cooling are provided by the same refrigeration system using a four-way reversing valve (heat pump) in which the refrigeration flow changes when cooling mode is changed to heating mode and vice versa. Auxiliary electric heating is provided if necessary.

Rooftop packaged units are single packaged units. Their cooling capacity may vary from 3 to 220 tons with a corresponding volume flow rate of 1200 to 80,000 cfm. Rooftop packaged units are the most widely used packaged units.

Indoor Packaged Units

An *indoor packaged unit* is also a single packaged and factory-fabricated unit. It is usually installed in a fan room or a machinery room. A small or medium-sized indoor packaged unit could be floor mounted directly inside the conditioned space with or without ductwork. The cooling capacity of an indoor packaged unit may vary from 3 to 100 tons and volume flow rate from 1200 to 40,000 cfm.

Indoor packaged units are also subdivided into:

- Indoor packaged cooling units
- Indoor packaged cooling/heating units, in which heating may be provided from a hot water heating coil, a steam heating coil, and electric heating
- Indoor packaged heat pumps

Indoor packaged units have either an air-cooled condenser on the rooftop or a shell-and-tube or double-tube water-cooled condenser inside the unit.

Split Packaged Units

A *split packaged unit* consists of two separate pieces of equipment: an indoor air handler and an outdoor condensing unit. The indoor air handler is often installed in the fan room. Small air handlers can be ceiling hung. The condensing unit is usually located outdoors, on a rooftop or podium or on the ground.

A split packaged unit has its compressors and condenser in its outdoor condensing unit, whereas an indoor packaged unit usually has its compressors indoors. The cooling capacity of split packaged units varies from 3 to 75 tons and the volume flow rate from 1200 to 30,000 cfm.

Rating Conditions and Minimum Performance

Air Conditioning and Refrigeration Institute (ARI) Standards and ASHRAE/IES Standard 90.1-2001 specified the following rating indices:

- Energy efficiency ratio (EER) is the ratio of equipment cooling capacity, in Btu/hr, to the electric input, in W, under rating conditions.
- SEER is the seasonal EER, or EER during the normal annual usage period.
- IPLV is the integrated part-load value. It is the summarized single index of part-load efficiency of PUs based on weighted operations at several load conditions.
- HSPF is the heating seasonal performance factor. It is the total heating output of a heat pump during its annual usage period for heating, in Btu, divided by the total electric energy input to the heat pump during the same period, in watt-hours.

For water- and evaporatively cooled packaged units including heat pumps, refer to ASHRAE/IES Standard 90.1-2001 and also ARI Standards.

Coils

Coils, Fins, and Water Circuits

Coils are indirect contact heat exchangers. Heat transfer or heat and mass transfer takes place between conditioned air flowing over the coil and water, refrigerant, steam, or brine inside the coil for cooling, heating, dehumidifying, or cooling/dehumidifying. Chilled water, brine, and refrigerants that are used to cool and dehumidify the air are called *coolants*. Coils consist of tubes and external fins arranged in rows along the air flow to increase the contact surface area. Tubes are usually made of copper; in steam coils they are sometimes made of steel or even stainless steel. Copper tubes are staggered in 2, 3, 4, 6, 8, or up to 10 rows.

Fins are extended surfaces often called *secondary surfaces* to distinguish them from the *primary surfaces*, which are the outer surfaces of the tubes. Fins are often made from aluminum, with a thickness F_t = 0.005 to 0.008 in., typically 0.006 in. Copper, steel, or sometimes stainless steel fins are also used. Fins are often in the form of continuous plate fins, corrugated plate fins to increase heat transfer, crimped spiral or smooth spiral fins that may be extruded from the aluminum tubes, and spine pipes, which are shaved from the parent aluminum tubes. Corrugated plate fins are most widely used.

Fin spacing S_f is the distance between two fins. *Fin density* is often expressed in fins per inch and usually varies from 8 to 18 fins/in.

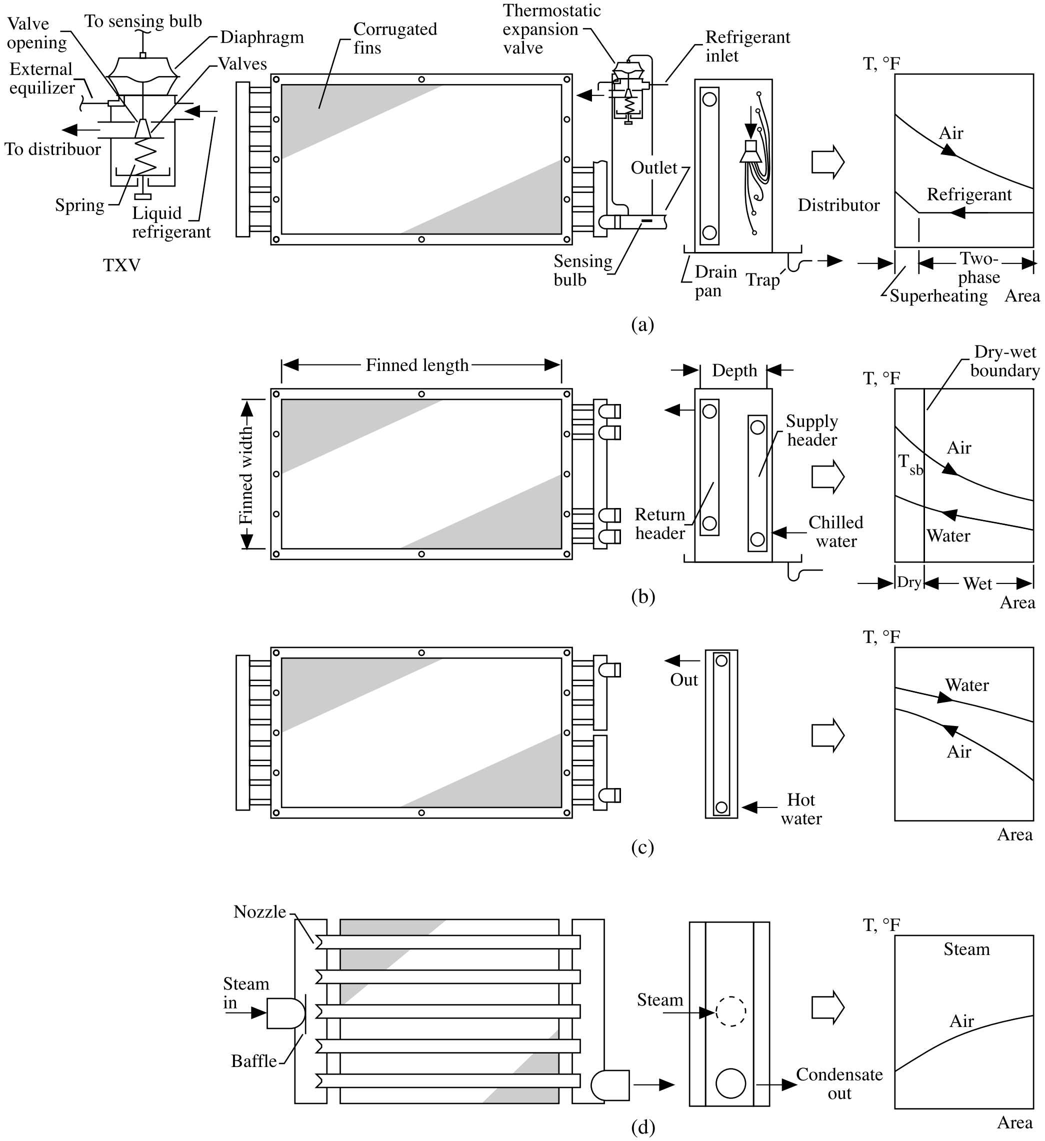
In a water cooling coil, *water circuits* or *tube feeds* determine the number of water flow passages. The greater the finned width, the higher the number of water circuits and water flow passages.

Direct Expansion (DX) Coil

In a *direct expansion coil*, the refrigerant, R-22, R-134a, or others, is evaporated and expanded directly inside the tubes to cool and dehumidify the air as shown in Figure 9.7.3(a). Refrigerant is fed to a distributor and is then evenly distributed to various copper tube circuits typically 0.375 in. in diameter. Fin density is usually 12 to 18 fins/in. and a four-row DX coil is often used. On the inner surface of the copper tubes, microfins, typically at 60 fins/in. and a height of 0.008 in., are widely used to enhance the boiling heat transfer.

Air and refrigerant flow is often arranged in a combination of counterflow and cross flow and the discharge header is often located on the air-entering side. Refrigerant distribution and loading in various circuits are critical to the coil's performance. Vapor refrigerant cleaning the DX coil is superheated 10 to 20°F in order to prevent any liquid refrigerant from flooding back to the reciprocating compressors and damaging them. Finally, the vapor refrigerant is discharged to the suction line through the header.

For comfort air-conditioning systems, the evaporating temperature of refrigerant T_{ev} inside the tubes of a DX coil is usually between 37 and 50°F. At such a temperature, the surface temperature of the coil is often lower than the dew point of the entering air. Condensation occurs at the coil's outside surface,



(a)

(b)

(c)

(d)

FIGURE 9.7.3 Types of coils: (a) direct expansion coil, (b) water cooling coil, (c) water heating coil, and (d) steam heating coil.

and the coil becomes a wet coil. A condensate *drain pan* is necessary for each vertically banked DX coil, and a trap should be installed to overcome the negative pressure difference between the air in the coil section and the ambient air. Some units are equipped with IAQ drainpans — drain pans that are sloped to drain connections so that they completely drain.

Face velocity of the DX coil v_a, in fpm, is closely related to the blow-off of the water droplets of the condensate, the heat transfer coefficients, the air-side pressure drop, and the size of the air system. For corrugated fins, the upper limit is 600 fpm, with an air-side pressure drop of 0.20 to 0.30 in. WG/row. A large DX coil is often divided into two refrigerant sections, each with its own expansion valve, distributor, and discharge header.

For a packaged unit of a specific model, size, face velocity and condition of entering air and outdoor air, the DX coil's cooling capacities in nominal tons, number of rows, and fin density are all fixed values.

Water Cooling Coils — Dry–Wet Coils

In a water cooling coil, chilled water at a temperature of 40 to 50°F, brine, or glycol-water at a temperature of 34 to 40°F during cold air distribution enters the coil. The temperature of chilled water, brine, or glycol-water is usually raised 12 to 24°F before it leaves the water cooling coil.

The water tubes are usually copper tubes of 1/2 to 5/8 in. diameter with a tube wall thickness of 0.01 to 0.02 in. They are spaced at a center-to-center distance of 0.75 to 1.25 in. longitudinally and 1 to 1.5 in. transversely. These tubes may be staggered in 2, 3, 4, 6, 8, or 10 rows. Chilled water coils are often operated at a pressure of 175 to 300 psig.

As in a DX coil, the air flow and water flow are in a combination of counterflow and cross flow. The temperature of the outer surface of a chilled water cooling coil at the air entering side T_{se} is often greater than the dew point of the entering air T''_{ae}, or $T_{se} > T''_{ae}$. The outer surface temperature of the coil at the air leaving side T_{sl} may be smaller than T''_{ae}, or $T_{sl} < T''_{ae}$. Then the water cooling coil becomes a dry–wet coil with part of the dry surface on the air entering side and part of the wet surface on the air leaving side. A *dry–wet boundary* divides the dry and wet surfaces. At the boundary, the tube outer surface temperature $T_{sb} = T''_{ae}$ as shown in Figure 9.7.3(b). A condensate drain pan is necessary for a dry–wet coil.

A water cooling coil is selected from the manufacturer's selection program or from its catalog at (1) a dry and wet bulb temperature of entering air, such as 80°F dry bulb and 67°F wet bulb; (2) an entering water temperature, such as 44 or 45°F; (3) a water temperature rise between 10 and 24°F; and (4) a coil face velocity between 400 and 600 fpm. The number of rows and fins per inch is varied to meet the required sensible and cooling coil load, in Btu/hr.

Water Cooling Coil–Dry Coil

When the temperature of chilled water entering the water cooling coil $T_{we} \geq T''_{ae}$, condensation will not occur on the outer surface of the coil. This coil becomes a sensible cooling–dry coil, and the humidity ratio of the conditioned air w_a remains constant during the sensible cooling process.

The construction of a sensible cooling–dry coil, such as material, tube diameter, number of rows, fin density, and fin thickness, is similar to that of a dry–wet coil except that a dry coil always has a poorer surface heat transfer coefficient than a wet coil, and therefore a greater coil surface area is needed; the maximum face velocity of a dry coil can be raised to $v_a \leq 800$ fpm; and the coil's outer surface is less polluted. The effectiveness of a dry coil $\in_{dry}$ is usually 0.55 to 0.7.

Water Heating Coil

The construction of a water heating coil is similar to that of a water cooling coil except that in water heating coils hot water is supplied instead of chilled water and there are usually fewer rows, only 2, 3, and 4 rows, than in water cooling coils. Hot water pressure in water heating coils is often rated at 175 to 300 psig at a temperature up to 250°F. Figure 9.7.3(c) shows a water heating coil.

Steam Heating Coil

In a steam heating coil, latent heat of condensation is released when steam is condensed into liquid to heat the air flowing over the coil, as shown in Figure 9.7.3(d). Steam enters at one end of the coil, and the condensate comes out from the opposite end. For more even distribution, a baffle plate is often installed after the steam inlet. Steam heating coils are usually made of copper, steel, or sometimes stainless steel.

For a steam coil, the coil core inside the casing should expand or contract freely. The coil core is also pitched toward the outlet to facilitate condensate drainage. Steam heating coils are generally rated at 100 to 200 psig at 400°F.

Coil Accessories and Servicing

Coil accessories include air vents, drain valves, isolation valves, pressure relief valves, flow metering valves, balancing valves, thermometers, pressure gauge taps, condensate drain taps, and even distribution baffles. They are employed depending on the size of the system and operating and serving requirements.

Coil cleanliness is important for proper operation. If a medium-efficiency air filter is installed upstream of the coil, dirt accumulation is often not a problem. If a low-efficiency filter is employed, dirt accumulation may block the air passage and significantly increase the pressure drop across the coil. Coils should normally be inspected and cleaned every 3 months in urban areas when low-efficiency filters are used. Drain pans should be cleaned every month to prevent buildup of bacteria and microorganisms. IAQ drain pans can be specified to minimize this cleaning.

Coil Freeze-Up Protection

Improper mixing of outdoor air and recirculating air in the mixing box of an AHU or PU may cause coil freeze-up when the outdoor air temperature is below 32°F. Outdoor air should be guided by a baffle plate and flow in an opposite direction to the recirculating air stream so that they can be thoroughly mixed without stratification. Preheat coils can also be used to temper outside air before it enters the mixing box.

Run the chilled water pump for the idle coil with a water velocity of 2.5 ft/sec, so that the cooling coil will not freeze when the air temperature drops to 32°F. A better method is to drain the water completely. For a hot water coil, it is better to reset the hot water temperature at part-load operation instead of running the system intermittently. A steam heating coil with inner distributor tubes and outer finned heating tubes provides better protection against freeze-up.

Air Filters

Air Cleaning and Filtration

Air cleaning is the process of removing airborne particles from the air. Air cleaning can be classified as air filtration and industrial air cleaning. Industrial air cleaning involves the removal of dust and gaseous contaminants from manufacturing processes as well as from the space air, exhaust air, and flue gas for air pollution control. In this section, only air filtration is covered.

Air filtration involves the removal of airborne particles presented in the conditioned air. Most of the airborne particles removed by air filtration are smaller than 1 μm, and the concentration of these particles in the airstream seldom exceeds 2 mg/m^3. The purpose of air filtration is to benefit the health and comfort of the occupants as well as meet the cleanliness requirements of the working area in industrial buildings.

An *air filter* is a kind of air cleaner that is installed in AHUs, PUs, and other equipment to filter the conditioned air by inertial impaction or interception and to diffuse and settle fine dust particles on the fibrous medium. The filter medium is the fabricated material that performs air filtration.

Operating performance of air filters is indicated by their:

- *Efficiency* or effectiveness of dust removal
- *Dust holding capacity* m_{dust}, which is the amount of dust held in the air filter, in grains/ft^2
- *Initial pressure drop* when the filter is clean Δp_{fi} and *final pressure drop* Δp_{ff} when the filter's m_{dust} is maximum, both in in. WG
- *Service life,* which is the operating period between Δp_{fi} and Δp_{ff}

Air filters in AHUs and PUs can be classified into low-, medium-, and high-efficiency filters and carbon activated filters.

Test Methods

The performance of air filters is usually tested in a test unit that consists of a fan, a test duct, the tested filter, two samplers, a vacuum pump, and other instruments. Three test methods with their own test dusts and procedures are used for the testing of low-, medium-, and high-efficiency air filters.

The *weight arrestance test* is used for low-efficiency air filters to assess their ability to remove coarse dusts. Standard synthetic dusts that are considerably coarser than atmospheric dust are fed to the test unit. By measuring the weight of dust fed and the weight gain due to the dust collected on the membrane of the sampler after the tested filter, the arrestance can be calculated.

The *atmospheric dust spot efficiency test* is used for medium-efficiency air filters to assess their ability to remove atmospheric dusts. *Atmospheric dusts* are dusts contained in the outdoor air, the outdoor atmosphere. Approximately 99% of atmospheric dusts are dust particles <0.3 μm that make up 10% of the total weight; 0.1% of atmospheric dusts is particles >1 μm that make up 70% of the total weight.

Untreated atmospheric dusts are fed to the test unit. Air samples taken before and after the tested filter are drawn through from identical fiber filter-paper targets. By measuring the light transmission of these discolored white filter papers, the efficiency of the filter can be calculated. Similar atmospheric dust spot test procedures have been specified by American Filter Institute (AFI), ASHRAE Standard 52.1, and former National Bureau of Standards (NBS).

The *DOP penetration and efficiency test* or simply *DOP test* is used to assess high-efficiency filters removing dusts particles of 0.18 μm. According to U.S. Military Standard MIL-STD-282 (1956), a smoke cloud of uniform dioctyl phthalate (DOP) droplets 0.18 μm in diameter, generated from the condensation of the DOP vapor, is fed to the test unit. By measuring the concentration of these particles in the air stream upstream and downstream of the tested filter using an electronic particle counter or laser spectrometer, the penetration and efficiency of the air filter can be calculated.

Low-Efficiency Air Filters

ASHRAE weight arrestance for low-efficiency filters is between 60 and 95%, and ASHRAE dust spot efficiency for low-efficiency filters is less than 20%. These filters are usually in panels as shown in Figure 9.7.4(a). Their framework is typically 20 × 20 in. or 24 × 24 in. Their thickness varies from 1 to 4 in.

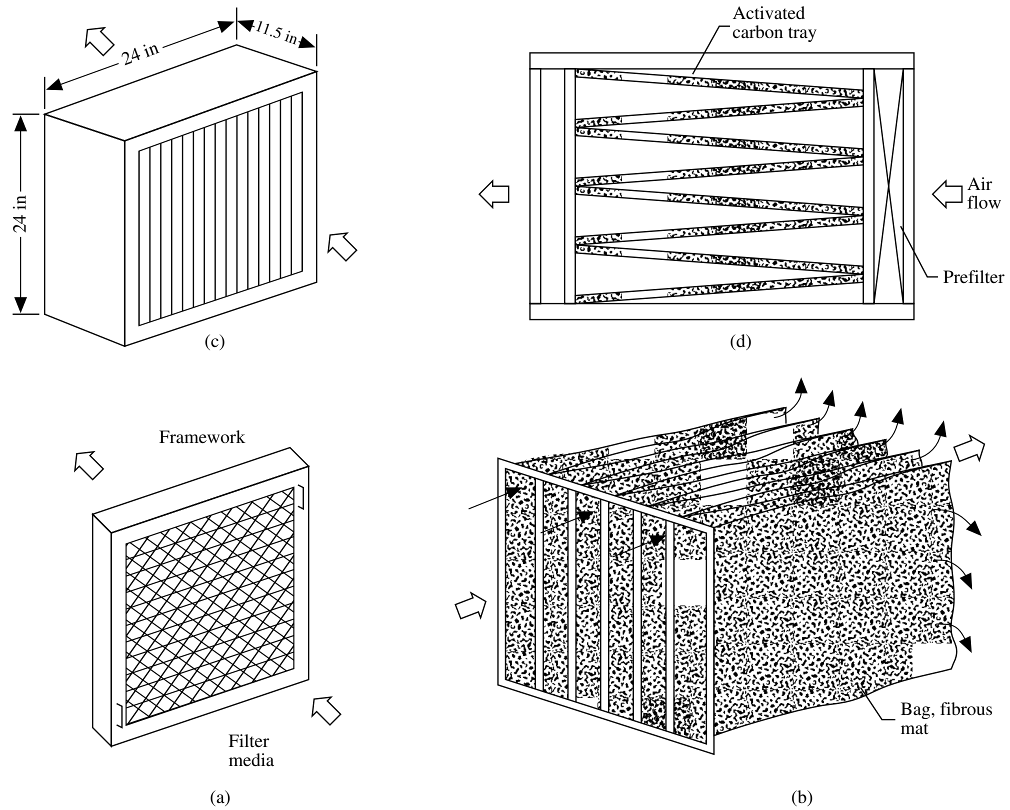


FIGURE 9.7.4 Various types of air filters: (a) low efficiency, (b) medium efficiency, (c) HEPA and ULPA filters, and (d) activated carbon filter.

For low-efficiency filters, the filter media are often made of materials such as

- Corrugated wire mesh and screen strips coated with oil, which act as adhesives to enhance dust removal. Detergents may be used to wash off dusts so that the filter media can be cleaned and reused — they are therefore called *viscous and reusable*.
- Synthetic fibers (nylon, terylene) and polyurethane foam can be washed, cleaned, and reused if required — *dry and reusable*.
- Glass fiber mats with fiber diameter greater than 10 μm. The filter medium is discarded when its final pressure drop is reached — *dry and disposable*. The face velocity of the panel filter is usually between 300 and 600 fpm. The initial pressure drop varies from 0.05 to 0.25 in. WG and the final pressure drop from 0.2 to 0.5 in. WG.

Medium-Efficiency Air Filters

These air filters have an ASHRAE dust spot efficiency usually between 20 and 95%. Filter media of medium-efficiency filters are usually made of glass fiber mat with a fiber diameter of 10 to 1 μm using nylon fibers to join them together. They are usually dry and disposable. In addition:

- As the dust spot efficiency increases, the diameter of glass fibers is reduced, and they are placed closer together.
- Extended surfaces, such as pleated mats or bags, are used to increase the surface area of the medium as shown in Figure 9.7.4(b). Air velocity through the medium is 6 to 90 fpm. Face velocity of the air filter is about 500 fpm to match the face velocity of the coil in AHUs and PUs.
- Initial pressure drop varies from 0.20 to 0.60 in. WG and final pressure drop from 0.50 to 1.20 in. WG.

High-Efficiency Particulate Air (HEPA) Filters and Ultra-Low-Penetration Air (ULPA) Filters

HEPA filters have a DOP test efficiency of 99.97% for dust particles ≥0.3 μm in diameter. *ULPA filters* have a DOP test efficiency of 99.999% for dust particles ≥0.12 μm in diameter.

A typical HEPA filter, shown in Figure 9.7.4(d), has dimensions of 24 × 24 × 11.5 in. Its filter media are made of glass fibers of submicrometer diameter in the form of pleated paper mats. The medium is dry and disposable. The surface area of the HEPA filter may be 50 times its face area, and its rated face velocity varies from 190 to 390 fpm, normally at a pressure drop of 0.50 to 1.35 in. WG for clean filters. The final pressure drop is 0.8 to 2 in. WG. Sealing of the filter pack within its frame and sealing between the frame and the gaskets are critical factors that affect the penetration and efficiency of the HEPA filter.

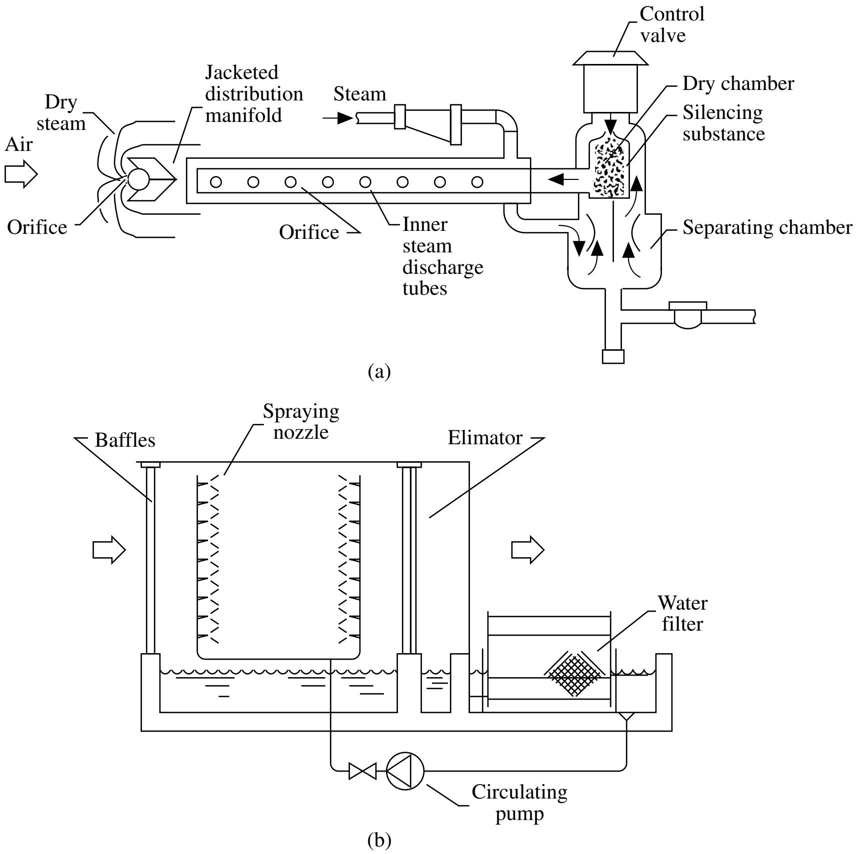
An ULPA filter is similar to a HEPA filter in construction and filter media. Both its sealing and filter media are more efficient than those of a HEPA filter.

To extend the service life of HEPA filters and ULPA filters, both should be protected by a medium-efficiency filter, or a low-efficiency and a medium-efficiency filter in the sequence low–medium just before the HEPA or ULPA filters. HEPA and ULPA filters are widely used in clean rooms and clean spaces. Often the removal and disposal of HEPA and ULPA filters require special handling due to the concentration of biological species present on the filter.

Activated Carbon Filters

These filters are widely used to remove objectional odors and irritating gaseous airborne particulates, typically 0.003 to 0.006 μm in size, from the air stream by adsorption. *Adsorption* is physical condensation of gas or vapor on the surface of an activated substance like activated carbon. Activated substances are extremely porous. One pound of activated carbon contains 5,000,000 ft^2 of internal surface.

Activated carbon in the form of granules or pellets is made of coal, coconut shells, or petroleum residues and is placed in trays to form activated carbon beds as shown in Figure 9.7.4(d). A typical carbon tray is 23 × 23 × 5/8 in. thick. Low-efficiency prefilters are used for protection. When air flows through the carbon beds at a face velocity of 375 to 500 fpm, the corresponding pressure drop is 0.2 to 0.3 in. WG.



(a)

(b)

FIGURE 9.7.5 Steam grid humidifier (a) and air washer (b).

Humidifiers

A *humidifier* adds moisture to the air. Air is humidified by: (1) heating the liquid to evaporate it; (2) atomizing the liquid water into minute droplets by mechanical means, compressed air, or ultrasonic vibration to create a larger area for evaporation; (3) forcing air to flow through a wetted element in which water evaporates; and (4) injecting steam into air directly before it is supplied to the conditioned space.

For comfort air-conditioning systems, a steam humidifier with a separator as shown in Figure 9.7.5(a) is widely used. Steam is supplied to a jacketed distribution manifold. It enters a separating chamber with its condensate. Steam then flows through a control valve, throttles to a pressure slightly above atmospheric, and enters a dry chamber. Due to the high temperature in the surrounding separating chamber, the steam is superheated. Dry steam is then discharged into the ambient air stream through the orifices on the inner steam discharge tubes.

For an air system of cold air supply with humidity control during winter mode operation, an air washer is economical for large-capacity humidification in many industrial applications.

An air washer is a humidifier, a cooler, a dehumidifier, and an air cleaner. An air washer usually has an outer casing, two banks of spraying nozzles, one bank of guide baffles at the entrance, one bank of eliminators at the exit, a water tank, a circulating pump, a water filter, and other accessories as shown in Figure 9.7.5(b). Outer casing, baffles, and eliminators are often made of plastics or sometimes stainless steel. Spraying nozzles are usually made of brass or nylon, with an orifice diameter of 1/16 to 3/16 in., a smaller orifice for humidification, and a larger orifice for cooling and dehumidification. An eccentric inlet connected to the discharge chamber of the spraying nozzle gives centrifugal force to the water stream and atomizes the spraying water. Water is supplied to the spraying nozzle at a pressure of 15 to 30 psig. The distance between two spraying banks is 3 to 4.5 ft, and the total length of the air water from 4 to 7 ft. The air velocity inside an air washer is usually 500 to 800 fpm.

Selection of AHUs and PUs

- The size of an AHU is usually selected so that the face velocity of its coil is 600 fpm or less in order to prevent entrained condensate droplets. The cooling and heating capacities of an AHU can be varied by using coils of different numbers of rows and fin densities. The size of a PU is determined by its cooling capacity. Normally, the volume flow rate per ton of cooling capacity in PUs is 350 to 400 cfm. In most packaged units whose supply fans have belt drives, the fan speed can be selected so that the volume flow rate is varied and external pressure is met.
- To improve the indoor air quality, save energy, and prevent smudging and discoloring building interiors, a medium-efficiency filter of dust spot efficiency ≥50% and an air economizer are preferable for large AHUs and PUs.
- See ANSI/ASHRAE/IESNA 90.1-2001 for energy standards on equipment selection.

9.8 Refrigeration Components and Evaporative Coolers

Shan K. Wang

Refrigeration Compressors

A refrigeration compressor is the heart of a vapor compression system. It raises the pressure of refrigerant so that it can be condensed into liquid, throttled, and evaporated into vapor to produce the refrigeration effect. It also provides the motive force to circulate the refrigerant through condenser, expansion valve, and evaporator.

According to the compression process, refrigeration compressors can be divided into *positive displacement* and *nonpositive displacement* compressors. A positive displacement compressor increases the pressure of the refrigerant by reducing the internal volume of the compression chamber. Reciprocating, scroll, rotary, and screw compressors are all positive displacement compressors. The centrifugal compressor is the only type of nonpositive displacement refrigeration compressor widely used in refrigeration systems today.

Based on the sealing of the refrigerant, refrigeration compressors can be classified as

- *Hermetic compressors*, in which the motor and the compressor are sealed or welded in the same housing to minimize leakage of refrigerant and to cool the motor windings by using suction vapor
- *Semihermetic compressors*, in which motor and compressor are enclosed in the same housing but are accessible from the cylinder head for repair and maintenance
- *Open compressors*, in which compressor and motor are enclosed in two separate housings

Refrigeration compressors are often driven by a motor directly or by a gear train.

Performance Indices

Volumetric efficiency η_v of a refrigeration compressor is defined as

$$\eta_v = \mathring{V}_{a.v} / \mathring{V}_p \tag{9.8.1}$$

where

$\mathring{V}_{a.v}$ = actual induced volume of the suction vapor at suction pressure, cfm

$\mathring{V}_p$ = calculated displacement of the compressor, cfm

Isentropic efficiency η_{isen}, *compression efficiency* η_{cp}, compressor efficiency η_{com}, and *mechanical efficiency* η_{mec} are defined as

$$\begin{aligned}\eta_{\text{isen}} &= (h_2 - h_1)/(h_2' - h_1) = \eta_{\text{cp}}\eta_{\text{mec}} = \eta_{\text{com}} \\ \eta_{\text{cp}} &= W_{\text{sen}}/W_{\text{v}} \\ \eta_{\text{mec}} &= W_{\text{v}}/W_{\text{com}}\end{aligned} \tag{9.8.2}$$

where

h_1, h_2, h_2' = enthalpy of the suction vapor, ideal discharged hot gas, and actual discharged hot gas, respectively, Btu/lb

W_{isen}, W_{v}, W_{com} = isentropic work = $(h_2 - h_1)$, work delivered to the vapor refrigerant, and work delivered to the compressor shaft, Btu/lb

The actual power input to the compressor P_{com}, in hp, can be calculated as

$$\begin{aligned}P_{\text{com}} &= \mathring{m}_{\text{r}}(h_2 - h_1)/(42.41\eta_{\text{isen}}\eta_{\text{mo}}) \\ \mathring{m}_{\text{r}} &= \mathring{V}_{\text{p}}\,\eta_{\text{v}}\rho_{\text{suc}} \\ \eta_{\text{mo}} &= P_{\text{com}}/P_{\text{mo}}\end{aligned} \tag{9.8.3}$$

where

$\mathring{m}_{\text{r}}$ = mass flow rate of refrigerant, lb/min

ρ_{suc} = density of suction vapor, lb/ft^3

P_{mo} = power input to the compressor motor, hp

Power consumption, kW/ton refrigeration, is an energy index used in the HVAC&R industry in addition to EER and COP.

Currently used refrigeration compressors are reciprocating, scroll, screw, rotary, and centrifugal compressors.

Reciprocating Compressors

In a reciprocating compressor, as shown in Figure 9.8.1(a), a crankshaft connected to the motor shaft drives 2, 3, 4, or 6 single-acting pistons moving reciprocally in the cylinders via a connecting rod.

The refrigeration capacity of a reciprocating compressor is a fraction of a ton to about 200 tons. Refrigerants R-22 and R-134a are widely used in comfort and processing systems and sometimes R-717 in industrial applications. The maximum compression ratio R_{com} for a single-stage reciprocating compressor is about 7. Volumetric efficiency η_{v} drops from 0.92 to 0.65 when R_{com} is raised from 1 to 6. Capacity control of reciprocating compressor including: on-off and cylinder unloader in which discharge gas is in short cut and return to the suction chamber.

Although reciprocating compressors are still widely used today in small and medium-sized refrigeration systems, they have little room for significant improvement and will be gradually replaced by scroll and screw compressors.

Scroll Compressors

A scroll compressor consists of two identical spiral scrolls assembled opposite to each other, as shown in Figure 9.8.1(b). One of the scrolls is fixed, and the other moves in an orbit around the motor shaft whose amplitude equals the radius of the orbit. The two scrolls are in contact at several points and therefore form a series of pockets.

Vapor refrigerant enters the space between two scrolls through lateral openings. The lateral openings are then sealed and the formation of the two trapped vapor pockets indicates the end of the suction process. The vapor is compressed and the discharge process begins when the trapped gaseous pockets open to the discharge port. Compressed hot gas is then discharged through this opening to the discharge

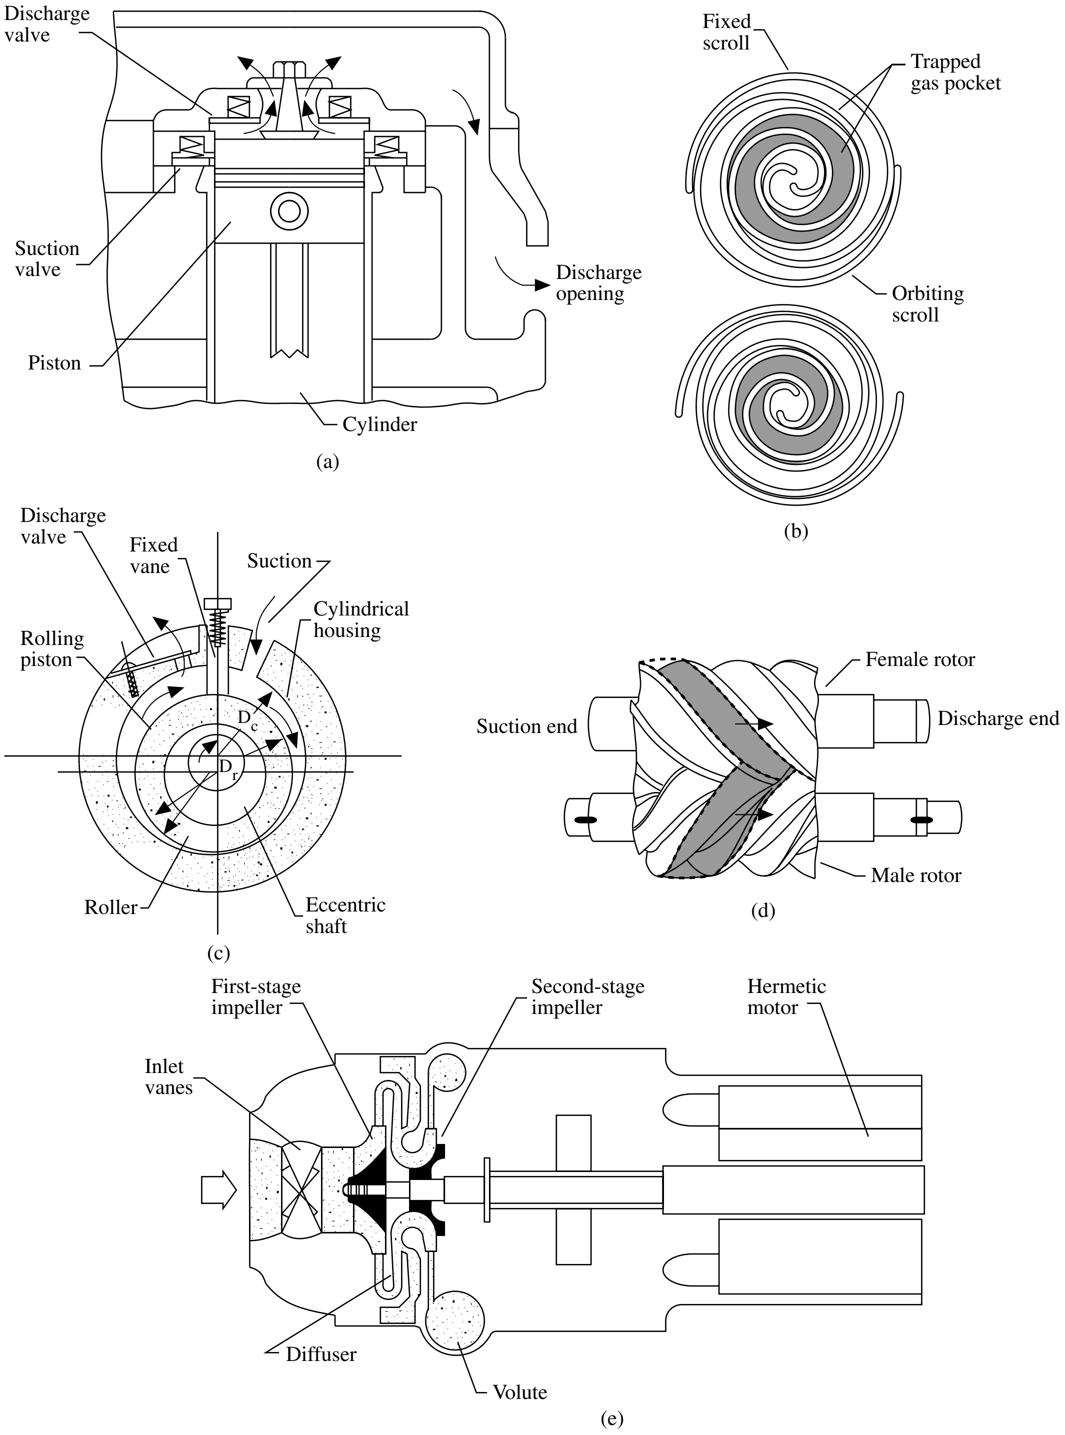


FIGURE 9.8.1 Various types of refrigeration compressors: (a) reciprocating, (b) scroll, (c) rotary, (d) twin-screw, and (e) centrifugal.

line. In a scroll compressor, the scrolls touch each other with sufficient force to form a seal but not enough to cause wear.

The upper limit of the refrigeration capacity of currently manufactured scroll compressors is 60 tons. A scroll compressor has $\eta_v > 95\%$ at $R_{com} = 4$ and $\eta_{isen} = 80\%$. A scroll compressor also has only about half as many parts as a reciprocating compressor at the same refrigeration capacity. Few components result in higher reliability and efficiency. Power input to the scroll compressor is about 5 to 10% less than to the reciprocating compressor. A scroll compressor also operates more smoothly and is quieter.

Rotary Compressors

Small rotary compressors for room air conditioners and refrigerators have a capacity up to 4 tons. There are two types of rotary compressors: rolling piston and rotating vane. A typical rolling piston rotary compressor is shown in Figure 9.8.1(c). A rolling piston mounted on an eccentric shaft is kept in contact with a fixed vane that slides in a slot. Vapor refrigerant enters the compression chamber and is compressed by the eccentric motion of the roller. When the rolling piston contacts the top housing, hot gas is squeezed out from the discharge valve.

Screw Compressors

These are also called *helical rotary compressors*. Screw compressors can be classified into single-screw compressors, in which there is a single helical rotor and two star wheels, and twin-screw compressors. Twin-screw compressors are widely used.

A typical twin-screw compressor, as shown in Figure 9.8.1(d) consists of a four-lobe male rotor and a six-lobe female rotor, a housing with suction and discharge ports, and a sliding valve to adjust the capacity during part load. Normally, the male rotor is the driver. Twin-screw compressors are often direct driven and of hermetic type.

Vapor refrigerant is extracted into the interlobe space when the lobes are separated at the suction port. During the successive rotations of the rotor, the volume of the trapped vapor is compressed. When the interlobe space is in contact with the discharge port, the compressed hot gas discharges through the outlet. Oil injection effectively cools the rotors and results in a lower discharge temperature. Oil also provides a sealing effect and lubrication. A small clearance of 0.0005 in. as well as the oil sealing minimizes leakage of the refrigerant.

The refrigeration capacity of twin-screw compressors is 50 to 1500 tons. The compression ratio of a twin-screw compressor can be up to 20:1. R-22 and R-134a are the most widely used refrigerants in comfort systems. In a typical twin-screw compressor, η_v decreases from 0.92 to 0.87 and η_{isen} drops from 0.82 to 0.67 when R_{com} increases from 2 to 10. Continuous and stepless capacity control is provided by moving a sliding valve toward the discharge port, which opens a shortcut recirculating passage to the suction port.

Twin-screw compressors are more efficient than reciprocating compressors. The low noise and vibration of the twin-screw compressor together with its positive displacement compression results in more applications today.

Centrifugal Compressors

A *centrifugal compressor* is a turbomachine and is similar to a centrifugal fan. A hermetic centrifugal compressor has an outer casing with one, two, or even three impellers internally connected in series and is driven by a motor directly or by a gear train. At the entrance to the first-stage impeller are inlet guide vanes positioned at a specific opening to adjust refrigerant flow and therefore the capacity of the centrifugal compressor.

Figure 9.8.1(e) shows a two-stage hermetic centrifugal compressor. The total pressure rise in a centrifugal compressor, often called head lift, in psi, is due to the conversion of the velocity pressure into static pressure. Although the compression ratio R_{com} of a single-stage centrifugal compressor using R-123 and R-22 seldom exceeds 4, two or three impellers connected in series satisfy most of the requirements in comfort systems.

Because of the high head lift to raise the evaporating pressure to condensing pressure, the discharge velocity at the exit of the second-stage impeller approaches the acoustic velocity of saturated vapor v_{ac} of R-123, 420 ft/sec at atmospheric pressure and a temperature of 80°F. Centrifugal compressors need high peripheral velocity and rotating speeds (up to 50,000 rpm) to produce such a discharge velocity. It is not economical to manufacture small centrifugal compressors. The available refrigeration capacity for centrifugal compressors ranges from 100 to 10,000 tons. Centrifugal compressors have higher volume flow per unit refrigeration capacity output than positive displacement compressors. Centrifugal compressors are efficient and reliable. Their volumetric efficiency almost equals 1. At design conditions, their η_{isen} may reach 0.83, and it drops to 0.6 during part-load operation. They are the most widely used refrigeration compressors in large air-conditioning systems.

Refrigeration Condensers

A *refrigeration condenser* or simply a *condenser* is a heat exchanger in which hot gaseous refrigerant is condensed into liquid and the latent heat of condensation is rejected to the atmospheric air, surface water, or well water. In a condenser, hot gas is first desuperheated, then condensed into liquid, and finally subcooled.

The capacity of a condenser is rated by its *total heat rejection* Q_{rej}, in Btu/hr, which is defined as the total heat removed from the condenser during desuperheating, condensation, and subcooling. For a refrigeration system using a hermetic compressor, Q_{rej} can be calculated as

$$Q_{rej} = U_{con} A_{con} \Delta T_m = 60 \mathring{m}_r \left(h_2 - h_3'\right) = q_{rl} + \left(2545 P_{com}\right) / \eta_{mo} \tag{9.8.4}$$

where

U_{con} = overall heat transfer coefficient across the tube wall in the condenser, Btu/hr.ft^2.°F
A_{con} = condensing area in the condenser, ft^2
ΔT_m = logarithmic temperature difference, °F
$\mathring{m}_r$ = mass flow rate of refrigerant, lb/min
h_2, h_3' = enthalpy of suction vapor refrigerant and hot gas, Btu/lb
q_{rl} = refrigeration load at the evaporator, Btu/hr

A factor that relates Q_{rej} and q_{rl} is the *heat rejection factor* F_{rej}, which is defined as the ratio of total heat rejection to the refrigeration load, or

$$F_{rej} = Q_{rej} / q_{rl} = 1 + \left(2545 P_{com}\right) / \left(q_{rl} \eta_{mo}\right) \tag{9.8.5}$$

Fouling factor R_f, in hr.ft^2.°F/Btu, is defined as the additional resistance caused by a dirty film of scale, rust, or other deposits on the surface of the tube. ARI Standard 550-88 specifies the following for evaporators and condensers:

Field fouling allowance	0.00025 hr.ft^2.°F/Btu
New evaporators and condensers	0

According to the cooling process used during condensation, refrigeration condensers can be classified as air-cooled, water-cooled, and evaporative-cooled condensers.

Air-Cooled Condensers

In an *air-cooled condenser*, air is used to absorb the latent heat of condensation released during desuperheating, condensation, and subcooling.

An air-cooled condenser consists of a condenser coil, a subcooling coil, condenser fans, dampers, and controls as shown in Figure 9.8.2(a). There are refrigeration circuits in the condensing coil. Condensing coils are usually made of copper tubes and aluminum fins. The diameter of the tubes is 1/4 to 3/4 in., typically 3/8 in., and the fin density is 8 to 20 fins/in. On the inner surface of the copper tubes, microfins, typically 60 fins/in. with a height of 0.008 in., are used. A condensing coil usually has only two to three rows due to the low pressure drop of the propeller-type condenser fans. A subcooling coil is located at a lower level and is connected to the condensing coil.

Hot gas from the compressor enters the condensing coil from the top. When the condensate increases, part of the condensing area can be used as a subcooling area. A receiver is necessary only when the liquid refrigerant cannot all be stored in the condensing and subcooling coils during the shut-down period in winter.

Cooling air is drawn through the coils by a condenser fan(s) for even distribution. Condenser fans are often propeller fans for their low pressure and large volume flow rate. A damper(s) may be installed to adjust the volume flow of cooling air.

In air-cooled condensers, the volume flow of cooling air per unit of total heat rejection $\mathring{V}_{ca}/Q_{u.rej}$ is 600 to 1200 cfm/ton of refrigeration capacity at the evaporator, and the optimum value is about 900 cfm/ton. The corresponding cooling air temperature difference — cooling air leaving temperature minus outdoor temperature ($T_{ca.l} - T_o$) — is around 13°F.

The condenser temperature difference (CTD) for an air-cooled condenser is defined as the difference between the saturated condensing temperature corresponding to the pressure at the inlet and the air intake temperature, or ($T_{con.i} - T_o$). Air-cooled condensers are rated at a specific CTD, depending on the evaporating temperature of the refrigeration system T_{ev} in which the air-cooled condenser is installed. For a refrigeration system having a lower T_{ev}, it is more economical to equip a larger condenser with a smaller CTD. For a comfort air-conditioning system having a T_{ev} of 45°F, CTD = 20 to 30°F.

A higher condensing temperature T_{con}, a higher condensing pressure p_{con}, and a higher compressor power input may be due to an undersized air-cooled condenser, lack of cooling air or low $\mathring{V}_{ca}/Q_{u.rej}$ value, a high entering cooling air temperature at the roof, a dirty condensing coil, warm air circulation because of insufficient clearance between the condenser and the wall, or a combination of these. The clearance should not be less than the width of the condensing coil.

If p_{con} drops below a certain value because of a lower outdoor temperature, the expansion valve in a reciprocating vapor compression system may not operate properly. At a low ambient temperature T_o, the following controls are often used:

- Duty cycling, turning the condenser fans on and off until all of them are shut down, to reduce cooling air volume flow
- Modulating the air dampers to reduce the volume flow
- Reducing the fan speed

Some manufacturers' catalogs start low ambient control at T_o = 65°F and some specify a minimum operating temperature at T_o = 0°F.

Water-Cooled Condensers

In a *water-cooled condenser*, latent heat of condensation released from the refrigerant during condensation is extracted by water. This cooling water, often called condenser water, is taken directly from river, lake, sea, underground well water or a cooling tower.

Two types of water-cooled condensers are widely used for air-conditioning and refrigeration: double-tube condensers and horizontal shell-and-tube condensers.

A *double-tube condenser* consists of two tubes, one inside the other. Condenser water is pumped through the inner tube and refrigerant flows within the space between the inner and outer tubes in a counterflow arrangement. Because of its limited condensing area, the double-tube condenser is used only in small refrigeration systems.

A horizontal *shell-and-tube water-cooled condenser* using halocarbon refrigerant usually has an outer shell in which copper tubes typically 5/8 to 3/4 in. in diameter are fixed in position by tube sheets as shown in Figure 9.8.2(b). Integral external fins of 19 to 35 fins/in. and a height of 0.006 in. and spiral internal grooves are used for copper tubes to increase both the external and the inner surface area and their heat transfer coefficients.

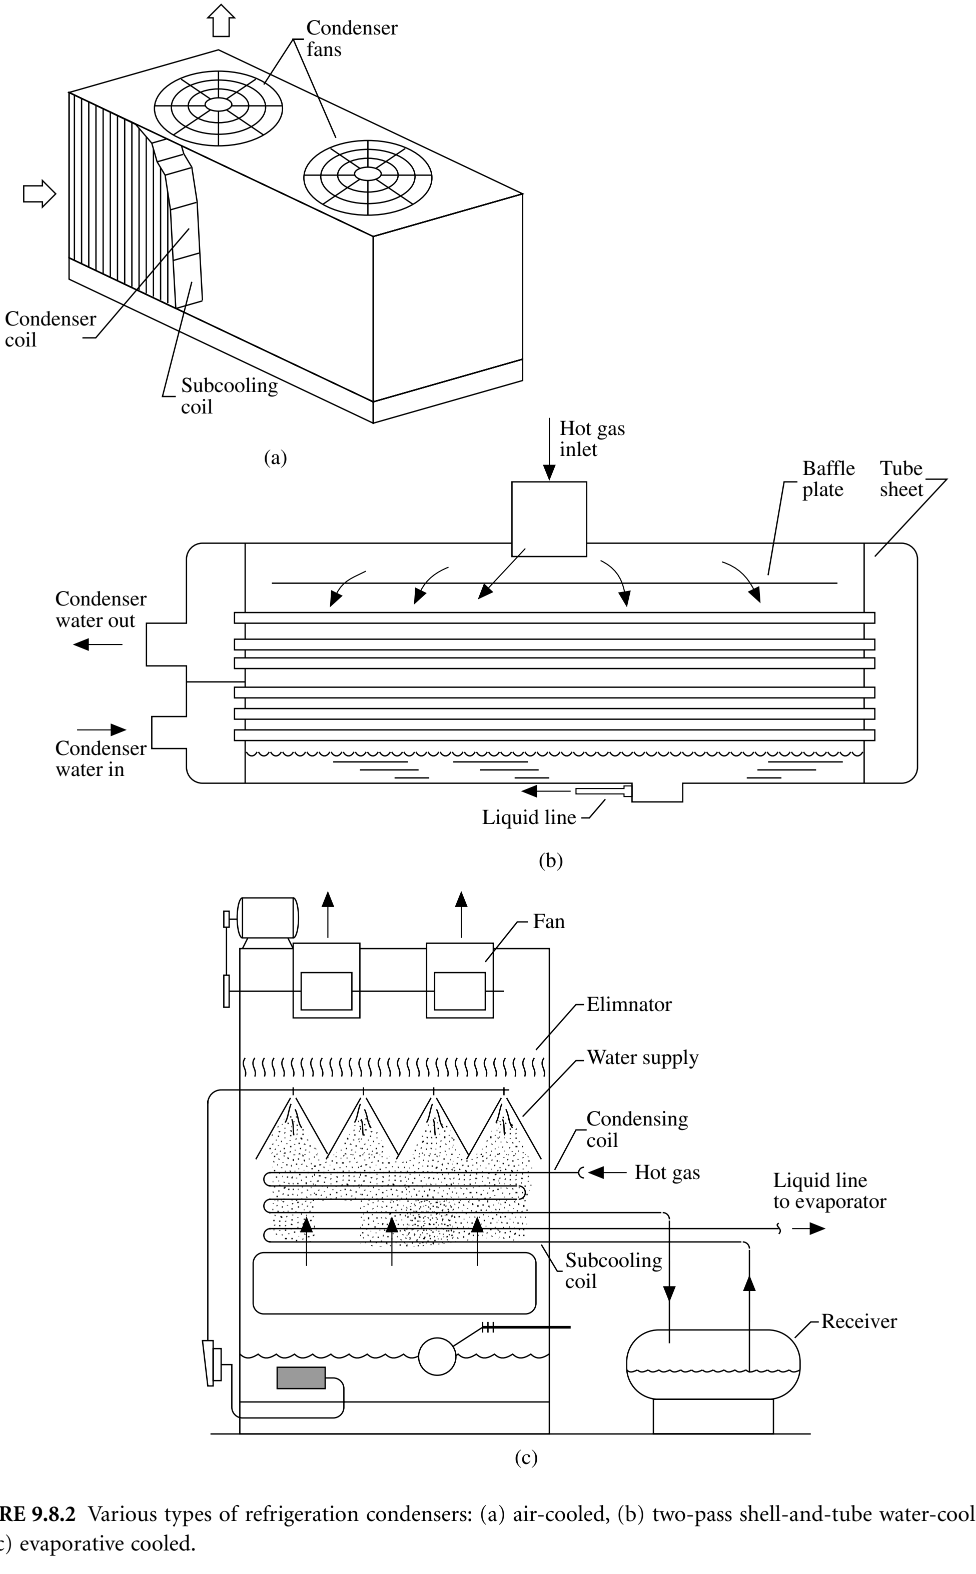

FIGURE 9.8.2 Various types of refrigeration condensers: (a) air-cooled, (b) two-pass shell-and-tube water-cooled, and (c) evaporative cooled.

Hot gas from the compressor enters the top inlet and is distributed along the baffle to fill the shell. Hot gas is then desuperheated, condensed, subcooled into liquid, and discharged into the liquid line at the bottom outlet. Usually one sixth of the volume is filled with subcooled liquid refrigerant. Subcooling depends on the entering temperature of condenser water T_{ce}, in °F, and usually varies between 2 and 8°F.

Condenser water enters the condenser from the bottom for effective subcooling. After extracting heat from the gaseous refrigerant, condenser water is discharged at a higher level. Two-pass or three-pass water flow arrangements are usually used in shell-and-tube water-cooled condensers. The two-pass arrangement means that water flows from one end to the opposite end and returns to the original end. Two-pass is the standard setup. In a shell-and-tube water-cooled condenser, the condensing temperature T_{con} depends mainly on the entering temperature of condenser water T_{ce}, the condenser area, the fouling factor, and the configuration of the copper tube.

Evaporative Condenser

An *evaporative condenser* uses the evaporation of water spray on the outer surface of the condensing tubes to remove the latent heat of condensation of refrigerant during condensation.

An evaporative condenser consists of a condensing coil, a subcooling coil, a water spray, an induced draft or sometimes forced draft fan, a circulating water pump, a water eliminator, a water basin, an outer casing, and controls as shown in Figure 9.8.2(c). The condensing coil is usually made of bare copper, steel, or sometimes stainless steel tubing.

Water is sprayed over the outside surface of the tubing. The evaporation of a fraction of condenser water from the saturated air film removes the sensible and latent heat rejected by the refrigerant. The wetted outer surface heat transfer coefficient h_{wet} is about four or five times greater than the dry surface heat transfer coefficient h_o, in Btu/hr.ft^2.°F. The rest of the spray falls and is collected by the basin. Air enters from the inlet just above the basin. It flows through the condensing coil at a face velocity of 400 to 700 fpm, the water spray bank, and the eliminator. After air absorbs the evaporated water vapor, it is extracted by the fan and discharged at the top outlet. The water circulation rate is about 1.6 to 2 gpm/ton, which is far less than that of the cooling tower.

An evaporative condenser is actually a combination of a water-cooled condenser and a cooling tower. It is usually located on the rooftop and should be as near the compressor as possible. Clean tube surface and good maintenance are critical factors for evaporative condensers. An evaporative condenser also needs low ambient control similar as in an air-cooled condenser.

Comparison of Air-Cooled, Water-Cooled, and Evaporative Condensers

An air-cooled condenser has the highest condensing temperature T_{con} and therefore the highest compressor power input. For an outdoor dry bulb temperature of 90°F and a wet bulb temperature of 78°F, a typical air-cooled condenser has $T_{con} = 110$°F. An evaporative condenser has the lowest T_{con} and is most energy efficient. At the same outdoor dry and wet bulb temperatures, its T_{con} may be equal to 95°F, even lower than that of a water-cooled condenser incorporating with a cooling tower, whose T_{con} may be equal to 100°F. An evaporative condenser also consumes less water and pump power. The drawback of evaporative condensers is that the rejected heat from the interior zone is difficult to recover and use as winter heating for perimeter zones and more maintenance is required.

Evaporators and Refrigerant Flow Control Devices

An *evaporator* is a heat exchanger in which the liquid refrigerant is vaporized and extracts heat from the surrounding air, chilled water, brine, or other substance to produce a refrigeration effect.

Evaporators used in air-conditioning can be classified according to the combination of the medium to be cooled and the type of refrigerant feed, as the following.

Direct expansion DX coils are air coolers, and the refrigerant is fed according to its degree of superheat after vaporization. DX coils were covered earlier.

Direct expansion ice makers or *liquid overfeed ice makers* are such that liquid refrigerant is forced through the copper tubes or the hollow inner part of a plate heat exchanger and vaporized. The refrigeration effect freezes the water in the glycol-water that flows over the outside surface of the tubes or the plate heat exchanger. In direct expansion ice makers, liquid refrigerant completely vaporizes inside the copper tubes, and the superheated vapor is extracted by the compressor. In liquid overfeed ice makers, liquid refrigerant floods and wets the inner surface of the copper tubes or the hollow plate heat exchanger. Only part of the liquid refrigerant is vaporized. The rest is returned to a receiver and pumped to the copper tubes or plate heat exchanger again at a circulation rate two to several times greater than the evaporation rate.

Flooded shell-and-tube liquid coolers, or simply *flooded liquid coolers*, are such that refrigerant floods and wets all the boiling surfaces and results in high heat transfer coefficients. A flooded shell-and-tube liquid cooler is similar in construction to a shell-and-tube water-cooled condenser, except that its liquid refrigeration inlet is at the bottom and the vapor outlet is at the top. Water velocity inside the copper tubes is usually between 4 and 12 ft/sec and the water-side pressure normally drops below 10 psi. Flooded liquid coolers can provide larger evaporating surface area and need minimal space. They are widely used in large central air-conditioning systems.

Currently used refrigerant flow control devices include thermostatic expansion valves, float valves, multiple orifices, and capillary tubes.

A *thermostatic expansion valve* throttles the refrigerant pressure from condensing to evaporating pressure and at the same time regulates the rate of refrigerant feed according to the degree of superheat of the vapor at the evaporator's exit. A thermostatic expansion valve is usually installed just prior to the refrigerant distributor in DX coils and direct-expansion ice makers.

A thermostatic expansion valve consists of a valve body, a valve pin, a spring, a diaphragm, and a sensing bulb near the outlet of the DX coil, as shown in Figure 9.7.3(a). The sensing bulb is connected to the upper part of the diaphragm by a connecting tube.

When the liquid refrigerant passes through the opening of the thermostatic expansion valve, its pressure is reduced to the evaporating pressure. Liquid and a small fraction of vaporized refrigerant then flow through the distributor and enter various refrigerant circuits. If the refrigeration load of the DX coil increases, more liquid refrigerant vaporizers. This increases the degree of superheat of the leaving vapor at the outlet and the temperature of the sensing bulb. A higher bulb temperature exerts a higher saturated pressure on the top of the diaphragm. The valve pin then moves downward and widens the opening. More liquid refrigerant is allowed to enter the DX coil to match the increase of refrigeration load. If the refrigeration load drops, the degree of superheat at the outlet and the temperature of the sensing bulb both drop, and the valve opening is narrower. The refrigeration feed decreases accordingly. The degree of superheat is usually 10 to 20°F. Its value can also be adjusted manually by varying the spring tension. The bulbs of the thermostatic expansion valves can be charged with the same refrigerant as in the system or "cross-charged" by using a different refrigerant to improve response.

A *float valve* is a valve in which a float is used to regulate the valve opening to maintain a specific liquid refrigerant level. A lower liquid level causes a lower valve pin and therefore a wider opening and vice versa.

In a centrifugal refrigeration system, two or more orifice plates, *multiple orifices*, are sometimes installed in the liquid line between the condenser and the flash cooler and between the flash cooler and the flooded liquid cooler to throttle their pressure as well as to regulate the refrigerant feed.

A *capillary tube*, sometimes called a *restrictor tube*, is a fixed length of small-diameter tubing installed between the condenser and the evaporator to throttle the refrigerant pressure from p_{con} to p_{ev} and to meter the refrigerant flow to the evaporator. Capillary tubes are usually made of copper. The inside diameter D_{cap} is 0.05 to 0.06 in. and the length L_{cap} from an inch to several feet. There is a trend to use short capillary tubes of L_{cap}/D_{cap} between 3 and 20. Capillary tubes are especially suitable for a heat pump system in which the refrigerant flow may be reversed.

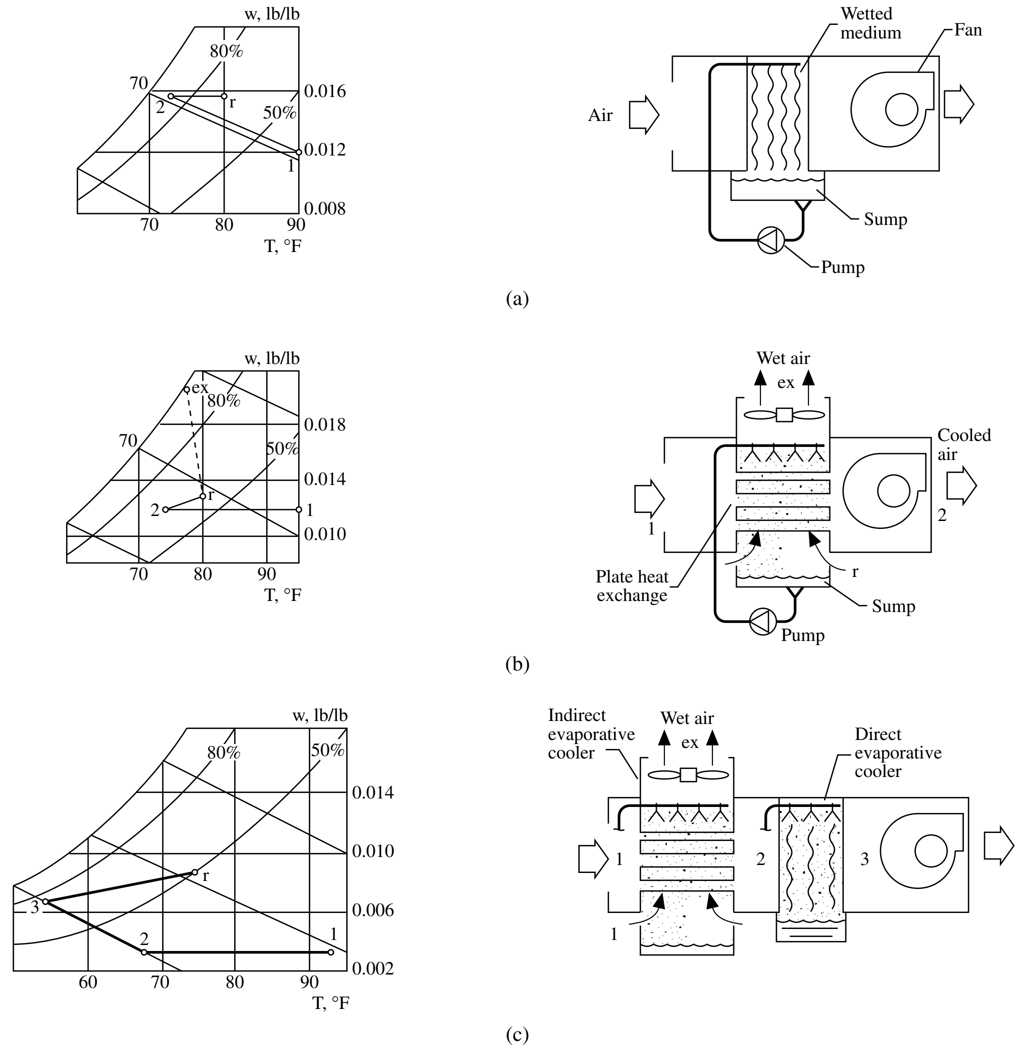

FIGURE 9.8.3 Types of evaporative coolers: (a) direct, (b) indirect, and (c) indirect–direct.

Evaporative Coolers

An evaporative cooling system is an air-conditioning system in which air is cooled evaporatively. It consists of evaporative coolers, fan(s), filters, dampers, controls, and others. A mixing box is optional. An evaporative cooler could be a stand-alone cooler or installed in an air system as a component. There are three types of evaporative coolers: (1) direct evaporative coolers, (2) indirect evaporative coolers, and (3) indirect–direct evaporative coolers.

Direct Evaporative Cooler

In a *direct evaporative cooler*, the air stream to be cooled directly contacts the water spray or wetted medium as shown in Figure 9.8.3(a). Evaporative pads made of wooden fibers with necessary treatment at a thickness of 2 in., rigid and corrugated plastics, impregnated cellulose, or fiber glass all dripping with water are wetted mediums.

The direct evaporation process 12 takes place along the thermodynamic wet bulb line on the psychrometric chart. Saturation effectiveness ε_{sat} is an index that assesses the performance of a direct evaporative cooler:

$$\varepsilon_{\text{sat}} = \left(T_{\text{ae}} - T_{\text{al}}\right) / \left(T_{\text{ae}} - T^{*}_{\text{ae}}\right) \tag{9.8.6}$$

where T, T^{*} = temperature and thermodynamic wet bulb temperature of air stream, °F. Subscript ae indicates the entering air and al the leaving air. ε_{sat} usually varies between 0.75 and 0.95 at a water–air ratio of 0.1 to 0.4.

Indirect Evaporative Coolers

In an *indirect evaporative cooler*, the cooled-air stream to be cooled is separated from a wetted surface by a flat plate or tube wall as shown in Figure 9.8.3(b). A wet-air stream flows over the wetted surface so that liquid water is evaporated and extracts heat from the cooled-air stream through the flat plate or tube wall. The cooled-air stream is in contact with the wetted surface indirectly.

The core part of an indirect evaporative cooler is a plate heat exchanger. It is made of thin polyvinyl chloride plates 0.01 in. thick and spaced from 0.08 to 0.12 in. apart to form horizontal passages for cooled air and vertical passages for wet air and water. As in a direct evaporative cooler, there are also fan(s), water sprays, circulating pump, air intake, dampers, controls, etc.

An indirect evaporative cooling process is represented by a horizontal line on a psychrometric chart, which shows that humidity ratio remains constant. If the space air is extracted and used as the wet air intake, the wet air will be exhausted at point x at nearly saturated state.

The performance of an indirect evaporative cooler can be assessed by its performance factor e_{in}, which is calculated as:

$$e_{\text{in}} = \left(T_{\text{ca.e}} - T_{\text{ca.l}}\right) / \left(T_{\text{ca.e}} - T_{\text{s.a}}\right) \tag{9.8.7}$$

where $T_{\text{ca.e}}$, $T_{\text{ca.l}}$ = temperature of cooled air entering and leaving the indirect evaporative cooler, °F, and $T_{\text{s.a}}$ = temperature of the saturated air film on the wet air side and is about 3°F higher than the wet bulb temperature of the entering air, °F.

An indirect evaporative cooler could be so energy efficient as to provide evaporative cooling with an EER up to 50 instead of 9 to 12 for a reciprocating compression refrigeration system.

Direct–Indirect Evaporative Cooler. A direct–indirect evaporative cooler is a two-stage evaporating cooler, as shown in Figure 9.15.6(c), in which the first-stage indirect evaporative cooler is connected in series with a second-stage direct evaporative cooler for the purpose of increasing the evaporating effect.

Operating Characteristics. The saturation effectiveness ε_{sat} and performance factor e_{in} are both closely related to the air velocity flowing through the air passages. For a direct evaporative cooler, face velocity is usually less than 600 fpm to reduce drift carryover. For an indirect evaporative cooler, face velocity v_s is usually between 400 to 1000 fpm. A higher v_s results at a greater air-side pressure drop.

Scofield et al. (1984) reported the performance of an indirect–direct evaporative cooler in Denver, Colorado. Outdoor air enters the indirect cooler at a dry bulb of 93°F and a wet bulb of 67.5° and was evaporatively cooled to 67.5°F dry bulb and 49.8°F wet bulb with an $e_{\text{in}} = 0.76$ as shown in Figure 9.8.3(c). In the direct cooler, conditioned air was further cooled to a dry bulb of 53.5°F and the wet bulb remained at 49.8°F at a saturation effectiveness $\varepsilon_{\text{sat}} = 0.8$.

In locations where outdoor wet bulb $T'_o \le 60$°F, a direct evaporative can often provide an indoor environment of 78°F and a relative humidity of 60%. In locations $T'_o \le 68$°F, an indirect–direct evaporative cooler can maintain a comfortable indoor environment. In locations $T'_o \ge 72$°F, an evaporative cooler with a supplementary vapor compression refrigeration may be cost effective. Because the installation cost of an indirect–direct cooler is higher than that of refrigeration, cost analysis is required to select the right choice. Evaporative coolers are not suitable for dehumidification except in locations where $T'_o \le 60$°F.

9.9 Water Systems

Herbert A. Ingley and Shan K. Wang

Types of Water Systems

In central and space conditioning air-conditioning systems, water that links the central plant and the air handling units or terminals, that extracts condensing heat, or that provides evaporative cooling may be classified as

- *Chilled water system*, in which chilled water is first cooled in the centrifugal, screw, and reciprocating chillers in a central plant. Chilled water is then used as a cooling medium to cool the air in the cooling coils in AHUs and terminals.
- *Evaporative-cooled water system*, used to cool air directly or indirectly in evaporative coolers.
- *Hot water system*, in which hot water is heated in the boiler and then used to heat the air through heating coils in AHUs, terminals, or space finned-tube heaters.
- *Dual-temperature water system*, in which chilled water and hot water are supplied to and returned from the coils in AHUs and terminals through separate or common main and branch pipes. Using common main and branch pipes requires a lengthy changeover from chilled water to hot water or vice versa for a period of several hours.
- *Condenser water system*, which is a kind of cooling water system used to extract the latent heat of condensation from the condensing refrigerant in a water-cooled condenser and heat of absorption from the absorber.

Water systems can also be classified according to their operating characteristics.

Closed System

In a closed system, water forms a closed loop for water conservation and energy saving when it flows through the coils, chillers, boilers, heaters, or other heat exchangers and water is not exposed to the atmosphere.

Open System

In an open system, water is exposed to the atmosphere. A condenser water system with a cooling tower would be an example of an open system.

Once-Through System

In a once-through system, water flows through a heat exchanger(s) only once without recirculation. A condenser water system using well water that is ultimately rejected to a pond would be an example of a once-through system.

Basics

Volume Flow and Temperature Difference

The rate of heat transfer between water and air or water and refrigerant when water flows through a heat exchanger q_w, in Btu/hr, can be calculated as

$$q_w = 500 \mathring{V}_{gal} \left(T_{wl} - T_{we}\right) = 500 \mathring{V}_{gal} \Delta T_w \tag{9.9.1}$$

where

$\mathring{V}_{gal}$ = volume flow rate of water, gpm
T_{wl}, T_{we} = temperature of water leaving and entering the heat exchanger, °F
ΔT_w = temperature rise or drop of water when it flows through a heat exchanger, °F
$500 \cong 8.34$ lb/gal $*$ 1 Btu/lb°F $*$ 60 min/hr

The temperature of chilled water leaving the water chiller T_{el} should not be lower than 38°F in order to prevent freezing in the evaporator. Otherwise, brine or glycol-water should be used. The T_{el} of chilled water entering the coil T_{we} and the temperature difference of chilled water leaving and entering the coil ΔT_w directly affect the temperature of air leaving the cooling coil T_{cc}. The lower T_{we}, the higher will be the compressor power input. The smaller ΔT_w, the greater will be the water volume flow rate, the pipe size, and the pump power. For chilled water in conventional comfort systems, T_{we} is usually 40 to 45°F and ΔT_w 12 to 24°F. Only in cold air distribution, T_{we} may drop to 34°F. For a cooling capacity of 1 ton refrigeration, a ΔT_w of 12°F requires a $\overset{\circ}{V}_{gal} = 2$ gpm.
