For hot water heating systems in buildings, hot water often leaves the boiler and enters the heating coil or heaters at a temperature T_{we} of 180 to 200°F. It returns at 150 to 160°F. For dual-temperature systems, hot water is usually supplied at 100 to 150°F and returns at a ΔT_w of 20 to 40°F.

Pressure Drop

Usually the pressure drop of water in pipes due to friction for HVAC&R systems, H_f, is in the range 1.0 ft/100 ft length of pipe to 4 ft/100 ft. A pressure loss of 2.5 ft/100 ft is most often used. Figure 9.9.1(a), (b), and (c) shows the friction charts for steel, copper, and plastic pipes for closed water systems.

Water Piping

The piping materials of various water systems for HVAC&R are as follows:

Chilled water	Black and galvanized steel
Hot water	Black steel, hard copper
Condenser water	Black steel, galvanized ductile iron, polyvinyl chloride (PVC)

The pipe thickness varies from Schedule 10, a light wall pipe, to Schedule 160, a very heavy wall pipe. Schedule 40 is the standard thickness for a pipe of up to 10 in. diameter. For copper tubing, type K is the heaviest, and type L is generally used as the standard for pressure copper tubes.

Steel pipes of small diameter are often joined by threaded cast-iron fittings. Steel pipes of diameter 2 in. and over, welded joints, and bolted flanges are often used.

In a water system, the maximum allowable working pressure for steel and copper pipes at 250°F varies from 125 to 400 psig, depending on the pipe wall thickness. Not only pipes, but also their joints and fittings should be considered.

During temperature changes, pipes expand and contract. Both operating and shut-down periods should be taken into consideration. Bends like U-, Z-, and L-bends, loops, and sometimes packed expansion joints, bellows, or flexible metal hose mechanical joints are used.

ASHRAE/IES Standard 90.1-2001 specifies minimum thickness of pipe insulation for chilled water and heating hot water piping.

Corrosion, Impurities, and Water Treatments

Corrosion is a destructive process caused by a chemical or electrochemical reaction on metal or alloy. In water systems, dissolved *impurities* cause corrosion and scale and the growth of microbiologicals like algae, bacteria, and fungi. *Scale* is the deposit formed on a metal surface by precipitation of the insoluble constituents. In addition to the dissolved solids, unpurified water may contain suspended solids.

Currently used chemicals include crystal modifiers to change the crystal formation of scale and sequestering chemicals. Growth of bacteria, algae, and fungi is usually treated by biocides to prevent the formation of an insulating layer resulting in lower heat transfer as well as restricted water flow. Chlorine and its compounds are effective and widely used. Blow-down is an effective process in water treatment and should be considered as important as chemical treatments.

Piping Arrangements

Main and Branch Pipes. In a piping circuit as shown in Figure 9.9.2(a), chilled water from a chiller or hot water from a boiler is often supplied to a *main pipe* and then distributed to *branch pipes* that connect

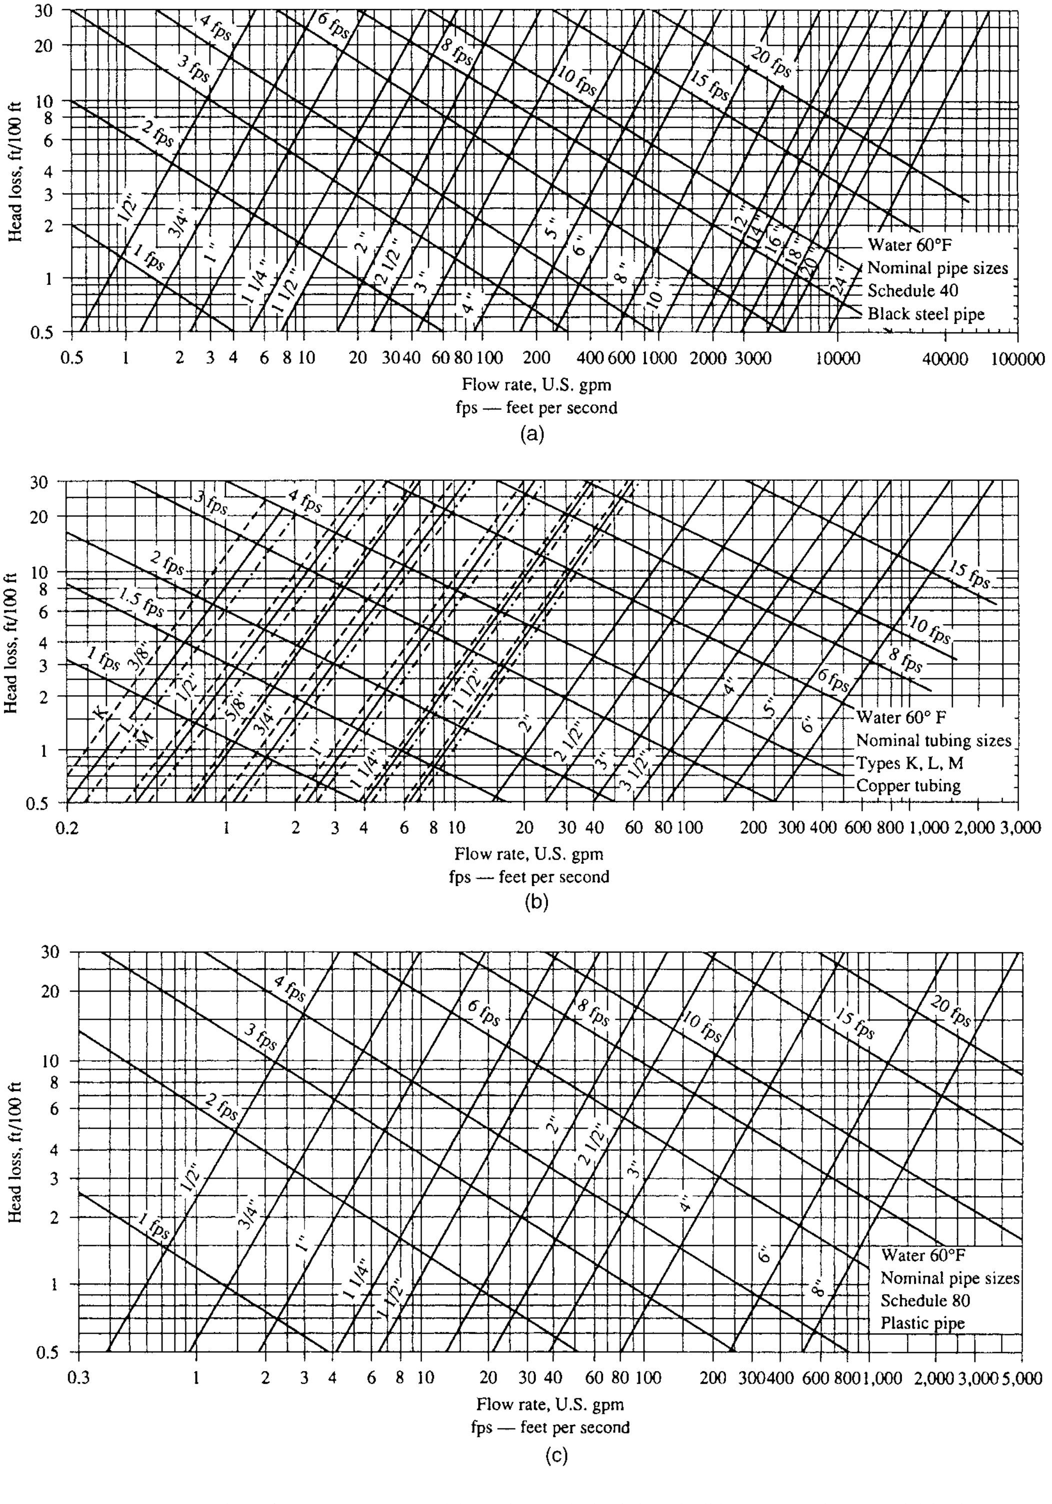

FIGURE 9.9.1 Friction chart for water in pipes: (a) steel pipe (schedule 40), (b) copper tubing, and (c) plastic pipe (schedule 80). (Souce: *ASHRAE Handbook 1993 Fundamentals*. Reprinted with permission.)

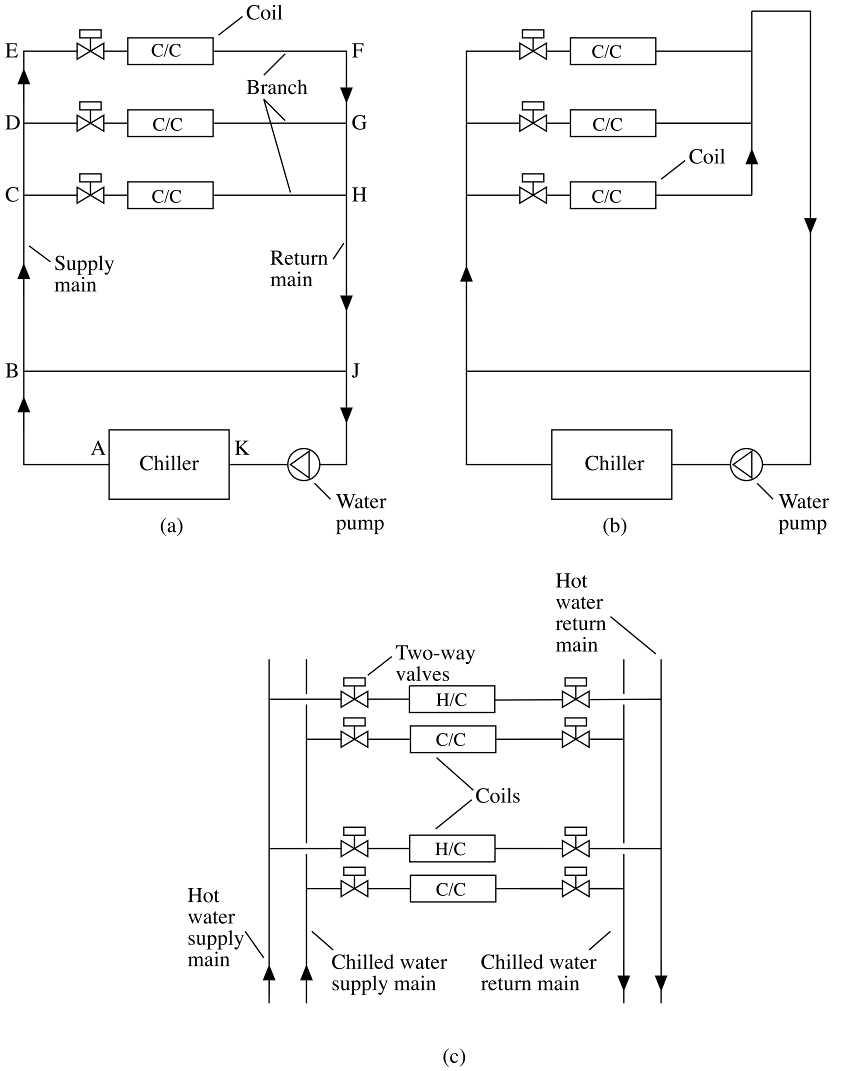

FIGURE 9.9.2 Piping arrangements: (a) two-pipe direct return system, (b) two-pipe reverse system, and (c) four-pipe system.

to coils and heat exchangers. Chilled or hot water from the coils and heat exchangers is accumulated by the return main pipe through return branch pipes and then returned to the chiller or boiler.

Constant Flow and Variable Flow. In a constant-flow water system, the volume flow rate at any cross-sectional plane of the supply and return mains remains constant during the entire operating period. In a variable-flow water system, the volume flow rate varies when the system load changes during the operating period.

Direct Return and Reverse Return. In a *direct return* system, the water supplies to and returns from various coils through various piping circuits. ABCHJKA, … ABCDEFGHJKA are not equal in length, as shown in Figure 9.9.2(a). Water flow must be adjusted and balanced by using balance valves to provide required design flow rates at design conditions. In a *reverse-return* system, as shown in Figure 9.9.2(b), the piping lengths for various piping circuits including the branch and coil are almost equal. Water flow rates to various coils are easier to balance.

Two-Pipe or Four-Pipe. In a dual-temperature water system, the piping from the chiller or boiler to the coils can be either a *two-pipe* system with a supply main and return main as shown in Figure 9.9.2(a) or (b) or a *four-pipe* system with a chilled water supply main, a hot water supply main, a chilled water return main, and a hot water return main as shown in Figure 9.9.2(c). The two-pipe system needs a changeover from chilled to hot water and vice versa. A four-pipe system is more expensive to install.

9.10 Heating Systems

Shan K. Wang

Warm Air Furnaces

A *warm air furnace* is a device in which gaseous or liquid fuel is directly fired or electric resistance heaters are used to heat the warm supply air. Natural gas, liquefied petroleum gas (LPG), oil, electric energy, or occasionally wood may be used as the fuel or energy input. Among these, natural gas is most widely used. In a warm air furnace, the warm air flow could be *upflow*, in which the warm air is discharged at the top, as shown in Figure 9.10.1(a) and (b); downflow, with the warm air discharged at the bottom; or *horizontal flow*, with the warm air discharged horizontally.

Natural Vent Combustion Systems. There are two types of combustion systems in a natural gas-fired warm air furnace: natural vent or power vent combustion systems. In a *natural vent* or *atmospheric vent* combustion system, the buoyancy of the combustion products carries the flue gas flowing through the heat exchanger and draft hood, discharging from the chimney or vent pipe. The gas burner is an *atmospheric burner.* In an atmospheric burner, air is exracted for combustion by the suction effect of the high-velocity discharged gas and the buoyance effect of the combustion air. An atmospheric burner can be either an in-shot or an up-shot burner or multiple ports. Atmospheric burners are simple, require only a minimal draft of air, and need sufficient gas pressure for normal functioning.

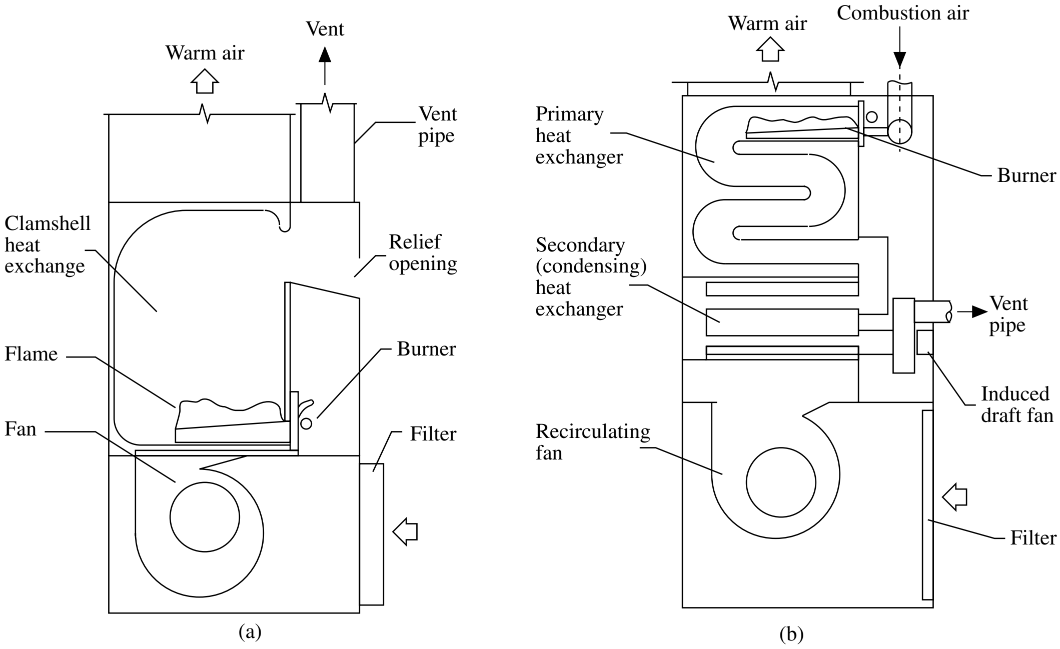

FIGURE 9.10.1 Upflow warm air gas furnace: (a) a natural-vent gas furnace and (b) a power-vent high-efficiency gas furnace.

Two types of ignition have been used in burners: standing pilot and spark ignition. In *standing pilot ignition*, the small pilot flame is monitored by a sensor and the gas supply is shut off if the flame is extinguished. *Spark ignition* fires intermittently only when ignition is required. It saves gas fuel if the furnace is not operating.

In a natural vent combustion system, the heat exchanger is often made from cold-rolled steel or aluminized steel in the shape of a clamshell or S. A fan or blower is always used to force the recirculating air flowing over the heat exchanger and distribute the heated air to the conditioned space. A low-efficiency disposable air filter is often located upstream of the fan to remove dust from the recirculating air. A draft hood is also installed to connect the flue gas exit at the top of the heat exchanger to a vent pipe or chimney. A relief air opening is employed to guarantee that the pressure at the flue gas exit is atmospheric and operates safely even if the chimney is blocked. The outer casing of the furnace is generally made of heavy-gauge steel with access panels.

Power Vent Combustion Systems. In a *power vent* combustion system, either a forced draft fan is used to supply the combustion air or an induced draft fan is used to induce the flue gas to the vent pipe or chimney. A power vent is often used for a large gas furnace or a high-efficiency gas furnace with condensing heat exchangers.

Gas burners in a power vent system are called *power burners*. The gas supply to the power burner is controlled by a pressure regulator and a gas valve to control the firing rate. Intermittent spark ignition and *hot surface ignition* that ignites the main burners directly are often used.

Usually, there are two heat exchangers in a power vent combustion system: a primary heat exchanger and a secondary or condensing heat exchanger. The primary heat exchanger constitutes the heating surface of the combustion chamber. When the water vapor in the flue gas is condensed by indirect contact with the recirculating air, part of the latent heat of condensation released is absorbed by the air. Thus the furnace efficiency is increased in the *secondary* or *condensing heat exchanger*. Both primary and secondary heat exchangers are made from corrosion-resistant steel. A fan is also used to force the recirculating air to flow over the heat exchangers and to distribute the heated air to the conditioned space.

Most natural gas furnaces can use LPG. LPG needs a pressure of 10 in. WG at the manifold, compared with 3 to 4 in. for natural gas. It also needs more primary air for gas burners. Oil furnaces are usually forced draft and installed with pressure-atomizing burners. The oil pressure and the orifice size of the injection nozzle control the firing rate.

Furnace Performance Indices. The performance of a gas-fired furnace is usually assessed by the following indices:

- Thermal efficiency E_t, in percent, is the ratio of the energy output of heated air or water to the fuel energy input during specific test periods using the same units:

$$E_t = 100(\text{fuel energy output})/(\text{fuel energy input}) \tag{9.10.1}$$

- Annual fuel utilization efficiency (AFUE), in percent, is the ratio of the annual output energy from heated air or water to the annual input energy using the same units:

$$\text{AFUE} = (100 \text{ annual output energy})/(\text{annual input energy}) \tag{9.10.2}$$

- Steady-state efficiency (SSE) is the efficiency of a given furnace according to an ANSI test procedure, in percent:

$$\text{SSE} = 100(\text{fuel input} - \text{fuel loss})/(\text{fuel input}) \tag{9.10.3}$$

Jakob et al. (1986) and Locklin et al. (1987), in a report on ASHRAE Special Project SP43, gave the following performance indices based on a nighttime setback period of 8 hr with a setback temperature of 10°F:

Description	AFUE (%)	SSE (%)
Natural vent		
Pilot ignition	64.5	77
Intermittent ignition	69	77
Intermittent ignition plus vent damper	78	77
Power vent		
Noncondensing	81.5	82.5
Condensing	92.5	93

ASHRAE/IES Standard 90.1-2001 specifies AFUEs for both gas-fired and oil-fired furnaces of heating capacity <225,000 Btu/hr.

Operation and Control. Gas is usually brought from the main to the pressure regulator, where its pressure is reduced to 3.5 in. WG. Gas then flows through a valve and mixes with the necessary amount of outside primary air. The mixture mixes again with the ambient secondary air and is burned. The combustion products flow through the heat exchanger(s) due either to natural draft or power vent by a fan. The flue gas is then vented to the outside atmosphere through a vent pipe or chimney.

Recirculating air is pulled from the conditioned space through the return duct where it may be mixed with the ventilation air. The mixture is forced through the heat exchanger(s) by a fan and is then heated and distributed to the conditioned space. The fan is often started 1 min after the burner is fired in order to prevent a cold air supply.

At part-load operation, the reduction of the heating capacity of the warm air furnace is usually controlled by the gas valve and the ignition device. For small furnaces, the gas valve is often operated at on–off control. For large furnaces, a two-stage gas valve operates the furnace at 100, 50, and 0% heating capacity as required.

Low NO_x Emissions. NO_x means nitrogen oxides NO and NO_2. They are combustion products in the flue gas and become air pollutants with other emissions like SO_2, CO and CO_2 when they are discharged to the atmosphere. NO_x cause ozone depletion as well as smog.

Southern California regulations required that NO_x emissions should be 30 ppm or less for gas-fired warm air furnaces and boilers. Many gas burner manufactures use induced flue gas recirculation to cool the burner's flame, a cyclonic-type burner to create a swirling high-velocity flame, and other technologies to reduce NO_x and other emissions while retaining high furnace and boiler efficiencies.

Hot Water Boilers

Types of Hot Water Boilers. A *hot water boiler* is an enclosed pressure vessel used as a heat source for space heating in which water is heated to a required temperature and pressure without evaporation. Hot water boilers are fabricated according to American Society of Mechanical Engineers (ASME) codes for boilers and pressure vessels. Boilers are generally rated on the basis of their gross output delivered at the boiler's outlet. Hot water boilers are available in standard sizes from 50 to 50,000 MBtu/hr (1 MBtu/hr = 1000 Btu/hr).

Hot water boilers can be classified as *low-pressure boilers*, whose working pressure does not exceed 160 psig and working temperature is 250°F or less, and *medium-* and *high-pressure boilers*, whose working pressure is above 160 psig and working temperature above 250°F. Most of the hot water boilers are low-pressure boilers except those in campus-type or district water heating systems.

Based on their construction and material, hot water boilers can be classified as fire tube boilers, water tube boilers, cast iron sectional boilers, and electric boilers. Water tube boilers are used mainly to generate steam. Cast iron sectional boilers consist of many vertical inverted U-shaped cast iron hollow sections. They are lower in efficiency and used mainly for residential and small commercial buildings. Electric boilers are limited in applications because of their higher energy cost in many locations in the United States.

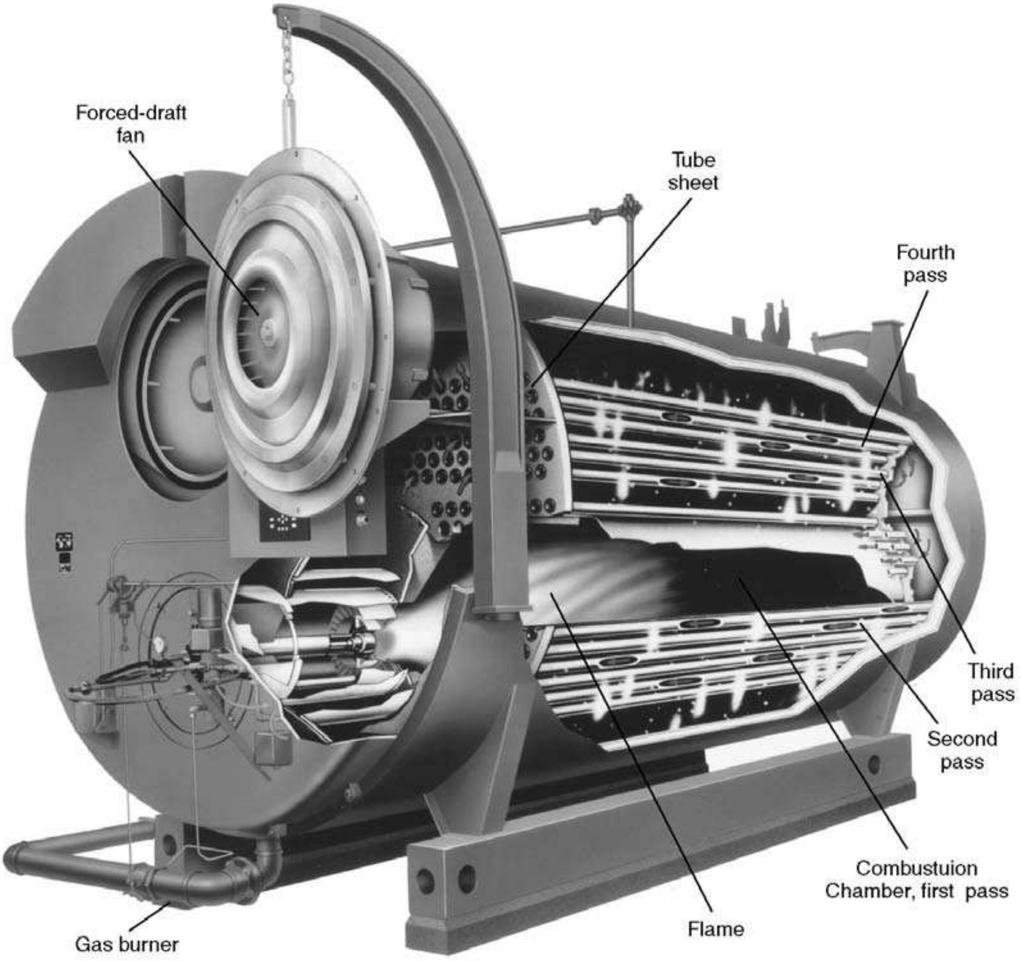

FIGURE 9.10.2 A Scotch Marine packaged boiler. (Source: Cleaver Brooks. Reprinted by permission.)

Scotch Marine Boiler. In a *fire tube* hot water boiler, the combustion chamber and flue gas passages are in tubes. These tubes are enclosed by an outer shell filled with water. A recently developed fire tube model is the modified Scotch Marine packaged boiler, which is a compact, efficient, and popular hot water boiler used today.

A *Scotch Marine* boiler, as shown in Figure 9.10.2, consists of a gas, oil, or gas/oil burner, a mechanical forced-draft fan, a combustion chamber, fire tubes, flue gas vent, outer shell, and corresponding control system. A packaged boiler is a one-piece factory-assembled boiler.

The dew point of the flue gas is often 130°F. If the temperature of the return water in a *condensing boiler* is below 125°F, it can be used as a condensing cooling medium to condense the water vapor contained in the flue gas. Latent heat of condensation of water vapor can then be recovered. Corrosion in the condensing heat exchanger and the flue gas passage should be avoided.

The *chimney*, or *stack*, is the vertical pipe or structure used to discharge flue gas, which usually has a temperature rise of 300 to 400°F above the ambient temperature. The chimney or stack should be extended to a specified height above adjacent buildings according to local codes.

Operation and Safety Controls. During part-load operation, reduction of heating capacity is achieved by sensing the temperature of return water and controlling the firing rate of the gas burners in on–off, high–low–off, or modulating modes.

For gas burners, two pressure sensors are often provided to maintain the gas pressure within a narrow range. For modulating controls, the ratio of maximum to minimum input is called the *turn-down* ratio. The minimum input is usually 5 to 25% of the maximum input, that is, a turn-down ratio of 20:1 to 4:1. The boiler should be shut off if the input is less than the minimum.

Pressure and temperature relief valves should be installed in each boiler. An additional high limit control is often equipped to shut down the boiler in case the sensed water pressure or temperature exceeds the predetermined limits. A flame detector is often used to monitor the flame and an airflow sensor to verify the combustion airflow. As soon as the flame is extinguished or the combustion airflow is not sensed, the fuel valve closes and the boiler is shut down. ASHRAE/IES Standard 90.1-2001 specifies the minimum AFUE for gas-fired boilers.

Low-Pressure Warm Air Heating Systems

A *low-pressure warm air heating system* is often equipped with an upflow gas-fired furnace having a furnace heat capacity Q_f to air flow $\mathring{V}_a$ ratio, $Q_f / \mathring{V}_a$, of 50 to 70 Btu/hr.cfm and a temperature rise immediately after the furnace of 50 to 70°F. The external pressure loss of the supply and return duct system is usually not higher than 0.5 in. WG. The supply temperature differential $(T_s - T_r)$ is often 20 to 35°F. The heating system is often integrated with a cooling system, forming a heating/cooling system.

Low-pressure warm air heating systems usually have a heating capacity not exceeding 100,000 Btu/hr. They are often used in residences and sometimes in small commercial buildings.

System Characteristics. A low-pressure warm air heating system is equipped with either supply and return ducts or a supply duct and a return plenum. Recirculating air is then returned from living, dining, bed, and study rooms to the return plenum through door undercuts in case the doors are closed.

When a low-pressure warm air heating system is operating, the supply duct leakage in the attic or basement raises its pressure to a positive value and promotes exfiltration. Return duct leakage extracts the ambient air, lowers the attic or basement pressure to a negative value, and induces infiltration. Gammage et al. (1986) reported that both types of leakage increase the whole house infiltration to 0.78 ach when the low-pressure warm air heating system is operating. The infiltration rate is only 0.44 ach when the low-pressure warm air heating system is shut off.

If the supply temperature differential $\Delta T_s = (T_s - T_r)$ exceeds 30°F, or if there is a high ceiling, thermal stratification may form in the conditioned space. Greater supply volume flow rates and suitable locations of the supply and return outlets may reduce thermal stratification and vertical temperature difference.

Part-Load Operation and Control. For a low-pressure warm air heating system, a space thermostat is often used to control the gas valve of the furnace operated in on–off or high–low–off mode. The proportion of on and off times in an operating cycle can be varied to meet the change of space heating load. The time period of an on–off operating cycle is usually 5 to 15 min.

A warm-air heating system that has an external pressure higher than 0.5 in. WG is often integrated with a cooling system and becomes a part of an air-conditioning system.

Low-Temperature Hot Water Heating System Using Fin-Tube Heaters

In a *low-temperature hot water heating system*, the operating temperature is 250°F or less with a maximum working pressure not exceeding 150 psig, usually less than 30 psig. Low-temperature hot water heating systems are widely used for space heating in residences and commercial buildings.

Fin-Tube Heaters. A *fin-tube heater* or convector is a device installed directly inside the conditioned space to add heat to the space through radiant and convective heat transfer. A fin-tube heater consists of a finned-tube element and an outer casing as shown in Figure 9.10.3(a). The tubes are often made of copper and steel. Copper tubes are generally 0.75, 1, and 1.25 in. in diameter and steel tubes 1.25 and 2 in. in diameter. The fins are usually made of aluminum for copper tubes and of steel for steel tubes. Fin density may vary from 24 to 60 fins per foot. A fin heater may have a maximum length of 12 ft. The outer casing of a finned-tube heater always has a bottom inlet and top outlet for better convection.

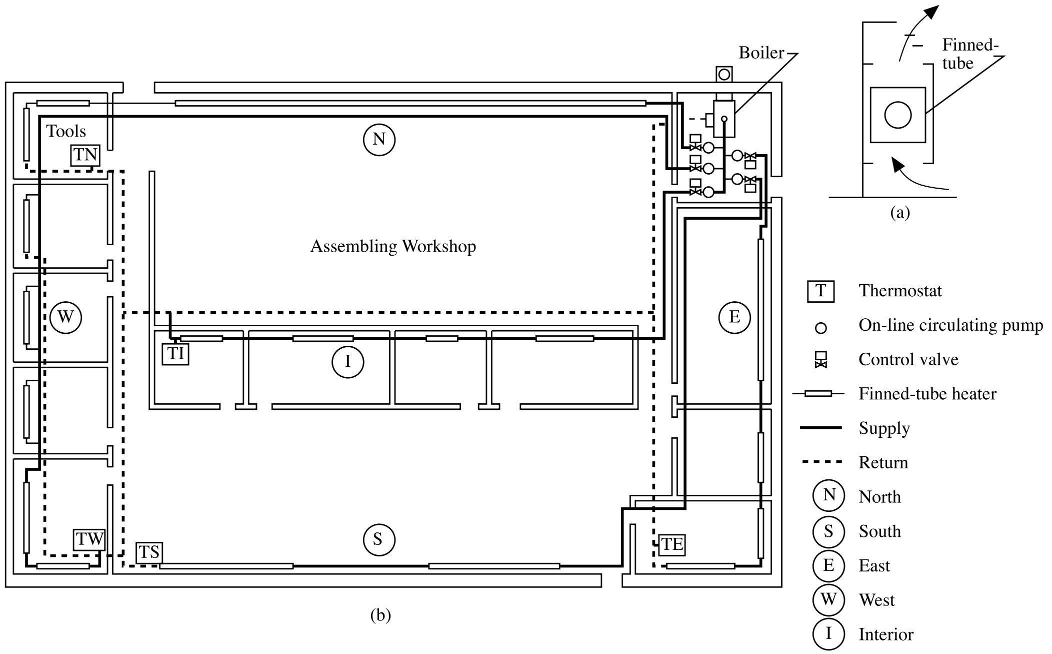

FIGURE 9.10.3 A two-pipe individual-loop low-temperature hot water heating system: (a) finned-tube heater and (b) piping layout.

The most widely used finned-tube heater is the *baseboard heater*, which is often mounted on cold walls at a level 7 to 10 in. from the floor. It is usually 3 in. deep and has one fin-tube row. A wall finned-tube heater has a greater height. A convector has a cabinet-type enclosure and is often installed under the windowsill.

Two-Pipe Individual-Loop Systems. Current low-temperature hot water heating systems using finned-tube heaters are often equipped with zone controls. Zone controls can avoid overheating rooms facing south and underheating rooms facing north because of the effects of solar radiation.

Figure 9.10.3(b) shows the piping layout of a *two-pipe individual-loop system* that is widely used in low-temperature hot water heating systems. Two-pipe means that there are a supply main and a return main pipe instead of one common main for both supply and return. Individual-loop means that there is an individual loop for each control zone. Several finned-tube heaters in a large room can be connected in series, while finned-tube heaters in several small rooms can be connected in reverse return arrangement.

The sizing of low-temperature hot water pipes is usually based on a pressure drop of 1 to 3 ft per 100 ft of pipe length. For a small low-temperature hot water heating system, an open-type expansion tank is often used. A diaphragm tank is often used for a large system. On-line circulating pumps with low head are often used.

Part Load and Control. Usually a hot water sensor located at the exit of the hot water boiler is used to control the firing rate of the boiler at part-load operation. Its set point is usually reset according to the outdoor temperature. Zone control is provided by sensing the return hot water temperature from each individual loop or zone and then varying the water volume flow rate supplied to that zone by modulating the speed of each corresponding on-line circulating pump or its control valve. For hot water heating systems using multiple boilers, on and off for each specific boiler depend not only on the heating demand, but also on minimizing the energy cost.

Infrared Heating

Infrared heating is a process that uses radiant heat transfer from a gas-fired or electrically heated high-temperature device to provide space heating on a localized area for the health and comfort of the occupants or to maintain a suitable indoor environment for a manufacturing process.

An *infrared heater* is a device used to provide infrared heating. Heat radiates from an infrared heater in the form of electromagnetic waves and scatters in all directions. Most infrared heaters have reflectors to focus the radiant beam onto a localized area. Therefore, they are often called *beam radiant heaters.* Infrared heaters are widely used in high-ceiling supermarkets, factories, warehouses, gymnasiums, skating rinks, and outdoor loading docks.

Gas Infrared Heaters. Infrared heaters can be divided into two categories: gas and electric infrared heaters. *Gas infrared heaters* are again divided into porous matrix gas infrared heaters and indirect gas infrared heaters. In a *porous matrix gas infrared heater*, a gas and air mixture is supplied and distributed evenly through a porous ceramic, a stainless steel panel, or a metallic screen, which is exposed to the ambient air and backed by a reflector. Combustion takes place at the exposed surface with a maximum temperature of about 1600°F. An indirect infrared heater consists of a burner, a radiating tube, and a reflector. Combustion takes place inside the radiating tube at a temperature not exceeding 1200°F.

Gas infrared heaters are usually vented and have a small conversion efficiency. Only 10 to 20% of the input energy of an open combustion gas infrared heater is radiated in the form of infrared radiant energy. Usually 4 cfm of combustion air is required for 1000 Btu/hr gas input. A thermostat often controls a gas valve in on–off mode. For standing pilot ignition, a sensor and a controller are used to cut off the gas supply if the flame is extinguished.

Electric Infrared Heaters. An *electric infrared heater* is usually made of nickel–chromium wire or tungsten filaments mounted inside an electrically insulated metal tube or quartz tube with or without inert gas. The heater also contains a reflector that directs the radiant beam to the localized area requiring heating. Nickel–chromium wires often operate at a temperature of 1200 to 1800°F. A thermostat is also used to switch on or cut off the electric current. An electric infrared heater has a far higher conversion efficiency and is cleaner and more easily managed.

Design Considerations. An acceptable radiative temperature increase ($T_{rad} - T_r$) of 20 to 25°F is often adopted for normal clothed occupants using infrared heating. The corresponding required watt density for infrared heaters is 30 to 37 W/ft^2. At a mounting height of 11 ft, two heaters having a spacing of 6.5 ft can provide a watt density of 33 W/ft^2 and cover an area of 12 × 13 ft. The mounting height of the infrared heaters should not be lower than 10 ft. Otherwise the occupants may feel discomfort from the overhead radiant beam. Refer to Grimm and Rosaler (1990), *Handbook of HVAC Design,* for details.

Gas and electric infrared heaters should not be used in places where there is danger of ignitable gas or materials that may decompose into toxic gases.

9.11 Refrigeration Systems

Herbert A. Ingley and Shan K. Wang

Classifications of Refrigeration Systems

Most of the refrigeration systems used for air-conditioning are vapor compression systems. Because of the increase in the energy cost of natural gas in the 1980s, the application of absorption refrigeration systems has dropped sharply. Air expansion refrigeration systems are used mainly in aircraft and cryogenics.

Refrigeration systems used for air-conditioning can be classified mainly in the following categories:

- Direct expansion (DX) systems and heat pumps
- Centrifugal chillers
- Screw chillers
- Absorption systems

Each can be either a single-stage or a multistage system.

Direct Expansion Refrigeration Systems

A *direct expansion refrigeration (DX) system*, or simply *DX system*, is part of the packaged air-conditioning system. The DX coil in the packaged unit is used to cool and dehumidify the air directly as shown in Figure 9.11.1(a).

Refrigerants R-22 and R-134a are widely used. Azeotropes and near azeotropes are the refrigerants often used for low-evaporating-temperature systems like those in supermarkets. Because of the limitation of the size of the air system, the refrigeration capacity of DX systems is usually 3 to 100 tons.

Components and Accessories. In addition to the DX coil, a DX refrigeration system has the following components and accessories:

- *Compressor(s)* — Both reciprocating and scroll compressors are widely used in DX systems. Scroll compressors are gradually replacing reciprocating compressors because they have fewer parts and comparatively higher efficiency. For large DX systems, multiple compressors are adopted.
- *Condensers* — Most DX systems in rooftop packaged units are air cooled. Water-cooled condensers are adopted mainly for DX systems in indoor packaged units due to their compact volume. Evaporative-cooled condensers are also available.
- *Refrigeration feed* — Thermostatic expansion valves are widely used as the throttling and refrigerant flow control devices in medium and large DX systems, whereas capillary tubes are used in small and medium-sized systems.
- *Oil lubrication* — R-22 is partly miscible with mineral oil. Since R-134a is not miscible with mineral oil, synthetic polyolester oil should be used. For medium and large reciprocating compressors, an oil pump of vane, gear, or centrifugal type is used to force the lubricating oil to the bearings and moving surfaces via grooves. For small reciprocating compressors, splash lubrication using the rotation of the crankshaft and the connecting rod to splash oil onto the bearing surface and the cylinder walls is used.

A scroll compressor is often equipped with a centrifugal oil pump to force the oil to lubricate the orbiting scroll journal bearing and motor bearing. For the scroll contact surfaces, lubrication is provided by the small amount of oil entrained in the suction vapor.

- *Refrigerant piping* — Refrigerant piping transports refrigerant through the compressor, condenser, expansion valve, and DX coil to provide the required refrigeration effect. As shown in Figure 9.11.1(a), from the exit of the DX coil to the inlet of the compressor(s) is the *suction line*. From the outlet of the compressor to the inlet of the air-cooled condenser is the *discharge line*. From the exit of the condenser to the inlet of the expansion valve is the *liquid line*.

Halocarbon refrigerant pipes are mainly made of copper tubes of L type. In a packaged unit, refrigerant pipes are usually sized and connected in the factory. However, the refrigerant pipes in field-built and split DX systems for R-22 are sized on the basis of a pressure drop of 2.91 psi corresponding to a change of saturated temperature ΔT_{suc} of 2°F at 40°F for the suction line and a pressure drop of 3.05 psi corresponding to 1°F at 105°F for the discharge and liquid line. The pressure drop includes pressure losses of pipe and fittings. Refrigerant pipes should also be sized to bring back the entrained oil from the DX coil and condenser through the discharge and suction lines.

Accessories include a filter dryer to remove moisture from the refrigerant, strainer to remove foreign matter, and sight glass to observe the condition of refrigerant flow (whether bubbles are seen because of the presence of flash gas in the liquid line).

Capacity Controls. In DX systems, control of the mass flow rate of refrigerant through the compressor(s) is often used as the primary refrigeration capacity control. Row or intertwined face control at the DX coil is also used in conjunction with the capacity control of the compressor(s).

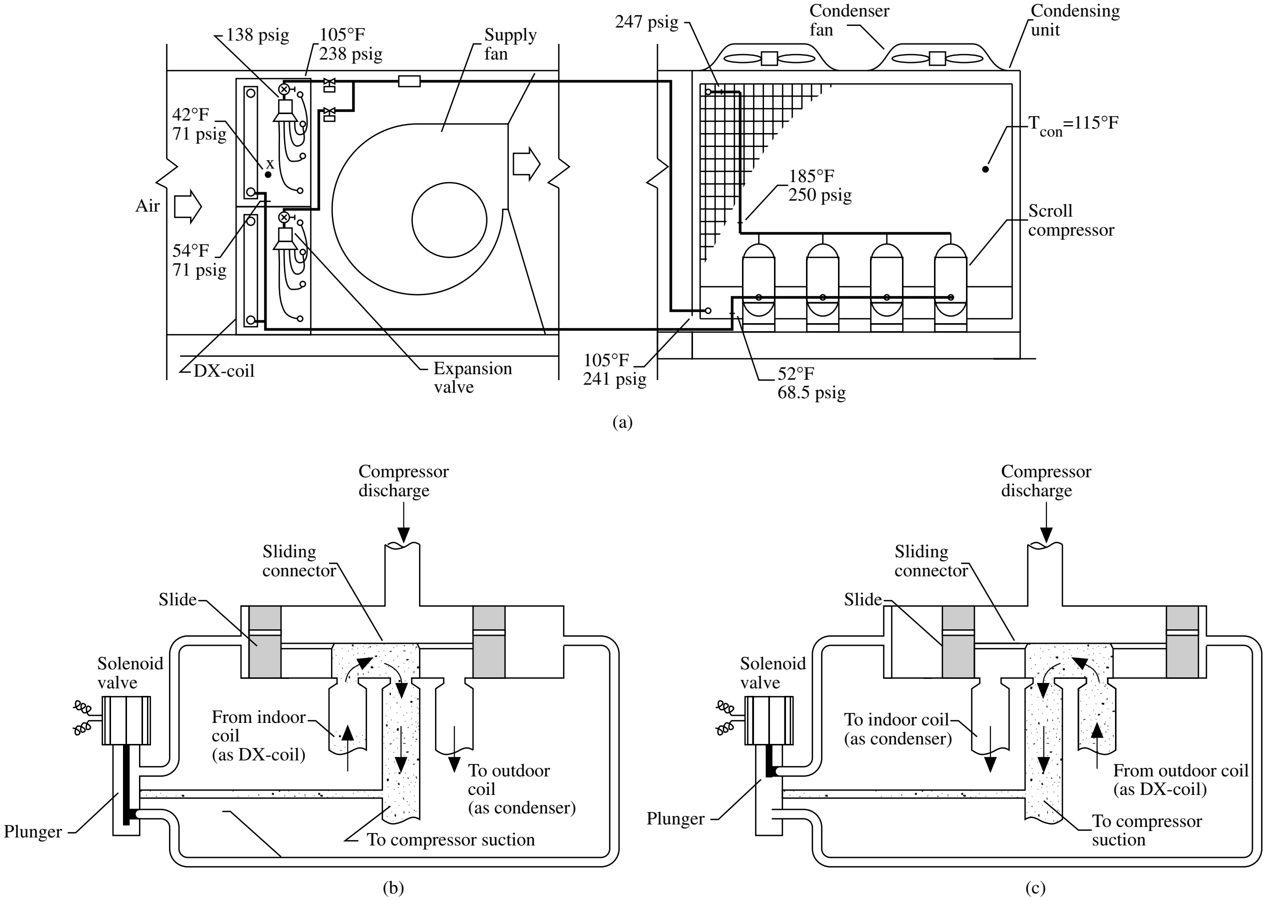

FIGURE 9.11.1 A DX refrigeration system: (a) schematic diagram: (b) four-way reversing valve, cooling mode; and (c) four-way reversing valve, heating mode.

Three methods of capacity controls are widely used for reciprocating and scroll compressors in DX systems:

- *On–off control* — Starting or stopping the compressor is a type of step control of the refrigerant flow to the compressor. It is simple and inexpensive, but there is a 100% variation in capacity for DX systems installed with only a single compressor. On–off control is widely used for small systems or DX systems with multiple compressors.
- *Cylinder unloader* — For a reciprocating compressor having multiple cylinders, a cylinder unloader mechanism bypasses the compressed gas from one, two, or three cylinders to the suction chamber to reduce the refrigeration capacity and compressing energy.
- *Speed modulation* — A two-speed motor is often used to drive scroll or reciprocating compressors so that the capacity can be reduced 50% at lower speed.

Safety Controls. In *low- and high-pressure control*, the compressor is stopped when suction pressure drops below a preset value, the cut-in pressure, or the discharge pressure of the hot gas approaches a dangerous level, the cut-out pressure.

In *low-temperature control*, a sensor is mounted on the outer pipe surface of the DX coil. When the surface temperature drops below 32°F, the controller stops the compressor to prevent frosting.

If the pressure of the oil discharged from the pump does not reach a predetermined level within a certain period, a mechanism in *oil pressure failure control* opens the circuit contact and stops the compressor.

In *motor overload control*, a sensor is used to measure the temperature of the electric winding or the electric current to protect the motor from overheating and overloading.

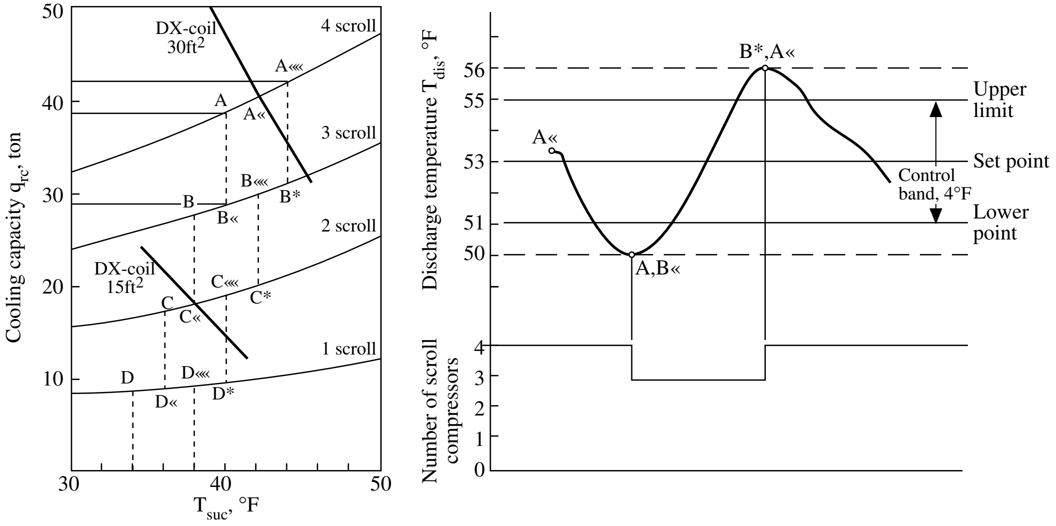
Pump-down control is an effective means of preventing the migration of the refrigerant from the DX coil (evaporator) to the crankcase of the reciprocating compressor. This prevents mixing of refrigerant and oil to form slugs, which may damage the compressor.

When a rise of suction pressure is sensed by a sensor, a DDC controller opens a solenoid valve and the liquid refrigerant enters the DX coil. As the buildup of vapor pressure exceeds the cut-in pressure, the compressor starts. When the DX system needs to shut down, the solenoid valve is closed first; the compressor still pumps the gaseous refrigerant to the condenser. As the suction pressure drops below the cut-in pressure, the compressor stops.

Full- and Part-Load Operations. Consider a DX system in a rooftop packaged unit using four scroll compressors, each with a refrigeration capacity of 10 tons at full load. Performance curves of the condensing unit and the DX coil of this DX system are shown in Figure 9.11.2(a). A DDC controller actuates on–off for these scroll compressors based on the signal from a discharge air temperature T_{dis} sensor.

On a hot summer day, when the rooftop packaged unit starts with a DX coil load or refrigeration capacity, $q_{rc} \approx 40$ tons, all four scroll compressors are operating. The operating point is at A′ with a suction temperature T_{suc} of about 42°F, and the discharge air temperature T_{dis} is maintained around 53°F. As the space cooling load q_{rc} as well as T_{dis} decreases, the required DX coil load q_{rl} drops to 35 tons. Less evaporation in the DX coil causes a decrease of T_{suc} to about 40°F, and the operating point may move downward to point A with a DX coil refrigeration capacity of 39 tons. Since $q_{rc} > q_{rl}$, T_{dis} drops continually until it reaches 50°F, point A in Figure 9.11.2(b), and the DDC controller shuts down one of the scroll compressors. The operating point immediately shifts to B′ on the three-compressor curve.

Because the refrigeration capacity at point B′ q_{rc} is 29 tons, which is less than the required $q_{rl} = 35$ tons, both T_{dis} and T_{suc} rise. When the operating point moves up to B* and T_{dis} reaches 56°F, the DDC controller starts all four scroll compressors at operating point A″ with a refrigeration capacity of 42 tons. Since $q_{rc} > q_{rl}$, the operating point again moves downward along the four-compressor curve and forms an operating cycle A″AB′ and B*. The timing of the operating period on four- or three-compressor performance curves balances any required q_{rl} between 29 and 42 tons. Less evaporation at part load in the DX coil results in a greater superheating region and therefore less refrigeration capacity to balance the reduction of refrigeration capacity of the compressor(s) as well as the condensing unit. The condition



(a)

(b)

FIGURE 9.11.2 Capacity control of a DX refrigeration system: (a) performance curves and operating points and (b) locus of control point.

will be similar when q_{rl} < 30 tons, only three- or two-compressor, or two- or one-compressor, or even on–off of one compressor forms an operating cycle.

Main Problems in DX Systems

- *Liquid slugging* is formed by a mixture of liquid refrigerant and oil. It is formed because of the flooding back of liquid refrigerant from the DX coil to the crankcase of the reciprocating compressor due to insufficient superheating. It also may be caused by migration of liquid refrigerant from the warmer indoor DX coil to the colder outdoor compressor during the shut-down period in a split packaged unit. Liquid slugging dilutes the lubricating oil and causes serious loss of oil in the crankcase of the reciprocating compressor. Liquid slugging is incompressible. When it enters the compression chamber of a reciprocating compressor, it may damage the valve, piston, and other components. Pump-down control and installation of a crankcase heater are effective means of preventing liquid refrigerant migration and flooding back.
- *Compressor short cycling* — For on–off control, too short a cycle, such as less than 3 min, may pump oil away from the compressor or damage system components. It is due mainly to a too close low-pressure control differential or to reduced air flow.
- *Defrosting* — If the surface of a DX coil is 32°F or lower, frost accumulates on it. Frost blocks the air passage and reduces the rate of heat transfer. It should be removed periodically. The process of removing frost is called defrosting.
- Air at a temperature above 36°F, hot gas inside the refrigerant tubes and an installed electric heating element can be used for defrosting. The defrosting cycle is often controlled by sensing the temperature or pressure difference of air entering the DX coil during a fixed time interval.
- *Refrigerant charge* — Insufficient refrigerant charge causes lower refrigeration capacity, lower suction temperature, and short on–off cycles. Overcharging refrigerant may cause a higher condensing pressure because part of the condensing surface becomes flooded with liquid refrigerant.

Heat Pumps

A *heat pump* in the form of a packaged unit is also a *heat pump system*. A heat pump can either extract heat from a heat source and reject heat to air and water at a higher temperature for heating, or provide refrigeration at a lower temperature and reject condensing heat at a higher temperature for cooling. During summer, the heat extraction, or refrigeration effect, is the useful effect for cooling in a heat pump. In winter, the rejected heat and the heat from a supplementary heater provide heating in a heat pump.

There are three types of heat pumps: air-source, water-source, and ground-coupled heat pumps. Ground-coupled heat pumps have limited applications. Water-source heat pump systems are covered in detail in a later section.

Air-Source Heat Pump. An *air-source heat pump*, or *air-to-air heat pump*, is a DX system with an additional four-way reversing valve to change the refrigerant flow from cooling mode in summer to heating mode in winter and vice versa. The variation in connections between four means of refrigerant flow — compressor suction, compressor discharge, DX coil exit, and condenser inlet — causes the function of the indoor and outdoor coils to reverse. In an air-source heat pump, the coil used to cool or to heat the recirculating/outdoor air is called the *indoor coil*. The coil used to reject heat to or absorb heat from the outside atmosphere is called the *outdoor coil*. A short capillary or restrict tube is often used instead of a thermostatic expansion valve. Both reciprocating and scroll compressors are used in air-source heat pumps. R-22 is the refrigerant widely used. Currently available air-source heat pumps usually have a cooling capacity of $1^1/_2$ to 40 tons.

Cooling and Heating Mode Operation. In *cooling mode operation*, as shown in Figure 9.11.1(b), the solenoid valve is deenergized and drops downward. The high-pressure hot gas pushes the sliding connector to the left end. The compressor discharge connects to the outdoor coil, and the indoor coil connects to the compressor inlet.

In *heating mode operation*, as shown in Figure 9.11.1(c), the solenoid plunger moves upward and pushes the slide connector to the right-hand side. The compressor discharge connects to the indoor coil, and the outdoor coil exit connects to the compressor suction.

System Performance. The performance of an air-source heat pump depends on the outdoor air temperature T_o, in °F as well as the required space heating load q_{rh}. During cooling mode operation, both the refrigeration capacity q_{rc}, in Btu/hr, and EER for the heat pump EER_{hp}, in Btu/hr.W, increase as T_o drops. During heating mode operation, the heating capacity q_{hp}, in Btu/hr, and COP_{hp} decrease, and q_{rh} increases as the T_o drops. When $q_{rh} > q_{hp}$, supplementary heating is required. If COP_{hp} drops below 1, electric heating may be more economical than a heat pump.

If on–off is used for compressor capacity control for an air-source heat pump in a split packaged unit, refrigerant tends to migrate from the warmer outdoor coil to the cooler indoor coil in summer and from the warmer indoor coil to the cooler outdoor coil in winter during the off period. When the compressor starts again, 2 to 5 min of reduced capacity is experienced before the heat pump can be operated at full capacity. Such a loss is called a *cycling loss*.

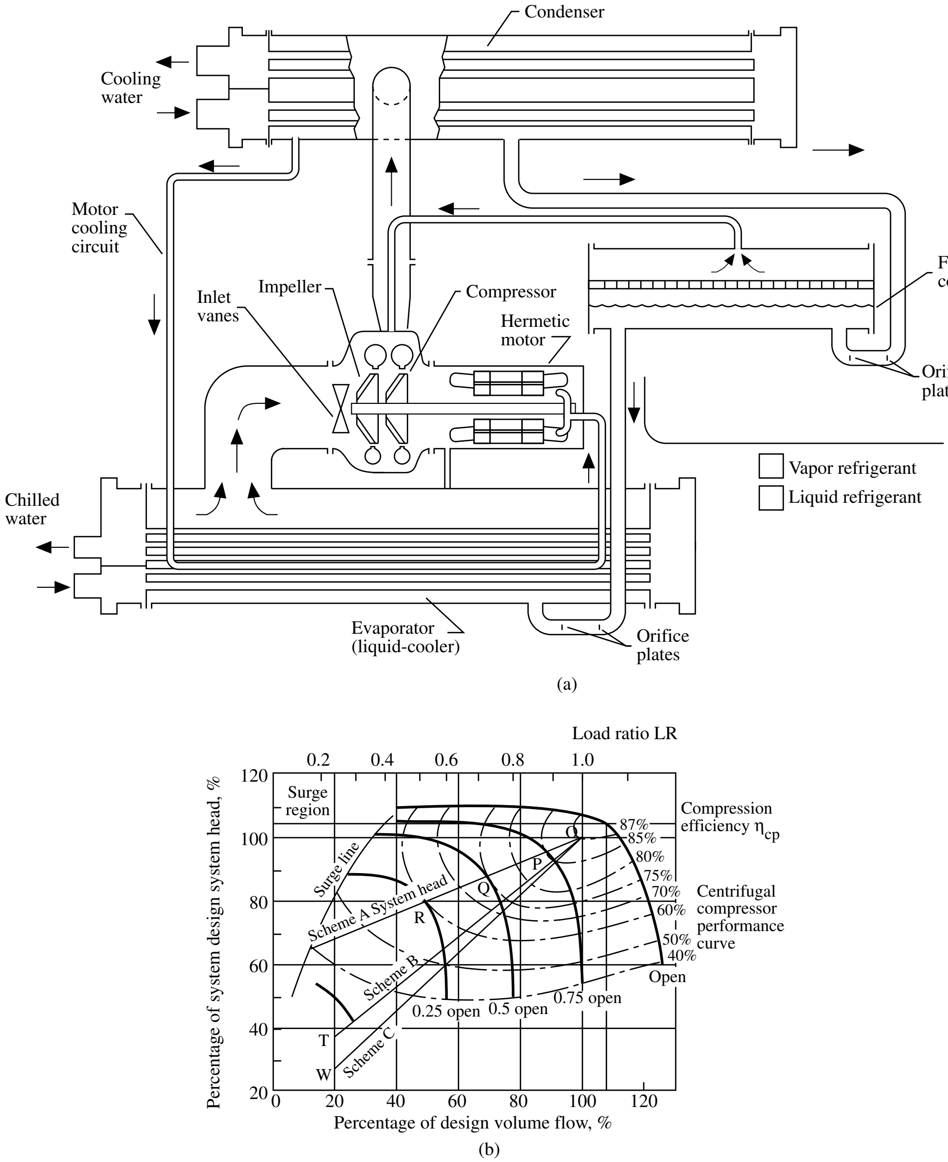
In winter, most air-source heat pumps switch from the heating mode to cooling mode operation and force the hot gas to the outdoor coil to melt frost. After the frost is melted, the heat pump is switched back to heating mode operation. During defrosting, supplementary electric heating is often necessary to prevent a cold air supply from the air-source heat pump.

Minimum Performance. ANSI/ASHRAE/IESNA Standard 90.1-2001 specifies a minimum performance for air-cooled DX systems in packaged units as covered in Section 9.7.

Centrifugal Chillers

A chiller is a refrigeration machine using a liquid cooler as an evaporator to produce chilled water as the cooling medium in a central air-conditioning system. A *centrifugal chiller*, as shown in Figure 9.11.3(a), is a refrigeration machine using a centrifugal compressor to produce chilled water. It is often a factory-assembled unit with an integrated DDC control system and sometimes may separate into pieces for transportation. A centrifugal chiller is also a *centrifugal vapor compression refrigeration system*.

Refrigerants. As mentioned in Section 9.4, production of CFCs, including R-11 and R-12, ceased at the end of 1995 with limited exception for service. R-123 (HCFC) will replace R-11. The chiller's efficiency



(a)

(b)

FIGURE 9.11.3 A two-stage water-cooled centrifugal chiller: (a) schematic diagram and (b) centrifugal compressor performance map at constant speed.

may drop 2 to 4%, and a capacity reduction of 5% is possible. R-123 has low toxicity. Its allowable exposure limit was raised to 50 ppm in 1997 from 30 ppm in 1993 by its manufacturers. A monitor and alarm device to detect R-123 in air should be installed in plant rooms and places where there may be refrigerant leaks. See ANSI/ASHRAE Standard 15-2001 for other requirements.

R-134a (HFC) will replace R-12. According to Lowe and Ares (1995), as a result of the changeout from R-12 to R-134a for a 5000-hp centrifugal chiller in Sears Tower, Chicago, its speed increased from 4878 to 5300 rpm, its cooling capacity is 12 to 24% less, and its efficiency is 12 to 16% worse.

System Components. A centrifugal chiller consists of a centrifugal compressor, an evaporator or liquid cooler, a condenser, a flash cooler, throttling devices, piping connections, and controls. A purge unit is optional.

- Centrifugal compressor — According to the number of internally connected impellers, the centrifugal compressor could have a single, two, or more than two stages. A two-stage impeller with a flash cooler is most widely used because of its higher system performance and comparatively simple construction. Centrifugal compressors having a refrigeration capacity less than 1200 tons are often hermetic. Very large centrifugal compressors are of open type. A gear train is often required to raise the speed of the impeller except for very large impellers using direct drive.
- Evaporator — Usually a liquid cooler of flooded shell-and-tube type evaporator is adopted because of its compact size and high rate of heat transfer.
- Condenser — Water-cooled, horizontal shell-and-tube condensers are widely used.
- Flash cooler — For a two-stage centrifugal compressor, a single-stage flash cooler is used. For a three-stage compressor, a two-stage flash cooler is used.
- Orifice plates and float valves — Both multiple-orifice plates such as that shown in Figure 9.11.3(a) and float valves are used as throttling devices in centrifugal chillers.
- Purge unit — R-123 has an evaporating pressure p_{ev} = 5.8 psia at 40°F, which is lower than atmospheric pressure. Air and other noncondensable gases may leak into the evaporator through cracks and gaps and usually accumulate in the upper part of the condenser. These noncondensable gases raise the condensing pressure, reduce the refrigerant flow, and lower the rate of heat transfer. A purge unit uses a cooling coil to separate the refrigerant and water from the noncondensable gases and purge the gases by using a vacuum pump.

Performance Ratings. The refrigeration cycle of a typical water-cooled, two-stage centrifugal chiller with a flash cooler was covered in Section 9.4. Centrifugal chillers have the same refrigeration capacity as centrifugal compressors, 100 to 10,000 tons.

The integrated part-load value (IPLV) of a centrifugal chiller or other chillers at standard rating conditions can be calculated as:

$$\text{IPLV} = 0.1(A + B)/2 + 0.5(B + C)/2 + 0.3(C + D)/2 + 0.1D \tag{9.11.1}$$

where A, B, C, and D = kW/ton or COP at 100, 75, 50, and 25% load, respectively. If the operating conditions are different from the standard rating conditions, when T_{el} is 40 to 50°F, for each °F increase or decrease of T_{el}, there is roughly a 1.5% difference in refrigeration capacity and energy use; when T_{ce} is between 80 to 90°F, for each °F of increase or decrease of T_{ce}, there is roughly a 1% increase or decrease in refrigeration capacity and 0.6% in energy use.

ANSI/ASHRAE/IESNA Standard 90.1-2001 and ARI Standard 550 specify the minimum performance for water-cooled water chillers.

Air-cooled centrifugal chillers have COPs from 2.5 to 2.8. Their energy performance is far poorer than that of water-cooled chillers. Their application is limited to locations where city water is not allowed to be used as makeup water for cooling towers.

Capacity Control. The refrigeration capacity of a centrifugal chiller is controlled by modulating the refrigerant flow at the centrifugal compressor. There are mainly two types of capacity controls: varying the opening and angle of the inlet vanes, and using an adjustable-frequency AC inverter to vary the rotating speed of the centrifugal compressor.

When the opening of the inlet vanes has been reduced, the refrigerant flow is throttled and imparted with a rotation. The result is a new performance curve at lower head and flow. If the rotating speed of a centrifugal compressor is reduced, it also has a new performance curve at lower volume flow and head. Inlet vanes are inexpensive, whereas the AC inverter speed modulation is more energy efficient at part-load operation.

Centrifugal Compressor Performance Map. Figure 9.11.3(b) shows a single-stage, water-cooled *centrifugal compressor performance map* for constant speed using inlet vanes for capacity modulation. A performance map consists of the compressor's performance curves at various operating conditions. The *performance* *curve* of a centrifugal compressor shows the relationship of volume flow of refrigerant $\overset{\circ}{V}_r$ and its head lift Δp or compression efficiency η_{cp} at that volume flow. It is assumed that η_{cp} for a two-stage compressor is equal to the average of the two single-stage impellers having a head of their sum.

On the map, the required *system head curve* indicates the required system head lift at that volume flow of refrigerant. The intersection of the performance curve and the required system head curve is called the *operating point* O, P, Q, R, … as shown in Figure 9.11.3(b). One of the important operating characteristics of a centrifugal chiller (a centrifugal vapor compression refrigeration system as well) is that the required system head lift is mainly determined according to the difference in condensing and evaporating pressure $\Delta p_{c\text{-}e} = (p_{con} - p_{ev})$. The pressure losses due to the refrigerant piping, fittings, and components are minor.

In Figure 9.11.3(b), the abscissa is the percentage of design volume flow of refrigerant, % $\overset{\circ}{V}_r$, or load ratio; the ordinate is the percentage of design system head $\Delta H_{s.d}$, or percentage of design temperature lift $(T_{con} - T_{ev})$. Here load ratio LR is defined as the ratio of the refrigeration load to the design refrigeration load $q_{rl}/q_{rl.d}$. There are three schemes of required system head curves:

- Scheme A — T_{ce} = constant and T_{el} = constant
- Scheme B — T_{el} = constant and a drop of 2.5°F of T_{ce} for each 0.1 reduction of load ratio
- Scheme C — A reset of T_{el} of 1°F increase and a drop of 2.5°F of T_{ce} for each 0.1 reduction of load ratio

At design $\overset{\circ}{V}_r$ and system head $H_{s.d}$, $\eta_{cp} = 0.87$. As $\overset{\circ}{V}_r$, load ratio, and required system head Δp decrease, η_{cp} drops accordingly.

Surge is a unstable operation of a centrifugal compressor or fan resulting in vibration and noise. In a centrifugal chiller, surge occurs when the centrifugal compressor is unable to develop a discharge pressure that satisfies the requirement at the condenser. A centrifugal compressor should never be operated in the surge region.

Part-Load Operation. During part-load operation, if T_{el} and T_{ce} remain constant, the evaporating temperature T_{ev} tends to increase from the design load value because there is a greater evaporating surface and a smaller temperature difference $(T_{el} - T_{ev})$. Similarly, T_{con} tends to decrease.

The ratio of actual compressor power input at part load to the power input at design load may be slightly higher or lower than the load ratios, depending on whether the outdoor wet bulb is constant or varying at part load or whether there is a T_{el} reset; it also depends on the degree of drop of η_{cp} at part load.

Specific Controls. In addition to generic controls, specific controls for a centrifugal chiller include:

- Chilled water leaving temperature T_{el} and reset
- Condenser water temperature T_{ce} control
- On and off of multiple chillers based on actual measured coil load
- Air purge control
- Safety controls like oil pressure, low-temperature freezing protection, high condensing pressure control, motor overheating, and time delaying

Centrifugal Chillers Incorporating Heat Recovery. A *HVAC&R heat recovery system* converts waste heat or waste cooling from any HVAC&R process into useful heat and cooling. A heat recovery system is often subordinate to a parent system, such as a heat recovery system to a centrifugal chiller.

A centrifugal chiller incorporating a heat recovery system often uses a double-bundle condenser in which water tubes are classified as tower bundles and heating bundles. Heat rejected in the condenser may be either discharged to the atmosphere through the tower bundle and cooling tower or used for heating through the heating bundle. A temperature sensor is installed to sense the temperature of return hot water from the heating coils in the perimeter zone. A DDC controller is used to modulate a bypass three-way valve which determines the amount of condenser water supplied to the heating bundle. The tower and heating bundles may be enclosed in the same shell, but baffle sheets are required to guide the water flows.

A centrifugal chiller incorporating a heat recovery system provides cooling for the interior zone and heating for the perimeter zone simultaneously in winter with a higher COP_{hr}. However, it needs a higher condenser water-leaving temperature T_{cl} of 105 to 110°F, compared with 95°F or even lower in a cooling-only centrifugal chiller. An increase of 10 to 12°F of the difference ($T_{con} - T_{ev}$) requires an additional 10 to 15% power input to the compressor. For a refrigeration plant equipped with multiple chillers, it is more energy efficient and lower in first cost to have only part of them equipped with double-bundle condensers.

Screw Chillers

A *screw chiller* or a *helical rotary chiller* is a refrigeration machine using a screw compressor to produce chilled water. A factory-fabricated and assembled screw chiller itself is also a screw vapor compression refrigeration system.

Twin-screw chillers are more widely used than single-screw chillers. A twin-screw chiller consists of mainly a twin-screw compressor, a flooded shell-and-tube liquid cooler as evaporator, a water-cooled condenser, throttling devices, an oil separator, an oil cooler, piping, and controls as shown in Figure 9.11.4(a). The construction of twin-screw compressors has already been covered. For evaporator, condenser, and throttling devices, they are similar to those in centrifugal chillers. Most twin-screw chillers have a refrigeration capacity of 100 to 1000 tons.

Following are the systems characteristics of screw chillers.

Variable Volume Ratio. The ratio of vapor refrigerant trapped within the interlobe space during the intake process V_{in} to the volume of trapped hot gas discharged V_{dis} is called the *built-in volume ratio* of the twin-screw compressor $V_i = V_{in}/V_{dis}$, or simply *volume ratio*, all in ft^3.

There are two types of twin-screw chiller: fixed and variable volume ratio. For a twin-screw chiller of *fixed volume ratio*, the isentropic efficiency η_{isen} becomes maximum when the system required compression ratio $R_{s.com} \approx V_i$. Here $R_{s.com} = p_{con}/p_{ev}$. If $p_{dis} > p_{con}$, overcompression occurs, as shown in Figure 9.11.4(b). The discharged hot gas reexpands to match the condensing pressure. If $p_{dis} < p_{con}$, undercompression occurs (Figure 9.11.4[c]). A volume of gas at condensing pressure reenters the trapped volume at the beginning of the discharge process. Both over- and undercompression cause a reduction of η_{isen}.

For a twin-screw chiller of *variable volume ratio*, there are two slides: a sliding valve is used for capacity control and a second slide. By moving the second slide back and forth, the radial discharge port can be relocated. This allows variation of suction and discharge pressure levels and still maintains maximum efficiency.

Economizer. The hermetic motor shell is connected to an intermediate point of the compression process and maintains an intermediate pressure p_i between p_{con} and p_{ev}. Liquid refrigerant at condensing pressure p_{con} is throttled to p_i, and a portion of the liquid is flashed into vapor. This causes a drop in the temperature of the remaining liquid refrigerant down to the saturated temperature corresponding to p_i. Although the compression in a twin-screw compressor is in continuous progression, the mixing of flashed gas with the compressed gas at the intermediate point actually divides the compression process into two stages. The resulting economizing effect is similar to that of a two-stage compound refrigeration system with a flash cooler: an increase of the refrigeration effect and a saving of the compression power from ($p_{con} - p_{ev}$) to ($p_{con} - p_i$).

Oil Separation, Oil Cooling, and Oil Injection. Oil entrained in the discharged hot gas enters an oil separator. In the separator, oil impinges on an internal perforated surface and is collected because of its inertia. Oil drops to an oil sump through perforation. It is then cooled by condenser water in a heat exchanger. A heater is often used to vaporize the liquid refrigerant in the oil sump to prevent dilution of the oil. Since the oil sump is on the high-pressure side of the refrigeration system, oil is forced to the rotor bearings and injected to the rotors for lubrication.

Oil slugging is not a problem for twin-screw compressors. When suction vapor contains a small amount of liquid refrigerant that carries over from the oil separator, often called *wet suction*, it often has the benefit of scavenging the oil from the evaporator.

Twin-screw compressors are positive displacement compressors. They are critical in oil lubrication, sealing, and cooling. They are also more energy efficient than reciprocating compressors. Twin-screw chillers are gaining more applications, especially for ice-storage systems with cold air distribution.

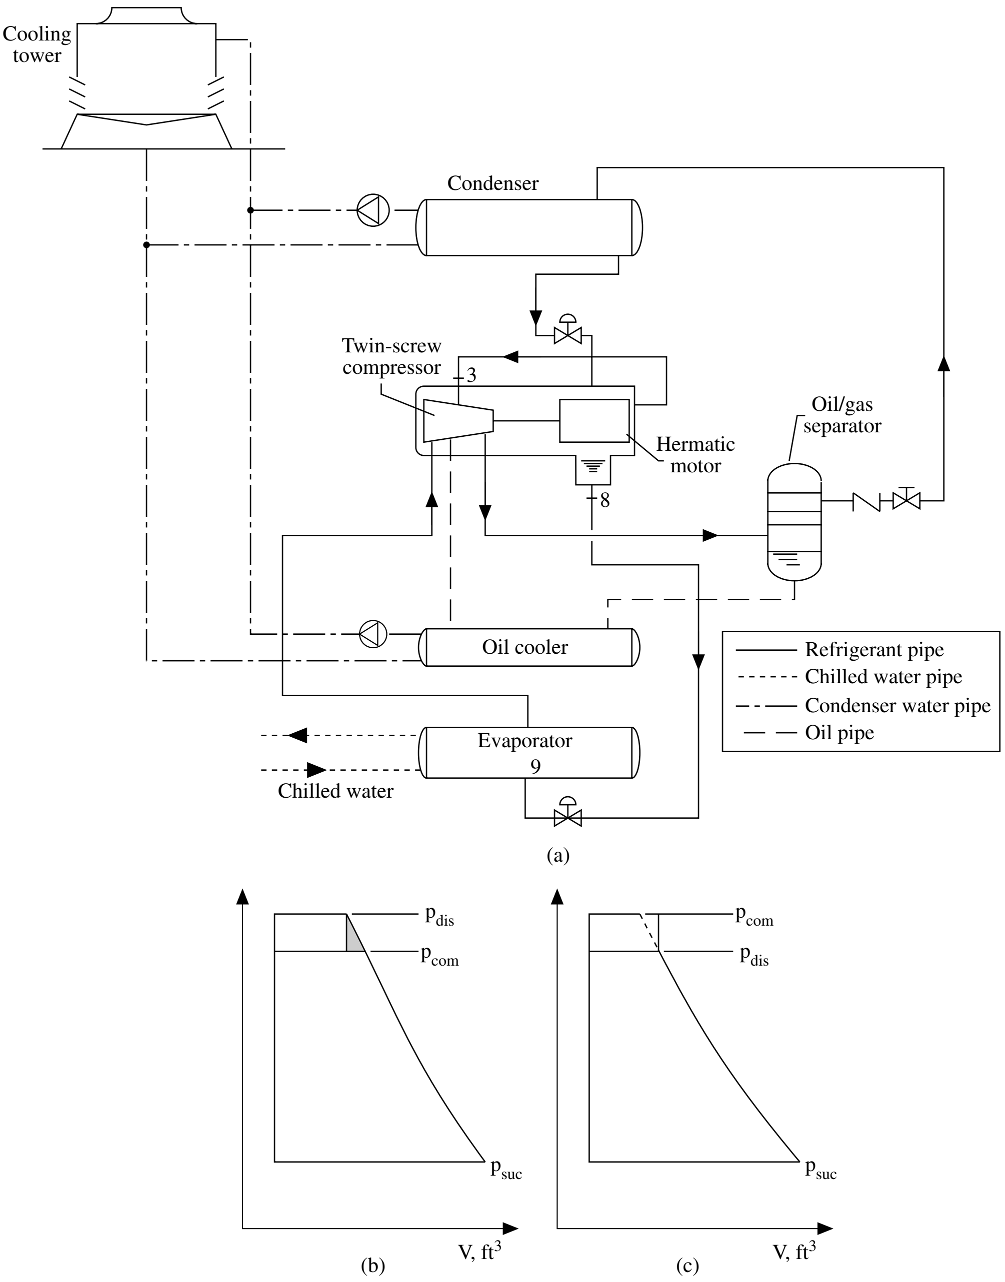


FIGURE 9.11.4 A typical twin-screw chiller: (a) schematic diagram, (b) over-compression, and (c) under-compression.

9.12 Thermal Storage Systems

Shan K. Wang

Thermal Storage Systems and Off-Peak Air-Conditioning Systems

Many electric utilities in the United States have their *on-peak hours* between noon and 8 p.m. during summer weekdays, which include the peak-load hours of air-conditioning. Because the capital cost of a new power plant is so high, electric utilities tend to increase their power output by using customers' thermal energy storage (TES) systems, or simply thermal storage systems, which are much less expensive.

A *thermal storage system* as shown in Figure 9.12.1(a) may have the same refrigeration equipment, like chillers, additional storage tank(s), additional piping, pumps, and controls. The electric-driven compressors are operated during off-peak, partial-peak, and on-peak hours. *Off-peak hours* are often nighttime hours. *Partial-peak hours* are hours between on-peak and off-peak hours in a weekday's 24-hr day-and-night cycle. Chilled water or ice is stored in tanks to provide cooling for buildings during on-peak hours when higher electric demand and electric rates are effective. Although thermal storage systems operate during nighttime when outdoor dry and wet bulbs are lower, they are not necessarily energy saving due to lower evaporating temperature, additional pump power, and energy losses. Thermal storage systems significantly reduce the electric energy cost.

Utilities in the United States often use higher electric demand and rates as well as incentive bonus to encourage the shift of electric load from on-peak to off-peak hours by using thermal storage systems and others. Such a shift not only saves expensive capital cost, but also increases the use of base-load high-efficiency coal and nuclear plants instead of inefficient diesel and gas turbine plants.

The air-conditioning systems that operate during off-peak and partial-peak hours for thermal storage, or those that use mainly natural gas to provide cooling to avoid higher electric demand and rates during on-peak hours, are called *off-peak air-conditioning systems*. These systems include ice-storage and chilled-water storage systems, desiccant cooling systems, absorption systems, and gas engine chillers.

Absorption chillers and desiccant cooling systems are covered in other sections. Gas engine-driven reciprocating chillers are often a cogeneration plant with heat recovery from engine jacket and exhaust gas, and will not be covered here.

Full Storage and Partial Storage

Ice and chilled-water storage systems are the two most common thermal energy storage systems today. Knebel (1995) estimated that more than 4000 cool storage systems are operated in various commercial buildings.

The unit of stored thermal energy for cooling is ton-hour, or ton.hr. One *ton.hr* is the refrigeration capacity of one refrigeration ton during a 1-hr period, or 12,000 Btu.

In order to achieve minimum life-cycle cost, thermal storage systems could be either full storage or partial storage. For a *full-storage*, or *load shift,* thermal storage system, all refrigeration compressors cease to operate during on-peak hours. Building refrigeration loads are entirely offset by the chilled water or brine from the thermal storage system within an on-peak period. In a *partial storage*, or *load-leveling*, thermal storage system as shown in Figure 9.12.1(b) all or some refrigeration compressor(s) are operated during on-peak hours.

Direct cooling is the process in which refrigeration compressors produce refrigeration to cool the building directly. During a specific time interval, if the cost of direct cooling is lower than the stored energy, the operation of a thermal storage system is said to be in *chiller priority.* On the contrary, if the cost of direct cooling is higher than the cost of stored energy, the operation is said to be at *storage priority.*

The optimum size of a thermal storage system is mainly determined according to the utility's electric rate structure, especially a time-of-day structure whose electric rates are different between on-peak, partial-peak, and off-peak hours. Not only the design day's instantaneous building peak cooling load is important, but also an hour-by-hour cooling load profile of the design day is required for thermal storage design. A simple payback or a life-cycle cost analysis is usually necessary.

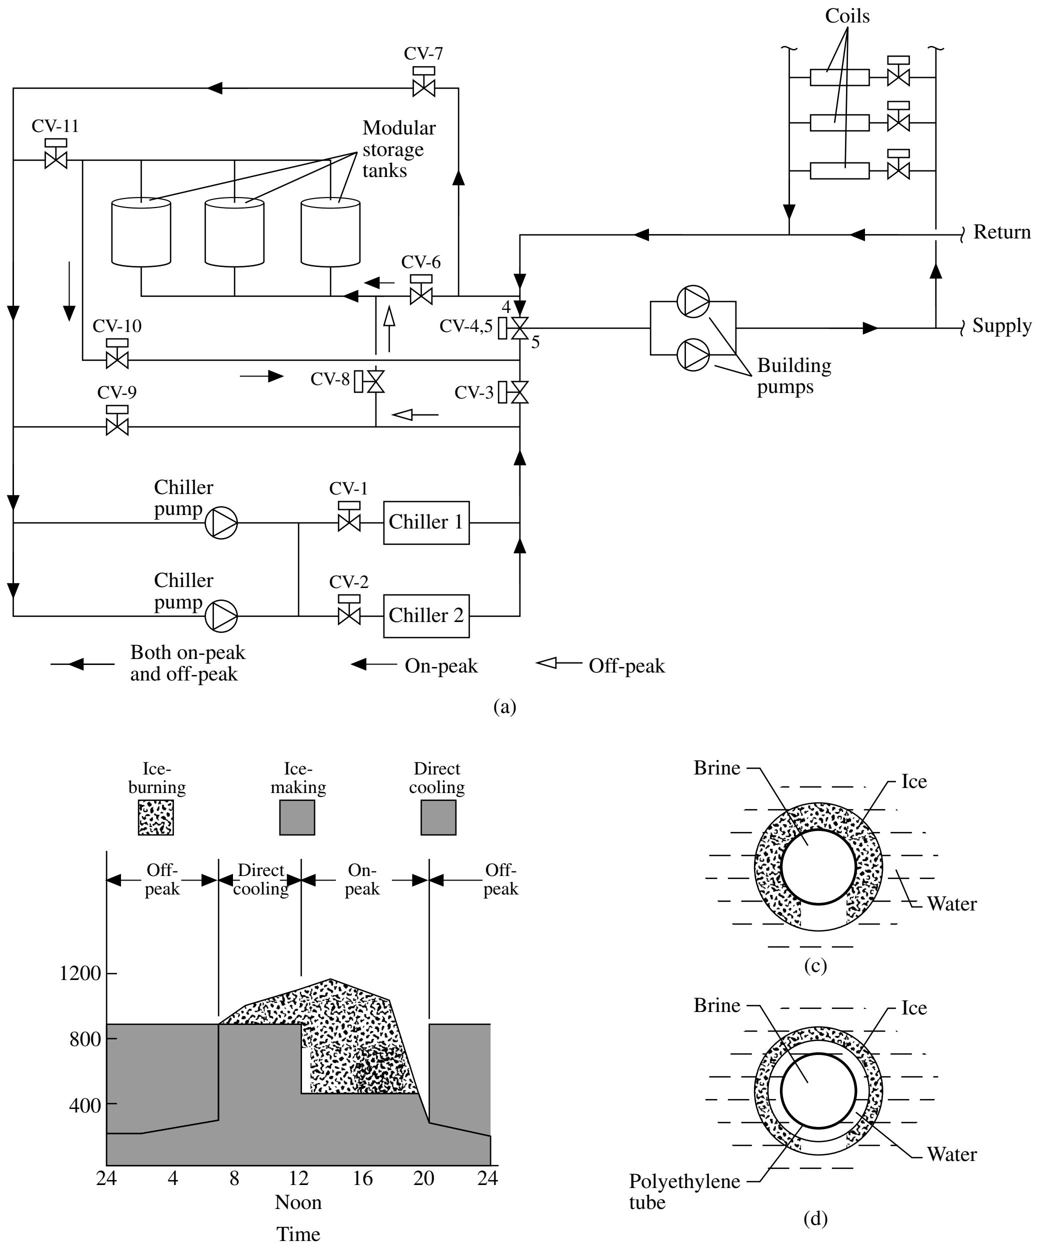

FIGURE 9.12.1 A brine-coil ice-storage system: (a) schematic diagram, (b) partial-storage time schedule, (c) ice making, and (d) ice burning.

Ice-Storage Systems

System Characteristics

In an *ice-thermal-storage* system, or simply an *ice-storage* system, ice is stored in a tank or other containers to provide cooling for buildings in on-peak hours or on- and partial-peak hours. One pound of ice can store [(1 × 144) + (55 – 35)] = 164 Btu instead of (60 – 44) = 16 Btu for chilled water storage. For the same cooling capacity, the storage volume of ice is only about 12% of chilled water. In addition, an air-conditioning system using ice storage often adopts cold air distribution to supply conditioned air at a temperature typically at 44°F. Cold air distribution reduces the size of air-side equipment, ducts, and investment as well as fan energy use. It also improves the indoor air quality of the conditioned space. Since the late 1980s, ice storage has gained more applications than chilled water storage.

Brine is a coolant that does not freeze and flash during normal operation. The freezing point of brine, which has a mass fraction of ethylene glycol of 25%, drops to 10°F, and a mass fraction of a propylene glycol brine of 25% drops to 15°F. Glycol-water, when glycol is dissolved in water, is another coolant widely used in ice-storage systems. Ice crystals are formed in glycol-water when its temperature drops below its freezing point during normal operation.

In an ice-storage system, *ice making* or *charging* is a process in which compressors are operated to produce ice. *Ice burning*, or *discharging*, is a process in which ice is melted to cool the brine or glycol-water to offset a refrigeration load.

Brine-Coil Ice-Storage Systems. Currently used ice-storage systems include brine-coil, ice-harvester, and ice-on-coil systems. According to Knebel (1995), the brine-coil ice-storage system is most widely used today because of its simplicity, flexibility, and reliability as well as using modular ice-storage tanks.

In a typical brine-coil ice-storage system, ice is charged in multiple modular factory-fabricated storage tanks as shown in Figure 9.12.1(a). In each storage tank, closely spaced polyethylene or plastic tubes are surrounded by water. Brine, a mixture of 25 to 30% of ethylene glycol by mass and 70 to 75% water, circulates inside the tubes at an entering temperature of 24°F during the ice-making process. The water surrounding the tubes freezes into ice up to a thickness of about 1/2 in. as shown in Figure 9.12.1(c). Brine leaves the storage tank at about 30°F. Water usually at atmospheric pressure is separated from brine by a plastic tube wall. Plastic tubes occupy about one tenth of the tank volume, and another one tenth remains empty for the expansion of ice. Multiple modular storage tanks are always connected in parallel.

During the ice-melting or -burning process, brine returns from the cooling coils in the air-handling units (AHUs) at a temperature of 46°F or higher. It melts the ice on the outer surface of the tubes and is thus cooled to a temperature of 34 to 36°F, as shown in Figure 9.12.1(d). Brine is then pumped to the AHUs to cool and dehumidify the air again.

Ice-Harvester Ice-Storage Systems. In an *ice-harvester* system, glycol-water flows on the outside surface of the evaporator and forms ice sheets with a thickness of 0.25 to 0.40 in. within 20 to 30 min. Ice is harvested in the form of flakes when hot gas is flowing inside the tubes of the evaporator during a time interval of 20 to 30 sec. Ice flakes fall to the glycol-water in the storage tank below. The glycol-water at a temperature of 34°F is then supplied to the cooling coils in AHUs for conditioning. After cooling and dehumidifying the air, glycol-water returns to the storage tank at a temperature of 50 to 60°F and is again cooled to 34°F again.

Ice harvesting is an intermittent process. It has a cycle loss due to harvesting of about 15%. In addition, because of its operating complexity and maintenance, its applications are more suitable for large ice-storage systems.

Ice-on-Coil Ice-Storage Systems. In an ice-on-coil system, refrigerant is evaporated in the coils submerged in water in a storage tank. Ice of a thickness not exceeding 0.25 in. builds up on the outer surface of the coils. The remaining water in the storage tank is used for cooling in AHUs. Ice-on-coil systems need large amounts of refrigerant charge and are less flexible in operation. They are usually used in industrial applications.

Ice-in-Containers Ice-Storage Systems. Ice-in-containers ice-storage systems store ice in enclosed containers. Brine circulating over the containers produces the ice inside containers. Complexity in control of the ice inventory inside the containers limits the application of the ice-in-containers systems.

Chilled-Water Storage Systems

Basics

Chilled-water storage uses the same water chiller and a similar coolant distribution system, except for additional water storage tanks and corresponding piping, additional storage pumps, and controls. The larger the chilled-water storage system, the lower the installation cost per ton.hr storage capacity.

Various types of storage tanks had been used in chilled-water storage systems during the 1970s. A diaphragm tank uses a rubber diaphragm to separate the colder and warmer water. Baffles divide the tank into cells and compartments. Today, stratified tanks have become the most widely used chilled-water storage systems because of their simplicity, low cost, and negligible difference in loss of cooling capacity between stratified tanks and other types of storage tanks.

During the storage of chilled water, the loss in cooling capacity includes direct mixing, heat transfer between warmer return chilled water and colder stored chilled water, and also heat transfer between warmer ambient air and colder water inside the tank. An enthalpy-based easily measured index called *figure of merit* (*FOM*) is often used to indicate the loss in cooling capacity during chilled-water storage. FOM is defined as:

$$\text{FOM} = q_{\text{dis}}/q_{\text{ch}} \tag{9.12.1}$$

where

q_{dis} = cooling capacity available in the discharge process, Btu/hr
q_{ch} = theoretical cooling capacity available during charging process, Btu/hr

Charging is the process of filling the storage tank with colder chilled water from the chiller. At the same time, warmer return chilled water is extracted from the storage tank and pumped to the chiller for cooling.

Discharging is the process of discharging the colder stored chilled water from the storage tank to AHUs and terminals. Meanwhile, the warmer return chilled water from the AHUs and terminals fills the tank.

Stratified Tanks. Stratified tanks utilize the buoyancy of warmer return chilled water to separate it from the colder stored chilled water during charging and discharging. Colder stored chilled water is always charged and discharged from bottom diffusers, and the warmer return chilled water is introduced to and withdrawn from the top diffusers.

Chilled-water storage tanks are usually vertical cylinders and often have a height-to-diameter ratio of 0.25:0.35. Steel is the most commonly used material for above-grade tanks, with a 2-in.-thick spray-on polyurethane foam, a vapor barrier, and a highly reflective coating. Concrete, sometimes precast, prestressed tanks are widely used for underground tanks.

A key factor to reduce loss in cooling capacity during chilled water storage is to reduce mixing of colder and warmer water streams at the inlet. If the velocity pressure of the inlet stream is less than the buoyancy pressure, the entering colder stored chilled water at the bottom of tank will stratify. Refer to Wang's handbook (1993) and Knebel (1995) for details.

A *thermocline* is a stratified region in a chilled-water storage tank of which there is a steep temperature gradient. Water temperature often varies from 42°F to about 60°F. Thermocline separates the bottom colder stored chilled water from the top warmer return chilled water. The thinner the thermocline, the lower the mixing loss.

Diffusers and symmetrical connected piping are used to evenly distribute the incoming water streams with sufficient low velocity, usually lower than 0.9 ft/sec. Inlet stream from bottom diffusers should be downward and from the top diffusers should be upward or horizontal.

Field measurements indicate that stratified tanks have a FOM between 0.85 to 0.9.

9.13 Air System Basics

Shan K. Wang

Fan-Duct Systems

Flow Resistance

Flow resistance is a property of fluid flow which measures the characteristics of a flow passage resisting the fluid flow with a corresponding total pressure loss Δp, in in. WG, at a specific volume flow rate $\overset{\circ}{V}$, in cfm:

$$\Delta p = R\mathring{V}^2 \tag{9.13.1}$$

where R = flow resistance (in. WG/(cfm)^2).

For a duct system that consists of several duct sections connected in series, its flow resistance R_s, in in. WG/(cfm)^2, can be calculated as

$$R_s = R_1 + R_2 + \ldots + R_n \tag{9.13.2}$$

where R_1, R_2, … R_n = flow resistance of duct section 1, 2, … n in the duct system (in. WG/(cfm)^2).

For a duct system that consists of several duct sections connected in parallel, its flow resistance R_p, in in. WG/(cfm)^2, is:

$$1/\sqrt{R_p} = 1/\sqrt{R_1} + 1/\sqrt{R_2} + \ldots + 1/\sqrt{R_n} \tag{9.13.3}$$

Fan-Duct System

In a *fan-duct system*, a fan or several fans are connected to ductwork or ductwork and equipment. The volume flow and pressure loss characteristics of a duct system can be described by its performance curve, called *system curve*, and is described by $\Delta p = R\,\mathring{V}^2$.

An *air system* or an air handling system is a kind of fan-duct system. In addition, an outdoor ventilation air system to supply outdoor ventilation air, an exhaust system to exhaust contaminated air, and a smoke control system to provide fire protection are all air systems, that is, fan-duct systems.

Primary, Secondary, and Transfer Air

Primary air is the conditioned air or makeup air. Secondary air is often the induced space air, plenum air, or recirculating air. Transfer air is the indoor air that moves to a conditioned space from an adjacent area.

System-Operating Point

A *system-operating point* indicates the operating condition of an air system or fan-duct system. Since the operating point of a fan must lie on the fan performance curve, and the operating point of a duct system on the system curve, the system operating point of an air system must be the intersection point P_s of the fan performance curve and system curve as shown in Figure 9.13.1(a).

Fan-Laws

For the same air system operated at speeds n_1 and n_2, both in rpm, their relationship of $\mathring{V}$ volume flow rate, in cfm, system total pressure loss, in in. WG, and fan power input, in hp, can be expressed as

$$\begin{aligned} \mathring{V}_2/\mathring{V}_1 &= n_2/n_1 \\ \Delta p_{t2}/\Delta p_{t1} &= (n_2/n_1)^2(\rho_2/\rho_1) \\ P_2/P_1 &= (n_2/n_1)^3(\rho_2/\rho_1) \end{aligned} \tag{9.13.4}$$

where ρ = air density (lb/ft^3). Subscripts 1 and 2 indicate the original and the changed operating conditions. For air systems that are geometrically and dynamically similar:

$$\begin{aligned} \mathring{V}_2/\mathring{V}_1 &= (D_2/D_1)^3(n_2/n_1) \\ \Delta p_{t2}/\Delta p_{t1} &= (D_2/D_1)^2(n_2/n_1)^2(\rho_2/\rho_1) \\ P_2/P_1 &= (D_2/D_1)^5(n_2/n_1)^3(\rho_2/\rho_1) \end{aligned} \tag{9.13.5}$$

where D = diameter of the impeller (ft).

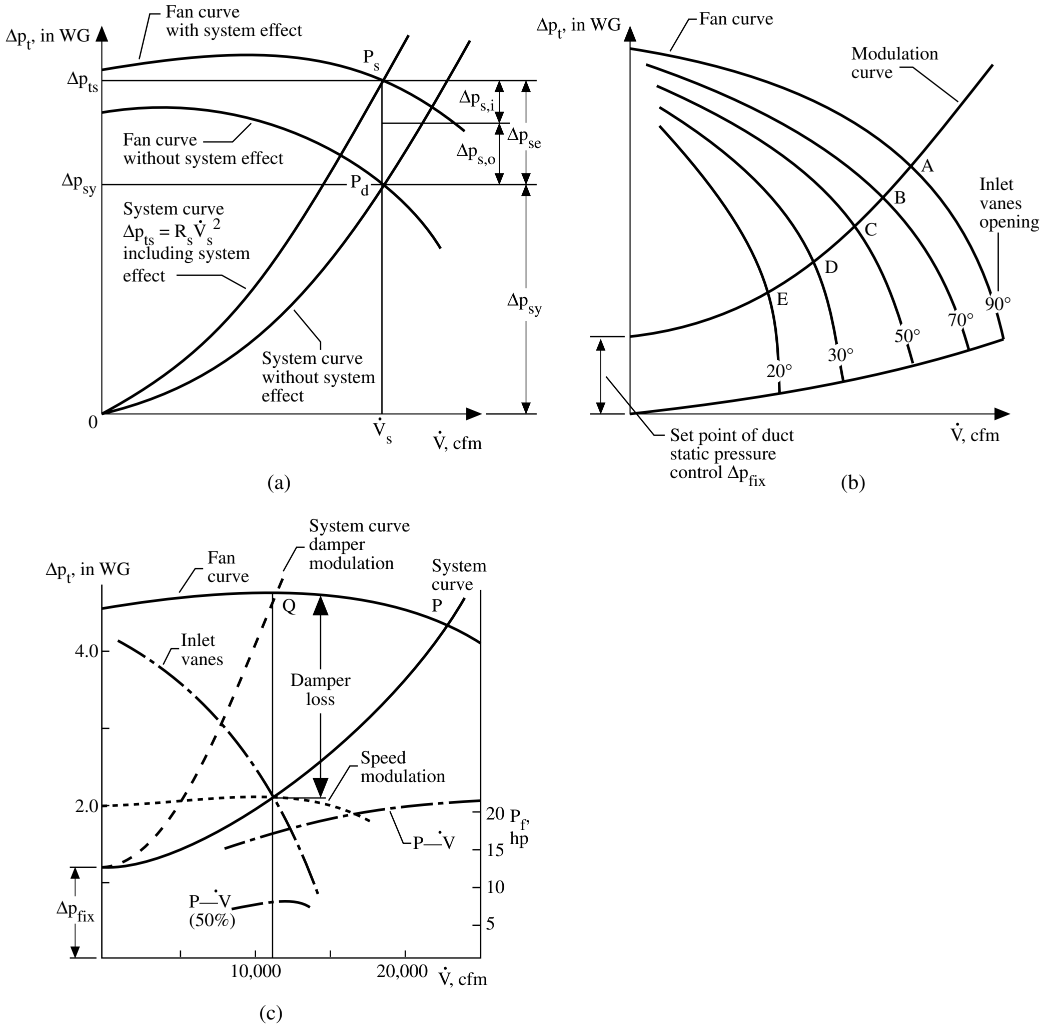

FIGURE 9.13.1 Air system $\mathring{V}$ - Δp_t performance: (a) system operating point and system effect, (b) modulation curve, and (c) damper, inlet vanes, and fan speed modulation.

Geometrically similar means that two systems are similar in shape and construction. For two systems that are dynamically similar, they must be geometrically similar, and in addition, their velocity distribution or profile of fluid flow should also be similar. When fluid flows in the air systems are at high Reynolds number, such as Re > 10,000, their velocity profiles can be considered similar to each other.

System Effect

The system effect Δp_{se}, in in. WG, of an air system is its additional total pressure loss caused by uneven or nonuniform velocity profile at the fan inlet, or at duct fittings after the fan outlet, due to the actual inlet and outlet connections as compared with the total pressure loss of the fan test unit during laboratory ratings. The selected fan total pressure which includes the system effect Δp_{ts}, in in. WG, as shown in Figure 9.13.1(a), can be calculated as

$$\begin{aligned}\Delta p_{ts} &= \Delta p_{sy} + \Delta p_{se} = \Delta p_{sy} + \Delta p_{s.i} + \Delta p_{s.o} \\ &= \Delta p_{sy} + C_{s.i}\left(v_{fi}/4005\right)^2 + C_{s.o}\left(v_{fo}/4005\right)^2\end{aligned} \tag{9.13.6}$$

where

Δp_{sy} = calculated total pressure loss of the air system, in WG
$\Delta p_{s.i}, \Delta p_{s.o}$ = fan inlet and outlet system effect loss, in WG
$C_{s.i}, C_{s.o}$ = local loss coefficient of inlet and outlet system effect, in WG
v_{fi}, v_{fo} = velocity at fan inlet (fan collar) and fan outlet, fpm

Both $C_{s.i}$ and $C_{s.o}$ are mainly affected by the length of connected duct between the duct fitting and fan inlet or outlet, by the configuration of the duct fitting, and by the air velocity at the inlet or outlet. Because v_{fi} and v_{fo} are often the maximum velocity of the air system, system effect should not be overlooked.

Modulation of Air Systems

Air systems can be classified into two categories according to their operating volume flow: constant volume and variable-air-volume systems. The volume flow rate of a *constant volume system* remains constant during all the operating time. Its supply temperature is raised during part load. For a *variable-air-volume* (*VAV*) *system,* its volume flow rate is reduced to match the reduction of space load at part-load operation. The system pressure loss of a VAV system can be divided into two parts: variable part Δp_{var} and fixed part Δp_{fix}, which is the set point of the duct static pressure control as shown in Figure 9.13.1(b) and (c). The *modulation curve* of a VAV air system its its operating curve, or the locus of system operating points when its volume flow rate is modulated at full- and part-load operation.

The volume flow and system pressure loss of an air system can be modulated either by changing its fan characteristics or by varying its flow resistance of the duct system. Currently used types of modulation of volume flow rate of VAV air systems are

1. *Damper modulation* uses an air damper to vary the opening of the air flow passage and therefore its flow resistance.
2. *Inlet vanes modulation* varies the opening and the angle of inlet vanes at the centrifugal fan inlet and then gives different fan performance curves.
3. *Inlet cone modulation* varies the peripheral area of the fan impeller and therefore its performance curve.
4. *Blade pitch modulation* varies the blade angle of the axial fan and its performance curve.
5. *Fan speed modulation* using *adjustable frequency AC drives* varies the fan speed by supplying a variable-frequency and variable-voltage power source. There are three types of AC drives: adjustable voltage, adjustable current, and pulse width modulation (PWM). The PWM is universally applicable.

Damper modulation wastes energy. Inlet vanes are low in cost and are not so energy efficient compared with AC drives and inlet cones. Inlet cones are not expensive and are suitable for backward curved centrifugal fans. Blade pitch modulation is energy efficient and is mainly used for vane and tubular axial fans. AC or variable frequency drives (VFD) are the most energy-efficient type of modulation; however, they are expensive and often considered cost effective for air systems using larger centrifugal fans.

Example 9.13.1

A multizone VAV system equipped with a centrifugal fan has the following characteristics:

$\overset{\circ}{V}$ (cfm)	5,000	10,000	15,000	20,000	25,000
Δp_t, in. WG	4.75	4.85	4.83	4.60	4.20
P, hp		17.0	18.6	20.5	21.2

At design condition, it has a volume flow rate of 22,500 cfm and a fan total pressure of 4.45 in. WG. The set point of duct static pressure control is 1.20 in. WG.

When this VAV system is modulated by inlet vanes to 50% of design flow, its fan performance curves show the following characteristics:

$\overset{\circ}{V}$ (cfm)	5,000	10,000	11,250
Δp_t, in. WG	3.6	2.5	2.1
P, hp		7.5	7.8

Determine the fan power input when damper, inlet vanes, or AC drive fan speed modulation is used. Assume that the fan total efficiency remains the same at design condition when the fan speed is reduced.

Solutions

1. At 50% design flow, the volume flow of this VAV system is 0.5 × 22,500 = 11,250 cfm. The flow resistance of the variable part of this VAV system is

$$R_{\text{var}} = \Delta p_{\text{va}} = R\overset{\circ}{V}^2 = (4.45 - 1.20)/(22{,}500)^2 = 6.42 \times 10^{-9} \text{ in. WG}/(\text{cfm})^2$$

   When damper modulation is used, the system operating point Q must be the intersection of the fan curve and the system curve that has a higher flow resistance and a $\overset{\circ}{V}$ = 11,250 cfm. From Figure 9.13.1(c), at point Q, the fan power input is 17.0 hp.
2. From the given information, when inlet vane modulation is used, the fan power input is 7.8 hp.
3. The total pressure loss of the variable part of the VAV system at 50% volume flow is

$$\Delta p_{\text{var}} = R_{\text{var}}\overset{\circ}{V}^2 = 6.42 \times 10^{-9}(11{,}250)^2 = 0.81 \text{ in. WG}$$

   From Figure 9.13.1(c), since the fan power input at design condition is 21.2 hp, then its fan total efficiency is:

$$\eta_f = \overset{\circ}{V}\Delta p_{\text{tf}}/(6356P_f) = 22{,}500 \times 4.45/(6356 \times 21.2) = 74.3\%$$

   The fan power input at 50% design volume flow is:

$$P = \overset{\circ}{V}\Delta p_{\text{tf}}/(6356\eta_f) = 11{,}250(0.81 + 1.20)/(6356 \times 0.743) = 4.8 \text{ hp}$$

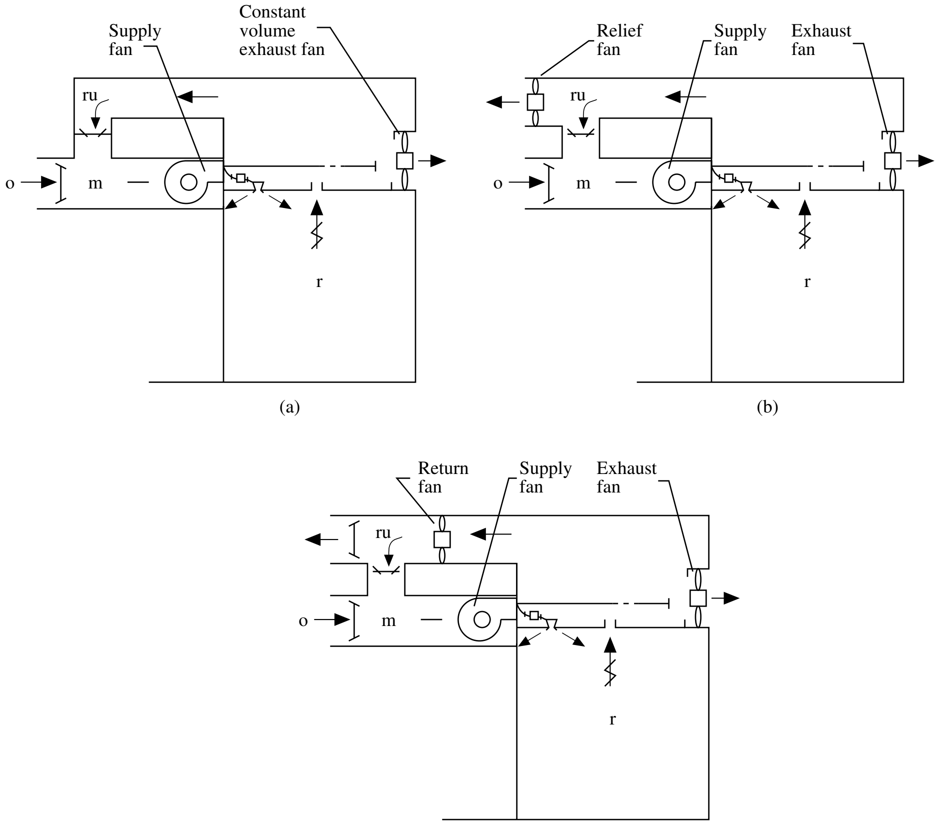
   Damper modulation has a energy waste of (17 – 4.8) = 12.2 hp

Fan Combinations in Air-Handling Units and Packaged Units

Currently used fan combinations in air-handling units (AHUs) and packaged units (PUs) (except dual-duct VAV systems) are shown in Figure 9.13.2(a), (b), and (c):

Supply and Exhaust Fan/Barometric Damper Combination

An air system equipped with a single supply fan and a constant-volume exhaust fan, or a supply fan and a barometric damper combination as shown in Figure 9.13.2(a), is often used in buildings where there is no return duct or the pressure loss of the return duct is low. An all-outdoor air economizer cycle is usually not adopted due to the extremely high space pressure. A barometric relief damper is often installed in or connected to the conditioned space to prevent excessively high space pressure. When the space-positive pressure exerted on the barometric damper is greater than the weight of its damper and/or a spring, the damper is opened and the excessive space pressure is relieved.



(a)

(b)

(c)

FIGURE 9.13.2 Fan combinations: (a) supply and exhaust fan, (b) supply and relief fan, and (c) supply and return fan.

Supply and Relief Fan Combination

Figure 9.13.2(b) shows the schematic diagrams of an air system of supply fan and relief fan combination. A relief fan is used to relieve undesirable high positive space pressure by extracting space air and relieving it to the outside atmosphere. A relief fan is always installed in the relief flow passage after the junction of return flow, relief flow, and recirculating flow passage, point ru. It is usually energized only when the air system is operated in air economizer mode. A relief fan is often an axial fan. Since the relief fan is not energized during recirculating mode operation, the volume flow and pressure characteristics of a supply fan and relief fan combination are the same as that in a single supply fan and barometric damper combination when they have the same design parameters.

Supply Fan and Return Fan Combination

A *return fan* is always installed at the upstream of the junction of return, recirculating, and exhaust flow passage, point ru as shown in Figure 9.13.2(c). A supply and return fan combination has similar pressure and volume flow characteristics as that of a supply and relief fan combination, except a higher total pressure at point ru. If the return fan is improperly selected and has an excessive fan total pressure, total pressure at point m may be positive. There will be no outdoor intake at the PU or AHU, and at the same time there will also be a negative space pressure and an infiltration to the space.

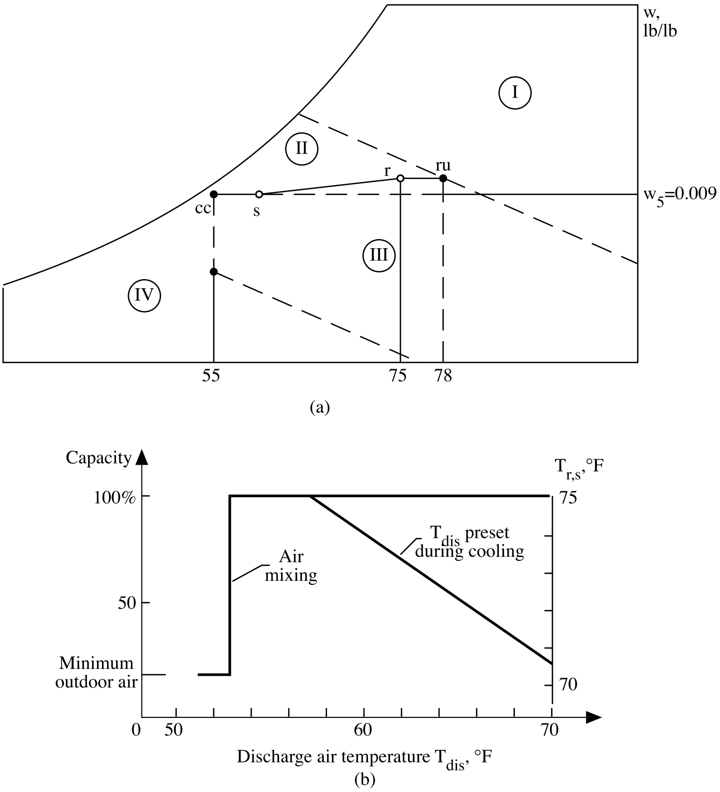


FIGURE 9.13.3 (a) Year-round operation and (b) discharge air temperature for a VAV reheat system.

Comparison of These Three Fan Combination Systems

A supply fan and barometric damper combination is simpler and less expensive. It is suitable for an air system which does not operate in an air economizer mode and has a low pressure drop in the return system.

For those air systems whose pressure drop for the return system does not exceed 0.3 in. WG, or there is a considerable pressure drop in relief or exhaust flow passage, a supply and relief fan combination is recommended. For air systems whose return system has a pressure drop exceeding 0.6 in. WG, or those requiring a negative space pressure, a supply and return fan combination seems more appropriate.

Year-Round Operation and Economizers

Consider a typical single-duct VAV reheat system to serve an occupied space whose indoor temperature is 75°F with a relative humidity of 50%. During summer, the off-coil temperature is 55°F. The year-round operation of this air system can be divided into four regions on the psychrometric chart, as shown in Figure 9.13.3(a):

- *Region I — Refrigeration/evaporative cooling.* In this region, the enthalpy of the outdoor air h_o is higher than the enthalpy of the recirculating air h_{ru}, $h_o > h_{ru}$. It is more energy efficient to condition the mixture of recirculating air and minimum outdoor air.
- *Region II — Free cooling and refrigeration.* In this region, $h_o \le h_{ru}$. It is more energy efficient and also provides better indoor air quality to extract 100% outdoor air.

- *Region III — Free cooling evaporative cooling, and refrigeration.* In this region, extract 100% outdoor air for free cooling because $h_o \le h_{ru}$. Use evaporative cooling and refrigeration to cool and humidify if necessary.
- *Region IV — Winter heating.* Maintain a 55°F supply temperature by mixing the recirculating air with the outdoor air until the outdoor air is reduced to a minimum value. Provide heating if necessary.

An economizer is a device consisting of dampers and control that uses the free cooling capacity of either outdoor air or evaporatively cooled water from the cooling tower instead of mechanical refrigeration. An air economizer uses outdoor air for free cooling. There are two kinds of air economizers: enthalpy-based, in which the enthalpy of outdoor and recirculating air is compared, and temperature-based, in which temperature is compared. Economizers require routine maintenance and calibration in order to realize maximum savings. A water economizer uses evaporatively cooled water.

Fan Energy Use

For an air system, fan energy use for each cfm of conditioned air supplied from the AHUs and PUs to the conditioned space within a certain time period, in W/cfm, can be calculated as

$$\text{W/cfm} = 0.1175\Delta p_{sy} / (\eta_f \eta_m) \tag{9.13.7}$$

where

Δp_{sy} = mean system total pressure loss during a certain time period, in. WG
η_f = fan total efficiency
η_m = combined motor and drive (direct drive or belt drive) efficiency

For an air system using a separate outdoor ventilation system, its fan energy use, in W/cfm, is then calculated as

$$\text{W/cfm} = (1 + R_{o.s}) \left[0.1175\Delta p_{sy} / (\eta_f \eta_m) \right] \tag{9.13.8}$$

where $R_{o.s}$ = ratio of outdoor air volume flow rate to supply volume flow rate.

Outdoor Ventilation Air Supply

Basics

- An adequate amount of outdoor ventilation air supply is the key factor to provide acceptable indoor air quality (IAQ) for a conditioned space. Although an inadequate amount of outdoor ventilation air supply causes poor IAQ, an oversupply of outdoor ventilation air other than in an air economizer cycle is often a waste of energy.
- According to local codes and ANSI/ASHRAE Standard 62, the minimum outdoor ventilation rate for each person must be provided at the outdoor air intake of AHU or PU, or by an outdoor air ventilation system. If the minimum outdoor ventilation air rate is reduced by using higher efficiency filters to remove air contaminants in the recirculating air, then indoor air contaminant concentration must be lower than the specified level in ANSI/ASHRAE Standard 62.
- For a multizone air system, although the ratio of outdoor ventilation air rate to supply air volume flow rate required may be varied from zone to zone, the excessive outdoor air supply to a specified zone will increase the content of unused outdoor air in the recirculating air in AHU or PU. This helps to solve the problem in any zone that needs more outdoor air.
- Since the occupancy in many buildings is often variable and intermittent, a demand-based variable amount of outdoor ventilation air control should be used instead of time-based constant volume outdoor ventilation air control, except during the air economizer cycle.

- Carbon dioxide (CO_2) is a gaseous body effluent. CO_2 is an indicator of representative odor and an indicator of adequate outdoor ventilation rate at specific outdoor and indoor air concentration in a control zone at steady state. For most of the comfort air-conditioning systems, it is suitable to use CO_2 as a key parameter to control the intake volume flow rate of outdoor ventilation air to maintain an indoor CO_2 concentration not exceeding 800 to 1000 ppm in a critical or representative zone. As mentioned in Section 9.5, Persily (1993) showed that the actual measured indoor daily maximum CO_2 concentration levels in five buildings were all within 400 to 820 ppm.

If a field survey finds that a specific indoor air contaminant exceeds a specified indoor concentration, then a gas sensor for this specific contaminant or a mixed gas sensor should be used to control this specific indoor concentration level.

Types of Minimum Outdoor Ventilation Air Control. There are four types of minimum outdoor ventilation air control that are currently used:

- Type I uses a CO_2 sensor or a mixed gas sensor and a DDC controller to control the volume flow rate of outdoor ventilation air for a separate outdoor ventilation air system on the demand-based principle.
- Type II uses a CO_2 or mixed gas sensor and a DDC controller to control the ratio of the openings between outdoor and recirculating dampers and, therefore, the volume flow rates of outdoor air and recirculating air in AHUs or PUs on the demand-based principle.
- Type III uses a flow sensor or a pressure sensor and a DDC controller to control the openings of outdoor and recirculating dampers to provide a nearly constant volume outdoor air intake in VAV AHUs or VAV PUs.
- Type IV adjusts the opening of the outdoor damper manually to provide a constant volume of outdoor air in constant-volume AHUs and PUs. If the outdoor intake is mounted on the external wall without a windshield, the volume flow of outdoor ventilation air intake will be affected by wind force and direction.

Type I is the best minimum outdoor ventilation air control for the air system. For a VAV system, it is expensive. Type II is a better choice. Type III is more complicated and may cause energy waste. Type IV has the same result as Type III and is mainly used in constant-volume systems.

Outdoor intake must be located in a position away from the influence of exhaust outlets. Fans, control dampers, and filters should be properly operated and maintained in order to provide a proper amount of outdoor ventilation air as well as an acceptable IAQ.

9.14 Absorption System

Shan K. Wang

Absorption systems use heat energy to produce refrigeration as well as heating if it is required. Water is the refrigerant and aqueous lithium bromide (LiBr) is widely used as the carrier to absorb the refrigerant and provide a higher coefficient of performance.

The mixture of water and anhydrous LiBr is called *solution*. The composition of a solution is usually expressed by its mass fraction, or percentage of LiBr, often called *concentration*. When the water vapor has boiled off from the solution, it is called *concentrated solution.* If the solution has absorbed the water vapor, it is called *diluted solution.*

Absorption systems can be divided into the following categories:

- *Absorption chillers* use heat energy to produce refrigeration.
- *Absorption chiller/heaters* use direct-fired heat input to provide cooling or heating separately.
- *Absorption heat pumps* extract heat energy from the evaporator, add to the heat input, and release them both to the hot water for heating.
- *Absorption heat transformers* raise the temperature of the waste heat source to a required level.

Most recently installed absorption chillers use direct-fired natural gas as the heat source in many locations in the United States where there are high electric demand and electric rates at on-peak hours. Absorption chillers also are free from CFC and HCFC refrigerants. An energy cost analysis should be done to determine whether an electric chiller or a gas-fired absorption chiller is the suitable choice.

Absorption heat pumps have only limited applications in district heating. Most absorption heat transformers need industrial waste heat. Both of them will not be covered here.

Double-Effect Direct-Fired Absorption Chillers

Figure 9.14.1(a) shows a double-effect direct-fired absorption chiller. *Double effect* means that there are two generators. *Direct fired* means that gas is directly fired at the generator instead of using steam or hot water. A single-effect absorption chiller using steam as the heat input to its single generator has a COP only from 0.7 to 0.8, whereas a double-effect direct-fired absorption chiller has a COP approximately equal to 1 and therefore is the mot widely used absorption chiller in the United States for new and retrofit projects today. The refrigeration capacity of double-effect direct-fired absorption chillers varies from 100 to 1500 tons.

A double-effect direct-fired absorption chiller mainly consists of the following components and controls:

- Evaporator — An *evaporator* is comprised of a tube bundle, spray nozzles, a water trough, a refrigerant pump, and an outer shell. Chilled water flows inside the tubes. A refrigerant pump sprays the liquid refrigerant over the outer surface of the tube bundle for a higher rate of evaporation. A water trough is located at the bottom to maintain a water level for recirculation.
- Absorber — In an *absorber*, there are tube bundles in which cooling water flows inside the tubes. Solution is sprayed over the outer surface of the tube bundle to absorb the water vapor. A solution pump is used to pump the diluted solution to the heat exchanger and low-temperature generator.
- Heat exchangers — There are two heat exchangers: *low-temperature heat exchanger* in which the temperature of hot concentrated solution is lower, and *high-temperature heat exchanger* in which the temperature of hot concentrated solution is higher. In both heat exchangers, heat is transferred from the hot concentrated solution to the cold diluted solution. Shell-and-tube or plate-and-frame heat exchangers are most widely used for their higher effectiveness.
- Generators — *Generators* are also called *desorbers*. In the *direct-fired generator*, there are the fire tube, flue tube, vapor/liquid separator, and flue-gas economizer. Heat is supplied from the gas burner or other waste heat source. The *low-temperature generator* is often of the shell-and-tube type. The water vapor vaporized in the direct-fired generator is condensed inside the tubes. The latent heat of condensation thus released is used to vaporize the dilute solution in the low-temperature generator.
- Condenser — A condenser is usually also of the shell-and-tube type. Cooling water from the absorber flows inside the tubes.
- Throttling devices — Orifices and valves are often used as throttling devices to reduce the pressure of refrigerant and solution to the required values.
- Air purge unit — Since the pressure inside the absorption chiller is below atmospheric pressure, air and other noncondensable gases will leak into it from the ambient air. An *air purge unit* is used to remove these noncondensable gases from the chiller. A typical air purge unit is comprised of a pickup tube, a purge chamber, a solution spray, cooling water tubes, a vacuum pump, a solenoid valve, and a manual shut-off valve.

When noncondensable gases leak into the system, they tend to migrate to the absorber where pressure is lowest. Noncondensable gases and water vapor are picked from the absorber through the pickup tube. Water vapor is absorbed by the solution spray and returned to the absorber through a liquid trap at the bottom of the purge chamber. Heat of absorption is removed by the cooling water inside the tubes. Noncondensable gases are then evacuated from the chamber periodically by a vacuum pump to the outdoor atmosphere.

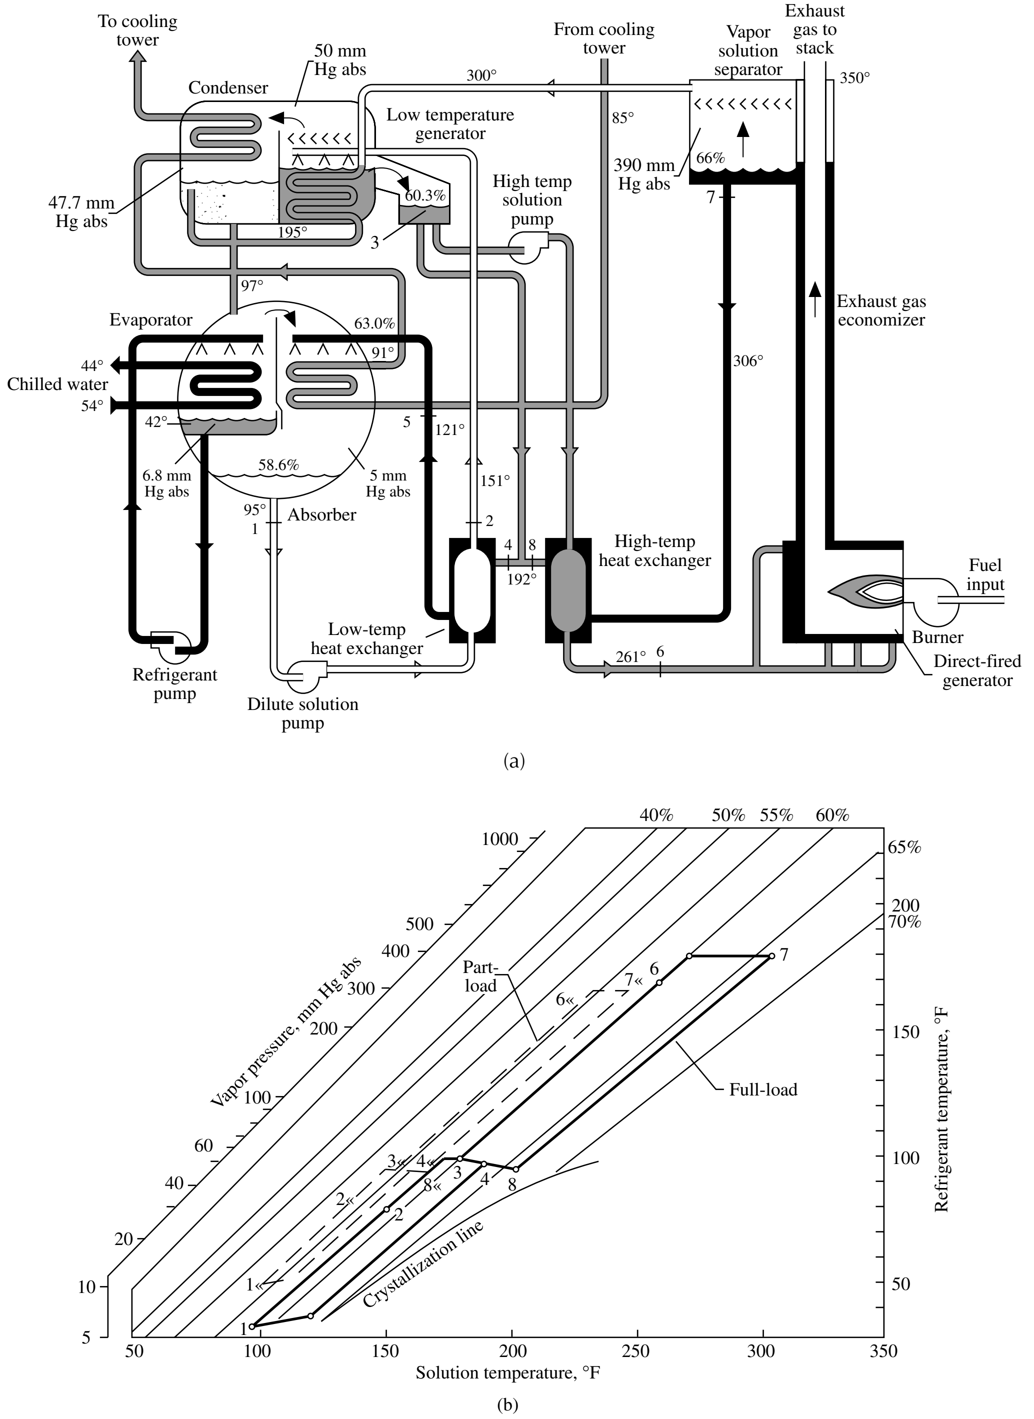

FIGURE 9.14.1 A double-effect direct-fired reverse-parallel-flow absorption chiller: (a) schematic diagram (reprinted by permission from the Trane catalog) and (b) absorption cycle.

Palladium cells are used to continuously remove a small amount of hydrogen that is produced due to corrosion. Corrosion inhibitors like lithium chromate are needed to protect the machine parts from the corrosive effect of the absorbent when air is present.

Absorption Cycles, Parallel-, Series-, and Reverse-Parallel Flow

An *absorption* cycle shows the properties of the solution and its variation in concentrations, temperature, and pressure during absorbing, heat exchanging, and concentration processes on an equilibrium chart as shown in Figure 9.14.1(b). The ordinate of the equilibrium chart is the saturated temperature and pressure of water vapor, in °F and mm Hg abs. The abscissa is the temperature of the solution, in °F. Concentration lines are incline lines. At the bottom of the concentration lines, there is a *crystallization line* or *saturation line*. If the mass of fraction of LiBr in a solution which remains at constant temperature is higher than the saturated condition, that part of LiBr exceeding the saturation condition tends to form solid crystals.

Because there are two generators, the flow of solution from the absorber to generators can be in series flow, parallel flow, or reverse-parallel flow. In a series-flow system, the diluted solution from the absorber is first pumped to the direct-fired generator and then to the low-temperature generator. In a parallel-flow system, diluted solution is pumped to both direct-fired and low-temperature generators in parallel. In a reverse-parallel-flow system as shown in Figure 9.14.1(a), diluted solution is first pumped to the low-temperature generator. After that, the partly concentrated solution is then sent to the direct-fired generator as well as to the intermediate point 4 between high- and low-temperature heat exchangers in parallel. At point 4, partly concentrated solution mixes with concentrated solution from a direct-fired generator. A reverse-parallel-flow system is more energy efficient.

Solution and Refrigerant Flow

In a typical double-effect direct-fired reverse-parallel-flow absorption chiller operated at design full load, water is usually evaporated at a temperature of 42°F and a saturated pressure of 6.8 mm Hg abs in the evaporator. Chilled water returns from the AHUs or fan coils at a temperature typically 54°F, cools, and leaves the evaporator at 44°F. A refrigeration effect is produced due to the vaporization of water vapor and the removal of latent heat of vaporization from the chilled water.

Water vapor in the evaporator is then extracted to the absorber due to its lower vapor pressure. It is absorbed by the concentrated LiBr solution at a pressure of about 5 mm Hg abs. After absorption, the solution is diluted to a concentration of 58.6% and its temperature increases to 95°F (point 1). Most of the heat of absorption and the sensible heat of the solution is removed by the cooling water inside the tube bundle. Diluted solution is then pumped by a solution pump to the low-temperature generator through a low-temperature heat exchanger.

In the low-temperature generator, the dilute solution is partly concentrated to 60.3% at a solution temperature of 180°F (point 3). It then divides into two streams: one of them is pumped to the direct-fired generator through a high-temperature heat exchanger, and the other stream having a slightly greater mass flow rate is sent to the intermediate point 4. In the direct-fired generator, the concentrated solution leaves at a concentration of 66% and a solution temperature of 306°F (point 7).

The mixture of concentrated and partly concentrated solution at point 4 has a concentration of 63% and a temperature of 192°F. It enters the low-temperature heat exchanger. Its temperature drops to 121°F before entering the absorber (point 5).

In the direct-fired generator, water is boiled off at a pressure of about 390 mm Hg abs. The boiled-off water vapor flows through the submerged tube in the low-temperature generator. The release of latent heat of condensation causes the evaporation of water from the dilution solution at a vapor pressure of about 50 mm Hg abs. The boiled-off water vapor in the low-temperature generator flows to the condenser through the top passage and is condensed into liquid water at a temperature of about 99°F and a vapor pressure of 47.7 mm Hg abs. This condensed liquid water is combined with the condensed water from the submerged tube at the trough. Both of them return to the evaporator after its pressure is throttled by an orifice plate.

Part-Load Operation and Capacity Control

During part-load operation, a double-effect direct-fired reverse-parallel-flow absorption chiller adjusts its capacity by reducing the heat input to the direct-fired generator through the burner. Lower heat input results at less water vapor boiled off from the solution in the generators. This causes the drop in solution concentration, the amount of water vapor extracted, the rate of evaporation, and the refrigeration capacity. Due to less water vapor being extracted, both evaporating pressure and temperature will rise. Since the amount of water vapor to be condensed is greater than that boiled off from the generators, both the condensing pressure and condensing temperature decrease.

Coefficient of Performance (COP)

The COP of an absorption chiller can be calculated as

$$\mathrm{COP} = 12{,}000/q_{1g} \tag{9.14.1}$$

where q_{1g} = heat input to the direct-fired generator per ton of refrigeration output (Btu/hr.ton).

9.15 Air-Conditioning Systems and Selection

Shan K. Wang

Basics in Classification

The purpose of classifing air-conditioning or HVAC&R systems is to distinguish one type from another so that an optimum air-conditioning system can be selected according to the requirements. Proper classification of air-conditioning systems also will provide a background for using knowledge-based expert systems to help the designer to select an air-conditioning system and its subsystems.

Since air system characteristics directly affect the space indoor environmental parameters and the indoor air quality, the characteristics of an air system should be clearly designated in the classification.

The system and equipment should be compatible with each other. Each system has its own characteristics which are significantly different from others.

Individual Systems

As described in Section 9.1, air conditoning or HVAC&R systems can be classified as individual, space, packaged, and central systems.

Individual systems usually have no duct and are installed only in rooms that have external walls and external windows. Individual systems can again be subdivided into the following.

Room Air-Conditioner Systems

A room air conditioner is the sole factory-fabricated self-contained equipment used in the room air-conditioning system. It is often mounted on or under the window sill or on a window frame as shown in Figure 9.1.1. A room air-conditioner consists mainly of an indoor coil, a small forward-curved centrifugal fan for indoor coil, a capillary tube, a low-efficiency dry and reusable filter, grilles, a thermostat or other controls located in the indoor compartment, and a rotary, scroll, or reciprocating compressor, an outdoor coil, and a propeller fan for the outdoor coil located in the outdoor compartment. There is an outdoor ventilation air intake opening and a manually operated damper on the casing that divides the indoor and outdoor compartments. Room air-conditioners have a cooling capacity between 1/2 to 2 tons.

The following are system characteristics of a room air-conditioner system:

Room heat pump system is a room air-conditioner plus a four-way reversing valve which provides both the summer cooling and winter heating.

Air system: single supply fan
- Fan, motor, and drive combined efficiency: 25%
- Fan energy use: 0.3 to 0.4 W/cfm
- Fan speed: HI-LO 2-speed or HI-MED-LO 3-speed
- Outdoor ventilation air system: type IV

Cooling system: DX system, air-cooled condenser
    EER 7.5 to 9.5 Btu/hr.W
    Evaporating temperature T_{ev} at design load: typically 45°F
Heating system: electric heating (if any)
Part-load: on–off of refrigeration compressor
Sound level: indoor NC 45 to 50
Maintenance: More maintenance work is required.

Summer and winter mode air-conditioning cycles of a room air-conditioning system are similar to that shown in Figure 9.3.4.

Packaged Terminal Air-Conditioner (PTAC) Systems

A packaged terminal air-conditioner is the primary equipment in a PTAC system. A PTAC system is similar to a room air-conditioner system. Their main differences are

- A PTAC uses a wall sleeve and is intended to be mounted through the wall.
- Heating is available from hot water, steam, heat pump, electric heater, and sometimes even direct-fired gas heaters.

PTACs are available in cooling capacity between 1/2 to 1 1/2 tons and a heating capacity of 2500 to 35,000 Btu/hr. Larger PTAC units have capacities in the range of 5 to 7 1/2 tons and may come equipped with heat recovery options.

Space (Space-Conditioning) Systems

Most space conditioning air-conditioning systems cool, heat, and filtrate their recirculating space air above or in the conditioned space. Space conditioning systems often incorporate heat recovery by transferring the heat rejected from the interior zone to the perimeter zone through the condenser(s). Space systems often have a separate outdoor ventilation air system to supply the required outdoor ventilation air.

Space systems can be subdivided into four-pipe fan-coil systems and water-source heat pump systems.

Four-Pipe Fan-Coil Systems

In a four-pipe fan-coil unit system, space recirculating air is cooled and heated at a fan coil by using four pipes: one chilled water supply, one heating hot water supply, one chilled water return, and one heating hot water return. Outdoor ventilation air is conditioned at a make-up AHU or primary AHU. It is then supplied in a neutral thermal state to the fan coil where it mixes with the recirculating air, as shown in Figure 9.15.1(a), or is supplied to the conditioned space directly.

A *fan-coil unit* or a *fan coil* is a *terminal* as shown in Figure 9.15.1(b). Fan-coil units are available in standard sizes 02, 03, 04, 06, 08, 10, and 12 which correspond to 200 cfm, 400 cfm, and so on in volume flow.

The following are system characteristics of a four-pipe fan-coil system:

A *water-cooling electric heating fan-coil system* uses chilled water for cooling and an electric heater for heating as shown in Figure 9.1.2. This system is often used in a location that has a mild winter.

Air system:
    Fan-coil, space air recirculating
    Fan, motor, and drive combined efficiency: 25%
    Fan speed: HI-LO 2-speed and HI-MED-LO 3-speed
    External pressure for fan coil: 0.06 to 0.2 in. WG
    System fan(s) energy use: 0.45 to 0.5 W/cfm
    No return air and return air duct
    Outdoor ventilation air system: type I
    An exhaust system to exhaust part of the outdoor ventilation air

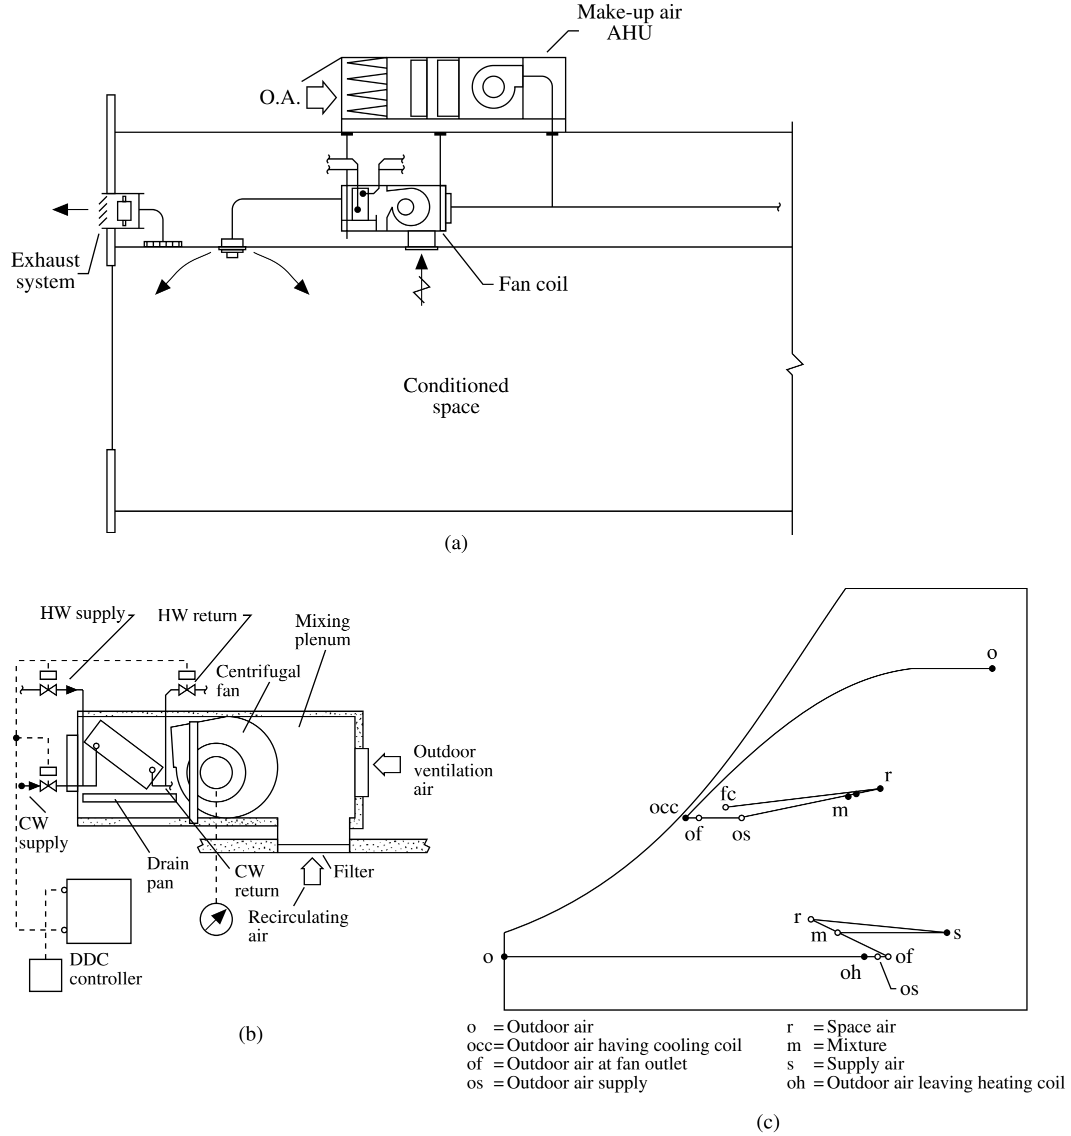

FIGURE 9.15.1 A four-pipe fan-coil system: (a) schematic diagram, (b) fan-coil unit, and (c) air-conditioning cycle.

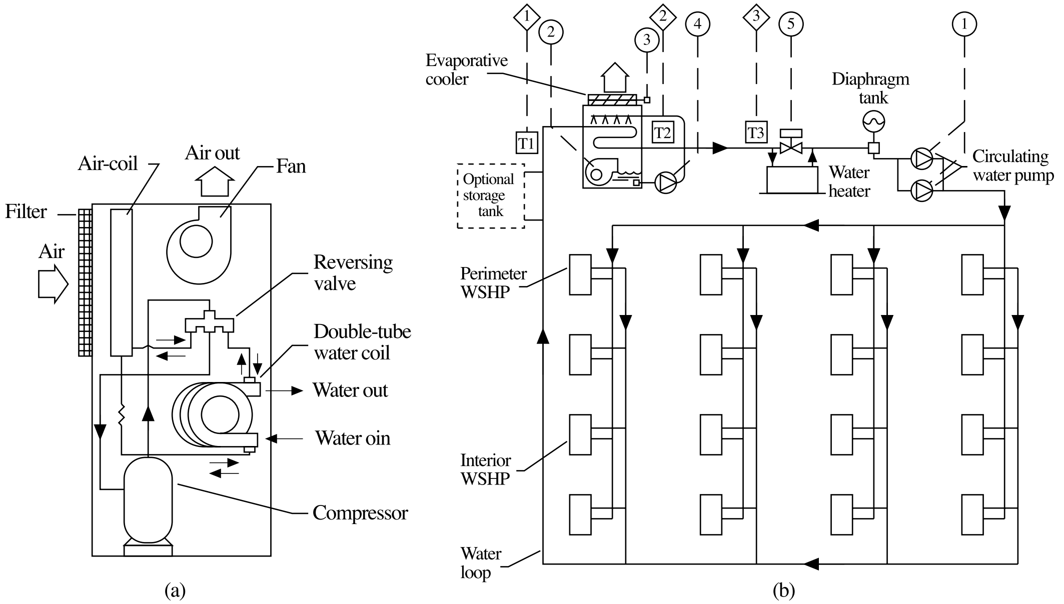
Cooling system: chilled water from centrifugal or screw chiller
Water-cooled chiller energy use: 0.4 to 0.65 kW/ton
Heating system: hot water from boiler, electric heater
Part load: control the flow rate of chilled and hot water supplied to the coil. Since air leaving coil temperature T_{cc} rises during summer mode part load, space relative humidity will be higher.
Sound level: indoor NC 40 to 45
Maintenance: higher maintenance cost
System fan(s) energy use: 0.45 to 0.55 W/cfm (includes all fans in the four-pipe fan-coil system)

An air-conditioning cycle for a four-pipe fan-coil system with outdoor ventilation air delivered to the suction side of the fan coil is shown in Figure 9.15.1(c). A part of the space cooling and dehumidifying load is usually taken care by the conditioned outdoor ventilation air from the make-up AHU. A double-bundle



(a) (b)

FIGURE 9.15.2 A water-source heat pump system: (a) vertical system and (b) system schematic diagram.

condenser is often adopted in a centrifugal chiller to incorporate heat recovery for providing winter heating.

Water-Source Heat Pump Systems

Water-source heat pumps (WSHPs) are the primary equipment in a water-source heat pump system as shown in Figure 9.15.2(a). A *water-source heat pump* usually consists of an air coil to cool and heat the air; a water coil to reject and extract heat from the condenser water; a forward-curved centrifugal fan; reciprocating, rotary, or scroll compressor(s); a short capillary tube; a reversing valve; controls; and an outer casing. WSHPs could be either a horizontal or vertical unit. WSHPs usually have cooling capacities between 1/2 to 26 tons. Small-capacity WSHPs of 3 tons or less without ducts are used in perimeter zones, whereas large-capacity WSHPs with ductwork are used only in interior zones.

In addition to the WSHPs, a WSHP system usually is also comprised of an evaporative cooler or cooling tower to cool the condenser water; a boiler to provide the supplementary heat for the condenser water if necessary; two circulating pumps, one of them being standby; and controls, as shown in Figure 9.15.2(b). A separate outdoor ventilation air system is required to supply outdoor air to the WSHP or directly to the space.

During hot humid weather, when the outdoor wet bulb can reach 78°F, all the WSHPs are operated in the cooling mode. Condenser water leaves the evaporative cooler at a temperature typically 92°F and absorbs condensing heat rejected from the condensers — the water coils in WSHPs. Condenser water is then raised to 104°F and enters the evaporative cooler. In an evaporative cooler, condenser water is evaporatively cooled indirectly by atmospheric air, so that it would not foul the inner surface of water coils in WSHPs.

During moderate weather, the WSHPs serving the shady side of a building may be in heating mode, and while serving the sunny side of the building and the interior space in cooling mode. During cold weather, most of the WSHPs serving perimeter zones are in heating mode, while serving interior spaces are in cooling mode except morning warm-up. Cooling WSHPs reject heat to the condenser water loop; meanwhile heating WSHPs absorb heat from the condenser water loop. The condenser water is usually maintained at 60 to 90°F. If its temperature rises above 90°F, the evaporative cooler is energized. If it drops below 60°F, the boiler or electric heater is energized. A WSHP system itself is a combination of

WSHP and a heat recovery system to transfer the heat from the interior space and sunny side of the building to the perimeter zone and shady side of building for heating in winter, spring, and fall.

System characteristics of air, cooling, and heating in a WSHP system are similar to a room conditioner heat pump system. In addition:

Outdoor ventilating air system: type I and IV
Water system: two-pipe, close circuit
Centrifugal water circulating pump
Water storage tank is optional

To prevent freezing in locations where outdoor temperature may drop below 32°F, isolate the outdoor portion of the water loop, outdoor evaporative cooler, and the pipe work from the indoor portion by using a plate-and-frame heat exchanger. Add ethylene or propylene glycol to the outdoor water loop for freezing protection.

There is another space system called a panel heating and cooling system. Because of its higher installation cost and dehumidification must be performed in the separate ventilation systems, its applications are very limited.

A space conditioning system has the benefit of a separate demand-based outdoor ventilation air system. A WSHP system incorporates heat recovery automatically. However, its indoor sound level is higher; only a low-efficiency air filter is used for recirculating air, and more space maintenance is required than central and packaged systems. Because of the increase of the minimum outdoor ventilation air rate, it may gain more applications in the future.

Packaged Systems

In packaged systems, air is cooled directly by a DX coil and heated by direct-fired gas furnace or electric heater in a packaged unit (PU) instead of chilled and hot water from a central plant in a central system. Packaged systems are different from space conditioning systems since variable-air-volume supply and air economizer could be features in a packaged system. Packaged systems are often used to serve two or more rooms with supply and return ducts instead of serving individual rooms only in an individual system.

As mentioned in Section 9.7, packaged units are divided according to their locations into rooftop, split, or indoor units. Based on their operating characteristics, packaged systems can be subdivided into the following systems:

Single-Zone Constant-Volume (CV) Packaged Systems

Although a single-zone CV packaged system may have duct supplies to and returns from two or more rooms, there is only a single zone sensor located in the representative room or space. A CV system has a constant supply volume flow rate during operation except the undesirable reduction of volume flow due to the increase of pressure drop across the filter.

A single-zone CV packaged system consists mainly of a centrifugal fan, a DX coil, a direct-fired gas furnace or an electric heater, a low or medium efficiency filter, mixing box, dampers, DDC controls, and an outer casing. A relief or a return fan is equipped for larger systems.

A single-zone CV packaged system serving a church is shown in Figure 9.1.3. This system operates on basic air-conditioning cycles as shown in Figure 9.3.4 during cooling and heating modes.

The system characteristics of a single-zone CV packaged system are

Air system: single supply fan, a relief or return fan for a large system
    Fan, motor, and drive combined efficiency: 40 to 45%
    Fan total pressure: 1.5 to 3 in. WG
    Fan(s) energy use: 0.45 to 0.8 W/cfm
    Outdoor ventilation air system: type IV and II
    Enthalpy or temperature air economizer

Cooling systems: DX system, air cooled
    Compressor: reciprocating or scroll
    EER: 8.9 to 10.0 Btu/hr.W
Heating system: direct-fired gas furnace, air-source heat pump, or electric heating
Part load: on–off or step control of the compressor capacity, DX-coil effective area, and the gas flow to the burner
Sound level: indoor NC 35 to 45
Maintenance: higher maintenance cost than central systems

Single-zone, CV packaged systems are widely used in residences, small retail stores, and other commercial buildings.

Constant-Volume Zone-Reheat Packaged Systems

System construction and system characteristics of a CV zone-reheat system are similar to the single-zone CV packaged systems except:

1. It serves multizones and has a sensor and a DDC controller for each zone.
2. There is a reheating coil or electric heater in the branch duct for each zone.

A CV zone-reheat packaged system cools and heats simultaneously and therefore wastes energy. It is usually used for the manufacturing process and space needs control of temperature and humidity simultaneously.

Variable-Air-Volume Packaged Systems

A variable-air-volume (VAV) system varies its volume flow rate to match the reduction of space load at part load. A VAV packaged system, also called a *VAV cooling packaged system*, is a multizone system and uses a VAV box in each zone to control the zone temperature at part load during summer cooling mode operation, as shown in Figure 9.15.3(a).

A *VAV box* is a terminal in which the supply volume flow rate of the conditioned supply air is modulated by varying the opening of the air passage by means of a single blade damper, as shown in Figure 9.15.3(b), or a moving disc against a cone-shaped casing.

The following are the system characteristics of a VAV packaged system:

Single-zone VAV packaged system which serves a single zone without VAV boxes. A DDC controller modulates the position of the inlet vanes or the fan speed according to the signal of the space temperature sensor.

Air system: a supply/relief fan or supply/return fan combination. Space pressurization control by a relief/return fan
    Fan, motor, and drive combined efficiency: 45%
    Supply fan total pressure: 3.75 to 4.5 in. WG
    Fan(s) energy use at design condition: 1 to 1.25 W/cfm
    VAV box minimum setting: 30% of peak supply volume flow
    Outdoor ventilation air system: type II and III
Economizer: enthalpy air economizer or water economizer
Cooling system: DX coil, air-, water-, or evaporative-cooled condenser
    Compressor: reciprocating, scroll, and screw
    EER: 8.9 to 12 Btu/hr.W
Capacity: 20 to 100 tons
Part load: zone volume flow modulation by VAV box; step control of compressor capacity; modulation of gas flow to burner; and discharge air temperature reset
Smoke control: exhausts smoke on the fire floor, and supplies air and pressurizes the floors immediately above or below the fire floor
Diagnostics: a diagnostic module displays the status and readings of various switches, dampers, sensors, etc. and the operative problems by means of expert system

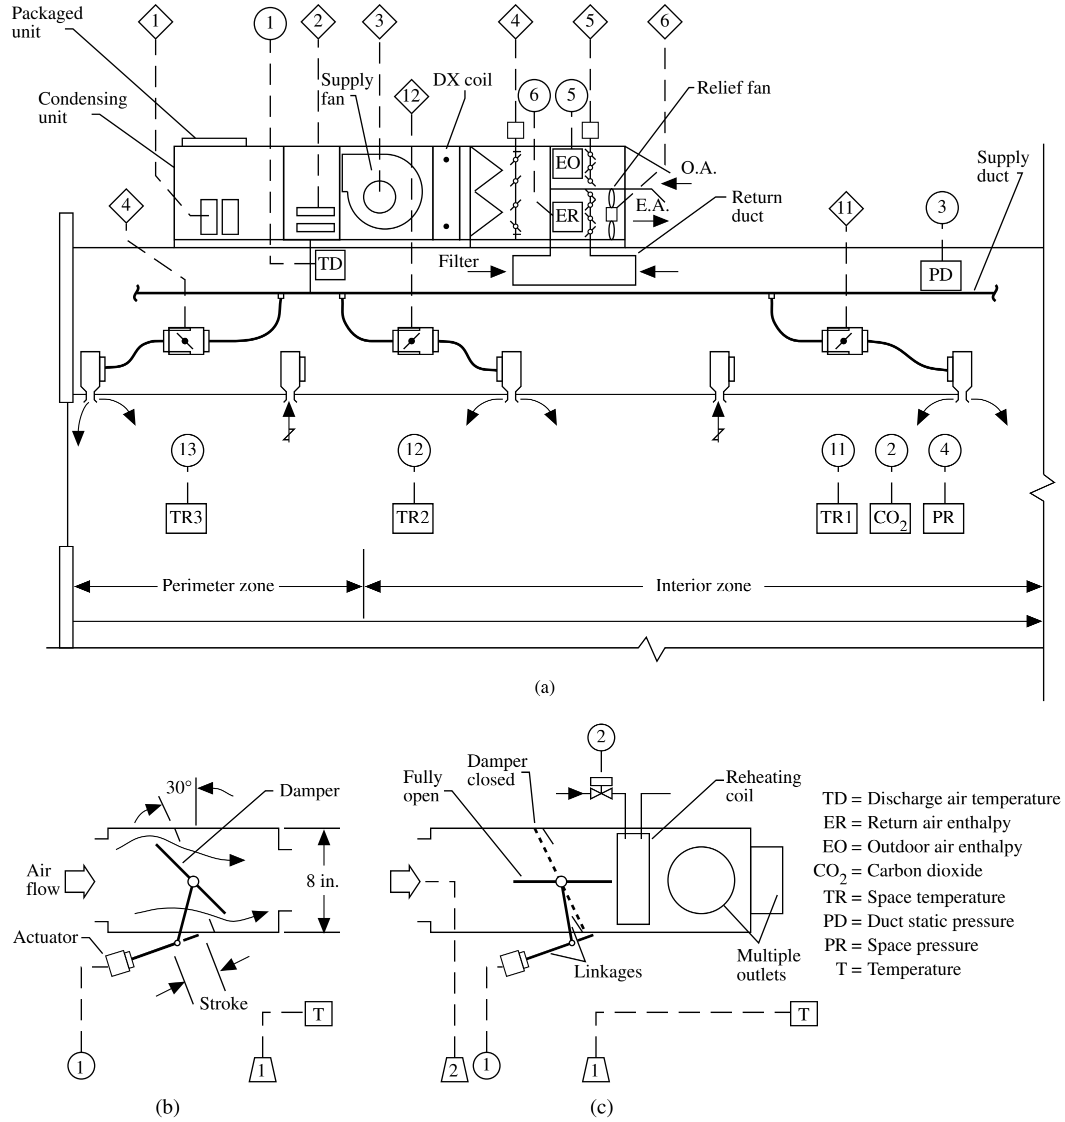


FIGURE 9.15.3 A variable-air-volume (VAV) package system: (a) schematic diagram, (b) VAV box, (c) reheating box, (d) parallel-flow fan-powered VAV box.

Maintenance: higher than central system
Sound level: indoor NC 30 to 45

Heating system characteristics as well as the air-conditioning cycles are similar as that in a single-zone CV packaged system.

VAV Reheat Packaged Systems

A VAV reheat packaged system has its system construction and characteristics similar to that in a VAV packaged system except in each VAV box there is an additional reheating coil. Such a VAV box is called a *reheating VAV box*, as shown in Figure 9.15.2(a) and 9.15.3(c). VAV reheat packaged systems are used to serve perimeter zones where winter heating is required.

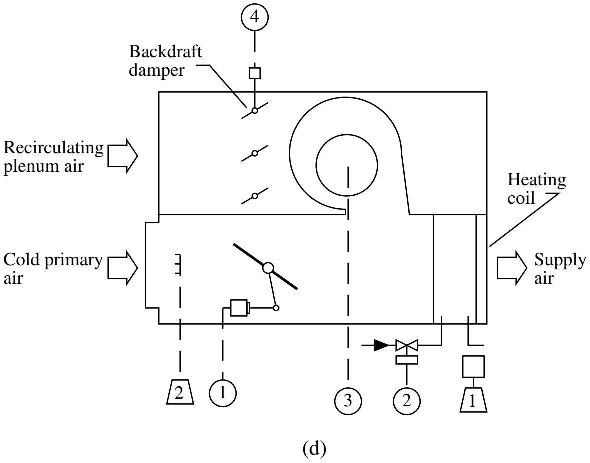

FIGURE 9.15.3d

Fan-Powered VAV Packaged Systems

A fan-powered VAV packaged system is similar to that of a VAV packaged system except *fan-powered VAV boxes* as shown in Figure 9.15.3(d) are used instead of VAV boxes.

There are two types of fan-powered VAV boxes: parallel-flow and series-flow boxes. In a *parallel-flow* fan-powered box, the plenum air flow induced by the fan is parallel with the cold primary air flow through the VAV box. These two air streams are then combined and mixed together. In a *series-flow* box, cold primarily from the VAV box is mixed with the induced plenum air and then flows through the small fan. The parallel-flow fan-powered VAV box is more widely used.

In a fan-powered VAV box, volume flow dropping to minimum setting, extracting of ceiling plenum air, and energizing of reheating coil will actuate in sequence to maintain the space temperature during part-load/heating mode operation. A fan-powered VAV box can also mix the cold primary air from cold air distribution with the ceiling plenum air and provides greater space air movements during minimum space load.

Packaged systems are lower in installation cost and occupy less space than central systems. During the past two decades, DDC-controlled packaged systems have evolved into sophisticated equipment and provide many features that only a built-up central system could provide before.

Central Systems

Central systems use chilled and hot water that comes from a central plant to cool and heat the air in the air-handling units (AHUs). Central systems are built-up systems. The most clean, most quiet thermal-storage systems, and the systems which offer the most sophisticated features, are always central systems. Central systems can be subdivided into the following.

Single-Zone Constant-Volume Central Systems

A single-zone CV central system uses a single controller to control the flow of chilled water, hot water, or the opening of dampers to maintain a predetermined indoor temperature, relative humidity, or air contaminants. They are often used in manufacturing factories. The system characteristics of a single-zone CV central system are

Single-zone CV air washer central system uses an air washer to control both space relative humidity and temperature. This system is widely used in textile mills. The reason to use constant volume is to dilute the fiber dusts produced during manufacturing. A rotary filter is often used for high dust-collecting capacity.

Air system: supply and return fan combination
    Fan, motor, and drive combined efficiency: 45 to 50%
    Outdoor ventilation air system: type II and IV
Economizer: air or water economizer
Smoke control: exhaust smoke on the fire floor, and pressurize adjacent floor(s) or area
Cooling system: centrifugal or screw chiller, water-cooled condenser
    Cooling energy use: 0.4 to 0.65 kW/ton
Heating system: hot water from boiler or from heat recovery system
Part load: modulate the water mass flow to cooling and heating coils in AHUs, and discharge air temperature reset
Sound level: indoor NC 30 to 45. Silencers are used both in supply and return air systems if they are required
Maintenance: in central plant and fan rooms, lower maintenance cost

Single-Zone CV Clean Room Systems

This is the central system which controls the air cleanliness, temperature, and relative humidity in Class 1, 10, 100, 1000, and 10,000 clean rooms for electronic, pharmaceutical, and precision manufacturing and other industries. Figure 9.15.4(a) shows a schematic diagram of this system. The recirculating air unit (RAU) uses prefilter, HEPA filters, and a water cooling coil to control the space air cleanliness and required space temperature, whereas a make-up air unit (MAU) supplies conditioned outdoor air, always within narrow dew point limits to the RAU at any outside climate, as shown in Figure 9.15.4(b). A unidirectional air flow of 90 fpm is maintained at the working area. For details, refer to *ASHRAE Handbook 1991 HVAC Applications* and Wang's *Handbook of Air Conditioning and Refrigeration*.

CV Zone-Reheat Central Systems

These systems have their system construction and characteristics similar to that for a single-zone CV central system, except they serve multizone spaces and there is a reheating coil, hot water, or electric heating in each zone. CV zone-reheat central systems are often used for health care facilities and in industrial applications.

VAV Central Systems

A VAV central system is used to serve multizone space and is also called *VAV cooling central system*. Its schematic diagram is similar to that of a VAV packaged system (Figure 9.15.3) except air will be cooled or heated by water cooling or heating coils in the AHUs. The same VAV box shown in Figure 9.15.3(b) will be used in a VAV central system. The system characteristics of VAV central systems are as follows:

Single-zone VAV central system differs from a VAV central system only because it serves a single zone, and therefore there is no VAV box in the branch ducts. Supply volume flow is modulated by inlet vanes and AC inverter.

Air system: supply and relief/return fan combination
    Fan, motor, and drive combined efficiency for airfoil centrifugal fan with AC inverter fan speed modulation: 55%
    Fan(s) energy use: 0.9 to 1.2 W/cfm
    VAV box: minimum setting 30% of peak supply volume flow
    Outdoor ventilation air system: type I, II, and III
Cooling system: centrifugal, screw, and reciprocating chillers, water-cooled condenser, with energy use 0.4 to 0.65 kW/ton; or sometimes absorption chiller
Heating system: hot water from boiler or electric heating at the terminals
Economizer: air and water economizer
Part load: zone volume flow modulation, discharge air temperature reset, and chilled water temperature reset
Smoke control: exhausts smoke from the fire floor and pressurizes the immediate floors above and below

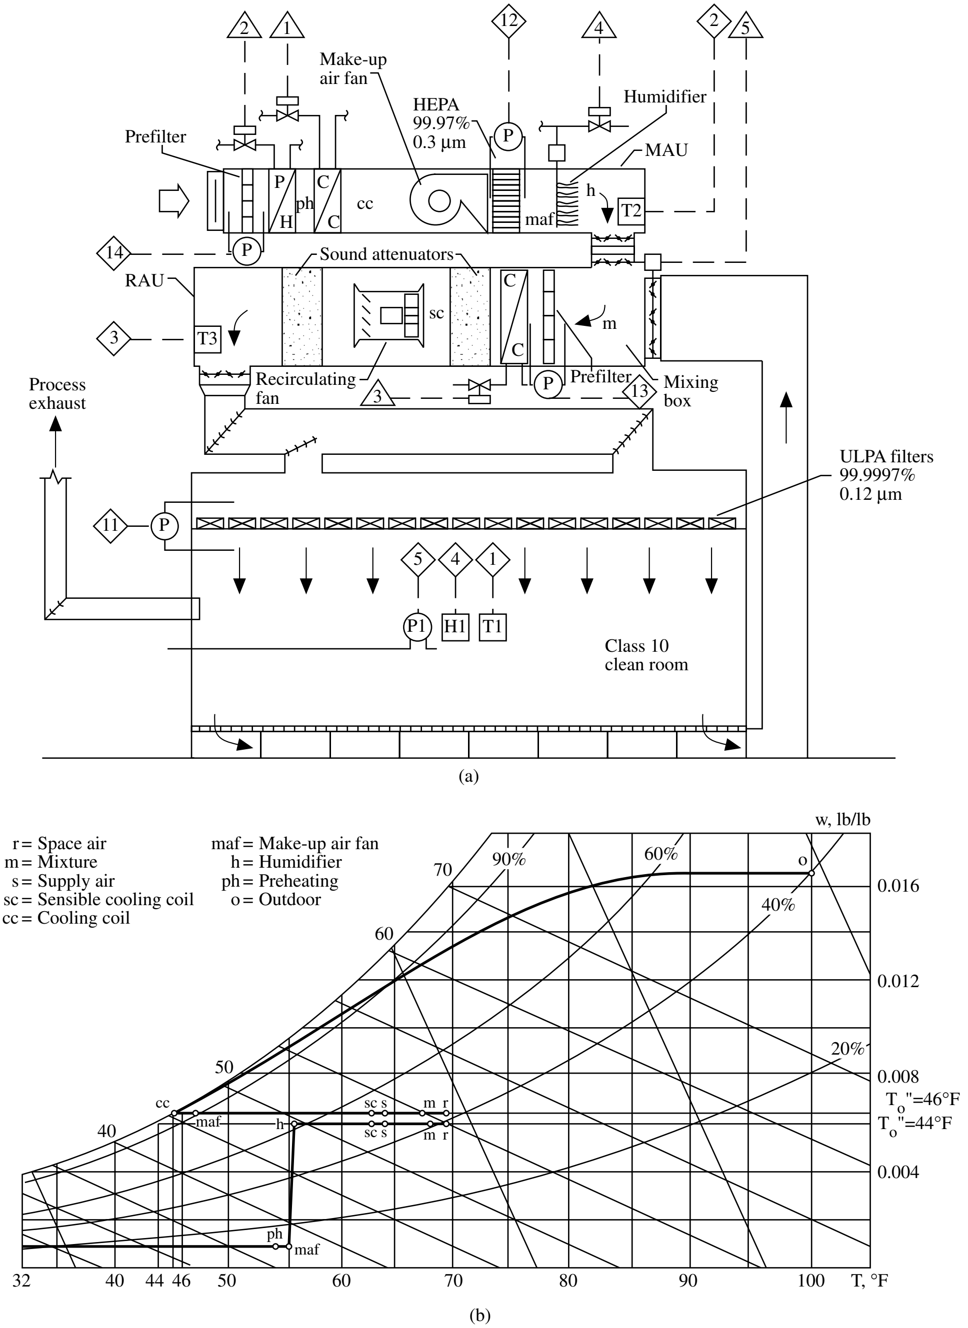

FIGURE 9.15.4 A single-zone CV clean room system: (a) schematic diagram and (b) air-conditioning cycle. (Source: Wang, S. K., *Handbook of Air Conditioning and Refrigeration*, McGraw-Hill, 1993. Reprinted by permission.)

Sound level: indoor NC 20 to 40. Silencers are often used both in supply and return systems.
Maintenance: less space maintenance

VAV central systems are widely used for interior zone in buildings.

VAV Reheat Central Systems

A VAV reheat system is similar in system construction and characteristics to that in a VAV central system except that reheating boxes are used instead of VAV boxes in a VAV central system.

Fan-Powered VAV Central Systems

A fan-powered VAV central system is similar in system construction and characteristics to that in a VAV central system except that fan-powered VAV boxes are used instead of VAV boxes.

Dual-Duct VAV Central Systems

A dual-duct VAV system uses a warm air duct and a cold air duct to supply both warm and cold air to each zone in a multizone space. Warm and cold air are first mixed in a mixing VAV box, and are then supplied to the conditioned space. The warm air duct is only used for perimeter zones.

A *mixing VAV box* consists of two equal air passages, one for warm air and one for cold air, arranged in parallel. Each of them has a single blade damper and its volume flow rate is modulated. Warm and cold air are then combined, mixed, and supplied to the space.

A dual-duct VAV system is usually either a single supply fan and a relief/return fan combination, or a warm air supply fan, a cold air supply fan, and a relief/return fan. A separate warm air fan and cold air supply fan are beneficial in discharge air temperature reset and fan energy use.

During summer cooling mode operation, the mixture of recirculating air and outdoor air is used as the warm air supply. The heating coil is not energized. During winter heating mode operation, the mixture of outdoor and recirculating air or 100% outdoor air is used as the cold air supply; the cooling coil is not energized.

Because there is often air leakage at the dampers in the mixing VAV box, more cold air supply is needed to compensate for the leaked warm air or leaked cold air.

Other system characteristics of a dual-duct VAV central system are similar to a VAV central system.

Dual-Duct CV Central System

This is another version of a dual-duct VAV central system and is similar in construction to a dual-duct VAV system, except that a mixing box is used instead of a mixing VAV box. The supply volume flow rate from a mixing box is nearly constant. Dual-duct CV central systems have only limited applications, like health care facilities, etc.

Some of the air-conditioning systems are not listed because they are not effective or are a waste of energy, and therefore rarely used in new and retrofit projects such as:

- High-velocity induction space conditioning systems which need a higher pressure drop primary air to induce recirculating air in the induction unit and use more energy than fan-coil systems
- Multizone central systems which mix warm and cool air at the fan room and use a supply duct from fan room to each control zone
- Air skin central systems which use a warm air heating system to offset transmission loss in the perimeter zone and overlook the effect of the solar radiation from variation building orientations

In the future, there will be newly developed systems added to this classification list.

Air-Conditioning System Selection

As described in Section 9.1, the goal of an air-conditioning or HVAC&R system is to provide a healthy, comfortable, manufacturable indoor environment at acceptable indoor air quality, keeping the system energy efficient. Various occupancies have their own requirements for their indoor environment. The basic considerations to select an air-conditioning system include:

1. The selection of an air-conditioning system must satisfy the required space temperature, relative humidity, air cleanliness, sound level, and pressurization. For a Class 100 clean room, a single-zone CV clean room system is always selected. A four-pipe fan-coil space conditioning system is

usually considered suitable for guest rooms in hotels for operative convenience, better privacy, and a guaranteed outdoor ventilation air system. A concert hall needs a very quiet single-zone VAV central system for its main hall and balcony.

2. The size of the project has a considerable influence on the selection. For a small-size residential air-conditioning system, a single-zone constant-volume packaged system is often the first choice.
3. Energy-efficient measures are specified by local codes. Comparison of alternatives by annual energy-use computer programs for medium and large projects is often necessary. Selection of energy source includes electricity or gas, and also using electrical energy at off-peak hours, like thermal storage systems is important to achieve minimum energy cost.

   For a building whose sound level requirement is not critical and conditioned space is comprised of both perimeter and interior zones, a WSHP system incorporating heat recovery is especially suitable for energy saving.
4. First cost or investment is another critical factor that often determines the selection.
5. Selection of an air-conditioning system is the result of synthetical assessment. It is difficult to combine the effect of comfort, reliability, safety, and cost. Experience and detailed computer program comparisons are both important.

The selection procedure usually begins whether an individual, space conditioning, packaged, central system, or CV, VAV, VAV reheat, fan-powered VAV, dual-duct VAV, or thermal storage system is selected. Then the air, refrigeration, heating, and control subsystems will be determined. After that, choose the option, the feature, the construction, etc. in each subsystem.

Comparison of Various Systems

The sequential order of system performance — excellent, very good, good, satisfactory — regarding temperature and relative humidity control (T&HC), outdoor ventilation air (OA), sound level, energy use, first cost, and maintenance for individual, space conditioning (SC), packaged, and central systems is as follows:

	Excellent (low or less)	Very Good	Good	Satisfactory
T&HC	Central	Packaged	Space	Individual
IAQ	Space	Central	Packaged	Individual
Sound	Central	Packaged	Space	Individual
Energy use	Individual	Space	Packaged	Central
First cost	Individual	Packaged	Space	Central
Maintenance	Central	Packaged	Space	Individual

Among the packaged and central systems, VAV cooling systems are used only for interior zones. VAV reheat, fan-powered VAV, and dual-duct VAV central systems are all for perimeter zones. VAV reheat systems are simple and effective, but have a certain degree of simultaneous cooling and heating when their volume flow has been reduced to minimum setting required for proper ventilation. Fan-powered VAV systems have the function of mixing cold primary air with ceiling plenum air. They are widely used in ice-storage systems with cold air distribution. Fan-powered VAV is also helpful to create a greater air movement at minimum cold primary air flow. Dual-duct VAV systems are effective and more flexible in operation. They are also more complicated and expensive.

Subsystems

Air Systems

The economical size of an air system is often 10,000 to 25,000 cfm. A very large air system always has higher duct pressure loss and is more difficult to balance. For highrise buildings of four stories and higher, floor-by-floor AHU(s) or PU(s) (one or more AHU or PU per floor) are often adopted. Such an arrangement is beneficial for the balance of supply and return volume flow in VAV systems and also for fire protection. A fan-powered VAV system using a riser to supply less cold primary to the fan-powered VAV box at various floors may have a larger air system. Its risers can be used as supply and exhaust ducts for a smoke-control system during a building fire.

In air systems, constant-volume systems are widely used in small systems or to dilute air contaminants in health care facilities and manufacturing applications. VAV systems save fan energy and have better operating characteristics. They are widely used in commercial buildings and in many factories.

Refrigeration Systems

For comfort air-conditioning systems, the amounts of required cooling capacity and energy saving are dominant factors in the selection of the refrigeration system. For packaged systems having cooling capacity less than 100 tons, reciprocating and scroll vapor compression systems with air-cooled condensers are most widely used. Evaporative-cooled condensers are available in many packaged units manufactured for their lower energy use. Scroll compressors are gradually replacing the reciprocating compressors for their simple construction and energy saving. For chillers of cooling capacity of 100 tons and greater, centrifugal chillers are still most widely used for effective operation, reliability, and energy efficiency. Screw chillers have become more popular in many applications, especially for ice-storage systems.

Heating Systems

For locations where there is a cold and long winter, a perimeter baseboard hot water heating system or dual-duct VAV systems are often a suitable choice. For perimeter zones in locations where winter is mild, winter heating is often provided by using warm air supply from AHU or PU from terminals with electric or hot water heaters. Direct-fired furnace warm air supply may be used for morning warm-up. For interior or conditioned zones, a cold air supply during occupied periods in winter and a warm air supply from the PUs or AHUs during morning warm-up period is often used.

Control Systems

Today, DDC microprocessor-based control with open data communication protocol is often the choice for medium- and large-size HVAC&R projects. For each of the air, cooling, and heating systems, carefully select the required generic and specific control systems. If a simple control system and a more complicated control system can provide the same required results, the simple one is always the choice.

Energy Conservation Recommendations

1. Turn off electric lights, personal computers, and office appliances when they are not needed. Shut down AHUs, PUs, fan coils, VAV boxes, compressors, fans, and pumps when the space or zone they serve is not occupied or working.
2. Provide optimum start and stop for the AHUs and PUs and terminals daily.
3. Temperature set point should be at its optimum value. For comfort systems, provide a dead band between summer and winter mode operation. Temperature of discharged air from the AHU or PU and chilled water leaving the chiller should be reset according to space or outdoor temperature or the system load.
4. Reduce air leakages from ducts and dampers. Reduce the number of duct fittings and pipe fittings and their pressure loss along the design path if this does not affect the effectiveness of the duct system. The maximum design velocity in ducts for comfort systems should not exceed 3000 fpm.
5. Adopt first the energy-efficient cooling methods: air and water economizer, evaporative cooler, or ground water instead of refrigeration.
6. Use cost-effective high-efficiency compressors, fans, pumps, and motors as well as evaporative-cooled condensers in PUs. Use adjustable-frequency fan speed modulation for large centrifugal fans. Equipment should be properly sized. Over-sized equipment will not be energy efficient.

7. Use heat recovery systems and waste heat for winter heating or reheating. Use a heat-pump system whenever its COP_{hp} is greater than 1.
8. For medium- and large-size air-conditioning systems, use VAV systems instead of CV systems except for health care or applications where dilution of air contaminant is needed. Use variable flow for building-loop and distribution-loop water systems.
9. Use double- and triple-pane windows with low emissive coatings. Construct low U-value roofs and external walls.

9.16 Desiccant Dehumidification and Air-Conditioning

Zalman Lavan

Introduction

Desiccant air-conditioning is a promising emerging technology to supplement electrically driven vapor compression systems that rely almost exclusively on R22 refrigerant that causes depletion of the ozone layer. To date, this technology has only a limited market, e.g., in supermarkets where the latent heat loads are very high, in specialized manufacturing facilities that require very dry air, and in hospitals where maximum clean air is required. However, recent emphasis on increased air change requirements (see ASHRAE standards, ANSI 62), improved indoor air quality, and restriction on use of CFC refrigerants (see The Montreal Protocol Agreement, as amended in Copenhagen in 1992, United Nations Environmental Programme, 1992) may stimulate wider penetration of desiccant-based air-conditioning which can be used as stand-alone systems or in combination with conventional systems. (See Table 9.4.1 for properties of some refrigerants.)

Sorbents and Desiccants

Sorbents are materials which attract and hold certain vapor or liquid substances. The process is referred to **absorption** if a chemical change takes place and as **adsorption** if no chemical change occurs. **Desiccants**, in both liquid and solid forms, are a subset of sorbents that have a high affinity to water molecules. Liquid desiccants *absorb* water molecules, while solid desiccants *adsorb* water molecules and hold them on their vast surfaces (specific surface areas are typically hundreds of square meters per gram).

While desiccants can sorb water in both liquid and vapor forms, the present discussion is limited to **sorption** of water vapor from adjacent air streams. The sorption driving force for both liquid and solid desiccants is a vapor pressure gradient. Adsorption (in solid desiccants) and absorption (in liquid desiccants) occur when the water vapor partial pressure of the surrounding air is larger than that at the desiccant surface. When an air stream is brought in contact with a desiccant, water vapor from the air is attracted by the desiccant, the air is **dehumidified**, and the water content of the desiccant rises. As the water sorbed by the desiccant increases, the sorption rate decreases and finally stops when *sorption equilibrium* is reached. For dehumidification to be resumed, water must be removed from the desiccant by heating. This process is referred to as **desorption**, **reactivation**, or **regeneration**. The heat of sorption (or desorption) is generally higher than the latent heat of vaporization of water; it approaches the latter as sorption equilibrium is reached.

Some typical *liquid desiccants* are water solutions of calcium chloride (CaCl), lithium chloride (LiCl), lithium bromide (LiBr), and triethylene glycol. The equilibrium water vapor pressure at the solution surface as a function of temperature and water content is shown in Figure 9.16.1 for water-lithium chloride solution. The surface vapor pressure (and dew point) increases with increasing solution temperature and decreases with increasing moisture content.

Common *solid desiccants* are silica gel, molecular sieves (zeolites), activated alumina, and activated carbon. The equilibrium sorption capacity (or moisture content) at a constant temperature, referred to

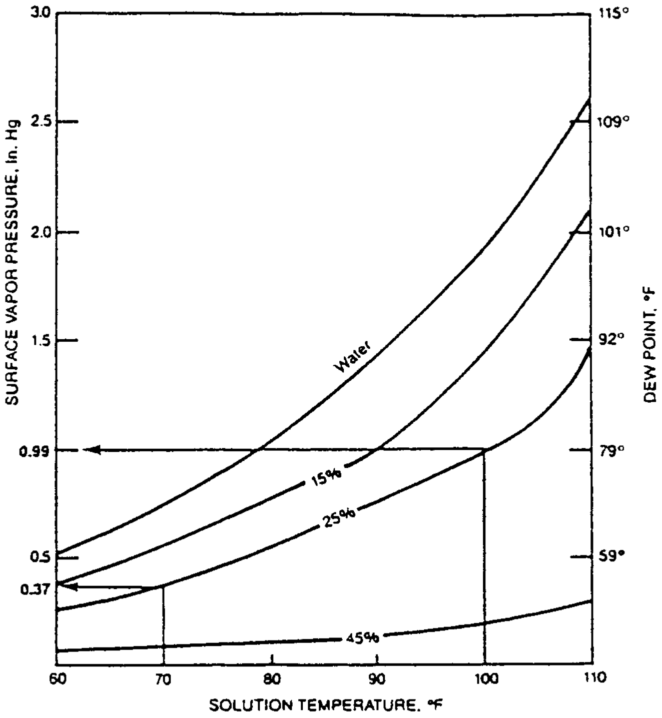

FIGURE 9.16.1 Surface vapor pressure of water-lithium chloride solutions. (Source: ASHRAE 1993, *Fundamentals Handbook*, chap. 19. With permission.)

as an **isotherm**, is usually presented as percent water (mass of water divided by mass of dry desiccant) vs. percent relative humidity (vapor pressure divided by saturation vapor pressure). Sorption capacity decreases with increasing temperature, but the spread of isotherms is relatively small (especially for concave down isotherms). Figure 9.16.2 shows normalized loading (sorption capacity divided by sorption capacity at 100% relative humidity) vs. relative humidity for silica gel, molecular sieve, and a generic desiccant, type 1 (modified) or simply 1-M (Collier et al., 1986).

Dehumidification

Dehumidification by vapor compression systems is accomplished by cooling the air below the dew point and then reheating it. The performance is greatly hindered when the desired outlet dew point is below 40°F due to frost formation on the cooling coils (*ASHRAE, Systems and Equipment Handbook,* 1992).

Desiccant dehumidification is accomplished by direct exchange of water vapor between an air stream and a desiccant material due to water vapor pressure difference. Figure 9.16.3 shows the cyclic operation of a desiccant dehumidification system.

In *sorption (1–2),* dry and cold desiccant (point 1) sorbs moisture since the vapor pressure at the surface is lower than that of the air stream. During this process the moisture content (loading or uptake) increases, the surface vapor pressure increases, and the liberated heat of sorption raises the desiccant temperature. During *desorption (2–3)*, the desiccant is subjected to a hot air stream, and moisture is removed and transferred to the surrounding air. The surface vapor pressure is increased and the desiccant temperature rises due to the added heat. The cycle is closed by *cooling (3–1)*. The desiccant is cooled while its moisture content is constant and the surface vapor pressure is lowered. The above cycle of sorption, desorption, and cooling can be modified by combining the sorption process with cooling to approach isothermal rather than adiabatic sorption.

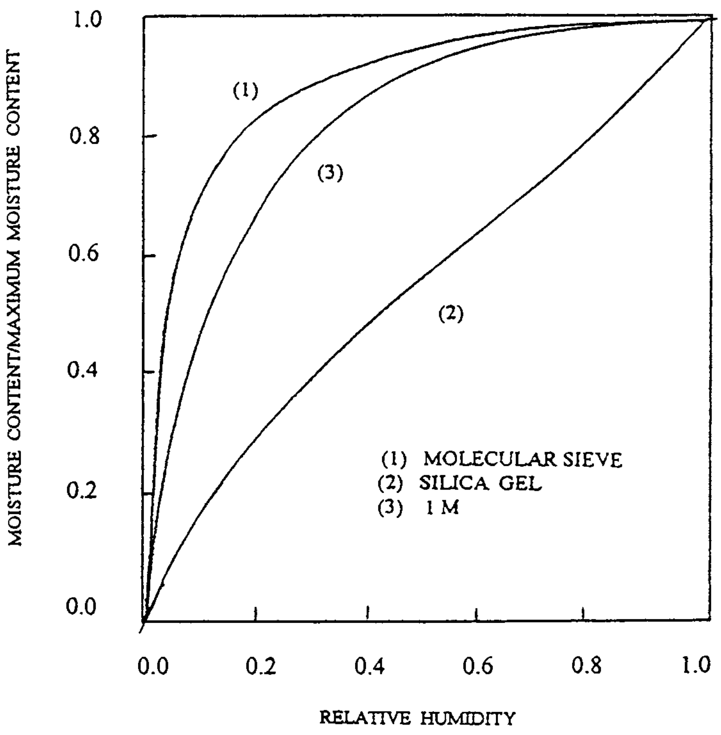

FIGURE 9.16.2 Normalized solid desiccant isotherms.

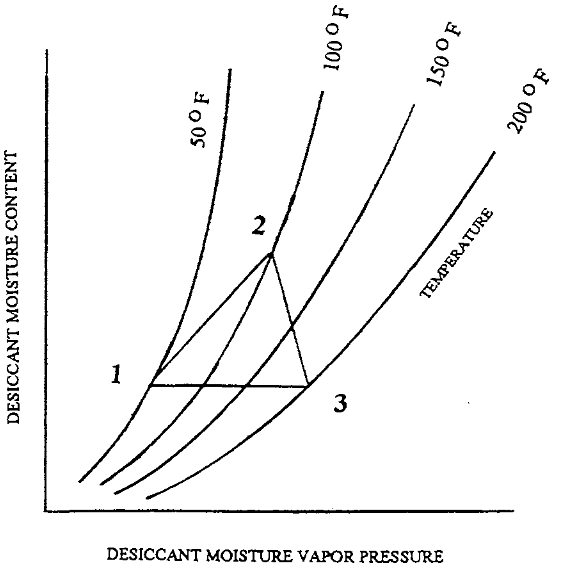

FIGURE 9.16.3 Cyclic dehumidification processes.

Desirable Characteristics for High-Performance Liquid and Solid Desiccant Dehumidifiers

High equilibrium moisture sorption capacity
High heat and mass transfer rates
Low heat input for regeneration
Low pressure drop

Large contact transfer surface area per unit volume
Compatible desiccant/contact materials
Inexpensive materials and manufacturing techniques
Minimum deterioration and maintenance

Additional Requirements for Liquid Desiccant Dehumidifiers

Small liquid side resistance to moisture diffusion
Minimum crystallization

Additional Requirements for Solid Desiccant Dehumidifiers

The desiccant should not deliquesce even at 100% relative humidity.
The airflow channels should be uniform.
The desiccant should be bonded well to the matrix.
The material should not be carciogenic or combustible.

Liquid Spray Tower

Figure 9.16.4 is a schematic of a liquid spray tower. A desiccant solution from the sump is continuously sprayed downward in the absorber, while air, the process stream, moves upward. The air is dehumidified and the desiccant solution absorbs moisture and is weakened. In order to maintain the desired solution concentration, a fraction of the solution from the sump is passed through the regenerator, where it is heated by the heating coil and gives up moisture to the desorbing air stream. The strong, concentrated solution is then returned to the sump. The heat liberated in the absorber during dehumidification is removed by the cooling coil to facilitate continuous absorption (see Figure 9.16.1 and Figure 9.16.3). The process air stream exits at a relatively low temperature. If sufficiently low water temperature is available (an underground well, for example), the process stream could provide both sensible and latent cooling.

The heating and cooling coils, shown in Figure 9.16.4, are often eliminated and the liquid solutions are passed through heating and cooling heat exchangers before entering the spray towers.

Advantages

The system is controlled to deliver the desired level of dry air by adjusting the solution concentration.

Uniform exit process stream conditions can be maintained.
A concentrated solution can be economically stored for subsequent drying use.
The system can serve as a humidifier when required by simply weakening the solution.
When used in conjunction with conventional A/C systems, humidity control is improved and energy is conserved.

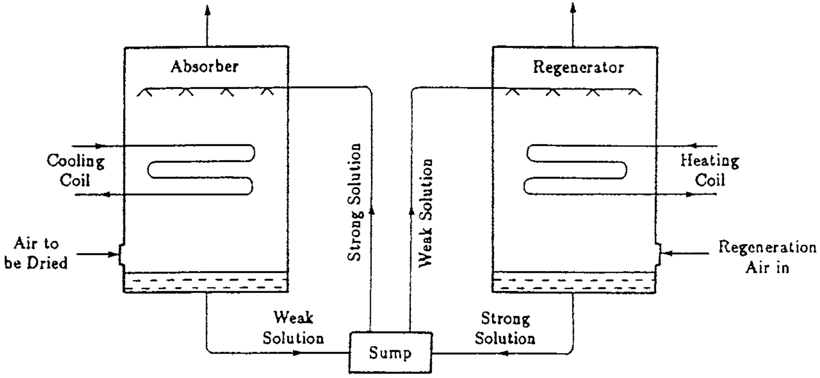

FIGURE 9.16.4 Liquid desiccant dehumidifier with heating and cooling coils.

Disadvantages

Some desiccants are corrosive.
Response time is relatively large.
Maintenance can be extensive.
Crystallization may be a problem.

Solid Packed Tower

The dehumidification system, shown in Figure 9.16.5, consists of two side-by-side cylindrical containers filled with solid desiccant and a heat exchanger acting as a desiccant cooler. The air stream to be processed is passed through dry desiccant in one of the containers, while a heated air stream is passed over the moist desiccant in the other. Adsorption (1–2) takes place in the first container, desorption (2–3) in the other container, and cooling (3–1) occurs in the desiccant cooler. The function of the two containers is periodically switched by redirecting the two air streams.

Advantages

No corrosion or crystallization
Low maintenance
Very low dew point can be achieved

Disadvantages

The air flow velocity must be low in order to maintain uniform velocity through the containers and to avoid dusting.
Uniform exit process stream dew point cannot be maintained due to changing moisture content in the adsorbing desiccant.

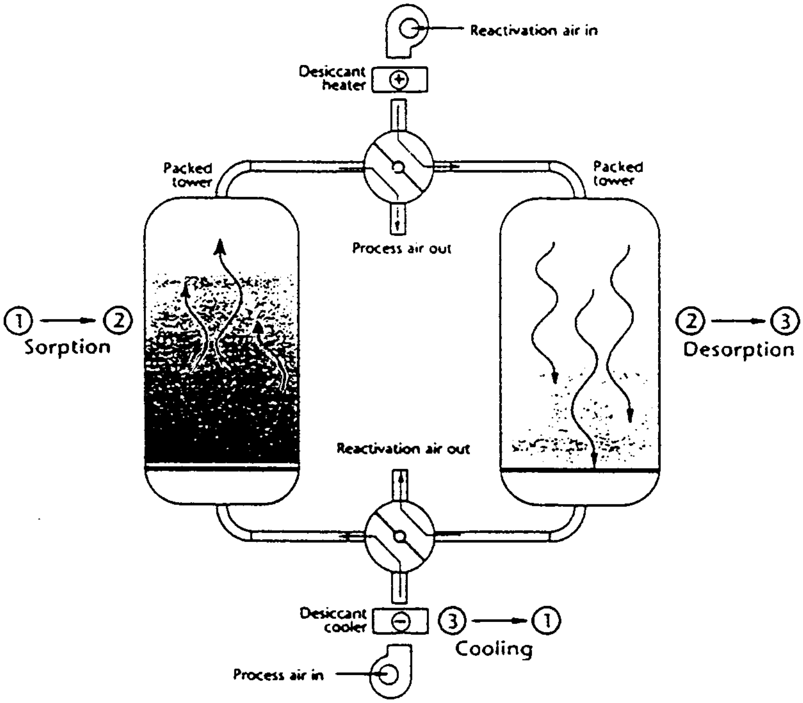

FIGURE 9.16.5 Solid packed tower dehumidification. (From Harriman, L. G., III. 1990. *The Dehumidification Handbook*, 2nd ed. Munters Cargocaire. With permission.)

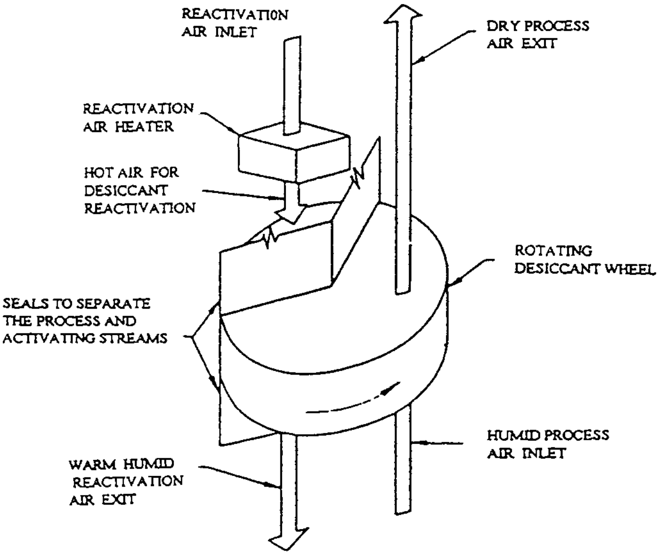

FIGURE 9.16.6 Rotary desiccant dehumidification wheel. (Source: ASHRAE 1992, *Systems and Equipment Handbook*, chap. 22. With permission.)

Rotary Desiccant Dehumidifiers

A typical rotary solid desiccant dehumidifier is shown in Figure 9.16.6. Unlike the intermittent operation of packed towers, rotary desiccant dehumidifiers use a wheel (or drum) that rotates continuously and delivers air at constant humidity levels.

Desiccant wheels typically consist of very fine desiccant particles dispersed and impregnated with a fibrous or ceramic medium shaped like a honeycomb or fluted corrugated paper. The wheel is divided into two segments. The process stream flows through the channels in one segment, while the regenerating (or reactivating) stream flows through the other segment.

Desiccant Material

The desired desiccant properties for optimum dehumidification performance are a suitable isotherm shape and a large moisture sorption capacity. The isotherms of silica gel are almost linear. The moisture sorption capacity is high; the desiccant is reactivated at relatively low temperatures and is suitable for moderate dehumidification. Molecular sieves have very steep isotherms at low relative humidity. The desiccant is reactivated at relatively high temperatures and is used for deep dehumidification. The isotherm of the type 1-M yields optimum dehumidification performance (Collier et al., 1986), especially when used in conjunction with high regeneration temperatures.

The Desiccant Wheel

Some considerations for selection of desiccant wheels are:

Appropriate desiccant materials
Large desiccant content
Wheel depth and flute size (for large contact surface area and low pressure drop)
Size and cost

The actual performance depends on several additional factors that must be addressed. These include:

Inlet process air temperature and humidity
Desired exit process air humidity
Inlet reactivating air temperature and humidity

Face velocity of the two air streams
Size of reactivation segment

It should be noted that:

Higher inlet process air humidity results in higher exit humidity and temperature (more heat of sorption is released).
Lower face velocity of the process stream results in lower exit humidity and higher temperature.
Higher regeneration temperatures result in deeper drying, hence lower exit process air humidity and higher temperature.
When lower exit air temperature is required, the exit process air should be cooled by a heat exchanger.
Final cooling of the exit process air can be achieved by partial humidification (this counteracts in part previous dehumidification).

The following is a range of typical parameters for rotary desiccant wheels:

Rotation speed: 4 to 10 rpm
Desiccant fraction: 70 to 80%
Flute size: 1 to 2 mm
Reactivation segment: 25 to 30% of wheel
Face velocity: 300 to 700 fpm
Reactivating temperature: 100 to 300°F

Hybrid Cycles

A limited number of hybrid systems consisting of desiccant dehumidifiers and electrically driven vapor compression air-conditioners are presently in use in supermarkets. This application is uniquely suited for this purpose since the latent heat loads are high due to the large number of people and frequent traffic through doors. Also, low relative humidity air is advantageous for open-case displays.

Vapor compression systems are inefficient below a dew point of 45 to 50°F. When used in supermarkets, they require high airflow rates, the air must be reheated for comfort, and the evaporator coils must be defrosted frequently. Hybrid systems offer improved performance and lower energy cost in these cases.

Figure 9.16.7 shows a typical hybrid air-conditioning system for supermarkets. A mixture of outdoor and recirculated air is first passed through the desiccant and sensible heat exchanger wheels, where it is dehumidified and precooled. It then enters the conventional chiller before it is introduced to the interior of the supermarket. The sensible heat exchanger wheel is cooled by outdoor air and the desiccant wheel is regenerated by air heated with natural gas. Energy cost can be further reduced by preheating the reactivating air stream with waste heat rejected from the condenser of the refrigeration and/or air-conditioning systems.

The advantages of these hybrid systems are

Air-conditioning requirement is reduced by up to 20%.
The vapor compression system operates at a higher coefficient of performance (COP) since the evaporator coils are at a higher temperature.
Airflow requirements are reduced; electric fan energy is saved and duct sizes are reduced.
The refrigeration cases run more efficiently since the frequency of defrost cycles is greatly reduced.

Solid Desiccant Air-Conditioning

Several stand-alone desiccant air-conditioning systems were suggested and extensively studied. These systems consist of a desiccant wheel, a sensible heat exchanger wheel, and evaporating pads. Sorption can be adiabatic or cooled (if cooling is combined with sorption). When room air is dehumidified and recirculated, the system is said to operate in the **recirculating** mode. When 100% outside air is used as the process stream, the system operates in the **ventilating mode**.

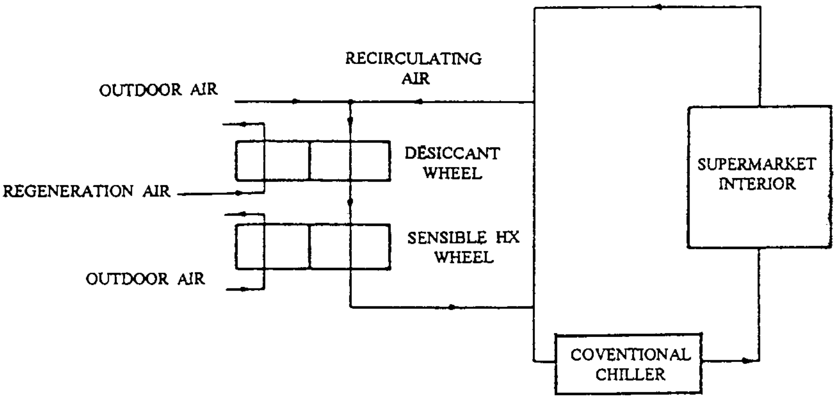

FIGURE 9.16.7 Hybrid air-conditioning system for supermarkets.

Ventilation Mode

In the *adsorption path* the process air stream drawn from the outdoors is passed through the dry section of the desiccant wheel where it is dehumidified and heated by the liberated heat of sorption. It then passes through the sensible heat exchanger wheel and exits as dry but slightly warm air. The hot and dry air leaving the dehumidifier enters the heat exchanger, where it is sensibly cooled down to near room temperature. It is then passed through the evaporative cooler, where it is further cooled and slightly humidified as it enters the conditioned space.

In the *desorption path,* air is drawn from the conditioned space; it is humidified (and thus cooled) in the evaporative cooler. The air stream enters the sensible heat exchanger, where it is preheated, and it is then heated to the desired regeneration temperature by a suitable heat source (natural gas, waste heat, or solar energy), passed through the desiccant wheel (regenerating the desiccant material), and discharged out of doors.

Performance. In order to achieve high performance, the maximum moisture content of the desiccant should be high and the isotherm should have the optimum shape (1 M). In addition, Zheng et al. (1993) showed that the optimum performance is very sensitive to the rotational speed of the desiccant wheel. Glav (1966) introduced stage regeneration. He showed that performance is improved when the reactivation segment of the wheel is at a temperature which increases in the direction of rotation. Collier (Collier et al., 1986) showed that well-designed open-cycle desiccant cooling systems can have a thermal COP of 1.3. This, however, would require the use of high-effectiveness sensible heat exchangers, which would be large and expensive. Smaller and more affordable heat exchangers should yield system COPs in the order of unity. An extensive review of the state-of-the-art assessment of desiccant cooling is given by Pesaran et al. (1992).

Conclusions

Desiccant-based air-conditioning offers significant advantages over conventional systems. Desiccant systems are already successfully used in some supermarkets. It is expected that these systems will gradually attain wider market penetration due to environmental requirements and potential energy savings.

The advantages of desiccant air-conditioning are summarized below:

No CFC refrigerants are used.
Indoor air quality is improved.
Large latent heat loads and dry air requirements are conveniently handled.
Individual control of temperature and humidity is possible.
The energy source may be natural gas and/or waste heat.
Less circulated air is required.
Summer electric peak is reduced.

Defining Terms

Absorb, absorption: When a chemical change takes place during sorption.
Adsorb, adsorption: When no chemical change occurs during sorption.
Dehumidification: Process of removing water vapor from air.
Desiccant: A subset of sorbents that has a particular affinity to water.
Desorb, desorption: Process of removing the sorbed material from the sorbent.
Isotherm: Sorbed material vs. relative humidity at a constant temperature.
Reactivation: Process of removing the sorbed material from the sorbent.
Recirculation: Indoor air only is continuously processed.
Regeneration: Process of removing the sorbed material from the sorbent.
Sorbent: A material that attracts and holds other gases or liquids.
Sorption: Binding of one substance to another.
Staged regeneration: When the temperature of the regeneration segment of the desiccant wheel is not uniform.
Ventilation mode: 100% of outdoor air is processed.

Introduction

Frank Kreith

An efficient and economically viable transportation system is an essential part of a modern industrial society. This is particularly true in the U.S., where growth of suburbia requires the average American worker to commute a considerable distance daily between home and work. The situation is exacerbated in many locations by a lack of adequate public transportation, which requires commuters to travel by private automobiles. The use of single occupancy vehicles not only causes congestion, delays, and air pollution, but also imposes a severe economic penalty on many Americans. A recent consumer expenditure survey showed that transportation for most Americans is an expense second only to housing. The vast majority of the transportation spending (98%) is for the purchase, operation, and maintenance of automobiles.

From a national perspective, the transportation sector presents enormous challenges for the future. At present, more than 97% of the fuel used for ground transportation in the U.S. is petroleum-based and over 50% is imported. The transportation sector accounts for approximately 20% of the gross domestic product, and the cost of gas and oil has become a growing concern to the government. In 1999, the U.S. Department of Energy presented three oil price scenarios with predictions through the year

2020. In the reference case, prices were predicted to rise slowly to $23 per barrel by 2020, and in the high price scenario, an increase to about $30 per barrel was predicted. Today, the price of oil already exceeds $40 per barrel, and barring a worldwide recession, there is no reason to expect a long-term drop in crude oil prices in the future. The transportation sector is also the nation's largest single source of air pollution, with personal vehicles producing 26% of volatile organic compounds, 32% of nitrous oxide, and 62% of carbon monoxide. Thus, ways to promote transportation efficiency are one of the most important facets of reducing fossil fuel consumption and improving environmental quality.

Transportation engineering is a highly intradisciplinary field, dealing with the planning, design, construction, maintenance, and operation of various transportation modes. This section presents an overview of transportation engineering, emphasizing planning, design, operation, environmental impact, system analysis, and emerging issues, such as alternative fuels, electric and hybrid vehicles, and intelligent highway systems. Emphasis is placed on those facets of transportation that impact the mechanical engineering profession, but the area also needs social, political, and management inputs to arrive at appropriate engineering solutions of specific problems.

10.1 Transportation Planning

Michael D. Meyer

Transportation planning is undertaken for a variety of reasons. With the provision of much of the world's transportation infrastructure the responsibility of governments, transportation planning is undertaken primarily to support public officials in their choice of most cost-effective investments. Because transportation investment has a strong influence on how a community evolves, transportation planning must necessarily consider a variety of factors when assessing the cost effectiveness of alternative investment options. For example, transportation investment can strongly influence land use patterns, the attractiveness of different parts of a region for economic development, the equitable distribution of mobility benefits among different population groups, and the environmental consequences of both the construction and operation of transportation facilities. Transportation planning must therefore be forward-looking, as well as give attention to current problems in the transportation system.

Basic Framework of Transportation Planning

The basic framework for transportation planning that could be applied at any scale of application is shown in Figure 10.1.1. The steps shown in this framework are discussed in the following sections.

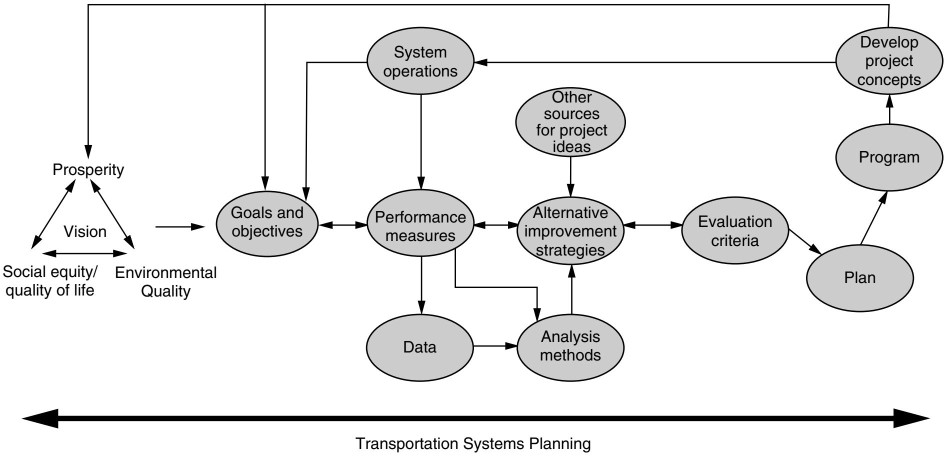

FIGURE 10.1.1 Transportation planning process.

Define a Vision

The transportation system can impact society in a variety of ways — providing mobility and accessibility, promoting economic development, contributing to quality of life, as well as negatively affecting the natural environment. The first step in transportation planning thus usually consists of defining what it is that the nation, state or region desires in terms of its future characteristics.

Identify Goals and Objectives

Once a desired vision is articulated, *goals* can be identified that relate the vision to the ultimate achievement of a transportation plan. *Objectives* are more specific statements that indicate the means by which these goals will be achieved. Goals and objectives not only provide overall direction to the transportation planning process, but they also help define the criteria, known as *measures of effectiveness,* that are used later in the process for evaluating alternative courses of action.

Identify Performance Measures

An important aspect of a continuing transportation planning process is the monitoring of system performance. This monitoring systematically identifies areas where improvements might occur, and, in addition, helps transportation officials assess the effectiveness of previously implemented actions. Performance measures can focus explicitly on transportation system operations, e.g., the level of freeway delay during the morning peak travel hours, or on other issues of importance to transportation officials, e.g., the level of transportation-related air pollutants emitted during specified periods of time.

Collect Data

Given that transportation investment is usually aimed at upgrading the *physical condition* of a facility (e.g., repaving a road or building a new bridge) or at improving its *performance* (e.g., providing new person-carrying capacity by setting aside highway lanes for multi-occupant vehicles or by building a new road), engineers are continually collecting data on the many different components of the transportation system. The base condition or performance of all the different facilities or services that make up a transportation system is called an *inventory.*

Forecasting future demand for transportation requires engineers and planners to characterize the current and likely future states of the factors that influence this demand. Thus, for example, the type of data that is collected includes such things as current land use and socioeconomic characteristics of the traveling population. Current land use is readily attained through land use inventories. The methods of estimating future land use range from trends analysis to large-scale land use models that predict household and employment sites decades into the future. Important socioeconomic characteristics include level of household income, number of members of the household, number of autos in the household, number of children, age of the head of household, and highest level of education achieved. Each of these factors has been shown through research to influence the amount and type of travel associated with a typical household.

Use Analysis Tools to Identify System Deficiencies or Opportunities

The analysis tools and methods used to identify transportation deficiencies and improvement opportunities can vary widely. In some cases, computer-based transportation network models are used to estimate future traffic volumes and transit ridership, with the results then compared to existing system capacity to handle such volumes. This comparison relies on one of the more popular performance measures used in transportation planning today, the volume-to-capacity (V/C) ratio. However, given the many different goals and objectives that can characterize a transportation planning process, a wide variety of measures are often used for determining system deficiencies. Other types of analysis tools include time–distance diagrams, queuing models, fluid-flow approximation methods, macro- and micro-simulation models, and mathematical programming techniques.

Develop and Analyze Alternatives

Various types of strategies can result from the planning process:

1. Improving the *physical infrastructure* of the transportation system — for example, adding new highway lanes or extending an existing subway line
2. Improving *system operations* — for example, coordinating traffic signals, improving traffic flow through improved geometric design of intersections, or making transit operations more efficient through schedule coordination
3. Reducing *travel demand* so that the transportation system can handle peak loads more effectively — for example, flexible working hours, increasing average vehicle occupancy through such measures as carpools or transit use, or raising the "price" of travel through the use of tolls

In the past 10 years, the application of advanced transportation technologies to the operation of the transportation system, known *as intelligent transportation systems* (ITS), has become an important type of strategy in many cities. Thus, it is not uncommon for major cities to now have a centralized traffic management center, with a regional surveillance and traveler communication system that permits transportation system managers to communicate to travelers the best times for travel and which routes are least congested.

Evaluate Alternatives

Evaluation brings together all of the information gathered on individual alternatives/plans and provides a systematic framework to compare the relative worth of each. This evaluation process most often relies on the various measures of effectiveness that link to the goals and objectives defined at the beginning of the process. Different types of evaluation methods include use of benefit/cost ratios, cost-effectiveness indices, goals matrix analysis, and subjective assessment of the merits of individual alternatives.

Develop Transportation Plan

One of the most important products of the transportation planning process is the *transportation plan.* The plan outlines the many different strategies and projects that are necessary to meet the challenges and opportunities facing a state or region. In the U.S., federal law requires that every state and every metropolitan area over 50,000 population have a transportation plan. The state department of transportation (DOT) is responsible for preparing the state transportation plan; an agency called the metropolitan planning organization (MPO) is responsible for preparing the metropolitan transportation plan.

Implement Plan

Another major product of the transportation planning process is a strategy for implementing all of the actions identified in the plan. In the U.S., federal law requires each state and every metropolitan area over 50,000 population to produce a *transportation improvement program* that lists the projects that will be implemented over the next 3 to 5 years, identifies which agency is responsible for each project, and describes the source of project funding.

The implemented projects will affect the performance of the transportation system. Through a continuing monitoring process, linked directly to important performance measures, the performance of individual projects or of the entire transportation system can be fed back into the planning process as a means of identifying new problems.

Transportation Modeling

The level of transportation analysis can vary according to the level of complexity and scale of application of potential solution strategies. Thus, for example, the consideration of a new subway system would necessarily have to be examined from a metropolitan level, while the transportation impacts of a new development site would likely be analyzed at a subregional level. In most cases, however, the modeling process consists of four major steps — trip generation, trip distribution, mode split, and trip assignment. Even though recent models combine some of these steps together during the analysis process, the concept of the "trip" consisting of these four stages still holds. Each study area (whether a nation, state, metropolitan

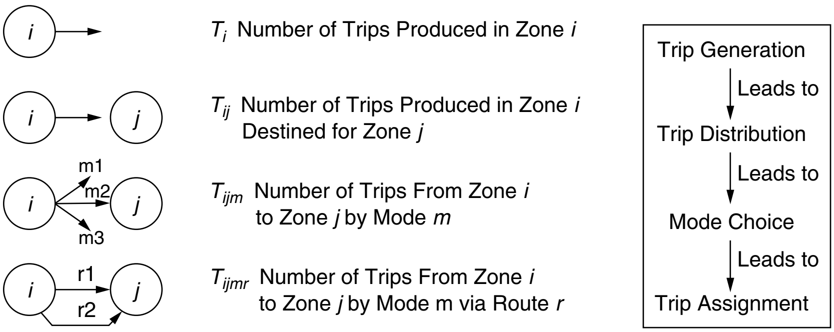

FIGURE 10.1.2 Transportation modeling framework.

area, or community) is divided into *zones* of homogeneous characteristics (e.g., similar household incomes) that can then be used as the basic foundation for estimating trips from or attracted to that zone. Most planning studies define these zones to be similar to those used in other data collection activities (e.g., the U.S. census tracts) so that data useful to the transportation study collected by others can be readily linked to the transportation analysis. The transportation system is represented in models as a network of links and nodes. Links represent line-haul facilities, such as roads or transit lines, and nodes represent points of connection, such as an intersection or transit terminal. Given the complex nature of transportation systems, the typical transportation network consists of links representing only highly used facilities or other facilities that are critical to the overall performance of the transportation system.

The steps in a typical modeling exercise are shown in Figure 10.1.2. Basic to this approach is the concept of *derived demand*. Derived demand means that a trip is taken to accomplish some activity at a destination, and that the trip itself is simply a means of reaching this activity. There is no intrinsic value of the trip itself. Thus, modeling trip-making requires linking travel behavior to the characteristics of the trip-maker and to the activities at the origin and destination ends of the trip that will influence the way the trips are made.

Trip generation is the process of analytically deriving the number of trips that will be generated from a location or zone based on socioeconomic characteristics of the household, or in the case of freight movement, the zonal economic characteristics. Trip generation also includes predicting the number of trips that will be attracted to each zone in the study area.

$$\text{Number of trips produced in a zone} = f\,(\text{Population socio-economic characteristics, land use, transportation mode availability})$$

$$\text{Number of trips attracted to a zone} = f\,(\text{Attractiveness of the zone})$$

Two approaches are often used to estimate the number of trips generated. The first uses trip rate models that are based on trip-making behavior as compared to important variables. For example, see Table 10.1.1. The other approach is to use regression models that are estimated either from survey data

TABLE 10.1.1 Cross-Classification Analysis, Trips per Day, by Household Size and Income

	Number of People in Households		
	1	2	3+
Low income	2.4	3.3	4.5
Medium income	3.5	3.8	4.8
High income	3.9	4.2	5.4

collected throughout the study area or from some other data source, such as the U.S. Census. The following regression equations illustrate this approach.

Zone Trip Productions: $T_i = 184.2 + 120.6\ (\text{Workers}_i) + 34.5\ (\text{Autos}_i)$

Household Trip Productions: $T_{ih} = 0.64 + 2.3 + (\text{Employee}_i) + 1.5\ (\text{HHAuto}_i)$

Zonal Attractions: $T_j = 54.2 + 0.23\ (\text{Office}_j) + 0.43\ (\text{Retail}_j)$

where T_i = total number of trips generated in zone *i*; T_{ih} = total trips generated per household in zone *i*; T_j = total trips attracted to zone *j*; Workers_i = number of workers in zone *i*; Autos_i = number of autos in zone *i*; Employee_i = number of employees per household in zone *i*; HHAuto_i = number of autos per household in zone *i*; Office_j = number of office employees in zone *j*; and Retail_j = number of retail employees in zone *j*.

Trip distribution is the process of estimating the number of trips that travel from each zone to every other zone in the study area. The results of the trip distribution process is a matrix called the *trip table,* which shows the number of trips traveling between each origin–destination (O-D) pair for the time period being examined. A common method for distributing trips in a zonal system is the gravity model, which is of the following form:

$$T_{ij} = P_i \times \frac{A_i \times F_{ij} \times K_{ij}}{\sum (A_j \times F_{ij} \times K_{ij})}$$

where T_{ij} = total trips originating in zone *i* and destined to zone *j*; P_i = number of trips produced in zone *i*; A_j = level of attractiveness of zone *j* (e.g., number of retail employees); F_{ij} = friction or impedance factor between zones *i* and *j* (a value usually a function of travel time); and K_{ij} = socioeconomic adjustment factors for trips between zones *i* and *j* (a value that represents variables that influence trip making not accounted for by other variables).

Mode choice is the process of estimating the percentage of travelers who will use one mode of transportation vs. the others available for a given trip. The basic approach in making this estimation is that each mode has associated with it some empirically known characteristics that, when combined with characteristics of the traveler in a mathematical equation, can define that mode's *utility.* Variables such as travel time, travel cost, modal reliability, and so on are often incorporated into a mode's *utility function*, along with socioeconomic characteristics of the traveler. Freight models use a similar concept in estimating commodity flows by mode. One of the most familiar forms of mode choice models, based on the concept of consumer choice, is the logit model, which predicts mode shares based on the following equation:

$$P_{ik} = \frac{e_k^U}{\sum e_m^U} \quad \text{for all modes } n$$

where P_{ik} = probability of individual *i* choosing mode *k*; U_k = utility of mode *k*; U_m = utility of mode *m*; *n* = number of modes available for trip.

The utility of each mode is often represented as a linear function of those variables found to influence an individual's choice of mode. For example, a utility function for the automobile mode might be of the form,

$$U_a = 6.3 - 0.21\ (X_1) - 0.43\ (X_2) - 0.005\ (X_3)$$

where U_a = utility of automobile; X_1 = access and egress time when automobile is chosen; X_2 = line-haul travel time; and X_3 = cost of travel.

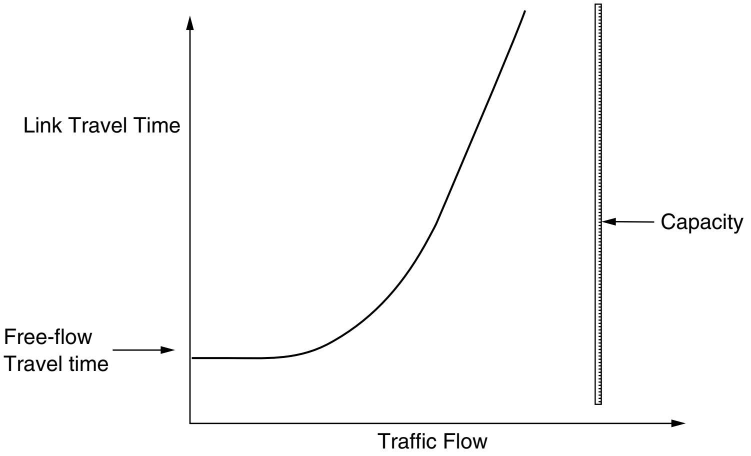

FIGURE 10.1.3 Link performance function.

The utility functions of other modes available for a specific trip would be similarly specified. The respective probabilities would then be multiplied by the total number of trips between an origin and destination to obtain the number of trips made by mode.

Trip assignment is the process of estimating the trip paths through a transportation network based on a trip table (which is produced in trip distribution). The basic concept found in all trip assignment methods is that travelers choose modes that will minimize travel time, that is, they will choose the shortest path through a network (once again, the assumption of derived demand influencing the analysis approach). Link performance functions that relate travel time to the number of vehicles or riders on that link are used to iteratively update estimated link travel times so that minimum path travel times reflect the effect of congestion (see Figure 10.1.3). A portion of the total O-D travel demand is assigned to the network, with travel times then updated based on the link performance function, given the volume on each link. An additional portion of the O-D travel is next assigned given the updated travel times, still following the minimum travel time path through the network. This process continues until all estimated trips have been assigned to a link path in the network. Stochastic assignment is also used in many planning studies. This assignment recognizes that, in certain cases, some subset of trip routes will have associated with them some characteristics that attract specific types of travelers, even if the travel time is longer. A probabilistic approach takes these characteristics into account.

In order to develop more behaviorally based travel models, researchers in recent years have focused on the fact that travel arises out of the need to participate in out-of-home activities (work, shopping, school, etc.). This directly leads to the conclusion that what one should study in the first instance is not travel per se, but rather the participation in the *activities* that ultimately generate travel. This approach has been referred to as “activity-based modeling.” Figure 10.1.4 shows the difference in the traditional approach toward modeling and the activity-based approach. Many activity-based models are being implemented within a *micro-simulation* framework, within which the behavior of each individual is dynamically simulated over time.

Defining Terms

Demand management: Reducing the demand for travel during specific time periods by shifting trips to other times, diverting trips to other routes or modes, or reducing the need for trip-making to begin with.

Derived demand: An assumption that travelers make a trip to accomplish some objective at the destination and that the trip itself is simply a means of reaching that activity.

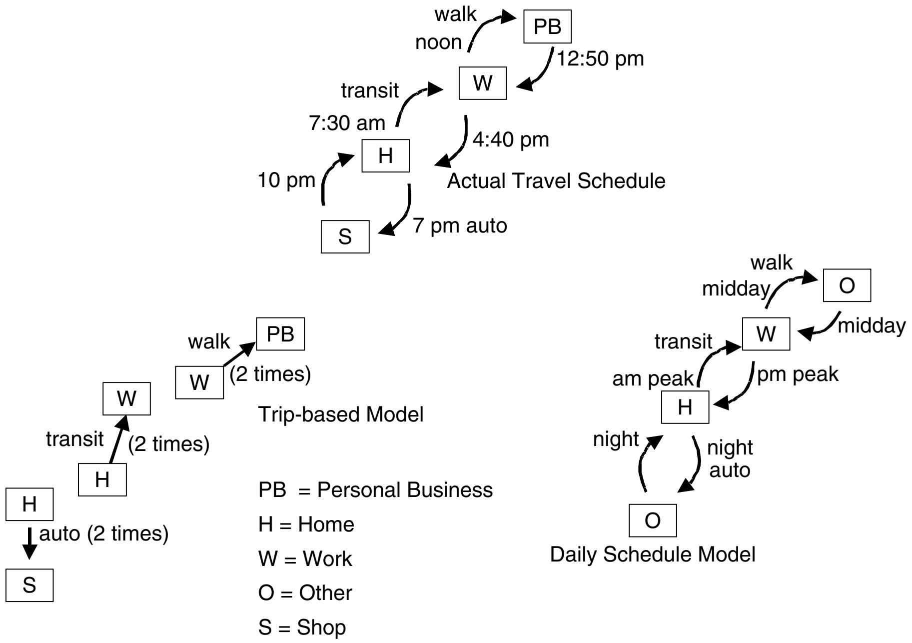

FIGURE 10.1.4 Difference between trip-based modeling and activity-based modeling.

Intelligent transportation systems: Application of surveillance, communication, and control technologies to the management of the transportation system, and in some cases, to the control of individual vehicles.

Transportation network: A transportation system is represented in models as a network of links and nodes. Links represent line-haul facilities, such as roads and transit lines, and nodes represent points of connection.

Utility function: A mathematical formulation that assigns a numerical value to the attractiveness of individual modes of transportation based primarily on that mode's characteristics.

Zonal system: Each study area (whether nation, state, metropolitan region, or community) is divided into zones of homogeneous characteristics that can then be used as the basic foundation for estimating trips from, or attracted to, that zone.

10.2 Design of Transportation Facilities

John Leonard II and Michael D. Meyer

The efficient movement of people and goods requires transportation systems and facilities that are designed to provide sufficient capacity for the demands they face in as safe a manner as possible. In addition, in most modern societies, the design of transportation facilities must explicitly minimize harm to the natural and human-made environment while providing for mitigation measures that relate to those impacts that are unavoidable. In many ways the critical challenge to today's designers of transportation projects is successfully designing a facility that minimally harms the environment.

The design of a transportation facility almost always takes place within the context of a much broader **project development process.** This process can vary in complexity with the type of project under design and with the scale of implementation. The importance of the project development process to the designer is that it:

- Establishes the key characteristics of the project that must be considered in the design
- Indicates the time frame that will be followed for project design
- Establishes which agencies and groups will be involved in the process and when this involvement will likely occur
- Links the specific elements of the project design with other tasks that must be accomplished for the project to be constructed
- Satisfies legal requirements for a design process that is open for public review and comment
- Indicates the specific products that must be produced by the designers to complete the project design process

In most cases the project development process consists of a well-defined set of tasks that must be accomplished before the next task can occur. These tasks include both technical activities and public involvement efforts that are necessary for successful project development.

Components of the Project Development Process

Identify Project Need

A project need can be identified through a formal planning process or from a variety of other sources, including suggestions from elected officials, agency managers, transportation system users, and citizens. Important in this early portion of project development is an indication of what type of improvement is likely to be initiated. For example, a project could relate to one or more of the following types of improvement strategies:

- *New construction.* A transportation facility constructed at a new location
- *Major reconstruction.* Addition of new capacity or significant changes to the existing design of a facility, but usually occurring within the area where the current facility is located
- *Rehabilitation/restoration.* Improvements to a facility usually as it is currently designed and focusing on improving the physical condition of the facility or making minor improvements to enhance safety
- *Resurfacing.* Providing new pavement surface to a transportation facility that prolongs its useful life
- *Spot improvements.* Correction of a problem or hazard at an isolated or specific location

Establish Project Limits and Context

One of the very first steps in the design process is to define the boundaries or limits of the project. This implies establishing how far the project will extend beyond the area being targeted for improvement and the necessary steps to ensure smooth connections to the existing transportation system. Project boundaries also have important influence on the amount of right-of-way that might have to be purchased by an agency to construct a project.

Establish Environmental Impact Requirements

The design of a project will most likely be influenced by environmental laws or regulations that require design compliance with environmental mandates. These mandates could relate to such things as wetland protection, preservation of historic properties, use of public park lands, maintaining or enhancing water quality, preserving navigable waterways, protecting fish and wildlife, reducing air pollutants and noise levels, and protecting archaeological resources. One of the first steps in project development is to determine whether the likely project impacts are significant enough to require a detailed environmental study.

Develop Strategy for Interagency Coordination and Public Involvement

Depending on the complexity and potential impact of a project, the project designer could spend a great deal of time interacting with agencies having some role in or jurisdictional control over areas directly related to the project. These agencies could have jurisdiction by law (e.g., wetlands) or have special expertise that is important to project design (e.g., historic preservation). In addition to interagency coordination, transportation project development is often subject to requirements for public outreach and/or public hearings. An important aspect of recent project development efforts is to develop very early in the process a consensus among involved agencies on what environmental impacts will have to be carefully studied and on the definition of the project purpose and need.

Initiate Project Design and Preliminary Engineering

Topographic data of the study area and forecasted vehicular volumes expected to use the facility in the design year are used as input into the preliminary design of the horizontal and vertical alignment of the facility, that is, the physical space the facility will occupy once finished. This preliminary engineering step also includes the preparation of initial right-of-way (ROW) plans, which indicate the amount of land that must be available to construct the facility. Preliminary engineering is a critical step for environmental analysis in that it provides the first detailed examination of the scope and extent of potential environmental impacts.

Project Engineering

Once preliminary engineering has provided the basic engineering information for the project, the more detailed project design begins. This entails specific layouts of horizontal and vertical geometry, soils/subsurface examination and design, design of utility location, drainage design, more detailed ROW plans, and initial construction drawings. Concurrent with this design process, the environmental process continues with updated information on project changes that might cause additional environmental harm, the initiation of any permitting process that might be needed to construct the project (e.g., environmental agency permission to affect wetlands), and public hearings/meetings to keep the public involved with project development.

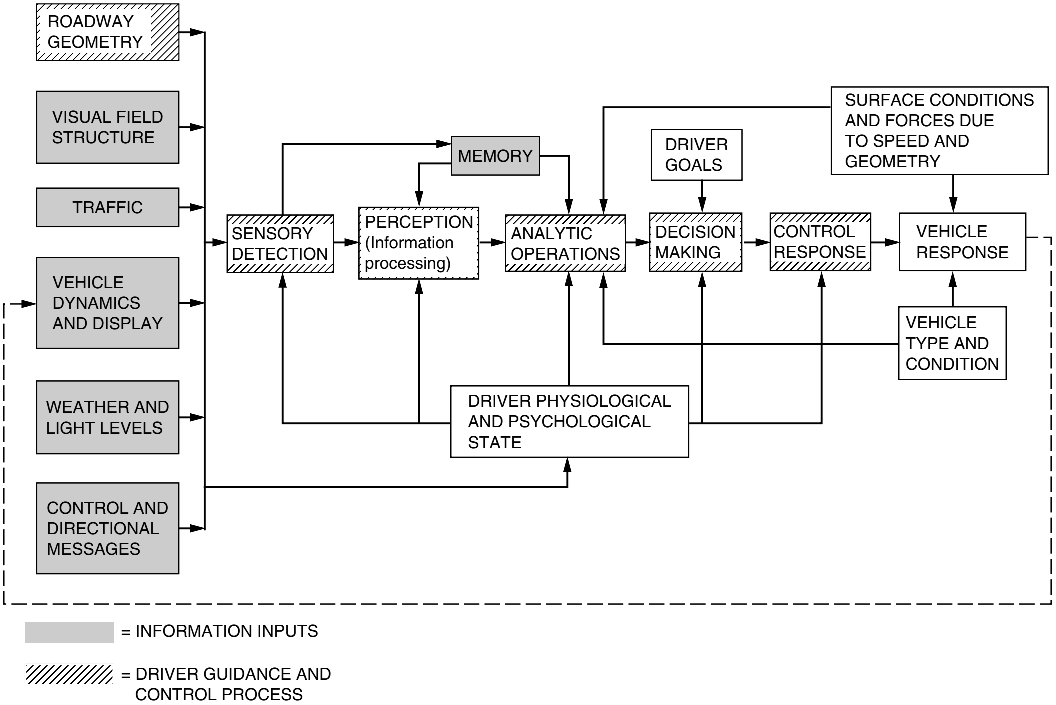

FIGURE 10.2.1 Driver-vehicle-roadway interface.

Final Engineering

The final engineering step is the culmination of the design process, which completes the previous design plans to the greatest level of detail. This step includes finalizing ROW plans, cost estimates, construction plans, utility relocation plans, and any agreements with other agencies or jurisdictions that might be necessary to complete the project. Environmental permits are received and final project review for environmental impacts is completed.

Context-Sensitive Design

One of the important characteristics of transportation facility design is the potentially negative impact that new facilities could have on the surrounding community and natural environment. Engineers and planners have begun to consider such impacts earlier in the project development process so that the context within which a facility is constructed is incorporated into the design itself. This process is called **context-sensitive design.**

Basic Concepts of Project Design

Human Factors

Human factors have a great deal of influence on the design of transportation facilities in such things as width of facility, length and location of access/egress points, vehicle braking distance, location of information/guidance aids such as signs, and geometric characteristics of the facility's alignment. The driver-vehicle-roadway interface is shown in Figure 10.2.1.

Vehicle or User Performance Factors

The dynamics of vehicle motion play an important role in determining effective and safe design. The key vehicle characteristics that relate to facility design criteria include:

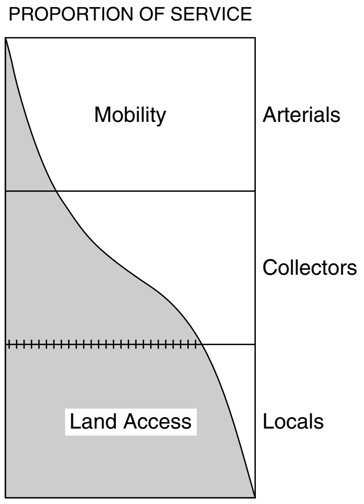

FIGURE 10.2.2 Relationship of functionally classified systems in relation to traffic mobility and land access. (*Source:* American Association of State Highway and Transportation Officials. 2001. *A Policy on the Geometric Design of Highways and Streets,* AASHTO, Washington, DC. Figure 1 through Figure 5.)

- *Vehicle size.* Influences vertical and horizontal clearances, turning radii, alignment width, and width of vehicle storage berths.
- *Vehicle weight.* Influences strength of material needed to support vehicle operations.
- *Vehicle or user performance.* Influences specifications for horizontal and vertical geometry, braking distances, operational performance and needed capacity to allow passing and successful maneuvering (e.g., assumed walking speed of pedestrians crossing a road that dictates how long a traffic signal must remain red).

Classification Schemes

The transportation system serves many functions, ranging from providing access to specific locations to providing high-speed, high-capacity movement over longer distances. Classification schemes are used to represent these various roles and influence the design criteria that are associated with the facilities in each classification category. A common **functional classification** scheme for highways is shown in Figure 10.2.2.

Capacity and Level of Service

Every design usually begins with some estimation of the demand for the transportation facility that will likely occur if the facility is built. The key design question then becomes, what facility capacity (e.g., number of road lanes, runways, transit lines, or vehicle departures) is necessary if a certain level of performance is desired? These different levels of performance are referred to as **level of service (LOS).** Level of service is a critical element in establishing important design factors (see Figure 10.2.3).

Design Standards

Design standards dictate minimum or maximum values of project characteristics that are associated with a particular facility type. Design standards usually result from extensive study of the relationship between various facility characteristics, vehicle performance, and the safe handling of the vehicles by human operators. Design standards often vary by the "design speed" of the facility (and thus the importance of the facility classification) and by the "design vehicle." Design standards are often the basis for developing typical cross-sections (see Figure 10.2.4 and Figure 10.2.5).

FREEWAYS

Level of Service	Maximum Density (pc/mi/ln)	Minimum Speed (mph)	Max Service Flow Rate (pcphpl)	Maximum *v/c* Ratio
Free-Flow Speed = 70 mph

F	<13	<10	< 7

FIGURE 10.2.3 *Continued.*

Intermodal Transportation Terminals or Transfer Facilities

Terminals or transfer facilities are locations where users of the transportation system change from one mode of travel to another. The effective design of such facilities is a critical element of successful transportation system performance, given the potential bottlenecks they represent if not designed appropriately. The design of terminals and transfer facilities must pay special attention to the needs of the users of the facility, in that they serve to establish the effective capacity of the facility, for example:

1. Internal pedestrian movement facilities and areas (stairs, ramps, escalators, elevators, corridors, etc.)
2. Line-haul transit access area (entry control, fare collection, loading, and unloading)
3. Components that facilitate movements between access modes and the station (ramps or electric doors)
4. Communications (public address systems and signage)
5. Special provisions for disabled patrons (elevators and ramps)

The criteria that could relate to the design of such a facility include threshold values for pedestrian level of service, delay at access points, connectivity from one area of the facility to another, and low-cost maintenance. For the vehicle side of such terminals, special consideration must be given to the performance of the design vehicle (e.g., turning radii of buses or semitrailer trucks) and the vehicle storage requirements (e.g., the number, size, and orientation of loading/unloading berths).

RECOMMENDED ROADWAY SECTION WIDTHS

Functional Class	U/R	Number of Lanes	Travel Lane	Shoulder	
				Right	Left[1]
Freeway	Urban	4–8	12	10	4[2]
	Rural	4–8	12	10	4[2]
Arterial	Urban	Multilane with median	12	10	4
	Urban	Multilane without median	11–12	8–10*	N/A
	Rural	2 lane	12	See Table 5.2	N/A
	Rural	Multilane with median	12	8–10	4

WIDTH OF USABLE SHOULDER—EACH SIDE OF TRAVEL WAY
RURAL TWO-LANE ARTERIAL

	Design Traffic Volume				
	Current ADT Under 400	Current ADT Over 400	DHV 100–200	DHV 200–400	DHV Over 400
All design speeds	4 ft	6 ft	6 ft	8 ft	10 ft

RECOMMENDED WIDTH OF TRAVEL WAY AND GRADED SHOULDER
RURAL COLLECTOR

	Design Traffic Volume				
Design Speed (mph)	Current ADT Under 400	Cuurent ADT Over 400	DHV 100–200	DHV 200–400	DHV Over 400
30	20 ft	20 ft	20 ft	22 ft	24 ft
40	20 ft	22 ft	22 ft	22 ft	24 ft
50	20 ft	22 ft	22 ft	24 ft	24 ft
60	22 ft	22 ft	22 ft	24 ft	24 ft

Advanced Technology Projects

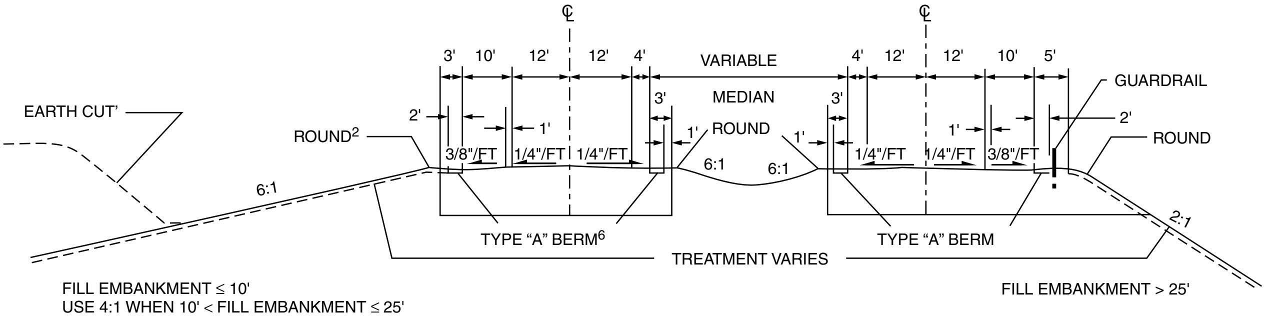
One of the characteristics of transportation system development in recent years has been the increased application of advanced (usually electronic) technologies to improve system performance. Known as **intelligent transportation systems (ITS),** the following steps apply in their design.

Define Problems and Needs

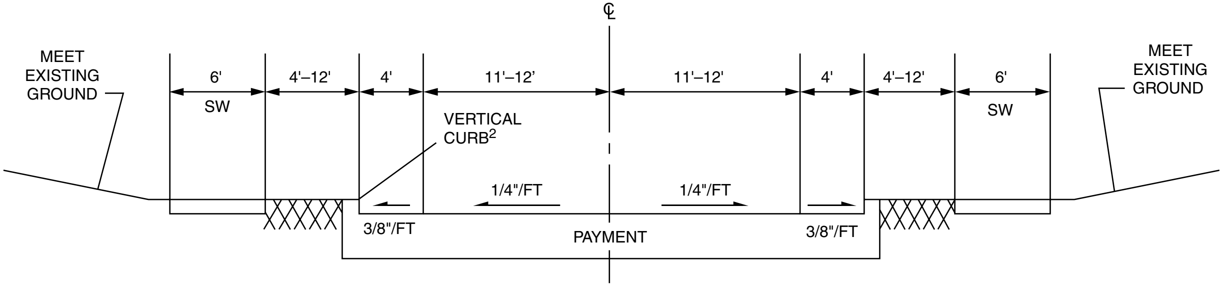
Typical problems or needs might relate to congestion, excessively high accident rates, or improving current system capabilities and levels of service.

Define System

A system definition should include a mission statement, listing of physical components (e.g., roads, travelers, buses, rolling stock, existing rail lines, control centers, and communication links), and the physical relationship between those components.



Typical Freeway/Expressway Section



Typical Urban Collector and Local Road

FIGURE 10.2.5 Example cross-sections.

Define Users

System users is a rather broad description of all individuals, organizations, and other systems that might interact or have a stake in the fully implemented transportation system under study.

Establish Institutional Framework and Partnerships

Various organizations possess differing missions, priorities, and policies — sometimes in conflict. Strong emphasis on coalition building during the early stages of project planning and engineering can help diffuse potential project-stopping disagreements later in the process.

Develop User Service Plan

The development of a user service plan consists of the following steps: (1) establish user services, (2) identify technology areas, and (3) map user services to technology areas. User services might include:

- Traveler information services
- Freight and fleet management services
- Emergency vehicle management services
- Traffic management services
- Public transport services

Available technologies fall within one of the following functional areas: (1) surveillance, (2) communications, (3) traveler interface, (4) control strategies, (5) navigation/guidance, (6) data processing, and (7) in-vehicle sensors.

Define System Architecture

A logical architecture consists of a *block diagram* identifying the major systems and subsystems, the participating agencies, and users. Through the use of arrows, the flow of information between these elements is identified. A logical architecture also shows the allocation of responsibilities throughout the transportation system.

Evaluate Alternative Technologies

Some of the factors to be considered in this evaluation include (1) cost, (2) performance, (3) reliability, (4) compatibility, (5) environmental impacts, and (6) compliance to standards.

Defining Terms

Context-sensitive design: A design process in which the community and environmental context is considered very early in the project development process. Mitigation and avoidance of significant impacts are proposed at this stage.

Design standard: Physical characteristics of a proposed facility that are professionally accepted and often based on safety considerations.

Functional classification: Classifying a transportation facility based on the function it serves in the transportation system. Such classification becomes important in that design standards are often directly related to the functional classification of a facility.

Intelligent transportation systems: Use of information and surveillance technologies to monitor and control the operation of the transportation system. Many of these systems are targeted at specific travel markets.

Level of service: An assessment of the performance of a transportation facility based on measurable physical characteristics (e.g., vehicular speed, average delay, density, flow rate). Level of service is usually subjectively defined as ranging from level of service A (good performance) to level of service F (bad or heavily congested performance).

Project development process: The steps that are followed to take a project from initial concept to final engineering. This process includes not only the detailed engineering associated with a project design but also the interaction with the general public and with agencies having jurisdiction over some aspect of project design.

10.3 Operations and Environmental Impacts

Michael D. Meyer, Paul W. Shuldiner, and Kenneth B. Black

The safe and efficient movement of vehicles and people are the two most important goals of highway design. This is accomplished through careful geometric design of the layout and physical features of the roads, and through operational procedures and devices designed to guide, advise, and regulate vehicle operators in their use of the road. Proper design is based on a thorough understanding of the complex interactions among driver, vehicle, and roadway characteristics. For example, the design of a highway passing lane reflects the performance characteristics of the vehicle, the reaction time of the driver, and the ability of the road itself to provide sufficient distance that allows safe vehicle passing.

The following sections present the fundamental equations of vehicle flow and engineering principles upon which good highway design is based.

Fundamental Equations

Flow, q, is given by the following formula:

$$q = \frac{n \times 3600}{T} \quad \text{vehicles per hour} \tag{10.3.1}$$

where n = number of vehicles passing a point in T seconds.

Density, k, is given by

$$k = \frac{n}{L} \times 5280 \quad \text{vehicles per mile} \tag{10.3.2}$$

where n = number of vehicles occupying a length of road, L, and L is in feet, or by

$$k = \frac{n}{L} \times 1000 \quad \text{vehicles per kilometer} \tag{10.3.3}$$

where n = number of vehicles occupying a length of road, L, and L is in meters.

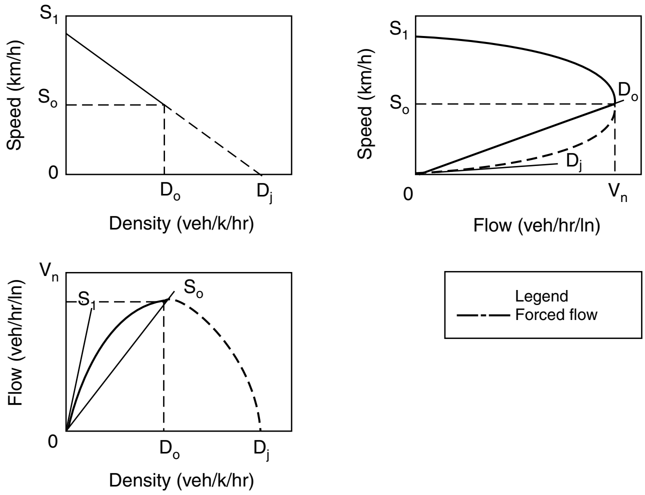

FIGURE 10.3.1 Relationships among flow, density, and speed.

Average speed, $\bar{u}$, is given by

$$\bar{u}_t = \frac{1}{n}\sum_{i=1}^{n} u_i \tag{10.3.4}$$

where u_i = speed of the *i*th vehicle, termed the *time mean speed*, and by

$$\bar{u}_s = \frac{n \cdot s}{\sum_{i=1}^{n} t_i} \tag{10.3.5}$$

where t_i = time for the *i*th vehicle to traverse distance *s*, termed the *space mean speed.* The values $\bar{u}_s$ and $\bar{u}_t$ usually differ very slightly from one another unless there are wide variations among the speeds of individual vehicles.

Flow, Speed, and Density Relationships

The fundamental equation relating flow, density, and speed can be formulated as follows:

$$q = k \times \bar{u}_s \tag{10.3.6}$$

For simplicity, it is often assumed that average speed, *u*, decreases linearly as density, *k*, increases. Given this assumption and the dimensional identity expressed in Equation (10.3.6), it follows that flow, density, and speed are related as shown in Figure 10.3.1. It may be seen from Figure 10.3.1 that

1. When density on the highway is zero, there are no vehicles on the highway and the flow is zero.
2. As density goes to its maximum, flow goes to zero as vehicles line up — essentially bumper to bumper.
3. As density increases, flow also increases — up to the point where $k = kj/2$ — and then decreases as density increases.
4. As flow increases from zero to a maximum (the capacity of the roadway), speed also decreases. Once the flow approaches capacity, any impediment to the steady movement of traffic will reduce both flow and speed abruptly, with a concomitant rapid increase in density.

Level of Service (LOS)

Level of service is a measure of how freely a given transportation system is operating. It is affected primarily by traffic **volume**, but other factors such as proportion of heavy vehicles, roadway geometrics, and incidents also affect the level of service. LOS is designated by letters A through F. LOS A is characterized as *free flow* and is applied to conditions of very low traffic volume in which there is little or no restriction to traffic flow. LOS F is characterized as *forced flow* with congested, stop-and-go movement. LOS C involves some restriction to free movement of traffic and is the level of service commonly used as the target for road design. The maximum flow along a facility occurs at LOS E.

Different elements of the road system emphasize different LOS measures. For example, the following measures are the key determinants in the LOS for the identified element of the road network.

Urban street:	Average travel speed for through vehicles
Freeway:	Average speed, freedom to maneuver, and proximity of other vehicles
Freeway ramp:	Vehicle density
Signalized intersection:	Average traffic control delay per vehicle
Two-lane highways:	Percent time spent following other vehicles, and average speed
Pedestrian walkways:	Space per pedestrian, flow rate, and average speed

The calculation of road level of service varies by type of road. For example, the *Highway Capacity Manual,* the manual that defines how level of service should be calculated, describes different methodologies for the following transportation facilities: urban streets, signalized intersections, unsignalized intersections, pedestrian walkways, bicycle facilities, two-lane highways, multi-lane highways, freeway facilities, basic freeway segments, freeway weaving sections, ramps, interchange ramp terminals, and transit services.

As an example, the LOS for a freeway segment is calculated with the following two equations:

$$\mathrm{FFS} = \mathrm{BFFS} - f_{LW} - f_{LC} - f_N - f_{ID} \tag{10.3.7}$$

where FFS = free flow speed (mi/h); BFFS = base free flow speed (70 mi/h for urban and 75 mi/h for rural); f_{LW} = adjustment for lane width; f_{LC} = adjustment for right-shoulder lateral clearance; f_N = adjustment for number of lanes; and f_{ID} = adjustment for interchange density.

$$D = \frac{V}{S \times (\mathrm{PHF} \times N \times f_{HV} \times f_P)} \tag{10.3.8}$$

where D = density (pc/mi/ln); S = average passenger car speed (mi/h); V = hourly volume (veh/h); PHF = peak hour factor (variation in traffic low within hour); N = number of lanes; f_{HV} = heavy vehicle adjustment factor; and f_P = driver population factor.

The results of these two equations for the circumstances of a specific freeway segment are then entered into a table that defines a corresponding level of service.

Highway Capacity

The **capacity** of a highway, that is the maximum flow of vehicles or passengers, depends on many geometric and traffic characteristics. The capacity of a road occurs at LOS E. Equation 10.3.7 and Equation 10.3.8 indicate that the most important of these factors include number of lanes, width of lanes, lateral clearance to obstructions, percentage of the traffic stream made up of trucks and buses, characteristics of the driver population and percent grade of the roadway (incorporated into the heavy vehicle adjustment factor). Lane widths will vary according to the type of road; however, for high-capacity, high-speed roads such as freeways, the lane width should be at least 12 ft. Obstructions should be a minimum of 6 ft from the edge of pavement. Vertical grades of 3% or more that are one-half mile long or longer will reduce the capacity of a highway, especially where commercial vehicles are present. For freeways, maximum lane capacity under ideal conditions is generally assumed to be 2400 vehicles/hr per lane. Ideal conditions, however, are seldom achieved.

Intersection Capacity

The *Highway Capacity Manual* provides a detailed method for estimating the capacity of a signalized intersection. This method examines the geometric, traffic and signalization conditions for each lane approach to the intersection. Similar to Equation 10.3.7 and Equation 10.3.8, the following equation is used to determine the saturation flow rate for each group of lanes entering an intersection.

$$S = s_0 \times N \times f_W \times f_{HV} \times f_g \times f_p \times f_{bb} \times f_a \times f_{LU} \times f_{LT} \times f_{RT} \times f_{Lpb} \times f_{Rpb} \qquad (10.3.9)$$

where S = saturation flow rate for each group of lanes (veh/h); s_0 = base saturation flow rate per lane (pc/h/ln); N = number of lanes in lane group; f_W = adjustment for lane width; f_{HV} = adjustment for heavy vehicles (trucks and buses); f_g = adjustment for approach grade; f_p = adjustment for existence of parking lane and parking activity adjacent to lane group; f_{bb} = adjustment for blocking effect of local buses that stop within intersection area; f_a = adjustment for area type; f_{LU} = adjustment for lane utilization; f_{LT} = adjustment for left turns in lane group; f_{RT} = adjustment for right turns in lane group; f_{Lpb} = pedestrian–bicycle adjustment factor for left-turn movements; and f_{Rpb} = pedestrian–bicycle adjustment factor for right-turn movements.

The result of Equation 10.3.9 is then multiplied by the amount of green time per total signal cycle time for the lane group being analyzed to obtain the capacity of the lane group. As shown, Equation 10.3.9 illustrates the basic concept of first starting with an "ideal" capacity or saturation flow and then modifying this value with adjustments that reflect physical characteristics of the existing facility and area.

Traffic Control Devices

Traffic signs, signals, and pavement markings (**traffic control devices**) are used to regulate, warn, and guide the users of the road. The effectiveness of such devices is greatly enhanced through the uniformity of their design — including shape, color, and message — and through their use and placement on the roadway. Uniformity is ensured by adherence to the standards promulgated in the *Manual of Uniform Traffic Control Devices* [U.S. DOT and FHWA, 2000] or an equivalent manual adopted by each state highway agency. As stated in the **Manual**, to be effective, a traffic control device should meet five basic requirements: fulfill a need, command attention, convey a simple and clear meaning, command respect from road users, and give adequate time for proper response.

One of the ways that traffic control devices gain respect from road users is by using them in situations where such devices are clearly warranted. Experience over many decades and engineering judgement have become the basis for "warrants," guidelines that are used by engineers to justify the use of particular traffic control devices. Two examples of how this principle is used by engineers are provided below for STOP signs and traffic signals.

STOP signs should be used only where one or more of the following conditions or warrants hold:

1. At an intersection of a less important road with a main road where application of the normal right-of-way rule would not be expected to provide reasonably safe operation
2. Where a street enters a through highway or street
3. At an unsignalized intersection in a signalized area
4. At other intersections where a combination of high speed, restricted view, and crash records indicate a need for control by a STOP sign

Traffic control signals should not be installed unless at least one of several signal warrants is met (the *Manual* defines eight warrants). Eleven signal warrants are used to account for such factors as traffic volume, crash experience, school crossings, and pedestrian volumes. In addition to a review of these warrants, an engineering study should be conducted to show that the installation of such a signal would improve the overall safety and operation of the intersection.

Consideration should be given to other, less restrictive measures before these warrants are applied.

Coordinated System Operations

The efficient operation of a road network requires more than simply placing traffic control devices at warranted locations. A regional road network for a modern metropolitan area consists of many different road types, whose jurisdiction is shared by numerous different organizations. One of the key challenges facing many metropolitan areas today is coordinating the many different responsibilities for operating a regional road network. This can be accomplished through ad hoc working groups focusing on specific operations strategies (e.g., coordinating traffic signals across jurisdictions) or by the creation of a regional entity with a legislative mandate to operate all transportation services in a region (much more common in countries other than the U.S.). In the U.S., some of the strategies used to coordinate system operations include:

1. Standardized strategies to be implemented in response to expected incidents or events
2. Shared databases and information retrieval
3. Corridor teams that focus on network operations
4. Regional programs, e.g., incident management efforts or traffic signal coordination, which target key determinants of system performance
5. Regional traffic management centers that collect data on system performance and provide information and guidance to road network users
6. Formal information and technological systems architecture that specifies protocols and processes for computer-supported approaches to system operations

With the advent of more powerful computers and improved sensors, it seems likely that future developments in coordinated system operations will to a large extent rely on the application of advanced technology.

Environmental Impacts

One of the most important characteristics of transportation system performance is the corresponding impact on the natural and human environment. This impact occurs not only during the construction of transportation facilities themselves but also from the resulting operations. For example, automobile travel in many urban areas is a primary source of many air pollutants. In terms of energy consumption, total auto travel accounts for approximately 25% of U.S. oil consumption, with about two-thirds of this consumption occurring in urban areas. Table 10.3.1 shows the environmental impacts that are of concern to transportation officials. Of those shown, the impacts that are directly linked to the operations of a facility or transportation system include air quality, noise, vibration, stormwater, energy consumption, and ecological effects.

It is often difficult to determine the best operations strategy for minimizing these impacts. For example, the air quality impacts of motor vehicles are a function of the number, type, and condition of vehicles on the highway and of the speed and efficiency with which these vehicles operate. Carbon monoxide, hydrocarbons, and oxides of nitrogen are the primary pollutants emitted by vehicular traffic. The level of emission of each pollutant is complicated and difficult to predict. In general, the emission of carbon monoxide and hydrocarbons is minimized at speeds between 35 and 45 mi/h, whereas the emission of oxides of nitrogen increases over this speed range. Therefore, there is no ideal speed at which the level of emission of all three pollutants will be minimized. Nevertheless, smoothly flowing traffic will tend to produce less pollution, and, therefore, whatever can be done to reduce delay and congestion — especially when combined with a reduction in total vehicle miles traveled — will result in an improvement in air quality.

TABLE 10.3.1 Transportation System Impacts of Concern to Transportation Officials

Natural System Impacts	Social and Cultural Impacts
Terrestrial ecology (habitats and animals)	Historic and archaeological
Aquatic ecology (habitats and animals)	Displacement of people
	Community cohesion
Physical Impacts	Resource consumption
Air quality	Land use
Noise	Aesthetics
Vibration	Infrastructure effects
Water quality	Accessibility of facilities, services, and jobs
Hazardous wastes	Environmental justice
Stormwater	Employment, income, and business activity
Energy consumption	
Erosion and sedimentation	
Farmland conversion	

The reader is referred to the following site for information on the many environmental impacts that are of concern to transportation officials: http://www.fhwa.dot.gov/environment/index.htm

Defining Terms

Capacity: A maximum flow of vehicles or persons at a specific location, given the characteristics of the facility.

Density (*k*): Number of vehicles or persons occupying a given length of a facility at an instant in time; usually expressed as veh/mi or veh/km for vehicles and persons/ft^2 or persons/m^2 for individuals.

Flow (*q*): Time rate of flow of facility users; usually expressed as veh/h or passenger/h.

Level of service (LOS): The quality of movement experienced by the users of a facility in a traffic stream; usually expressed in terms of the freedom of movement of facility users, ranging from little or no restriction (LOS A) to stopped flow (LOS F).

Speed (*u*): Average speed of vehicles in a traffic stream; usually expressed as miles per hour (mph) or kilometers per hour (kph).

Traffic control devices: Signs, signals, and pavement markings placed on streets or highways to guide, inform, or regulate the movement of vehicles on those facilities.

10.4 Transportation Systems

Paul Schonfeld

The various forms of transportation that have been developed over time are called **modes**. The classification of modes may be very broad (e.g., highway transportation or air transportation) or more restrictive (e.g., chartered helicopter service). The major distinctions among transportation modes that help to classify them include:

1. Medium (e.g., air, space, surface, underground, water, underwater)
2. Users (e.g., passengers vs. cargo, general-purpose vs. special trips or commodities, common vs. private carrier)
3. Service type (scheduled vs. **demand responsive**, fixed vs. variable route, nonstop vs. express or local, mass vs. personal)
4. Right-of-way type (exclusive, semi-exclusive, shared)
5. Technology:
   a. Propulsion (e.g., electric motors, diesel engines, gas turbines, linear induction motors, powered cables)
   b. Energy sources (e.g., petroleum fuels, natural gas, electric batteries, electric power from conducting cables)
   c. Support (e.g., aerodynamic lift, flotation on water, steel wheels on two steel rails, monorails, air cushions, magnetic levitation, suspension from cables)
   d. Local control (e.g., lateral control by steering wheels, wheel flanges on railroad vehicles, rudders, longitudinal control by humans or automatic devices)
   e. Network guidance and control systems (with various degrees of automation and optimization)

A mode may be defined by its combination of such features. The number of conceivable combinations greatly exceeds the number of modes that have been actually tried, which, in turn, exceeds the number of successful modes. Success may be limited to relatively narrow markets and applications (e.g., for helicopters or aerial cablecars) or may be quite general. Thus, automobiles are successful in a very broad range of applications and have become the basis for distinct transportation modes such as taxis, carpools, or ambulances.

The relative success of various transportation modes depends on available technology and socioeconomic conditions at any particular time, as well as on geographic factors. As technology or socioeconomic conditions change, new transportation modes appear, develop, and may later decline as more effective competitors appear. For many centuries water transportation was considerably cheaper than overland transportation. Access to waterways was quite influential in the location of economic activities and cities. Access to good transportation is still very important to industries and communities. Technological developments have so drastically improved the relative effectiveness of air transportation that within a short period (approximately 1950 to 1965) aircraft almost totally replaced ships for transporting passengers across oceans. It is also notable that as economic prosperity grows, personal transportation tends to shift from the walking mode to bicycles, motorcycles, and then automobiles. Geography can significantly affect the relative attractiveness of transportation modes. Thus, natural waterways are highly valuable where they exist. Hilly terrain decreases the economic competitiveness of artificial waterways or conventional railroads while favoring highway modes. In very mountainous terrain even highways may become uncompetitive compared to alternatives such as helicopters, pipelines, and aerial cablecars.

The relative shares of U.S. intercity passenger and freight traffic are shown in Table 10.4.1. The table shows the relative growth since 1929 of airlines, private automobiles, and trucks and the relative decline of railroad traffic.

Transportation System Components

The major components of transportation systems are:

1. Links
2. Terminals
3. Vehicles
4. Control systems

Certain "continuous-flow" transportation systems such as pipelines, conveyor belts, and escalators have no discrete vehicles and, in effect, combine the vehicles with the link.

Transportation systems may be developed into extensive networks. The networks may have a hierarchical structure. Thus, highway networks may include freeways, arterials, collector streets, local streets, and driveways. Links and networks may be shared by several transportation modes (e.g., cars, buses, trucks, taxis, bicycles, and pedestrians on local streets). Exclusive lanes may be provided for particular modes (e.g., pedestrian or bicycles) or groups of modes (e.g., buses and carpools).

Transportation terminals provide interfaces among modes or among vehicles of the same mode. They may range from marked bus stops or truck loading zones on local streets to huge airports or ports.

Evaluation Measures

Transportation systems are evaluated in terms of their effects on their suppliers, users, and environment. Both their costs and benefits may be classified into supplier, user, and external components. Private transportation companies normally seek to maximize their profits (i.e., total revenues minus total supplier costs). Publicly owned transportation agencies should normally maximize net benefits to their jurisdictions, possibly subject to financial constraints.

From the supplier's perspective, the major indicators of performance include measures of **capacity** (maximum throughput), speed, **utilization rate** (i.e., fraction of time in use), **load factor** (i.e., fraction of maximum payload actually used), energy efficiency (e.g., Btu per ton-mile or per passenger mile), and labor productivity (e.g., worker hours per passenger mile or per ton-mile). Measures of environmental impact (e.g., noise decibels or parts of pollutant per million) are also increasingly relevant. To users, price and service quality measure, including travel time, wait time, access time, reliability, safety, comfort (ride quality, roominess), simplicity of use, and privacy are relevant in selecting modes, routes, travel times, and suppliers.

Air Transportation

Air transportation is relatively recent, having become practical for transporting mail and passengers in the early 1920s. Until the 1970s its growth was paced primarily by technological developments in propulsion, aerodynamics, materials, structures, and control systems. These developments have improved its speed, load capacity, energy efficiency, labor productivity, reliability, and safety, to the point where it now dominates long-distance mass transportation of passengers overland and practically monopolizes it over oceans. Airliners have put ocean passenger liners out of business because they are much faster and also, remarkably, more fuel and labor efficient. However, despite this fast growth, the cargo share of air transportation is still small.

For cargoes that are perishable, high in value, or urgently needed, air transportation is preferred over long distances. For other cargo types, ships, trucks, and railroads provide more economical alternatives. In the 1990s, the nearest competitors to air cargo are containerships over oceans and trucks over land. For passengers, air transportation competes with private cars, trains, and intercity buses over land, with practically no competitors over oceans. The growth of air transportation has been restricted to some extent by the availability of adequate airports, by environmental concerns (especially noise), and by the fear of flying of some passengers.

There are approximately 10,000 commercial jet airliners in the world, of which the largest (as of 1997) are Boeing B-747 types, of approximately 800,000 lb gross takeoff weight, with a capacity of 550 passengers. The economical cruising speed of these and smaller "conventional" (i.e., **subsonic**) airliners has stayed at around 560 mph since the late 1950s. A few supersonic transports (SSTs) capable of cruising at approximately 1300 mph were built in the 1970s (the Anglo-French Concorde and the Soviet Tu-144) but, due to high capital and fuel costs, were not economically successful. About eight Concorde SSTs are still operating, with government subsidies.

The distance that an aircraft can fly depends on its payload, according to the following equation:

$$R = \frac{V}{c'}\left(\frac{L}{D}\right)\ln\left(W_{\mathrm{TO}}/W_L\right) \tag{10.4.1}$$

where

R = range (mi)
c' = specific fuel consumption (lb fuel/lb thrust × h)
(L/D) = lift-to-drag ratio (dimensionless)
W_{TO} = aircraft takeoff weight (lb) = $W_L + W_F$
W_L = aircraft landing weight (lb) = $W_E + W_R + P$
W_E = aircraft empty weight (lb)
W_R = reserve fuel weight (lb)
W_F = consumed fuel weight (lb)
P = payload (lb)

This equation assumes that the difference between the takeoff weight and landing weight is the fuel consumed. For example, suppose that for a Boeing B-747 the maximum payload carried (based on internal fuselage volume and structural limits) is 260,000 lb, maximum W_{TO} is 800,000 lb, $W_R = 15{,}000$ lb, $W_E = 370{,}000$, $L/D = 17$, $V = 580$ mph, and $c' = 0.65$ lb/lb thrust × h. The resulting weight ratio [$W_{\mathrm{TO}}/W_L = 800/(370 + 15 + 260)$] is 1.24 and the range R is 3267 mi. Payloads below 260,000 lb allow greater ranges.

Most airline companies fly scheduled routes, although charter services are common. U.S. airlines are largely free to fly whatever routes (i.e., origin–destination pairs) they prefer in the United States. In most of the rest of the world, authority to serve particular routes is regulated to negotiated by international agreements. The major components of airline costs are direct operating costs (e.g., aircraft depreciation or rentals, aircrews, fuel, and aircraft maintenance) and indirect operating costs (e.g., reservations, advertising and other marketing costs, in-flight service, ground processing of passengers and bags, and administration).

The efficiency and competitiveness of airline service is heavily dependent on efficient operational planning. Airline scheduling is a complex problem in which demand at various times and places, route authority, aircraft availability and maintenance schedules, crew availability and flying restrictions, availability of airport gates and other facilities, and various other factors must all be considered. Airline management problems are discussed in (Wells, 1984).

Airports range from small unmarked grass strips to major facilities requiring many thousands of acres and billions of dollars. Strictly speaking, an airport consists of an airfield (or "airside") and terminal (or "landside"). Airports are designed to accommodate specified traffic loads carried by aircraft up to a "design aircraft," which is the most demanding aircraft to be accommodated. The design aircraft might determine such features as runway lengths, pavement strengths, or terminal gate dimensions at an airport. Detailed guidelines for most aspects of airport design (e.g., runway lengths and other airfield dimensions, pavement characteristics, drainage requirements, allowable noise and other environmental impacts, allowable obstruction heights, lighting, markings, and signing) are specified by the U.S. Federal Aviation Administration (FAA) in a series of circulars.

Airport master plans are prepared to guide airport growth, usually in stages, toward ultimate development. These master plans:

1. Specify the airport's requirements.
2. Indicate a site if a new airport is considered.
3. Provide detailed plans for airport layout, land use around the airport, terminal areas, and access facilities.
4. Provide financial plans, including economic and financial feasibility analysis.

Major new airports tend to be very expensive and very difficult to locate. Desirable airport sites must be reasonably close to the urban areas they serve yet far enough away to ensure affordable land and acceptable noise impacts. Many other factors—including airspace interference with other airports, obstructions (e.g., hills, buildings), topography, soil, winds, visibility, and utilities—must be reconciled. Hence, few major new airports are being built, and most airport engineering and planning work in the United States is devoted to improving existing airports. Governments sometimes develop multi-airport system plans for entire regions or countries.

National agencies (such as the FAA in the United States) are responsible for traffic control and airspace management. Experienced traffic controllers, computers, and specialized sensors and communication systems are required for this function. Increasingly sophisticated equipment has been developed to maintain safe operations even for crowded airspace and poor visibility conditions. For the future we can expect increasing automation in air traffic control, relying on precise aircraft location with global positioning satellite (GPS) systems and fully automated landings. Improvements in the precision and reliability of control systems are increasing (slowly) the capacity of individual runways as well as the required separation among parallel runways, allowing capacity increases in restricted airport sites.

Railroad Tranportation

The main advantages of railroad technology are low frictional resistance and automatic lateral guidance. The low friction reduces energy and power requirements but limits braking and hill-climbing abilities. The lateral guidance provided by wheel flanges allows railroad vehicles to be grouped into very long trains, yielding economies of scale and, with adequate control systems, high capacities per track. The potential energy efficiency and labor productivity of railroads is considerably higher than for highway modes, but is not necessarily realized, due to regulations, managerial decisions, demand characteristics, or terrain.

The main competition of railroads include automobiles, aircraft, and buses for passenger transportation, and trucks, ships, and pipelines for freight transportation. To take advantage of their scale economies, railroad operators usually seek to combine many shipments into large trains. Service frequency is thus necessarily reduced. Moreover, to concentrate many shipments, rail cars are frequently re-sorted into different trains, rather than moving directly from origin to destination, which results in long periods spent waiting in classification yards, long delivery times, and poor vehicle utilization. An alternative operational concept relying on direct nonstop “unit trains” is feasible only when demand is sufficiently large between an origin–destination pair.

Substantial traffic is required to cover the relatively high fixed costs of railroad track. Moreover, U.S. railroads, which are privately owned, must pay property taxes on their tracks, unlike their highway competitors. By 1920 highway developments had rendered low-traffic railroad branch lines noncompetitive in the United States. Abandonment of such lines has greatly reduced the U.S. railroad network, even though the process was retarded by political regulation.

The alignment of railroad track is based on a compromise between initial costs and operating costs. The latter are reduced by a more straight and level alignment, which requires more expensive earthwork, bridges, or tunnels. Hay (1982) provides design guidelines for railroads.

In general, trains are especially sensitive to gradients. Thus, compared to highways, railroad tracks are more likely to go around rather than over terrain obstacles, which increases the **circuity factors** for railroad transportation.

The resistance for railroad vehicles may be computed using the Davis equation (Hay, 1982):

$$r = 1.3 + 29/w + bV + CAV^2/wn + 20G + 0.8D \tag{10.4.2}$$

where

G = gradient (%)
D = degree of curvature
r = unit resistance (lb of force per ton of vehicle weight)
w = weight (tons per axle of car or locomotive)
n = number of axles
b = coefficient of flange friction, swaying, and concussion (0.045 for freight cars and motor cars in trains, 0.03 for locomotives and passenger cars, and 0.09 for single-rail cars)
C = drag coefficient of air [0.0025 for locomotives (0.0017 for streamlined locomotives) and single- or head-end-rail cars, 0.0005 for freight cars, and 0.00034 for trailing passenger cars, including rapid transit]
A = cross-sectional area of locomotives and cars (usually 105 to 120 ft^2 for locomotives, 85 to 90 ft^2 for freight cars, 110-120 ft^2 for multiple-unit and passenger cars, and 70 to 110 ft^2 for single- or head-end-rail cars)
V = speed (mph)

The coefficients shown for this equation reflect relatively old railroad technology and can be significantly reduced for modern equipment (Hay, 1982). The equation provides the unit resistance in pounds of force per ton of vehicle weight. The total resistance of a railroad vehicle (in lb) is

$$R_v = rwn \tag{10.4.3}$$

The total resistance of a train R is the sum of resistances for individual cars and locomotives. The rated horsepower (hp) required for a train is:

$$\text{hp} = \frac{RV}{375\eta} \tag{10.4.4}$$

where η = transmission efficiency (typically about 0.83 for a diesel electric locomotive).

The hourly fuel consumption for a train may be computed by multiplying hp by a specific fuel consumption rate (approximately 0.32 lb/hp × h for a diesel electric locomotive).

Diesel electric locomotives with powers up to 5000 hp haul most trains in the United States. Electric locomotion is widespread in other countries, especially those with low petroleum reserves. It is especially competitive on high-traffic routes (needed to amortize electrification costs) and for high-speed passenger trains. Steam engines have almost disappeared.

The main types of freight rail cars are box cars, flat cars (often used to carry truck trailers or intermodal containers), open-top gondola cars, and tank cars. Passenger trains may include restaurant cars and sleeping cars. Rail cars have tended toward increasing specialization for different commodities carried, a trend that reduces opportunities for back hauls. Recently, many "double-stack" container cars have been built to carry two tiers of containers. Such cars require a vertical clearance of nearly 20 ft, as well as reduced superelevation (banking) on horizontal curves. In the United States standard freight rail cars with gross weights up to 315,000 lb are used.

High-speed passenger trains have been developed intensively in Japan, France, Great Britain, Italy, Germany, and Sweden. The most advanced (in 1995) appear to be the latest French TGV versions, with cruising speeds of 186 mph and double-deck cars. At such high speeds, trains can climb long, steep grades (e.g., 3.5%) without slowing down much. Construction costs in hilly terrain can thus be significantly reduced. Even higher speeds are being tested in experimental railroad and magnetic levitation (MAGLEV) trains.

Highway Transportation

Highways provide very flexible and ubiquitous transportation for people and freight. A great variety of transportation modes, including automobiles, buses, trucks, motorcycles, bicycles, pedestrians, animal-drawn vehicles, taxis, and carpools, can share the same roads. From unpaved roads to multilane freeways, roads can vary enormously in their cost and performance. Some highway vehicles may even travel off the roads in some circumstances. The vehicles also range widely in cost and performance, and at their lower range (e.g., bicycles) are affordable for private use even in poor societies.

Flexibility, ubiquity, and affordability account for the great success of highway modes. Personal vehicles from bicycles to private automobiles offer their users great freedom and access to many economic and social opportunities. Trucks increase the freedom and opportunities available to farmers and small businesses. Motor vehicles are so desirable and affordable that in the United States the number of registered cars and trucks approximates the number of people of driving age. Other developed countries are approaching the same state despite strenuous efforts to discourage motor vehicle use.

The use of motor vehicles brings significant problems and costs. These include:

1. Road capacity and congestion. Motor vehicles require considerable road space, which is scarce in urban areas and costly elsewhere. Shortage of road capacity results in severe congestion and delays.
2. Parking availability and cost.
3. Fuel consumption. Motor vehicles consume vast amounts of petroleum fuels. Most countries have to import such fuels and are vulnerable to price increases and supply interruptions.
4. Safety. The numbers of people killed and injured and the property damages in motor vehicle accidents are very significant.
5. Air quality. Motor vehicles are major contributors to air pollution.
6. Regional development patterns. Many planners consider the low-density "sprawl" resulting from motor vehicle dominance to be inefficient and inferior to the more concentrated development produced by mass transportation and railroads.

In the United States trucks have steadily increased their share of the freight transportation market, mostly at the expense of railroads, as shown in Table 10.4.1. They can usually provide more flexible, direct, and responsive service than railroads, but at higher unit cost. They are intermediate between rail and air transportation in both cost and service quality. With one driver required per truck, the labor productivity is much lower than for railroads, and there are strong economic incentives to maximize the load capacity for each driver. Hence, the tendency has been to increase the number, dimensions, and weights allowed for trailers in truck-trailer combinations, which requires increased vertical clearances (e.g., bridge overpasses), geometric standards for roads, and pavement costs.

The main reference for highway design is the AASHTO manual [AASHTO, 1990]. For capacity, the main reference is the Transportation Research Board *Highway Capacity Manual* (TRB, 1985). Extensive software packages have been developed for planning, capacity analysis, geometric design, and traffic control.

Water Transportation

Water transportation may be classified into (1) marine transportation across seas and (2) inland waterway transportation; their characteristics differ very significantly. Inland waterways consist mostly of rivers, which may be substantially altered to aid transportation. Lakes and artificial canals may also be part of inland waterways. Rivers in their natural states are often too shallow, too fast, or too variable in their flows. All these problems may be alleviated by impounding water behind dams at various intervals. (This also helps generate electric power.) Boats can climb or descend across dams by using **locks** or other elevating systems (Hochstein, 1981). In the U.S. inland waterway network there are well over 100 major lock structures, with chambers up to 1200 ft long and 110 ft wide. Such chambers allow up to 18 large barges (35 × 195 ft) to be raised or lowered simultaneously.

In typical inland waterway operations, large diesel-powered “towboats” (which actually push barges) handle a rigidly tied group of barges (a “tow”). Tows with up to 48 barges (35 × 195 ft, or about 1300 tons per barge) are operated on the lower Mississippi, where there are no locks or dams. On other rivers, where locks are encountered at frequent intervals, tow sizes are adjusted to fit through locks. The locks constitute significant bottlenecks in the network, restricting capacity and causing significant delays.

Table 10.4.1 indicates that the waterway share of U.S. freight transportation has increased substantially in recent years. This is largely attributable to extensive improvements to the inland waterway system undertaken by the responsible agency, the U.S. Army Corps of Engineers.

The main advantage of both inland waterway and marine transportation is low cost. The main disadvantage is relatively low speed. Provided that sufficiently deep water is available, ships and barges can be built in much larger sizes than ground vehicles. Ship costs increase less than proportionally with ship size, for ship construction, crew, and fuel. Energy efficiency is very good at low speeds [e.g., 10–20 knots (nautical mi/h)]. However, at higher speeds the wave resistance of a conventional ship increases with the fourth power of speed (V^4). Hence, the fuel consumption increases with V^4 and the power required increases with V^5. Therefore, conventional-displacement ships almost never exceed 30 knots in commercial operation. Higher practical speed may be obtained by lifting ships out of the water on hyrdrofoils or air cushions. However, such unconventional marine vehicles have relatively high costs and limited markets at this time, ships have increased in size and specialization. Crude oil tankers of up to 550,000 tons (of payload) have been built. Tankers carrying fluids are less restricted in size than other ships because they can pump their cargo from deep water offshore without entering harbors. Bulk carriers (e.g., for coal, minerals, or grains) have also been built in sizes exceeding 300,000 tons. They may also be loaded through conveyor belts built over long pier structures to reach deep water. General cargo ships and containerships are practically always handled at shoreline berths and require much storage space nearby.

The use of intermodal containers has revolutionized the transportation of many cargoes. Such containers greatly reduce the time and cost required to load and unload ships. Up to 4500 standard 20-ft containers (20 × 8 × 8 ft) can be carried at a speed of about 24 knots on recently built containerships.

Port facilities for ships should provide shelter from waves and sufficiently deep water, including approach channels to the ports. In addition, ports should provide adequate terminal facilities, including loading and unloading equipment, storage capacity, and suitable connections to other transportation networks. Ports often compete strenuously with other ports and strive to have facilities that are at least equal to those of competitors. Since ports generate substantial employment and economic activities, they often receive financial and other support from governments.

Geography limits the availability of inland waterways and the directness of ship paths across oceans. Major expensive canals (e.g., Suez, Panama, Kiel) have been built to provide shortcuts in shipping routes. These canals may be so valuable that ship dimensions are sometimes compromised (i.e., reduced) to fit through these canals. In some parts of the world (e.g., Baltic Sea, North Sea, most U.S. coasts) the waters are too shallow for the largest ships in existence. Less efficient, smaller ships must be used there. The dredging of deeper access channels and ports can increase the allowable ship size, if the costs and environmental impacts are considered acceptable.

Public Transportation

Public transportation is the term for ground passenger transportation modes available to the general public. It connotes public availability rather than ownership. "Conventional" public transportation modes have fixed routes *and* fixed schedules and include most bus and rail transit services. "Unconventional" modes (also labeled "paratransit") include taxis, carpools and van pools, rented cars, dial-a-ride services, and subscription services.

The main purposes of public transportation services, especially conventional mass transportation services in developed countries, are to provide mobility for persons without automobiles (e.g., children, poor, nondrivers); to improve the efficiency of transportation in urban areas; to reduce congestion effects, pollution, accidents, and other negative impacts of automobiles; and to foster preferred urban development patterns (e.g., strong downtowns and concentrated rather than sprawled development).

Conventional services (i.e., bus and rail transit networks) are quite sensitive to demand density. Higher densities support higher service frequencies and higher network densities, which decrease user wait times and access times, respectively. Compared to automobile users, bus or rail transit users must spend extra time in access to and from stations and in waiting at stations (including transfer stations). Direct routes are much less likely to be available, and one or more transfers (with possible reliability problems) may be required. Thus, mass transit services tend to be slower than automobiles unless exclusive rights-of-way (e.g., bus lanes, rail tunnels) can favor them. Such exclusive rights-of-way can be quite expensive if placed on elevated structures or in tunnels. Even when unhindered by traffic, average speeds may be limited by frequent stops and allowable acceleration limits for standing passengers. Prices usually favor mass transit, especially if parking for automobiles is scarce and expensive.

The capacity of a transit route can be expressed as:

$$C = FLP \tag{10.4.5}$$

where

C = one-way capacity (passengers/hour) past a certain point
F = service frequently (e.g., trains/hour)
L = train length (cars/train)
P = passenger capacity of cars (spaces/car)

For rail transit lines where high capacity is needed in peak periods, C can reach 100,000 passengers/hour (i.e., 40 trains/hour × 10 cars/train × 250 passenger spaces/car). There are few places in the world where such capacities are required. For a bus line the train length L would usually be 1.0. If no on-line stops are allowed, an exclusive bus lane also has a large capacity (e.g., 1000 buses/hour × 90 passenger spaces/bus), but such demand levels for bus lanes have not been observed.

The average wait time of passengers on a rail or bus line depends on the headways, which is the interval between successive buses or trains. This can be approximated by:

$$\overline{W} = \overline{H}/2 + \mathrm{var}(H)/2\overline{H} \tag{10.4.6}$$

where

$\overline{W}$ = average wait time (e.g., minutes)
$\overline{H}$ = average headway (e.g., minutes)
$\mathrm{var}(H)$ = variance of headway (e.g., minutes^2)

It should be noted that the headway is the inverse of the service frequency.

The number of vehicles N required to serve a route is:

$$N = RFL \tag{10.4.7}$$

where R = vehicle round trip time on route (e.g., hours).

The effectiveness of a public transportation system depends on many factors, including demand distribution and density, network configuration, routing and scheduling of vehicles, fleet management, personnel management, pricing policies, and service reliability. Demand and economic viability of services also depend on how good and uncongested the road system is for automobile users.

Engineers can choose from a great variety of options for propulsion, support, guidance and control, vehicle configurations, facility designs, construction methods, and operating concepts. New information and control technology can significantly improve public transportation systems. It will probably foster increased automation and a trend toward more personalized (i.e., taxilike) service rather than mass transportation.

Defining Terms

Capacity: The maximum flow rate that can be expected on a transportation facility. “Practical” capacity is sometimes limited by “acceptable:” delay levels, utilization rates, and load factors.

Circuity factor: Ratio of actual distance on network to shortest airline distance.

Delay: Increase in service time due to congestion or service interruptions.

Demand-responsive: A mode whose schedule or route is adjusted in the short term as demand varies, such as taxis, charter airlines, and “TRAMP” ships.

Load factor: Fraction of available space or weight-carrying capability that is used.

Lock: A structure with gates at both ends which is used to lift or lower ships or other vessels.

Modes: Distinct forms of transportation.

Subsonic: Flying below the speed of sound (Mach 1), which is approximately 700 mph at cruising altitudes of approximately 33,000 ft.

Utilization rate: Fraction of time that a vehicle, facility, or equipment unit is in productive use.

Further Information

The ITE Handbook (Homburger, 1992) and Morlok (1978) cover most transportation modes. Horonjeff and McKelvey (1994), Hay (1982). Wright and Paquette (1987), Brun (1981), and Vuchic (1981) are more specialized textbooks covering airports, railroads, highways, ports, and urban public transportation systems, respectively. Periodicals such as *Aviation Week & Space Technology, Railway Age, Motor Ship, and Mass Transit* cover recent developments in their subject areas.

10.5 Alternative Fuels for Motor Vehicles

Paul Norton and Wendy Clark

Overview

Motor vehicle fuels that provide an alternative to conventional gasoline or diesel include ethanol, methanol, natural gas, propane, electricity, and biodiesel. Legislation such as the Clean Air Act Amendments of 1990 (CAAA) and the Energy Policy Act of 1992 (EPACT) has increased interest in alternative fuels. This legislation promotes alternative fuels for their potential to decrease emissions from cars and trucks and lessen the dependence of the United States on imported petroleum. These fuels may also have benefits in terms of reduced emissions of global warming gases.

Modifications must be made to conventional vehicles to use many of these alternative fuels. However, all are burned in internal combustion engines similar to those used for conventional gasoline or diesel fuel. Notable exceptions are 10% ethanol/gasoline blends and 20% biodiesel/diesel blends that require no engine or fuel system modifications. The engine and fuel system must be modified to account for the properties of the alternative fuel. The components that are typically added or changed to transform a gasoline vehicle into a compressed natural gas vehicle are shown in Figure 10.5.1. A major challenge is finding space on the vehicles for enough gas cylinders to give the vehicle an acceptable range between refuelings. These cylinders store the natural gas at pressures of 3000 to 3600 psi and must be protected from road debris and corrosive substances such as battery acid.

In light-duty "flexible-fueled" or "variable-fueled" vehicles, ethanol and methanol is blended with gasoline in the vehicle's fuel tank. The car can be fueled on any mix of the specified alcohol and gasoline

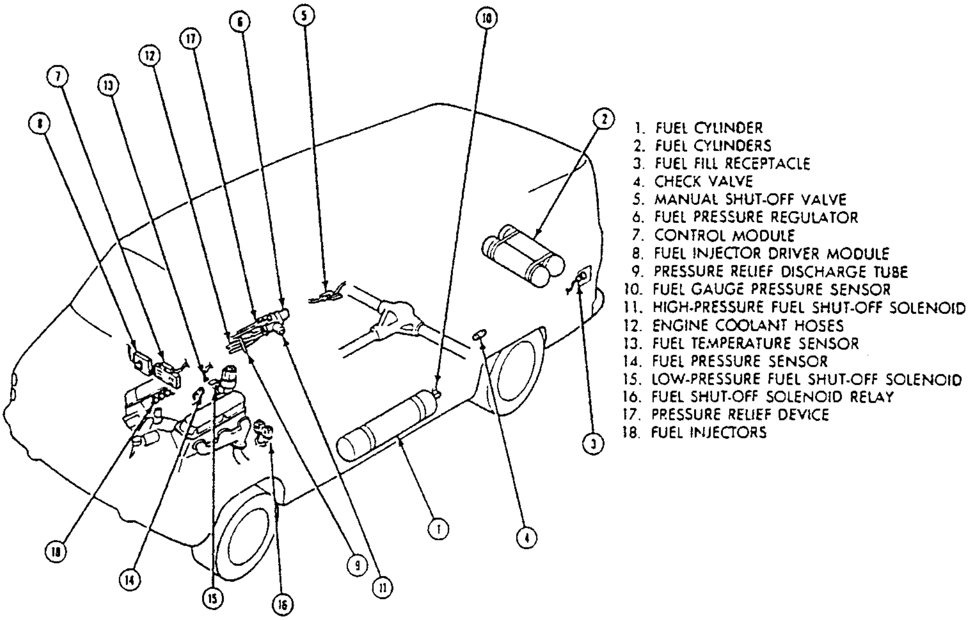

FIGURE 10.5.1 Typical Components of a compressed natural gas vehicle.

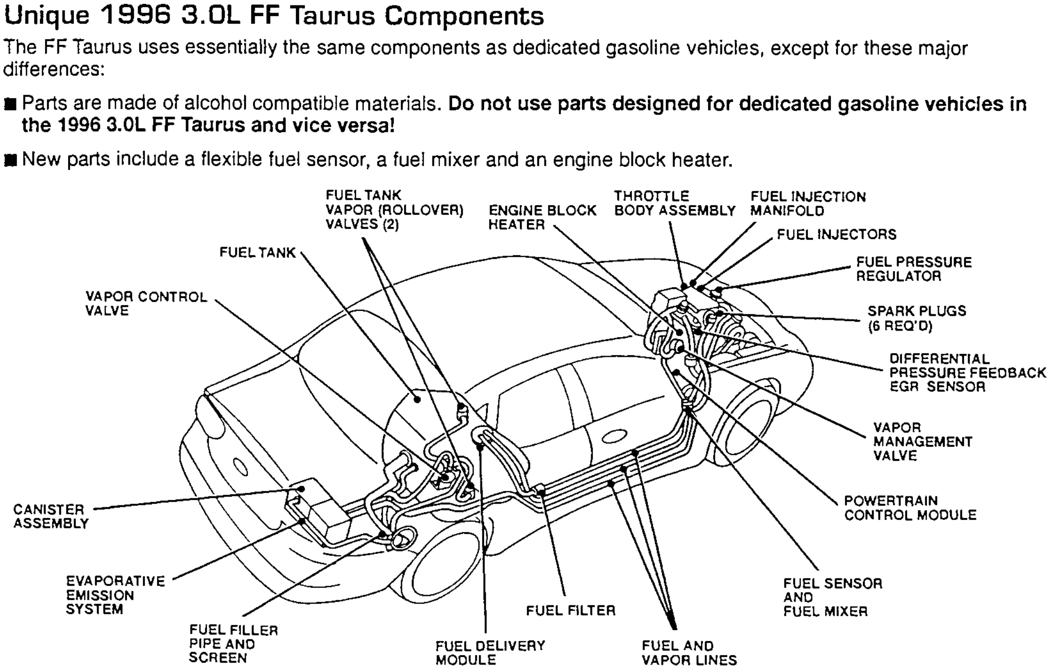

Unique 1996 3.0L FF Taurus Components

The FF Taurus uses essentially the same components as dedicated gasoline vehicles, except for these major differences:

- Parts are made of alcohol compatible materials. **Do not use parts designed for dedicated gasoline vehicles in the 1996 3.0L FF Taurus and vice versa!**
- New parts include a flexible fuel sensor, a fuel mixer and an engine block heater.

FIGURE 10.5.2 Components of a flexible fuel vehicle.

up to 85% alcohol. Therefore an ethanol flexible-fueled vehicle (FFV) could be fueled on 85% ethanol (E85) at one refueling, and pure gasoline at the next. A sensor in the fuel line constantly measures the percentage of ethanol in the fuel and the engine control system adjusts the air/fuel ratio accordingly. The typical unique components in an FFV are shown in Figure 10.5.2. All components in the fuel system must be compatible with ethanol or methanol. The fuel injectors must have a higher flow capacity to account for the lower heating value of ethanol and methanol compared to gasoline.

Vehicles can be modified to run on an alternative fuel by the original manufacturer (OEM) or they can be modified by an aftermarket conversion shop. In general, alternative fuel vehicles produced by an OEM go through a much more rigorous development and testing process than an aftermarket conversion. The alternative fuel system for the OEM vehicle is designed for one specific model of vehicle or engine, whereas the aftermarket conversion is designed to fit on a wide variety of vehicles. Therefore the OEM system can be optimized for the one vehicle it was designed for, but the aftermarket conversion kit must be a compromise that will work with many different vehicles. Today's cars and trucks are highly developed and difficult to improve upon. Recent studies have found that compressed natural gas and propane aftermarket conversions had higher emissions in some regulated properties than they did on gasoline before the conversions (Motta et al., 1996). The same study points out that tests on OEM compressed natural gas cars showed substantially lower levels of all four regulated emissions than their gasoline powered counterparts.

Advantages and Disadvantages of Alternative Fuels

Each alternative fuel has unique physical properties that lead to advantages and disadvantages compared to conventional fuels and to each other. All the alternative fuels contain less energy per unit volume than gasoline or diesel fuel. This leads to the need to store more fuel on the vehicle to achieve the same operating range between refuelings. In many cases, this disadvantage is balanced by lower fuel cost and/or lower emissions than a gasoline or diesel vehicle. A summary of some of the properties of the most popular alternative fuels is shown in Table 10.5.1. Some of the advantages and disadvantages of using these fuels are outlined in Table 10.5.2.

TABLE 10.5.1 Properties of Conventional and Alternative Fuels

Fuel	Cetane Number	Research Octane Number	Motor Octane Number	Density (lb/gal)	LHV[a] (Btu/gal)	LHV[a] Btu/lb)	DEE[b] Gallons	DEE[b] Pounds
Liquids at atm. Pressure								
100% Ethanol		109	90	6.6	75600	11500	0.59	0.66
85% Ethanol (E85)	—	105	89	6.5	83600	12855	0.64	0.72
10% Ethanol/gasoline	—	96.5	86	6.1	111000	18000	0.86	1.39
10% Ethanol/diesel	45	—	—	7.0	123000	17500	0.95	1.01
100% Methanol	approx. 5	109	89	6.7	56200	8400	0.44	0.48
100% (Soy methyl-ester) 20% Biodiesel (B20)	49			7.3	120200	16500	0.93	0.95

[a] Lower heating value.

[b] Diesel energy equivalent = the LHV of the alternative fuel divided by the LHV of #2 Diesel = the number of gallons (or pounds) of diesel fuel that has the same energy content as one gallon (or pound) of the alternative fuel.

[c] Average values for natural gas in the United States.

[d] 100% Methane at –263°F.

TABLE 10.5.2 Advantages and Disadvantages of Alternative Fuels

Fuel	Advantages	Disadvantages
Liquefied Petroleum Gas (LPG) Liquefied petroleum gas is the most widely used alternative fuel. In the U.S., LPG is mostly propane with small amounts of butane and ethane. In 1993, an estimated 350,000 vehicles powered by propane (mostly conversions) were plying the nation's highways.	• Most widely available alternative fuel with an estimated 11,000 refueling sites nationwide • LPG is nontoxic • Liquefies at relatively low pressures • One gallon of liquefied propane has about 70% energy content of gasoline • Can reduce carbon monoxide and ozone forming hydrocarbon emissions • Refueling stations are relatively inexpensive	• 45% of LPG in the U.S. is derived from oil • Proper detection and ventilation are required for indoor storage and maintenance of vehicles • Starting problems may occur at very low temperatures due to low vapor pressure • Perception of a safety problem
Compressed Natural Gas (CNG) Natural gas is composed primarily of methane. It is stored on the vehicle under 3000 to 4000 psi of pressure. There are currently (2001) an estimated 110,000 vehicles operating on compressed natural gas in U.S. fleets.	• High North American resource base • Natural gas reserves are more globally distributed than oil reserves • Can reduce all regulated emissions • Is especially effective in reducing particulate emissions from large trucks • Less expensive than gasoline in some areas • Eliminates evaporative emissions because the fuel system is sealed • Can be produced from renewable resources at high cost	• Requires bulky pressure cylinders and high pressure fuel lines • Fuel system costs as much as $2500 more than gasoline for cars • Refueling infrastructure is expensive • Energy storage density is low, making it difficult to achieve equivalent range • Composition of natural gas varies regionally

TABLE 10.5.2 Advantages and Disadvantages of Alternative Fuels (continued)

Fuel	Advantages	Disadvantages
Methanol Methanol is an alcohol which can be produced from coal, wood, methane, or natural gas. It is often blended with gasoline; e.g., "M85" contains 85 percent methanol and 15 percent gasoline to overcome cold start and poor flame visibility problems.	• Can be produced domestically but near-term sources are likely to be imports • Can be produced from renewable resources, but is currently produced predominantly from natural gas • Can reduce ozone-forming hydrocarbon emissions and particulate emissions • Eliminates toxic benzene emissions • A liquid fuel at ambient temperatures	• May increase formaldehyde emissions • Corrosive and toxic • Requires the use of special methanol-compatible materials in fuel system • Poor flame visibility • Has a lower energy content than gasoline, therefore requires larger fuel tanks • Currently significantly more expensive than gasoline • Lack of refueling infrastructure • Difficult to start in cold temperatures
Ethanol (E85) Ethanol is an alcohol derived from biomass-corn and other agricultural products such as sugar cane. Ethanol is denatured by blending with natural gasoline to avoid taxation as an alcoholic beverage.	• Is produced domestically from renewable resources • Can reduce carbon dioxide and ozone-forming hydrocarbon emissions • Eliminates toxic benzene emissions • A liquid fuel at ambient temperatures • May increase acetaldehyde emissions • Has higher energy content than methanol	• Currently significantly more expensive than gasoline • Has a lower energy content than gasoline; therefore reduces vehicle range • Lack of significant refueling infrastructure although this is growing in corn-growing states • Requires the use of special ethanol-compatible materials in fuel system
Ethanol (E10)	• Domestic, renewable • Reduces vehicle CO (especially in older vehicles), CO_2, and benzene tailpipe emissions • All vehicle fuel system materials produced since the early 1980s are compatible	
Liquefied Natural Gas (LNG) Natural gas can be stored on the vehicle as a cryogenic liquid at about –260F. LNG is used primarily for heavy-duty vehicles.	Same advantages as CNG plus: • Has higher storage density than CNG so a higher range can be achieved • Usually higher methane content than CNG • Does not require high pressure cylinders for storage	• Is a cryogenic liquid with special handling requirements • Requires vacuum-insulated storage tank • Refueling infrastructure is expensive • Lack of refueling infrastructure • Poor compression-ignition quality
Biodiesel Biodiesel is a methyl ester that can be made from a variety of products. Most biodiesel used in the U.S. is made from soybean oil or waste grease. Biodiesel is usually blended with diesel. The most common blend is 20% biodiesel, 80% conventional diesel.	• Is made from a renewable resource • Is produced domestically • Can reduce carbon monoxide, hydrocarbon, and particulate matter emissions • Is used in existing diesel engines without modifications • Is nontoxic • Has energy content comparable to diesel • Can reduce global warming	• Is more expensive than conventional diesel • Can increase emissions of oxides of nitrogen • Needs to be blended with conventional diesel to reduce gelling effect at low temperatures • Currently only limited engine warranty coverage is available for the use of B20
Dimethyl Ether (DME) DME can be made from natural gas and is a liquid at relatively low pressures (similar to LPG). It appears to be a good candidate for heavy-duty trucks. Prototype engines are currently being produced.	• Can reduce emissions significantly • Has a high cetane number so it can be used in a diesel engine • Can be produced from domestic renewable sources	• No commercially available engines at this time • Limited fuel supply • No refueling infrastructure • Uncertain production cost

* Reformulated gasoline is considered a "clean fuel" in the Clean Air Act Amendments, but is not considered an alternative fuel in the Energy Policy Act of 1992.

10.6 Electric and Hybrid Vehicles

Iqbal Husain

Electric and hybrid electric vehicles (EV), enabled by high efficiency electric motors and controllers, provide the means for an environmentally friendly urban transportation system. The interest in electric vehicles soared in recent years with intense drive from the government, environmental activists, and associated industries to advance the technology. The legislative mandates are for zero emission vehicles (ZEVs). Electric vehicles, powered by alternative renewable energy sources, is the only solution for a true zero emission vehicle. The California Air Resources Board mandate requires that 4% of vehicles sold by a company selling more than 35,000 vehicles in California must be ZEVs by 2003 and an additional 6% of the sales must be made up of either more ZEVs and partial ZEVs.[1–3] However, this mandate was not enforced.

The electric vehicles paved their way into public use as early as in the middle of the 19th century, even before the introduction of gasoline powered vehicles.[4,5] In 1900, 4200 automobiles were sold out of which 40% were steam powered, 38% were electric powered and 22% were gasoline powered. The invention of the starter motor, improvements in mass production technology of gas-powered vehicles and inconvenience in battery charging led to the disappearance of electric vehicles in the early 1900s. The interest in EVs resurged in the 1960s due to environmental pollution concerns and the unpleasant dependence on foreign oil. The growth in the enabling technologies, added to the environmental and economic concerns over the next several decades, increased the demand for investing in research and development for electric vehicles.

The significant R&D efforts focused on developing ZEV technologies have been hindered by unsuitable battery technologies. In addition, the battery charging requirements place increased demand on the power grid, and ultimatley the generating sources, thus only shifting the pollution location. A near term solution for minimizing the environmental pollution problem due to the absence of a suitable, high energy density energy store or source for electric vehicles is perceived in the hybrid electric vehicles. The hybrid vehicles use both an electric motor and an internal combustion engine and thus do not solve the pollution problem. The current research interest is focused on developing the fuel cell technology that will lead to affordable and competitive electric vehicles for public use. The fuel cell electric vehicles (FCEV) can be a viable alternative to battery electric vehicles to serve as zero emission vehicles without the range problem.

EV System

An electric vehicle (EV) is a transportation unit having the two features: (1) The energy source is portable and electromechanical or electromechanical in nature, and (2) traction effort is supplied only by an electric motor. The primary components of an electric vehicle system are the motor, controller, power source, and transmission. The structure of an electric vehicle system along with the available choice of various components is shown in Figure 10.6.1.[1]

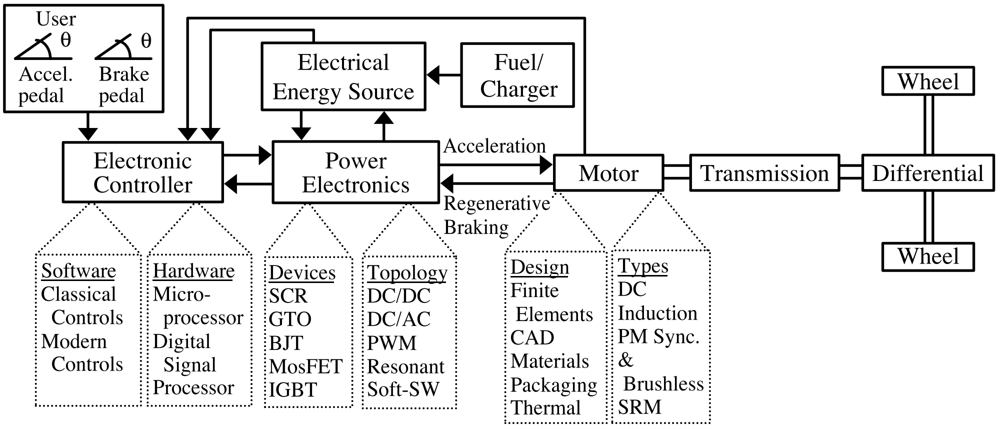

FIGURE 10.6.1 Major components and available choices for an electric vehicle system

Energy Sources and Stores

The electrical energy required in electric vehicles for vehicle propulsion is typically obtained through conversion of chemical energy stored in devices such as batteries and fuel cells. The issue of portability of the energy source is the biggest challenge for mass production of electric vehicles. Electrochemical batteries have been the traditional choice of portable energy source, but the low-power density problem, slow recharge time, and high replacement cost are the biggest obstacles for commercialization of battery-powered road vehicles. The fuel cells, which have been used by NASA successfully in space missions since the Apollo programs in the early 1960s, are a possible candidate for portable energy source. The fuel cell converts chemical energy directly into electrical energy, and the by-product is simply water when hydrogen is used as the fuel. The flywheel is an alternative portable source, in which energy is stored in mechanical form to be converted into electrical energy on demand for vehicle propulsion. The ultracapacitor technology has also advanced tremendously in the recent years, although it is unlikely to achieve specific energy levels high enough to serve as the sole energy source of a vehicle. However, the ultracapacitors in conjunction with a battery or fuel cell have the possibility of providing an excellent portable energy source with sufficient specific energy and specific power for the next generation vehicles.

Ragone Plots

The two important parameters for energy sources are specific energy *(SE)* and specific power *(SP)*. Specific energy defines the amount of energy that can be stored in an energy source and is represented by discharge energy per unit mass. Specific power is related to how rapidly energy can be released from a source and is given in terms of power delivered per unit mass. The plot of *SP* vs. *SE* on a log-log scale is known as a Ragone plot. The Ragone plots of some common batteries, along with those of ultracapacitors, fuel cells, and heat engines, are shown in Figure 10.6.2.

Batteries

The desirable features of batteries for EV and hybrid EV (HEV) applications are high-specific power, high-specific energy, high-charge acceptance rate for both recharging and regenerative braking, and long calendar and cycle life. Additional technical issues include methods and designs to balance the battery segments or packs electrically and thermally, accurate techniques to determine a battery's state of charge, and recycling facilities of battery components. Above all, the cost of batteries must be reasonable for EVs and HEVs to be commercially viable. The batteries need a charger to restore the stored energy level once its available energy is near depletion due to usage. The specific power of a battery energy source is low, leading to the limited range problem of battery-powered vehicles.

Lead/acid batteries have been the primary choice because of their well-developed technology and low cost, although promising new battery technologies are being tested in many prototype vehicles. The

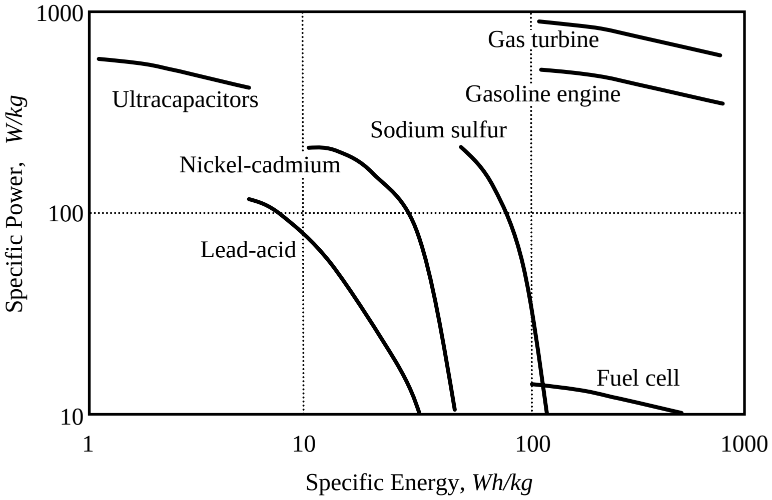

FIGURE 10.6.2 Specific power vs. specific energy (Ragone plots) of batteries, gasoline engine, and fuel cell. (From Husain, I., 2003, *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

recently introduced hybrid vehicles, Toyota Prius and Honda Civic, use NiMH, which is an alkaline battery where electrical energy is derived from the chemical reaction of a metal with oxygen in an alkaline electrolyte medium. The NiMH is likely to survive as the leading rechargeable battery in the future for traction applications, with strong challenges coming from lithium-ion and lithium-polymer batteries. The lithium-metal has high electrochemical reduction potential (3.045V) and the lowest atomic mass (6.94). The lithium-ion batteries have high-specific energy, high-specific power, high-energy efficiency, good high-temperature performance, and low self-discharge. The components of Li-ion batteries are also recyclable. The Li-polymer batteries, using solid electrolytes, have potential for the highest specific energy and power.[2,3]

Batteries can be configured in series or in parallel, or in a combination thereof. The design depends on the output voltage and the discharge requirements. The series connection yields the required voltage, whereas the parallel connection delivers the desired capacity for the battery pack for minimum runtime before recharging. The battery pack also includes electronics, which are typically located outside the battery pack. The electronic circuit of a multilevel battery pack controls charging and ensures reliability and protection against overcharge, overdischarge, short circuits, and thermal abuse.

Fuel Cells

A fuel cell is an electrochemical device that produces electricity by means of a chemical reaction, much like a battery.[4] The major difference between batteries and fuel cells is that the latter can produce electricity as long as fuel is supplied, whereas batteries produce electricity from stored chemical energy and hence require frequent recharging. The basic structure of a fuel cell is shown in Figure 10.6.3. The fuels supplied to the cell are hydrogen and oxygen. The concept of the fuel cell is the opposite of electrolysis of water, where hydrogen and oxygen are combined to form electricity and water.

The alkaline fuel cells with their high efficiencies were first considered for mobile applications.[5,6] They require pure hydrogen as fuel, and operate at low temperatures (80°C). The current choice of fuel cells for electric vehicles is the proton exchange membrance (PEM) fuel cells. These fuel cells also operate at low temperatures (around 80°C), and use a perfluorinated sulphonated polymer membrane (e.g., Nafion) as the electrolyte. While having lower electrical efficiency than the alkaline cells (about 40%), these fuel cells are rugged, and stacks of cells can be easily constructed. Many automotive companies have decided to explore the use of methanol as a fuel by onboard reforming it into hydrogen because of the higher energy density and ease of handling of this hydrocarbon fuel when compared to hydrogen gas. A direct methanol fuel cell (DMFC) works on the same premise as the PEM except that the temperature is

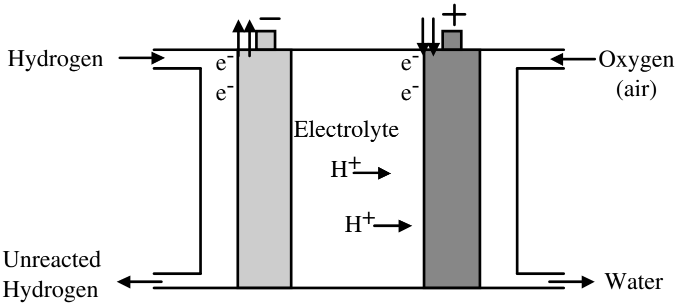

FIGURE 10.6.3 Basic fuel cell structure. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

increased (to the range of 90 to 120°C) such that internal reformation of methanol into hydrogen is possible. This type of fuel cell is still in the design stages since the search for a good electro-catalyst to both reform the methanol efficiently and to reduce oxygen in the presence of methanol is still ongoing. This type of cell has low electrical efficiency, at about 30%.

Electric Motors

The electric machine converts the available onboard electrical energy into mechanical energy for vehicle propulsion.[7,8] The desirable features in an electric motor for EV/HEV applications are ruggedness, high torque-to-inertia ratio, high power-to-weight ratio, extended constant power region, flexible drive control, fault tolerance, high efficiency, and low acoustic noise.

The electric machine also processes regenerative energy during vehicle braking, which can be used to recharge the batteries of EVs or HEVs. The energy available during braking is the kinetic energy that was acquired by the vehicle during acceleration, and part of this energy can be recovered through an appropriate motor controller. Regenerative braking can increase the range of EVs by about 10 to 15%.

The strength of electric motors and integrated circuit (IC) engines are typically described with horsepower (HP) ratings, although a comparison between electric motors and IC engines in terms of HP only is not fair. The power that an electric motor can continuously deliver without overheating is its rated HP, which is typically a derated figure. For short periods of time the motor can deliver 2 to 3 times the rated HP. Therefore, at starting a high power is available from an electric motor for acceleration, and the motor torque can be the maximum under stall conditions, that is, at zero speed. On the contrary, an IC engine is rated at a specific r/min level for maximum torque and maximum HP. The torque characteristics of motors are shown in Figure 10.6.4 along with torque characteristics of IC engines. The electric motor has constant power characteristics over a wide speed range. Therefore, the electric motor can be attached directly to the drive wheels and accelerate the vehicle from zero all the way up to the top speed. The motor and hence the vehicle speed can be controlled directly through the power electronic converter feeding the current into the motor. There is essentially no requirement for a transmission with an electric motor, other than a fixed gear for appropriately sizing the motor and matching the vehicle and motor speeds.

AC motors are preferred over DC motors for electric propulsion applications because of their ruggedness, simplicity in construction, and higher torque and power densities. Although the controls are complex for AC motors, the recent developments in IC technology enable complex control implementations in microprocessor and digital signal processors with high degrees of accuracy and excellent performance. The choice of AC motors suitable for propulsion applications are induction motors, permanent magnet (PM) motors, and switched reluctance motors (SRMs).[9] The well-established technology and ruggedness of induction motors make it a very good choice for traction applications, and it has been used in vehicles like Saturn EV1 from GM. Although the costs of permanent magnet motors are relatively higher compared to its competitors, the high-power density and excellent performance make it the first

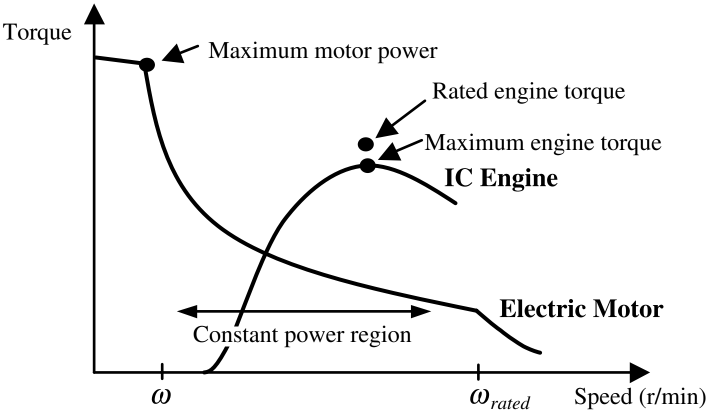

FIGURE 10.6.4 Electric motor and IC engine torque characteristics. (From Husain, I. 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

choice for many automotive manufacturers of electric vehicles. The SRM can be an ideal motor for traction applications, with its simplicity and fault-tolerance characteristics. However, the technology of SRM is not mature, and the acoustic noise problems need to be overcome before it can find widespread applications for electric vehicle propulsion.

Electric Motor Drive

The electric motor is driven by a power electronics–based power processing unit that converts the fixed dc voltage available from the source into a variable-voltage, variable-frequency source controlled to maintain the desired operation of the vehicle. The power electronic converter segment of the motor drive is made of solid-state devices and handles the flow of bulk power from the source to the motor input terminals.[10,11] The controller processes the command input and the feedback information to generate the switching signals for the power converter solid-state switches. The coordination of the components of the motor drive with the source and the motor is shown in Figure 10.6.5.

A power converter is made of high-power, fast-acting semiconductor devices, such as bipolar junction transistor (BJT), metal oxide semiconductor field effect transistor (MOSFET), insulated gate bipolar transistor (IGBT), silicon controlled rectifier or thyristor (SCR), gate turn-off SCR (GTO), and MOS-controlled thyristor (MCT). These solid-state devices, configured in a certain circuit topology, function as an on-off electronic switch to convert the fixed-supply voltage into a variable-voltage and variable-frequency supply. All these devices have a control input gate or base through which the devices are turned on and off according to the command generated by the controller. The tremendous advances in the power semiconductor technology over the past two decades have enabled the development of compact, efficient, and reliable dc-dc and dc-ac power electronic converter topologies.

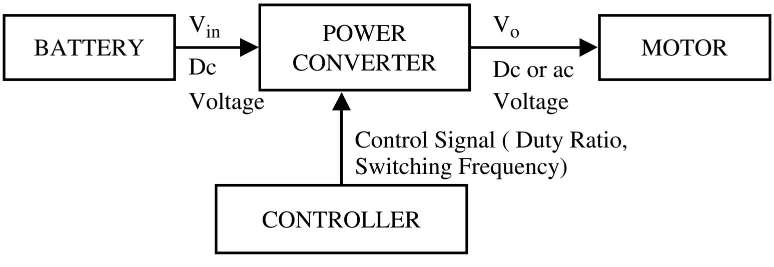

FIGURE 10.6.5 Block diagram of a motor drive. (From Husain, I., 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

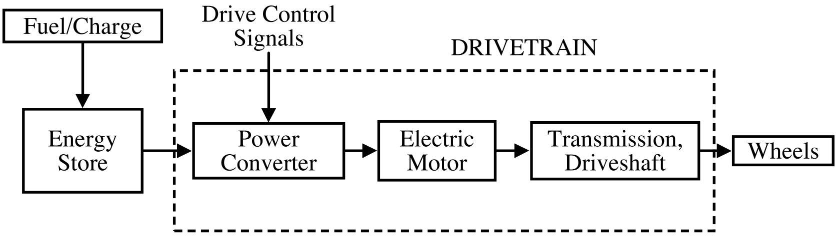

FIGURE 10.6.6 Drivetrain of an electric vehicle

EV Drivetrain

The *drivetrain* of the vehicle is the electromechanical energy conversion linkage system between the vehicle energy store and the wheels. The drivetrain of an EV is shown in Figure 10.6.6. The drivetrain has electrical as well as mechanical components. The electric vehicles can be either a front-wheel drive or a rear-wheel drive. In the case of front-wheel drive, the electric motor drives the gearbox mounted on the front axle. A single motor can drive the transaxle on a common axis, delivering power to the two wheels differentially through a hollow motor shaft. Altenatively, two motors mounted on the chassis or on the half-shafts can be used to drive the front two wheels in order to simplify the transmission and to eliminate the differential. In-wheel motor arrangement is also a possibility, but the cost associated with high-power, high-torque motors is the primary impediment for such arrangement. The transmission is more complex in the case of a rear-wheel drive, which requires a differential to accommodate unequal speeds of the inside and outside wheels of the rear axle during vehicle cornering.

Hybrid Electric Vehicles

The hybrid electric vehicles evolved out of two basic configurations: series and parallel. A *series* hybrid is one in which only one energy converter can provide propulsion power. The heat engine or IC engine acts as a prime mover in this configuration to drive an electric generator that delivers power to the battery or energy storage link and the propulsion motor. The component arrangement of a series HEV is shown in Figure 10.6.7. In series HEVs, the power required to propel the vehicle is provided solely by the electric motor. Beyond the heat engine and the generator, the propulsion system is exactly the same as in an EV, making the electric motor power requirements exactly the same as in the EV. The series hybrid has a simpler drivetrain, but all three drivetrain components — namely, IC engine, generator, and motor — need to be sized for maximum power for long distance–sustained, high-speed driving. This is required since the batteries will exhaust fairly quickly, leaving the IC engine to supply all the power through the generator.

A *parallel* hybrid is one in which more than one source can provide propulsion power. The heat engine and the eletric motor are configured in parallel with a mechanical coupling that blends the torque coming from the two sources. The component arrangements of a parallel hybrid are shown in Figure 10.6.8. In

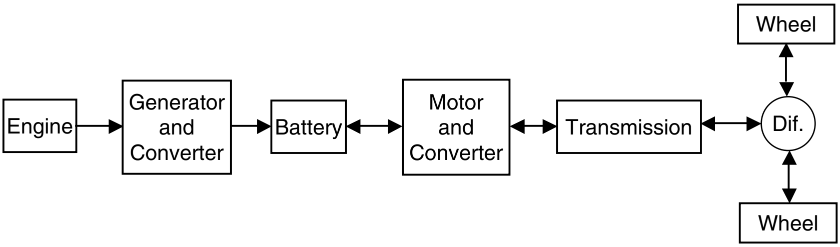

FIGURE 10.6.7 Series hybrid electric vehicle drivetrain. (From Husain, I., 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

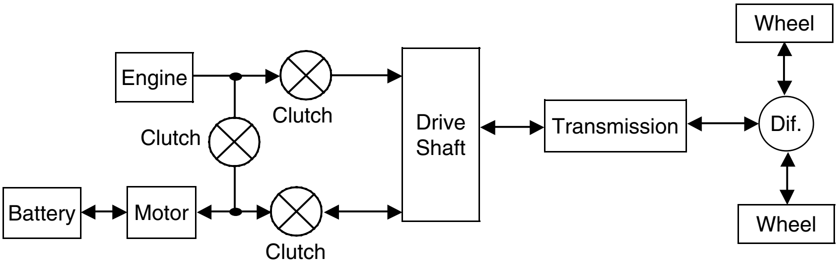

FIGURE 10.6.8 Parallel hybrid electric vehicle drivetrain. (From Husain, I., 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

a parallel HEV, both the heat engine and the electric motor are connected to the driveshaft through separate clutches. The parallel hybrid needs two propulsion components: an ICE and an electric machine, with the latter functioning both as a motor and a generator. The control complexity increases significantly, since power flow needs to be regulated and blended from two parallel sources.

Both series and parallel hybrids come in a variety of types. The mission of the vehicle and the optimum design for that mission dictates the choice. Although HEVs initially evolved as either series or parallel, manufacturers later realized the advantages of a combination of the series and parallel configuration for practical road vehicles. In these combination hybrids, the heat engine is also used to charge the battery. The recently available Toyota Prius is an example of such a hybrid, where a small series element is added to the primarily parallel HEV. The small series element ensures that the battery remains charged in prolonged wait periods, such as at traffic lights or in a traffic jam.

Internal Combustion Engines

The heat engines of interest for the EV/HEV applications are the internal combustion engine and the gas turbine. The internal combustion engines used in automobiles, trucks, and buses use the reciprocating piston-cylinder arrangement. The two types of reciprocating IC engines are the spark-ignition engine (SI) and the compression-ignition (CI) engine.[12] The two engines are commonly known as gasoline/petrol engine and diesel engine. The gas turbines used in power plants are also internal combustion engines, where the processes occur in an interconnected series of different components. The Brayton cycle gas-turbine engine has been adapted to the automotive propulsion engine; it has the advantage of burning fuel that requires little refining and the fuel burns completely. The gas turbines have fewer moving parts because there is no need to convert the rotary motion of the turbine. The disadvantages of gas-turbines are their complex construction and lower efficiency. Nevertheless, gas turbines are being considered for hybrid electric vehicles, and prototype vehicles have been developed.

Fuel Cell EVs

A fuel cell EV consists of a fuel storage system that is likely to include a fuel processor to reform raw fuel to hydrogen, the fuel cell stack and its control unit, the power processing unit and its controller, and the propulsion unit consisting of the electric machine and drivetrain. The fuel cell has current source type characteristics, and the output voltage of a cell is low. Several fuel cells have to be stacked in series to obtain a higher voltage level, and then the output voltage needs to be boosted in order to interface with the dc/ac inverter driving an ac propulsion motor, assuming that an ac motor is used for higher power density. The block diagram of a fuel cell EV system is shown in Figure 10.6.9. The power electronic interface circuit between the fuel cell and electric motor includes the dc/dc converter for voltage boost, the dc/ac inverter to supply an ac motor, the microprocessor/digital signal processor for controls, and battery/capacitors for energy storage. The time constant of the fuel cell stack is much slower than that of the electrical load dynamics. A battery storage system is necessary to supply the power during transient and overload conditions and also to absorb the reverse flow of energy due to regenerative braking.

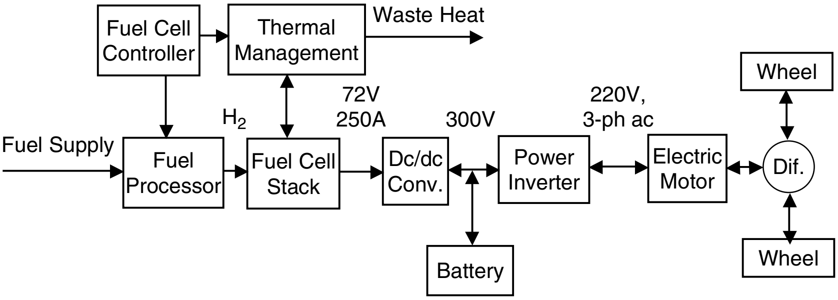

FIGURE 10.6.9 A fuel cell electric vehicle. (From Husain, I., 2003. *Electric and Hybrid Vehicles: Design Fundamentals*, CRC Press, Boca Raton, FL.)

EV Advantages and Disadvantages

The relative advantages and disadvantages of electric vehicles and IC engine vehicles can be better appreciated from a comparison of the two on the basis of efficiency, pollution, cost, and dependence on oil. In order to evaluate the efficiencies of IC engine vehicle (ICEV), battery EV, hybrid EV, and fuel cell EV (FCEV) on a level ground, we must consider the complete process in all systems, starting with crude oil in the wells to power available at the wheels. The ICEV energy conversion starts with the conversion of crude oil to fuel oil in the refinery. The ICEV process includes the transmission of fuel oil from refinery to gas stations, power conversion in the internal combustion engine of the vehicle, and power transfer from the engine to the wheels through the transmission before it is available at the wheels. The EV process starts not at the vehicles but at the source of raw power, whose conversion efficiency must be considered to calculate the overall efficiency of electric vehicles. For battery EVs, the efficiencies of electricity generation and transmission to the outlets need to be considered, since batteries must be recharged regularly. For FCEVs, the fuel production and fuel cell efficiencies must be evaluated in addition to the efficiencies of the electrical and mechanical components of the drivetrain. The well-to-wheel efficiencies for conventional ICEVs, battery EVs, and FCEVs using various types of fuels are presented in Table 10.6.1. The table has been compiled using experimental data from various sources and was originally published in reference 13. The numbers will obviously vary for experiments conducted for vehicles or engines with

TABLE 10.6.1 Comparison of Well-to-Wheel Efficiencies of Different Types of Vehicles

Propulsion System	Fuel	Fuel Production Efficiency[1] (%)	Peak Brake Engine Efficiency/ Stack Efficiency (%)	Part Load Efficiency Factor	Transmission Efficiency (%)	Weight Factor × Idle Factor[2]	Total Cycle Efficiency (%)
Conventional SI	NG	87.5	38	0.68	85	1.0	19
	H_2	59					13[3]
Conventional Diesel	F-T Diesel	70	45	0.77	85	1.9	21
	Dual Fuel	86	40	0.77	85	1.0	22.5
Hybrid SI	NG	87.5	38	0.85	85	1.3	31

3. Experimental data provided vehicle tank-to-wheel efficiency.

a different design, but one can get a representative figure from this table. The table shows that the efficiencies of IC engine vehicles and electric vehicles are of the same order of magnitude, with all of them around 20% when the overall process is considered. The most promising technology, as far as efficiency is concerned, are the HEVs, with efficiencies exceeding 30% for those powered by natural gas (NG), Fisher-Tropsch (F-T) diesel, or dual-fuel. The Fisher-Tropsch refers to the chemical process of producing liquid fuel from natural gas or coal. The fuel obtained by combining approximately 10% diesel fuel with natural gas is known as *dual-fuel*. Experiments showed that auto-ignition can be achieved at a higher compression ratio than in a spark ignition (SI) engine with dual-fuel, resulting in greater efficiency.[13]

Transportation accounts for one third of all energy usage, making it the leading cause of environmental pollution through carbon emissions.[14] The U.S. Department of Energy has projected that if 10% of automobiles nationwide were zero-emission vehicles, regulated air pollutants would be cut by one million tons per year and 60 million tons of greenhouse carbon dioxide gas would be eliminated. On the other hand, thermal pollution by large power plants would increase with increased EV usage. With stricter sulfur-dioxide (SO_2) power-plant emission standards, EVs would have little impact on SO_2 levels. Emissions due to power generation at localized plants are much easier to regulate than those emanating from IC engine vehicles that are individually maintained and scattered all over. The people dwelling in cities are not exposed to power plant–related emissions, since these facilities are mostly located outside urban areas. The environmental benefits of battery and fuel cell electric vehicles can be better appreciated when electricity or fuel is produced for the respective propulsion units from renewable sources such as wind or solar.

The initial EV capital costs are higher than ICEV capital cost primarily due to the lack of mass production opportunities. However, EV capital costs are expected to decrease as volume increases. Capital costs of EVs easily exceed capital costs of ICEVs due to the cost of the battery. The total life-cycle cost of an EV is projected to be less than that of a comparable ICEV.

The transportation industry depends heavily on oil, with more than half of the oil used for ground transportation in the U.S. being imported. An average ICEV in its lifetime uses 94 barrels of oil based on 28 mi/gal fuel consumption. On the other hand, an average EV uses two barrels of oil in its lifetime based on 4mi/kWh. The oil is used in the EV process during electricity generation, although only 4% of electricity generated is from oil.

The appropriate infrastructure must also be in place for battery or fuel cell EVs to become more popular. The infrastructure-related issues for battery electric vehicles are battery charging facilities, standardization of EV components, sales and distribution, service and technical support ,and parts supply. For fuel cell EVs powered by hydrogen only, it will be necessary to build a hydrogen distribution infrastructure. The alternative is to use methanol as the fuel with a reformer and utilize the current gasoline infrastructure with certain modifications to address the corrosivity of methanol.[6] The issues of standardization of electrical components, sales and distribution, service and technical support, and parts supply for fuel cell EVs are similar to those of battery EVs.

10.7 Intelligent Transportation Systems

Sumit Ghosh

Origin of ITS

As ITS America[1] noted in 1994, surface transportation in the U.S. is at a crossroads. While the nation's 4 million miles of paved roads are badly clogged with 200 million vehicles and congestion continuing to rise, the conventional wisdom of building more roads is not working for financial and environmental reasons. Since that time, the situation has only continued to worsen.[2] Today, at the beginning of the twenty-first century there is little money for repairing existing highways, let alone for building new highways; the cost of adding lanes is escalating quickly, especially in the suburbs and urban areas where congestion is severe and land availability is low; and many pavements are in poor repair. With the push for increasing productivity, the average driver's impatience is on the rise, further aggravating an already stressful situation. In the surface transportation industry, even veteran professional drivers are quitting in large numbers, citing increased stress from requirements to conform to limited time windows for just-in-time delivery and pickup in highly congested areas.[3] In 2000, congestion costs were estimated at $100 billion[4] annually in lost productivity, energy wastage, vehicle deterioration, road rage, and increased emissions from vehicle idling. Traffic accidents in 1993 alone caused 40,000 deaths and 5 million injuries.

In response to the growing problems, the U.S. Congress passed the Intermodal Surface Transportation Efficiency Act (ISTEA) of 1991, whose basic goal is to develop a national transportation system that is economically efficient and environmentally sound, and that can move people and goods in an energy-efficient manner. Following the passage of ISTEA, the U.S. Department of Transportation, led by the Federal Highway Administration, immediately launched the Intelligent Vehicle Highway System (IVHS) program. IVHS did not aim to address the capacity problem. Its goal was to steering drivers away from bottlenecks and to introduce and manage reasonable enforcement measures such as congestion pricing. Surface transportation related problems are not unique to the U.S. In fact, in countries with higher population densities, such as Japan and European countries, the problem is far more acute. The Programme for a European Traffic with Highest Efficiency and Unprecedented Safety (PROMETHEUS)[5] project in Europe and the Advanced Mobile Traffic Information and Communication System (AMTICS) program[6] in Japan closely paralleled the IVHS program in the U.S.

A careful analysis reveals that the problem of efficiently moving people and goods is not just confined to surface transportation, that is, vehicles and roadways, but that it involves trains, passenger planes, air cargo, ferries, ships, and every available and currently utilized mode of transportation. This thinking helped foster the broader notion of the intelligent transportation system (ITS), superseding IVHS. Clearly, to synthesize a genuine and practical solution at the national level, possibly international level, one must adopt a holistic approach that takes into consideration complex interdependencies between the many transportation modes and that is guided by a fundamental goal, namely, minimizing the transit time for every traveler and merchandise in transit, subject to fair distribution of available resources.

Underlying ISTEA and the ITS America movement is the general belief that the solution to this complex problem rests on two key scientific and engineering advances. The first is the increased availability of computing power in the form of powerful desktop workstations and mobile laptops, palmtops, and handheld PDAs. The second is the increasing availability of networking, both wire-line and wireless, for communications and control. However, the mere availability of computing power and networking does not automatically guarantee a solution. For instance, Carley[7] from the General Electric locomotive-building unit reports that locomotives sit idle as much as 40% due to bottlenecks in the rail corridors stemming from poor information, coordination, and control. With annual fuel budgets for many of the railroad companies running in excess of $800 million, and the need to leave diesel locomotive engines running even when idle, the extent of fuel wastage is staggering. The key to successful solutions to complex transportation problems, according to reference 8, lies in the comprehensive understanding of the control and coordination algorithms that, while abstract, serve to unify the computing and networking resources in a synergistic, nontangible manner. Analysis of historical evidence reveals the critical role played by these algorithms in different forms in the past two revolutions[8] in transportation. Analysis also shows that we are poised to experience the third major revolution and possibly the most complex — the transformation from the centralized paradigm to the asynchronous, distributed paradigm.

Current Status of ITS

Despite the ISTEA of 1991, to virtually every driver today the current interstate and state highway system continues to be a source of great frustration, the principal reason being congestion. The problem is not new; congestion has been around for a very long time. In London, the average vehicular speed in 2003 was 17 mph, unchanged from 100 years ago when horse-drawn carriages were around.[9] In Manhattan, pedestrians today average a speed of 3.3 mph that, ironically, is higher than that of vehicular traffic, at 3.1 mph. In 1986, King[10] observed that driver navigational waste was equal to 6.4% of all distance and 12% of all time spent in travel by noncommercial motorists, amounting to millions of dollars. In 1992, the Rhode Island Department of Transportation (RIDOT)[11,12] estimated that 60% of all vehicle-hours lost was due to accidents, stalled vehicles, and other road mishaps that are dynamic and unpredictable a priori. Similar findings were reported by other state DOT agencies. In 1997, Peters, McGurrin, Shank, and Cheslow[13] estimated that the ITS infrastructure must improve vehicle-handling capacity by 30% in order to keep congestion from growing beyond the current level. In 2000, congestion costs were estimated at $100 billion[4] annually in lost productivity, energy wastage, vehicle deterioration, road rage, and increased emissions from vehicle idling. Based on a ten-year study of the five most congested areas (Los Angeles; Washington, DC; San Francisco-Oakland; Miami; and Chicago), Lomax[2] reported in 2002 that the average travel delay, in the form of idle waiting, equates to one workweek per year per driver and that the cost of wasted fuel from idling totals $8.6 billion annually in Los Angeles alone. The worst travel delay equals 75 hours per year in the San Bernardino-Riverside area, and the highest per capita fuel wastage of $860 occurs in Washington, DC.

This section presents the current status of ITS from two distinct perspectives. The first perspective consists of a review of the scientific literature on ITS research. It addresses a number of areas, including assessing overall ITS approach, system planning, vehicular traffic modeling, system evaluation, vehicle tracking, autonomous driving and Global Positioning System (GPS)-based guidance, signal control, braking, lane detection and steering control, intelligent cruise control, disseminating road work information to drivers, noise pollution, platooning, simulators for evaluating ITS systems, and training ITS personnel. White[3] observes that the surface transportation problem is complicated by increased congestion, decreased use of public transportation, and shifting demographics coupled with escalating cost of adding lanes. Nitz and Chung[14] stress that in the spirit of ITS, copper cables must be replaced with optical fibers to improve communications in rapid transit systems. Horioka[15] presents an architecture for a universal traffic management system (UTMS) for the city of Kochi, where all traffic signals are managed at centralized traffic control. In support of the UTMS architecture, Hayashi and Sugimoto[16] recompute and adjust the length of the red signals in increments of 1% at intervals of 5 minutes to improve efficiency. Fu, Hellinga, and Zhu[17] recognize the challenge of modeling congested arterials and present flow conservation-based traffic models to predict congestion. Widodo and Hasegawa[18] propose utilizing intervehicle communications to enhance traffic flow and pack vehicles more closely on the roadway. In evaluating the Rockwell-developed "National System Architecture Program," Weissenberger, Lo, and Hickman[19] reflect on the challenge of assessing the architecture stemming from the uncertainty associated with technology performance and cost. Chen, Shyu, and Zhang[20] utilize video indexing to identify and track vehicles and, in turn, measure congestion. Their effort is largely theoretical and fails to address clutter, presence of large numbers of cars, and real-world scenarios.

Laugier, Paromtchik, and Parent[21] report on the use of experimental electric cars for autonomous maneuvering studies under lane-following and lane-changing scenarios. Their test results reveal that linear cameras at 1000 Hz provide relative distance accurate down to 1 mm at a distance of 10 m and a speed of 60 km/hr, with a deceleration of 2 m/sec^2. While Goh and Wang[22] describe the navigation of a two-wheel steerable vehicle using sensor data from a differential GPS, Kim and Lee[23] describe a route-guidance approach in which cars in transit upload their positions and travel times to a centralized operations center, which then predicts the traffic between any two points in the system, statistically, and downloads the information to in-car navigation systems. In the spirit of assisting drivers, Kase, Hattori, Ohsuga, and Honide[24] propose automatic downloading of parking vacancies to cars while in transit. A key component of autonomous maneuvering consists of intelligent braking. Goodrich, Boer, and Inoue[25] report on an effort to model human braking behavior under emergency that has been incorporated in an adaptive cruise control (ACC). While the driver reveals unique skills in some areas, they note that the ACC exhibits superior abilities elsewhere. Yoshizawa[26] argues that road repair information is critical in route selection and recommends that the police consolidate and disseminate the information. Building on this idea, Onoue[27] recommends that the consolidated information be analyzed and employed to control traffic signals. Focusing on the environmental aspect of ITS, Araya, Shingaki, and Oota[28] investigate the relationship between traffic noise and traffic volume along National Route 43 in Japan and report that significant noise is generated in acceleration zones, especially where cars speed from 30 to 52 km/hr. To increase transport efficiency, Lee, Kim, Yim, Jung, Oh, and Kim[29] propose platooning of vehicles subject to longitudinal and lateral control. Headway controllers employing millimeter wave (MMW) radar are placed on each car to monitor the distance from the preceding vehicle. Mayr and Bauer[30] propose an intelligent cruise control that is characterized by two separate control systems. The first control system engages when the vehicles are proceeding smoothly and is responsible for ensuring safe distance between cars. However, in the event the car ahead brakes due to an emergency, a second control system takes over and ensures adequate deceleration in a timely manner. Handmann, Leefken, Tzomakas, and von Seelen[31] stress the difficulty in obtaining reliable and accurate data from real-world scenarios that is critical for designing practical ITS systems. Yim and Oh[32] present an image-processing algorithm that is capable of automatically extracting lane information without any a priori information about the lanes or even requiring manual intervention. However, the authors neglect to address the issue of performance, especially where the lane markings may have faded with age. To reduce costly rear-end collisions and improve safety, Ikeda and Matano[33] propose equipping every vehicle with display boards that inform drivers how far ahead the tail of the congestion is located.

There is general agreement in the ITS community that modeling and simulation constitute a key to testing complex ideas prior to developing expensive prototypes or even deploying them in the real world that may inadvertently cause irreversible damage. Yamashita and Muramatsu[34] present a simulator that models every vehicle and traffic signal. For each vehicle, its speed, direction, and acceleration or deceleration are modeled. Assuming a traffic insertion rate of 2000 vehicles/hr, they report limiting the wall clock time to 1 hour for a simulation of 120 sec of actual traffic. Uno, Sakaguchi, and Tsugawa[35] report developing a simulator to study how to integrate a merging control algorithm with intervehicle communication under the platoon concept. Dahlgren[36] acknowledges the critical role of simulation but warns that the cost of a simulation and the accuracy that it may yield must be weighed against the benefit to the project. Adler, Wallace, and Yavuz[37] report on a professional capacity-building program utilized by the Federal Highway Administration in 1996. It employed an interactive multimedia educational tool that featured a computer game for electronic design, a toll-collection system, and experiments in wireless communications.

The second perspective consists of a critical examination of the products and services that have been introduced into the market by the ITS industry since 1991. For example, in many of the U.S. cities, there are toll-free phone numbers (e.g., Boston) and public web sites (e.g., Seattle, WA) where one can obtain up-to-date information on the congestion states of the roadways. These services are immensely valuable, but there are three key problems. First, the information is limited to the major roadways, which are generally few in number, and is missing or outdated for the many more secondary roads. Second, the time necessary to broadcast complete information on all of the highways is usually so long that its usefulness to any given driver is severely limiting. Third, the information is not dynamic in that it may change substantially due to accidents or incidents while the driver is in transit. Today, a number of trucks, airport shuttle service vans, and luxury automobiles are equipped with GPS-based navigation aids. The principal difficulty again is the lack of accurate congestion information in a timely manner. A number of highway authorities have turned to AM radio to broadcast ramp closures, lane constrictions due to construction, and other relevant highway conditions. This effort, while of great value, has run into unique problems that originate from the lack of comprehensive thinking. Consider the following actual anecdote. On a weekday in March 2003, at 9:00 AM, the New Jersey Turnpike authority broadcasts on radio station 1680 on the AM dial, that, due to heavy congestion, the high-occupancy vehicle (HOV) lane has been opened to all traffic regardless of the number of passengers per car. Yet, the HOV lane is virtually empty from exit 11 all the way to exit 14 while vehicles on all other lanes are at a standstill. AM station 1680 is silent except for an annoying buzz and sporadic crosstalk from an adjacent station. After an hour delay, one approaches the tollbooth near Holland Tunnel, only to hear the broadcast that the HOV lane had been open all the time.

Among the state departments of transportation, there is a strong drive to mount cameras along highways and freeways, feed the signals back to a centralized traffic control center, and monitor congestion. The Minneapolis traffic control center has been a pioneer in this effort, and a similar center was recently installed in Phoenix, AZ. While installation and maintenance costs are high, the cameras can be immensely valuable in zooming onto accident sites and guiding en-route police and paramedics or reading license plates of vehicles under suspicion. However, relative to the issue of congestion monitoring and control, the impact of the cameras is minimal.[18] In fact, other devices, including optical fibers embedded underneath the pavements as in the case of Interstate 10 in Phoenix, are relatively inexpensive and highly reliable.

Electronic toll-collection systems, such as the E-ZPass in the Eastern U.S. and along the Interstate 95 corridor, have been viewed by many in the ITS community as a major achievement. The thinking is that cars can whiz by at speeds of up to 15 mph, avoiding the need to come to a complete stop to conduct cash transactions. In reality, however, E-ZPass's performance has been, at best, mixed, especially because many drivers have chosen not to sign up, concerned by E-ZPass's technical and administrative problems. On any given weekday during rush hour, thousands of cars hurl toward the tollbooths, dangerously zigzagging their way from their current lanes toward the appropriate toll lanes, with some slowing down and others coming to a dead stop, in effect creating a highly stressful and unsafe environment. While the queues at the cash tollbooths are significantly long, E-ZPass toll lanes barely register average vehicle speeds of more than 2 or 3 mph. Beyond the tollbooths, the combination of the abrupt reduction of ten toll lanes down to three or four highway lanes, along with drivers accelerating trying to make up for lost time, creates an even more dangerous environment. The concept of electronic toll collection, as currently deployed, is inefficient in that it slows down traffic unnecessarily, unsafe in that it fosters a dangerous driving environment, and environmentally unsound, all of which fundamentally contradicts the basic goals of ISTEA and the objectives of ITS.

Careful analysis of ITS products and services to date reveals that the slow progress may be attributed to two factors: (1) failure to recognize fundamental principles underlying ITS, and (2) lack of a holistic, comprehensive approach to solving ITS problems. Both factors are addressed in greater detail in the next section. For insight into the need for a comprehensive approach to ITS, consider the issue of improving air travel in the future. The first thought that is likely to arise in one's mind is the need to design commercial jets that can fly faster than the current limit of 600 mph. However, upon deeper thinking, one quickly realizes that the real cause of delay in air travel emanates from waiting for flight connections and layovers in the current hub-and-spoke air transport system, not to mention the lengthy airport security checks and travel to and from the airport. According to Boeing Corp., even if faster and consequently less-fuel-efficient jetliners were to be developed, the reduction of uncertainties and air travel delays will be minimal to none.

Key Principles Underlying ITS

Here are some important points underlying ITS:

- The single biggest cause of driver impatience that leads to reckless driving, incidents, road rage, and accidents is ignorance. When a driver encounters an obstacle and does not know what lies ahead, a rational or irrational fear may arise in that he or she might not succeed in reaching the destination on time, which, in turn, may have untold consequences. The ITS architecture's greatest contribution may consist in providing logically relevant and accurate information in a timely manner to needy drivers in a form that they can utilize to determine alternatives and recompute their plans. For example, consider that Joe, a busy executive in some city, scheduled to be on a flight, say XYZ, from a nearby airport, is late in leaving the office. Joe panics and drives recklessly, nearly running over a pedestrian, and barely makes into the airport in time to catch the flight, only to find out that XYZ has been delayed for 2 hours since the incoming aircraft had developed an unexpected mechanical problem. If under ITS the flight delay information, as soon as it becomes available, is automatically transmitted to every passenger scheduled for XYZ, in this case Joe's cell phone, most if not all of Joe's driving-related problems may disappear immediately.
- Except under truly emergency conditions, the ITS architecture should neither attempt to control nor dictate drivers' behavior, for two reasons. First, no centralized authority[8] can know with certainty the goals, objectives, and thinking of every driver, and therefore, any attempt to control will invariably be based on erroneous assumptions. Second, in the long run, drivers will resent the intrusion on their freedom to make their own decisions and ultimately abandon ITS. The key principle is to provide drivers with as much relevant information as possible and equip them with appropriate networking and computing resources so that they can determine and freely choose the right course of action under the given circumstances.
- Information must be accurate, timely, relevant, and consistent. Otherwise, drivers will begin to question the value of the ITS technology and abandon it prematurely. Any out-of-date piece of data can quickly assume the form of misinformation with severe unintended consequences. Consider two recent occurrences, intended to serve as examples of what must not be permitted under ITS. In June 2002, a programmable overhead electronic information board on Interstate 10 warns drivers that the air quality between Phoenix and Tucson is poor. The driver reading the sign finds the information interesting but irrelevant since he or she is driving west toward Los Angeles and is just about to leave behind the Phoenix city line. The information should have been displayed on the opposite side of the interstate between Phoenix and Tucson. In July 2003, a similar highway sign near exit 6 on the New Jersey Turnpike flashes an urgent bulletin that there is congestion up ahead. The problem is that it is late Sunday night at 11 PM and there seems to be no sign of congestion. In reality, the sign had been turned on in the afternoon during severe congestion stemming from lane constriction but someone neglected to turn it off.
- The ITS architecture must be fundamentally centered around each individual driver or traveler, subject to safety and fair resource availability for all. That is, while gross metrics such as pavement

utilization, average travel time, network bandwidth usage, and compute horsepower are important to the planners and operational managers, the individual driver's parameters must remain at the forefront.

- ITS architectures must acquire, process, and disseminate accurate, that is, precise and up-to-date, information to the drivers. Automated decision-making computer systems may greatly facilitate this function. In the traditional approach, data is first collected at a centralized unit and then processed, and the resulting information is disseminated to the geographically dispersed customers. Given the geographical distance and the finite speed of propagation of electromagnetic radiation, when a customer intercepts information relative to the transport of a unit in transit, a finite time interval has elapsed since the information was originally generated. For dynamic systems, this delay implies that the information received by the customer has incurred latency and is, in essence, inaccurate and imprecise. The degree of the error due to latency is a function of the length of the delay, relative to the dynamic nature of the system, and the resolution of accuracy. Thus, latency is fundamental to every transportation system. ITS architectures must focus on distributed schemes that aim at eliminating all unnecessary sources of latency, where possible, and realizing efficient, accurate, and timely decisions.
- A fundamental, enabling characteristic of transportation networks is as follows. Although it is an obvious fact that matter in the form of goods and people is transported in a transportation network, the implication is profound. The material units being transported may carry with them their own computing engines, which, at the present time, are necessarily matter. In contrast, in a communications network, the units of information constitute pure electromagnetic energy and they cannot carry with them their own computing engines while in transit. While carried along with the goods and people, the computers, in turn, may facilitate dynamic, travel-related computations and decision making. Also, since the constituent units of a transportation system may communicate with one another while in motion, utilizing wireless or infrared techniques, there is hope that the need for centralizing the information gathering and decision-making functions may be eliminated. The trend of decreasing physical size and cost, increasing capability, and lower power consumption in computer designs is encouraging and will likely render their use in transportation networks increasingly practical.
- ITS architectures must develop innovative computational and networking techniques to offer flexibility, personalized services, accurate estimates, efficiency, and freedom of choice. To achieve precise control and coordination, new distributed control techniques[8,38] must be utilized. Because the constituent units and the resources of any transportation system are geographically dispersed, the use of distributed algorithms is a logical choice. The units to be transported across a network are likely to request service, independent of one another and at irregular intervals of time. Thus, the interactions in the system, in essence, will be asynchronous, requiring the design of asynchronous, distributed algorithms for control, coordination, and resource allocation. Although challenging, these techniques underlie most processes in nature and are exceptionally effective and reliable.

  By design, an asynchronous, distributed algorithm for a transportation system must necessarily reflect the highest, meta-level purpose or intent of the system. The algorithm manifests itself in the behavior of every constituent unit. It will hold the potential of exploiting the maximal parallelism inherent in the system. Furthermore, local computations must be maximized while minimizing the communications between the entities, thereby implying high throughput, robustness, and scalability.
- For many of today's transportation systems, given the increasing size and complexity (which implies a large number of variables and parameters that characterize a system), the wide variation in their values, and the great diversity in the behaviors, the results of the analytical efforts have been restrictive. ITS systems are likely to be complex, implying that modeling and large-scale asynchronous distributed simulation may be the most logical and, often, the only mechanism to study them objectively. Key benefits of modeling and simulation are many. First, they enable one to detect design errors, prior to developing a prototype, in a cost-effective manner. Second,

simulation of system operations may identify potential problems, including rare and otherwise elusive ones, during operations. Third, analysis of simulation results may yield performance estimates of the target system architecture.

- By their very nature, complex systems may contain design errors that manifest rarely and are elusive. To address this weakness, ITS architectures must incorporate automatic mechanisms to continually accept any errors reported by users and bubble them up to the system-architect level so that corrections and refinement may be effected. For example, as of August 2002, the Internet Mapquest program provided erroneous directions to a retail store located in Saddlebrook, NJ, misdirecting drivers to a neighborhood, say X. The neighbors reported that hundreds of other drivers have made the same error over the past 2 years and complained that calls to the store have been in vain since Mapquest provides no mechanism to accept user-reported errors.
- Any ITS architecture must be based on sound logical principles, and where established norms pose inconsistencies, they must be carefully analyzed. For example, virtually everywhere in the U.S., HOV lanes, where present, are located at the extreme left. Since pavements to the left are designated fast lanes, the immediate connotation is that the HOV is a fast lane. This is reinforced by the fact that, often, fast non-HOV cars use the HOV lane to overtake and pass slower cars in the left lane. Furthermore, to get to this lane, an HOV entering the highway from a ramp typically located on the right must maneuver through fast-moving cars in the left lanes, if at all possible on a congested day, leading one to an underlying assumption that HOV drivers intend to drive fast. The assumption may be seriously wrong since many of the HOV vehicles may represent families traveling together who would prefer to drive at the speed limit and avoid accidents. As a second example, consider the nature of many of the highways whose origins date back to the 1700s before the union was formed. To drive from town S to T, one is advised to follow highway H, which will lead straight to a major interstate freeway. Although H appears as a straight-line road on the map with no major intersecting highways until the interstate freeway, a driver unexpectedly encounters forks at three different locations. The peculiarity of these forks is that if one follows the most obvious branch of the fork, which has the same make and feel of the road that he or she was on, that would be a mistake. To continue on H, one would have to make a sharp turn, left or right, on the less obvious branch of the fork. There are signs posted at the forks, but they are worn out and obscured by years of overgrown vegetation. Presumably, pieces of the road date back hundreds of years, and when these pieces were consolidated into highway H, the sharp jogs were left in place to avoid running through people's homes, places of worship, and so forth. Clearly, thousands of drivers following H must have gotten lost, frustrated, and angry. The cumulative delay over the past 50 decades must run into hundreds of thousands of hours, and clearly, such waste is very difficult to justify today. If unabated, this will continue for the next hundred years and the future generation may not view us kindly. For ITS to make a real difference, these problems must be addressed scientifically yet compassionately.

For a true revolution in the transportation scene, across the U.S. and throughout the world, the cultivation of an entirely new breed of ITS engineers is an absolute necessity. In addition to the teaching them pavement design, these engineers must be trained in key aspects of automobile technology, optical-fiber behavior under stress, networking, algorithm design, computing structures, programming, and large-scale distributed software, from an entirely new way of precision thinking.

Promises for the Future

In our vision, the future will witness remarkable progress in ITS in two key fronts. First, in the near future, the key ideas underlying the intelligent transportation of matter will extend beyond vehicular traffic and trains to other modes of transportation, including cargo air transport, passenger air transport, marine ferries, and personalized rapid transport (PRT) systems. The distant future may even witness its extension into interplanetary travel. The need for intelligent transportation will be felt most acutely under three scenarios — increased travel speeds, significant increase in the number of travelers, and increased demand for precise and timely information by travelers, all of which are highly likely in the future. From the scientific and engineering perspective, the advances in intelligent transportation will occur in the theoretical plane and in the form of technological innovations. From the ordinary traveler's point of view, however, the real advance and the direct benefit will occur in the seamless and natural integration of the various modes of transportation. As a result of the integration, the traveler will (1) gain access to fairly accurate status information of any transportation mode, anywhere in the world, from any point in the system, and (2) be permitted to effect reservations, dynamically, even while en route, on any transportation mode in the world. Precision and timeliness of information are crucial to developing faith and trust in the system among travelers. In general, this is best achieved through asynchronous distributed systems. Utilizing intelligent personalized decision aids, the traveler may process the available information to compute the most efficient route or re-route across all different transportation modes, including air, railways, automobiles, and ferries. The most frequent causes for replanning include changes in the traveler's intention and needs and unscheduled delays in a currently reserved transportation system.

Second, ITS systems are complex and very expensive, and once they are deployed, it is logical to expect them to remain in service for a reasonably long period of time. It is, therefore, absolutely essential to develop a sound and comprehensive understanding since such systems must be amenable to enhancements as societal needs evolve with time. For this as well as for efficiency and economy, the exact details of the system architecture and design trade-offs must be studied thoroughly, utilizing the most practical scientific tool available to us today — behavior modeling and asynchronous distributed simulation. Under asynchronous distributed simulation, a single simulation run for a highly complex system may be executed in a matter of days, whereas the current uniprocessor simulators may require up to months. Given that a study may require up to hundreds of simulation runs, behavior modeling and asynchronous distributed simulation may yield insights into the behaviors of such complex systems, thereby constituting an indispensable tool for developing future ITS systems. As an example, consider the need to interconnect a number of traffic-management centers in a given geographical region of the U.S. A behavior modeling and simulation effort may provide meaningful and valuable insights into the topology of the interconnection and the nature of the information exchange between the centers, for a given set of long-term, high-level objectives. It would not be logical to invest millions of dollars and deploy a system that, after completion, reveals an inability to meet the objectives and sustain growth.

11.1 Introduction

Ashok V. Kumar

Engineering design practice has evolved over the years and has undergone significant changes in the last few decades as a result of advances in technology. It has been strongly influenced by technological tools that became available to assist in the design, as well as by design philosophies and methodologies that have evolved in academia and in various industries. Often some of the tools and methodologies vary from industry to industry due to specialized needs. However, over the years a few design tools and methods have become invaluable and are widely used across many industries. In particular, geometry design and engineering analyses are required in all industries. Therefore, it is not surprising that the tools developed to assist in these areas are used across a wide variety of industries. The focus of this chapter is on design methodology, tools, and theories that are widely applicable irrespective of industry or application area.

The section on design theories (11.2) focuses primarily on design methodologies, theories, algorithms, and strategies that are general in nature and that are particularly valuable in generating design concepts and formulating the problem. The next section (11.3) deals with two design tools that are not only widely used but have contributed to significant improvement in the productivity of design engineers and also in quality of the designed products. These tools are the solid modeling technology for designing geometry and the finite element method, which helps in engineering analysis and simulation. Significant advances have occurred in the last two decades in the geometric and solid modeling technologies, available to engineers via computer-aided design (CAD) software. These advances have enhanced the ability of engineers to design an entire product or system on a computer, starting often with the conceptual stages of design. The finite element method is a numerical technique that is used for a wide variety of engineering analysis. It has become the preferred method for analyzing the performance of structures and machine components during design. An important aspect of structural design is failure analysis. Criteria for failure under static and dynamic loading conditions are presented in the section following design tools (11.4).

The final section of this chapter (11.5) deals with design-optimization techniques. Optimization algorithms can be used to automate some aspects of the design process, enabling design engineers to compute optimal parameters and dimensions of the design that would maximize or minimize some design objective. The application of these techniques for structural optimization and sensitivity analysis is described, followed by a brief listing of the important optimization algorithms.

11.2 Elements of the Design Process

Nam P. Suh

All design activities must do the following:

1. *Know* the "*customers' needs.*"
2. *Define the essential problems* that must be solved to satisfy the needs.
3. *Conceptualize the solution through synthesis,* which involves the task of satisfying several different functional requirements using a set of inputs such as product design parameters within given constraints.
4. *Analyze* the proposed solution to establish its optimum conditions and parameter settings.
5. *Check the resulting design solution* to see if it meets the original customer needs.

Design proceeds from abstract and qualitative ideas to quantitative descriptions. It is an iterative process by nature: new information is generated with each step, and it is necessary to evaluate the results in terms of the preceding step. Thus, design involves a continuous interplay between *the requirements the designer wants to achieve* and *how the designer wants to achieve these requirements*.

Designers often find that a clear description of the design requirements is a difficult task. Therefore, some designers deliberately leave them implicit rather than explicit. Then they spend a great deal of time trying to improve and iterate the design, which is time consuming at best. To be efficient and generate the design that meets the perceived needs, the designer must specifically state the users' requirements before the synthesis of solution concepts can begin.

Solution alternatives are generated after the requirements are established. Many problems in mechanical engineering can be solved by applying practical knowledge of engineering, manufacturing, and economics. Other problems require far more imaginative ideas and inventions for their solution. The word "creativity" has been used to describe the human activity that results in ingenious or unpredictable or unforeseen results (e.g., new products, processes, and systems). In this context, creative solutions are discovered or derived by inspiration and/or perspiration, without ever defining specifically what one sets out to create. This creative "spark" or "revelation" may occur, since our brain is a huge information storage and processing device that can store data and synthesize solutions through the use of associative memory, pattern recognition, digestion and recombination of diverse facts, and permutations of events. Design will always benefit when "inspiration" or "creativity," and/or "imagination" plays a role, but this process must be augmented by amplifying human capability systematically through fundamental understanding of cognitive behavior and by the development of scientific foundations for design methods.

11.3 Design Tools

Ashok V. Kumar

Geometry Design

For mechanical and structural systems, geometry design is an important and necessary aspect of the overall design process. For structural components, the geometry is clearly important because it determines the overall stiffness and strength of the component. But for both structural and nonstructural components, the geometry is significant for many other reasons as well, including aesthetics, ergonomics, ease of manufacturing, assembly, and disassembly. Geometry design of a component or structure is often an iterative process because the geometry is designed to satisfy multiple purposes. Traditionally, the final detailed geometry is recorded as an engineering drawing after the design process is over. Creating such a drawing is not usually part of the design iterations because it is an expensive process. Drafting software made engineering drawings easier to create and edit but were not quite useful as a design tool. However, over the last two decades, many new geometry design tools have evolved that have had a profound impact on the design process.

CAD software evolved as design tools from simple geometry and solid modeling software that were originally difficult to use and were often thought of as visualization tools rather than design tools. With the evolution of dimension-driven solid modeling technology, it became easier to create and edit complex three-dimensional geometry, allowing even major design changes to be made with minimal effort. Dimension-driven solid models, also referred to as parametric models, can be automatically regenerated or updated in response to dimension (or parameter) changes. In order to ensure that the model updates in accordance to the designer's intent, the history of the solid creation as well as a variety of geometric constraints are recorded as the geometry is being created. This enables the software to update the solid model automatically to reflect dimension changes while maintaining the design intent.

Another capability available in modern solid modeling software that enhances design engineers' productivity is feature-based modeling. Design features can be thought of as geometric primitives that are building blocks to be used to create more complex geometry. These features are driven by a set of rules and definitions, and can be controlled by finite number of dimensions or parameters. User-defined features can be created by combining simple features already available. This capability significantly improves the productivity of engineers by allowing commonly occurring design features to be defined once and reused in many different designs. In addition to feature-based and dimension-driven solid modeling, CAD software available today includes a variety of other applications, such as drawing generation from solid models, engineering analysis tools, manufacturing planning, and tool path generation capabilities.

This section summarizes important concepts and results from geometric modeling theory that forms the basis of the geometry design tools built into CAD software. Geometric models are mathematical and computational models used to represent the geometry of curves, surfaces, and solids. Very broadly, geometric models can be classified as wireframe models, surface models, and solid models. Most CAD software supports all three types of models.

Wireframe models were the earliest and simplest geometric models, where a shape is represented as a collection of characteristic points (vertices), lines, and curves (edges). Although it has some advantages, such as simple user inputs and ease of implementation, there are many disadvantages that make this representation unsuitable for modeling solids. First, the shapes represented by only curves and points are very ambiguous since it is not always possible to determine whether a given point is inside or outside the solid. Second, there is no information about bounding surfaces of the object. Therefore, it cannot be used for mass property computation, tool path generation, or finite element analysis.

Surface models have bounding surface information in addition to the information contained in wireframe models. Therefore, it is possible to generate realistic graphical displays as well as to generate tool paths for the numerically controlled (NC) machining. However, surface models are also ambiguous because they do not have information to distinguish between the inside and outside of the object, which makes it difficult or impossible to construct algorithms for automatically computing mass properties or to construct Boolean combinations of such models. However, surface models are sufficient for many applications, including computer graphics, visualization, and imaging.

For engineering applications, a precise, unambiguous, and editable model of a solid is essential. *Solid modeling* was introduced to overcome some of the limitations of wireframe and surface models. The two popular solid modeling schemes are *boundary representation* (or B-Rep) and *constructive solid geometry* (CSG).[1–4] These two representation schemes are described in the following section.

Constructive Solid Geometry (CSG)

Constructive solid geometry (CSG) representation is based on set theory, and therefore in this approach, solids are modeled as a set of points in space. Complex solids are constructed as Boolean combinations

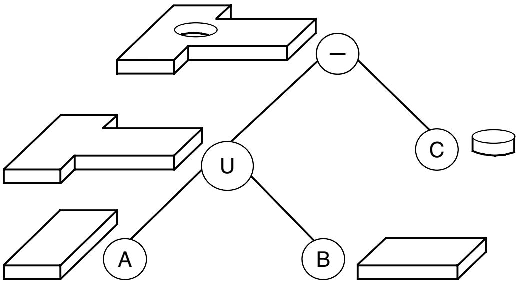

FIGURE 11.3.1 Example of CSG binary tree structure.

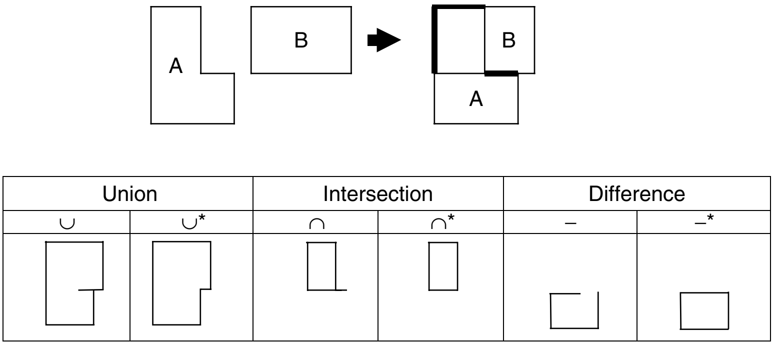

FIGURE 11.3.2 Comparison between the ordinary Boolean and regularized Boolean operation.

of simpler solids called *primitives*. A binary tree data structure is used to represent the Boolean operations between primitives. Figure 11.3.1 shows an example of a CSG tree data structure, where the final solid is generated by the union of the primitives A and B, followed by subtraction of the primitive C. In this tree structure, leaf nodes represent primitive solids and branch nodes represent Boolean types, such as union, difference, and intersection. Boolean operations as defined in set theory are not suited for direct application to solid modeling because they often produce results that are not valid solids and may have dangling edges or faces. For a solid modeling scheme to be unambiguous, it is necessary that any given point be classified as a point inside, outside, or on the boundary of the solid. Such a classification is referred to as *point membership classification*. For a solid to be valid, it should be dimensionally homogeneous. In particular, it is essential that if a point is classified as being on the boundary of the solid based on the Boolean definition, then there should be some points in its neighborhood that are inside the solid and some that are outside. All the points in the neighborhood of a point should be inside the solid if it is classified as an internal point, and vice versa. To ensure these properties, a modified set of Boolean operations have been defined for solid modeling that are referred to as *regularized Boolean* operations, where the Boolean combination of primitives are valid and dimensionally homogeneous solids that do not have dangling edges or faces.

Figure 11.3.2 shows the difference between ordinary and regularized Boolean operations. Regularized Boolean operations are denoted by $\cup^*$, $\cap^*$, and $-^*$ respectively, whereas the ordinary Boolean operations are denoted by $\cup$, $\cap$, and $-$.

As shown in Figure 11.3.2, an ordinary Boolean operation may result in a solid that has dangling edges because a point that is on the boundary of both primitives is classified as a point on the boundary of the union (or intersection) of the two primitives, even though with respect to the Boolean result, every point in its neighborhood may be entirely inside or outside the solid. The problems always occur when the boundaries of the primitives overlap. At such boundaries it is necessary to use additional information to determine whether points are on, in, or outside the regularized Boolean result. One way to make this

		$\cup^*$	ON	IN
$\cap^*$	ON	OUT
$-^*$	OUT	ON

FIGURE 11.3.3 Point membership classification for overlapping boundaries.

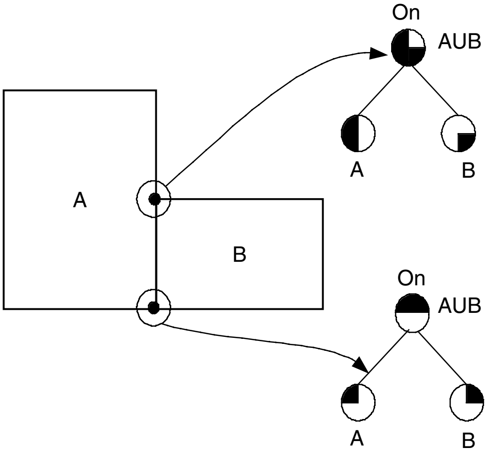

FIGURE 11.3.4 Examples of neighborhood models on the vertices in 2D.

determination is by comparing the directions of the normal vectors of both the boundaries. For example, for the regularized intersection, if both normal vectors have same directions, then the point is also on the boundary of the regularized Boolean combination; otherwise, this point is an external point. Figure 11.3.3 shows the classification of points on the overlapping boundary of primitive A and B based on the direction of the boundary normal vectors of A and B.

The method just described for classifying points for regularized Boolean combination cannot be used when multiple normal vectors are involved. For instance, vertices and points on edges cannot be classified using this approach because a unique normal cannot be defined for these points. In such cases, it is necessary to inspect the neighborhood of the point to correctly classify it. Figure 11.3.4 shows a two-dimensional example where small disks are used to symbolize the neighborhood of a point with respect to a solid and the shaded area of the disk represents the region that is inside the solid. The neighborhood of a point with respect to the Boolean combination of two primitives can be obtained as the Boolean combination of the neighborhoods of the point with respect to the primitives, as shown in Figure 11.3.4. If the neighborhood thus obtained is fully shaded, it implies that every point in the neighborhood is inside the solid and therefore the point is internal. Similarly, if all points in the neighborhood are external, then the point is an external point. If the disk is partially shaded, then it implies that some points in the neighborhood are internal while others are external; therefore, this point must be on the boundary of the solid. This approach can be extended to three dimensions by using spheres to represent the neighborhood of points.

Primitives are simple shapes, such as a block, cylinder, sphere, or cone, and are defined as the intersection of a set of half-spaces expressed as $f(x,y,z) \geq 0$. A half-space divides the space into two regions; for instance, the *x-y* plane ($z = 0$) divides the space into a region where $z \geq 0$ and a region where $z < 0$ as shown in Figure 11.3.5(a). Figure 11.3.5(b) and Figure 11.3.5(c) show a block and cylinder defined using half-spaces. The block is represented as the intersection of six planar half-spaces and the

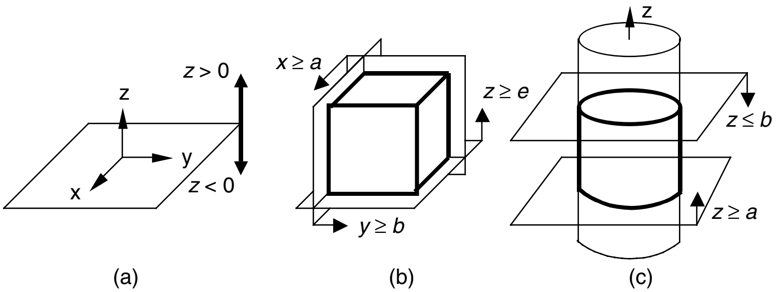

FIGURE 11.3.5 Mathematical description of the primitives by half-spaces: (a) half-space by x-y plane, (b) block by half-spaces, (c) cylinder by half-spaces.

cylinder is represented as the intersection of a cylindrical half-space and two planar half-spaces. The arrows indicate the direction of the material.

The equations of half-spaces used to create the block and cylinder can be stated compactly as follows:

$$\text{Block: } a \le x \le b\,,\ c \le y \le d\,,\ e \le z \le f$$

$$\text{Cylinder: } r^2 - x^2 + y^2 \ge 0\,,\ a \le z \le b$$

The boundaries of the primitives defined in this manner are implicit equations of curves and surfaces in the form $f(x,y,z)=0$. Implicit equations simplify point membership classification because the sign of the implicit function indicates which side of the function the point is on. Despite this advantage, implicit equations are not favorable for application to solid modeling because these equations are axes dependent so that any change in the coordinate system can change the form of the equation. Furthermore, graphical display is difficult and computationally expensive to generate when the boundaries of the solid are represented by implicit equations. CSG representation does not explicitly store information about the connectivity between boundary entities, such as which two bounding surfaces intersect to create an edge. Such connectivity information is needed for many reasons, including interactive solid editing, mesh generation, and tool path generation for machining. For these reasons, in more modern CAD software the solid is stored using the B-Rep scheme described in the next section, even though the concepts of primitives and Boolean trees are often used in conjunction.

Boundary Representation (B-Rep)

The B-Rep model of a solid describes the boundaries of a solid using both geometric information and connectivity information.[5–6] The geometry information in a B-Rep model is composed of surface equations, curve equations, and point coordinates that together define the boundaries of the solid. The connectivity information, also referred to as the *topology* or *combinatorial structure*, records how these geometrical entities are connected together.

B-Rep models are based on the idea that the boundary of a solid consists of *faces* (surfaces) bounded by *edges* (curves), which in turn are bounded by *vertices* (points). A face is a subset or limited region of some more extensive surface. For example, planar faces are subsets of infinite planes that are bounded by one or more boundaries. These boundaries can be defined using edges. The geometry of the edges themselves are curves represented using parametric equations bounded by vertices. Figure 11.3.6 shows a cube whose six faces have been named F1–F6 in the figure. The geometries associated with these faces are planes. Each face has only one boundary, and the boundaries are defined using edges that have lines as their geometry.

To define the solid precisely and unambiguously, we must formally define the topological entities and strictly follow the definition and conventions when building a data structure to represent the solid. The

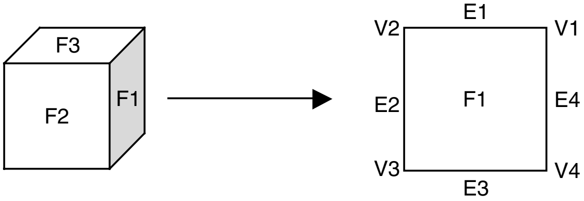

FIGURE 11.3.6 Basic concept of the B-Rep model.

topological entities used to define B-Rep solid model using half-edge data structure are vertices, edges, co-edges/half-edges, loops, faces, shells, lumps, and the body.

A solid model is represented in B-Rep as a collection of lumps. A *lump* can be defined as a simply connected region in space whose boundaries are defined by closed shells. A *shell* is a collection of faces; it is *closed* if it divides space into two disconnected regions, one of which is finite and the other infinite. A closed shell is a *peripheral shell* if the finite region created by the shell is defined as the inside of the shell, whereas it is a *void* if its infinite region is considered the inside of the shell.

A *face* is a finite, simply connected region of a surface that is non-self-intersecting and has a direction. The geometry of a face is represented using a parametric equation of a surface in the form $\mathbf{R}(u, v)$, where $\mathbf{R}$ is the position vector of points on the surface expressed as a function of two parameters, u and v. The boundaries of a face are defined using loops, and its direction is specified by a normal vector. A face can have multiple boundaries, each defined by a separate loop.

A *loop* is a piecewise, non-self-intersecting, closed space curve that defines the boundary of a face. It lies on the surface representing the face and is defined as an ordered sequence of half-edges.

A *half-edge* (also referred to as a *co-edge*) is used to record the occurrence of an edge in a loop, and it defines the direction of the loop with respect to the direction of the edge. Half-edge directions are defined such that when connected together they form a loop whose direction satisfies the right-hand rule with the normal to the face. Another way to define this orientation is that the loop direction is such that as one travels along the loop in its specified direction, points on the left are inside the face and points on the right are outside (assuming that you are on the outside surface of the face). This convention is used so that simple algorithms can be constructed to perform point membership classification to determine whether a given point is inside, outside, or on the boundary of a face.

An *edge* is defined as a bounded, directed, finite, non-self-intersecting space curve. The geometry is represented by a parametric equation of a curve, $\mathbf{R}(u)$, where $\mathbf{R}$ is the position vector of a point on the curve expressed as a function of a parameter u. Since this curve may not be bounded (and can be infinite), the start and end points of an edge are defined using vertices. The vertices defined as the beginning and the end of an edge need not be distinct if the edge is a closed curve. The direction of the edge can be defined by the sequence of its bounding vertices or by the direction of curve corresponding to the increasing parameter value. Finally, vertices are topological entities that are used to bound edges. The geometry of a vertex is defined by the position vector of a point.

Hybrid Systems

Creating B-Rep models manually by defining each vertex, edge, and surface is extremely cumbersome. Therefore, hybrid systems are used in most modern CAD systems, where the solid is represented procedurally using a CSG tree but the primitives are represented using B-Rep instead of defining them as intersections of half-spaces. The B-Rep model of the solid represented by the CSG tree is evaluated automatically using *boundary evaluator* algorithms.[7] For each regularized Boolean operation, the boundary evaluator algorithm detects intersections between participating solids, computes intersection geometries (intersection points and curves as well as subdivided faces), and classifies them using set membership classification algorithms to determine whether the geometry is in, on, or outside the final solid defined by the Boolean operation. While set membership classification is easy when the solid is represented as a combination of half-spaces (where the surfaces are implicit equations, $f(x,y,z) = 0$), it is more difficult to do for B-Reps. Furthermore, constructing the topology of the resultant solid automatically is also difficult. As a result, it is very expensive to build robust and reliable software that can handle every special case. However, over the years many commercial systems have been developed that have reliable boundary evaluator algorithms that are robust and that can handle almost all special and degenerate cases.

Sweep Features

A sweep feature is defined by sweeping a planar shape along an arbitrary space curve referred to as a sweep trajectory, where the cross section of the sweep solid can be either constant or varying. This is a popular and useful method due to the fact that the solid represented by sweeping is simple to understand and execute. If the sweep trajectory is a straight line, it is called as a *translational sweep* (or extruded solid). When the sweep trajectory is a circular arc, it is termed a *rotational sweep* (or revolved solid). When the sweep trajectory is an arbitrary parametric curve, it is referred to as a *general sweep*. In modern CAD systems, it has now become common practice to use a feature-based approach for constructing a solid model. Each sweep feature can be thought as a user-defined primitive; it is a sweep solid that is created interactively by defining one or more two-dimensional geometries (or profiles) and a trajectory for sweep. Upon defining the sweep using its profile and trajectory, the software automatically constructs the B-Rep model of this primitive so that the user does not have to define the topological and geometric entities of this B-Rep manually.

The profile for the sweep can be sketched on a face of a previously created feature or a reference plane, thus positioning the sweep with respect to previously created geometry. Boolean operations are performed automatically between the newly created feature and the previously defined solid to construct the B-Rep model of the solid with the feature applied.

Parametric Equation of a Curve

The equations of curves in B-Rep models are expressed as parametric equations[8] because it is convenient to generate points on the curve for graphics and most properties of the curve can be easily evaluated. Curves commonly used in solid models include simple analytic curves such as lines, circles, and ellipses, as well as freeform (or synthetic) curves that can only be created interactively. Equations of commonly used analytic curves as well as freeform curves are listed next.

Lines

A line passing through the points $\mathbf{P}_1$ and $\mathbf{P}_2$ is

$$\mathbf{R}(u) = \mathbf{P}_1 + (\mathbf{P}_2 - \mathbf{P}_1)u \tag{11.3.1}$$

Circles and Ellipses

An ellipse with center at the point $\mathbf{P}_c$ and whose major and minor axes are along the unit vectors $\hat{\mathbf{m}}$ and $\hat{\mathbf{n}}$ and whose major radius = A and minor radius = B can be stated as

$$\mathbf{R}(u) = \mathbf{P}_c + A\cos(u)\hat{\mathbf{m}} + B\sin(u)\hat{\mathbf{n}} \tag{11.3.2}$$

A circle is a special case of an ellipse when $A = B$ = radius of the circle. Any two mutually perpendicular vectors in the plane of the circle can be used as $\hat{\mathbf{m}}$ and $\hat{\mathbf{n}}$.

Parabolas

The equation of a parabola on a plane defined by two mutually perpendicular unit vectors, $\hat{\mathbf{m}}$ and $\hat{\mathbf{n}}$ (where $\hat{\mathbf{m}}$ is the axis of symmetry), can be stated as

$$\mathbf{R}(u) = \mathbf{P}_v + Au^2\hat{\mathbf{m}} + Bu\hat{\mathbf{n}} \tag{11.3.3}$$

$\mathbf{P}_v$ is the vertex of the parabola where it intersects with its line of symmetry.

Hermite Curves

The equation of a cubic polynomial curve between points $\mathbf{P}_1$ and $\mathbf{P}_2$ whose tangents at these points are $\dot{\mathbf{P}}_1$ and $\dot{\mathbf{P}}_2$ can be expressed using Hermite polynomials as basis functions and is therefore called a Hermite curve:

$$\mathbf{R}(u)=\mathbf{P}_1H_1(u)+\mathbf{P}_2H_2(u)+\dot{\mathbf{P}}_1H_3(u)+\dot{\mathbf{P}}_2H_4(u) \tag{11.3.4}$$

where $H_i(u)$ are Hermite polynomials defined as

$$\begin{aligned} H_1(u)&=2u^3-3u^2+1\\ H_2(u)&=-2u^3+3u^2\\ H_3(u)&=u^3-2u^2+u\\ H_4(u)&=u^3-u^2 \end{aligned} \tag{11.3.5}$$

Alternatively, the Hermite curve can be expressed using matrix notation as

$$\mathbf{R}(u)=\{\mathbf{U}\}^T[\mathbf{H}]\{\mathbf{P}\} \tag{11.3.6}$$

where $\{\mathbf{U}\}^T=\left\{u^3 \quad u^2 \quad u \quad 1\right\}$

$$[\mathbf{H}]=\begin{bmatrix} 2 & -2 & 1 & 1\\ -3 & 3 & -2 & -1\\ 0 & 0 & 1 & 0\\ 1 & 0 & 0 & 0 \end{bmatrix} \text{ and } \{\mathbf{P}\}=\begin{Bmatrix} \mathbf{P}_1\\ \mathbf{P}_2\\ \dot{\mathbf{P}}_1\\ \dot{\mathbf{P}}_2 \end{Bmatrix} \tag{11.3.7}$$

Bezier Curves

A Bezier curve is a polynomial of degree n that is controlled by n+1 control points, $\mathbf{P}_i$, i = 1, …, n+1:

$$\mathbf{R}(u)=\sum_{i=0}^{n}\mathbf{P}_iB_{i,n}(u), \quad u\in[0,1] \tag{11.3.8}$$

where the basis functions $B_{i,n}(u)$ are Bernstein polynomials defined as

$$B_{i,n}(u)=\frac{n!}{i!(n-i)!}u^i(1-u)^{n-i} \tag{11.3.9}$$

The curve can be interactively edited by moving the control points. The curve passes through the first and last control points, and its tangents at the beginning and end are parallel to the first and last segments of the control polygon (obtained by joining the control points by lines):

$$\dot{\mathbf{R}}(0)=n(\mathbf{P}_1-\mathbf{P}_0) \text{ and } \dot{\mathbf{R}}(1)=n(\mathbf{P}_n-\mathbf{P}_{n-1}) \tag{11.3.10}$$

B-Spline Curves

A polynomial of degree (K-1), controlled by n control points $\mathbf{P}_i$, i = 1, …, n, is given by

$$\mathbf{R}(u)=\sum_{i=0}^{n}\mathbf{P}_iN_{i,K}(u) \tag{11.3.11}$$

where the basis functions can be recursively defined as

$$N_{i,k}(u)=\frac{(u-t_i)N_{i,k-1}(u)}{t_{i+k-1}-t_i}+\frac{(t_{i+k}-u)N_{i+1,k-1}(u)}{t_{i+k}-t_{i+1}} \quad \text{for } k = 2, \ldots, \mathrm{K} \tag{11.3.12}$$

$$\begin{aligned} N_{i,1}(u)&=1 \quad \text{if } t_i \le u < t_{i+1} \\ &=0 \quad \text{Otherwise} \end{aligned} \tag{11.3.13}$$

The t_j are knot values defined for $j = 0, \ldots, n + \mathrm{K}$ as

$$\begin{aligned} t_j &= 0 && \text{if } j < \mathrm{K} \\ t_j &= j-K+1 && \text{if } \mathrm{K} \le j \le n \\ t_j &= n-K+2 && \text{if } j < n \end{aligned} \tag{11.3.14}$$

The degree of the B-spline curve, K, is independent of the number of control points n. The curve passes through the first and last control points, and can be edited interactively by moving control points. Each control point affects only four spans of the curve, thus allowing local control of the curve during interactive editing. A cubic B-spline curve is C^2 continuous so that at every point its tangent and normal are defined and the curvature varies continuously.

Properties of the Parametric Curves

Let $\mathbf{R}(u)$ be the parametric equation of a curve defined over a domain $a \le u \le b$. A vector tangent to this curve at any point can be computed as

$$\text{Tangent vector} = \mathbf{T} = \mathbf{R}_u = \frac{d\mathbf{R}}{du} \quad \text{and Unit tangent vector} = \hat{\mathbf{T}} = \frac{\mathbf{T}}{|\mathbf{T}|} \tag{11.3.15}$$

The magnitude of the derivative of $\mathbf{R}(u)$ is called the speed of the curve, and it is often denoted as

$$\dot{s} = \left|\frac{d\mathbf{R}}{du}\right| \tag{11.3.16}$$

The curvature of a curve is defined as the rate of turning angle of a curve with respect to arc length:

$$\text{Curvature} = \kappa = \frac{1}{\rho} = \frac{d\phi}{ds} \tag{11.3.17}$$

where ρ = radius of curvature, ϕ = turning angle, and s = arc length. The second derivative of $\mathbf{R}(u)$ is a vector on the plane of the curve defined by the tangent and normal of the curve at any point:

$$\ddot{\mathbf{R}} = \mathbf{R}_{uu} = \frac{d^2\mathbf{R}}{du^2} = \ddot{s}\hat{\mathbf{T}} + \dot{s}^2\kappa\hat{\mathbf{N}} \tag{11.3.18}$$

where κ = curvature and $\hat{\mathbf{N}}$ = unit normal vector. The vector normal to the plane of the curve at any point on the curve is called its binormal. It can be conveniently computed as the cross-product of the first and second derivatives of $\mathbf{R}(u)$:

$$\text{Binormal vector} = \mathbf{B} = \dot{\mathbf{R}} \times \ddot{\mathbf{R}} = \dot{s}^3 k\hat{\mathbf{B}} \tag{11.3.19}$$

$\hat{\mathbf{B}}$ = Unit Binormal vector

The curvature of a curve at any point can be computed as follows:

$$\text{Curvature} = \kappa = \frac{\left|\dot{\mathbf{R}} \times \ddot{\mathbf{R}}\right|}{\left|\dot{\mathbf{R}}\right|^3} \tag{11.3.20}$$

Parametric Equations of Surfaces

Parametric equations of the form $\mathbf{R}(u, v)$ are the preferred method for representing surfaces for B-Rep models.[8] It is easy to generate points on the surface by computing the equation for various values of the parameter within its domain, $(u, v) \in [a,b] \times [c,d]$. The common method for defining simple analytical surfaces is by sweeping a curve over another curve. Surfaces defined in this fashion are used for defining the boundaries of sweep solids. Freeform surfaces are most often defined using Hermite, Bezier, and B-spline patches. Some of the most commonly used surfaces are defined next.

Planar Surfaces

Let $\mathbf{P}_1$ be a point on the plane and $\mathbf{m}$ and $\mathbf{n}$ be two nonparallel vectors (preferably perpendicular unit vectors) on the plane. Its equation can be written as

$$\mathrm{R}(u, v) = \mathbf{P}_1 + u\mathbf{m} + v\mathbf{n} \tag{11.3.21}$$

A plane can also be defined by specifying three noncollinear points on the plane: $\mathbf{P}_1$, $\mathbf{P}_2$, and $\mathbf{P}_3$. The equation for this plane can be written as

$$\mathrm{R}(u, v) = \mathbf{P}_1 + u(\mathbf{P}_2 - \mathbf{P}_1) + v(\mathbf{P}_3 - \mathbf{P}_1) \tag{11.3.22}$$

Extruded Surfaces (or Tabulated Surfaces)

Let $\mathrm{R}_1(u)$ be the equation of a curve that is extruded in the direction $\mathbf{n}$. The equation of the extruded surface can be written as

$$\mathrm{R}(u, v) = \mathrm{R}_1(u) + v\mathbf{n} \tag{11.3.23}$$

Revolved Surfaces

Let $\mathbf{n}_1$, $\mathbf{n}_2$, and $\mathbf{n}_3$ be three mutually perpendicular vectors and let $\mathbf{G}(u)$ be the parametric equation of a curve on the $\mathbf{n}_1 - \mathbf{n}_3$ plane. The equation of the surface obtained by revolving $\mathbf{G}(u)$ around $\mathbf{n}_3$ is given by

$$\mathrm{R}(u, v) = g_1(u)\cos(2\pi v)\mathbf{n}_1 + g_1(u)\sin(2\pi v)\mathbf{n}_2 + g_3(u)\mathbf{n}_3, \quad (u, v) \in [0,1] \times [0,1] \tag{11.3.24}$$

where $\mathrm{G}(u) = \begin{Bmatrix} g_1(u) \\ g_3(u) \end{Bmatrix}$ is the planar curve revolved around $\mathbf{n}_3$.

Blended or Ruled Surfaces

Let $\mathrm{R}_1(u)$ and $\mathrm{R}_2(u)$, $u \in [0,1]$ be the parametric equations of two curves. The blended or ruled surface (also known as lofted surface) between these two curves can be defined as

$$\mathrm{R}(u, v) = v\mathbf{R}_1(u) + (1 - v)\mathbf{R}_2(u), \quad v \in [0,1] \tag{11.3.25}$$

General Sweep Surfaces

Let $\mathbf{C}(u)$, $u \in [0,1]$ be the parametric equation of the curve representing the sweep trajectory, and let $\mathbf{G}(v)$ be the planar profile curve being swept along this trajectory. The equation of the sweep surface is

$$\mathbf{R}(u,v) = \mathbf{C}(u) + g_1(v)\hat{\mathbf{N}} + g_2(v)\hat{\mathbf{B}} \tag{11.3.26}$$

where the planar profile curve is $\mathbf{G}(v) = \begin{Bmatrix} g_1(v) \\ g_2(v) \end{Bmatrix}$, $v \in [0,1]$

and $$\hat{\mathbf{B}} = \text{unit binormal} = \frac{\dot{\mathbf{C}}(u) \times \ddot{\mathbf{C}}(u)}{\left|\dot{\mathbf{C}}(u) \times \ddot{\mathbf{C}}(u)\right|}, \quad \hat{\mathbf{N}} = \text{unit normal vector} = \hat{\mathbf{B}} \times \hat{\mathbf{T}}, \quad \hat{\mathbf{T}} = \frac{\dot{\mathbf{C}}(u)}{\left|\dot{\mathbf{C}}(u)\right|} \tag{11.3.27}$$

Hermite Patches

The equation of a Hermite bicubic surface patch can be written in terms of its four corner points, two tangents in the parametric directions, and the twist vector at these points as

$$\mathbf{R}(u,v) = \{\mathbf{U}\}^T [\mathbf{H}][\mathbf{B}][\mathbf{H}]\{\mathbf{V}\} \tag{11.3.28}$$

where $\{\mathbf{U}\}^T = \{u^3 \;\; u^2 \;\; u \;\; 1\}$ and $\{\mathbf{V}\}^T = \{v^3 \;\; v^2 \;\; v \;\; 1\}$

$$[\mathbf{H}] = \begin{bmatrix} 2 & -2 & 1 & 1 \\ -3 & 3 & -2 & -1 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix} \tag{11.3.29}$$

$$[\mathbf{B}] = \begin{bmatrix} \mathbf{P}_0 & \mathbf{P}_1 & \mathbf{P}_{v0} & \mathbf{P}_{v1} \\ \mathbf{P}_2 & \mathbf{P}_3 & \mathbf{P}_{v2} & \mathbf{P}_{v3} \\ \mathbf{P}_{u0} & \mathbf{P}_{u1} & \mathbf{P}_{uv0} & \mathbf{P}_{uv1} \\ \mathbf{P}_{u2} & \mathbf{P}_{u3} & \mathbf{P}_{uv2} & \mathbf{P}_{uv3} \end{bmatrix} \tag{11.3.30}$$

The four corner points of the patch are $\{\mathbf{P}_0 \;\; \mathbf{P}_1 \;\; \mathbf{P}_2 \;\; \mathbf{P}_3\}$.
Tangents at the corner points in the u direction are $\{\mathbf{P}_{u0} \;\; \mathbf{P}_{u1} \;\; \mathbf{P}_{u2} \;\; \mathbf{P}_{u3}\}$.
Tangents at the corner points in the v direction are $\{\mathbf{P}_{v0} \;\; \mathbf{P}_{v1} \;\; \mathbf{P}_{v2} \;\; \mathbf{P}_{v3}\}$.
Twist vectors at the corner points are $\{\mathbf{P}_{uv0} \;\; \mathbf{P}_{uv1} \;\; \mathbf{P}_{uv2} \;\; \mathbf{P}_{uv3}\}$.

Bezier Patches

A Bezier surface patch is an extension of the Bezier curve and has two parameter directions, u and v. Its shape is controlled by $(n+1)\times(m+1)$ control points $\mathbf{P}_{ij}$ that form a control polyhedron:

$$\mathbf{R}(u,v) = \sum_{i=0}^{n}\sum_{j=0}^{m} \mathbf{P}_{ij} B_{i,n}(u) B_{j,m}(v), \quad (u,v) \in [0,1]\times[0,1] \tag{11.3.31}$$

where the basis functions are the Bernstein polynomials

$$B_{i,n}(u) = \frac{n!}{i!(n-i)!} u^i (1-u)^{n-i} \tag{11.3.32}$$

The Bezier surface interpolates the four corner points, and the surface is tangent to the corner segments of the control polyhedron.

B-Spline Patches

A B-spline surface can be created by extending the B-spline curve to a surface defined by an array of $(n + 1) \times (m + 1)$ control points:

$$\mathbf{R}(u,v) = \sum_{i=0}^{n} \sum_{j=0}^{m} \mathbf{P}_{ij} N_{i,k}(u) N_{j,l}(v) \ , \ \ (u,v) \in [0,u_{\max}] \times [0,v_{\max}] \tag{11.3.33}$$

The basis functions of the B-spline surface are the same as for the curve (defined earlier in (Equation 11.3.12, Equation 11.3.13, and Equation 11.3.14). B-spline surfaces provide local control over the patch. The degree of the patch is independent of the number of control points. The surface is C^2 continuous.

Properties of Parametric Surfaces

Tangents

For a parametric surface $\mathbf{R}(u,v)$, a series of isoparametric curves can be defined on it for various fixed values of u and v. Two isoparametric curves, $\mathbf{R}(u,v_0)$ and $\mathbf{R}(u_0,v)$, on this surface intersect at the point $\mathbf{R}(u_0,v_0)$, and one can compute the tangent vectors for these two curves as

$$\text{Tangent to surface in the u-direction} = \mathbf{R}_u = \frac{\partial \mathbf{R}(u,v_0)}{\partial u} \tag{11.3.34}$$

$$\text{Tangent to surface in the v-direction} = \mathbf{R}_v = \frac{\partial \mathbf{R}(u_0,v)}{\partial v} \tag{11.3.35}$$

Since these two curves lie on the surface, these vectors are also tangents to the surface. Using these two vectors, we can express the tangent plane to the surface at the point $\mathbf{R}(u_0,v_0)$ as

$$\mathbf{T}(r,s) = \mathbf{R}(u_0,v_0) + r\mathbf{R}_u(u_0,v_0) + s\mathbf{R}_v(u_0,v_0) \tag{11.3.36}$$

Let $\mathbf{P}(t) = \begin{Bmatrix} u(t) \\ v(t) \end{Bmatrix}$ be an arbitrary curve in the parametric space of the surface. The equation of the corresponding curve in real space is $\mathbf{R}(t) = \mathbf{R}(u(t),v(t))$.

The tangent vector along this curve is

$$\mathbf{R}_t = \frac{d\mathbf{R}}{dt} = \frac{\partial \mathbf{R}}{\partial u}\frac{\partial u}{\partial t} + \frac{\partial \mathbf{R}}{\partial v}\frac{\partial v}{\partial t} = \mathbf{R}_u \dot{u} + \mathbf{R}_v \dot{v} \tag{11.3.37}$$

The speed of this curve is the magnitude of this tangent vector:

$$\dot{s} = \left|\mathbf{R}_t\right| = \sqrt{\mathbf{R}_u \cdot \mathbf{R}_u \dot{u}^2 + 2\mathbf{R}_u \cdot \mathbf{R}_v \dot{u}\dot{v} + \mathbf{R}_v \cdot \mathbf{R}_v \dot{v}^2} \tag{11.3.38}$$

The length of this curve from t = a to t = b is:

$$S = \int_a^b \sqrt{\mathbf{R}_u \cdot \mathbf{R}_u \dot{u}^2 + 2\mathbf{R}_u \cdot \mathbf{R}_v \dot{u}\dot{v} + \mathbf{R}_v \cdot \mathbf{R}_v \dot{v}^2}\, dt \tag{11.3.39}$$

Equation 11.3.39 is often written in the following form, which is referred to as the *First Fundamental Quadratic Form* of a surface:

$$ds^2 = E(u,v)du^2 + 2F(u,v)dudv + G(u,v)dv^2 \tag{11.3.40}$$

where

$$E = \mathbf{R}_u \cdot \mathbf{R}_u, F = \mathbf{R}_u \cdot \mathbf{R}_v, G = \mathbf{R}_v \cdot \mathbf{R}_v \tag{11.3.41}$$

The Curvature of a Curve on a Surface

The curvature of the curve $\mathbf{P}(t)$ can be computed by taking the dot product between the second derivative of the curve with the unit normal to the curve:

$$\hat{\mathbf{n}}.\ddot{\mathbf{R}} = \hat{\mathbf{n}}.\mathbf{R}_{uu}\left(\frac{du}{dt}\right)^2 + 2\hat{\mathbf{n}}.\mathbf{R}_{uv}\frac{du}{dt}\frac{dv}{dt} + \hat{\mathbf{n}}.\mathbf{R}_{vv}\left(\frac{dv}{dt}\right)^2 = \dot{s}^2\kappa \tag{11.3.42}$$

Therefore, the curvature of the curve $\mathbf{P}(t)$ on the surface is

$$\kappa = \frac{\hat{\mathbf{n}}.\mathbf{R}_{uu}\dot{u}^2 + 2\hat{\mathbf{n}}.\mathbf{R}_{uv}\dot{u}\dot{v} + \hat{\mathbf{n}}.\mathbf{R}_{vv}\dot{v}^2}{\mathbf{R}_u \cdot \mathbf{R}_u\dot{u}^2 + 2\mathbf{R}_u \cdot \mathbf{R}_v\dot{u}\dot{v} + \mathbf{R}_v \cdot \mathbf{R}_v\dot{v}^2} = \frac{L\dot{u}^2 + 2M\dot{u}\dot{v} + N\dot{v}^2}{E\dot{u}^2 + 2F\dot{u}\dot{v} + G\dot{v}^2} \tag{11.3.43}$$

Equation 11.3.43, written in the following form, is referred to as the *Second Fundamental Quadratic Form* of a surface:

$$ds^2\kappa = Ldu^2 + 2Mdudv + Ndv^2 \tag{11.3.44}$$

where

$$L = \hat{\mathbf{n}}.\mathbf{R}_{uu}, M = \hat{\mathbf{n}}.\mathbf{R}_{uv}, N = \hat{\mathbf{n}}.\mathbf{R}_{vv} \tag{11.3.45}$$

The Curvature of a Surface

At any given point, the curvature of an arbitrary curve through the point is given by Equation 11.3.43. This equation can be rewritten as follows:

$$\begin{Bmatrix} du & dv \end{Bmatrix}\begin{bmatrix} E & F \\ F & G \end{bmatrix}\begin{Bmatrix} du \\ dv \end{Bmatrix}k = \begin{Bmatrix} du & dv \end{Bmatrix}\begin{bmatrix} L & M \\ M & N \end{bmatrix}\begin{Bmatrix} du \\ dv \end{Bmatrix} \tag{11.3.46}$$

This is a generalized eigenvalue problem, and the eigenvalues represent the maximum ($k_{\max}$) and minimum ($k_{\min}$) curvature of the surface at the point. The eigen vectors represent the direction in which the surface has the maximum and minimum curvature. Because the curvature is different in every direction, the following measures of curvature are commonly used to define the curvature of a surface at a point:

$$\text{Gaussian curvature} = K = k_{\max}k_{\min} = \frac{LN - M^2}{EG - F^2} \tag{11.3.47}$$

$$\text{Mean curvature} = H = \frac{1}{2}(k_{\max} + k_{\min}) = \frac{EN + GL - 2FM}{2(EG - F^2)} \tag{11.3.48}$$

$$\text{Maximum curvature} = k_{\max} = H + \sqrt{H^2 - K} \tag{11.3.49}$$

$$\text{Minimum curvature} = k_{\min} = H - \sqrt{H^2 - K} \tag{11.3.50}$$

Engineering Analysis Tools: Finite Element Analysis

The finite element method (FEM) is a numerical method that can be used for solving boundary value problems that occur frequently in engineering analysis.[9–11] Structural analysis has been the most popular application of FEM, but it is now routinely used for solving a variety of linear and nonlinear engineering analysis problems that arise during the design of structures and machines. These include problems in solid mechanics, heat conduction, fluid flow, dynamics and vibrations, electrostatics, and electromagnetism. Commercial finite element analysis (FEA) programs provide all these capabilities and therefore have now become an indispensable tool for engineering design. FEA software is now routinely used to simulate the performance of engineering components that have been designed but not yet manufactured. The design of mechanical components is often an iterative process involving design, analysis, modification of design, and repeated analysis. Alternatively, FEA has also been used in conjunction with optimization software to automate these iterations to synthesize mechanical components and assemblies that satisfy functional requirements.

A summary of the major concepts and results related to application of FEM for solving linear static problems most commonly encountered in engineering design, including static structural and heat conduction problems, is presented here. The governing equations for these problems are partial differential equations that must be satisfied for equilibrium. These equations must be satisfied over a domain that is the geometry of the structure/component being analyzed while also satisfying some constraints (referred to as boundary conditions) along the boundaries of the domain. Such problems are commonly referred to as *boundary value problems*. FEM solves the weak form of these boundary value problems derived using Galerkin's method.[10] The solutions to these problems are field variables, such as the displacement field (a vector field) for structural problems or temperature field (a scalar field) for heat-conduction problems. FEM divides the domain of analysis (or the geometry) into simple elements to create a mesh. The field variable is "discretized" by defining it as a piecewise interpolation so that within each element the field variables are interpolated using the values at the nodes of the elements. This allows the values at the nodes to be used as the discrete variables to be solved for, instead of solving for the original scalar or vector field, which are continuous functions. The weak form of boundary value problems is an integral equation that involves integration over the volume of the geometry. FEM carries out this integration piecewise over each element to derive the equilibrium equations for each element and then assembles them to form the global equations for the entire domain.

In this section, the various elements commonly available in FEA software are first listed and categorized as one-, two-, and three-dimensional elements. The basis functions (also known as shape functions) used for interpolating the field variables within each element and the common applications of each type of element are listed. Then, a variety of engineering analysis problems and the elements used for the analysis are described. For each analysis type, the boundary value problem (or governing equations) and the corresponding weak forms are given. The element type used for the analysis, the formulation of the element equations, and typical boundary conditions are also described.

Element Types

One-Dimensional Elements

A problem where the field variable can be expressed as a function of a single spatial coordinate is a one-dimensional problem and can be solved using a one-dimensional element whose geometry is a line or a curve. The real geometry of all structures is three-dimensional, of course, so this is an idealization that is used to simplify problems where the field variable varies in only one direction.

Two-Node Linear Elements. A one-dimensional two-node element assumes that the field variable varies linearly within the element. If $u(r)$ is the field variable expressed in terms of a local (or parametric) coordinate system r and the values of this variable at the nodes of the element are u_1 and u_2, then the variable is interpolated within the element as

$$u(r) = u_1 N_1(r) + u_2 N_2(r) \tag{11.3.51}$$

where $N_i(r)$ are the shape functions (or the basis functions):

$$N_1(r) = \frac{1}{2}(1-r)\,,\quad N_2(r) = \frac{1}{2}(1+r) \tag{11.3.52}$$

Since the variable is interpolated as a function of $r \in [-1,1]$, a mapping between this parameter space and the real space is necessary. In the isoparametric elements the interpolation functions defined above are also used to define the mapping between the local coordinates and the global coordinate x as follows:

$$x(r) = x_1 N_1(r) + x_2 N_2(r) \tag{11.3.53}$$

Three-Node Quadratic Elements. The field variable within a three-node isoparametric element is interpolated using quadratic polynomial basis functions as

$$u(r) = u_1 N_1(r) + u_2 N_2(r) + u_3 N_3(r) \tag{11.3.54}$$

where $r \in [-1,1]$, u_i are the nodal values at the three nodes of the element and

$$N_1(r) = -\frac{1}{2}r(1-r),\quad N_2(r) = \frac{1}{2}r(1+r) \text{ and } N_3(r) = (1-r^2) \tag{11.3.55}$$

The mapping between local coordinates and the global coordinate x is

$$x(r) = x_1 N_1(r) + x_2 N_2(r) + x_3 N_3(r) \tag{11.3.56}$$

Two-Node Hermite Elements. The Hermite element provides a tangent continuous cubic polynomial interpolation of the field variable by using both the value of the variable and its derivative at each node for the interpolation:

$$u(r) = u_1 N_1(r) + u_2 N_2(r) + \dot{u}_1 N_3(r) + \dot{u}_2 N_4(r) \tag{11.3.57}$$

where u_i are the values of the variable, $\dot{u}_i$ are the derivates of the variable at the nodes, and the shape functions $N_i(r)$ are

$$\begin{aligned} N_1(r) &= 2r^3 - 3r^2 + 1 \\ N_2(r) &= -2r^3 + 3r^2 \\ N_3(r) &= L_e(r^3 - 2r^2 + r) \\ N_4(r) &= L_e(r^3 - r^2) \end{aligned}\quad,\quad r = \frac{x}{L_e} \tag{11.3.58}$$

where x is the local coordinate (distance along the element) and L_e is the length of the element.

Two-Dimensional Elements

A problem can be modeled as two-dimensional when the field variable varies within a plane and is constant in the direction normal to the plane. Therefore, the field variables can be expressed as a function of two spatial coordinates, and geometry of the element is a two-dimensional planar region of constant thickness. Some of the most commonly used two-dimensional elements and their shape functions are listed next.

Three-Node Triangular Elements. The three-node triangular element interpolates a field variable, $u(x, y)$, linearly within a triangle. If u_i are the nodal values of this variable, then the interpolation within the element can be written as

$$u(x,y) = u_1 L_1(x,y) + u_2 L_2(x,y) + u_3 L_3(x,y) \tag{11.3.59}$$

where L_i the shape functions for this element, also known as area coordinates and barycentric coordinates, satisfy the following relations:

$$\begin{Bmatrix} 1 \\ x \\ y \end{Bmatrix} = \begin{bmatrix} 1 & 1 & 1 \\ x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \end{bmatrix} \begin{Bmatrix} L_1 \\ L_2 \\ L_3 \end{Bmatrix} \tag{11.3.60}$$

$$L_i = a_i + b_i x + c_i y \qquad i = 1,2,3 \tag{11.3.61}$$

$$\begin{Bmatrix} a_1 \\ a_2 \\ a_3 \end{Bmatrix} = \frac{1}{2A} \begin{Bmatrix} x_2 y_3 - x_3 y_2 \\ x_3 y_1 - x_1 y_3 \\ x_1 y_2 - x_2 y_1 \end{Bmatrix}, \quad \begin{Bmatrix} b_1 \\ b_2 \\ b_3 \end{Bmatrix} = \frac{1}{2A} \begin{Bmatrix} y_2 - y_3 \\ y_3 - y_1 \\ y_1 - y_2 \end{Bmatrix}, \quad \begin{Bmatrix} c_1 \\ c_2 \\ c_3 \end{Bmatrix} = \frac{1}{2A} \begin{Bmatrix} x_3 - x_2 \\ x_1 - x_3 \\ x_2 - x_1 \end{Bmatrix} \tag{11.3.62}$$

where A is the area of the triangle.

In the above equations, (x_i, y_i) are the coordinates of the nodes of the triangular element. The interpolation is linear, and therefore the derivatives of the field variable are constant for this element.

Four-Node Quadrilateral Elements. The four-node quadrilateral element is formulated as an isoparametric element where the interpolations are with respect to a local (or parametric) coordinate system. This element provides a bilinear interpolation of the nodal values of the field variable, $u(r, s)$, as follows:

$$u(r,s) = \sum_{i=1}^{4} u_i N_i(r,s) \tag{11.3.63}$$

where the shape functions are

$$\begin{aligned} N_1(r,s) &= \frac{1}{4}(1+r)(1+s) \\ N_2(r,s) &= \frac{1}{4}(1+r)(1-s) \\ N_3(r,s) &= \frac{1}{4}(1-r)(1-s) \\ N_4(r,s) &= \frac{1}{4}(1-r)(1+s) \end{aligned} \tag{11.3.64}$$

The mapping between the parametric coordinates (*r, s*) and the global coordinates (*x, y*) is expressed as

$$x(r,s)=\sum_{i=1}^{4}x_iN_i(r,s)$$
$$y(r,s)=\sum_{i=1}^{4}y_iN_i(r,s) \tag{11.3.65}$$

Three-Dimensional Elements

Problems that cannot be modeled as one- or two-dimensional, because the field variable varies in all the spatial directions, have to be modeled using three-dimensional elements. The commonly used elements and their shape functions are discussed next.

Four-Node Tetrahedral Elements. The four-node tetrahedral element is the three-dimensional analog of the triangular element. It interpolates the field variable, $u(x,y,z)$, linearly within a tetrahedral region. As for the triangular element, barycentric coordinates (or volume coordinates) can be used as shape functions that satisfy the relations

$$\begin{Bmatrix}1\\x\\y\\z\end{Bmatrix}=\begin{bmatrix}1&1&1&1\\x_1&x_2&x_3&x_4\\y_1&y_2&y_3&y_4\\z_1&z_2&z_3&z_4\end{bmatrix}\begin{Bmatrix}L_1\\L_2\\L_3\\L_4\end{Bmatrix} \tag{11.3.66}$$

where (x_i,y_i,z_i) are the coordinates of the four nodes of the tetrahedron. The inverse of the above equation gives relations for barycentric coordinates with respect to (x,y,z). The field variable, $u(x,y,z)$, is interpolated as

$$u(x,y,z)=\sum_{i=1}^{4}u_iL_i(x,y,z)\ . \tag{11.3.67}$$

As for the triangular element, the derivatives of the field variable are constant within this element because the field variable is linearly interpolated.

Eight-Node Hexahedral Elements. The eight-node hexahedral element is formulated as an isoparametric element and is the three-dimensional analog of the four-node quadrilateral element. The field variable is interpolated using trilinear shape functions that are expressed in terms of a local (or parametric) coordinate system (r,s,t) as

$$u(r,s,t)=\sum_{i=1}^{8}u_iN_i(r,s,t) \tag{11.3.68}$$

where N_i are the shape functions that are defined as

$$N_i=\frac{1}{8}(1+r_ir)(1+s_is)(1+t_it) \tag{11.3.69}$$

where (r_i,s_i,t_i) are the coordinates of the ith node of the element in the parametric coordinate system. In this coordinate system, the element is a perfect cube of size 2 × 2 × 2 centered at the origin. The mapping between the parametric coordinates and the global (x,y,z) coordinates is given as

$$x=\sum_{i=1}^{8}x_iN_i(r,s,t)\ ,\quad y=\sum_{i=1}^{8}y_iN_i(r,s,t)\ ,\quad z=\sum_{i=1}^{8}z_iN_i(r,s,t) \tag{11.3.70}$$

Engineering Analysis Problems

The interpolation schemes defined in the previous section are used to solve various engineering analysis problems. The type of element and interpolation used depends on whether the physical problem involved can be idealized as one-, two-, or three-dimensional. It also depends on the boundary value problem that needs to be solved. In this section, we examine a few engineering analysis problems frequently encountered in engineering design and the corresponding elements.

Rods and Trusses

Rod-like structures that are subjected to purely axial load (tension or compression) can be modeled using rod/truss elements. The term "truss" is used to refer to a structure constructed by connecting together many rods by frictionless pin joints and are loaded and supported only at these joints. Under these conditions, each rod in the structure will be subjected only to pure axial load and therefore can be modeled using rod (or truss) elements. The field variable for this element is the axial displacement of points on the element $u(s)$, where s is a local coordinate along the axis of the rod. The displacement in this element can be modeled using the two-node linear element described earlier. Since the displacement varies linearly within an axially loaded rod (within elastic limit) as assumed in the two-node linear element, the analysis using this element gives an exact solution of the mathematical model. The governing equation for this element can be written as

$$\frac{d}{ds}\left(EA\frac{du}{ds}\right)=0 \tag{11.3.71}$$

where E = Young's modulus of elasticity and A = area of cross section of the element. The weak form of this differential equation can be stated as

$$\int_0^L \frac{d\delta u}{ds}EA\frac{du}{ds}ds = F_1\delta u_1 + F_2\delta u_2 \tag{11.3.72}$$

In the previous equation, L is the length of the element, δu is the virtual displacement, and F_i and δu_i are the forces and virtual displacements at the two nodes of the element. The boundary conditions that can be applied on this element are

Essential boundary condition: $u_i = a_i$, where a_i = prescribed displacement at node i

Natural boundary condition: $EA\dfrac{du}{ds} = F_i$

The equilibrium equation for an element can be expressed as $[\mathbf{K}_e]\{\mathbf{X}_e\} = \{\mathbf{F}_e\}$, where

$$\left[\mathbf{K}_\mathbf{e}\right]=\frac{EA}{Le}\begin{bmatrix}1 & -1\\ -1 & 1\end{bmatrix},\ \left\{\mathbf{X}_e\right\}=\begin{Bmatrix}u_1\\ u_2\end{Bmatrix} \text{ and } \left\{\mathbf{F}_e\right\}=\begin{Bmatrix}F_1\\ F_2\end{Bmatrix} \tag{11.3.73}$$

The field variables just described are with respect to a local coordinate system, s, that is attached to the truss element. However, a truss-like structure is constructed using many such elements, and therefore it is convenient to express the displacement at each node with respect to a global coordinate system, as shown in Figure 11.3.7. The three components of the displacement along the global coordinate axes correspond to three degrees of freedom at each node. Thus a general "3D truss" element available in FEA software can be used for constructing a three-dimensional truss structure with each element arbitrarily oriented in space. At each node, three components of displacement or forces can be specified.

Beams and Frames

A slender rod-like structure subjected to bending and transverse loads can be modeled using a beam element. As in the case of truss elements, this is a one-dimensional element because its field variables

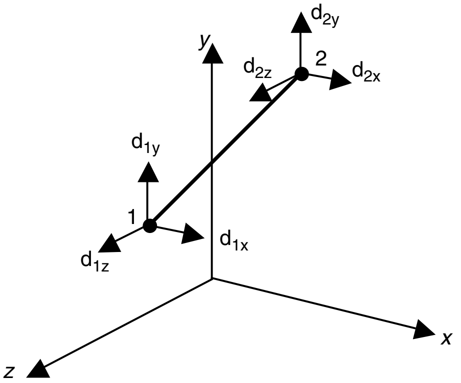

FIGURE 11.3.7 Truss element.

can be expressed as a function of one spatial dimension, *s*, which is a local coordinate system that measures distance along the axis of the beam. It is possible to formulate the beam equations with respect to this local coordinate system to get a simple equilibrium equation for a beam element that has only two degrees of freedom per node and is subjected only to bending and transverse load as described next. This simple beam element would have only two degrees for freedom per node (transverse deflection and rotation). However, the beam element implemented in most FEA software is more general, and it is expressed in terms of a global coordinate system and can be subjected to axial loads and torsion as well.

The governing equation of the beam expresses the condition for static equilibrium as follows:

$$\frac{d^2}{ds^2}\left(EI\frac{d^2w}{ds^2}\right)=f \tag{11.3.74}$$

where $w(s)$ is the transverse displacement field, f is the distributed transverse load acting on the structure, E = Young's modulus of elasticity, and I is the moment of inertia of the cross-section. The weak form of this equation can be stated as

$$\int_0^L \frac{d^2\delta w}{\mathrm{ds}^2}EI\frac{d^2w}{ds^2}ds=\delta w_1V_1+\delta\theta_1M_1+\delta w_2V_2+\delta\theta_2M_2+\int_0^L f\delta w ds \tag{11.3.75}$$

where L is the length of the element, δw is the virtual transverse deflection, V_i and M_i are the shear force and bending moment, respectively, at node *i*, while δw_i and $\delta\theta_i$ are the virtual deflection and rotation at node *i*.

Since the weak form involves the second derivatives of the transverse deflection, it is necessary that the interpolation of this field is tangent (or C^1) continuous. Therefore, for this element the Hermite interpolation described earlier is used. This interpolation requires two nodal degrees of freedom: the transverse deflection and its derivative, which is the slope. For small deflections, the slope is the same as angular displacement or rotation. The boundary conditions that can be specified for this element are

Essential boundary conditions:

(i) Deflection at a node: $w_i = d_i$ = specified deflection at node *i*

(ii) Slope at a node: $\left.\frac{dw}{ds}\right|_i = \theta_i$ = specified rotation at node *i*

Natural boundary conditions:

(i) Bending moment at node: $\left.EI\frac{d^2w}{ds^2}\right|_i = M_i$ = specified bending moment at node *i*

(ii) Shear force at node: $\left.EI\frac{d^3w}{ds^3}\right|_i = V_i$ = specified shear force at node *i*

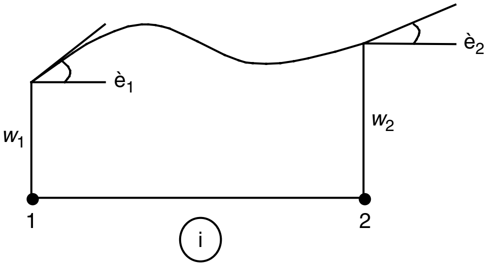

FIGURE 11.3.8 Hermite element.

The displacement field within the element is interpolated as shown next using Hermite polynomials N_i defined earlier in Equation 11.3.58.

$$w(s) = w_1N_1 + \theta_1N_1 + w_2N_3 + \theta_2N_4 \tag{11.3.76}$$

The equilibrium equations for one beam element can be derived using this interpolation in the weak form as $[\mathbf{K}_e]\{\mathbf{X}_e\} = \{\mathbf{F}_e\}$, where

$$\text{Stiffness matrix} = [\mathbf{K}_e] = \frac{EI}{L^3}\begin{bmatrix} 12 & 6L & -12 & 6L \\ 6L & 4L^2 & -6L & 2L^2 \\ -12 & -6L & 12 & -6L \\ 6L & 2L^2 & -6L & 4L^2 \end{bmatrix}, \tag{11.3.77}$$

$$\text{Displacement vector} = \{\mathbf{X}_e\} = \begin{Bmatrix} w_1 \\ \theta_1 \\ w_2 \\ \theta_2 \end{Bmatrix}, \tag{11.3.78}$$

$$\text{Force vector} = \{\mathbf{F}_e\} = \begin{Bmatrix} V_1 \\ M_1 \\ V_2 \\ M_2 \end{Bmatrix} + \int_0^L f \begin{Bmatrix} N_1 \\ N_2 \\ N_3 \\ N_4 \end{Bmatrix} ds \tag{11.3.79}$$

If the distributed load f is a uniform load across the beam, then the nodal values of the load that is equivalent to the distributed load can be computed as

$$\{\mathbf{F}_d\} = \frac{fL}{12}\begin{Bmatrix} -6 \\ -L \\ -6 \\ L \end{Bmatrix} \tag{11.3.80}$$

Most FEA software provides multiple beam elements, including sometimes the simple beam formulation with two degrees of freedom as described above. However, to construct frame-like structures by assembling multiple beam elements, it is necessary to use appropriate transformation so that the nodal variables are expressed as displacement components along a global coordinate system. In the most general case, the beam can be oriented arbitrarily in space as shown in Figure 11.3.9. Therefore, at each node there are six degrees of freedom corresponding to translations (d_{ix}, d_{iy}, d_{iz}) and rotations (θ_{ix}, θ_{iy}, θ_{iz}) along the x, y, and z axes.

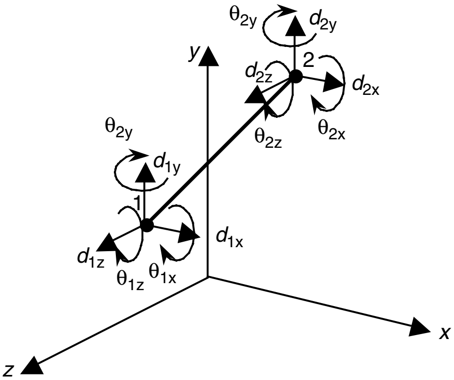

FIGURE 11.3.9 Beam element.

The element shown in Figure 11.3.9 is the general "3D beam" element for which one can specify up to three components of displacement and three components of angular displacement as boundary conditions. Similarly, at any node one can specify three components of force and moments about the three axes. The general 3D beam includes not only the bending stiffness described earlier, but also axial stiffness (similar to the truss element) and torsional stiffness. Furthermore, since the applied moments need not be about the axes of symmetry of the beam cross section, it is necessary to specify all components of the moments of inertia of the cross section. The geometric constants that need to be specified for the general 3D beam include, A = area of cross section, I_{yy}, I_{zz}, and I_{yz} the three components of moment of inertia, J = Polar moment of inertia, d_{sc} = distance from the centroid of the cross section to its shear center, as well as the (y,z) coordinates of the points at which stress needs to be computed.

Since the common node between two elements share the angle of rotation at that node, the deformed shape of the beam is guaranteed to be C^1 or tangent continuous if the elements are collinear before deforming. Similarly, if the two beam elements meet at an angle, they behave as if they are welded together. In other words, during the deformation any change in angle between the elements requires a bending moment transmission from one element to the other. Therefore, frame-like structures constructed by welding together slender beams can be modeled using these beam elements. Beam element formulation ignores shear strain energy; therefore, beam elements give accurate answers only if the beam length is much larger (at least ten times) than the beam cross-sectional dimensions.

Plane Stress Problems

Structural problems where the displacement vector can be expressed as a function of just two spatial coordinates can be modeled using two-dimensional finite elements. The field variable is the displacement vector and can be expressed as $\mathbf{u}(x,y) \in \mathbf{R}^2$. A plane stress problem is one such example where the stress in the structure is limited to a plane so that all stress components normal to this plane are zero.

The most common example is a plate-like structure that is only subjected to in-plane loads such as the plate shown in Figure 11.3.10. There are no loads acting on this plate that have a component perpendicular to the plate, and there are no bending moments, either. Therefore, the structure does not deflect in the direction perpendicular to the plane of the plate, and the displacement vector is two-dimensional and can be expressed as

$$\mathbf{u}(x,y) = \{\mathbf{u}\} = \begin{Bmatrix} u_x(x,y) \\ u_y(x,y) \end{Bmatrix} \tag{11.3.81}$$

Assuming that the stress components are restricted to the x-y plane, the stress and strain components for a plane stress problem can be expressed as the following column matrix:

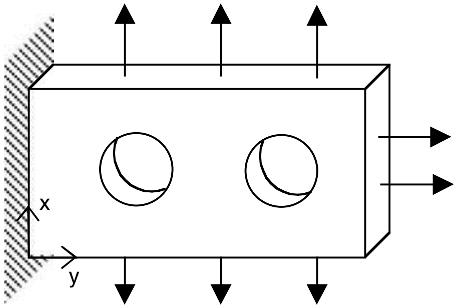

FIGURE 11.3.10 Plane stress problem.

$$\text{Stress} = \{\sigma\} = \begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \tau_{xy} \end{Bmatrix} \text{ and Strain} = \{\varepsilon\} = \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{yy} \\ \gamma_{xy} \end{Bmatrix} \tag{11.3.82}$$

Even though the stress components normal to the *x-y* plane are zero, the strain component is not necessarily zero. In fact, the normal stress in the *z* direction can be shown to be equal to

$$\varepsilon_{zz} = \frac{\nu}{E}\left(\sigma_{xx} + \sigma_{yy}\right) \tag{11.3.83}$$

The stress-strain relation for isotropic linear elastic materials is *Hooke's law*, which can be stated as follows for the plane stress problem:

$$\{\sigma\} = \left[C_{pstress}\right]\{\varepsilon\} \tag{11.3.84}$$

$$\text{where } [C_{pstress}] = \begin{bmatrix} \hat{\lambda}+2\mu & \hat{\lambda} & 0 \\ \hat{\lambda} & \hat{\lambda}+2\mu & 0 \\ 0 & 0 & \mu \end{bmatrix}, \ \hat{\lambda} = \frac{E\nu}{1-\nu^2} \text{, and } \mu = \frac{E}{2(1+\nu)} \tag{11.3.85}$$

The weak form for two- and three-dimensional problems is the *principle of virtual work*, which can be stated as follows for the plane stress problem:

$$\int_V \{\delta\varepsilon\}^T \left[C_{pstress}\right]\{\varepsilon\} dV = \int_S \{\delta u\}^T \{T\} dS + \int_V \{\delta u\}^T \{B\} dV \tag{11.3.86}$$

In the Equation 11.3.86, {**δu**} and {δε} are the virtual displacement and virtual strain, respectively. {**T**} is the traction acting on the boundary of the solid *S*, and {**B**} is the body force (or force per unit volume) acting on the structure. In order to carry out the integration over the volume and surface of the structure, a mesh needs to be generated over the volume using any of the two-dimensional elements described earlier. The material properties that need to be specified for plane stress problems for isotropic linear elastic material are *E* = Young's modulus and ν = Poisson's ratio. The only geometric property that needs to be specified is the thickness, because plane stress problems are plate-like structures with uniform thickness that are subjected only to in-plane forces.

Plane Strain Problems

If the deformation of a structure is planar so that the displacement at all points is restricted to a plane and all components of strain and displacement normal to this plane are zero, then the structure can be modeled using plane strain elements. If the plane of deformation is assumed to be the *x-y* plane, then the displacement component and the strain components in the *z*-direction are zero. Using the same notation for stress and strain vectors as in the plane stress case, the stress-strain relation (Hooke's law) can be stated as follows for the plane strain problem:

$$\{\sigma\} = [\mathbf{C}_{pstrain}]\{\varepsilon\} \tag{11.3.87}$$

where

$$[\mathbf{C}_{pstrain}] = \begin{bmatrix} \lambda+2\mu & \lambda & 0 \\ \lambda & \lambda+2\mu & 0 \\ 0 & 0 & \mu \end{bmatrix}, \ \lambda = \frac{E\nu}{(1+\nu)(1-2\nu)}, \ \mu = \frac{E}{2(1+\nu)} = G = \text{shear modulus} \tag{11.3.88}$$

Even though the strain components in the *z*-direction are zero, the stress component in the *z*-direction is non-zero for the plane strain problem. It can be shown using the generalized Hooke's law that the normal stress in the *z*-direction is

$$\sigma_{zz} = \nu(\sigma_{xx} + \sigma_{yy}) \tag{11.3.89}$$

The weak form (or the principle of virtual work) may be stated as follows for the plane strain problem:

$$\int_V \{\delta\varepsilon\}^{\mathrm{T}} [\mathbf{C}_{pstrain}]\{\varepsilon\} dV = \int_S \{\delta\mathbf{u}\}^{\mathrm{T}} \{\mathrm{T}\} dS + \int_V \{\delta\mathbf{u}\}^{\mathrm{T}} \{\mathrm{B}\} dV \tag{11.3.90}$$

The only difference between the plane strain element and the plane stress element is in the elasticity matrix $[\mathbf{C}_{pstrain}]$. Plane strain elements can also use any of the two-dimensional interpolation schemes including three-node triangles and four-node quadrilaterals that are described earlier. Again two elastic moduli (E and ν) are sufficient to specify the material properties if the material is isotropic and linear elastic. There is no need to specify the thickness of the structure since plane strain problems usually correspond to structures that are very thick in the *z*-direction compared to its dimensions in the *x-y* plane. Therefore, unit thickness is assumed for plane strain elements. When applying loads on plane strain models, we must take care to ensure that the applied loads are calculated as load per unit depth.

Three-Dimensional Structural Problems

Structures that cannot be modeled using one- and two-dimensional idealization have to be modeled using three-dimensional elements. These elements assume that the displacement at any point in the structure can be in any arbitrary direction in space; therefore, the displacement vector is

$$\{\mathbf{u}(x,y,z\} = \begin{Bmatrix} u_x(x,y,z) \\ u_y(x,y,z) \\ u_z(x,y,z) \end{Bmatrix} \tag{11.3.91}$$

The stress and strain components for the general three-dimensional problem can be expressed as tensors using 3 × 3 matrices. However, for expressing the stress strain relation, it is easier to represent stress and strains using column matrices. The generalized Hooke's law can be written in the following form:

$$\{\sigma\} = [C]\{\varepsilon\} \tag{11.3.92}$$

where [**C**] is a 6 × 6 square matrix and {σ}, {ε} are 6 × 1 column matrices

$$\{\sigma\} = \begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{zz} \\ \tau_{xy} \\ \tau_{yz} \\ \tau_{zx} \end{Bmatrix}, \quad \{\varepsilon\} = \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{yy} \\ \varepsilon_{zz} \\ \gamma_{xy} \\ \gamma_{yz} \\ \gamma_{zx} \end{Bmatrix} \quad [C] = \begin{bmatrix} \lambda+2\mu & \lambda & \lambda & 0 & 0 & 0 \\ \lambda & \lambda+2\mu & \lambda & 0 & 0 & 0 \\ \lambda & \lambda & \lambda+2\mu & 0 & 0 & 0 \\ 0 & 0 & 0 & \mu & 0 & 0 \\ 0 & 0 & 0 & 0 & \mu & 0 \\ 0 & 0 & 0 & 0 & 0 & \mu \end{bmatrix} \tag{11.3.93}$$

$$\lambda = \frac{E\nu}{(1+\nu)(1-2\nu)}, \quad \mu = \frac{E}{2(1+\nu)} = G = \text{shear modulus} \tag{11.3.94}$$

The weak form for the three-dimensional static structural boundary value problem is the three-dimensional principle of virtual work, which looks similar to two-dimensional versions except that the stress and strain vectors are now 6 × 1 vectors. The displacements, virtual displacements {**δu**}, surface traction {**T**}, and body force {**B**} are all now three-dimensional vectors:

$$\int_V \{\delta\varepsilon\}^T [C]\{\varepsilon\} dV = \int_S \{\delta u\}^T \{T\} dS + \int_V \{\delta u\}^T \{B\} dV \tag{11.3.95}$$

The field variable is the three-dimensional displacement vector {**u**}, which can be interpolated within any three-dimensional elements, including the four-node tetrahedral elements and eight-node hexahederal elements described earlier. The material properties that are required are the elastic moduli (E and ν) for isotropic linear elastic materials.

Heat Transfer

Heat-conduction problems in one, two and three dimensions can be solved using linear static heat-conduction elements available in most FEA software. The field variable is the temperature field $T(x, y, z)$ within a solid that is conducting heat. The general three-dimensional governing equations and the weak form are described next. These can be easily simplified into one- and two-dimensional equations.

The governing equation for heat conduction is the following partial differential equation, which is derived from the condition of equilibrium in heat flow and Fourier's law relating heat flow to temperature gradient:

$$\nabla \cdot (k\nabla T) + f = 0 \tag{11.3.96}$$

Here f is the heat generation per unit volume of the solid and k is the thermal conductivity of the material assuming that the material is isotropic. The gradient of temperature ∇T is a two- or three-dimensional vector depending on the dimension of the problem. Three different types of boundary conditions that may be applied for heat conduction problems:

1. Temperature specified on part of the boundary S_1
2. Heat flux specified on part of the boundary S_2: $q_n = -q_0$ (if q_0 is flowing out), where q_n = heat flux normal to boundary, $q_n = \mathbf{q} \cdot \hat{\mathbf{n}} = -(k\nabla T) \cdot \hat{\mathbf{n}}$, where $\hat{\mathbf{n}}$ is the unit vector normal to the surface
3. Heat transfer by convection along S_3: $q_n = -(k\nabla T) \cdot \hat{\mathbf{n}} = h(T - T_a)$, where h = convection coefficient and T_a = ambient temperature

The weak form of the heat-conduction problem can be stated as

$$\int_V \nabla\delta T k \nabla T dV = \int_S (k\nabla T)\cdot\hat{\mathbf{n}}\delta T dS + \int_V f\delta T dV \tag{11.3.97}$$

The surface integral on the right-hand side of the equation can be split into integration over regions of the surface on which the various different boundary conditions have been applied. This yields the following modified weak form:

$$\int_V \nabla\delta T k \nabla T dV + \int_{S_3} hT\delta T ds = \int_{S_2} q_0\delta T ds + \int_{S_3} hT_a\delta T ds + \int_V f\delta T dV \tag{11.3.98}$$

Heat-conduction elements can be used to compute temperature distribution in solids. The material property to be specified is k, the thermal conductivity of the material. If convective heat transfer is occurring along part of the boundary, then the convection coefficient also needs to be specified along with the ambient temperature or the temperature of the surrounding to which heat transfer due to convection is occurring. Heat generation per unit volume, f, can also be specified if heat is being generated within the material, for example, due to electrical current flow.

11.4 Structural Design Criteria

Nagaraj K. Arakere

Mechanical failure is generally referred to as any change in the size, shape, or material properties of a structure, machine, or machine part that renders it incapable of satisfactorily performing its intended function.[1] This is an extremely broad definition of mechanical failure, and in the context of this book we will cover only specific types of failure. We will examine what kind of stress causes failure: Is it tensile, compressive, or shear stress? To answer these questions, we need to know the type of material and its relative strengths in compression, tension, and shear; whether the loading was static or dynamic; and whether there are cracks in the material.[1-4] The failure criteria are restricted to metallic isotropic structural materials and, for the most part, to ductile materials. Materials that exhibit a ductility of 5% or more elongation in a 2-in. gage length are classified as nominally ductile materials, whereas materials that exhibit a ductility of less than 5% elongation in a 2-in. gage length are classified as nominally brittle materials.[1] Metallic materials used in engineering applications are largely isotropic polycrystalline ductile metallic alloys. Specialized topics such as static and fatigue failure due to contact mechanics and high-temperature effects such as creep and thermomechanical fatigue are not addressed.

Static Failure Criteria

In general, ductile materials subjected to static tensile loading are limited by their shear strengths, whereas brittle materials are limited by their tensile strengths, although there can be exceptions to this rule.[1,4] This requires that we have different failure criteria for ductile and brittle materials. Failure is defined by the onset of yield that can result in the significant distortion of the part. A part may also fail by fracturing or separating. The mechanisms that cause fractures can be very different. In general, only ductile materials yield significantly before fracturing. Static loads are slowly applied and remain essentially constant with time. Dynamic loads are suddenly applied (impact loads) or are cyclic loads that vary with time (fatigue loads), or they can be both. There are significant differences in failure mechanisms under static and dynamic loading, and hence we will address them separately.

Failure of Ductile Materials Under Static Loading

We will establish yield criteria for ductile materials subjected to static loading. Ductile materials will fracture if statically stressed beyond their ultimate tensile strength. However, failure is generally defined by the onset of yield under static loading. The yield strength of a ductile material is less than its ultimate strength.[4]

The state of stress and strain at a point in a body can be described by six stress components (σ_x, σ_y, σ_z, τ_{xy}, τ_{xz}, τ_{yz}) and six strain components (ε_x, ε_y, ε_z, γ_{xy}, γ_{xz}, γ_{yz}) acting on orthogonal planes x, y, and z. Stresses and strains acting in any other direction or plane can be found by using appropriate transformation equations or graphically by using Mohr's circle. Of special significance to both static and fatigue analysis are the magnitudes and directions of the maximum normal principal stress, σ_1; the maximum shearing stress, τ_{max}; the maximum normal principal strain, ε_1; and the maximum shearing strain, γ_{max}, acting at the critical location in the part. Even though only a few planes experience the maximum principal normal stress (or strain) and the maximum shearing stress (or strain), many other planes can experience a large percentage of these quantities.[3] Consider the case of simple uniaxial tension where, even though only the loading plane experiences the maximum normal stress σ_1, all planes oriented between ±13 degrees from the loading plane experience at least 95% of σ_1. Also, a shearing stress is present on every stressed plane, except for the loading plane.

For any three-dimensional stress state in a body in mechanical equilibrium, the principal normal stresses, which act on orthogonal planes that are free of shear stresses, can be found by solving the stress cubic equation given by

$$\sigma^3 - I_1\sigma^2 - I_2\sigma - I_3 = 0 \tag{11.4.1}$$

where I_1, I_2 and I_3, are called the stress invariants, and they are independent of the orientation of the coordinate system chosen to describe the stress components. They are given by

$$\begin{aligned} I_1 &= \sigma_{ii} = \sigma_{11} + \sigma_{22} + \sigma_{33} \\ I_2 &= \frac{1}{2}(\sigma_{ij}\sigma_{ij} - I_1^2) = \frac{1}{2}(\sigma_{11}^2 + \sigma_{22}^2 + \sigma_{33}^2 + 2\sigma_{12}^2 + 2\sigma_{23}^2 + 2\sigma_{31}^2 - I_1^2) \\ I_3 &= \det\left[\sigma_{ij}\right] \end{aligned} \tag{11.4.2}$$

The principal stresses are denoted by σ_1, σ_2, and σ_3 with $\sigma_1 \geq \sigma_2 \geq \sigma_3$. The normal mean stress or the hydrostatic stress, σ_H, is defined as

$$\sigma_H = \sigma_{mean} = \frac{1}{3}(\sigma_1 + \sigma_2 + \sigma_3) = \frac{1}{3}\sigma_{kk} = \frac{I_1}{3} \tag{11.4.3}$$

The hydrostatic stress σ_H causes a change in volume only and does not distort or change the shape of an isotropic body. The deviatoric stress components are defined as

$$s_{ij} = \sigma_{ij} - \frac{\delta_{ij} I_1}{3} = \sigma_{ij} - \delta_{ij}\sigma_H \tag{11.4.4}$$

These deviatoric stress components bring about a change of shape or distortion in the body and influence plastic deformation. A new set of scalar invariants, J_1, J_2 and J_3, based on the deviatoric stresses, can be defined as

$$\begin{aligned} J_1 &= \sigma_{ii} - I_1 = 0 \\ J_2 &= \frac{1}{2}(s_{ij}s_{ij} - J_1^2) = \frac{1}{2}s_{ij}s_{ij} = -(s_{11}s_{22} + s_{22}s_{33} + s_{33}s_{11}) \\ J_3 &= \frac{1}{3}(s_{ij}s_{jk}s_{ki}) = s_{11}s_{22}s_{33} \end{aligned} \tag{11.4.5}$$

The shear stresses and strains on the octahedral planes are of importance in yielding prediction and fatigue analysis.[3] There are eight octahedral planes making equal angles with the three principal stress directions. The shearing stress on these planes is given by

$$\tau_{oct} = \frac{1}{3}\sqrt{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2} \tag{11.4.6}$$

The normal stress on an octahedral plane is the hydrostatic stress σ_H given by

$$\sigma_{oct} = \sigma_H = \sigma_{mean} = \frac{1}{3}(\sigma_1 + \sigma_2 + \sigma_3) \tag{11.4.7}$$

The shear strain on an octahedral plane is given by

$$\gamma_{oct} = \frac{2}{3}\sqrt{(\varepsilon_1 - \varepsilon_2)^2 + (\varepsilon_2 - \varepsilon_3)^2 + (\varepsilon_3 - \varepsilon_1)^2} \tag{11.4.8}$$

When a ductile material is loaded beyond the elastic limit, it undergoes permanent plastic deformation. The total strain imposed on the elastic-plastic solid ε_{ij} can be written as a sum of the elastic and plastic strain components ε_{ij}^e and ε_{ij}^P, respectively. Plastic flow in metals can be assumed to be incompressible ($\varepsilon_{ii}^P = 0$).[1,2] The basic elements of plasticity theory consist of a yield function to determine when plastic flow begins, a flow rule that relates the applied stress increments to the resulting plastic strain increments once the plastic flow has begun, and a hardening rule that describes the change in yield criterion as a function of plastic strains.[2,3] Thus, yielding depends on the instantaneous increments of stress or strain and on the prior history of the material.

The yield criterion is a function $f(\sigma_{ij})$ of the current state of stress. Rate-independent plasticity theories postulate that material response is elastic for $f(\sigma_{ij}) < 0$. Elastic unloading occurs from a plastic state when $f(\sigma_{ij}) = 0$ and $(\partial f / \partial \sigma_{ij}) d\sigma_{ij} < 0$, where $d\sigma_{ij}$ is the stress increment. Plastic deformation occurs when $f(\sigma_{ij}) = 0$ and $(\partial f / \partial \sigma_{ij}) d\sigma_{ij} \geq 0$. The deformation of metals is insensitive to moderate levels of hydrostatic stress σ_H and hence the yield function depends only on the deviatoric stress s_{ij}.[2]

The yield criterion can be visualized in a stress space in which each of the coordinate axes represents one principal stress. The von Mises and Tresca yield criteria are two of the most widely used flow criteria for metal plasticity. The von Mises condition states that

$$f \equiv J_2 - k^2 \equiv \frac{1}{2} s_{ij} s_{ij} - k^2 = 0 \tag{11.4.9}$$

In terms of principal stresses, the von Mises yield function can be written as

$$f = \frac{1}{6}\left[(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2\right] - k^2 = 0 \tag{11.4.10}$$

The von Mises yield criterion can be visualized as a right circular cylinder in the stress space. The axis of the cylinder passes through the origin of the coordinates, and is inclined at equal angles to the three coordinate axes and represents pure hydrostatic stress. For an elastic, perfectly plastic solid k is a constant, and it is influenced by prior strain history in a work-hardening material. The von Mises yield condition implies that plastic flow occurs when the distortional energy reaches a critical value. For uniaxial tension, $\sigma_1 = \sigma_y$, $\sigma_1 = \sigma_3 = 0$, and $k = \sigma_y/\sqrt{3}$, where σ_y is the tensile yield stress. For pure shear $\sigma_1 = -\sigma_3 = \tau_y$, $\sigma_2 = 0$, and $k = \tau_y$, where τ_y is the shear yield stress.[2] The multiaxial stress state can be written in terms of an equivalent stress, σ_e, given by

$$\sigma_e = \frac{1}{\sqrt{2}} \sqrt{\left[(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2\right]} = \sqrt{3 J_2} \tag{11.4.11}$$

or

$$\sigma_e = \frac{1}{\sqrt{2}} \sqrt{\left[(\sigma_x - \sigma_y)^2 + (\sigma_y - \sigma_z)^2 + (\sigma_z - \sigma_x)^2 + 6(\tau_{xy}^2 + \tau_{yz}^2 + \tau_{zx}^2\right]} \tag{11.4.12}$$

Yielding occurs when $\sigma_e = \sigma_y$. The equivalent stress σ_e is also related to the octahedral shear stress τ_{oct}, and hence the von Mises yield theory is sometimes also called the octahedral shear stress theory.

The Tresca yield condition (maximum shear stress theory) states that the material will yield when the maximum shear stress reaches a critical value:

$$\frac{1}{2}\left|\sigma_1 - \sigma_3\right| = k \tag{11.4.13}$$

where the principal stresses have been arranged in the order $\sigma_1 \geq \sigma_2 \geq \sigma_3$. For uniaxial tension, the Tresca condition predicts that $k = \sigma_y/2$. The yield surface represented by the Tresca condition is a regular hexagonal prism. Figure 11.4.1 shows experimental data from tensile tests superposed on three failure theories.

Once plastic deformation has begun, we need to establish a flow rule to relate stresses and plastic strains. Equations that relate stresses and plastic strains are also called *constitutive* equations and are generally based on the normality condition. This condition states that the increment of plastic strain caused by an increment of stress is such that the vector representing the plastic strain increment is normal to the yield surface during plastic deformation. A hardening rule is needed to describe the behavior of the material once it is plastically deformed or yielded. The isotropic hardening rule assumes that the

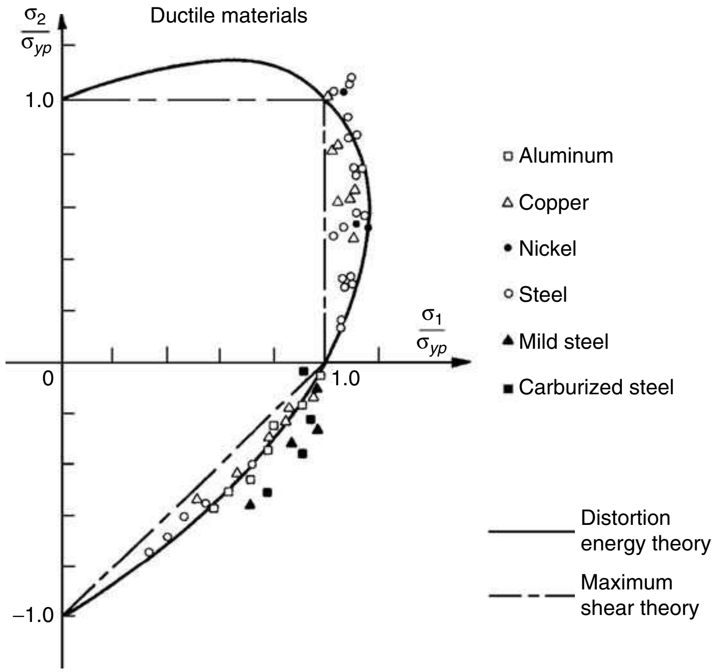

FIGURE 11.4.1 Comparison of yield theories for ductile materials under biaxial state of stress. [From Figure 6.8, p. 158, in reference 1.]

yield surface enlarges (i.e., an increase in σ_y) without a change in shape or position of the stress space. The kinematic rule assumes that strain hardening shifts the yield surface without changing its shape or size.[2,3,5]

Failure of Brittle Materials Under Static Loading

Brittle materials fracture rather than yield. The normal tensile stress is the determining factor for failure by brittle fracture in tension, and hence the maximum normal-stress theory is applicable to this case. The maximum normal stress theory states that failure will occur when the normal stress in the specimen reaches the tensile yield strength or ultimate tensile strength. Brittle fracture in compression is due to some combination of normal compressive stress and shear stress and requires a different theory of failure.[4]

Some brittle materials such as hardened tool steel have compressive strengths equal to their tensile strengths and are called *even materials*. Many cast materials, such as gray cast iron, are brittle but have compressive strengths much greater than their tensile strengths. These are called *uneven materials*.[4] For some cast brittle materials, the shear strength can be greater than their tensile strength. This is very different from ductile materials, where the shear strength is about one-half of the tensile strength. For uneven brittle materials, the preferred failure theory under static loading is the modified Mohr theory envelope, shown in Figure 11.4.2.[4]] For us to use this theory, it is convenient to have expressions for an effective stress that would account for all the applied stresses and allow direct comparison to a material strength property, as was done for ductile materials with von Mises effective stress, σ_e. Dowling[6] develops a set of expressions for this effective stress involving the three principal stresses:

$$C_1 = \frac{1}{2}\left[\left|\sigma_1 - \sigma_2\right| + \frac{S_{uc} + 2S_{ut}}{S_{uc}}(\sigma_1 + \sigma_2)\right]$$
$$C_2 = \frac{1}{2}\left[\left|\sigma_2 - \sigma_3\right| + \frac{S_{uc} + 2S_{ut}}{S_{uc}}(\sigma_2 + \sigma_3)\right] \qquad (11.4.14)$$

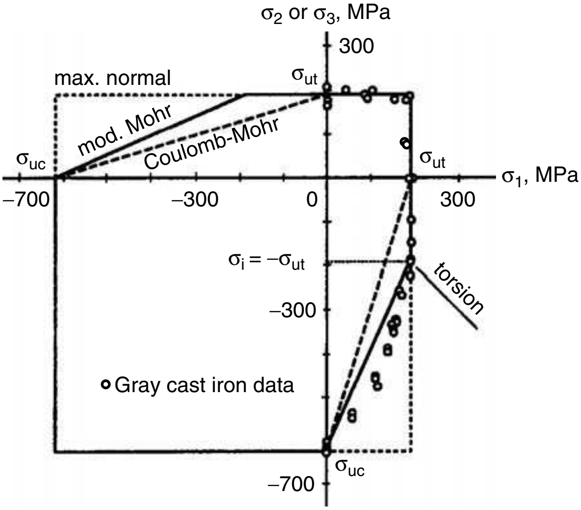

FIGURE 11.4.2 The modified Coulomb-Mohr theory for failure prediction of uneven brittle materials. [From Figure 7.13, p. 255, in reference 6.]

$$C_3 = \frac{1}{2}\left[\left|\sigma_3 - \sigma_1\right| + \frac{S_{uc} + 2S_{ut}}{S_{uc}}(\sigma_3 + \sigma_1)\right]$$

where S_{ut} and S_{uc} are the material strengths in tension and compression. The largest of the set of six values (C_1, C_2, C_3, σ_1, σ_2, σ_3) is the effective stress suggested by Dowling.[6]

$$\tilde{\sigma}_e = \mathrm{Max}(C_1, C_2, C_3, \sigma_1, \sigma_2, \sigma_3) \tag{11.4.15}$$

If all the arguments are negative, then the effective stress is zero. The effective stress, $\tilde{\sigma}_e$, is compared to either the yield stress or the ultimate tensile strength, to predict failure.

The Linear Elastic Fracture Mechanics (LEFM) Approach

The static failure theories discussed so far have all assumed that the material is perfectly homogeneous and isotropic, and free of any defects such as cracks, voids, or inclusions, which could act as stress raisers. This is rarely true for real materials, and typically all materials are considered to contain small flaws, whose size and distribution are dependent on the material and its processing. These may include nonmetallic inclusions, microstructural defects, microvoids, weld defects, quench marks, and so forth.[4] Development of predictive models of fracture in engineering structures and machines at the macroscopic level is well known as the area of *fracture mechanics*. Dislocation theory has been successful in explaining the mechanisms of deformation and fracture of engineering materials at the atomic level. However, it has not provided engineers with quantitative tools necessary to estimate potentially critical combinations of loading, geometry, and material properties.[1] The field of fracture mechanics was given impetus by numerous failures of engineering structures since the 1940s. Some examples are the 1289 failures out of 4694 Liberty Ships constructed during the 1940s, the Comet aircraft failures of the early 1950s, missile tank failures and large steam turbine failures of the mid-1950s, the Bomark helium tank failure in 1960, the large solid rocket motor case failures and Apollo tank failures of the mid-1960s, and many others to this day.[1] The reasons behind these failures involve the development of new higher strength materials, a thrust toward higher efficiency in design, the use of welding, reduction in the capacity of structural members to accommodate local plastic strain without fracture, residual stresses due to machining, fluctuating service loads of greater severity, and more aggressive environments. To prevent or minimize

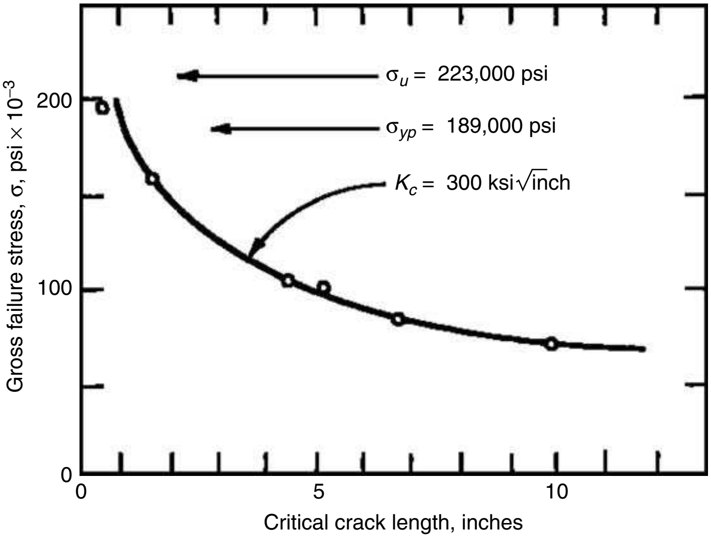

FIGURE 11.4.3 Influence of crack length on gross failure stress for center-cracked steel plate, 36 in. wide, 0.14 in. thick, room temperature, 4330 M steel. [From Figure 3.26, p. 51, in reference 1.]

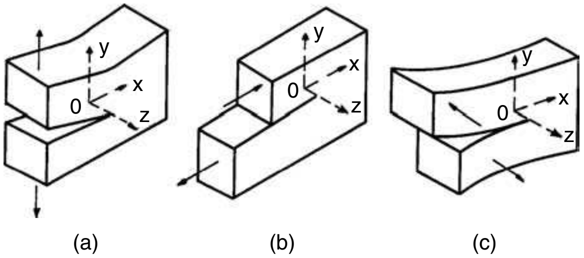

FIGURE 11.4.4 Basic modes of crack displacement [1]. (a) Mode I; (b) Mode II; (c) Mode III. [From Figure 5.3, p. 146, in reference 2.]

failure due to fracture, concepts of fracture control have evolved, which consist of controlling the combination of nominal stress and existing crack size so that they are always below a critical level for the material being used in a given structure/machine.[1]

The magnitude of nominal applied stress, which causes fracture, is related to the size of the crack or crack-like flaw within the structure. For example, Figure 11.4.3 shows the tensile stress required to cause unstable crack growth leading to failure, as a function of crack length, for central through-the-thickness cracks in a steel plate oriented normal to the applied tensile stress.[7] The figure indicates that for longer initial crack lengths the fracture stress, that is, the stress corresponding to rapid crack extension, was lower.[1]

The abrupt change from slow crack propagation to rapid crack propagation establishes an important material property called *fracture toughness*. It may be used as a design criterion in fracture prevention, just as the yield strength is used as a design criterion in prevention of yielding of a ductile material under static loading.[1]

The crack surface displacements in the three basic modes of separation are shown schematically in Figure 11.4.4. Mode I is the *tensile opening mode*, in which the crack faces separately in a direction normal to the plane of the crack and the corresponding displacements of the crack walls are symmetric with respect to the x-z and x-y planes. Mode II is the *in-plane sliding mode*, in which the crack faces are mutually sheared in a direction normal to the crack front. Here the displacements of the crack walls are

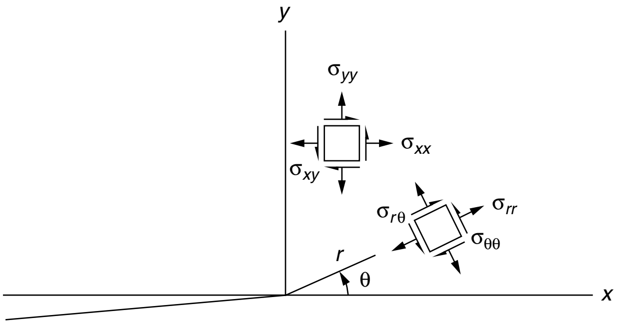

FIGURE 11.4.5 Stress field in the near-tip region of a crack in a plate. [From Figure 5.4, p. 147, in reference 2.]

symmetric with respect to the x-y plane and antisymmetric with respect to the x-z plane. Mode III is the *tearing or antiplane shear mode,* in which the crack faces are sheared parallel to the crack front. The displacements of the crack walls in this case are antisymmetric with respect to the x-z and x-y planes.[2]

The stress and displacement field in the near-tip region of a semi-infinite crack in an infinite plate (the plane problem, shown in Figure 11.4.5), for Mode I can be obtained as (an asymptotic solution with higher order terms neglected)[1–3]

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{xy} \end{Bmatrix} = \frac{K_I}{\sqrt{2\pi r}} \cos\frac{\theta}{2} \begin{Bmatrix} 1 - \sin\frac{\theta}{2}\sin\frac{3\theta}{2} \\ 1 + \sin\frac{\theta}{2}\sin\frac{3\theta}{2} \\ \sin\frac{\theta}{2}\cos\frac{3\theta}{2} \end{Bmatrix} + [O]r^{1/2} \tag{11.4.16}$$

$$\sigma_{zz} = \nu_1(\sigma_{xx} + \sigma_{yy}), \qquad \sigma_{xz} = \sigma_{yz} = 0$$

$$\begin{Bmatrix} u_x \\ u_y \end{Bmatrix} = \frac{K_I}{2E}\sqrt{\frac{r}{2\pi}} \begin{Bmatrix} (1+\nu)\left[(2\kappa - 1)\cos\frac{\theta}{2} - \cos\frac{3\theta}{2}\right] \\ (1+\nu)\left[(2\kappa - 1)\sin\frac{\theta}{2} - \sin\frac{3\theta}{2}\right] \end{Bmatrix}, \; u_z = -\left(\frac{\nu_2 z}{E}\right)(\sigma_{xx} + \sigma_{yy}) \tag{11.4.17}$$

In Equation 11.4.16 and Equation 11.4.17, *E* is the Young's modulus and *n* is the Poisson's ratio. For plane stress,

$$\kappa = \frac{(3-\nu)}{(1+\nu)}, \quad \nu_1 = 0, \quad \nu_2 = \nu \tag{11.4.18}$$

and, for plane strain,

$$\kappa = (3 - 4\nu), \quad \nu_1 = \nu, \quad \nu_2 = 0 \tag{11.4.19}$$

The stress and displacement fields for Modes II and III are similar and can be found in references 1–3. The term K_{I} in Equation 11.4.16 and Equation 11.4.17 is the Mode I stress intensity factor (SIF), which incorporates the boundary conditions of the cracked body and is a function of loading, crack length, and geometry. For plane problems, it is independent of elastic constants. The stress intensity factors for Modes II and III are denoted by K_{II} and K_{III}. Under LEFM assumptions, stress fields for combined loadings can be obtained by linear superposition.

The SIFs are a measure of the intensity of the near-tip fields under elastic conditions. The $1/\sqrt{r}$ singularity in the asymptotic stress solution indicates that a plastic zone will form near the crack tip. Metals and their alloys, except for a few intermetallics, are inherently ductile, that is, plastic deformation precedes fracture in these materials. Therefore, resistance to fracture is directly related to the development of the plastic zone at the crack tip. The plastic zone can be very small or even nonexistent in the case of brittle ceramics. The annular region ahead of the crack tip is known as the *K-dominant* region, within which the SIF provides a unique measure of the intensity of the stress, strain, or deformation. The outer radius of the annular zone is determined by the radial distance at which the approximate, asymptotic singular solutions, Equation 11.4.16 and Equation 11.4.17, deviate significantly from the full elasticity solutions, which include the higher-order terms. The asymptotic results in Equation 11.4.16 and Equation 11.4.17 provide a reasonable solution with the assumption of "small-scale yielding." This condition requires that the crack tip zone of inelastic deformation be confined well inside the region of K-dominance. An understanding of the conditions of K-dominance is essential for the characterization of fatigue fracture involving crystallographic crack growth, mixed-mode loading, or small fatigue flaws. These issues are discussed in great detail in reference 2.

Based on dimensional considerations[1] in Equation 11.4.16, the SIF K must have the form

$$K = C_I \sigma \sqrt{a} \tag{11.4.20}$$

For an infinite plate containing a through the thickness crack of length $2a$, the elasticity solution gives $C_I = \sqrt{\pi}$. For remote loadings, in general, the SIF are of the form

$$K = C\sigma\sqrt{\pi a} \tag{11.4.21}$$

where C is dependent on the type of loading and the geometry away from the crack. There is a large body of literature that exists for determining values of C for a wide variety of conditions; a good example is reference 8.

The SIF K increases proportionately with far-field nominal stress and is also a function of the instantaneous crack length a. The value of K associated with the onset of rapid crack extension is designated as the *critical stress intensity*, K_c, and provides a single-parameter fracture criterion based on the condition $K = C\sigma\sqrt{\pi a} \geq K_c$.

A simple correction factor to account for small-scale plasticity at the crack tip is to estimate the plastic zone radius, shown in Figure 11.4.6. The plastic zone correction factors for monotonic loading, plane stress, and plane strain conditions are given by reference 1:

$$\begin{aligned} r_{Y\sigma} &= \frac{1}{2\pi}\left(\frac{K}{\sigma_y}\right)^2 \quad \text{(planestress)} \\ r_{Y\varepsilon} &= \frac{1}{6\pi}\left(\frac{K}{\sigma_y}\right)^2 \quad \text{(planestrain)} \end{aligned} \tag{11.4.22}$$

Because of the crack-tip plastic deformation, the crack is blunted, as shown in Figure 11.4.6. An effective crack length $a' = a + r_Y$ is used, leading to

$$K = C\sigma\sqrt{\pi(a + r_Y)} \tag{11.4.23}$$

Evaluating Equation 11.4.23 requires an iterative solution since K and C depend on r_Y, and r_Y depends on the magnitude of K.

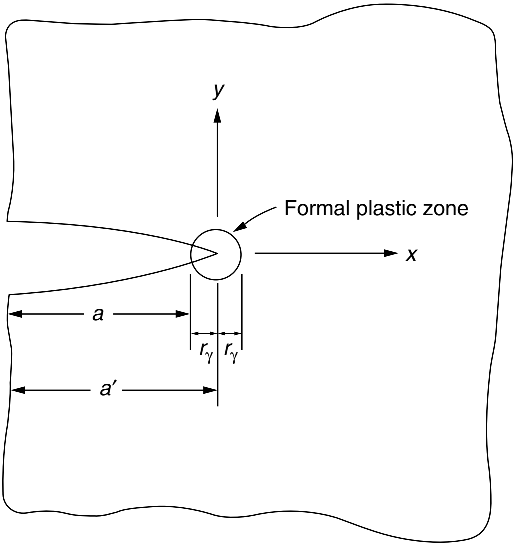

FIGURE 11.4.6 Definition of plastic zone at the crack tip. [From Figure 3.30, p. 59, in reference 1.]

The critical stress intensity K_c decreases to a lower limiting value as plane strain conditions are approached at the crack tip. This lower limiting value defines a basic material property K_{Ic}, the *plane strain fracture toughness* for the material. The minimum material thickness B required for plane strain conditions to exist at the crack tip can be estimated by the empirical relation:[1]

$$B \geq 2.5\left(\frac{K_{Ic}}{\sigma_y}\right)^2 \tag{11.4.24}$$

If plane strain conditions are not met, then the state of stress conditions prevail at the crack tip. The critical SIF for failure prediction under plane stress conditions K_c can be estimated using the semiempirical relation shown here:[1]

$$K_c = K_{Ic}\left(1 + \frac{1.4}{B^2}\left\{\frac{K_{Ic}}{\sigma_y}\right\}^4\right)^{1/2} \tag{11.4.25}$$

The strain energy release rate G, is related to and the SIF K as follows:

$$G = \frac{1}{E}\left(K_I^2 + K_{II}^2\right) \text{ (planestress)}; \quad G = \frac{(1-\nu^2)}{E}\left(K_I^2 + K_{II}^2\right) + \frac{(1+\nu)}{E}K_{III}^2 \text{ (planestrain)} \tag{11.4.26}$$

For self-similar, coplanar crack growth (crack advances in its own plane), the strain energy release rates for the different modes of fracture are simply additive.[2]

If the conditions of small-scale yielding are not satisfied at the crack tip, a better design approach would be to employ an appropriate elastic-plastic fracture mechanics procedure, such as the path-independent J-integral.[1–3]

Fatigue Failure Criteria

A majority of engineering structures and machine elements are subjected to fluctuating or cyclic loads. Such loading induces fluctuating or cyclic stresses that can result in failure by fatigue. Fatigue loading

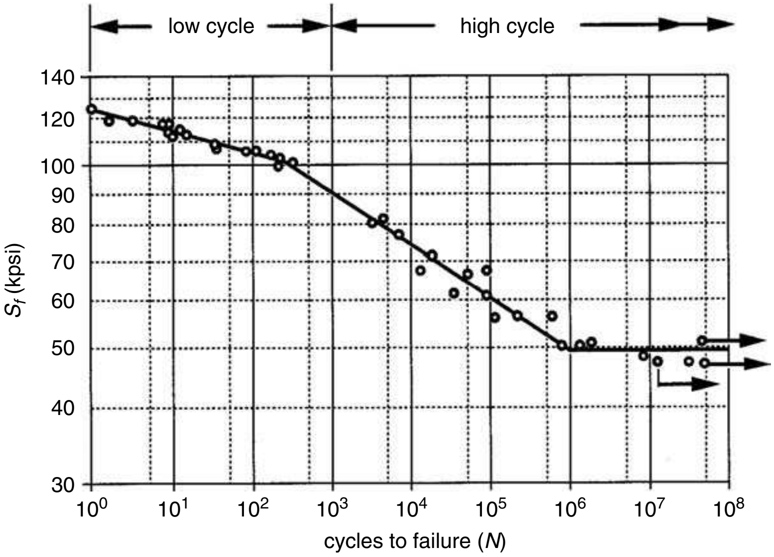

FIGURE 11.4.7 Fully reversed axial S-N diagram for AISI 4130 steel. [From Figure 6-13, p. 364, in reference 4.]

results in changes in properties of materials from the application of cyclic loads. Study of cyclic deformation and fracture of materials by fatigue dates back to the nineteenth century.[2] Characterizing fatigue life of machine components is generally done using phenomenological continuum approaches. The variables used are applied stress range, strain range, mean stress, and environmental conditions. These stress- or strain-based approaches attempt to evaluate the damage evolution, crack nucleation, and crack growth stages of fatigue using continuum formulations and experimental data. The fatigue life of a component is defined as the total number of cycles to induce fatigue damage and to initiate a dominant fatigue flaw that is propagated to failure.[2]

Stress-Life Approach

This approach is stress based and seeks to determine a fatigue strength and/or an endurance limit for the material so that the cyclic stresses can be kept below that level and avoid failure for the required number of cycles. This approach emerged from the work of Wöhler in 1860,[9] who characterized fatigue life in terms of nominal stress amplitudes using experimental data obtained from rotating bend tests on smooth specimens. The crack-initiation phase requires that localized plastic yielding occur in regions of stress concentration, leading to slip band formation. The stress cycling results in the formation of additional slip bands, which coalesce into microscopic cracks. Designing a part so that the stress amplitude never exceeds the material’s fatigue strength (or endurance limit) is an attempt to keep local stresses in notches so low that the crack-initiation phase never begins. The design goal in the stress-life approach is to ensure that the stresses and strains remain in the elastic region so that no yielding occurs to initiate a crack. This approach is generally used for high-cycle fatigue (HCF) applications where the life is expected to be greater than about 10^3 cycles and the stresses are likely to be in the elastic range. This approach is relatively easy to implement, although it is empirical and not accurate in terms of defining local stress/strain states in the part.

The basis for this method is the S-N diagram, an example of which is shown in Figure 11.4.7. The cycles to failure and the alternating stress amplitude are plotted on the x- and the y-axis, respectively, on a log-log scale. Note the slope change at around 10^3 cycles, which corresponds roughly to the transition from the LCF to the HCF regime. The endurance limit is reached at about 10^6 cycles. The data shown is for zero mean stress or fully reversed loading. Figure 11.4.8 shows the nomenclature for fatigue loading and the variation of stress with time.

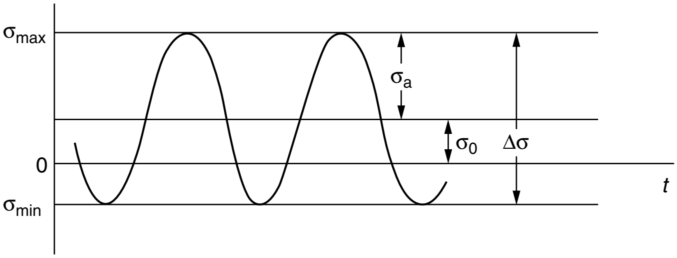

FIGURE 11.4.8 Nomenclature for fatigue loading. [From Figure 4.3, p. 131, in reference 2.]

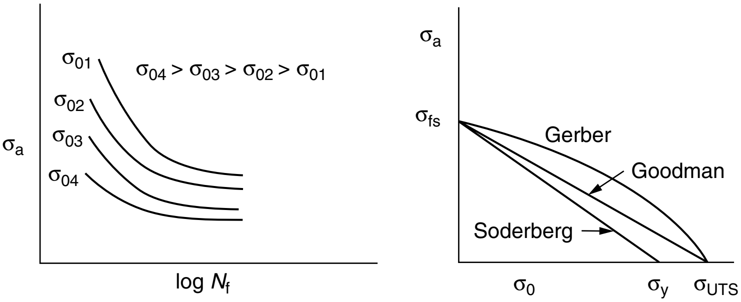

FIGURE 11.4.9 Effect of nonzero mean stress on fatigue life. [From Figure 4.4, p. 132, in reference 2.]

$$\begin{aligned}
&\Delta\sigma = \sigma_{\max} - \sigma_{\min} = \text{Stress range} \\
&\sigma_a = (\sigma_{\max} - \sigma_{\min})/2 = \text{ Stress amplitude} \\
&\sigma_0 = \sigma_m = (\sigma_{\max} + \sigma_{\min})/2 = \text{ Mean stress} \\
&R = \frac{\sigma_{\min}}{\sigma_{\max}}
\end{aligned} \tag{11.4.27}$$

The linear relationship seen in Figure. 11.4.7 on a log-log scale can be given in terms of a power law fit as

$$\frac{\Delta\sigma}{2} = \sigma_a = \sigma'_f\left(2N_f\right)^b \tag{11.4.28}$$

where σ'_f is the fatigue strength coefficient (which approximately equals the true fracture strength σ_f, corrected for necking, in a monotonic tension test for most metals), and b is the fatigue strength exponent or Basquin exponent, which for most metals, is in the range of –0.05 to –0.12.[2]

The presence of a tensile mean stress has a pronounced effect on fatigue life. The allowable alternating stress to achieve the same life is reduced with increasing tensile mean stress. Effects of mean stress on fatigue can be represented in terms of constant-life diagrams, as shown in Figure 11.4.9.[2] Different combinations of the stress amplitude and mean stress are plotted to provide a constant fatigue life in these models. The most commonly used model is that of Goodman:

$$\begin{aligned}
&\sigma_a = \sigma_{fs}\left(1 - \frac{\sigma_m}{\sigma_y}\right)\text{: Soderberg relation} \\
&\sigma_a = \sigma_{fs}\left(1 - \frac{\sigma_m}{\sigma_{UT}}\right)\text{: Goodman relation}
\end{aligned} \tag{11.4.29}$$

$$\sigma_a = \sigma_{fs}\left(1 - \left\{\frac{\sigma_m}{\sigma_{UT}}\right\}^2\right)\text{: Gerber relation}$$

where σ_a is the allowable stress amplitude in the presence of a nonzero mean stress σ_m, σ_{fs} is the fatigue strength for a fixed life for fully reversed loading ($\sigma_m = 0$), and σ_y and σ_{UT} are the yield strength and ultimate tensile strength of the material, respectively.

The stress-life approach discussed thus far applies for uniaxial fatigue loading. It can be extended for the case of multiaxial loading by using equivalent stress approaches, which are extensions of static yield criteria to fatigue. Equivalent mean and alternating stresses are calculated using the von Mises or the Tresca theories, thus reducing the problem to an equivalent uniaxial case. The appropriate S-N diagram along with a mean stress correction factor is used to evaluate fatigue life.

$$\begin{aligned}\sigma'_a &= \frac{1}{\sqrt{2}}\sqrt{\left[(\sigma_{1a}-\sigma_{2a})^2 + (\sigma_{2a}-\sigma_{3a})^2 + (\sigma_{3a}-\sigma_{1a})^2\right]} = \text{Equiv.alt.stress}\\ \sigma'_m &= \frac{1}{\sqrt{2}}\sqrt{\left[(\sigma_{1m}-\sigma_{2m})^2 + (\sigma_{2m}-\sigma_{3m})^2 + (\sigma_{3m}-\sigma_{1m})^2\right]} = \text{Equiv.mean stress}\end{aligned} \tag{11.4.30}$$

Cumulative Damage

Service load histories for engineering applications are usually variable amplitude, whereas the stress-life approach outlined is only applicable for constant amplitude loading. It is important to have a theory, verified by experimental observations, that will permit good design estimates to be made for operation under spectrum loading using the standard constant amplitude S-N curves that are available. Cumulative damage under spectrum loading is evaluated by taking into account the cyclic stress amplitude, the number of cycles of operationat that stress amplitude, and also the total number of cycles of life of an undamaged specimen at that stress amplitude. The damage incurred is considered permanent, and operation at several different stress amplitudes in sequence will result in an accumulation of total damage equal to the sum of the damage increments accrued at each individual stress level. When the total accumulated damage reaches a critical value, fatigue failure is predicted to occur.[1]

The linear damage rule by Palmgren and Miner is widely used because of its simplicity and is illustrated in Figure 11.4.10. At a given stress amplitude S_1 with total life N_1, the *damage fraction* for n_1 cycles (less than N_1) is defined as

$$D_1 = \frac{n_1}{N_1}.$$

For spectrum loading, failure is predicted to occur if the sum of the damage fractions is greater than or equal to unity, that is, $D_1 + D_2 + \ldots D_{i-1} + D_i \geq 1$. The assumption here is that the damage accumulation is linear and that the order of application of loads is not important. By the Palmgren-Miner rule, failure is predicted to occur if

$$\frac{n_1}{N_1} + \frac{n_2}{N_2} + \ldots + \frac{n_{i-1}}{N_{i-1}} + \frac{n_i}{N_i} \geq 1 \tag{11.4.31}$$

There is experimental evidence that the order of application of loads has a significant influence and also that damage rate at a given stress level is likely a function of prior stress history. For instance, a large stress cycle will produce a large plastic zone at a crack tip, inducing a residual compressive stress. For subsequent loading cycles, crack growth rate is retarded while the crack is propagating through the

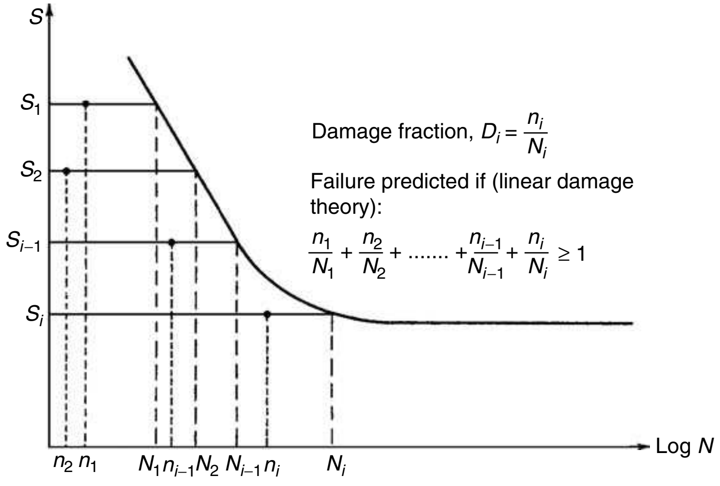

FIGURE 11.4.10 Palmgren-Miner linear damage hypothesis for spectrum loading. [From Figure 8.1, p. 256, in reference 1.]

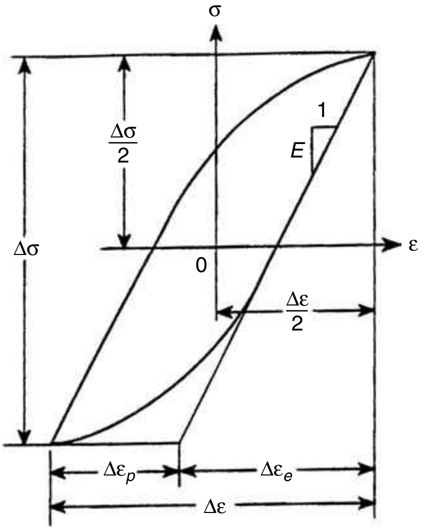

FIGURE 11.4.11 Representation of cyclic stress and strain amplitudes in a stabilized hysteresis loop.

residual compressive stress field. Many other cumulative damage theories account for such nonlinear effects, these are discussed in detail in references 1–3.

Strain-Life Approach

The strain-life method predicts the life expectancy based on the magnitude of strain amplitude. This method is appropriate when components have regions of high-stress concentration with constrained loading conditions, where the fatigue loading induces alternating plastic stresses and strains. In these situations, it is more appropriate to consider the life of a component under a strain-controlled condition that represents a constrained loading situation.[2]

The cyclic stress-strain relations in a stable hysteresis loop, shown in Figure 11.4.11, can be expressed as

$$\frac{\Delta\varepsilon}{2} = \frac{\Delta\varepsilon_e}{2} + \frac{\Delta\varepsilon_p}{2} = \frac{\Delta\sigma}{2E} + \left(\frac{\Delta\sigma}{2K'}\right)^{1/n'} \qquad (11.4.32)$$

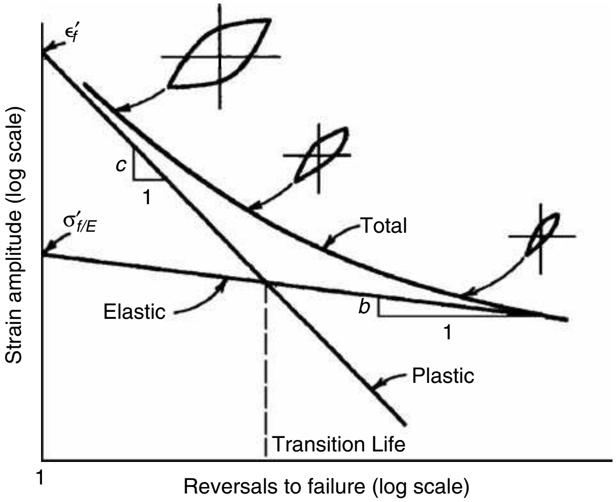

FIGURE 11.4.12 Representation of elastic, plastic, and total strain amplitude vs. fatigue life. [From Figure 11.7, p. 399, in reference 1.]

where $\Delta\varepsilon_e/2$ and $\Delta\varepsilon_p/2$ are the elastic and plastic strain amplitudes, respectively, K' is the cyclic strength coefficient, and n' is the cyclic strain hardening exponent.

The empirical Coffin-Manson equation, Equation 11.4.33, relates strain amplitude with numbers of fatigue cycles to nucleate a crack:

$$\frac{\Delta\varepsilon}{2} = \frac{\Delta\varepsilon_e}{2} + \frac{\Delta\varepsilon_p}{2} = \frac{\sigma_f'}{E}\left(2N_f\right)^b + \varepsilon_f'\left(2N_f\right)^c \tag{11.4.33}$$

where ε_f' is the fatigue ductility coefficient (which is experimentally found to be approximately equal to the true fracture ductility ε_f in monotonic tension) and c is the fatigue ductility exponent (which is in the range of –0.5 to –0.7 for most metals).[2]

This characterization is based on the observation that the logarithm of elastic and plastic strain amplitudes, $\Delta\varepsilon_e/2$ and $\Delta\varepsilon_p/2$, plotted against the logarithm of the number of load reversals to failure, $2N_f$, follows a linear relationship for metallic materials, as shown in Figure 11.4.12. The transition life, $(2N_f)_t$, which is the life at which the elastic and plastic strain amplitudes are equal, is given by

$$\left(2N_f\right)_t = \left(\frac{\varepsilon_f' E}{\sigma_f'}\right)^{1/(b-c)} \tag{11.4.34}$$

At short fatigue lives, that is, when $2N_f << (2N_f)_t$, plastic strain amplitudes are more dominant than the elastic strain amplitude and the fatigue life of the material is controlled by *ductility*. At long fatigue lives, that is, when $2N_f >> (2N_f)_t$, the elastic strain amplitude is more significant than the plastic strain amplitude and the fatigue life is dictated by *fracture strength*. Optimizing overall fatigue properties requires a judicious balance between strength and ductility.[2]

Mean stress effects can be incorporated into the strain-life method by using Manson's rule:

$$\frac{\Delta\varepsilon}{2} = \left(\frac{\sigma_f' - \sigma_m}{E}\right)\left(2N_f\right)^b + \varepsilon_f'\left(\frac{\sigma_f' - \sigma_m}{\sigma_f'}\right)^{1/n'}\left(2N_f\right)^c \tag{11.4.35}$$

Manson's rule does not account for stress relaxation at high plastic strains. Descriptions of other relations that account for effects of nonzero mean stress can be found in references 2 and 3.

Evaluating stress and strain amplitudes in regions of stress concentration such as notches requires the complex task of implementing three-dimensional elastic-plastic finite element modeling procedures with appropriate constitutive relations. To estimate the local stresses and strains in notches, Neuber's rule[10] is often used in conjunction with cyclic stress-strain properties and the fatigue stress concentration factor. If loads are such that the overall structural member is nominally elastic, then Neuber's rule can be adapted as shown here:

$$\Delta\sigma\,\Delta\varepsilon = \frac{(K_f\,\Delta S)^2}{E} \tag{11.4.36}$$

where K_f is the fatigue stress concentration factor and ΔS the nominal stress range. This relation is used in conjunction with Equation 11.4.32 to obtain the cyclic stress amplitude, using the nonlinear algebraic relation shown in Equation 11.4.37:

$$(\Delta\varepsilon)^2 - 2\Delta\varepsilon\left(\frac{(K_f\Delta S)^2}{2K'E\Delta\varepsilon}\right)^{1/n'} = \frac{(K_f\Delta S)^2}{E^2} \tag{11.4.37}$$

Once the cyclic strain amplitude, $\Delta\varepsilon/2$, is evaluated using Equation 11.4.37, fatigue life can be computed using Equation 11.4.33. If nonzero mean stress effects are present, Equation 11.4.35 can be used. Neuber's rule treats the stresses and strains in a notch from a uniaxial perspective, even though the state of stress is triaxial. The strain amplitude evaluated by Equation 11.4.37 can be viewed as von Mises or Tresca equivalent strain amplitude.

Critical Plane Methods and Nonproportional Loading

Cracks have been experimentally observed to nucleate and grow on specific planes, termed "critical planes." These critical planes can be planes of maximum shear stress or maximum tensile stress, depending on the material and loading conditions. *Critical plane models* are multiaxial fatigue models relating the fatigue damage process to stresses and/or strains on these planes. These models can predict not only the fatigue life but also the orientation of the crack or failure plane.[3] A detailed discussion of several critical plane models in use can be found in reference 3. The critical plane model by Fatemi and Socie[11] is presented here in Equation 11.4.38:

$$\frac{\Delta\gamma_{\max}}{2}\left(1 + k\frac{\sigma_{n,\max}}{\sigma_y}\right) = \frac{\tau'_f}{G}\left(2N_f\right)^{b_o} + \gamma'_f\left(2N_f\right)^{c_o} \tag{11.4.38}$$

The left-hand side of Equation 11.4.38 represents the fatigue damage parameter based on the critical plane model, where $\Delta\gamma_{\max}/2$ represents the maximum shear strain amplitude and $\sigma_{n,\max}$ is the maximum normal stress acting on the maximum shear strain amplitude plane. The damage parameter is an attempt to model the crack-tip driving forces using the shear strain along a crack face and the normal stress perpendicular to the crack that tends to separate the crack surfaces. At the microscopic level, cracks are shaped irregularly because the crack grows through the material grain structure. During cyclic shear loading, this causes friction forces and interlocking between the crack surfaces (i.e., crack closure). A tensile stress perpendicular to the crack plane tends to separate crack surfaces and reduce the interlocking and frictional forces, which in turn increases the crack-tip driving force. The material constant, k, can be found by fitting fatigue data from simple uniaxial tests to fatigue data from simple torsion tests. If test data are not available, $k \approx 1$ serves as a first approximation

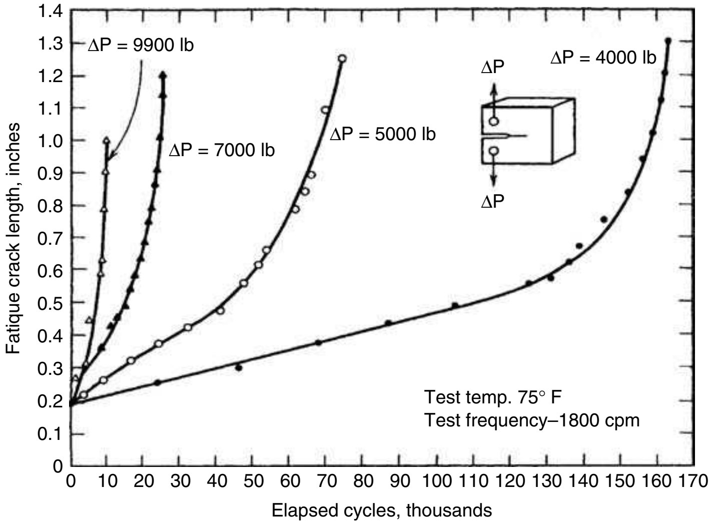

FIGURE 11.4.13 Effect of cyclic load range on crack growth in Ni-Mo-V steel for released tension loading (R=0). [From Figure 8.21, p. 295, in reference 1.]

Mean or residual stress effects on fatigue life in this model are accounted for by the maximum normal stress term:

$$\sigma_{n,\max} = \sigma_{n,a} + \sigma_{n,m} \tag{11.4.39}$$

where $\sigma_{n,a}$ and $\sigma_{n,m}$ are the alternating normal and mean or residual normal stresses, respectively.[3,11]

The right-hand side of Equation 11.4.38 represents the shear-strain life model, similar to Equation 11.4.33, where G is the shear modulus, τ'_f is the shear fatigue strength coefficient, γ'_f is the shear ductility coefficient, and b_0 and c_0 are shear fatigue strength and shear fatigue ductility exponents, respectively. These properties can be estimated from uniaxial strain-life properties as $\tau_f' \approx \sigma_f'/\sqrt{3}$, $b_o \approx b$, $\gamma_f' \approx \sqrt{3}\varepsilon_f'$ and $c_o \approx c$.[3]

The Fatemi and Socie model is applicable for *nonproportional* loading conditions. This can occur if the axial and torsional cyclic loading are out of phase, for example, leading to principal directions of the alternating stresses varying with respect to the loading axes, as a periodic function of time. The additional hardening that can result from nonproportional loading is incorporated by the maximum normal stress term since additional hardening results in an increase in the alternating normal stress, $\sigma_{n,a}$.

Linear Elastic Fracture Mechanics (LEFM) Approach for Fatigue Crack Growth

The fatigue crack growth rate under conditions of constant amplitude stress reversals is characterized in terms of the crack length increment per cycle, da/dN. Values of da/dN for different loading conditions are determined from experimentally measured changes in crack length over a certain number of elapsed fatigue cycles. When the applied stress range is held constant, the rate of growth of a fatigue crack generally climbs with an increasing number of fatigue cycles, although there can be exceptions to this trend. Figure 11.4.13 shows a typical fatigue crack growth curve. The mechanisms of crack propagation described in this section apply to those of “long” through-the-thickness fatigue cracks, typically several millimeters or more in all directions. Detailed discussions on small crack growth and what constitutes a “small” crack can be found in reference 2. It is assumed that conditions of LEFM are met, that is, the zone of plastic deformation ahead of the advancing fatigue crack is a minor perturbation in an otherwise elastic field.

Paris, Gomez, and Anderson[12] suggest that for a cyclic variation of imposed stress field, under LEFM assumptions, the rate of fatigue crack growth should be based on the stress intensity factor range:

$$\Delta K = K_{\max} - K_{\min} \tag{11.4.40}$$

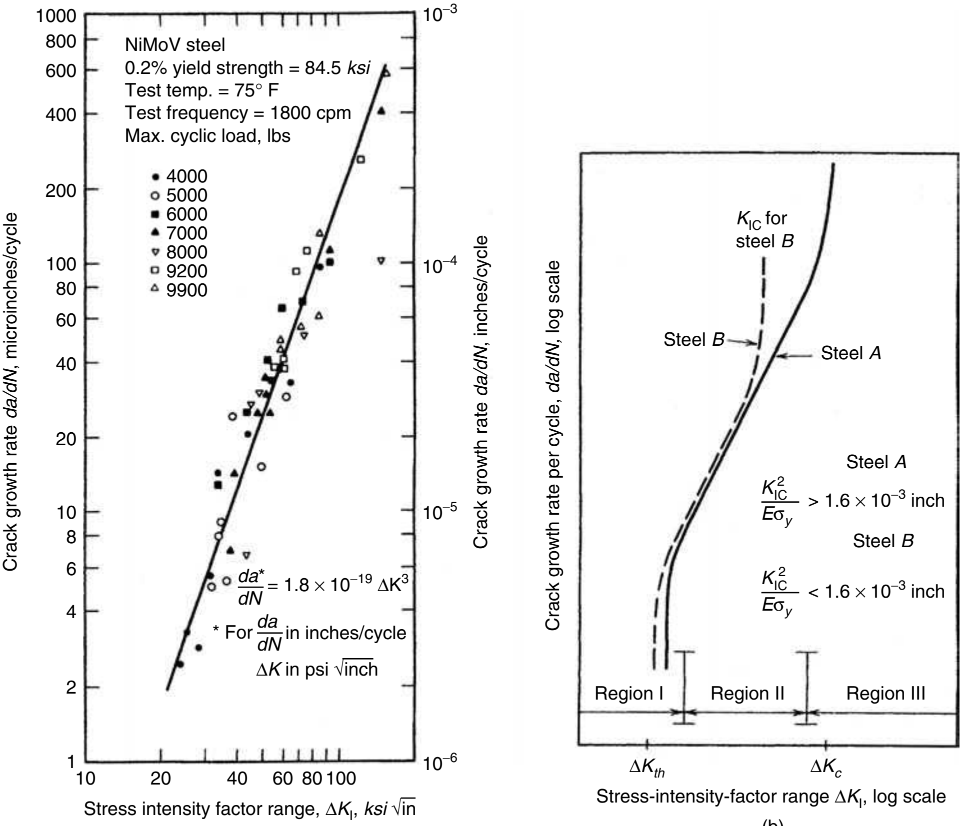
where $K_{\max}$ and $K_{\min}$ are the maximum and minimum values, respectively of the SIF during a fatigue stress cycle, and, following Equation 11.4.21, are given by

$$\begin{aligned} K_{\max} &= C\sigma_{\max}\sqrt{\pi a}, \quad K_{\min} = C\sigma_{\min}\sqrt{\pi a} \\ \Delta K &= C\Delta\sigma\sqrt{\pi a}, \quad \Delta\sigma = \sigma_{\max} - \sigma_{\min} \end{aligned} \tag{11.4.41}$$

The fatigue crack growth rate is related to the SIF range by the power law relationship:[12]

$$\frac{da}{dN} = C_m\left(\Delta K\right)^m \tag{11.4.42}$$

where C_m and m are scaling constants and are influenced by variables such as environment, material microstructure, cyclic load frequency, waveform, test temperature, and load ratio R. The exponent m is typically between two and four for ductile alloys.[2] Equation Equation 11.4.42 is widely known as the "Paris law," and is applicable for single-mode far-field loading. This power law relationship was based on the observation that the log-log plot of da/dN. vs. ΔK was a straight line fit over the "Region II" phase, as seen in Figure 11.4.14(b). Figure 11.4.14(a) shows the experimentally measured fatigue crack growth



(a) (b)

FIGURE 11.4.14 Crack growth rate as a function of stress intensity factor range (a) Experimental data for Ni-Mo-V steel [From Figure 8.22, p. 296, in reference 1]; (b) Fatigue crack growth rate in steel for regions I, II and III. [From Figure 8.23, p. 297, in reference 1.]

curve for Ni-Mo-V steel along with the curve fit parameters. Region I in Figure 11.4.13(b) corresponds to the crack nucleation region, and Region III corresponds to the transition into the unstable regime of rapid crack extension. The Paris law given by Equation 11.4.42 is applicable only to Region II, also called the Paris regime, which represents the stable crack growth phase. At extreme values of ΔK, both below and above that of the Paris regime, there is a steep rise in crack growth rates with increasing ΔK. The threshold SIF range, ΔK_{th}, shown in Figure 11.4.14(b), represents a lower limit below which cracks are either dormant or grow at undetectable rates. Region III corresponds to the transition into unstable regime of rapid crack growth where ΔK values are high.

The microscopic mode of fatigue crack growth in Region I is strongly affected by the slip characteristics of the material, characteristic microstructural dimensions, applied stress level, and the extent of near tip plasticity. When the crack and the zone of plastic deformation surrounding the crack tip are confined to within a few grain diameters, crack growth occurs predominantly by single shear, in the direction of primary slip system. This single slip mechanism leading to a zig-zag crack path is termed Region I or Stage I crack growth.[2] A detailed discussion of Region I crack growth is given in reference 2.

Paris and Erdogan[13] present crack growth experiments on aluminum alloys with different combinations of stress range and crack length with different specimen geometries that unambiguously established the validity of such a characterization. Although Equation 11.4.42 is empirical, it has remained one of the most useful expressions in the analysis of fatigue crack for a vast spectrum of materials and test conditions.[2]

Fatigue life calculations in the Paris regime are done by combining Equation 11.4.41 and Equation 11.4.42 to obtain

$$\frac{da}{dN} = C_m \left(C \, \Delta\sigma \sqrt{\pi a} \right)^m \tag{11.4.43}$$

and integrating from an assumed initial crack size a_o to a critical crack size a_f. The resulting fatigue life is[2]

$$\begin{aligned} N_f &= \frac{2}{(m-2) C_m C^m (\Delta\sigma)^m \pi^{m/2}} \left\{ \frac{1}{(a_o)^{(m-2)/2}} - \frac{1}{(a_f)^{(m-2)/2}} \right\}, \quad \text{for } m \neq 2 \\ N_f &= \frac{1}{C_m C^2 (\Delta\sigma)^2 \pi} \ln \frac{a_f}{a_o}, \quad \text{for } m = 2 \end{aligned} \tag{11.4.44}$$

In general, C varies with a and hence the integration is performed numerically. Note that when $a_o << a_f$ (which is usually the case for ductile alloys), N_f is not very sensitive to a_f, but is strongly influenced by the choice of a_o.[2]

Mixed-Mode Loading Conditions

Fatigue crack growth under the influence of multiaxial far-field stress states results in mixed-mode loading conditions at the crack tip. Even when a fatigue crack is subjected to purely tensile far-field loading, mixed-mode conditions may prevail ahead of the crack tip if it is inclined to the tensile axis, or microstructural and environmental factors promote a nonplanar fatigue crack growth. A characteristic of mixed-mode fatigue cracks is that they can grow in a nonplanar non-self similar manner, that is, the crack changes its direction of growth.[2,3] Different combinations of mixed-mode loading can exist from multiaxial loads. For instance, in simple torsion of smooth shafts, surface cracks can form and grow in longitudinal and/or transverse directions along the maximum shear planes, where mixed-mode II and III exists along the crack front. Cracks can also form and grow along the ±45-degree angle to the axis of the shaft along planes of maximum principal stress where they grow in Mode I. In plate components with edge or central cracks under in-plane biaxial tension mixed-mode I and II, crack growth prevails. However, the Mode I contribution often becomes dominant after a short period of crack growth.[3]

Several parameters have been used to correlate fatigue crack growth rates under mixed-mode conditions such as equivalent stress intensity factors, equivalent strain intensity factors, strain energy density, and the *J*-integral. Fatigue cracks can also deflect in new directions and branch into multiple cracks under mixed-mode loading conditions. References 2 and 3 discuss these complex fatigue crack growth issues in detail.

11.5 Design Optimization

Nam Ho Kim

Introduction

The design of a structural system has two categories: designing a new structure and improving the existing structure to perform better. The design engineer's experience and creative ideas are required in the development of a new structure, since it is difficult to quantify a new design using mathematical measures. Recently, limited inroads have been made in the creative work of the structural design using mathematical tools.[1] However, the latter evolutionary process is encountered much more frequently in engineering designs. For example, how many times does an automotive company design a new car using a completely different concept? The majority of a design engineer's work concentrates on improving the existing vehicle so that the new car can be more comfortable, more durable, and safer. In this section, we will focus on a design's evolutionary process by using mathematical models and computational tools.

Structural design is a procedure for improving or enhancing the performance of a structure by changing its parameters. A *performance measure,* which can be quite general in engineering fields, can include the following: the weight, stiffness, and compliance of a structure; the fatigue life of a mechanical component; the noise in the passenger compartment; the vibration level; the safety of a vehicle in a crash, and so forth. However, this does not address such aesthetic measures as whether a car or a structural design is attractive to customers. All performance measures are presumed to be measurable quantities. System parameters are variables that a design engineer can change during the design process. For example, the thickness of a vehicle body panel can be changed to improve vehicle performance. The cross section of a beam can be changed in designing bridge structures. System parameters that can be changed during the design process are called *design variables*, even including the geometry of the structure.

Great strides have been made during the past decade in computer-aided design (CAD) and computer-aided engineering (CAE) tools for mechanical system development. Discipline-oriented simulation capabilities in structures, mechanical system dynamics, aerodynamics, control systems, and numerous related fields are now being used to support a broad range of mechanical system design applications. Integration of these tools to create a robust simulation-based design capability, however, remains a challenge. Based on their extensive survey of the automotive industry in the mid-1980s, Clark and Fujimoto[2] concluded that simulation tools in support of vehicle development were on the horizon but not yet ready for pervasive application. The explosion in computer, software, and modeling and simulation technology that has occurred since the mid-1980s suggests that high-fidelity tools for simulation-based design are now at hand. Properly integrated, they can resolve uncertainties and significantly affect mechanical system design.

Modern developments of structural design are closely related to concurrent engineering environments by which multidisciplinary simulation, design, and manufacturing are possible. Even though concurrent engineering is not the focus of this section, we want to emphasize structural design as a component of concurrent engineering. An important feature of the concurrent engineering is database management using the CAD tool. Structural modeling and most interfaces are achieved using the CAD tool. Thus, design parameterization and structural model updates have to be carried out within the CAD model. Through the design parameterization, CAD, CAE, and CAM procedures are interrelated to form a concurrent engineering environment.

The structural engineering design in the simulation-based process consists of structural modeling, design parameterization, structural analysis, design problem definition, design sensitivity analysis, and design optimization. Figure 11.5.1 is a flowchart of the structural design process in which computational analysis and mathematical programming play essential roles in the design. The success of the system-level, simulation-based design process strongly depends on a consistent design parameterization, an accurate structural and design sensitivity analysis, and an efficient mathematical programming algorithm.

A design engineer simplifies the physical engineering problem into a mathematical model that can represent the physical problem up to the desired level of accuracy. A mathematical model has parameters that are related to the system parameters of the physical problem. A design engineer identifies those design variables to be used during the design process. *Design parameterization*, which allows the design engineer to define the geometric properties for each design component of the structural system being designed, is one of the most important steps in the structural design process. The principal role of design parameterization is to define the geometric parameters that characterize the structural model and to collect a subset of the geometric parameters as design variables. Design parameterization forces engineering teams in design, analysis, and manufacturing to interact at an early design stage, and supports a unified design variable set to be used as the common ground to carry out all analysis, design, and manufacturing processes. Only proper design parameterization will yield a good optimum design, since the optimization algorithm will search within a design space that is defined for the design problem. The design space is defined by the type, number, and range of design variables. Depending on whether it is a concept or detailed design, selected design variables could be non-CAD based parameters. An example of such a design variable is a tire's stiffness characteristic in vehicle dynamics during an early vehicle design stage.

Structural analysis can be carried out using experiments in actual or reduced scale, which is a straightforward and still prevalent method for industrial applications. However, the expense and inefficiency involved in fabricating prototypes make this approach difficult to apply. The analytical method may resolve these difficulties, since it approximates the structural problem as a mathematical model and solves

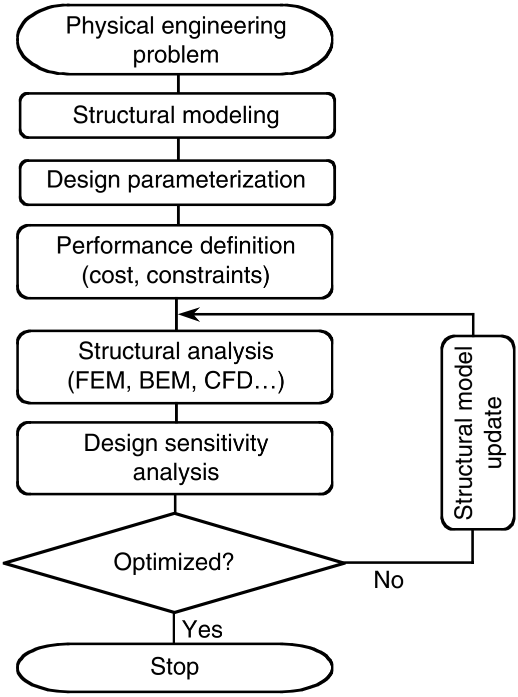

FIGURE 11.5.1 Structural design process.

it in a simplified form. The mathematical model can be used to evaluate the performance measures of a structural problem. However, the analytical method has limitations even for simple structural problems.

With the emergence of various computational capabilities, most analytical approaches to mathematical problems have been converted to numerical approaches, which are able to solve very complicated, real engineering applications. Finite element analysis (FEA), boundary element analysis (BEA), and meshfree analysis are a short list of mathematical tools used in structural analysis. The development of FEA is one of the most remarkable successes in structural analysis. The governing differential equation of the structural problem is converted to its integral form and then solved using FEA. Vast amounts of literature are published regarding FEA; for example, refer to Reference 3 and the references therein. The complex structural domain is discretized by a set of nonoverlapping, simple-shaped finite elements, and an equilibrium condition is imposed on each element. By solving a linear system of matrix equations, we can compute the performance measures of a structure in the approximated domain. The accuracy of the approximated solution can be improved by reducing the size of finite elements and/or increasing the order of approximation within an element.

Selection of a design space and an analysis method must be carefully determined since the analysis, both in terms of accuracy and efficiency, must be able to handle all possible designs in the chosen design space. That is, the larger the design space, the more sophisticated the analysis capability must be. For example, if larger shape design changes are expected during design optimization, mesh distortion in FEA could be a serious problem and a finite element model that can handle large shape design changes must be used.

A *performance measure* in a simulation-based design is the result of structural analysis. Based on the evaluation of analysis results, such engineering concerns as high stress, clearance, natural frequency, or mass can be identified as performance measures for design improvement. Typical examples of performance measures are mass, volume, displacement, stress, compliance, buckling, natural frequency, noise, fatigue life, and crashworthiness. A definition of performance measures permits the design engineer to specify the structural performance from which the sensitivity information can be computed.

Cost and constraints can be defined by combining certain performance measures with appropriate constraint bounds for interactive design optimization. The *cost function*, sometimes called the *objective function*, is minimized (or maximized) during optimization. Selection of a proper cost function is an important decision in the design process. A valid cost function has to be influenced by the design variables of the problem; otherwise, it is not possible to reduce the cost by changing the design. In many situations, an obvious cost function can be identified. In other situations, the cost function is a combination of different structural performance measures. This is called a *multiobjective* cost function.

Constraint functions are the criteria that the system has to satisfy for each feasible design. Among all design ranges, those that satisfy the constraint functions are candidates for the optimum design. For example, a design engineer may want to design a bridge whose weight is minimized and whose maximum stress is less than the yield stress. In this case, the cost function, or weight, is the most important criterion to be minimized. However, as long as stress, or constraint, is less than the yield stress, the stress level is not important.

Design sensitivity analysis is used to compute the sensitivity of performance measures with respect to design variables. This is one of the most expensive and complicated procedures in the structural optimization process. Structural design sensitivity analysis is concerned with the relationship between design variables available to the engineer and the structural response determined by the laws of mechanics. Design sensitivity information provides a quantitative estimate of desirable design change, even if a systematic design optimization method is not used. Based on the design sensitivity results, a design engineer can decide on the direction and amount of design change needed to improve the performance measures. In addition, design sensitivity information can provide answers to "what if" questions by predicting performance measure perturbations when the perturbations of design variables are provided.

Substantial literature has emerged in the field of structural design sensitivity analysis.[4] Design sensitivity analysis of structural systems and machine components has emerged as a much-needed design tool, not only because of its role in optimization algorithms but also because design sensitivity information can be used in a computer-aided engineering environment for early product trade-off in a concurrent design process.

Recently, the advent of powerful graphics-based engineering workstations with increasing computational power has created an ideal environment for making interactive design optimization a viable alternative to more monolithic batch-based design optimization. This environment integrates design processes by letting the design engineer create a geometrical model, build a finite element model, parameterize the geometric model, perform FEA, visualize FEA results, characterize performance measures, and carry out design sensitivity analysis and optimization.

Design sensitivity information can be used during a postprocessing of the interactive design process. The principal objective of the postprocessing design stage is to utilize the design sensitivity information to improve the design. Figure 11.5.2 shows the four-step interactive design process: (1) to visually display design sensitivity information, (2) to carry out what-if studies, (3) to make trade-off determinations, and (4) to execute interactive design optimization. The first three design steps, which are interactive modes of the design process, help the design engineer improve the design by providing structural behavior information at the current design stage. The last design step, which could be either interactive or a batch mode of the design process, launches a mathematical programming algorithm to perform design optimization. Depending on the design problem, the design engineer could use some or all of the four design steps to improve the design at each iterative step. As a result, new designs could be obtained from what-if, trade-off, or interactive optimization design steps.

For the purposes of design optimization, a mathematical programming technique is often used to find an optimum design that can best improve the cost function within a feasible region. Mathematical programming generates a set of design variables that require performance values from structural analysis and sensitivity information from design sensitivity analysis to find an optimum design. Thus, the structural model has to be updated for a different set of design variables supplied by mathematical programming. If the cost function reaches a minimum with all constraint requirements satisfied, then an optimum design is obtained.

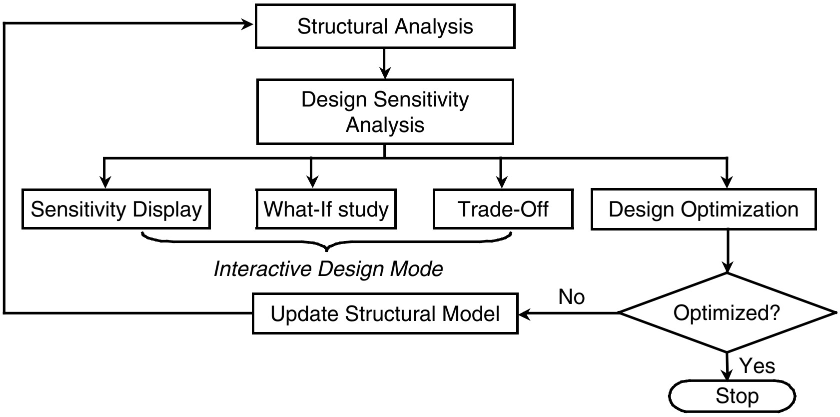

FIGURE 11.5.2 Postprocessing design stage.

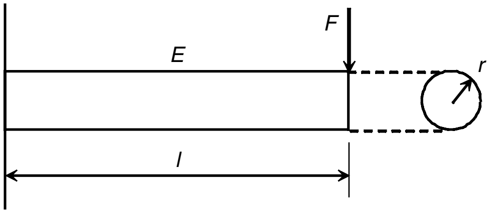

FIGURE 11.5.3 Parameters defining circular cross-sectional cantilever beam.

Structural Design Parameterization

In structural modeling, the physical problem is represented by mathematical expressions, which contain parameters for defining that problem. For example, the cantilever beam in Figure 11.5.3 has parameters that include the length l, the radius of cross section r, and Young's modulus E. These parameters, which define the system, are called *design variables*. If design variables are determined, then the structural problem can be analyzed. Obviously, different design variable values usually yield different analysis results. The aim of the structural design process is to find the values of design variables that satisfy all requirements.

All design variables must satisfy the physical requirements of the problem. For example, length l of the cantilever beam in Figure 11.5.3 cannot have a negative value. Physical requirements define the design variable bounds. Valid design variables may have to take into account various manufacturing requirements. For example, the radius of a cantilever beam satisfies its physical requirement if r is a positive number. However, in real applications, the circular cross-sectional beam may not be manufactured if its radius is bigger than r^0. Thus, the range of feasible design can be stated as $0 < r \leq r^0$.[1] In addition, the design engineer may want to impose certain design constraints on the problem. For example, the maximum stress of the beam may not exceed σ^0 and the maximum tip displacement of the beam must not be greater than z^0. A set of design variables that satisfy the constraints is called a *feasible design*, whereas a set that does not satisfy constraints is called an *infeasible design*. It is difficult to determine whether a current design is feasible unless the structural problem is analyzed. For complicated structural problems, it may not be simple to choose the appropriate design constraints so that the feasible region is not empty.

There are two types of design variables: continuous and discrete. Many design optimization algorithms consider design variables to be continuous. In this section, we presume that all design variables are

---

[1] In general, the bounds of design variables are denoted as $r^L \leq r \leq r^U$ where r^L is called the lower bound and r^U is called the upper bound, respectively.

continuous within their lower- and upper-bound limits. However, discrete design problems often appear in real engineering problems. For example, due to manufacturing limitations, the structural components of many engineering systems are only available in fixed shapes and sizes. Discrete design variables can be thought of as continuous design variables with constraints. As a result, it is more expensive to obtain an optimum design for a problem with discrete design variables. It is possible, however, to solve the problem assuming continuous design variables. After obtaining an optimum solution for the design problem, the nearest discrete values of the optimum design variables can be tested for feasibility. If the nearest discrete design variables are not feasible, then several iterations can be carried out to find the nearest feasible design.

It is convenient to classify design variables according to their characteristics. In the design of structural systems made of truss, beam, membrane, shell, and elastic solid members, there are five kinds of design variables: material property design variables such as Young's modulus; sizing design variables such as thickness and cross-sectional area; shape design variables such as length and geometric shape; configuration design variables such as orientation and location of structural components; and topological design variables.

The Material Property Design Variable

In structural modeling, the material property is used as a parameter of the structural problem. Young's modulus and Poisson's ratio, for example, are required in the linear elastic problem. If these material properties are subject to change, then they are called *material property design variables*. These kinds of design variables do not appear in regular design problems, since in most cases material properties are presumed to be constant. Analysis using such a constant material property is called the deterministic approach. Another approach uses probability and assumes that material properties are not constant but distributed within certain ranges. This is called the probabilistic approach and is more practical, since a number of experiments will usually yield a number of different test results. In this case, material properties are no longer considered to be constant and can therefore be used as design variables.

The Sizing Design Variable

The *sizing design variable* is related to the geometric parameter of the structure, and it is often called a parametric design variable. For example, most automotive and airplane parts are made from plate/shell components. It is natural that a design engineer wants to change the thickness (or gauge) of the plate/shell structure in order to reduce the weight of the vehicle. For a structural model, plate thickness is considered a parameter. However, the global geometry of the structure does not change. Plate thickness can be considered a sizing design variable. The sizing design variable is similar to the material property design variable in the sense that both variables change the parameters of the structural problem.

Another important type of sizing design variable is the cross-sectional geometry of the beam and truss. Figure 11.5.4 provides some examples of the shapes and parameters that define these cross sections. In the structural analysis of truss, for example, the cross-sectional area is required as a parameter of the problem. If a rectangular cross section is used, then the area would be defined as $A = b \times h$. Thus, without any loss of generality, b and h can be considered design variables of the design problem.

(a) Line Design Component (b) Surface Design Component

FIGURE 11.5.5 Line and surface design parameterization.

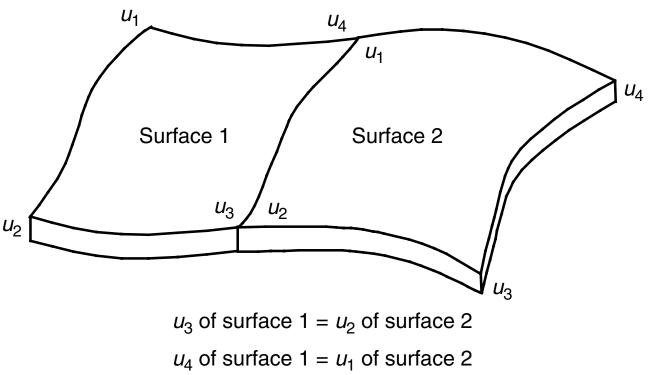

FIGURE 11.5.6 Design variable linking.

In this section, several possible design parameterizations, such as constant and linear designs as described in Figure 11.5.5, are introduced for the line and surface design components. These are not at all the only possible design parameters, and other more complicated design parameterizations can be used. However, the method presented in this section can be extended to other complicated design parameterizations. One important thing to consider when more complicated design parameterizations are used is that the finite element model must be sophisticated enough to support the design parameterization method used. Geometric parameters can be defined at the end grid points of a line, or at the corner points of a surface. A bilinear thickness distribution can be used to characterize a surface design component, as shown in Figure 11.5.5(b). Note that each dimension that defines the cross-sectional shape, such as width and height in Figure 11.5.5(a), can be treated as a design variable, and be allowed to vary to the same degree as the corresponding variable at the other end (constant parameterization), or to a different degree (linear parameterization). Moreover, in order to maintain design continuity for a symmetric design, or to reduce the number of design variables, design variables can change either independently of, or proportionally to, certain variables across design components through design variable linking, as shown in Figure 11.5.6.

Line Design Components

A three-dimensional line component can be used for truss or beam design components. A truss design component can handle tensile and compressive load and may be composed of several truss finite elements. A beam design component can handle tensile, compressive, and bending load. A linearly tapered cross-sectional shape can be considered within the design component. There are three cross-section types for this design component: symmetric, un-symmetric, and general. Figure 11.5.7 illustrates the geometry of a line design component.

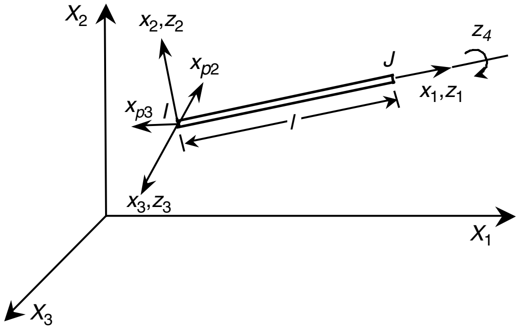

FIGURE 11.5.7 Line design component.

Material properties, such as mass density and Young's modulus, and geometric parameters that define the cross-sectional shape can be taken as design variables along the axial axis x_1. All material property design variables are assumed to be constant along the design component's axial axis.

The geometric design variables that can linearly vary along the axis of the design component are the dimensions of each cross-section, that is, r for a solid and hollow circular cross section, and b and h for other cross sections, as shown in Table 11.5.1 and Table 11.5.2.

TABLE 11.5.1 Symmetric Cross Sections

		Design Variable[a]					
Cross-Sectional Shape		1	2	3	4	5	6
Solid circular		r	E	ρ	—	—	—

T-section		*h*	*b*	*t*	*w*	*E*	ρ	—
Unsymmetric I-section		*h*	b_1	b_2	*t*	*w*	*E*	ρ

Proportionality can be used between two geometric design variables within a design component through design variable linking. Such proportional design variables are used to meet local buckling requirements for a structural design specification, to maintain geometric proportionality, or to reduce the number of design variables. The pairs of geometric design variables that may be considered for proportionality purposes are (t,b) and (w,h) for a hollow rectangle, an I-section, (b,h) for a solid rectangle, and (t,r) for a hollow circle.

The symmetric cross section has two perpendicular axes of symmetry, as shown in Table 11.5.1. These two axes are the principal axes of the cross section, and are usually taken as two component coordinates. The component's axial axis is assumed to be the same as the centroidal axis. Solid and hollow circles, solid and hollow rectangles, and the I-section are all placed in this category.

The unsymmetric cross section has either only one axis of symmetry, or no symmetry with some shape regularity, as shown in Table 11.5.2. The channel, angle, T-section, and unsymmetric I-section all fit into this category. The component coordinates x_2 and x_3 may be different from the principal axes x_{p2} and x_{p3}, respectively. The centroidal axis is assumed to coincide with the axial axis x_1 of the truss design component.

The general cross section has no regular shape and may be composed of several thin-walled segments, as shown in Table 11.5.3.

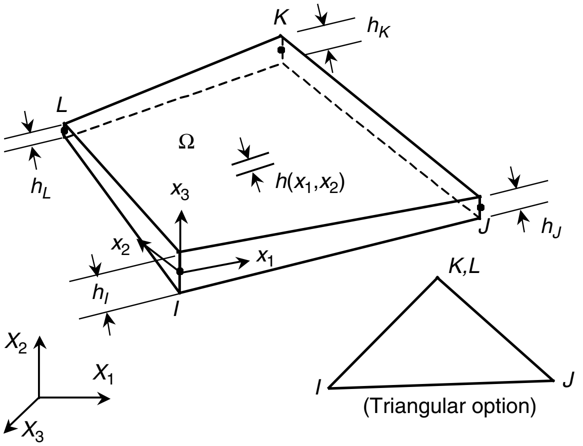

FIGURE 11.5.8 Surface design component.

Surface Design Components

A plane stress component can handle both an in-plane tensile and a compressive load. A shell component can handle an in-plane tensile, compressive, and bending load. The design component may be composed of several plane stress/shell finite elements. Figure 11.5.8 illustrates the geometry of a plane stress/shell design component.

Surface component design variables include thickness, mass density, and Young's modulus. Surface thickness is parameterized using a bilinear shape function. Four geometric design variables are defined for each surface design component: thickness h_I, h_J, h_K, and h_L at grid points I, J, K, and L, respectively, as shown in Figure 11.5.8 and Table 11.5.4.

The four-node quadrilateral surface component can be reduced to a triangular surface component by defining duplicate node numbers for the third and fourth (K and L) node locations. If node L is not defined, then it defaults to node K. The design component thickness is assumed to vary bi-linearly inside the design component.

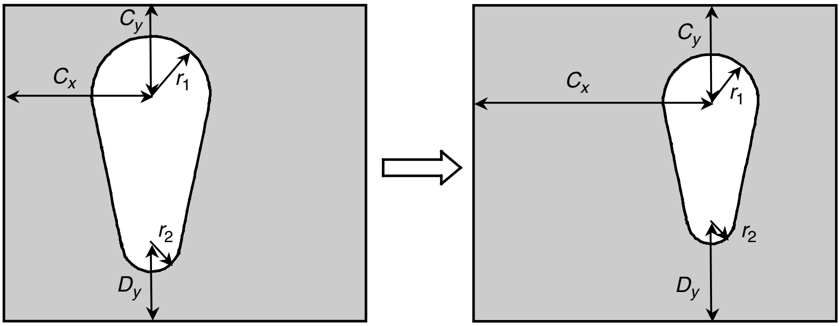

FIGURE 11.5.9 Shape design variables.

The Shape Design Variable

While material property and the sizing design variables are related to the parameters of the structural problem, the shape design variable is related to the structure's geometry. The shape of the structure does not explicitly appear as a parameter in the structural formulation. Although the design variables in Figure 11.5.4 determine the cross-sectional shape, they are not shape design variables, since these cross-sectional shapes are considered parameters in the structural problem. However, the length of the truss or beam should be treated as a shape design variable. Usually, the shape design variable defines the domain of integration in structural analysis. Thus, it is not possible to extract shape design variables from a structural model and to use them as sizing design variables.

Consider a rectangular block with a slot, as presented in Figure 11.5.9. The location and size of the slot is determined by the geometric values of C_x, C_y, D_y, r_1, and r_2, which are shape design variables. Different values of shape design variables yield different structural shapes. However, these shape design variables do not explicitly appear in the structural problem. If the finite element method is used to perform structural analysis, then integration is carried out over the structural domain (the gray area), which is the shape design variable. Since shape design variables do not explicitly appear in the structural problem, the shape design problem is more difficult to solve than the sizing design problem.

Shape design parameterization, which describes the boundary shape of a structure as a function of the design variables, is an essential step in the shape design process. Inappropriate parameterization can lead to unacceptable shapes.[5,6] To parameterize the structural boundaries and to achieve optimum shape design, boundary shape can be described in three ways: (1) by using boundary nodal coordinates, (2) by using polynomials, or (3) by using spline blending functions. However, it is important to point out that there are many methods of parameterization and that the methods presented in this section are only a few of them, including complicated parameterization methods developed in commercial CAD tools. One important aspect of shape design parameterization is the connection of the design parameterization to the computation of the design velocity field.

In the first method, boundary nodal coordinates of the finite element model are used as shape design variables. Although the method is simple and easy to use, it has the following drawbacks: (1) the number of design variables tends to become very large, which may lead to high computational costs and optimization problems that are difficult to solve; (2) the first derivative of the design boundary is not continuous across boundary nodes, which may lead to an unacceptable or impractical design; and (3) computational accuracy is not ensured, since it is difficult to maintain an adequate finite element mesh during the optimization process. One can use coordinates of selected master nodes as shape design variables and employ an isoparametric mapping to generate a finite element mesh.

Several methods have been developed to parameterize the design boundary with polynomials. Bhavikatti and Ramakrishnan[7] used a 5th-degree polynomial, with the coefficients taken as design variables, to parameterize the boundary shape of a rotating disk. Prasad and Emerson[8] used a similar approach to optimize an engine connecting rod. In a more general approach, such as that used by Kristensen and Madsen[9] and Pedersen and Laursen,[10] the boundary is parameterized using a linear combination of shape functions, with the coefficients as design variables. The total number of shape design variables can be reduced using polynomials for shape representation. However, using high-order polynomials to represent the boundary shape may result in oscillating boundaries.

Splines eliminate the problem of oscillating boundaries since they are composed of low-order polynomial segments that are combined to maximize the smoothness of the boundaries. Yang and Choi,[11] Luchi et al.,[12] and Weck and Steinke[13] used a cubic spline to define the boundary geometry. The spline representation was shown to yield better sensitivity accuracy than a piecewise linear representation of the boundary.[11] Braibant et al.[14] used Bezier and B-spline blending functions to describe the design boundary. Blending functions provide great flexibility for geometrical description. Using B-splines, Braibant and Fleury[15] optimized a beam in bending, a fillet, and a hole in a plate. Finally, Yao and Choi[16–18] used a Bezier surface to optimize an engine bearing cap and an arch dam.

The shape design parameterization method presented in this section deals with geometric features. A geometric feature is a subset of the geometric boundaries of a structural component. For example, a fillet or a circular hole is a geometric feature that contains characteristics associated with it and is likely to be chosen as a design variable. A geometric feature whose design variables are defined is known as a parameterized geometric feature, and is treated as a single entity in the shape design process. For example, a circular hole with its radius and center location defined as design variables is a parameterized geometric feature. Such a parameterized circular hole can be moved around in the structure with a varied size due to design changes. However, the shape of the circular hole itself remains constant.

Two steps are involved in the design parameterization process: geometric modeling and defining the design variables. A geometric model is first generated in the modeling process, with all its dimensions defined. Geometric features that can be varied in the design process need to be identified by both design and manufacturing engineers at the beginning of the design process. The design engineer then parameterizes the geometric model, using the geometric feature that is consistent with both engineering requirements and manufacturing limitations. The design parameterization developed in this section is based on the assumption that the geometric model has already been created and its dimensions defined.

In general, structural shape design problems can be classified into four types, in terms of the characteristics of the design boundary. In the first type, the shape of an arbitrary open or closed boundary is determined, such as a fillet[4] or a dam surface.[16] In the second type, the dimensions of predefined shapes are determined, such as the radius of a circular hole, the major and minor axes of an elliptic hole, the dimensions of a slot, the length of a rectangular membrane, or the radius of a rounded corner. In the third type, the design boundary location is determined, such as the center location of a circular hole, an elliptic hole, an arbitrarily shaped hole, or a slot. In the final type, a rotation angle of the design boundary, either arbitrary or predefined, is treated as the design variable. In this section, shape design parameterization of the first three types of design problems is considered.

In general, geometric entities can be represented using parametric cubic (PC) lines, patches (surfaces), and hyperpatches (solids). A parametric cubic line is represented by three functions:

$$\left.\begin{aligned} x &= x(u) \\ y &= y(u) \\ z &= z(u) \end{aligned}\right\} \tag{11.5.1}$$

where u is the parametric direction of the line with domain [0,1]. Each of these functions is, at most, a cubic polynomial of the form

$$z(u) = s_3 u^3 + s_2 u^2 + s_1 u + s_0 \tag{11.5.2}$$

The first and second derivatives of Equation 11.5.2 can be written as

$$z_{,u}(u) = 3s_3u^2 + 2s_2u + s_1 \tag{11.5.3}$$

$$z_{,uu}(u) = 6s_3u + 2s_2 \tag{11.5.4}$$

From Equation 11.5.3 and Equation 11.5.4, note that the slope of the cubic line can change its sign only twice, and that the curve can have only one inflection point. Thus, PC entities such as PC lines and PC patches minimize the possibility of yielding oscillating boundaries during the design process.[6] However, geometric entities with predefined or sophisticated shapes, such as a circular hole, cannot be represented by a single cubic curve. To minimize modeling errors, such a boundary can be broken into small pieces. These pieces are then "glued" together in the design process as one geometric feature by appropriately linking design variables. For shape design, planar parametric cubic lines and spatial parametric bicubic patches are utilized to represent the design boundaries of two-dimensional and three-dimensional structural components, respectively.

There are a number of methods for creating geometric entities, for example, defining four control points to create a Bezier curve, or constructing four edge curves to create a surface. Although geometric entities have different characteristics depending on the way they are created, they are nevertheless always represented by polynomials with the same order regardless of the way they are created. Consequently, a single geometric entity can be created using a variety of methods. For example, the planar curve shown in Figure 11.5.10(a) is created by defining four distinct points in the plane, and is thus called a four-point curve.

The mathematical expression of the four-point curve is given as

$$\left.\begin{aligned} x(u) &= 3u \\ y(u) &= 9u^3 - 13.5u^2 + 6.5u \end{aligned}\right\} \tag{11.5.5}$$

The same curve shown in Figure 11.5.10(b) can also be created by giving the position and slope at the endpoints, referred to as geometric coefficients:

$$\left.\begin{aligned} \mathbf{p}_0 &= [0,0] \\ \mathbf{p}_1 &= [3,2] \\ \mathbf{p}_0^u &= [3,6.5] \\ \mathbf{p}_1^u &= [3,6.5] \end{aligned}\right\} \tag{11.5.6}$$

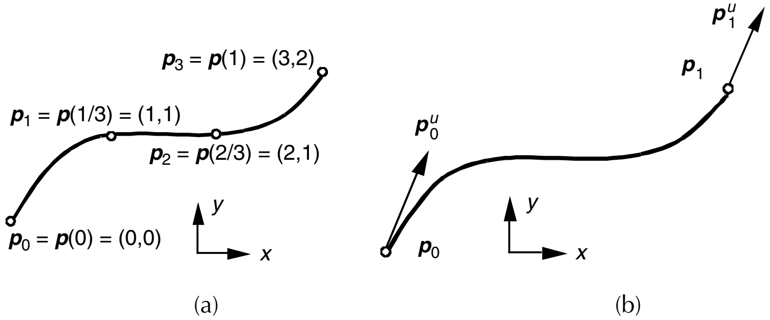

FIGURE 11.5.10 Planar parametric cubic curves (a) curve created by four points; (b) curve created by geometric coefficients.

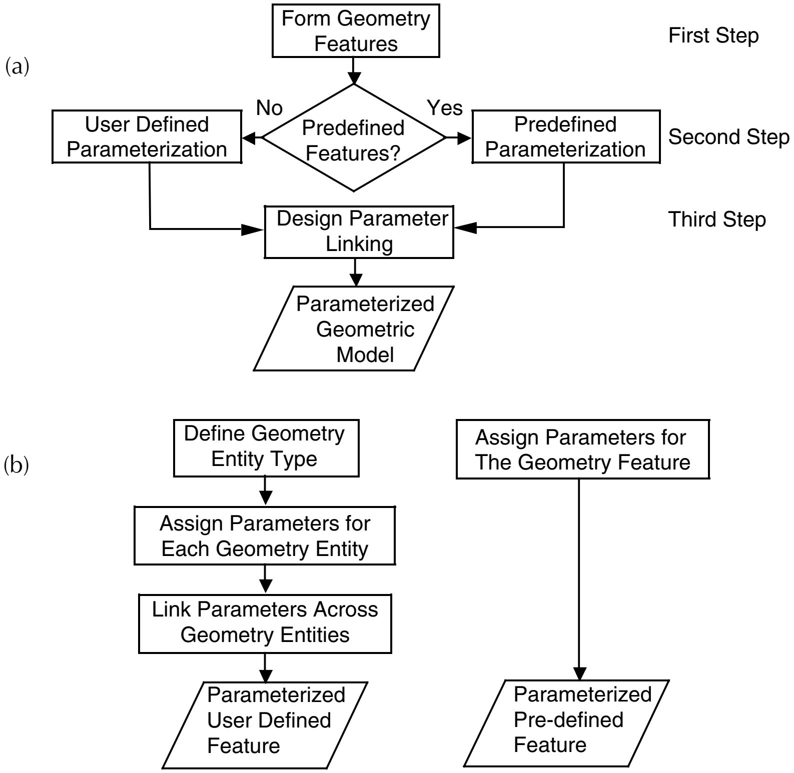

FIGURE 11.5.11 Shape design parameterization of features (a) overall design parameterization process; (b) parameterization for a user-defined feature; (c) parameterization for a predefined feature.

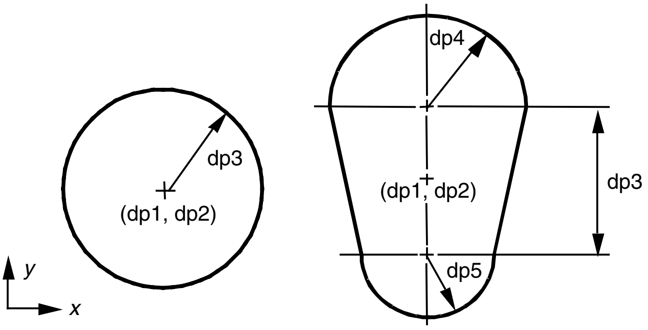
Therefore, one curve can be represented using different methods. However, these representations of curves and patches are mathematically equivalent, and one can be transformed into another by using certain linear transformations. For example, the geometric coefficients of a curve can be transformed into a four-point format, so the shape of the curve can be controlled according to the position of the four points. In fact, geometric coefficients are selected as unified geometric data, independent of the methods used to create geometric entities. Because design parameterization has the versatility of representing the same geometric entity in different ways, it can be systematically developed to provide the design engineer with sufficient resources for solving a wide variety of shape design problems.

The design parameterization method presented in this section is a three-step process, as illustrated in Figure 11.5.11. The first step is to create a geometric feature by grouping a number of interconnected geometric entities together, and by defining the type of geometric feature. The design engineer identifies the geometric entities that form the geometric features.

The second step is to define the design variables within each geometric feature. Geometric features that are frequently used in the construction of structural components can be put in the library of predefined geometric features. The design engineer can then parameterize these predefined features simply by selecting associated predefined shape design variables. To demonstrate the use of the library, two predefined geometric features have been defined, a circular hole and a tapered slot, as shown in Figure 11.5.12. For the circular hole, which is formed by connecting a number of circular arcs end to end with the same center point and radius, both the radius and center point of the circle can be defined as shape design variables. For the tapered slot, which is formed by connecting a number of straight lines and circular arcs, length dp3, radii dp4 and dp5, and center point dp1 and dp2 can all be defined as shape design variables. The design parameterization flow for the predefined geometric feature is illustrated in Figure 11.5.11(c).



(a) (b)

FIGURE 11.5.12 Predefined geometric features (a) circular hole; (b) tapered slot.

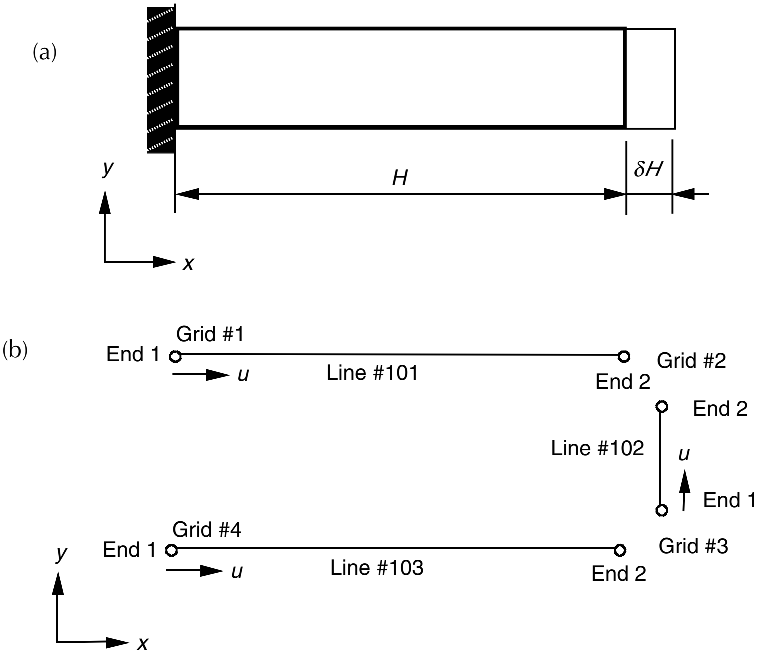


FIGURE 11.5.13 Parameterization of a cantilever beam (a) cantilever beam; (b) geometric feature of the beam.

A geometric feature that is not included in the library can be seen as a user-defined feature. To generate the latter, the design engineer can define the design variable by using geometric entities, and can then link these variables across the entities. For example, suppose a cantilever beam is to be parameterized such that its length *H* can be varied, as shown in Figure 11.5.13(a). To parameterize the beam, the following procedure can be used:

1. Identify lines #101, #102, and #103 to form the geometric feature, that is, the edges of the beam, as shown in Figure 11.5.13(b).
2. Define line #102 as a straight line and define the *x*-coordinate at end 1 of line 102, that is, grid #3, as the free design variable dp1, and the *x*-coordinate at end 2 of line #102, i.e., grid #2, to be proportional to dp1 with a proportionality of 1.0.
3. Define lines #101 and #103 as straight lines, and define the *x*-coordinate at end 2 of lines #101 and #103, that is, grids #2 and #3, as the free design variables dp2 and dp3, respectively.
4. Link dp2 and dp3 to dp1, with a proportionality of 1.0.

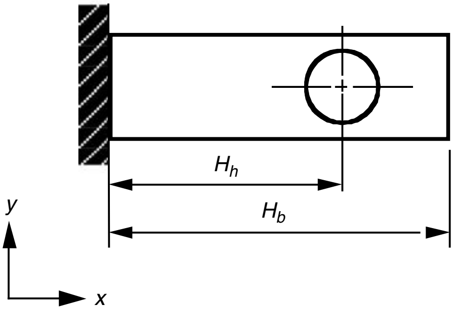

FIGURE 11.5.14 Design variable linking across parameterized geometric features.

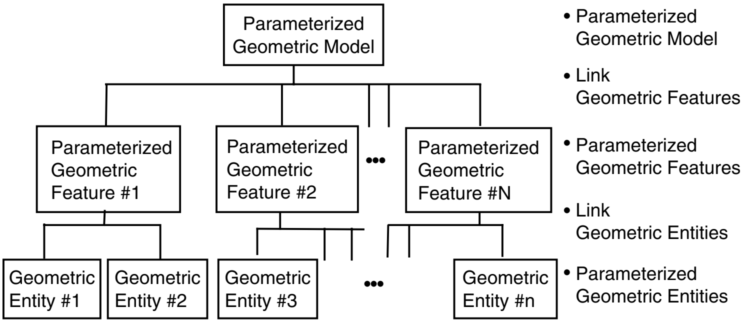

FIGURE 11.5.15 Hierarchy of shape design parameterization.

After design variable linking, only one design variable, dp1, the beam length represented by the *x*-coordinate of grid #3 in line #102, is allowed to vary independently. The parameterization flow for the user-defined feature is shown in Figure 11.5.11(b).

The shape design parameterization procedure for a user-defined geometric feature, as illustrated above, is summarized as follows:

1. Identify the types of geometric entities that are to be used to construct the user-defined geometric feature.
2. Parameterize the geometric entities by defining free and proportional design variables in each geometric entity.
3. Generate the parameterized geometric feature by linking free design variables across geometric entities.

Each predefined geometric feature that can be included in the feature library, such as the circular hole and tapered slot, is preconstructed by using this procedure.

If necessary, the third step is designed to link design variables across geometric features. For example, a cantilever beam with a circular hole, as shown in Figure 11.5.14, is to be parameterized so that the position of the hole is proportional to the beam length. The *x*-coordinate of the circular hole H_h can be parameterized by using the predefined parameterization process, as described in Figure 11.5.11(a). The length of beam H_b can be parameterized as a user-defined feature, as illustrated in Figure 11.5.13. With the two parameterized features, the *x*-coordinate of the hole can be linked to the beam length.

As described here, fundamental shape design parameterization is defined within geometric entities, and the parameterized features are created by using geometric entities. A hierarchy of the design parameterization method to build a parameterized geometric model is shown in Figure 11.5.15.

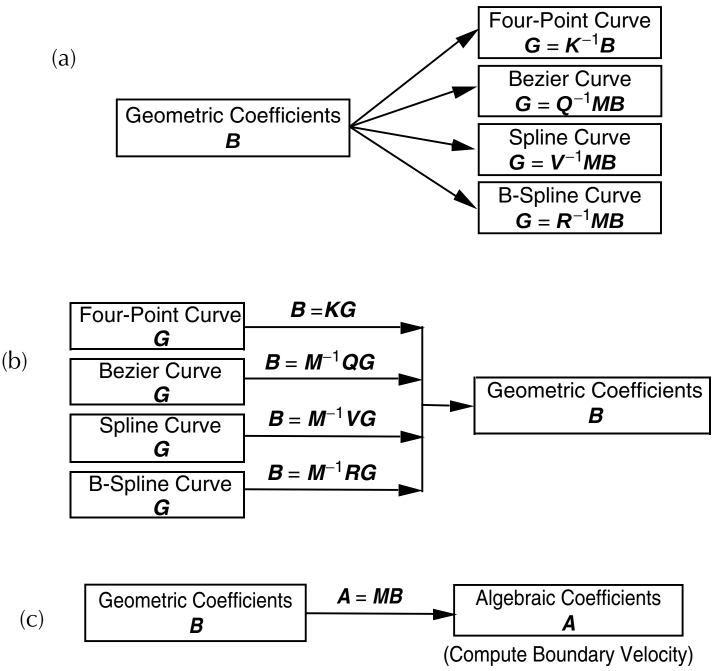

FIGURE 11.5.16 Curve format transformations for two-dimensional shape design (a) transformations from **B** to **G**; (b) transformations from **G** to **B**; (c) transformations from **B** to **A**.

Curve Design Parameterization

For a two-dimensional shape design, the boundaries are planar curves. In general, there are eight degrees of freedom for a planar cubic curve, as expressed in Equation 11.5.1 and Equation 11.5.2, with $z(u)$ serving as the constant. Planar curves with eight degrees of freedom are designated as basic curves, while predefined curves that are constrained, such as a circular arc, are designated as specialized curves. A specialized curve has fewer degrees of freedom since some of the basic degrees of freedom are linked (constrained) in order to define the required characteristics of the curve.

From a computational point of view, algebraic and geometric curves are the most interesting among the six basic types of curves. All parametric cubic entities can be transformed into various other formats by using certain linear transformations. For shape design, three major transformations are necessary: (1) from the geometric coefficient matrix **B** to the design variable matrix **G** to compute design variable values; (2) from matrix **G** to matrix **B** to update geometric entities for a perturbed design shape; and (3) from matrix **G** to the algebraic coefficient matrix **A** to compute the boundary velocity field. For the basic curves, the transformation from matrix **G** to matrix **B** for each curve format can be described by their corresponding 4×4 constant matrices. The curve format transformations are summarized in Figure 11.5.16.

Surface Design Parameterization

For three-dimensional shape design, design boundaries are surfaces in space. In general, there are 48 degrees of freedom for a parametric bicubic surface. For a parametric bicubic surface, the x-, y-, and z-components can be expressed using the three functions, as

$$\left.\begin{aligned} x &= x(u,w) \\ y &= y(u,w) \\ z &= z(u,w) \end{aligned}\right\} \tag{11.5.7}$$

where *u* and *w* are the parametric directions of the geometric entity, and $(u, w) \in [0,1] \times [0,1]$. Each of these functions is, at most, a bicubic function of the form

$$\begin{aligned} z(u,w) = {} & a_{33}u^3w^3 + a_{32}u^3w^2 + a_{31}u^3w + a_{30}u^3 \\ & + a_{23}u^2w^3 + a_{22}u^2w^2 + a_{21}u^2w + a_{20}u^2 \\ & + a_{13}u^1w^3 + a_{12}u^1w^2 + a_{11}u^1w^1 + a_{10}u \\ & + a_{03}w^3 + a_{02}w^2 + a_{01}w + a_{00} \\ = {} & \sum_{i,j=0}^{3} a_{ij}u^iw^j \end{aligned} \tag{11.5.8}$$

Surfaces with 48 degrees of freedom are defined as basic surfaces, whereas specialized surfaces are constrained to represent predefined conditions. As with the specialized curve, the specialized surface has fewer degrees of freedom. There are four basic surfaces — algebraic, geometric, 16-point, and Bezier — and there are also four specialized surfaces — plane, cylindrical, ruled, and surface of revolution, which have been developed to handle three-dimensional shape design problems. The B-spline surface is not recommended for three-dimensional shape design since, in contrast to the B-spline curve, the control points at the edges of the polyhedron are not on the B-spline surface. Therefore, the physical surface boundary does not closely resemble the characteristic polyhedron, and consequently, it is difficult to use in geometric modeling and design.

Similar to the basic types of curves, transformations between matrices **G**, **A**, and **B** of the basic surface can be used to obtain shape design variables, to update geometric entities, and to compute the boundary velocity field. The various surface format transformations are categorized in Figure 11.5.17.

The Configuration Design Variable

For those built-up structures made of truss, beam, and shell components, there is another type of design variable in addition to shape design; it's called the configuration design variable, and it is related to the structural component's orientation. These components have local coordinate systems fixed on the body of the structure, and state variables of the problem are described in local coordinate systems. If several components are connected together for the built-up structure, the state variables described in the local coordinate system are transformed to the global coordinate system. If the structural components change

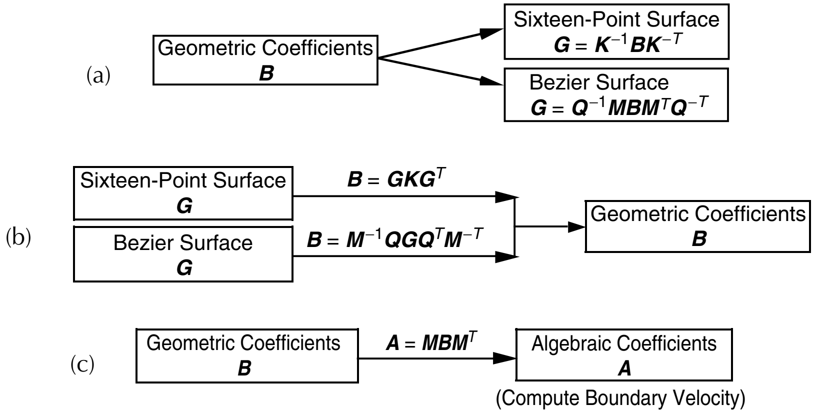

FIGURE 11.5.17 Surface format transformations for three-dimensional shape design (a) transformations from **B** to **G**; (b) transformations from **G** to **B**; (c) transformations from **B** to **A**.

their orientation in space, the transformation between the local and global coordinates also changes. Thus, this transformation can be considered the configuration design variable. Since configuration design variables are defined for built-up structures, they are inherently coupled with shape design variables. That is, in order to allow one member of the built-up structure to rotate, another member's shape needs to be changed. The configuration design variable is not applicable to solid components in which all rotations can be expressed in terms of shape changes.

The Topology Design Variable

If shape and configuration design variables represent changes in structural geometry and orientation, then topology design determines the structure's layout. For example, in Figure 11.5.9, shape design can change the size and location of the slot within the block. However, shape design cannot completely remove the slot from the block, or introduce a new slot. Topology design determines whether the slot can be removed or an additional slot is required.

The choice of the topology design variable is nontrivial compared to other design variables. Which parameter is capable of representing the birth or death of the structural layout? Early developments in topology design focused on truss structures. For a given set of points in space, design engineers tried to connect these points using truss structures, in order to find the best layout to support the largest load. Thus, the on-off types of topology design variables are used. These kinds of designs, however, could turn out to be discontinuous and unstable.

Recent developments in topology design are strongly related to FEA. The candidate design domain is modeled using finite elements, and then the material property of each element is controlled. If it is necessary to remove a certain region, then the material property value (e.g., Young's modulus) will approach zero, such that there will be no structural contribution from the removed region. Thus, material property design variables could be used for the purpose of topology design variables. The on-off type of design variable can be approximated by using continuous polynomials in order to remove the difficulties associated with discrete design variables.

In many applications, topology design is used at the concept design stage such that the layout of the structure is determined. After the layout is determined, sizing and shape designs are used to determine the detailed geometry of the structure.

A final comment on design parameterization: it is desirable to have a linearly independent set of design variables. If one does not, then relations between design variables must be imposed as constraints, which may make the design optimization process expensive, as the number of design variables and constraints increase. Furthermore, if design variable constraints are not properly established, meaningless design results will be obtained after an extensive amount of computational effort. As mentioned before, this problem is strongly related to structural modeling, since a well-defined structural model should have an independent set of parameters to define the entire system. Even if defining a good model is not an easy task for a complicated design problem, the design engineer nevertheless has to define a proper and independent set of parameters as much as possible in the structural modeling stage.

Design Variable Linking across Geometric Entities

There are three methods for categorizing the shape design problem: (1) identifying the arbitrary boundary shape, (2) determining the dimensions of the predefined shape, and (3) finding the locations of the boundaries. A design variable linking process is discussed in this section in order to support and ensure continuity between boundaries, as well as to retain predefined boundary shapes. For a geometric feature that is formed by a set of B-spline curves, C^2-continuity across curves is naturally retained.

As described in the previous sections, for the first type of shape design boundary any basic curve or surface can be utilized for parameterization. If constrained boundary shapes are required for two-dimensional structures, such as a straight edge or circular arc, then that specific type of curve must be used. For three-dimensional structures, the constrained boundaries can be predefined, such as a plane, cylinder, ball, or surface of revolution. If the geometric feature is composed of more than one curve or surface, continuity across curves or surfaces must be retained by linking shape design variables at the joint

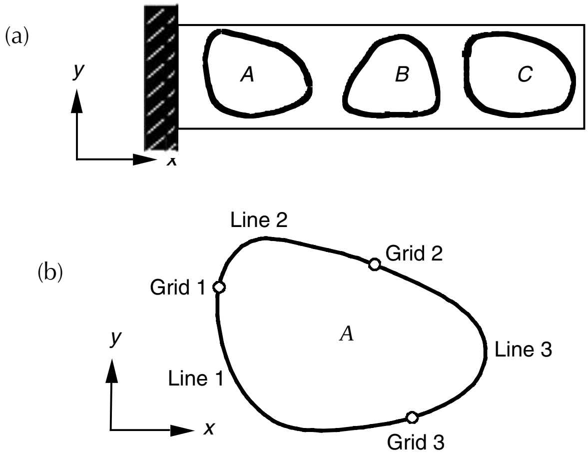

FIGURE 11.5.18 Parameterization of arbitrarily shaped holes (a) beam with arbitrarily shaped holes; (b) Hole *A* formed by three curves.

point or curve. As mentioned before, C^0-, C^1-, and C^2-continuities can be retained for two-dimensional structures by using the appropriate curve type and design variable linking. For three-dimensional problems, C^2-continuity is difficult to maintain. The following three examples illustrate how the design variable linking process can be used to support the three types of shape design problems.

Type One Problems — Identifying the Arbitrary Boundary Shape

A two-dimensional beam with arbitrarily shaped holes, shown in Figure 11.5.18(a), illustrates a design variable linking process that supports the first type of shape design problem.

Figure 11.5.18(b) shows that hole *A* is formed by three curves. To parameterize this hole, the curves are defined as geometric curves. The endpoints and tangent vectors at the endpoints of these connected curves are linked to retain C^0- and C^1-continuities, respectively.

The shape of the hole can be changed due to endpoint movement, length, or the direction of the tangent vector, as shown in Figure 11.5.19. Hole shape change due to movement δdp_1 of grid 3 in the negative *y*-direction is shown in Figure 11.5.19(a), such that the tangent vectors of lines 1 and 3 at grid 3 are kept the same. Moreover, hole shape change due to scaling the tangent vector of line 3 at grid 3 by δdp_2, shown in Figure 11.5.19(b), is such that the location of grid 3 and the direction of the tangent vector are kept the same. Finally, hole shape change due to change δdp_3 in the tangent vector direction of lines 1 and 3 is shown in Figure 11.5.19(c).

To avoid meaningless designs, for example, a hole that penetrates the boundary edges of a beam, the geometric boundaries can be displayed after the design change. Furthermore, numerical limits can be defined for design variables in order to restrict the degree of design perturbation.

Type Two Problems — Determining the Dimensions of a Predefined Shape

For the second type of shape design problem, specialized curves and surfaces are used to parameterize geometric entities. In addition, design variable linking may be carried out in the design process to group curves and surfaces that define the geometric feature.

The design variable linking method for parameterizing the second type of shape design boundary can be described using an elliptic hole formed by four conic curves, as shown in Figure 11.5.20. Each conic curve has three points to control its shape; however, relative altitude ρ is kept constant.

To vary the major axis, the *x*-coordinate of point $\mathbf{p}_7$ is defined as the independent design variable dp1. Points $\mathbf{p}_6$ and $\mathbf{p}_8$ are linked to dp1, with a proportionality of 1.0. In addition, the *x*-coordinates of points 1, 2, and 3 are linked to dp1 with a proportionality of –1.0. The elliptic hole varies in shape when the major axis is perturbed by δdp1, as shown in Figure 11.5.21(a). Similarly, for a design change in the minor axis, the *y*-coordinate of point $\mathbf{p}_4$ is defined as the independent design variable dp2. Points $\mathbf{p}_1$ and

$\mathbf{p}_6$ are linked to dp2, with a proportionality of 1.0. Also, the y-coordinates of points $\mathbf{p}_3$, $\mathbf{p}_5$, and $\mathbf{p}_8$ are linked to dp2, with a proportionality of –1.0. Shape change due to the perturbation δdp2 of the minor axis is shown in Figure 11.5.21(b).

(a)

(b)

FIGURE 11.5.23 Shape variation of a tapered semicylindrical surface (a) shape variation due to δdp1; (b) shape variation due to δdp2.

For three-dimensional problems, this type of shape design can be the radius of a ball, a shell, or a cylindrical hole. For example, the tapered semicylindrical surface shown in Figure 11.5.22 can be parameterized by linking the design variables defined in the two ruled surfaces that form the tapered semicylindrical surface. The first ruled surface $\mathbf{p}_1\mathbf{p}_2\mathbf{p}_4\mathbf{p}_5$ is created using circular arcs $\mathbf{p}_1\mathbf{p}_2$ and $\mathbf{p}_4\mathbf{p}_5$. The other ruled surface $\mathbf{p}_2\mathbf{p}_3\mathbf{p}_5\mathbf{p}_6$ is created using circular arcs $\mathbf{p}_2\mathbf{p}_3$ and $\mathbf{p}_5\mathbf{p}_6$.

To vary the radius R_1, the radius of arc $\mathbf{p}_1\mathbf{p}_2$ is defined as the independent design variable dp1, and the radius of arc $\mathbf{p}_2\mathbf{p}_3$ is linked to dp1 with a proportionality of 1.0. Similarly, the design variable dp2 can be defined for radius R_2. The shape of the tapered semicylindrical surface is defined by the shape design variables dp1 and dp2, as shown in Figure 11.5.23(a) and Figure 11.5.23(b), respectively.

Type Three Problems — Finding the Locations of the Boundaries

To support the third type of shape design problem, such geometric entities as curves or surfaces that form the geometric feature are linked together so that only *x*-, *y*-, and *z*-movements of the parameterized geometric feature are allowed. For example, the *x*-coordinate of points $\mathbf{p}_1$ to $\mathbf{p}_8$ of the elliptic hole shown in Figure 11.5.22 can be linked, with a proportionality of 1.0, so that the four conic curves can be moved together to form an elliptic hole.

Design Sensitivity Analysis

Design sensitivity analysis computes the rate of performance measure change with respect to design variable changes. With the structural analysis, the design sensitivity analysis generates a critical information, gradient, for design optimization. Obviously, the performance measure is presumed to be a differentiable function of the design, at least in the neighborhood of the current design point. For complex engineering applications, it is not simple to prove a performance measure's differentiability with respect to the design. For most problems in this section, one can assume that the performance measure is continuously differentiable with respect to the design.

In general, a structural performance measure depends on the design. For example, a change in the cross-sectional area of a beam would affect the structural weight. This type of dependence is simple if the expression of weight in terms of the design variables is known. For example, the volume of a straight beam with a circular cross-section can be expressed as

$$W(r) = \pi r^2 l$$

where $u = r$ is the radius and l is the length of the beam. If the radius is a design variable, then the design sensitivity of W with respect to r would be

$$\frac{dW}{dr} = 2\pi r l$$

This type of function is *explicitly dependent* on the design, since the function can be explicitly written in terms of that design. Consequently, only algebraic manipulation is involved, and no FEA is required to obtain the design sensitivity of an explicitly dependent performance measure.

However, in most cases, a structural performance measure does not explicitly depend on the design. For example, when the stress of a beam is considered as a performance measure, there is no simple way to express the design sensitivity of stress explicitly in terms of the design variable r. In the linear elastic problem, the stress of the structure is determined from the displacement, which is a solution to the FEA. Thus, the sensitivity of stress $\sigma(\mathbf{z})$ can be written as

$$\frac{d\sigma}{dr} = \frac{d\sigma}{d\mathbf{z}}^{\mathrm{T}} \frac{d\mathbf{z}}{dr} \tag{11.5.9}$$

where $\mathbf{z}$ is the displacement of the beam. Since the expression of stress as a function of displacement is known, $d\sigma/d\mathbf{z}$ can be easily obtained. The only difficulty is the computation of $d\mathbf{z}/dr$, which is the state variable (displacement) sensitivity with respect to the design variable r.

When a design engineer wants to compute the design sensitivity of performance measures such as stress $\sigma(\mathbf{z})$ in Equation 11.5.9, structural analysis (FEA, for example) has presumably already been carried out. Assume that the structural problem is governed by the following linear algebraic equation:

$$\mathbf{K}(u)\mathbf{z} = \mathbf{f}(u) \tag{11.5.10}$$

Equation 11.5.10 is a matrix equation of finite elements if $\mathbf{K}$ and $\mathbf{f}$ are understood to be the stiffness matrix and load vector, respectively. Suppose the explicit expressions of $\mathbf{K}(u)$ and $\mathbf{f}(u)$ are known and differentiable with respect to u. Since the stiffness matrix $\mathbf{K}(u)$ and load vector $\mathbf{f}(u)$ depend on the design u, solution $\mathbf{z}$ also depends on the design u. However, it is important to note that this dependency is implicit, which is why we need to develop a design sensitivity analysis methodology. As shown in Equation 11.5.9, $d\mathbf{z}/du$ must be computed using the governing equation of Equation 11.5.10. This can be achieved by differentiating Equation 11.5.10 with respect to u, as

$$\mathrm{K}(u)\frac{d\mathrm{z}}{du} = \frac{d\mathrm{f}}{du} - \frac{d\mathrm{K}}{du}\mathrm{z} \tag{11.5.11}$$

Assuming that the explicit expressions of $\mathbf{K}(u)$ and $\mathbf{f}(u)$ are known, $d\mathbf{K}/du$ and $d\mathbf{f}/du$ can be evaluated. Thus, if solution $\mathbf{z}$ in Equation 11.5.10 is known, then $d\mathbf{z}/du$ can be computed from Equation 11.5.11, which can then be substituted into Equation 11.5.9 to compute $d\sigma/du$. Note that the stress performance measure is *implicitly dependent* on the design through state variable $\mathbf{z}$.

In this text, it is assumed that the general performance measure ψ depends on the design explicitly and implicitly. That is, the performance measure ψ is presumed to be a function of design u, and state variable $\mathbf{z}(u)$, as

$$\psi = \psi\big(\mathbf{z}(u), u\big) \tag{11.5.12}$$

The sensitivity of ψ can thus be expressed as

$$\frac{d\psi(\mathbf{z}(u),u)}{du} = \left.\frac{\partial\psi}{\partial u}\right|_{\mathbf{z}=\text{const}} + \left.\frac{\partial\psi}{\partial \mathbf{z}}\right|^{T}_{u=\text{const}} \frac{d\mathbf{z}}{du} \tag{11.5.13}$$

The only unknown term in Equation 11.5.13 is $d\mathbf{z}/du$. Various computational methods to obtain $d\mathbf{z}/du$ are introduced in the following subsections.

Methods of Structural Design Sensitivity Analysis

Various methods employed in design sensitivity analysis are listed in Figure 11.5.24. Four approaches are used to obtain the design sensitivity: the finite difference, discrete, continuum, and computational derivatives. In the finite difference approach, design sensitivity is obtained by either the *forward finite difference* or the *central finite difference method*. In the discrete method, design sensitivity is obtained by taking design derivatives of the discrete governing equation. For this process, it is necessary to take the design derivative of the stiffness matrix. If this derivative is obtained analytically using the explicit expression of the stiffness matrix with respect to the design variable, it is an *analytical method*, since the analytical expressions of $\mathbf{K}(u)$ and $\mathbf{f}(u)$ are used. However, if the derivative is obtained using a finite difference method, the method is called a *semianalytical method*. In the continuum approach, the design derivative of the variational equation is taken before it is discretized. If the structural problem and sensitivity equations are solved as a continuum problem, then it is called the *continuum-continuum method*. However, only very simple, classical problems can be solved analytically. Thus, the continuum sensitivity equation is solved by discretization in the same way that structural problems are solved. Since differentiation is taken at the continuum domain and is then followed by discretization, this method is

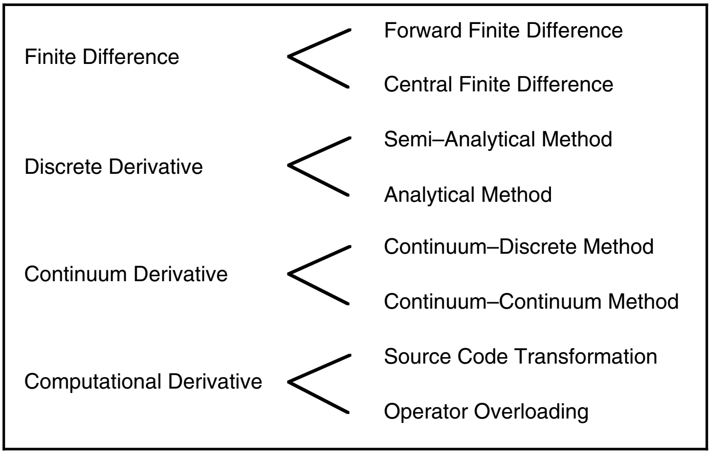

FIGURE 11.5.24 Approaches to design sensitivity analysis.

called the *continuum-discrete method*. Finally, computational, algorithmic or automatic differentiation refers to a differentiation of the computer code itself.

Except for the finite differences option, the other three come in direct and adjoint methods (called the reverse mode for computational derivative). In the direct method, one obtains the derivatives of the entire structural response, and often of intermediate quantities as well. The sensitivities of performance measures can then be obtained from the chain rule of differentiation. In the adjoint method, one defines an adjoint problem, which depends on the performance measure. The sensitivities of performance measures can then be obtained using the structural and adjoint responses. Thus, all of the system response sensitivities are not required, which is particularly an advantage in cases with many design variables, though few performance measures of interest.

The Global Finite Difference Method

The easiest way to compute sensitivity information of the performance measure is by using the finite difference method. Different designs yield different analysis results and, thus, different performance values. The finite difference method actually computes design sensitivity of performance by evaluating performance measures at different stages in the design process. If u is the current design, then the analysis results provide the value of performance measure $\psi(u)$. In addition, if the design is perturbed to $u+\Delta u$, where Δu represents a small change in the design, then the sensitivity of $\psi(u)$ can be approximated as

$$\frac{d\psi}{du} \approx \frac{\psi(u+\Delta u)-\psi(u)}{\Delta u} \tag{11.5.14}$$

Equation 11.5.14 is called the *forward difference method* since the design is perturbed in the direction of $+\Delta u$. If $-\Delta u$ is substituted in Equation 11.5.14 for Δu, then the equation is defined as the *backward difference method*. Additionally, if the design is perturbed in both directions, such that the design sensitivity is approximated by

$$\frac{d\psi}{du} \approx \frac{\psi(u+\Delta u)-\psi(u-\Delta u)}{2\Delta u} \tag{11.5.15}$$

then the equation is defined as the *central difference method*.

The advantage of the finite difference method is obvious. If structural analysis can be performed and the performance measure can be obtained as a result of structural analysis, then the expressions in Equation 11.5.14 and Equation 11.5.15 are virtually independent of the problem types considered. Consequently, this method is still popular in engineering design.

However, sensitivity computation costs become the dominant concern in the design process. If n represents the number of designs, then $n+1$ number of analyses have to be carried out for either forward or backward difference method, and $2n+1$ analyses are required for the central difference method. For modern, practical engineering applications, the cost of structural analysis is rather expensive. Thus, this method is not feasible for large-scale problems containing many design variables.

Another major disadvantage of the finite difference method is the accuracy of its sensitivity results. In Equation 11.5.14, accurate results can be expected when Δu approaches zero. Figure 11.5.25 shows some sensitivity results using the finite difference method. The tangential slope of the curve at u_0 is the exact sensitivity value. Depending on perturbation size, we can see that sensitivity results are quite different. For a mildly nonlinear performance measure, relatively large perturbation provides a reasonable estimation of sensitivity results. However, for highly nonlinear performances, a large perturbation yields completely inaccurate results. Thus, the determination of perturbation size greatly affects the sensitivity result. And even though it may be necessary to choose a very small perturbation, numerical noise becomes dominant for a too small perturbation size. That is, with a too small perturbation, no reliable difference can be found in the analysis results. The most obvious source of this type of errors is computational errors associated with arithmetic with finite number of digits and possibly ill-conditioning in the problem.

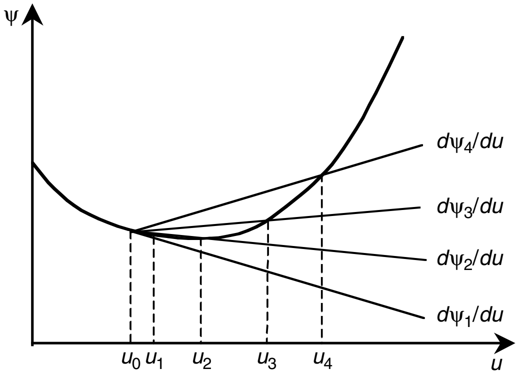

FIGURE 11.5.25 Influence of step-size in forward finite difference method.

For example, if up to five digits of significant numbers are valid in a structural analysis, then any design perturbation in the finite difference that is smaller than the first five significant digits cannot provide meaningful results. As a result, it is difficult to determine design perturbation sizes that work for all problems. Other potential sources are the discretization of both the spatial and the temporal domain. A typical example could be numerical noise induced by re-meshing.

Computational efficiency, accuracy and consistency, and implementation effort for global finite differences depend to a large extent on the type of solvers used for the linear system of Equation 11.5.10. The main issue is whether computational investments associated with solving the equations for the nominal structure can help reduce the effort associated with solving these equations for a perturbed structure.

When direct solvers are used for the solution, so that the matrix **K** has been factored, there is an array of methods that provide fast re-analysis of the perturbed structure. A disadvantage of many of these techniques is that accuracy is generally compromised, that is, certain inaccuracies will be introduced. When the perturbation leads to a low-rank modification of **K** — for example, because only a single finite element is modified — then an exact analysis of the perturbed structure can be performed using the Sherman-Morrison-Woodbury formulas.[19] The main computational cost of this approach is the solution of Equation 11.5.10 for a number of right-hand sides equal to the rank of the perturbation in **K**. Akgün et al.[19] discuss several variants of this approach, including the method of virtual distortions. When the perturbation in the matrix is more extensive, as in shape variation, it is still possible to use a binomial series solution[20,21] or a similar approximation of the inverse of **K** using a Neuman series.[22,23]

The Discrete Method

A structural problem is often discretized in finite dimensional space in order to solve complex problems. The discrete method computes the performance design sensitivity of the discretized problem, where the governing equation is a system of linear equations, as in Equation 11.5.10. If the explicit form of the stiffness matrix $\mathbf{K}(u)$ and the load vector $\mathbf{f}(u)$ are known, and if solution $\mathbf{z}$ of matrix equation $\mathbf{K}(u)\mathbf{z} = \mathbf{f}(u)$ is obtained, then the design sensitivity of the displacement vector can also be obtained, from Equation 11.5.11, as

$$\mathrm{K}(u)\frac{d\mathrm{z}}{du} = \mathrm{p} \tag{11.5.16}$$

where the pseudo-load vector **p** is defined as

$$\mathrm{p} = \frac{d\mathrm{f}}{du} - \frac{d\mathrm{K}}{du}\mathrm{z} \tag{11.5.17}$$

It is clear from Equation 11.5.16 that the design sensitivities require the solution of the same set of equations as solved for the response functions, but for another right-hand side (compare with Equation 11.5.10), the latter being the pseudo-load vector (see Equation 11.5.17).

In calculating the pseudo-load vector, it is not necessary to differentiate the global load vector and stiffness matrix, but to differentiate only those elements that are affected by the design variable. The evaluation of the pseudo-load vector is then carried out by an assembly of all individual nodal points and finite element contributions. These contributions are obtained by differentiating the finite element stiffness matrices with respect to the design variables and following a similar procedure for all load contributions. The fact that the pseudo-load vector only depends on elements that are affected may be exploited to make the computation of the pseudo-load vector more efficient. For shape design variables, this requires some additional attention. For that purpose, one often tries to link the design variables only to boundary elements, which means that only a boundary layer of elements is affected by the shape design variables.

The analytical differentiation process may become tedious. This especially holds true for shape design variables. Additional procedures must be implemented for each element used within the sensitivity analysis. The procedure must account for all possible design variables and particularly for shape design variables, as they are usually more complex than the original finite element routines. This type of discrete design sensitivity is referred to as *analytical* discrete design sensitivity.

It is not difficult to compute $d\mathbf{f}/du$, since the applied force is usually either independent of the design, or it has a simple expression. However, the computation of $d\mathbf{K}/du$ in Equation 11.5.16 depends on the type of problem. In addition, modern advances in the finite element method use numerical integration in the computation of $\mathbf{K}$. In this case, the explicit expression of $\mathbf{K}$ in terms of u may not be available. Moreover, in the case of the shape design variable, computation of the analytical derivative of the stiffness matrix is quite costly. Because of this, frequently approximations are accepted for the pseudo-load vector that reduces this effort. These approximations particularly involve finite difference schemes for evaluation of the pseudo-load vector. Forward and central finite difference schemes are the most popular. This type of design sensitivity is commonly denoted *semianalytical* discrete design sensitivity. However, Barthelemy and Haftka[24] show that the semianalytical method can have serious accuracy problems for shape design variables in structures modeled by beam, plate, truss, frame, and solid elements. They found that accuracy problems occur even for a simple cantilever beam. Moreover, errors in the early stage of approximation multiply during the matrix equation solution phase. As a remedy, Olhoff et al.[25] proposed an exact numerical differentiation method when the analytical form of the element stiffness matrix is available.

For shape design variables, design perturbation involves both the size of the perturbation and its distribution over the domain. For the choice of perturbation size, similar considerations as discussed for global finite differences play a role. Unfortunately, the semianalytical formulation may be extremely sensitive with respect to this choice. We will come back to this aspect extensively, and we only note here that this drawback may negate all advantages of a semianalytical formulation and motivates modifications to the semianalytical method.

The Continuum Method

In the continuum method, the design derivative of the variational equation (the continuum model of the structure) is taken before discretization. Since differentiation is taken before any discretization takes place, this method provides more accurate results than the discrete approach. In addition, profound mathematical proofs are available regarding the existence and uniqueness of the design sensitivity.

Sizing design variables are distributed parameters of the continuum equation. For shape design variables, the material derivative concept of continuum mechanics is used to relate variations in structural shape to the structural performance measures.[4] Using the continuum approach, we can obtain design sensitivity expressions in the form of integrals, with integrands written in terms of such physical quantities as displacement, stress, strain, and domain shape change. If exact solutions to the continuum equations are used to evaluate these design sensitivity expressions, then this procedure is referred to as the continuum-continuum method. On the other hand, if approximation methods such as the finite element, boundary element, or mesh-free method are used to evaluate these terms, then this procedure is called the continuum-discrete method. The continuum-continuum method provides the exact design sensitivity of the exact model, whereas the continuum-discrete method provides an approximate design sensitivity of the exact model. When FEA is used to evaluate the structural response, then the same discretization method as structural analysis has to be used to compute the design sensitivity of performance measures in the continuum-discrete method.

In the continuum approach, the design variables may be considered as fields that are functions of the spatial coordinates. As a consequence, sensitivity is to be understood as a variation of a function. Let us consider that the design variable s is perturbed to $s + \tau\eta$ in which τ is the scalar that measures the perturbation size and η is the direction of design change. For simplicity, it is assumed that the structural design variable s does not affect the domain. The variation of field response **u** with respect to s can then be defined as

$$\mathbf{u}' \equiv \lim_{\tau \to 0} \left\{ \frac{\mathbf{u}(s+\tau\eta) - \mathbf{u}(s)}{\tau} \right\} = \left. \frac{\partial \mathbf{u}}{\partial \tau} \right|_{\tau=0} \eta \tag{11.5.18}$$

Since the direction of design change η can be arbitrary, Equation 11.5.18 must be linear with respect to η and the coefficient of η is called the sensitivity of field response **u**, which is equivalent to the derivative in the context of other approaches.

The continuum method of design sensitivity analysis starts from the principle of virtual work, which is convenient for formulating the equations of equilibrium, as

$$\iint_V \delta\boldsymbol{\epsilon}^T \mathbf{C} \boldsymbol{\epsilon}\, dV = \iint_{\delta\mathbf{u}^T \mathbf{b} dV} \delta\mathbf{u}^T \mathbf{b}\, dV + \int_A \delta\mathbf{u}^T \mathbf{h}\, dA \tag{11.5.19}$$

for all $\delta\mathbf{u}$ that belong to the space of kinematically admissible displacements. In Equation 11.5.19, $\delta\boldsymbol{\epsilon}$ is the virtual strain; **C** is the elasticity matrix; $\boldsymbol{\epsilon}$ is the strain vector; **b** denotes the external load per unit volume; and **h** reflects tractions acting on the outer surface A of the structure.

Using Equation 11.5.18, the equations of equilibrium, Equation 11.5.19, can be differentiated to obtain the following continuum sensitivity equation:

$$\iint_V \delta\boldsymbol{\epsilon}^T \mathbf{C} \boldsymbol{\epsilon}'\, dV = \iint_V \delta\mathbf{u}^T \mathbf{b}'\, dV + \int_A \delta\mathbf{u}^T \mathbf{h}'\, dA - \iint_V \delta\varepsilon^T \mathbf{C}' \varepsilon\, dV \tag{11.5.20}$$

for all $\delta\mathbf{u}$ that belong to the space of kinematically admissible displacements. The left side of Equation 11.5.20 is the same as the left side of Equation 11.5.19 if **u** is replaced by $\mathbf{u}'$. The right side of Equation 11.5.20 defines a pseudo-load (or fictitious load), which explicitly depends on the design. Thus, solving the sensitivity equation is the same as solving original structural equilibrium equation with different load terms. The major advantage of the continuum approach is that the sensitivity formulation is independent of discrete model and numerical schemes. Once the continuum sensitivity equation is obtained, it can be discretized in the same manner as the original analysis equations in order to obtain a system of matrix equations similar to Equation 11.5.10.

When the design variables affect the shape of the domain, the differentiation of the equations of equilibrium is much more complicated because the integral domain depends on the design. Interested readers are referred to Haug et al.[4] for the material derivative approach and Arora[26] or Phelan and Haber[27] for the control volume approach.

One frequently asked question is "Are the discrete and continuum-discrete methods equivalent?" To answer this question, we have to give four conditions. First, the same discretization (shape function) used in the FEA method must be used for continuum design sensitivity analysis. Second, an exact integration (instead of a numerical integration) must be used in the generation of the stiffness matrix and in the evaluation of continuum-based design sensitivity expressions. Third, the exact solution (and not a numerical solution) of the finite element matrix equation and the adjoint equation should be used to compare these two methods. Fourth, the movement of discrete grid points must be consistent with the design parameterization method used in the continuum method. For the sizing design variable, it is shown in reference 4 that the discrete and continuum-discrete methods are equivalent under the conditions given above, using a beam as the structural component. It has also been argued that the discrete and continuum-discrete methods are equivalent in shape design problems under the conditions given above.[28] One point to note is that these four conditions are not easy to satisfy; in many cases, numerical integration is used and exact solutions of the FE matrix equation cannot be obtained.

Computational Derivative

Even if the finite element programs are composed of many complicated subroutines and functions, they are basically a collection of elementary functions. Computational (or automatic) differentiation method defines the partial derivatives of these elementary functions, and then the derivatives of complicated subroutines and functions are computed using propagation and the chain rule of differentiation. The arguments of elementary functions can be either one or two. Without loss of generality, let us assume that an elementary function has two arguments, defined as

$$a = f_{\text{elem}}(z_i, z_j) \tag{11.5.21}$$

where $f_{\text{elem}}(\gg,\gg)$ represents $(++, \sin(\gg), \ldots)$ operators for the single argument and (+, –, *, /, …) operators for the double arguments.

In the direct differentiation method, the derivative of Equation 11.5.21 can be defined as

$$\frac{\partial a}{\partial s} = \frac{\partial f_{\text{elem}}}{\partial z_i}\frac{\partial z_i}{\partial s} + \frac{\partial f_{\text{elem}}}{\partial z_j}\frac{\partial z_j}{\partial s} \tag{11.5.22}$$

This derivative can propagate through complicated functions and subroutines using the chain rule of differentiation. This propagation eventually produces the derivative of the structural response.

In the reverse mode, which corresponds to the adjoint method in the previous sections, the derivatives are computed backward through the computation. Due to the reverse procedure, this approach requires saving the entire function evaluation, which also requires a significant amount of memory.

Software that creates a computer program that calculates the derivatives of output of other computer programs is now available, and is applicable for small to medium-size programs.[24] The largest program that we found mentioned had about 140,000 lines.[30] Both first- and higher-order derivatives can be obtained. This approach was initially called automatic differentiation, but after a while it was realized that human intervention in the process is required in many cases to obtain a reasonably efficient code. So the name was generalized to computational differentiation.

There are several automatic differentiation tools widely available today, notably ADIFOR (Automatic Differentiation of Fortran[31] and ADOL-C for C/C++ programs.[32] In terms of implementation, there are two basic approaches to automatic differentiation — source code transformation and operator overloading. Source code transformation can be viewed as a precompiler that adds code for computing the derivatives. Operator overloading is available in modern computer languages, such as C++ and Fortran 90, that provide the ability to redefine the meaning of elementary operators (such as multiplication) for various classes of variables. By defining new variable types that have gradient objects associated with them, and overloading the elementary operators to produce gradients as well, we can transform the code without increasing its size substantially. ADOL-C and ADOL-F are examples of operator-overloading tools for automatic differentiation.

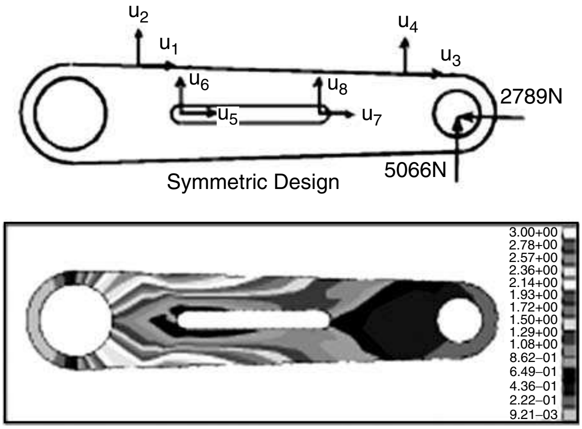

FIGURE 11.5.26 Design parameterization and mesh-free analysis results of a torque arm.

Examples

Torque Arm Model[33]

In order to show the accuracy of sensitivity calculation, a torque arm design problem, presented by Bennett and Botkin,[34] is used as a numerical example. The geometry of the torque arm (see Figure 11.5.26) is modeled using MSC/PATRAN,[35] and is represented by parametric coordinates. The displacement on the left hole is fixed, while the horizontal and vertical forces are applied at the center of the right hole. Design parameterization was performed by selecting the control points of the parametric curves such that the boundary curves move according to the design change. The design parameter was linked in order to obtain a symmetric design change. Design velocity vectors that represent the movement of particles in the direction of a given design parameter were computed by perturbing the parametric coordinates. This process is referred to as the isoparametric mapping method. Design parameterization and design velocity vector computation were also carried out by using a design sensitivity and optimization tool (DSO).[36] In all, eight design parameters were chosen in order to perturb the outer/inner boundary curves of the torque arm.

An automatic discretization procedure was used to discretize the torque arm structure. The domain of the torque arm was discretized by 478 degrees of freedom. The plane stress formulation is used with a thickness of 0.3 cm. The torque arm is made of steel with $E = 207$ GPa, and $\nu = 0.3$.

The structural analysis required 5.19 seconds, whereas by using one processor of HP Exemplar s-class workstation the sensitivity analysis required $4.55 \div 8 = 0.57$ seconds per each design parameter. The efficiency of the sensitivity computation derives from the fact that sensitivity analysis uses the same constitutive matrix, already factorized from the response analysis stage.

The sensitivity coefficients of the performance measures, including the structural area and stresses, were computed based on the continuum approach. The highest stress values at 19 locations are selected as the performance measure, which will be served as constraints during optimization. Using a very small perturbation size, the accuracy of the sensitivity coefficients is compared with the finite difference results, as shown in Table 11.5.5. Very accurate sensitivity results are observed. In Table 11.5.5, the first column represents design parameters, the second column represents performance measures, that is, structural area and von Mises stress at eight integration zones. The third column $\Delta\psi$ denotes the first-order sensitivity results obtained from the forward finite difference method with a perturbation of $\tau = 10^{-6}$. The fourth column represents the sensitivity computation results from the method employed. As has been shown in the fifth column, the ratio between the third and the fourth columns are very close to 100%, which means the calculated sensitivity information is very accurate.

Figure 11.5.27 shows the design sensitivity plot of the von Mises stress performance with respect to design u_3. Such a sensitivity plot graphically illustrates the effect of design change to the performance

TABLE 11.5.5 Design Sensitivity Results and Comparison with Finite Difference Results

u	ψ	$\Delta\psi$	ψ'	$\Delta\psi/\psi' \times 100$

change, which provides very useful information in the interactive design process without invoking the automated design optimization procedure.

The Road Arm Model[33]

A road arm structure, as shown in Figure 11.5.28, transfers a force and torque from a road wheel to a suspension unit for a combat vehicle. The road arm model is discretized with 4365 degrees of freedom. The road arm is made of steel with E = 206 GPa, and ν = 0.3. At the center of the right hole, a vertical force of 3736 N and a torque of 44,516 N-m are applied, whereas the displacement on the left hole is fixed. As was illustrated in Figure 11.5.28, the stress concentration appears in the left corner of the road arm. If the highest stress level in the left corner is considered as a reference value, then the dimension of the right corner cross section can be reduced, because this region has a large amount of safety margin.

Since two holes are connected to the road wheel and torsion bar, the dimension and the geometry of the holes are fixed. The design goal is to determine the dimension of the cross sections of the arm. The

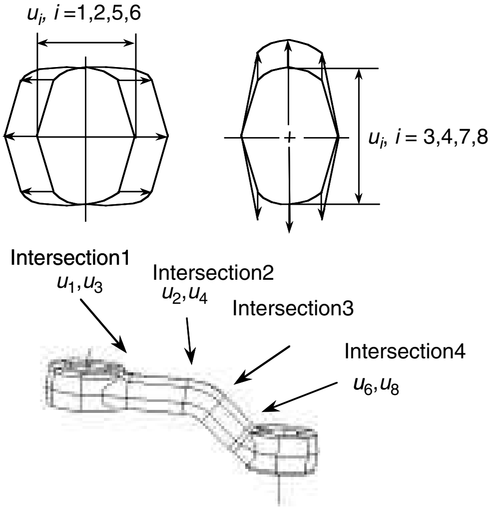

FIGURE 11.5.29 Design parameters for the rod arm model.

heights and widths of four sections are selected as design parameters (see Figure 11.5.29). Thus, a total of eight design parameters are considered in this example.

As the design variable changes, the boundary surface of the structure changes. At the same time, the discrete model also needs to be moved according to the design variable's change. Even if the design variable changes the boundary surface, it is recommended that the interior nodes be moved too. Otherwise, the accuracy of the perturbed model may deteriorate. The relation between a design variable and the motion of each node is denoted by the *design velocity field*. Figure 11.5.30 shows the design velocity field for two different design variables, u_2 and u_4, respectively. The arrows denote the magnitude and direction of nodal movement according to the corresponding design variable's change.

For a given design variable, the design sensitivity coefficients of various performance measures can be calculated using the design velocity field. Table 11.5.6 shows the design sensitivity coefficients, compared with the finite difference results. Displacement, stress, and volume of the structure are considered as performance measures. For example, zx4 represents the x-directional displacement at node 4, and sx10 is the x-directional normal stress at element 10. Very accurate sensitivity results are observed. This sensitivity information will be provided to the design optimization algorithm, to obtain the optimum design for given constraints.

Structural-Acoustic Design of a Vehicle[37]

As a last example, the design sensitivity analysis of a structural-acoustic problem is demonstrated. The goal is to estimate the sensitivity of a structure-borne noise caused by vibration of a vehicle. In order to calculate the noise level at the driver's ear position, sequential analysis procedure is employed. First, the

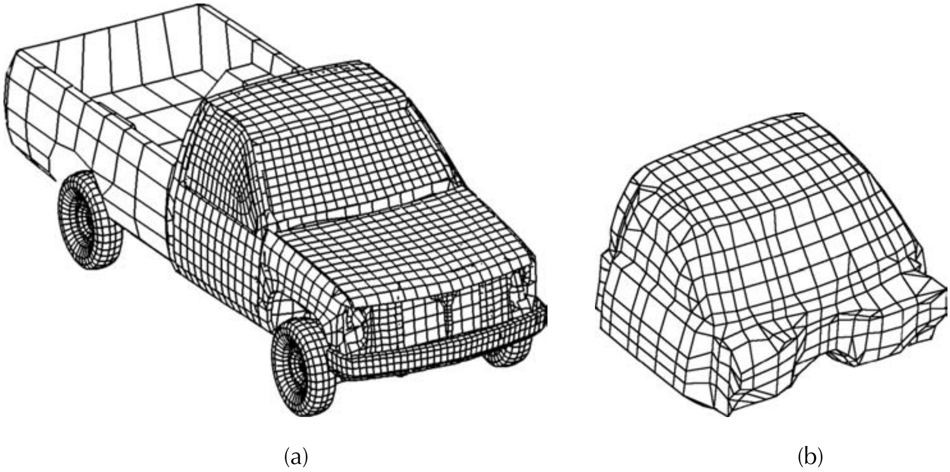

FIGURE 11.5.31 Computational model for structural-acoustic problem (a) finite element model of the vehicle; (b) boundary element model of the cabin compartment.

structural vibration problem is solved using the frequency response analysis. The vehicle structure is modeled using the finite element method, as shown in Figure 11.5.31(a). The sources of excitation are power-train vibration, wheel/terrain interaction, and a hydraulic pump load. Because of this additional source of excitation, vibration and noise is more significant than with a conventional power train. The frequency response analysis calculates the vibration velocity of vehicle's panels. Second, after solving for the panel velocity, the boundary element method is employed to calculate the pressure level in the cabin compartment using the panel velocity as a boundary condition. Figure 11.5.31(b) shows the boundary element model of the cabin compartment. In this example, the noise level of the passenger compartment is chosen as the performance measure, and vehicle-panel thicknesses are chosen as design variables. From the power-train analysis and rigid-body dynamic analysis, the harmonic excitations at 12 locations are obtained. The following frequency response analysis is carried out using MSC/NASTRAN to obtain the velocity response at eight frequencies, which correspond to the peak values of structure's velocity below 100 Hz:

$$[j\omega\mathbf{M} + \kappa\mathbf{K}]\{\mathbf{v}(\omega)\} = \{\mathbf{f}(\omega)\} \tag{11.5.23}$$

where $j = \sqrt{-1}$, ω is the excitation frequency, [**M**] is the structural mass matrix, $\kappa = (1 + j\phi)/j\omega$, ϕ is the structural damping coefficient, [**K**] is the stiffness matrix, {**v**} is the panel velocity vector, and {**f**} is the harmonic excitation force.

After solving the structure's velocity response, acoustic BEA is carried out using the cabin acoustic boundary element model, as shown in Figure 11.5.31(b). First, the emanating pressure from the panel is calculated using all panels' vibration velocity, as

$$[\mathbf{A}]\{\mathbf{p}_s\} = [\mathbf{B}]\{\mathbf{v}\} \tag{11.5.24}$$

where the matrices [**A**] and [**B**] are functions of geometry and {$\mathbf{p}_s$} is the surface pressure of the panel. After calculating the surface pressure distribution, the sound pressure at the interior of the cabin can be calculated from

$$p = \{\mathbf{b}\}^T\{\mathbf{v}\} + \{\mathbf{e}\}^T\{\mathbf{p}_s\} \tag{11.5.25}$$

where the vectors {**b**} and {**e**} are functions of geometry.

TABLE 11.5.7 Acoustic Pressures at the Driver's Ear Position

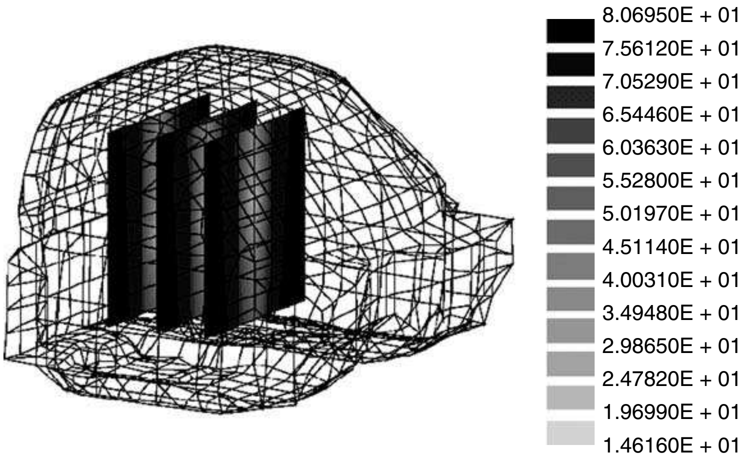

FIGURE 11.5.32 Acoustic pressure distribution inside the cabin compartment at 93.6 Hz.

Table 11.5.7 shows sound pressure levels at the driver's ear position. Since the sound pressure level at 93.6 Hz is significantly higher than at other frequencies, design modification is carried out at that frequency. In fact, this frequency corresponds to the fundamental frequency of the acoustic domain. Figure 11.5.32 shows the sound-pressure level inside the cabin compartment. The maximum sound pressure level at the driver's ear is 77.8 dB when the reference pressure of 2×10^{-8} kg/mm·s^2 is used.

In order to identify which panel thickness affects the sound pressure, the design sensitivity analysis has been performed. Forty design variables are selected in this example, which are grouped based on the manufacturing constraints. The adjoint method is employed in calculating the design sensitivity information because the number of performance measure (pressure at driver's ear position) is much smaller than the number of design variables. Table 11.5.8 shows the normalized sensitivity information for the 12 design variables whose effects are the most significant. The results show that a thickness change in the chassis component has the greatest potential for achieving a reduction in sound-pressure levels. Since the numerical integration process is carried out on each finite element, the element sensitivity information

TABLE 11.5.8 Normalized Sensitivity Values for Various Design Variables

Component	Sensitivity	Component	Sensitivity

Right wheelhouse	–0.25	Bumper	–0.03
Bed	–0.19	Rear glass	0.03

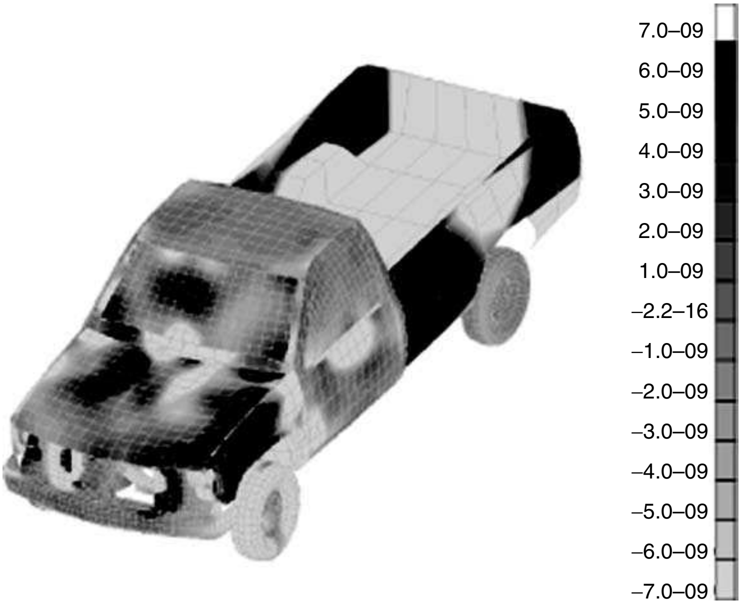

FIGURE 11.5.33 Design sensitivity contribution of each element to the sound pressure level.

can be calculated without any additional effort. Figure 11.5.33 plots the sensitivity contribution of the each element to the sound-pressure level. Such graphic-based sensitivity information is very helpful for the design engineer in determining the direction of the design modification.

As was shown in Table 11.5.8, the chassis component has the highest sensitivity for the sound-pressure level, which means that a change in the thickness of the chassis component is the most effective way to reduce the sound-pressure level. To see the effect of the chassis component, the thickness of the chassis is increased by 1.0 mm and the whole analysis process is repeated for the modified design. It turns out that the maximum value of the sound pressure is reduced from 77.8 dB to 75.0 dB.

Gradient-Based Design Optimization

When the design parameters are continuous, various numerical techniques have been developed to find the local optimum design systematically. Unfortunately, no mathematical theory exists that can find the global optimum design for general nonlinear functions. To find the optimum design, at least a possible candidate must exist within a feasible design region to satisfy problem constraints. Every design in the feasible region is an acceptable design, even if it is not the best one. The best design is usually the one that minimizes (or maximizes) the cost function of the design problem. Thus, the goal of the design optimization problem is to find a design that minimizes the cost function among all feasible designs. In this section, design optimization algorithms are briefly introduced. However, this brief discussion is by no means a complete treatment of optimization methods. For a more detailed treatment, see references 38, 39, and 40.

Most gradient-based optimization algorithms are based on the mathematical programming method, which requires the function values and sensitivity information at given design variables. Each algorithm has its own advantages and disadvantages. The performance of an optimization algorithm critically depends on the characteristics of the design problem and the types of cost and constraint functions.

The Linear Programming Method

The linear programming method can be used when cost and constraints are linear functions of the design variables.[41] Most structural design problems, however, are nonlinear with respect to their design variables. Thus, the linear programming method is not of much use for structural problems. However, a nonlinear problem can be solved by approximating a sequence of linear problems. The standard form of a linear programming problem is

$$\begin{aligned} &\text{minimize} \quad f = \mathbf{c}^T\mathbf{u} \\ &\text{subject to} \quad \mathbf{Au} = \mathbf{b} \\ &\qquad\qquad\quad \mathbf{u} \geq \mathbf{0} \end{aligned} \tag{11.5.26}$$

where $\mathbf{c} = [c_1, c_2, \ldots, c_n]^T$ is the coefficient of the cost function, **A** is the $m \times n$ matrix, and **b** is the $m \times 1$ vector. Inequality constraints can be treated as equality constraints by introducing slack variables. Since all functions are linear, the feasible regions defined by linear equalities are convex, along with the cost function. Thus, if any optimum solution of Equation 11.5.26 exists, then it is a global minimum solution of the problem. The reason for introducing the linear problem here is that a very efficient method exists for solving linear programming problems, namely *the simplex method*. A positive feature of a linear programming problem is that the solution always lies on the boundary of the feasible region. Thus, the simplex method finds a solution by moving each corner point of the convex boundary.

Unconstrained Optimization Problems

When cost and/or constraints are nonlinear functions of the design, the design problem is called a *nonlinear programming method*, as contrasted to the linear programming method discussed in the previous section. Most engineering problems fall into the former category. Because the properties of nonlinear programming are nonlinear, this method is frequently solved using the numerical, rather than the analytical, method.

When there are no constraints on the design problem, it is referred to as an *unconstrained optimization problem*. Even if most engineering problems have constraints, these problems can be transformed into unconstrained ones by using the penalty method, or the Lagrange multiplier method. The unconstrained optimization problem sometimes contains the lower and upper limits of a design variable, since this type of constraint can be treated in simple way. The standard form of an unconstrained optimization problem can be written as

$$\begin{aligned} &\text{minimize} \quad f(\mathbf{u}) \\ &\text{subject to} \quad u_k^L \leq u_k \leq u_k^U, \qquad k = 1, \cdots, n \end{aligned} . \tag{11.5.27}$$

In the following subsections, numerical methods for solving Equation 11.5.27 are discussed.

The Steepest Descent Method

The numerical procedure for solving Equation 11.5.26 is an iterative update of design **u**. If $\mathbf{u}^k$ is the value of the design at the k-th iteration, then the new design at the $(k+1)$-th iteration can be obtained by

$$\mathbf{u}^{k+1} = \mathbf{u}^k + \alpha \mathbf{d}^{k+1} \tag{11.5.28}$$

where $\mathbf{d}^{k+1}$ is called the descent direction and α is a step size, used to determine the amount of movement in the direction of $\mathbf{d}^{k+1}$. If the descent direction is given, then parameter α is determined by using the line search procedure to find the minimum value of a cost function in the descent direction. The steepest descent method uses the gradient of the cost function as the descent direction, such that

$$\mathbf{d}^{k+1} = -\frac{\partial f(\mathbf{u}^k)}{\partial \mathbf{u}^k} = -\nabla f(\mathbf{u}^k) \tag{11.5.29}$$

which is the design sensitivity of the cost function. This method suffers from a slow convergence near the optimum design, since it does not use any information from the previous design, and only first-order information of the function is used. Note that $\mathbf{d}^k$ and $\mathbf{d}^{k+1}$ are always orthogonal, such that a zigzagging pattern appears in the optimization process.

The Conjugate Gradient Method

The conjugate gradient method developed by Fletcher and Reeves[42] improves the rate of slow convergence in the steepest descent method by using gradient information from the previous iteration. The difference in this method is the computation of $\mathbf{d}^{k+1}$ in Equation 11.5.28. The new descent direction is computed by

$$\mathbf{d}^{k+1} = -\nabla f(\mathbf{u}^k) + \beta_k^2 \mathbf{d}^k \tag{11.5.30}$$

where

$$\beta_k = \frac{\left\| \nabla f(\mathbf{u}^k) \right\|}{\left\| \nabla f(\mathbf{u}^{k-1}) \right\|} \tag{11.5.31}$$

and where the first iteration is the same as Equation 11.5.28. This method tends to select the descent direction as a diagonal of two orthogonal steepest descent directions, such that a zigzagging pattern can be eliminated. This method always has better convergence than the steepest descent method.

The Newton Method

The previous methods we have examined use first-order information (first-order design sensitivity) of the cost function to find the optimum design, which is called linear approximation. The Newton method uses second-order information (second-order design sensitivity) to approximate the cost function as a quadratic function of the design. The major concern is how to compute the second-order design sensitivity (or Hessian) matrix. Let us define the Hessian matrix as second-order design sensitivity, as

$$\mathbf{H}(\mathbf{u}^k) \equiv \left[\frac{\partial f(\mathbf{u}^k)}{\partial u_i^k \partial u_j^k} \right], \quad i, j = 1, \cdots, n \tag{11.5.32}$$

The new design can then be determined, as

$$\mathbf{u}^{k+1} = \mathbf{u}^k + \Delta\mathbf{u}^{k+1} \tag{11.5.33}$$

where

$$\Delta\mathbf{u}^{k+1} = -\mathbf{H}(\mathbf{u}^k)^{-1} \nabla f(\mathbf{u}^k) \tag{11.5.34}$$

If the current estimated design $\mathbf{u}^k$ is sufficiently close to the optimum design, then Newton's method will show a quadratic convergence. However, the greater the number of design variables, the greater the cost of computing $\mathbf{H}(\mathbf{u}^k)$ in Equation 11.5.32. In addition, Newton's method does not guarantee a convergence. Thus, several modifications are available. For example, the design update algorithm in Equation 11.5.33 can be modified to include a step size by using a line search, as in Equation 11.5.28.

The Quasi-Newton Method

Although Newton's method has a quadratic convergence, the cost of computing the Hessian matrix, and the lack of a guaranteed convergence, are drawbacks to this method. The quasi-Newton method has an advantage over the steepest descent method and Newton's method: it only requires first-order sensitivity information, and it approximates the Hessian matrix to speed up the convergence.

The DFP (Davidon-Fletcher-Powell)[42] method approximates the inverse of the Hessian matrix using first-order sensitivity information. By initially assuming that the inverse of the Hessian is the identity matrix, this method updates the inverse of the Hessian matrix during design iteration. A nice feature of this method is that the positive definiteness of the Hessian matrix is preserved.

The BFGS (Broydon-Fletcher-Goldfarb-Shanno)[43] method updates the Hessian matrix directly, rather than updating its inverse as with the DFP method. Starting from the identity matrix, the Hessian matrix remains positive definite if exact line search is used.

Constrained Optimization Problems

Most engineering problems have constraints that must be satisfied during the design optimization process. These two types of constraints are handled separately: equality and inequality constraints. The standard form of the design optimization problem in constrained optimization can be written as

$$\begin{aligned} &\text{minimize} \quad f(\mathbf{u}) \\ &\text{subject to} \quad h_i(\mathbf{u}) = 0, \qquad i = 1,\cdots,p \\ &\qquad\qquad\quad g_j(\mathbf{u}) \le 0, \qquad j = 1,\cdots,m \\ &\qquad\qquad\quad u_l^L \le u_l \le u_l^U,\ l = 1,\cdots,n \end{aligned} \tag{11.5.35}$$

The computational method to find a solution to Equation 11.5.35 has two phases: first, to find a direction **d** that can reduce the cost $f(\mathbf{u})$ while correcting for any constraint violations that are violated; and second, to determine the step size of movement α in the direction of **d**.

Sequential Linear Programming (SLP)

The SLP method approximates the nonlinear problem as a sequence of linear programming problems such that the simplex method described earlier may be used to find the solution to each iteration. By using function values and sensitivity information, the nonlinear problem in Equation 11.5.35 is linearized in a similar way as Taylor's expansion method in the first order, as

$$\begin{aligned} &\text{minimize} \quad f(\mathbf{u}^k) + \nabla f^T \Delta\mathbf{u}^k \\ &\text{subject to} \quad h_i(\mathbf{u}^k) + \nabla h_i{}^T \Delta\mathbf{u}^k = 0, \quad i = 1,\cdots,p \\ &\qquad\qquad\quad g_i(\mathbf{u}^k) + \nabla g_i{}^T \Delta\mathbf{u}^k \le 0, \quad j = 1,\cdots,m \\ &\qquad\qquad\quad u_l^L \le u_l \le u_l^U, \qquad\qquad l = 1,\cdots,n \end{aligned} \tag{11.5.36}$$

Since all functions and their sensitivities at $\mathbf{u}^k$ are known, the linear programming problem in Equation 11.5.36 can be solved using the simplex method for $\Delta\mathbf{u}^k$. Even if the sensitivity information is not used to solve a linear programming problem, design sensitivity information is required in order to approximate the nonlinear problem as a linear one with SLP. In solving Equation 11.5.36 for $\Delta\mathbf{u}^k$, the move limit $\Delta\mathbf{u}_L^k \le \Delta\mathbf{u}^k \le \Delta\mathbf{u}_U^k$ is critically important for convergence.

Sequential Quadratic Programming (SQP)

Compared to previous methods, which use first-order sensitivity information to determine the search direction **d**, SQP solves a quadratic subproblem to find that search direction, which has both quadratic cost and linear constraints:

$$\begin{aligned} &\text{minimize} \quad f(\mathbf{u}^k) + \nabla f^T \mathbf{d} + \frac{1}{2}\mathbf{d}^T \mathbf{H}\mathbf{d} \\ &\text{subject to} \quad h_i(\mathbf{u}^k) + \nabla h_i{}^T \mathbf{d} = 0, \quad i = 1,\cdots,p \\ &\qquad\qquad\quad g_j(\mathbf{u}^k) + \nabla g_j{}^T \mathbf{d} \le 0, \quad j = 1,\cdots,m \end{aligned} \tag{11.5.37}$$

This special form of the quadratic problem can be effectively solved, for example, by using the Kuhn-Tucker condition and the simplex method. Starting from the identity matrix, the Hessian matrix **H** is updated at each iteration by using the aforementioned methods in unconstrained optimization algorithms. The advantage of solving Equation 11.5.37 in this way is that for positive definite **H** the problem is convex and the solution is unique. Moreover, this method does not require the move limit as in SLP.

The Constrained Steepest Descent Method

In the unconstrained optimization process described earlier, the descent direction **d** is obtained from the cost function sensitivity. When constraints exist, this descent direction has to be modified in order to include their effects. If constraints are violated, then these constraints are added to the cost function using a penalty method. Design sensitivity of the penalized cost function combines the effects of the original cost function and the violated constraint functions.

The Constrained Quasi-Newton Method

If the linear approximation of constraints in SQP is substituted for a quadratic approximation, then the convergence rate of Equation 11.5.37 will be improved. However, solving the optimization problem for quadratic cost and constraints is not an easy process. The constrained quasi-Newton method combines the Hessian information of constraints with the cost function by using the Lagrange multiplier method. Nevertheless, it is still necessary to compute the constraint function Hessian. The main purpose of the constrained quasi-Newton method is to approximate the Hessian matrix by using first-order sensitivity information. The extended cost function is

$$L(\mathbf{u},\mathbf{v},\mathbf{w}) = f(\mathbf{u}) + \sum_{i=1}^{p} v_i h_i(\mathbf{u}) + \sum_{j=1}^{m} w_i g_i(\mathbf{u}) \tag{11.5.38}$$

where both $\mathbf{v} = [v_1, v_2, \ldots, v_p]^T$ and $\mathbf{w} = [w_1, w_2, \ldots, w_m]^T$ are the Lagrange multipliers for equality and inequality constraints, respectively. Note that $\mathbf{w} > \mathbf{0}$. Let the second-order design sensitivity of L be $\nabla^2 L$. The extended quadratic programming problem of Equation 11.5.37 thus becomes

$$\begin{aligned}
\text{minimize} \quad & f(\mathbf{u}^k) + \nabla f^T \mathbf{d} + \frac{1}{2}\mathbf{d}^T \nabla^2 L \mathbf{d} \\
\text{subject to} \quad & h_i(\mathbf{u}^k) + \nabla h_i^T \mathbf{d} = 0, \quad i = 1,\cdots,p \\
& g_j(\mathbf{u}^k) + \nabla g_j^T \mathbf{d} \le 0, \quad j = 1,\cdots,m \\
& w_l \ge 0, \qquad\qquad l = 1,\cdots,m
\end{aligned} \tag{11.5.39}$$

The Feasible Direction Method

The feasible direction method is designed to allow design movement within the feasible region in each iteration. Based on the previous design, the updated design reduces the cost function and remains in the feasible region. Since all designs are feasible, a design at any iteration can be used, even if it is not an optimum design. Because this method uses the linearization of functions as in SLP, it is difficult to maintain nonlinear equality constraints. Thus, this approach is used exclusively for inequality constraints. Search direction **d** can be found by solving the following linear subproblem:

$$\begin{aligned}
\text{minimize} \quad & \beta \\
\text{subject to} \quad & \nabla f^T \mathbf{d} \le \beta \\
& \nabla g_i^T \mathbf{d} \le \beta, \quad i = 1,\cdots,m_{active} \\
& -1 \le d_j \le 1, \quad j = 1,\cdots,n
\end{aligned} \tag{11.5.40}$$

where m_{active} is the number of active inequality constraints. After finding a direction **d** that can reduce cost function and maintain feasibility, a line search is used to determine step size α.

The Gradient Projection Method

The feasible direction method solves the linear programming problem to find the direction of the design change. The gradient projection method, however, uses a simpler method for computing this direction. The direction obtained by the steepest descent method is projected on the constraint boundary, such that the new design can move along the constraint boundary. Thus, the direction of the design change reduces the cost function while maintaining the constraint along its boundary. For a general nonlinear constraint, however, a small movement along the tangent line of the boundary will violate this constraint. Thus, in actual implementation, a correction algorithm has to be followed. The gradient projection method behaves well when the constraint boundary is moderately nonlinear.

Examples

The Torque Arm Model

The torque arm model is used here to demonstrate the design optimization. The design optimization problem is formulated in such a way that the total area of the structure is minimized with respect to its shape design parameters, with design constraints defined as the second invariant of the stress tensors (von Mises stress), as

$$\begin{array}{ll} \text{minimize} & \text{mass} \\ \text{subject to} & \sigma_{\text{MAX}} \le 800\ \text{MPa} \end{array} \tag{11.5.41}$$

As has been shown in Figure 11.5.26, the maximum stress at the initial design was 305 MPa. Thus, the design that meets the constrained boundary in Equation 11.5.41 is far away from the initial design, which means the amount of shape change during design optimization is significantly large.

For design optimization, the sequential quadratic programming method described earlier has been used employing a commercially available optimization program.[39] The structural analysis provides the function values (i.e., mass and stress), whereas the sensitivity analysis provides the gradient information to the optimization algorithm. The design optimization problem converges after 20 numbers of iteration. Figure 11.5.34 shows the structural analysis results at optimum design where the stress constraints along the upper side of torque arm became active. The left diameter of the interior slot significantly increases to reduce the structural mass, whereas the right diameter is slightly decreased. The vertical position of the right boundary (u_4) is significantly reduced so that the thickness of the torque arm becomes constant.

Table 11.5.9 shows the values of design variables at the initial and optimum designs. The lower and upper bounds are selected such that the structure maintains its topology during design optimization. All design variables start from zero, which means the values of design variables are relative change of its coordinates. Four design variables are changed up to their lower or upper bounds.

Figure 11.5.35 provides an optimization history of the mass function. Through optimization, the structural mass was reduced from 0.878 kg to 0.421 kg (47.9%). The highest stress value initially, 305 MPa around the left hole, shifts to 800 MPa around the upper frame at optimum design. A total of 41 response analyses and 20 sensitivity analyses were carried out during 20 optimization iterations. When

TABLE 11.5.9 Design Variables at the Initial and Optimum Designs

Design	Lower Bound	Initial Design	Optimum Design	Upper Bound
u_1	−3.000	0.0	−3.000	2.000
u_2	−0.500	0.0	−0.500	2.000
u_3	−2.000	0.0	−0.589	2.000
u_4	−3.000	0.0	−2.700	2.000
u_5	−4.500	0.0	−4.490	2.000
u_6	−0.500	0.0	2.000	2.000
u_7	−2.000	0.0	4.460	5.000
u_8	−0.500	0.0	−0.00714	2.000

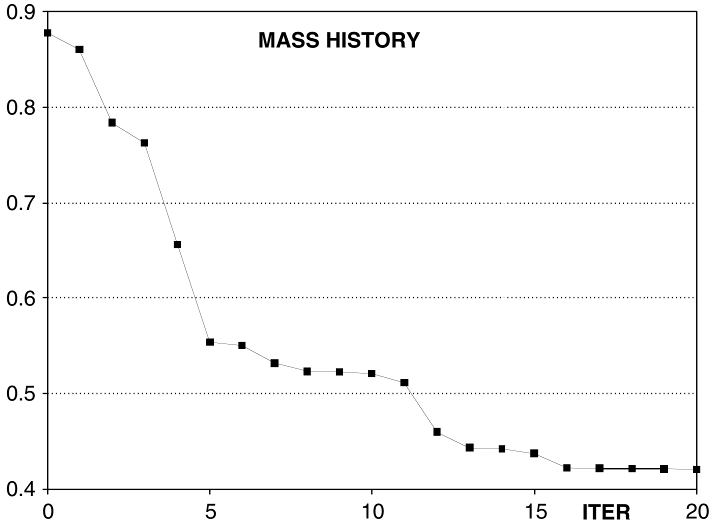

FIGURE 11.5.35 Histories of design optimization.

the finite difference methods are used with a re-meshing process,[34] the optimization process converged at 45 iterations with eight re-meshing processes. Thus, this approach reduces the cost of design more than 50%, without even mentioning the cost related to the re-meshing process.

The Road Arm Model

As a second example, the design optimization is carried out to minimize the structural weight of the road arm, while maintaining the maximum stress level. The same algorithm as with the torque arm model is used. Design optimization problem converges after eight iterations. Figure 11.5.36 compares the structural analysis result at the initial and optimum designs. The structural weight at the optimum design is reduced by 23% compared to the initial weight. Since the stress concentration appears in the left corner at the initial design, the optimization algorithm tried to reduce the cross section of the right corner so that both parts may have the same level of stress values. Figure 11.5.37 shows the optimization history of cost function and design variables. Due to the accurate sensitivity information, the optimization algorithm converges rather quickly. Also, the small design change can be another explanation of the fast convergence.

Gradient-Free Design Optimization

Genetic Algorithms

Genetic algorithms (GA) are inspired by Darwin's principle of evolution, which states that a population of individuals is capable of adapting to its environment because individuals who possess traits that make them less vulnerable than others are more likely to have descendents and therefore to pass on their desirable

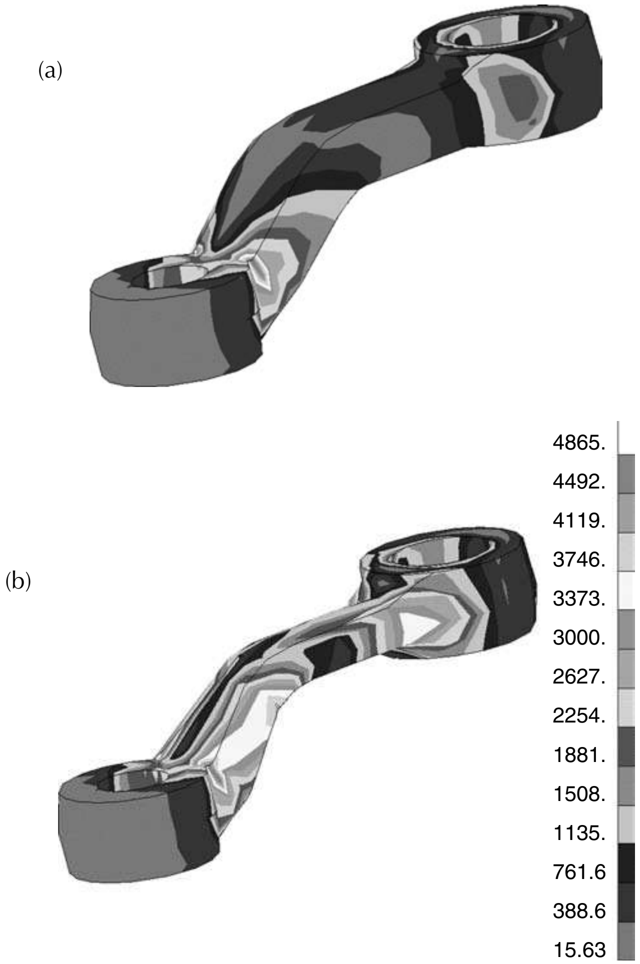

FIGURE 11.5.36 Structural analysis results (a) initial design; (b) optimum design.

traits to the next generation. One can think of this process of adaptation as an optimization process that probabilistically creates fitter individuals through selection and recombination of good characters. Genetic algorithms are simplified computer models of evolution, where the environment is emulated by the objective function to maximize, and the structure to optimize plays the role of the individuals.

A flowchart of a genetic algorithm is presented in Figure 11.5.38. GAs start by initializing a population of individuals at random. Each individual encode of a particular candidate structure in the form of one or several chromosomes, which are strings of finite length. Then the objective function of each individual, called the fitness function in the context of evolutionary computation, is computed. The fitness of each individual determines its probability of being selected for reproduction. Instead of moving from one design point to another, the search is based on a population of design points that evolve from one generation to another. Recombination and mutation operators are then applied to the selected individuals (the parents) to create a population of children. Finally a survival rule determines the individuals among the parent and child population that will be kept to form the new population.

When to Use Genetic Algorithms?

Genetic algorithms are computationally expensive compared to deterministic algorithms. Consequently, their domain of application consists of problems that would be difficult to solve by gradient-based algorithms, or problems that would be out of range for these algorithms. Some of the main advantages of GAs are the following:

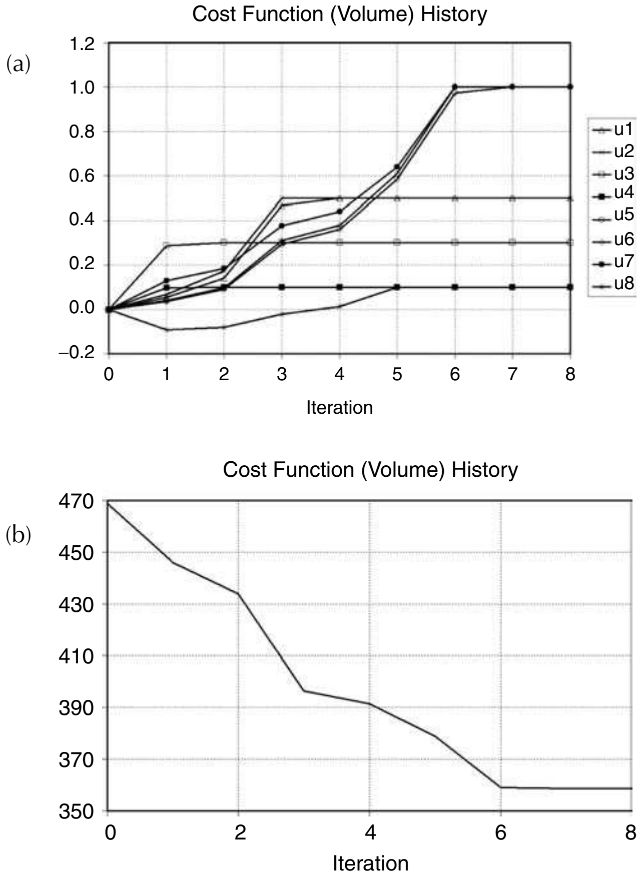

FIGURE 11.5.37 Design optimization history (a) cost function history; (b) design variable history.

- GAs do not require continuity or differentiability of the objective function. They do not need gradients.
- They are robust: they are very insensitive to noise.
- They are modular and therefore portable; because the evolutionary mechanism is separate from the problem representation, they can be transferred from problem to problem.
- They are particularly efficient on discrete and combinatorial problems, which are typically difficult to solve by conventional algorithms; they can be used for problems involving both discrete and continuous variables.
- Because they explore the design space with populations, GAs are “naturally” amenable to parallelization.

Examples of Applications

GAs have been used to solve a wide variety of engineering problems that would be difficult to tackle with other methods, such as scheduling problems, distribution network optimization, plant or product design, and real-time control of industrial processes and communications networks. A practical example of application is the optimization of the lay-up of composite laminate, where the goal is to determine the optimal fiber orientation of each of the layers of the laminate. This problem is difficult to solve by gradient-based algorithms because the objective function is often multimodal, and the fiber orientations have to be chosen from a set of discrete values to meet manufacturability requirements. On these problems, GAs prove to be very effective design tools.

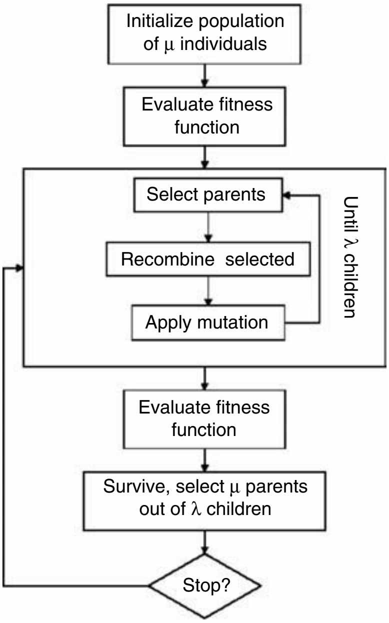

FIGURE 11.5.38 Genetic algorithm.

Simulated Annealing

Simulated annealing (SA) is based on a simple algorithm introduced by Metropolis et al.[44] to efficiently predict the behavior of a collection of atoms in equilibrium at a given temperature. The Metropolis approach simulates the cooling process by means of an iterative algorithm, in which each atom is given a small random displacement and the resulting change of energy ΔE is computed. If $\Delta E \leq 0$ the displacement is accepted and the resulting configuration is used as the initial point for the next iteration. If $\Delta E > 0$ a probability of acceptance is calculated with the Boltzmann factor:

$$P(\Delta E) = e^{-\left(\frac{\Delta E}{k_b T}\right)}$$

If ΔE is less than $P(\Delta E)$ the new configuration is accepted and used in the next iteration. This criterion ensures that the system will eventually evolve into a Boltzmann equilibrium distribution.

By using the Metropolis procedure with a cost function in place of system energy, the simulated annealing algorithm is obtained.[45] The configuration of atoms will then be a combination of design parameters, which are evaluated in the same manner.

The temperature T becomes a control parameter with the same units as the cost function, and is used to first “melt” the system at a high temperature, with a population of possible parameter configurations being generated. The iterative simulation is then run at this temperature until the system is considered to be in equilibrium, and only then is the temperature reduced by a small fraction. This cooling and equilibrium process continues until no further improvement becomes possible and the system is considered “frozen” or crystallized, with the design parameters at this condition optimal. The temperature reduction sequence and number of iterations allowed for the system to reach equilibrium are considered analogues to an annealing schedule.

An important difference from iterative improvement procedures such as gradient-based methods is that the Metropolis method need not get stuck since transitions out of a local optimum are always possible at a nonzero temperature.

Applications of this algorithm include the well-known traveling salesman problem,[46] and routing and layout of electrical connections on computers,[44] among others. Like genetic algorithms, this population-based method is relatively insensitive to noise, and doesn't require gradient information. A major drawback to this method, however, is the problem dependency of algorithm parameters, for example, it is important to use an annealing schedule that is tailored to the type of optimization problem being solved; otherwise, the optimizer will perform poorly. Various statistical methods have been proposed, all with limited success, to obtain optimum cooling rates to avoid entrapment in local optima.

12.1 Metals

Victor A. Greenhut

Introduction — Nature and Properties of Pure Metals

Metals achieve engineering importance because of their abundance, variety, and unique properties as conferred by metallic bonding. Twenty-four of the 26 most abundant elements in the Earth's crust are metals, with only two nonmetallic elements, oxygen and silicon, exceeding metals in frequency. The two

---

most abundant metallic elements, iron (5.0%) and aluminum (8.1%), are also the most commonly used structural metals. Iron is the most-used metal, in part because it can be extracted from its frequently occurring, enriched ores with considerably less energy penalty than aluminum, but also because of the very wide range of mechanical properties its alloys can provide (as will be seen below). The next 15 elements in frequency, found at least in parts per thousand, include most common engineering metals and alloys: calcium (3.6%), magnesium (2.1%), titanium (0.63%), manganese (0.10), chromium (0.037%), zirconium (0.026%), nickel (0.020%), vanadium (0.017%), copper (0.010%), uranium (0.008%), tungsten (0.005%), zinc (0.004%), lead (0.002%), cobalt (0.001%), and beryllium (0.001%). The cost of metals is strongly affected by strategic abundance as well as secondary factors such as extraction/processing cost and perceived value. Plain carbon steels and cast irons, iron alloys with carbon, are usually most cost-effective for ordinary mechanical applications. These alloys increase in cost with alloying additions.

A variety of metal properties are unique among materials and of importance technologically. These properties are conferred by metallic bonding, in which the “extra” outer valence electrons are “shared” among all metal ion cores. This bonding is different from other types of solids in that the electrons are free to acquire energy, and the metallic ions are relatively mobile, and quite interchangeable with regard to their positions in the crystal lattice, the three-dimensional repeating arrangement of atoms in a solid. This section of the chapter will concentrate on the mechanical properties of metals, for which metallic bonding provides ductile deformation, i.e., shows substantial permanent shape change under mechanical load prior to fracture. The ductility of metals at low and moderate temperature makes them formable as solids and also confers safety (fracture toughness) in mechanical applications, in that under impact loading the metal will absorb energy rather than break catastrophically.

Metals are good conductors of heat and electricity because thermal and electrical energy can be transferred by the free electrons. These two properties tend to parallel each other. For example, the pure noble metals (e.g., copper, silver, gold, platinum) are among the best electrical and thermal conductors. As a broad generalization, metallic elements with an odd number of valence electrons tend to be better conductors than those with an even number. These behaviors can be seen in Table C.6A of the Appendix. Thermal conductivity and electrical resistivity (inverse conductivity) have a reciprocal relationship and follow the indicted trends. As metals are alloyed with other elements, are deformed, contain multiple phases, and contain crystalline imperfections, their electrical and thermal conductivity usually decreases significantly from that of the pure, perfect, unalloyed metal. The specific values of thermal conductivity and electrical resistivity for several common engineering alloys is given in Table C.6B of the Appendix. Electrical and thermal conductivities tend to decrease proportionately to each other with increasing temperature for a specific metal. These conductivities may be altered if heating introduces metallurgical change during annealing (see subsection on mechanical forming).

Metals are opaque to and reflective of light and most of the electromagnetic spectrum, because electromagnetic energy is transferred to the free electrons and immediately retransmitted. This gives most metals a characteristic reflective “metallic color” or sheen, which if the metal is very smooth yields a mirror surface. At very short wavelengths (high energies) of the electromagnetic spectrum, such as X rays, the radiant energy will penetrate the material. This is applied in radiographic analysis of metals for flaws such as cracks, casting porosity, and inclusions.

Metals are almost always crystalline solids with a regular repeating pattern of ions. A number of atomic-level defects occur in this periodic array. A large number of atomic sites are “vacancies” (point defects) not occupied by atoms (Figure 12.1.1). The number and mobility of vacant sites increase rapidly with temperature. The number and mobility of vacancies in metals are quite high compared with other materials because there are no charge balance or local electron bond considerations. This means that solid metal can undergo significant changes with only moderate thermal excitation as vacancy motion (diffusion) provides atom-by-atom reconstruction of the material. Vacancies allow solid metals to homogenize in a “soaking pit” after casting and permit dissimilar metals to diffusion bond at moderate temperatures and within short times. In the process, substitutional metallic atoms (ions) shown in Figure 12.1.1 move via vacancy jumps while small interstitial atoms such as carbon (Figure 12.1.1) move from

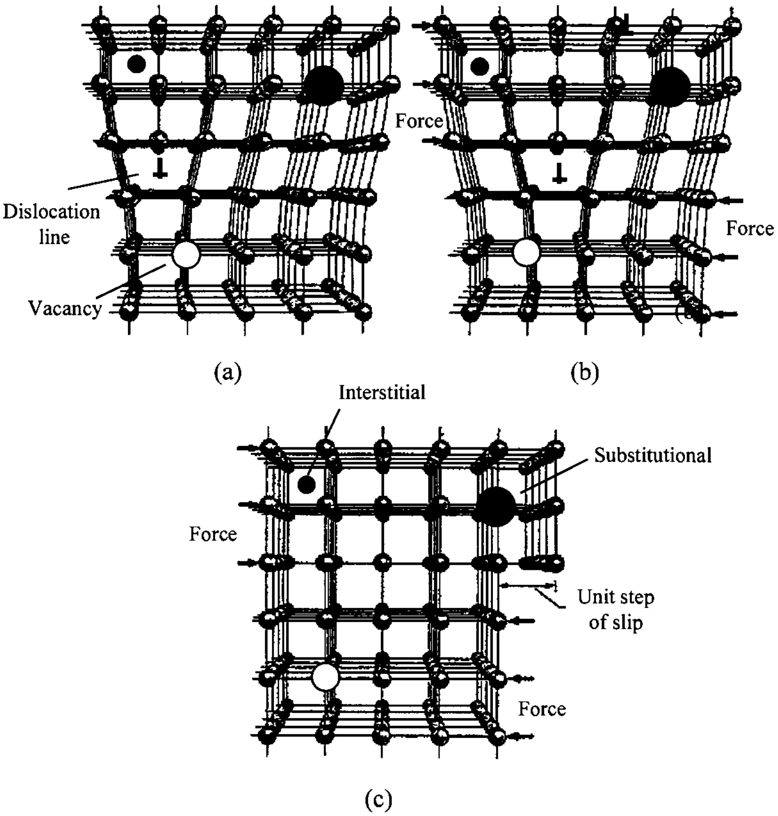

FIGURE 12.1.1 Point defects exist in the metal crystal structure: vacancies, substitutional atoms (ions), ions, and interstitial atoms (ions). A dislocation (⊥) line moves under an applied shear force until a surface step of plastic deformation is produced on the surface.

interstice to interstice. Vacancy mobility gives rise to major changes in mechanical properties during annealing (see subsection on mechanical forming) and is an important mechanism in creep deformation under load at elevated temperature (see subsection on corrosion and environmental effects).

At a slightly larger level, linear atomic packing defects known as dislocations, give rise to the ability of metallic materials to deform substantially under load. When a plane of atoms in the lattice ends, it gives rise to an edge "dislocation" such as that shown in Figure 12.1.1a. Such a dislocation can break and remake bonds relatively easily in a metal and thereby shift an atomic distance (Figure 12.1.1b). The process can continue until a surface step results. Many dislocations moving in this fashion can give rise to significant shape change in the material at moderate stresses. The onset of such massive dislocation motion in a metal is termed *yield* and occurs at the "yield stress" or "elastic limit" (see subsection on strength and deformation). Dislocations explain why the yield stress can be as low as about 100 Pa (10 psi) in a pure, pristine, single crystal of metal. Dislocations also explain how a fine-grained polycrystalline metal containing many microstructural features which interfere with dislocation motion may have a yield stress as great as 10 gPa (1000 ksi). Dislocations interact with each other in three dimensions and multiply. Therefore, dislocation motion can cause a major increase in dislocation density and yield stress, termed *cold work*. Vacancies can rearrange these dislocation tangles, restoring the metal to a condition closer to its original state, thereby lowering the yield stress. This can occur at moderate annealing temperatures (see subsection on mechanical forming).

The interaction of deformation, alloying elements, temperature, and time can cause a wide variety of microstructures in a solid metal down to near atomic levels with mechanical (and other) properties which can vary over a very wide range. It is possible to manipulate the properties of a single metal composition over a very wide range in the solid state — a behavior which can be used to mechanically form a particular metal and then use it in a demanding load-bearing application. The use of minor alloying additions can provide a yet wider range of properties with appropriate thermal and mechanical treatment.

Casting

One of the important technological advantages of metals is their ability to incorporate a wide variety of secondary elements in a particular metal and thereby create alloys of the metal. Alloying can increase the strength of a metal by several orders of magnitude and permit the strength and ductility to be varied over a wide range by thermal and/or mechanical treatment, resulting in ease of mechanical forming or resistance to deformation.

Several metal phases may exist together in the solid as grains (crystals), or secondary phases may occur as smaller entities on grain (intercrystal) boundaries or within grains. Often the strengthening phase is submicroscopic and cannot be detected by optical metallography (reflection optical microscopy). The size and distribution of secondary phases is manipulated by thermomechanical (thermal and/or mechanical) treatment of the solid metal as well as the original casting procedure.

Casting methods include expendable mold casting (investment/precision, plaster mold, dry sand, and wet sand casting), permanent mold casting (ingot, permanent mold, centrifugal, and die casting), and continuous casting (direct chill and "splat" casting). These are listed in approximate order of cooling rate in Figure 12.1.2. As cooling rate increases, the grain (crystal) size tends to be smaller and the strength increases while compositional segregation decreases, providing more uniform properties. At the extremely high casting rates (10^5 to 10^6/sec) of continuous splat casting, it is possible to produce homogeneous metals not possible in terms of phase diagrams, and many metals have been produced in the amorphous state, yielding unusual metallic glasses. Ingot casting and continuous direct chill casting are primarily used to produce solid metal which will be extensively mechanically formed to final shape. The other casting methods are used to produce shapes near final dimensions, but to varying extends may receive extensive machining, forming, or finishing prior to use. For the latter group, grain refiners are frequently added to reduce solidification grain size. Metal tends to solidify directionally, with grains elongated in the direction of heat flow. This gives rise to directional mechanical properties which should be accounted for in design.

To obtain optimum properties and prevent flaws which may cause failure, the casting procedure must avoid or control compositional segregation, shrinkage cavities, porosity, improper texture (grain directionality), residual (internal) stresses, and flux/slag inclusions. This can be accomplished with good

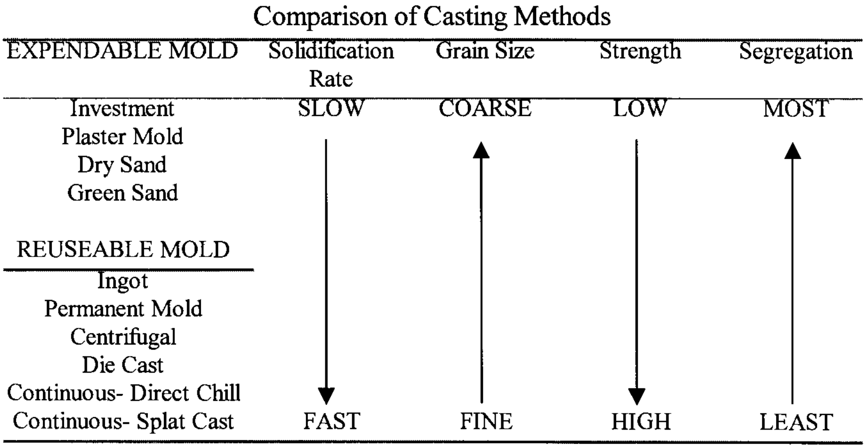

FIGURE 12.1.2 The effects of casting speed (solidification rate) are compared.

casting practice. With the exception of investment (lost wax, precision) casting and to a lesser extent die casting, it is difficult to achieve very exacting tolerances and fine surface finish without postfinishing or forming of a casting.

Strength and Deformation, Fracture Toughness

Figure 12.1.3 shows a typical stress–strain diagram for a metal. The first portion is a linear, spring-type behavior, termed *elastic*, and attributable to stretching of atomic bonds. The slope of the curve is the "stiffness" (given for various metals in Table C.3 of the Appendix). The relative stiffness is low for metals as contrasted with ceramics because atomic bonding is less strong. Similarly, high-melting-point metals tend to be stiffer than those with weaker atomic bonds and lower melting behavior. The stiffness behavior is frequently given quantitatively for uniaxial loading by the simplified expressions of Hooke's law:

$$\varepsilon_x = \sigma_x / E \qquad \varepsilon_y = \varepsilon_z = -\upsilon\sigma_x / E \tag{12.1.1}$$

where σ_x is the stress (force per unit area, psi or Pa) in the x direction of applied unidirectional tensile load, ε_x is the strain (length per unit length or percent) in the same direction ε_y and ε_z are the contracting strains in the lateral directions, E is Young's modulus (the modulus of elasticity), and υ is Poisson's ratio. Values of the modulus of elasticity and Poisson's ratio are given in Table C.6A of the Appendix for pure metals and in C.6B for common engineering alloys. It may be noted that another property which depends on atomic bond strength is thermal expansion. As the elastic modulus (stiffness) increases with atomic bond strength, the coefficient of linear expansion tends to decrease, as seen in Table C.6.

The relationship of Equation (12.1.1) is for an isotropic material, but most engineering metals have some directionality of elastic properties and other structure-insensitive properties such as thermal expansion coefficient. The directionality results from directional elongation or preferred crystal orientation, which result from both directional solidification and mechanical forming of metals. In most cases two

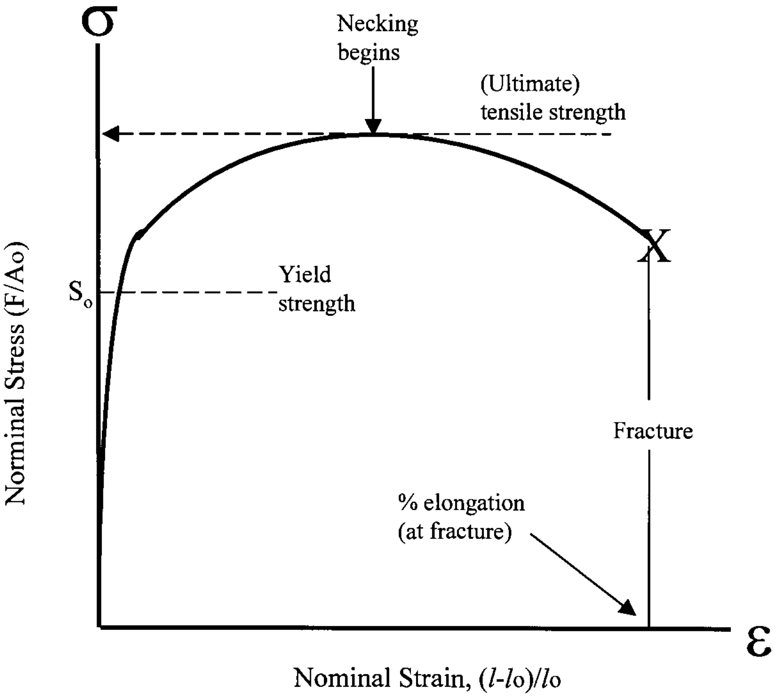

FIGURE 12.1.3 Typical engineering stress–strain curve for a metal.

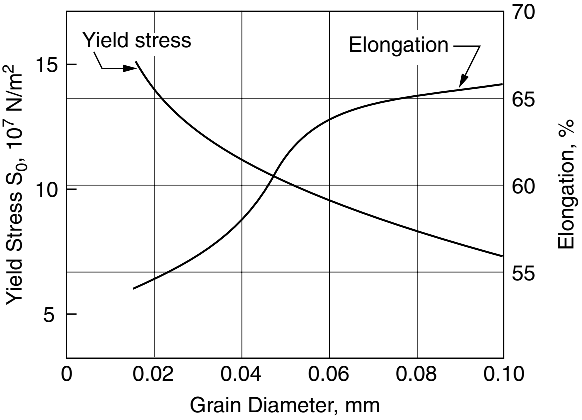

FIGURE 12.1.4 The effect of grain (crystal) size on yield stress and elongation to failure (ductility) for cartridge brass (Cu–30 Zn) in tension.

elastic moduli and a Poisson's ratio are required to fully specify behavior. A principal modulus might be given in the rolling direction of sheet or plate with a secondary modulus in the transverse direction. A difference of 2 to 5% should ordinarily be expected, but some metals can show an elastic modulus difference as great as a factor of 2 in the principal directions of heavily formed material. Such directional differences should be accounted for when spring force or dimensional tolerance under load (or change of temperature) is critical in a design.

At a critical stress the metal begins to deform permanently, as seen as a break in the straight-line behavior in the stress-strain diagram of Figure 12.1.3. The stress for this onset is termed the yield stress or elastic limit. For engineering purposes it is usually taken at 0.2% plastic strain in order to provide a predictable, identifiable value. An extensive table of yield values and usual applications for commercial metals and alloys is given in Appendix C.5. In the case of steel a small yield drop allows for clear identification of the yield stress and this value is used. The onset of yield is a structure-sensitive property. It can vary over many orders of magnitude and depends on such factors as grain size and structure, phases present, degree of cold work, and secondary phases in grains or on grain boundaries as affected by the thermal and mechanical treatment of the alloy. The extension to failure, the ductility, and maximum in the stress–strain curve, the "ultimate stress" or "tensile strength" (see Appendix C.5) are also structure-sensitive properties. The strength and specific strength (strength-to-weight ratio) generally decrease with temperature.

The ductility usually decreases as the strength (yield or ultimate) increases for a particular metal. Reduction in the grain size of the metal will usually increase yield stress while decreasing ductility (Figure 12.1.4). Either yield or ultimate strength are used for engineering design with an appropriate safety factor, although the former may be more objective because it measures the onset of permanent deformation. Ductility after yield provides safety, in that, rather than abrupt, catastrophic failure, the metal deforms.

A different, independent measure is needed for impact loads — "toughness." This is often treated in design, materials selection, and flaw evaluation by extending Griffith's theory of critical flaw size in a brittle material:

$$\sigma_f = K_{1c} / \gamma c^{1/2} \tag{12.1.2}$$

where σ_f is the failure stress, K_{1c} is a structure-sensitive materials property, the "fracture toughness" or "stress intensity factor" for a normal load, γ is a constant depending on orientation, and c is the depth of a long, narrow surface flaw or crack (or half that of an internal flaw). This is a separate design issue from that of strength. It is of particular importance when a metal shows limited ductility and catastrophic failure must be avoided. In some applications the growth of cracks, c is monitored to prevent catastrophic failure. Alternatively, as a performance test sufficient energy absorption as characteristic of a metal is determined when it is fractured in a Charpy or Izod impact test. Many metals will show a rapid decline in such energy absorption below a nil ductility temperature (NDT), which may establish a lowest use temperature for a particular metal in a particular state and for a particular application. Welds are often qualified by impact tests as well as strength testing. Care must be taken to apply the impact test appropriate to an application.

Hardness, the resistance of the near surface of a metal to penetration by an indentor, is also employed as a mechanical test. Increased hardness can often be correlated with an increase in yield and ultimate strengths. Typical hardness values for a large number of commercial metals and alloys are provided in Appendix C.5. A hardness indent is frequently done to "determine" the strength of a steel, using "equivalency" tables. Great caution must be taken in applying such tables because while hardness is an easy test to perform, it measures a complex and interactive set of properties, increasing with strength, elastic modulus, and work hardening rate. It is also an observation of surface properties which may not be characteristic of the bulk metal — particularly thick-gauge steel used in tension. Surface-hardening treatments can make the simplistic use of an "equivalency" table particularly dangerous. Application to nonferrous metals is also problematic. If a hardness tested part is to be put into service, the placement of hardness indents (surface flaws) can cause permanent failure.

A summary of important engineering metals can be found in Appendix C.5. This extensive table provides strength, hardness, and applications information for many commercial metals in varied heat treatments.

Mechanical Forming

Hot working is used when major shape change, cross-section reduction, or texture (directional) properties are desired. Cold working is preferred when close tolerances and fine surface finish are needed. The cold-worked form of a metal typically shows higher yield and tensile strength, as can be seen for several alloys listed in Appendix C.5. Rolling, forging, and extrusion are primarily done hot, while shape drawing, extrusion, deep drawing, stretching, spinning, bending, and high-velocity forming are more commonly performed cold. Hot rolling between parallel rollers is used to reduce ingots to plates, sheets, strips, and skelp, as well as structural shapes, rail, bar, round stock (including thick-walled pipe), and wire. Sheet metal and threads on round or wire stock may be rolled to shape cold. Closed die hot forging employs dies with the final part shape, while open die forging (including swaging and roll forging) uses less-shaped dies. Coining, embossing, and hobbing are cold-forging operations used to obtain precision, detailed surface relief or dimensions. Generally, extrusion and die drawing require careful control of die configuration and forming rate and, in the latter case, lubricant system. Impact extrusion, hydrostatic extrusion, and deep drawing (thin-walled aluminum cans) permit very large precise dimensional and cross-section changes to be made cold in a single pass. Stretching, spinning, bending are usually used to shape sheet or plate metal and the spring-back of the metal due to elastic modulus must be accounted for to obtain a precise shape.

Solute, Dispersion, and Precipitation Strengthening and Heat Treatment

Alloying additions can have profound consequences on the strength of metals. Major alloying additions can lead to multiphase materials which are stronger than single-phase materials. Such metal alloys may also give very fine grain size with further strengthening of material. Small alloying additions may also substantially increase strength by solute strengthening as solid solution substitutional or interstitial atoms and or by particle strengthening as dispersion or precipitation hardening alloys.

Substitutional solute strengthening of copper by various atoms is shown in Figure 12.1.5. As the amount of an alloying element in solution increases, the strength increases as dislocations are held in place by the "foreign" atoms. The greater the ionic misfit (difference in size — Sn is a much larger ion than Ni), the greater the strengthening effect. The strength increase can be quite dramatic — as much as a 20-fold

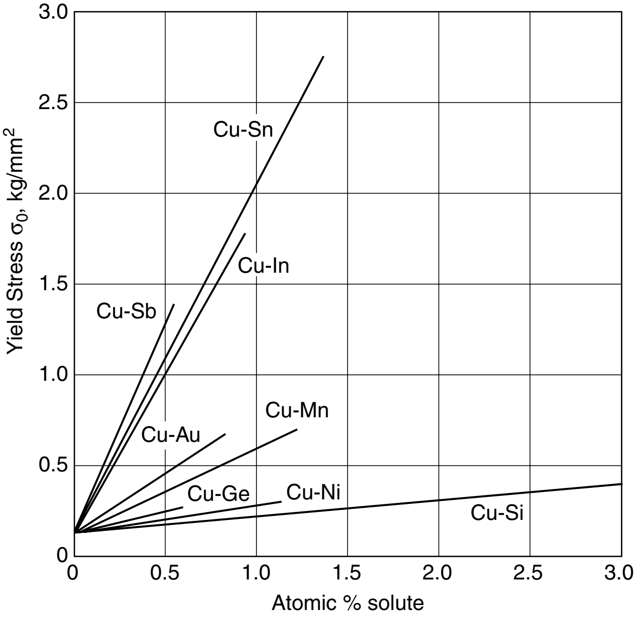

FIGURE 12.1.5 Effect of various substitutional atoms on the strength of copper. Note that as the ionic size of the substitutional atom becomes larger the strengthening effect becomes greater.

increase with a 1.5% addition to copper. Alternatively, a large addition of a very soluble element such as nickel can give major strengthening — monel, the Cu–70Ni alloy is more than four times stronger than pure copper (Figure 12.1.6). Interstitial solid solution carbon contributes to the strength of iron and is one contributor to strength in steels and cast irons. Solute strengthening can become ineffective in strengthening at elevated temperature relative to the absolute melting point of a metal as a result of rapid diffusion of substitutional and interstitial elements. The addition of more than one solute element can lead to synergistic strengthening effects, as this and other strengthening mechanisms can all contribute to the resistance of a metal to deformation.

Ultrafine particles can also provide strengthening. A second phase is introduced at submicroscopic levels within each crystal grain of the metal. This may be done by a variety of phase-diagram reactions, the most common being precipitation. In this case the solid alloy is heated to a temperature at which the secondary elements used to produce fine second-phase particles dissolve in the solid metal — this is termed *solution heat treatment*. Then the metal is usually quenched (cooled rapidly) to an appropriate temperature (e.g., room temperature or ice brine temperature) and subsequently held at an elevated temperature for a specified "aging" time during which particles precipitate and grow in size at near atomic levels throughout the solid metal. Temperature, time, alloy composition, and prior cold work affect the size and distribution of second-phase particles. The combination of treatments can be quite complex, and recently "thermomechanical treatments" combining temperature, time, and dynamic working have resulted in substantial property improvements. Heat treatment can be performed by the user, but it is difficult to achieve the optimum properties obtained by a sophisticated metallurgical mill. The heat treatment can manipulate structure and properties to obtain maximum strength or impact resistance. When metal is to be cold worked, a "softening treatment" can be employed which provides low yield stress and high ductility. The difference between the "dead soft" and maximum strength conditions can be over an order of magnitude — a useful engineering property change.

Alternative surface diffusion methods such as nitriding and carburizing, which introduce particles for fracture and wear resistance, are presented in the subsection on metal surface treatments.

In the case of dispersion strengthening (hardening), the fine strengthening particles are a discontinuous second phase without atomic continuity with the matrix. The behavior of such particles is shown

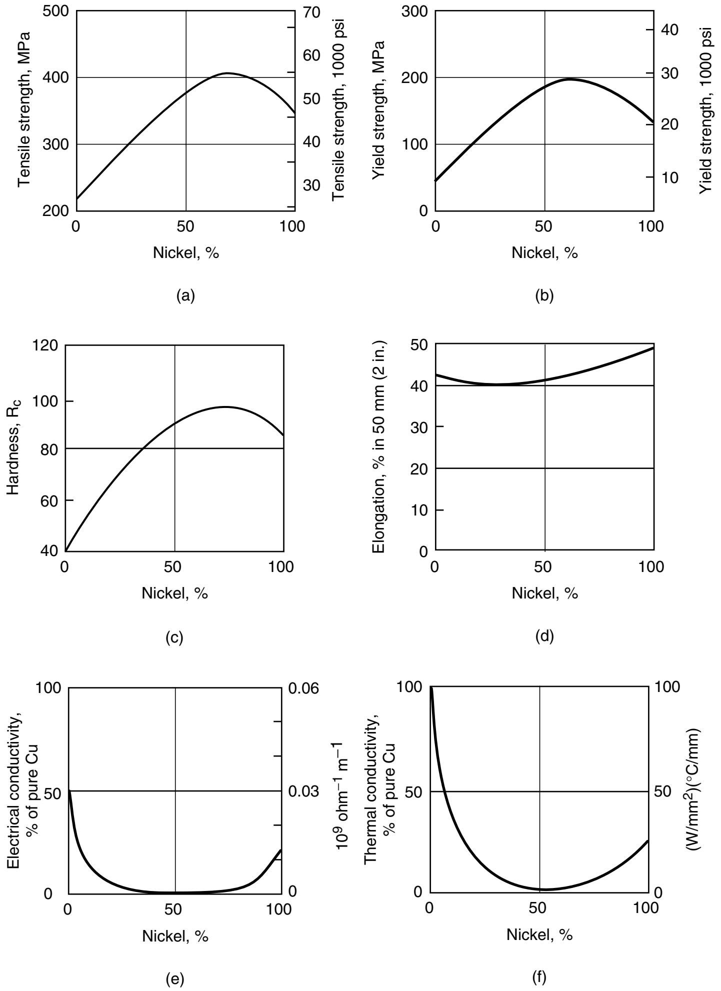

FIGURE 12.1.6 Variation in properties for copper–nickel random solid solution alloys. Note that over time at low temperature alloys (monel) may become nonrandom with significant strength increases.

schematically in Figure 12.1.7a as a function of increasing aging time or aging temperature (fixed time) which result in larger, more widely spaced dispersed-phase particles. Under stress, dislocations must move around (bypass) such particles, so that yield strength decreases with increased aging. Long aging times may be used to decrease yield strength ("soften") of the metal for fabrication. A short aging time, would be used for maximum strength. The dispersed phase can also provide some enhancement of ductility. A dispersion-strengthened metal for which the dispersed phase is stable at elevated temperatures can provide both high-temperature strength and creep resistance (subsection on high-temperature effects). Surface diffusion treatments usually produce dispersion hardening.

Precipitation strengthening (hardening) employs particles which have at least some atomic continuity with the matrix metal. Thus, when the metal is deformed, dislocations can either bypass or pass through (cut) the particles. The resulting behavior is shown in Figure 12.1.7b. As aging time or temperature increases (particles grow larger and more widely spaced), the yield stress increases to a maximum and then decreases. The maximum is termed *critically aged*, and when this designation is part of an alloy treatment, precipitation strengthening may be assumed. For fabrication by cold working, the lower-strength, higher-ductility *underaged* condition is usually employed. There are different possible combinations of thermal and mechanical treatment which will provide a maximum critical aging treatment.

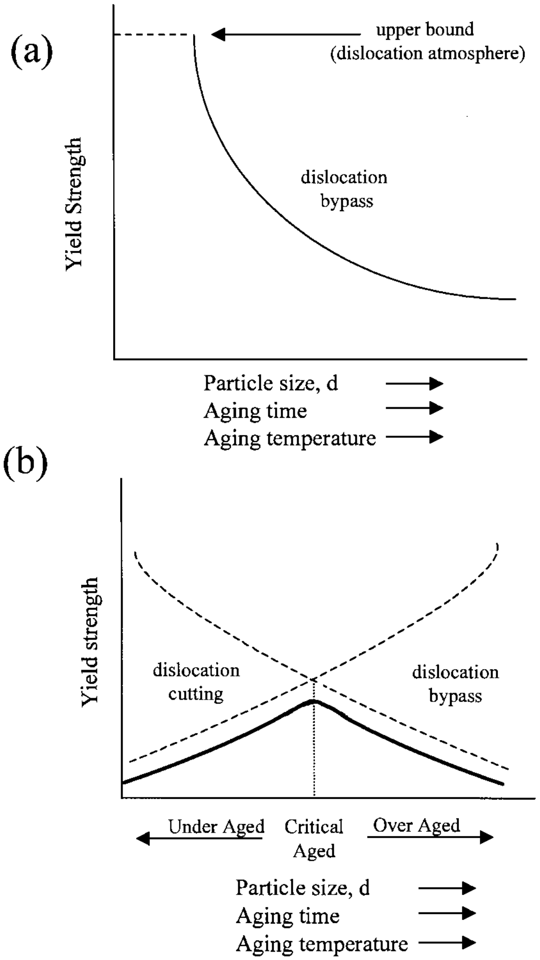

FIGURE 12.1.7 Effect of aging on dispersion- and precipitation-strengthened alloys for a fixed second–phase addition. (a) Dispersion strengthening: as aging time or temperature increases (dispersed phase particles larger and more separated), yield strength increases. A lower bound exists for near atomic size particles. (b) Precipitation hardening: two behaviors can occur giving a composite curve with a maximum at the critical aging time or temperature (optimum size and spacing of particles).

Usually the best optimum for strength is given in handbooks and data sheets. However, improved treatments may be available, particularly of the combined thermomechanical type.

Strengthening of Steels and Steel Heat Treatment

Steels, perhaps the most important of all engineering metals, are alloys of iron and carbon usually containing about 0.02 to 1.0 $^w/_o$ carbon. The binary Fe–C phase diagram is important in describing this behavior and is shown in Figure 12.1.8. This diagram shows what phases and structures will occur in quasi equilibrium at various carbon contents and temperatures (under atmospheric pressure). Steel forming and heat treatment center on the transformation from austenite, γ phase, at elevated temperature to ferrite (α phase) plus cementite (iron carbide, Fe_3C) below 727°C (1340°F), the Ac_1 temperature, a eutectoid transformation. If there are no other intentional alloying elements, the steel is a "plain carbon" steel and has an AISI (American Iron and Steel Institute) designation 1002 to 10100. The first two characters indicate that it is a plain carbon steel, while the latter characters indicate the "points" of

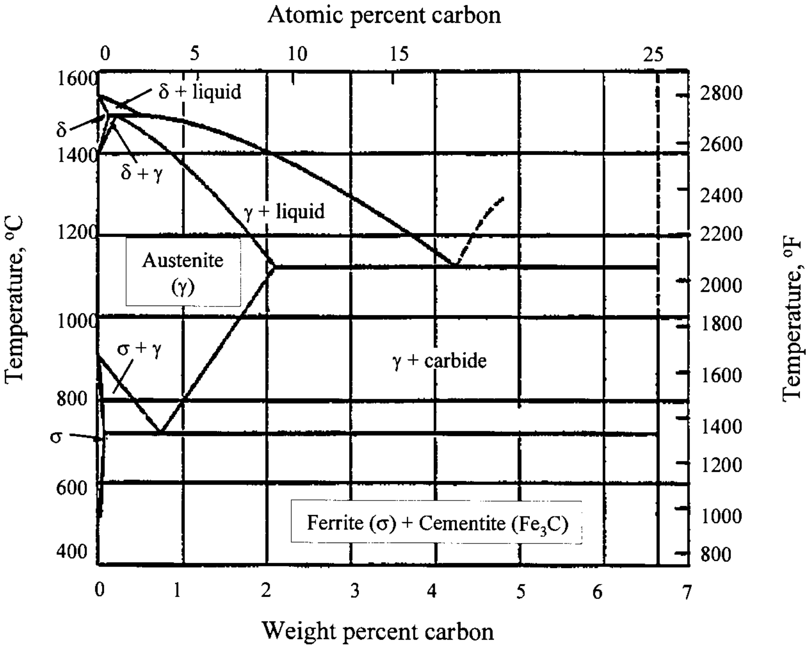

FIGURE 12.1.8 Iron–carbon phase diagram relevant for steel. The steel composition range is from about 0.02 to 1.00 $^{w}/_{o}$ carbon. Steel strengthening treatments require heating into the austenite region (above the Ac_3) and then quenching.

carbon.[1] Alloy steels, containing intentional alloying additions, also indicate the points of carbon by the last digits and together with the first digits provide a unique designation of alloy content. In the phase diagram (Figure 12.1.8) iron carbide (Fe_3C, cementite) is shown as the phase on the right. This is for all practical purposes correct, but the true thermodynamically stable phase is graphite (C) — relevant when the eutectic at 1148°C (2048°F) is used to produce cast irons (alloys greater than 2 $^{w}/_{o}$ C).

The solid-state eutectoid transformation is promoted by the magnetic effect in iron as nonmagnetic austenite transforms below the eutectoid (Ac_1) temperature to the two magnetic solid phases ferrite (iron with solid solution carbon) and cementite solid phase.[2] At the eutectoid composition, 0.77 $^{w}/_{o}$ carbon, the two phases form as a fine alternating set of plates (lamellae) termed *pearlite* because of their pearllike appearance in a metallographic microscope. This two-phase structure of metal (ferrite) and carbide (cementite) provides strength (very slowly cooled — about 65 ksi, 14% tensile elongation), which increases as a more-rapid quenching yields a finer pearlite microstructure (to about 120 ksi). As strength increases, ductility and fracture toughness decrease. With yet more rapid quenching and more local atomic diffusion, the austenite transforms to bainite, a phase of alternating carbon and iron-rich atomic planes. This has yet higher strength (to about 140 ksi) and lower ductility. When the metal is quenched so rapidly that carbon diffusion is prevented, the austenite becomes unstable. Below a critical temperature, the martensitic start temperature (M_s), the metal transforms spontaneously by shear to martensite. Full transformation occurs below the martensite finish temperature (M_f). The formation of this hard phase

---

[1] Plain carbon steels contain about 0.2 $^{w}/_{o}$ Si, 0.5 $^{w}/_{o}$ Mn, 0.02 $^{w}/_{o}$ P, and 0.02 $^{w}/_{o}$ S.

[2] It should be noted that austenitic stainless steels (300 and precipitation hardening, PH, series designations), nonmagnetic alloys with considerable chromium and nickel content to provide corrosion resistance, do not ordinarily transform from austenite to the lower-temperature phases. They are not intentionally alloyed with carbon, are not magnetic, and do not show the phase transformation strengthening mechanisms of steels. The term *steel* is something of a misnomer for these alloys.

introduces enormous microscopic deformation and residual stress. The strength is very much higher (about 300 ksi) but there is almost no ductility. This rapidly cooled material can spontaneously fail from "quench cracking," which results from residual stresses and the martensite acting as an internal flaw. To relieve stresses and provide some fracture toughness, martensitic steel is "tempered" at an intermediate temperature such as 500°C for about an hour to provide some ductility (about 7%) while sacrificing some strength (about 140 ksi). Tempering for shorter times or at lower temperatures can give intermediate properties. High-carbon steels are often used for cutting tools and forming dies because of their surface hardness and wear resistance. When a high-carbon steel (>0.7 $^w/_o$ C) requires fabrication at lower temperature, it may be held at a temperature just under the eutectoid for an extended time (e.g., for 1080 steel: 700°C, 1300°F — 100 hr) either after or without quenching to provide a soft condition (<60 ksi, 20% extension). A variety of different quenching temperatures, media, and procedures can be used to vary required combinations of the microstructures above and mechanical properties. The discussion above centered on eutectoid steel and holds for other high-carbon steels. Increasing carbon content favors the formation of martensite in steels, thereby providing increased strength, hardness, and wear resistance. However, such steels can be quite brittle.

At lower carbon content, "primary ferrite" forms (Figure 12.1.8) as the steel is quenched from above the boundary of austenitic (γ) region, the Ac_3. Subsequently, pearlite (ferrite and cementite), bainite, and/or martensite can form. Lower carbon content increases the amount of primary ferrite, a weaker/ductile phase, and decreases the tendency to form martensite, a stronger/brittle phase. The result is a more fracture tough, ductile ("safer") steel, but strength is lower. Such steels are also mechanically more forgiving if welded. Thus, a 1010 steel (0.10 $^w/_o$ C) might be used for applications where extreme "formability" and "weldability" are required, such as for car bodies and cans, while a 1020 steel (0.20 $^w/_o$ C) might be used for construction materials for which some increased strength is desired while maintaining safety. A medium-carbon steel such as a 1040 would be used when a balance of strength and toughness (and ease of welding) is needed.

In order to quench (and temper) steels continuous cooling transformation (CCT) diagrams are used such as that in Figure 12.1.9 for a 1040, medium-carbon steel. The steel is quenched from above the Ac_3. Vertical lines indicate quenching rates as shown in the lower left inset of the diagram. The cooling rate for the center of a round bar of given diameter quenched in air, oil, and water is given below the diagram. Solid lines on the diagram indicate percent transformation (start, 10%, 50%, 90%, finish of transformation), and a dotted line separates the region where primary ferrite forms from that of transformation to pearlite. The lower diagram shows the indentation hardness to be expected, as this and other mechanical behavior can be predicted from the CCT curve. As an example, the center of a 15 mm ($\sim ^1/_2$ in.) diameter bar quenched in air would be about 25% primary ferrite and 75% fine pearlite, with a Rockwell C hardness (HRC) of about 15. If quenched in oil, the bar center would be chiefly bainite with a small amount of martensite (HRC $\cong$ 25). The same bar quenched in water would be all martensite (HRC $\cong$ 55) before tempering. The transformation at other positions in the bar and for other engineering shapes (sheet, pipe, square rod, etc.) can be obtained from conversion curves.

It should be noted that layers in the steel closer to the quenched surface cool more quickly and are therefore displaced toward the left of the CCT diagram. There is a variation in structure and mechanical properties from the quenched surface to the center. One result is that the surface of the steel tends to be stronger, harder, and more wear resistant than the center. A steel beam undergoing bending has maximum strength at the near surface which undergoes the greatest stresses, while the center provides safety because of its relative fracture toughness and ductility. A thin knife edge cools quickly and can be resistant to deformation and wear, while the thick back prevents the blade from snapping in half when bent.

Many elements may be incorporated in steels to promote specific properties. Almost all common additions (other than cobalt) tend to promote strengthening by the formation of martensite (or bainite) instead of pearlite. When alloying additions tend to promote martensite throughout a thick section independent of cooling rate, the alloy is said to have *high hardenability.* Some elements such as chromium, molybdenum, and nickel also may help to provide high-temperature strength and environmental resistance. One class of alloys with relatively small alloying additions are termed *HSLA* steels (high strength,

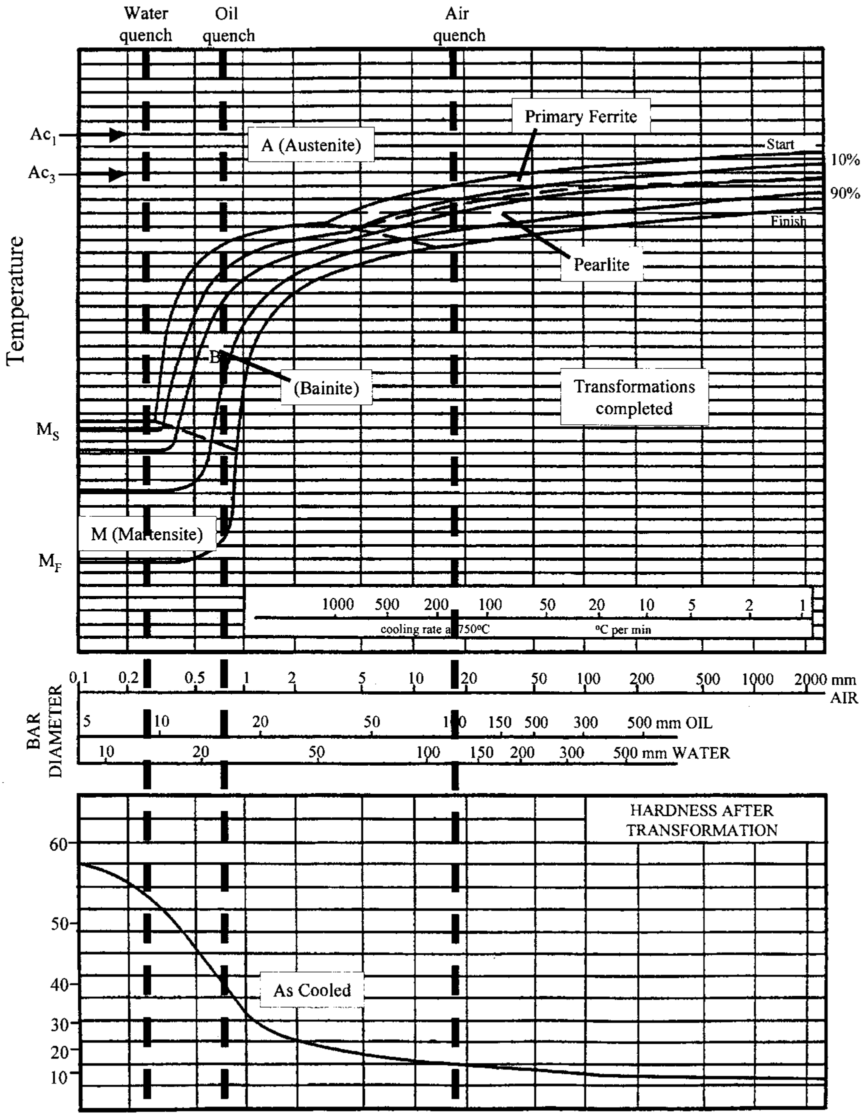

FIGURE 12.1.9 CCT diagram for 1040 steel. A 15-mm round bar air quenched from above the Ac_3 will be chiefly fine pearlite (ferrite and iron carbide, cementite) with about a quarter of the structure primary ferrite at the center. Quenching in oil will yield bainite with about 10% martensite. Water quenching will produce wholly martensite at the center. (After Atkins, M., *Atlas of Continuous Cooling Transformation Diagrams for Engineering Steels*, ASM International, Materials Park, OH, 1980.)

low alloy) and usually show somewhat superior mechanical properties to their plain carbon steel equivalents. As steel is alloyed, the relative cost increases substantially. A useful strategy in steel selection (and steels are usually the first engineering candidate on a cost basis) is to start by determining if a medium-carbon steel will do. If greater safety and formability are needed, a lower carbon content may be used (with slightly lower cost); alternatively, a higher-carbon steel would be chosen for greater strength and wear resistance. Heat treatment would be used to manipulate the properties. If plain carbon steels prove unsatisfactory, the HSLA steels would be the next candidate. For very demanding applications, environments, and long-term operations, specialty alloy steels would be selected insofar as they are cost-effective.

Fatigue

Fatigue is the repeated loading and unloading of metal due to direct load variation, eccentricity in a rotating shaft, or differential thermal expansion of a structure. Even substantially below the yield point (elastic limit) of a metal or alloy this repeated loading can lead to failure, usually measured in terms of the number of cycles (repeated load applications) to failure. Some studies have suggested that well over 80% of all mechanical failures of metal are attributable to fatigue.

High-stress, low-cycle fatigue usually occurs at stresses above the yield point and lifetimes are tens or hundreds of cycles (to about a thousand cycles). Failure occurs as a result of the accumulation of plastic deformation, that is, the area (energy) under the stress–strain curve (Figure 12.1.3). A simple lifetime predictive equation can be used to predict lifetime:

$$N \approx \left[\varepsilon_u / 2\varepsilon_{\mathrm{pf}}\right]^2 \tag{12.1.3}$$

where N is the number of cycles to failure, ε_u is total strain from the stress–strain curve, and $\varepsilon_{\mathrm{pf}}$ is the plastic strain amplitude in each fatigue cycle.

More commonly, metals are used well below their yield point and fail after many, many cycles of repeated loading in low-stress, high-cycle fatigue. There is microscopic, local plastic deformation (cold working) and vacancy generation (recovery effects) during such cyclic loading which result in "fatigue hardening" (strengthening) of unworked metal and "fatigue softening" of unworked metal. Some have even found success relieving residual stressed with a vibratory anneal. Early in the fatigue process surface flaws or in some cases severe internal flaws begin to propagate. The fatigue crack propagates in areas of high stress a small, usually submicroscopic, distance with each tensile loading. The propagation on each cycle frequently leaves identifiable marking on the failure surface termed *fatigue striations* which mark the progress of the subcritical crack. When the crack becomes so large that the fracture toughness criterion is exceeded (Equation 12.1.2), catastrophic overload failure occurs. When the future fatigue loading can be predicted and the cyclic crack propagation rate is known, fatigue cracks can be inspected or monitored in different applications such as aircraft structures and pressure vessels to decommission or replace parts before fatigue failure. This must be done cautiously because a change to a more aggressive (corrosive, oxidative, elevated temperature) environment can increase the crack propagation rate. If a harmonic resonance occurs in the metal part, vibratory maxima can cause premature fatigue failure. Harmonics can change as fatigue cracks propagate. Harmonic vibration can be prevented with vibratory (dynamic) design concepts and/or direct monitoring.

Figure 12.1.10 shows typical metal *S–N* curves (stress vs. number of cycles to failure) for a high-strength aluminum and for a titanium alloy. Note that the convention is to make stress the vertical axis and to plot the number of cycles to failure on a logarithmic scale. For high-stress, low-cycle fatigue ($<10^3$ cycles) the curve is flat and linear, consistent with the model of Equation12.1.3. For high cycle fatigue the lifetime is a rapidly varying function of stress until very low stresses (long lifetimes occur). The actual fatigue life varies statistically about the mean value shown in approximate proportion to the number of cycles to failure. These curves are for testing in ambient air. Fatigue life would be longer in an inert environment and may be shortened drastically in an aggressive environment. Iron- and titanium-based alloys, such as the example shown, usually have an "endurance limit," a stress below which lifetime is ostensibly infinite. In air, at room temperature, the endurance limit is about half the tensile strength for most iron and titanium alloys. Other metals appear to show no stress below which they last indefinitely. Therefore, a "fatigue limit" is designated — usually the stress at which the fatigue life is 10^8 cycles. This may be a long lifetime or not depending on the frequency of loading and engineering lifetime. The fatigue limit is generally about 0.3 times the tensile strength for metals with strengths below about 100 ksi (700 MPa). The factor is somewhat poorer for higher-strength metals. It is apparent that on a relative strength basis, iron- and titanium-based alloys are fatigue-resistant metals when compared with others. Dispersion-strengthened alloys have been seen to provide some lifetime advantage in fatigue.

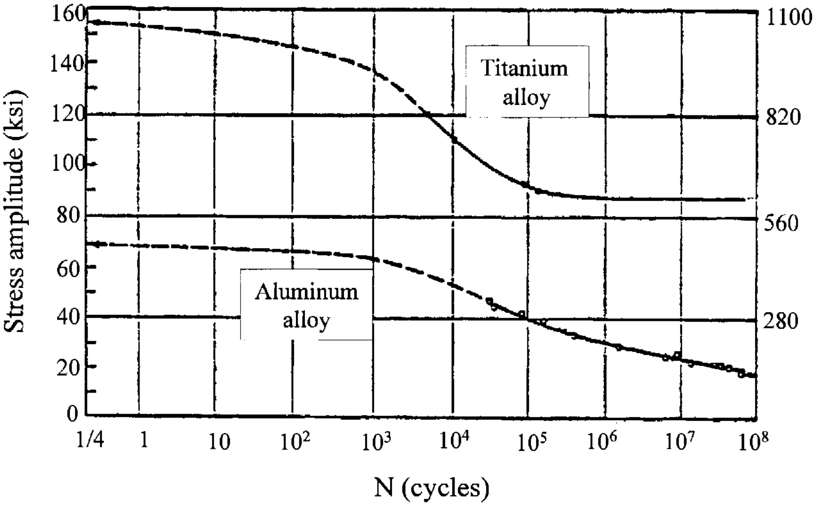

FIGURE 12.1.10 *S–N* (fatigue) curves for high-strength titanium (upper curve) and aluminum alloys. Note that titanium (and iron) alloys show an endurance limit, a stress below which the metal lasts indefinitely.

A number of mathematical relationships have been proposed to predict fatigue life, but none works with complete success and all require experimental data. Perhaps the most successful of the so-called fatigue "laws" are the "cumulative damage" laws. The simplest is Miner's law:

$$\sum i\left[n_i/N_i\right]=1 \tag{12.1.4}$$

where n_i is the number of cycles applied and N_i is the number of cycles for failure at a particular stress level, σ_i. The conceptual basis is that the number of fatigue cycles at a stress level uses up its relative fraction of total fatigue lifetime and may be correlated to fatigue crack propagation (striation spacing). Modifications of this model account for the order and relative magnitude of loads. Several techniques have met with partial success in increasing fatigue lifetime beyond that predicted by the cumulative damage models:

1. Coaxing — intermittent or continuous, superimposed vibration at very low stress,
2. Overstressing — intermittent or superimposed compressive loading,
3. Surface compression — intermittent shot peening or surface rolling,
4. Surface removal — chemical or mechanical surface polishing.

All but 1 are thought to close or eliminate fatigue cracks and surface damage. Coaxing has been said to introduce more of the vacancy-related recovery effects associated with fatigue.

High-Temperature Effects — Creep and Stress Rupture

Elevated temperature can cause a significant loss of strength and elastic modulus, so that a metal part may fail as a result of overheat even at loads which appear small at room temperature. High temperature is a relative matter and is usually judged as a fraction of the melting point measured on the absolute temperature scale. Thus, even moderate temperature excursions can be important for low-melting-point metals and alloys. As indicated in several sections above, many alloying and cold work strengthening methods depend upon heat treatment; an alloy can undergo metallurgical change due to overheat or to long-term holds at moderate temperatures and thereby alter properties significantly. Thus, the thermal

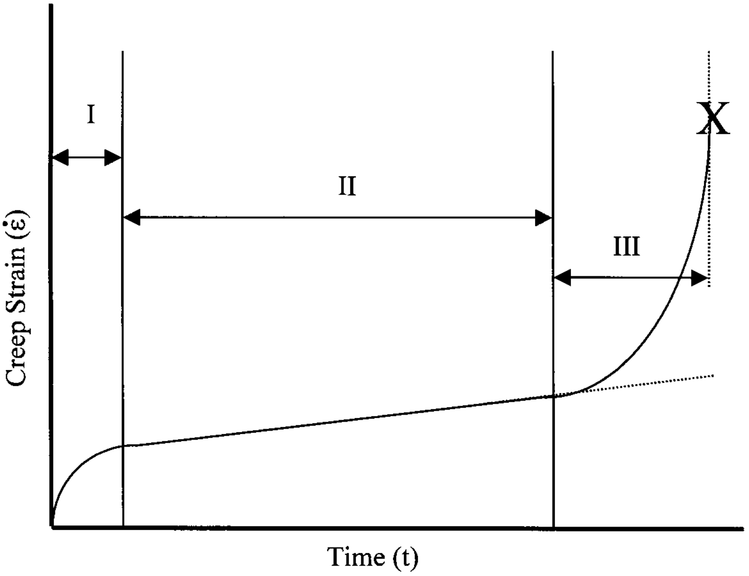

FIGURE 12.1.11 Schematic creep curve showing transient creep (I), steady-state creep (II), and tertiary creep (III). Note that the slope of the straight-line portion is the steady-state creep rate (minimum creep rate).

stability of the microstructure should be determined. For example, metallographic replica techniques have been developed for determining in the field if microstructure has coarsened, making the metal weak.

Creep deformation is the continued deformation of a metal under load at elevated temperature, usually at a design stress well below the yield point. While measurable creep can occur at low temperatures over very long times or at very high (compressive) loads, creep usually becomes of engineering importance above about two thirds the melting point (absolute) of an alloy. Thus, both lead, which creeps at room temperature, and tungsten, which creeps in an incandescent light bulb at white heat, require a mechanical support or creep-resistant alloying additions. Figure 12.1.11 shows a schematic creep curve plotting creep strain[3] vs. time, t, at a particular tensile load and temperature. After the immediate elastic strain ($t = 0$), "transient creep" occurs in Region I. At elevated temperature this usually follows a $t^{1/3}$ behavior (Andrade creep). The majority of the curve has a straight-line behavior (Region II) in which the extension with time is constant. The slope of this part of the curve is termed the *steady-state strain rate* or *minimum creep rate*. It is used to calculate the creep extension which could cause functional failure when dimensional tolerances are exceeded. A simplified predictive model is

$$\varepsilon' = A\sigma^m e^{-h/kT} \tag{12.1.5}$$

where ε' is the minimum creep rate, A is a constant, σ is the applied stress, m is the stress dependence exponent (often 4 to 8), h is the activation enthalpy for creep, and T the absolute temperature.

In Region III the creep rate accelerates as the metal necks down severely in a local area, thereby increasing the local stress. The steady-state rate would continue (dotted line) if the load were adjusted to give constant load at the minimum cross section. Since loads do not readjust to compensate for necking in real applications, a final accelerated stage can be experienced. For example, a blowout can occur in late creep of a pressurized high-temperature piping system. The time to failure is termed the *stress rupture lifetime*. Predictive models are developed from Equation (12.1.5) to provide lifetime information.

---

[3] If a constant extension is applied to an object, the force it generates will decline over time due to creep. This is called *stress relaxation* and can be treated in a similar way.

Lowering use temperature or applied stress decreases susceptibility to creep deformation and increases stress rupture lifetime. Frequently, a moderate temperature decrease is most effective in this regard. Higher-melting-point metals are more creep resistant, so that the refractory metals tungsten and molybdenum can be used but require an inert atmosphere or protective coating to prevent rapid oxidation. In air or other active atmosphere, niobium-, nickel-, titanium-, and iron-based alloys may be used for creep resistance. Dispersion hardening, particularly with a high-temperature stable phase, such as an oxide, nitride, or carbide, can confer a degree of creep resistance.

Corrosion and Environmental Effects

Corrosion usually involves the slow removal of metal due to chemical and/or electrochemical reaction with an environment. Most metallic corrosion involves a galvanic, that is, electrochemical, component and localized attack in the form of pitting, attack in crevices, grain boundary attack, selective leaching of one phase, and exfoliation (attack parallel to the surface causing layers to peel away). Uniform corrosion is less common and also less of a concern as long as the rate of material removal is gradual and predictable.

Galvanic corrosion requires a medium, usually liquid (water), often containing a specific agent which promotes corrosion, a potential difference, and a complete electrical circuit, as well as an anode and a cathode. The anode will be the attacked, corroded, portion of the system. One cause for potential corrosion is dissimilar metals. For example, the galvanic series in seawater shows magnesium alloys as most anodic followed by zinc, aluminum, iron, nickel, brass, and copper alloys which are progressively more cathodic. When coupled electrically, the more-anodic metal would be corroded and the more cathodic would promote corrosion. One way of preventing corrosion is to isolate with insulator material the metal parts electrically so that a circuit is interrupted. The surfaces can be isolated from the corroding medium with paint, protective metal, conversion coatings, or a corrosion inhibitor additive to the liquid. In this situation it is more important to coat the cathode (noncorroding metal) since it impresses corrosion on the anodic metal dependent on exposed area. When in doubt, all parts should be painted repeatedly to prevent pinholes. Other possibilities include cathodic protection with an impressed electrical counterpotential or use of a sacrificial anode which is attacked instead of the metal components. Some metals such as stainless steels and aluminum alloys provide protection via an oxide coating, a *passive film*, which will form under specific, controlled electrochemical conditions providing *anodic protection.*

Another source for an anode and cathode can be the solution itself. Differences in temperature, ion concentration, oxygen content, and pH can all lead to a potential difference which results in corrosion. Often corrosion occurs far more rapidly for a specific range of solution concentration — indeed, sometimes dilution may accelerate corrosive attack. An oxygen deficiency cell under dirt or in a crevice frequently causes attack at the resulting anode. Potential differences can also exist in the metal itself: between different phases, inclusions, or grain chemistries; between grains and grain boundaries; between surface films and metal; and between different grain orientations. Selective leaching such as dezincification of high-zinc brasses (Cu–Zn) is an example for composition differences, while exfoliation corrosion of aluminum alloys and sensitized stainless steel are examples of grain boundary attack. Cold-worked metal tends to be anodic to annealed material so that a heavily formed part of a metal part may corrode preferentially.

Another important environmental cause of failure is stress corrosion cracking (SCC). A combination of applied or residual tensile stress and environmental attack results in progressive slow crack propagation over a period of time. Eventually, the crack becomes critical in size (Equation 12.1.2) and catastrophic failure occurs. There need be no evidence of corrosion for SCC to occur. When the loading is of a cyclic nature the effect is termed *corrosion fatigue.* To prevent these long-term crack propagation effects the environment and/or the source of tensile load may be removed. Considerable effort has been made to identify an ion concentration below which stress corrosion cracking will not occur (e.g., Cl for austenitic stainless steels), but there may be no level for complete immunity, merely a practical maximum permissible level.

Hydrogen embrittlement and hydrogen cracking can occur in the presence of stress and a hydrogen source. Embrittlement results when hydrogen diffuses into the metal and/or acts on the crack tip altering the fracture toughness. Hydrogen cracking may be regarded as a special case of stress corrosion cracking. Either environmental effect can lead to catastrophic failure. The source of hydrogen can be an acid solution, hydrogen evolved during corrosion, electrochemical treatment (plating, electropolishing), or hydrocarbons. Often isolation from the hydrogen source is difficult because hydrogen diffuses quickly through most materials and barrier coatings. Glass coating has met with some success.

Metal Surface Treatments

A number of treatments are employed to strengthen the surface of steels and make them more resistant to failure or wear. Some of the techniques may also be applied to selected nonferrous alloys. Flame, induction, and laser hardening provide intense heat to the outer surface of a medium- or high-carbon (hardenable) steel bringing it into the austenitic region, above Ac_3 (see subsection on fatigue). The bulk of the metal is not heated so that the surface can then be quenched rapidly forming hardening phases and a compressive surface stress. This provides strength and wear resistance. Another surface-hardening technique is carburizing. This can also be used on steels with lower carbon content. The metal is exposed to a controlled balance of carbon monoxide and carbon dioxide or is packed in graphite. At elevated temperature (usually above the Ac_3) carbon diffuses into the surface, converting it to a high-carbon steel. The steel is then either quenched directly from the carburizing temperature or reaustenitized and quenched. The result is similar to flame hardening, but higher hardness and surface compression can be accomplished compared with flame hardening. The center of the piece, with much lower carbon content, can provide fracture toughness, ductility, and safety. Nitriding exposes steel containing appropriate alloying elements (chromium, aluminum, vanadium, …) to monatomic nitrogen in the form of cracked ammonia, cyanide, or high-energy dissociated nitrogen gas. This is done below the eutectoid (lower transformation) temperature. Dispersed-phase nitrides are formed as nitrogen diffuses into the surface which harden the surface without a need for further heat treatment. The effects of both carburizing and nitriding can be introduced by carbonitriding above the transformation temperature and quenching or nitrocarburizing below the transformation to austenite.

12.2 Polymers

James D. Idol and Richard L. Lehman

Introduction

Polymers constitute a wide range of materials which are derived at least in part from organic, usually petroleum-based, raw materials; they consist of repeating molecular units and have special properties obtained by engineering the form of the molecular structures. The term *polymer* is derived from Greek roots and means "having many parts," a term which aptly describes the infinite number of compounds which can be synthesized from a relatively limited number of monomer units. The term *plastic* is often used in describing polymers, although this term is not in current usage since it is a general descriptive which refers to the forming rheology of many polymers but is too general to accurately describe this group of materials.

Polymers are used as engineering materials in the neat form, i.e., as the pure material, or in combination with a large diversity of additives, both organic and inorganic. These additives may be, among others,

TABLE 12.2.1 Physical Properties of Polymers

Properties of Plastics	ρ (kg m^{-3})	Tensile Strength (N mm^{-2})	Elongation (%)	E (GN m^{-2})	BHN	Machinability
Thermoplastics						
PVC rigid	1330	48	200	3.4	20	Excellent
Polystyrene	1300	48	3	3.4	25	Fair
PTFE	2100	13	100	0.3	—	Excellent
Polypropylene	1200	27	200–700	1.3	10	Excellent
Nylon	1160	60	90	2.4	10	Excellent
Cellulose nitrate	1350	48	40	1.4	10	Excellent
Cellulose acetate	1300	40	10–60	1.4	12	Excellent
Acrylic (methacrylate)	1190	74	6	3.0	34	Excellent
Polyethylene (high density)	1450	20–30	20–100	0.7	2	Excellent
Thermosetting plastics						
Epoxy resin (glass filled)	1600–2000	68–200	4	20	38	Good
Melamine formaldehyde (fabric filled)	1800–2000	60–90	—	7	38	Fair

Phenol formaldehyde (mica filled)	1600–1900	38–50	0.5	17–35	36	Good
Acetals (glass filled)	1600	58–75	2–7	7	27	Good

Note: BHN = Brinell hardness number, ρ = density, E = Young's modulus.

plasticizers which reduce the rigidity or brittleness of the material, fillers which increase strength and load deflection behavior under load, or stabilizers which protect the polymer against ultraviolet radiation.

The following discussion will separate polymers into two groups, thermoplastic and thermosetting, based on the distinctly different thermal processing behavior of these two broad classes of polymers. Thermoplastic polymers soften when heated and can be reshaped, the new shape being retained on cooling. The process can be repeated many times by alternate heating and cooling with minimal degradation of the polymer structure. Thermosetting polymers (or thermosets) cannot be softened and reshaped by heating. They are plastic and moldable at some state of processing, but finally set to a rigid solid and cannot be resoftened. Thermosets are generally stronger and stiffer than thermoplastic.

Table 12.2.1 of this section gives an overview of the physical properties of the most commonly used industrial polymers. Table 12.2.2 provides an overview of properties such as chemical resistance, ease of machining, and compressive strength for thermoplastic and thermosetting plastics, while Table 12.2.3 is a selection guide for polymers by application. A detailed summary of polymer properties, including electrical properties, thermal properties, optical properties, and fabrication, is presented in Table 12.2.4.

Thermoplastic Polymers

Acetal and Polyacetal

These combine very high strength, good temperature and abrasion resistance, exceptional dimensional stability, and low coefficient of thermal expansion. They compete with nylon (but with many better properties) and with metal die castings (but are lighter). Chemical resistance is good except for strong acids. Typical applications are water-pump parts, pipe fittings, washing machines, car instrument housings, bearings, and gears.

Acrylics (Methylmethacrylate, PMMA)

These are noted for their optical clarity and are available as sheet, rod, tubings, etc., as Perspex (U.K.) and Plexiglas (U.S., Germany, etc.). They are hard and brittle and quite resistant to discoloring and, especially, weathering. Applications include outdoor display signs, optical lenses and prisms, transparent

TABLE 12.2.2 Relative Properties of Polymers

Material	Tensile Strength[a]	Compressive Strength[b]	Machining Properties	Chemical Resistance
Thermoplastics				
Nylon	E	G	E	G
PTFE	F	G	E	O
Polypropylene	F	F	E	E
Polystyrene	E	G	F	F
Rigid PVC	E	G	E	G
Flexible PVC	F	P	P	G
Thermosetting plastics				
Epoxy resin (glass-fiber filled)	O	E	G	E
Formaldehyde (asbestos filled)	G	G	F	G
Phenol formaldehye (Bakelite)	G	G	F	F
Polyester (glass-fiber filled)	E	G	G	F
Silicone (asbestos filled)	O	G	F	F

Note: O = outstanding, E = excellent, G = good, F = fair, P = poor.

[a] Tensile strength (typical): E = 55 $\mathrm{Nmm^{-2}}$; P = 21 $\mathrm{Nmm^{-2}}$.

[b] Compressive strength (typical): E = 210 $\mathrm{Nmm^{-2}}$; P = $\mathrm{Nmm^{-2}}$.

TABLE 12.2.3 Selection Guide for Polymers by Application

Application or Service	Properties Required	Suitable Plastics
Chemical and thermal equipment	Resistance to temperature extremes and to wide range of chemicals; minimum moisture absorption; fair to good strength	Fluorocarbons, chlorinated polyether, polyvinylidene fluoride, polypropylene, high-density polyethylene, and epoxy glass
Heavily stressed mechanical components	High-tensile plus high-impact strength; good fatigue resistance and stability at elevated temperatures; machinable or moldable to close tolerance	Nylons, TFE-filled acetals, polycarbonates, and fabric-filled phenolics
Electrostructural parts	Excellent electrical resistance in low to medium frequencies; high-strength and -impact properties; good fatigue and heat resistance; good dimensional stability at elevated temperatures	Allylics, alkyds, aminos, epoxies, phenolics, polycarbonates, polyesters, polyphenylene oxides, and silicones
Low-friction applications	Low coefficient of friction, even when nonlubricated; high resistance to abrasion, fair to good form stability and heat and corrosion resistance	Fluorocarbons (TFE and FEP), filled fluorocarbons (TFE), TFE fabrics, nylons, acetals, TFE-filled acetals, and high-density polyethylenes
Light-transmission components, glazing	Good light transmission in transparent or translucent colors; good to excellent formability and moldability; shatter resistance; fair to good tensile strength	Acrylics, polystyrenes, cellulose acetates, cellulose butyrates, ionomers, rigid vinyls, polycarbonates, and medium-impact styrenes
Housings, containers, ducts	Good to excellent impact strength and stiffness; good formability and moldability; moderate cost; good environmental resistance; fair to good tensile strength and dimensional stability	ABS, high-impact styrene, polypropylene, high-density polyethylene, cellulose acetate butyrate, modified acrylics, polyester–glass and epoxy–glass combinations

coverings, drafting instruments, reflectors, control knobs, baths, and washbasins. They are available in a wide range of transparent and opaque colors.

Acrylonitrile-Butadiene-Styrene (ABS)

This combination of three monomers gives a family of materials which are strong, stiff, and abrasion resistant with notable impact-resistance properties and ease of processing. The many applications include

Properties of Polymers [continued]

Chemical class	Polyketone							
	aliphatic thermoplastic							
	neat resin							
ELECTRICAL PROPERTIES								
D.C. resistivity, ohm-cm	103							
Dielectric constant, 60 cps	5-6							
Dielectric constant, 10^6 cps								
Dissipation factor, 60 cps								
Dissipation factor, 10^6 cps	0.04							
MECHANICAL PROPERTIES								
Modulus of elasticity, 10^3 psi	250							
Tensile strength, psi	>9000							
Ultimate elongation, %	300							
Yield stress, psi	9000							
Yield strain, %	2.2							
Rockwell hardness								
Notched Izod impact strength, ft lb/in.	4							
Specific gravity	1.24							
THERMAL PROPERTIES								
Burning rate								
Heat distortion, 264 psi. C	105-110							
Specific heat, cal/g								
Linear thermal expansion coefficient, 10^{-5}, C	9-11							
Maximum continuous service temperature, C								
CHEMICAL RESISTANCE								
Mineral acids, weak	Good							
Mineral acids, strong	Fair							
Oxidizing acids, concentrated	Fair							
Alkalies, weak	Good							
Alkalies, strong	Good							
Alcohols	Excellent							
Ketones	Excellent							
Esters	Excellent							
Hydrocarbons, aliphatic	Excellent							
Hydrocarbons, aromatic	Excellent							
Oils: vegetable, animal, mineral								
MISCELLANEOUS PROPERTIES								
Clarity	translucent							
Color	white crystals							
Refractive index, n_D								
FABRICATION								
Cl—calendering, Cs—casting, E—extrusion, F—hot forming or drawing, I—impregnation, MC—blow molding, MC—compression molding, MI—injection molding, S—spreading	E, MI							

pipes, refrigerator liners, car-instrument surrounds, radiator grills, telephones, boat shells, and radio and television parts. Available in medium, high, and very high impact grades.

Cellulosics

"Cellulose nitrate" is inflammable and has poor performance in heat and sunlight. Its uses are therefore limited. Cellulose acetate has good strength, stiffness, and hardness and can be made self-extinguishing. Glass-filled grades are made. Cellulose acetate-butyrate (CAB) has superior impact strength, dimensional stability, and service temperature range and can be weather stabilized. Cellulose proprionate (CP) is similar to CAB, but has better dimensional stability and can have higher strength and stiffness. Ethyl cellulose has better low-temperature strength and lower density than the others. Processing of cellulose plastics is by injection molding and vacuum forming. Applications include all types of moldings, electrical insulation, and toys.

Ethylene-Vinyl Acetate (EVA)

This material gives tough flexible moldings and extrusions suitable for a wide temperature range. The material may be stiffened by the use of fillers and is also specially formulated for adhesives. Applications include all types of moldings, disposable liners, shower curtains, gloves, inflatables, gaskets, and medical tubing. The material is competitive with polyvinyl chloride (PVC), polyethene, and synthetic rubbers, and is also used for adhesives and wax blends.

Fluorocarbons

This class of polymers, characterized by fluorine substitution, has outstanding chemical, thermal, and electrical properties and is characterized by the following four main classes of structures.

Polytetrafluoroethylene (PTFE), known commercially as Teflon or Fluon, is the best-known material and resists all known chemicals, weather, and heat, has an extremely low coefficient of friction, and is "non-stick." These materials are inert with good electrical properties. They are nontoxic, nonflammable, and have a working temperature range of –270 to 260°C. They may be glass filled for increased strength and rigidity. They do not melt and they must be formed by sintering of powders. Applications include chemical, mechanical, and electrical components, bearings (plain or filled with glass and/or bronze), tubing, and vessels for "aggressive" chemicals.

Fluoroethylenepropylene (FEP), unlike PTFE, can be processed on conventional molding machines and extruded, but thermal and chemical resistance properties are not quite as good.

Ethylenetetrafluoroethylene (ETFE) possess properties similar to but not as good as those of PTFE. However, the material exhibits a thermoplastic character similar to that of polyethylene which gives it a very desirable molding behavior.

Perfluoroalkoxy (PFA) is the fourth group of fluorinated polymers. These materials have the same excellent properties as PTFE, but the compound is melt processible and, therefore, suitable for linings for pumps, valves, pipes, and pipe fittings.

Ionomers

These thermoplastics are based on ethylene and have high melt strength, which makes them suitable for deep forming, blowing, and other similar forming processes. They are used for packaging, bottles, moldings for small components, tool handles, and trim. They have a high acceptance of fillers.

Polymethylpentene

Polymethylpentene (TPX) is a high-clarity resin with excellent chemical and electrical properties and the lowest density of all thermoplastics. It has the best resistance of all transparent plastics to distortion at high temperature — it compares well with acrylic for optical use, but has only 70% of its density. It is used for light covers, medical and chemical ware, high-frequency electrical insulation, cables, microwave oven parts, and radar components. It can withstand soft soldering temperatures.

Polyethylene Terephthalate

Polyethylene terephthalate (PETP) and modified versions thereof have high strength, rigidity, chemical and abrasion resistance, impact resistance in oriented form, and a low coefficient of friction. It is attacked by acetic acid and concentrated nitric and sulfuric acids. It is used for bearings, tire reinforcement, bottles, automotive parts, gears, and cams.

Polyamides (Nylons)

The polyamides are a family of thermoplastics, e.g., Nylon 6, Nylon 66, and Nylon 610, which are among the toughest engineering plastics with high vibration-damping capacity, abrasion resistance, inherent lubricity, and high load capacity for high-speed bearings. They have a low coefficient of friction and good flexibility. Pigment-stabilized types are not affected by ultraviolet radiation and chemical resistance is good. Unfilled nylon is prone to swelling due to moisture absorption. Nylon bearings may be filled with powdered molybdenum disulfide or graphite. Applications include bearings, electrical insulators, gears, wheels, screw fasteners, cams, latches, fuel lines, and rotary seals.

Polyethylene

Low-density polyethylene (orinally called *polythene*) is used for films, coatings, pipes, domestic moldings, cable sheathing, and electrical insulation. High-density polyethylene is used for larger moldings and is available in the form of sheet, tube, etc. Polyethylene is limited as an engineering material because of its low strength and hardness. It is attacked by many oxidizing chemical agents and some hydrocarbon solvents.

Polyketone, Aliphatic

Aliphatic polyketones are relatively strong, tough, ductile polymeric resins derived from equal proportions of ethylene and carbon monoxide with an additional few percent of higher olefin for property and processibility adjustment. Their physical, thermal, and mechanical properties are similar to polyamides and polyacetals. Mechanical properties are characterized by preservation of high levels of stiffness, toughness, and strength over a broad temperature range. Resistance to hydrolysis, swelling, and permeation provides broad chemical resistance. Relatively new in commercial supply, they find application in gears, machine components, and similar engineering applications. Tribological performance is very good, and in particular they have a low coefficient of friction and a low wear factor against steel. The electrical properties of the neat polyketone are typical of those of polar, semicrystalline thermoplastics.

Polyethersulfone

Polyethersulfone is a high-temperature engineering plastic — useful up to 180°C in general and some grades have continuous operating ratings as high as 200°C. It is resistant to most chemicals and may be extruded or injection molded to close tolerances. The properties are similar to those of nylons. Applications are as a replacement for glass for medical needs and food handling, circuit boards, general electrical components, and car parts requiring good mechanical properties and dimensional stability.

Polystyrene

This polymer is not very useful as an engineering material because of brittleness in unmodified forms, but it is well known for its use in toys, electrical insulation, refrigerator linings, packaging, and numerous commercial articles. It is available in unmodified form as a clear transparent resin and also in clear and opaque colors. High-impact forms are achieved by compounding with butadiene or other rubbery resins and heat-resistant forms are achieved by the use of fillers. Polystyrene can be stabilized against ultraviolet radiation and also can be made in expanded form for thermal insulation and filler products. It is attacked by many chemicals, notably aromatic hydrocarbon solvents, and by ultraviolet light.

Polysulfone

Polysulfone has properties similar to nylon, but these properties are retained up to 180°C compared with 120°C for nylon, which greatly expands the range of applications. Its optical clarity is good and its moisture absorption lower than that of nylon. Applications are as a replacement for glass for medical needs and chemistry equipment, circuit boards, and many electrical components.

Polyvinyl Chloride

This is one of the most widely used of all plastics. With the resin mixed with stabilizers, lubricants, fillers, pigments, and plasticizers, a wide range of properties is possible from flexible to hard types, in transparent, opaque, and colored forms. It is tough, strong, with good resistance to chemicals, good low-temperature characteristics and flame-retardant properties. PVC does not retain good mechanical performance above 80°C. It is used for electrical conduit and trunking, junction boxes, rainwater pipes and gutters, decorative profile extrusions, tanks, guards, ducts, etc.

Polycarbonate

Polycarbonate is an extremely tough thermoplastic with outstanding strength, dimensional stability, and electrical properties, high heat distortion temperature and low-temperature resistance (down to –100°C). It is available in transparent optical, translucent, and opaque grades (many colors). Polycarbonates have only fair resistance to chemicals as evidenced by the stress cracking caused by many solvents. The weathering tendencies can be stabilized against ultraviolet radiation by the use of proper additives. Polycarbonate compounds are used for injection moldings and extrusions for glazing panels, helmets, face shields, dashboards, window cranks, and gears. Polycarbonate is an important engineering plastic.

Polypropylene

Polypropylene is a low-density, hard, stiff, creep-resistant plastic with good resistance to chemicals, good wear resistance, low water absorption, and is relatively low cost. Polypropylene can be spun into filaments, converted into weaves, injection molded, and is commonly produced in a large variety of forms. Glass-filled polypropylene is widely used for its enhanced mechanical properties. It is used for food and chemical containers, domestic appliances, furniture, car parts, twine, toys, tubing, cable sheath, and bristles.

Polyphenylene Sulfide

Polyphenylene sulfide is a high-temperature plastic useful up to 260°C. Ambient temperature properties are similar or superior to those of nylon. It has good chemical resistance and is suitable for structural components subject to heat. Glass filler improves strength and enables very high heat resistance to 300°C. Uses are similar to those of nylon, but for higher temperatures.

Polyphenylene Oxide

This is a rigid engineering plastic similar to polysulfone in uses. It can be injection molded and has mechanical properties similar to those for nylon. It is used for automotive parts, domestic appliances, and parts requiring good dimensional stability. Frequently, the commercially available product is blended (or “alloyed”) with polystyrene which acts as a cost-effective extender.

Thermosetting Polymers

Alkyds

There are two main groups of alkyds: diallyphthalate (DAP) and diallylisopthalate (DIAP). These have good dimensional stability and heat resistance (service temperature 170°C; intermittent use 260°C), excellent electrical properties, good resistance to oils, fats, and most solvents, but limited resistance to strong acids and alkalis. The mechanical properties are improved by filling with glass or minerals. The main uses are for electrical components and encapsulation. A wide range of colors and fast-curing grades are available.

Amino Resins

These are based on formaldehyde reacted with urea or melamine and are formulated as coatings and adhesives for laminates, impregnated paper textiles, and molding powders. The resins are usually compounded with fillers of cellulose, wood flour, and/or other extenders. As composites with open-weave fabric, they are used for building panels. Uses also include domestic electrical appliances and electric light fittings; the melamine type is used for tableware. The strength is high enough for use in stressed components, but the material is brittle. Electrical, thermal, and self-extinguishing properties are good.

Epoxies

Epoxy resins are used extensively across industry as engineering polymers and as adhesives. They can be cold cured without pressure using a "hardener" or may be heat cured. Inert fillers, plasticizers, flexibilizers, and extenders give a wide range of properties from soft flexible to rigid solid materials. Bonding to nearly all materials, e.g., wood, metal, glass, is excellent as are the mechanical, electrical, and chemical properties. Epoxies are used in all branches of engineering, including large castings, electrical parts, circuit boards, potting, glass and carbon fiber structures, flooring, protective coatings, and adhesives. Importantly, they exhibit little or no shrinkage on cure.

Phenolics (Phenol Formaldehyde, PF)

PF, the original "Bakelite," is usually filled with 50 to 70% wood flour for molded nonstressed or lightly stressed parts. Other fillers are mica for electrical parts, asbestos for heat resistance, glass fiber for strength and electrical properties, nylon, and graphite. Phenolics represent one of the best polymers for low-creep applications. Moldings have good strength, good gloss, and good temperature range (150°C wood filled; intermittent use 220°C), but are rather brittle. Applications include electrical circuit board, gears, cams, and car brake linings (when filled with asbestos, glass, metal powder, etc.). The cost is low and the compressive strength very high.

Polyester

Polyester resins can be cured at room temperature with a hardener or alone at 70 to 150°C. It is used unfilled as a coating, for potting, encapsulation, linings, thread locking, castings, and industrial moldings. It is used mostly for glass-reinforced-plastic (GRP) moldings.

Polyimides

Polyimides are noted for their unusually high resistance to oxidation and service temperatures up to 250°C (400°C for intermittent use). The low coefficient of friction and high resistance to abrasion make them ideal for nonlubricated hearings. Graphite or molybdenum disulfide filling improves these properties. They are used for high-density insulating tape. Polyimides have high strength, low moisture absorption, and resist most chemicals, except strong alkalis and ammonia solutions.

Silicones

These may be cold or heat cured and are used for high-temperature laminates and electrical parts resistant to heat (heat distortion temperature 450°C). Unfilled and filled types are used for special-duty moldings. Organosilicones are used for surface coatings and as a superior adhesive between organic and nonorganic materials.

Laminated Polymer Structures

A wide range of composite structures are prepared from polymer resins combined with fibers. The reader is referred to Section 12.6 for a more extensive discussion of polymer composites. Laminated polymer structures consist of layers of fibrous material impregnated with and bonded together usually by a thermosetting resin to produce sheets, bars, rods, tubes, etc. The laminate may be "decorative" or "industrial," the latter being of load-bearing mechanical or electrical grade.

Phenolics

Phenolic plastics can be reinforced with paper, cotton fabric, asbestos paper fabric or felt, synthetic fabric, or wood flour. They are used for general-purpose mechanical and electrical parts. They have good mechanical and electrical properties.

Epoxies

These are used for high-performance mechanical and electrical duties. Fillers used are paper, cotton fabric, and glass fiber.

Tufnol

"Tufnol" is the trade name for a large range of sheet, rod, and tube materials using phenolic resin with paper and asbestos fabric and epoxy resin with glass or fabric.

Polyester

This is normally used with glass fabric (the cheapest) filler. The mechanical and electrical properties are inferior to those of epoxy. It can be rendered in self-colors.

Melamine

Fillers used for melamine are paper, cotton fabric, asbestos paper fabric, and glass fabric. Melamines have a hard, nonscratch surface, superior electrical properties, and can be rendered in self-colors. They are used for insulators, especially in wet and dirty conditions, and for decorative and industrial laminates.

Silicone

Silicone is used with asbestos paper and fabric and glass fabric fillers for high-temperature applications (250°C; intermittent use 300°C). It has excellent electrical but inferior mechanical properties.

Polyimide

Polyimide is most often used with glass fabric as filler. Polyimides have superior thermal and electrical properties with a service temperature similar to that for silicones but with two to three times the strength and flexibility.

Foam and Cellular Polymers

Thermoplastics

Polyurethane Foams. The "flexible" type is the one most used. It is "open cell" and used for upholstery, underlays, thermal and vibration insulation, and buoyancy. It can be generated *in situ*. The rigid type has "closed cells" and is used for sandwich construction, insulation, etc. Molded components may be made from rigid and semirigid types.

Expanded Polystyrene. This material is produced only in rigid form with closed cells. It can be formed *in situ*. The density is extremely low, as is the cost. Chemical resistance is low and the service temperature is only 70°C. It is used for packaging, thermal and acoustic insulation, and buoyancy applications.

Cellular Polyvinyl Chlorides. The low-density type is closed cell and flexible. It is used for sandwich structures, thermal insulation, gaskets, trim, to provide buoyancy, and for insulating clothing. The moderate- to high-density open-cell type is similar to latex rubber and is used as synthetic leather cloth. The rigid closed-cell type is used for structural parts, sandwich construction, thermal insulation, and buoyancy. Rigid open-cell PVC (microporous PVC) is used for filters and battery separators. In general, cellular PVC has high strength, good flame resistance, and is easy to work.

Polyethylene Foams. The flexible type is closed cell and has low density with good chemical resistance and color availability, but is a poor heat insulator and is costly. The flexible foams are used for vibration damping, packaging, and gaskets. The rigid type has high density and is used for filters and cable insulation. A structural type has a solid skin and a foam core.

Ethylene Vinyl Acetates. These are microcellular foams similar to microcellular rubber foam, but are much lighter with better chemical resistance and color possibilities.

Other Types. Other types of thermoplastics include cellular acetate, which is used as a core material in constructions; expanded acrylics, which have good physical properties, thermal insulation, and chemical resistance; expanded nylon (and expanded ABS), which are low-density, solid-skin constructions; expanded PVA, which has similar properties to expanded polystyrene; and expanded polypropylene, which gives high-density foams.

Thermosets

Phenolics. These can be formed *in situ*. They have good rigidity, thermal insulation, and high service temperature, but are brittle.

Urea Formaldehyde (UF) Foam. This is readily formed *in situ* and has good thermal insulation. It has open pores and is used for cavity-wall filling.

Expanded Epoxies. These have limited use because of their high cost. They give a uniform texture and good dimensional stability and are used for composite forms, e.g., with polystyrene beads.

Silicon Foams. These are rigid and brittle with a high service temperature (300°C; 400°C intermittent use). Their use is limited to high-temperature-resistant sandwich constructions. The flexible closed-cell type is costly but will operate up to 200°C and is used for high-temperature seals and gaskets.

Elastomers

Cellular Rubbers. There are three types: *sponge*, solid rubber blown to give an open-cell structure, *foam*, a liquid rubber expanded to form open or closed cells which is stiffer than sponge; and *expanded*, a solid rubber blown with mainly closed cells, also it is stiffer than sponge. Uses include gaskets, seals, thermal insulation, cushioning, shock absorption, sound and vibration damping, buoyancy, and sandwich constructions.

Elastomers

Elastomers, or rubbers, are essentially amorphous polymers with linear chain molecules with some cross-linking, which ensures elasticity and the return of the material to its original shape when a load is removed. They are characterized by large strains (typically 100%) under stress. The synthetic rubber styrene butadiene is the most-used elastomer, with natural rubber a close second. The following describes the commonly used elastomers and gives some applications and properties.

Natural Rubbers (Polyisoprene, NR)

These elastomers have high strength, flexibility, and resilience, but have poor resistance to fuels, oils, flame, and sunlight aging. They are more costly than synthetic rubbers, which often replace them. "Soft-rubber" contains 1 to 4% sulfur as a vulcanizer. Wear resistance is increased by inclusion of fillers such as carbon black, silicon dioxide, clay, and wood flour. "Hard rubber" may contain up to 25% sulfur. Applications include vehicle tires and tubes, seals, antivibration mountings, hoses, and belts. Full vulcanization of 45% produces ebonite. Shore hardness: 30 to 90. Temperature range: –55 to 82°C.

Synthetic Rubbers

Styrene Butadiene Rubbers (SBR, GRS, BUNAS). These are similar to natural rubbers in application, but are usually inferior in mechanical properties, although cheaper. They are used in car brake hydraulic systems and for hoses, belts, gaskets, and antivibration mountings. Shore hardness: 40 to 80. Temperature range: –50 to 82°C.

Butadiene Rubbers (Polynutadiene, BR). These are used as substitutes for natural rubber, but are generally inferior. They have similar applications as natural rubber. Shore hardness: 40 to 90. Temperature range: –100 to 93°C.

Butyl Rubbers (Isobutylene Isoprene, GR 1). These are extremely resistant to water, silicon fluids and grease, and gas permeation. They are used for puncture-proof tires, inner tubes, and vacuum seals. Shore hardness: 40 to 90. Temperature range: –45 to 150°C.

Nitrile Rubbers (Butadiene Acrylonitrile, BUNA, N.NBR). These have good physical properties and good resistance to fuels, oils, solvents, water, silicon fluids, and abrasion. They are used for O rings and other seals, petrol hoses, fuel-pump diaphragms, gaskets, and oil-resistant shoe soles. Shore hardness: 40 to 95. Temperature range: –55 to 82°C.

Neoprene Rubbers (Polychloroprene, Chloroprene). These are some of the best general-purpose synthetic rubbers. They have excellent resistance to weather aging, moderate resistance to oils, and good resistance to refrigerants and mild acids. Shore hardness: 40 to 95. Temperature range: –40 to 115°C.

Chlorosulfonated Polyethylene Rubbers (CSM). These have poor mechanical properties but good resistance to acids and heat with complete resistance to ozone. They are used in chemical plants, tank linings, and high-voltage insulation. Shore hardness: 45 to 100. Temperature range: –100 to 93°C.

Ethylene Propylene Rubbers (EP, FPM). These specialized rubbers are especially resistant to weather aging heat, many solvents, steam, hot water, dilute acids and alkalis, and ketones, but not petrol or mineral oils. They are used for conveyor belts, limited automotive applications, silicone fluid systems, and electrical insulation. Shore hardness: 40 to 90. Temperature hardness: –50 to 177°C.

Fluorocarbon Rubbers. These comprise a wide range of rubbers with excellent resistance to chemical attack, heat, acids, fuels, oils, aromatic compounds, etc. They have a high service temperature. They are particularly suitable for vacuum applications. Shore hardness: 60 to 90. Temperature hardness: –23 to 260°C.

Isoprenes (Polyisoprene, IR). These are chemically the same as natural rubber but are more costly. The properties and applications are similar to those of natural rubber. Shore hardness: 40 to 80. Temperature hardness: –50 to 82°C.

Polyacrylic Rubbers (ACM, ABR). This is a group of rubbers with properties midway between nitrile and fluorocarbon rubbers with excellent resistance to mineral oils, hypoid oils, and greases and good resistance to hot air and aging. The mechanical strength is low. They are often used for spark plug seals and transmission seals. Shore hardness: 40 to 90. Temperature hardness: –30 to 177°C.

Polysulfide Rubbers. These have poor physical properties and heat resistance, but good resistance to oils, solvents, and weathering and are impermeable to gases and moisture. They are used for caulking and sealing compounds and as a casting material. Shore hardness: 40 to 85. Temperature hardness: –50 to 121°C.

Polyurethane Rubbers. These have exceptional strength and tear and abrasion resistance (the best of all rubbers), low-temperature flexibility, and good resistance to fuels, hydrocarbons, ozone, and weather. Resistance to solutions of acids and alkalis, hot water, steam, glycol, and ketones is poor. They are used for wear-resistant applications such as floor coverings. Shore hardness: 35 to 100. Temperature hardness: –53 to 115°C.

Silicone Rubbers (SI). These have exceptionally high service-temperature ranges, but the mechanical properties and chemical resistance are poor. They cannot be used in applications which expose them to fuels, light mineral oils, or high-pressure steam. They are used for high- and low-temperature seals, high-temperature rotary seals, cable insulation, hydraulic seals, and aircraft door and canopy seals. Shore hardness: 30 to 90. Temperature hardness: –116 to 315°C (380°C for intermittent use).

Fluorosilicone Rubbers. These are similar to silicone rubbers but have better oil resistance and a lower temperature range. Shore hardness: 40 to 80. Temperature hardness: –64 to 204°C.

12.3 Adhesives

Richard L. Lehman

Introduction

Adhesives are substances capable of holding materials together in a useful manner by surface attachment. The principal attribute of adhesives is their ability to form strong bonds with surfaces of a wide range of materials and to retain bond strength under expected use conditions. Although most adhesives do not have excellent bulk properties and it is therefore important to keep adhesive films thin, some materials such as epoxies have bulk properties which qualify them as engineering materials and thus can be used in multifunctional applications.

Advantages and Limitations of Use

The principal advantages of adhesives are their ability to bond similar to dissimilar materials of different thickness; to enable the fabrication of complex shapes not feasible by other fastening means; to smooth external joint surfaces; to permit economic and rapid assembly; to distribute stresses uniformly over joined interfaces, to provide weight reduction in critical structures via the elimination of fasteners; to dampen vibrations; to prevent or reduce galvanic corrosion; and to provide thermal and electrical insulation.

The limitations of adhesives depend on the specific adhesive and application and may include the necessity of surface preparation, long curing times, service-temperature limitations, loss of properties during service, toxicity of flammability during assembly or use, and the tendency of many adhesives to creep under sustained load.

Classes of Adhesives

Thermoplastic adhesives are a general class of adhesives based upon long-chained polymeric structure, and are capable of being softened by the application of heat with subsequent hardening upon cooling (hot-melt adhesives). The softening process if reversible for numerous cycles, which facilitates assembly and disassembly of structures. Thermosetting adhesives are a general class of adhesives based upon cross-linked polymeric structures which develop strong bonds that cannot be reversibly broken once they are formed. Thus, the thermoset adhesives are incapable of being softened once solidified.

Thermoplastic and thermosetting adhesives are cured, a process often referred to as setting, by polymerization or solidification, by heat, catalysis, chemical reaction, free-radical activity, radiation, evaporation of solvent, or another process as governed by the chemical nature of the particular adhesive.

Elastomers are a special class of thermoplastic adhesive possessing the common quality of substantial flexibility or elasticity. Refer to Section 12.2 on polymers.

Anaerobic adhesives are a special class of thermoplastic adhesive, the polyacrylates, that set only in the absence of air (oxygen). The two basic types are (1) machinery — possessing shear strength only and (2) structural — possessing both tensile and shear strength.

Pressure-sensitive adhesives are permanently and aggressively tacky solids which form immediate bonds when two parts are brought together under pressure. They are available as films and tapes as well as hot-melt systems.

Performance of Adhesives

To obtain optimum mechanical performance of an adhesive, it is critical to select the proper compound for the target application. Table 12.3.1 illustrates compatibility of adhesives and five broad classes of common materials. Generally, for good adhesive bonds the chemistry of the adhesive must match or be similar to the surface energy, polarity, and/or chemistry of the material being bonded. The elastic modulus of the adhesive should not be greater than the bonded material.

Adhesives are used in two classes of application, those requiring only shear strength and those requiring structural properties, often tensile and shear strength. Table 12.3.2 provides a quick reference for some typical applications. A much more detailed summary and classification of adhesives is given in Table 12.3.3.

Table 12.3.3 presents a sample of a number of adhesives (with practical information) that are available from various sources. The table is adapted from the rather extensive one found in J. Shields, *Adhesives Handbook*, CRC Press, Boca Raton, FL, 1970. For other extensive lists of trade sources, the reader is referred to Charles V. Cagle, Ed., *Handbook of Adhesive Bonding*, McGraw-Hill, New York, 1972, and Lerner et al., *Adhesives Red Book*, Palmerton Publishing Co., New York, 1968.

TABLE 12.3.1 Relative Performance of Adhesive Resins

	Adherence To:					Resistance

TABLE 12.3.2 High-Performance Engineering and Machine Part Adhesives

Thread locking	• Anaerobic acrylic
Hub mounting	• Anaerobic acrylic — compatible materials or flow migration unimportant • Modified acrylic — large gaps or migration must be avoided • Epoxy — maximum strength at high temperatures
Bearing mounting	• Anaerobic acrylic — compatible materials necessary and flow into bearing area to be prevented • Modified acrylic — for lowest cost
Structural joining	• Epoxies and modified epoxies — for maximum strength (highest cost) • Acrylics — anaerobic or modified cyanacrylates
Gasketing	• Silicones — primarily anaerobic

TABLE 12.3.3 Properties and Applications of Adhesive Materials

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
			Animal		
Animal (hide)	Melted at 70–75°C; sets on cooling	<70	Paper, wood, textiles	Woodworking, carpet materials, paper, bookbinding	May be thinned with water
Animal (hide) + plasticizers	Applied as a melt at 60°C	<60	Paper, cellulosic materials	Bookbinding, stationery applications	Cures to permanent flexible film
Fish glue	1 hr at 20°C	<60	Wood, chipboard, paper	General-purpose for porous materials	Rapid setting; good flexibility, moderate resistance to water; high tack
Casein	Cold setting after 20 min standing period on mixing	<50	Timber with moisture content	Laminated timber arches and beams, plybox beams, and engineering timber work	Full bond strength developed after seasoning period of 48 hr
Casein + 60% latex	Cold setting after 20 min standing period on mixing	<60	Aluminum, wood, phenolic formaldehyde (rigid, leather, rubber)	Bonding of dissimilar materials to give flexible, water-resistant bond	Flexible
			Vegetable		
Dextrine	Air drying		Paper, cardboard, leather, wood, pottery	General-purpose glue for absorbent materials	Medium drying period of 2–3 hr
Dextrine–starch blend	Applied above 15°C air drying	<48	Cellulosic materials, cardboard, paper	Labeling, carton sealing, spiral-tube winding	Fast setting; may be diluted with water
Gum arabic	Cold setting	<50	Paper, cardboard	Stationery uses	Fast drying
			Mineral		
Silicate	8 hr at 20°C	10–430	Asbestos, magnesia	Lagging asbestos cloth on high-temperature insulation	Unsuitable where moisture; not recommended for glass or painted surfaces

TABLE 12.3.3 (continued) Properties and Applications of Adhesive Materials

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Silicate with china-clay filler	Dried at 80°C before exposure to heat	–180–1500	Asbestos, ceramics, brickwork, glass, silver, aluminum, steel (mild)–steel	General purpose cement for bonding refractory materials and metals; furnace repairs and gastight jointing of pipe work; heat-insulating materials	Resistant to oil, gasoline, and weak acids
Sodium silicate	Dried at 20–80°C before exposure to heat	0–850	Aluminum (foil), paper, wood–wood	Fabrication of corrugated fiber board; wood bonding, metal foil to paper lamination	Suitable for glass-to-stone bonding
Aluminum phosphate + silica filler	Dried $^{1}/_{2}$ hr at 20°C, then $^{1}/_{2}$ hr at 70°C + $^{1}/_{2}$ hr at 100°C + 1 hr at 200°C + 1 hr at 250°C; repeat for two overcoatings and finally cure at 1 hr at 350°C	<750	Steels (low-alloy), iron, brass, titanium, copper, aluminum	Strain-gauge attachment to heat-resistant metals; heater-element bonding	Particularly suited to heat-resistant steels where surface oxidation of metal at high temperatures is less detrimental to adhesion
Bitumen/latex emulsion	Dried in air to a tacky state	0–66	Cork, polystyrene (foam), polyvinyl chloride, concrete, asbestos	Lightweight thermal-insulation boards, and preformed sections to porous and nonporous surfaces; building applications	Not recommended for constructions operated below 0°C
			Elastomers		
Natural rubber	Air dried 20 min at 20°C and heat-cured 5 min at 140°C	<60	Rubber (styrene butadiene), rubber (latex), aluminum, cardboard, leather, cotton	Vulcanizing cement for rubber bonding to textiles and rubbers	May be thinned with toluene
Natural rubber in hydrocarbon solvent	Air dried 10 min at 20°C and heat-cured for 20 min at 150°C	<100	Hair (keratin), bristle, polyamide fiber	Brush-setting cement for natural- and synthetic-fiber materials	Resistant to solvents employed in oil, paint and varnish industries, can be nailed without splitting
Rubber latex	Air drying within 15 min	<60	Canvas, paper, fabrics, cellulosic materials	Bonding textiles, papers packaging materials; carpet bonding	Resistant to heat; should be protected from frosts, oils

TABLE 12.3.3 (continued) Properties and Applications of Adhesive Materials

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Chlorinated rubber in hydrocarbon solvents	Air dried 10 min at 20°C and contact bonded	–20–60	Polyvinyl chloride, acrylonitrile butadiene styrene, polystyrene, rubber, wood	General-purpose contact adhesive	Resistant to aging, water, oils, petroleum
Styrene–butadene rubber lattices	Air drying	–20–60	Polystyrene (foam), wood, hardboard, asbestos, brickwood	Bonding polystyrene foams to porous surface	—
Neoprene/nitrile rubbers in (?)	Dried 30 min in air and bonded under pressure; tacky	–20–60	Wood, linoleum, leather, paper, metals, nitrile rubbers, glass, fabrics	Cement for bonding synthetic rubbers to metals, woods, fabrics	May be thinned with ketones
Acrylonitrile rubber + phenolic resin	Primer air dried 60 min at 20°C, film cured 60 min at 175°C under pressure; pressure released on cooling at 50°C	–40–130	Aluminum (alloy)–aluminum to DTD 746	Metal bonding for structural applications at elevated temperatures	Subject to creep at 150°C for sustained loading
Polysulfide rubber in ketone solvent and catalyst	3 days at 25°C	–50–130, withstands higher temperatures for short periods	Metals	Sealant for fuel tanks and pressurized cabins in aircraft, where good weatherproof and waterproof properties are required	Resistant to gasoline, oil, hydraulic fluids, ester lubricants; moderate resistance to acids and alkalis
Silicone rubber	24 hr at 20°C (20% R.H.); full cure in 5 days	–65–260	Aluminum, titanium, steel (stainless), glass, cork, silicone rubber, cured rubber–aluminum, cured rubber–titanium, cured rubber–steel (stainless), aluminum–aluminum (2024 Alclad), cork–cork (phenolic bonded)	General-purpose bonding and scaling applications; adhesive/sealant for situations where material is expected to support considerable suspended weight; high-pressure exposure conditions	Resistant to weathering and moisture
Reclaim rubber	Contact bonded when tacky	<50	Fabric, leather, wood, glass, metals (primed)	General industrial adhesive for rubber, fabric, leather, porous materials	May be thinned with toluene
Polychloroprene	Air dried 10–20 min at 20°C	<60	Rubber, steel, wood, concrete	Bonding all types of rubber flooring to metals, woods, and masonry	Good heat resistance

TABLE 12.3.3 (continued) Properties and Applications of Adhesive Materials

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Modified polyurethane	3 hr at 18°C to 16 hr at –15°C	–80–110	Concrete, plaster, ceramics, glass, hardboards, wood, polyurethane (foam), phenol formaldehyde (foam), polystyrene (foam), copper, lead, steel, aluminum	Bonding to rigid and semirigid panels to irregular wall surfaces, wall cladding and floor laying; building industry applications	Foam remains flexible on aging even at elevated temperatures; will withstand a 12% movement
			Thermoplastic		
Nitrocellulose in ester solvent	Heat set 1 hr at 60°C after wet bonding	60	Paper, leather, textiles, silicon carbide, metals	Labeling, general bonding of inorganic materials including metals	Good resistance to mineral oils
Modified methyl cellulose	Dries in air	<50	Vinyl-coated paper, polystyrene foam	Heavy-duty adhesive; decorating paper and plastics	Contains fungicide to prevent biodeterioration
Ethylene vinyl acetate copolymer + resins	Film transfer at 70–80°C followed by bonding at 150–160°C	60, or 1 hr at 90	Cotton (duck)–cotton, resin rubber–leather, melamine laminate–plywood, steel (mild)–steel, acrylic (sheet) acrylic	Metals, laminated plastics, and textiles; fabrication of leather goods; lamination work	Good electrical insulation
Polyvinyl acetate	Rapid setting	<60	Paper, cardboard	Carton sealing in packaging industry	Resistant to water
Synthetic polymer blend	Applied as a melt at 177°C	<70	Paper, cardboard, polythene (coated materials)	Carton and paperbag sealing; packaging	—
Polychloroprene/resin blend in solvent	Air dried 10 min at 20°C and cured 4 days at 20°C to 7 hr at 75°C	<70	Chlorosulfonated polythene, polychloroprene fabrics, polyamide fabrics, leather, wood, textiles	Bonding synthetic rubbers and porous materials; primer for polyamide-coated fabrics such as nylon, terylene	—
Polychloroprene	Air dried 10–20 min at 20°C	—	Rubber, steel, wood, concrete	Bonding all types of rubber flooring to metals, woods, and masonry	Good heat resistance
Saturated polyester + isocyanate catalyst in ethyl acetate	Solvent evaporation and press cured at 40–80°C when tacky	—	Cellulose, cellulose acetate, polyolefins (treated film), polyvinyl chloride (rigid), paper, aluminum (foil), copper (foil)	Lamination of plastic films to themselves and metal foils for packaging industry, printed circuits	Resistant to heat, moisture, and many solvents

TABLE 12.3.3 (continued) Properties and Applications of Adhesive Materials

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Cyanoacrylate (anaerobic)	15 sec to 10 min at 20°C substrate dependent	Melts at 165	Steel–steel, steel–aluminum, aluminum–aluminum, butyl rubber–phenolic	Rapid assembly of metal, glass, plastics, rubber components	Anaerobic adhesive. Curing action is based on the rapid polymerization of the monomer under the influence of basic catalysts; absorbed outer layer on most surfaces suffices to initiate polymerization and brings about bonding
Polyacrylate resin (anaerobic)	3 min at 120°C to 45 min at 65°C or 7 days at 20°C	–55–95	Aluminum–aluminum	Assembly requirements requiring high resistance to impact or shock loading; metals, glass and thermosetting plastics	Anaerobic adhesive
			Thermosetting		
Urea formaldehyde	9 hr at 10°C to 1 hr at 21°C after mixing powder with water (22%)	<90	Wood, phenolic laminate	Wood gluing and bonding on plastic laminates to wood; plywood, chipboard manufacture; boat building and timber engineering	Excess glue may be removed with soapy water
Phenolic formaldehyde + catalyst PX-12	Cold acting	<100	Wood	Timber and similar porous materials for outdoor-exposure conditions; shop fascia panels	Good resistance to weathering and biodeterioration
Resorcinol formaldehyde + catalyst RXS-8	Cured at 16–80°C under pressure	<100	Wood, asbestos, aluminum, phenolic laminate, polystyrene (foam), polyvinyl chloride, polyamide (rigid)	Constructional laminates for marine craft; building and timber applications; aluminum–plywood bonding; laminated plastics	Recommended for severe outdoor-exposure conditions
Epoxy resin + catalyst	24–48 hr at 20°C to 20 min at 120°C	100	Steel, glass, polyester–glass fiber composite, aluminum–aluminum	General-purpose structural adhesive	—

TABLE 12.3.3 (continued) Properties and Applications of Adhesive Materials

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Epoxy resin + catalyst	8 hr at 24°C to 2 hr at 66°C to 45 min at 121°C	65	Steel, copper, zinc, silicon carbide, wood, masonry, polyester–glass fiber composite, aluminum–aluminum	Bonding of metals, glass, ceramics, and plastic composites	Cures to strong, durable bond
Epoxy + steel filler (80% w/w)	1–2 hr at 21°C	120	Iron, steel, aluminum, wood, concrete, ceramics, aluminum–aluminum	Industrial maintenance repairs; metallic tanks, pipes, valves, engine castings, castings	Good resistance to chemicals, oils, water
Epoxy + amine catalyst (ancamine LT)	2–7 days at 20°C for 33% w/w catalyst content	–5–60	Concrete stonework	Repair of concrete roads and stone surfaces	Excellent pigment-wetting properties; effective underwater and suited to applications under adverse wet or cold conditions
Epoxy resin (modified)	4–5 hr at 149°C to 20 min at 230°C to 7 min at 280°C	150	Aluminum, steel, ceramics	One-part structural adhesive for high-temperature applications	Good gap-filling properties for poorly fitting joints; resistant to weather, galvanic action
Epoxy	45 sec at 20°C	—	Gem stones, glass, steel, aluminum–aluminum	Rapid assembly of electronic components, instrument parts, printed circuits; stone setting in jewelry and as an alternative to soldering	—
Epoxy resin in solvent + catalyst	8 hr at 52°C to $^1/_2$ hr at 121°C	–270–371	Aluminum and magnesium alloys for elevated-temperature service	Strain gauges for cryogenic and elevated-temperature use; micromeasurement strain gauges	Cured material resists outgassing in high vacuum
Epoxy polyamide	8 hr at 20°C to 15 min at 100°C	100	Copper, lead, concrete, glass, wood, fiberglass, steel–steel aluminum–aluminum	Metals, ceramics, and plastics bonding; building and civil engineering applications	Resists water, acids, oils, greases

TABLE 12.3.3 (continued) Properties and Applications of Adhesive Materials

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Epoxy/polysulfide	24 hr at 20°C to 3 hr at 60°C to 20 min at 100°C	<120	Asbestos (rigid), ceramics, glass–fiber composites, carbon, polytetrafluoroethylene (treated), polyester (film), polystyrene (treated), rubber (treated), copper (treated), tungsten carbide, magnesium alloys, aluminum–aluminum, steel (stainless)–steel	Cold-setting adhesive especially suitable for bonding materials with differing expansion properties	Cures to flexible material; resistant to water, petroleum, alkalis, and mild acids
Phenol furfural + acid catalyst	2 days at 21°C	90–140	Alumina, carbon (graphite)	Formulation of chemically resistant cements; bedding and joining chemically resistant ceramic tiles	Extremely resistant to abrasion and heat
			Pressure-sensitive		
	Heated by air drying for several hours or 15–30 min at 210°F	—	Teflon–Teflon, Teflon–metal	—	Good resistance to acids and alkalis; excellent electrical properties
			Miscellaneous		
Ceramic-based	Dried for 1/2 hr at 77°C and cured 1/2 hr at 200°C + 1 hr at 250°C; postcured, 1 hr at 350°C	816	Metals	Strain gauges, temperature sensors for elevated-temperature work	—

12.4 Wood

Daniel J. Strange

Definition

Wood is the structural component of a tree. It is composed of dead cells which were originally formed near the cambium (just beneath the bark). As the tree grows, the cambium moves outward, leaving the dead cells behind to serve as structure.

The two broad classifications for types of wood and softwoods and hardwoods. Softwoods come from conifers while hardwoods come from deciduous trees, and as the name implies softwoods are generally softer and hence weaker and with lower elastic modulus than hardwoods, although this generalization is not universally true.

The wood closest to the bark is called sapwood, and this layer extends about an inch into the tree. Although most of the cells in this layer are dead, this is the layer which transports moisture to the rest of the tree by capillary action. Beneath the sapwood layer is the heartwood, which is almost totally inactive except to provide structural support.

Composition

Wood is a fibrous cellular material with the cell walls composed primarily of cellulose, hemicellulose, and lignin. Cellulose is a linear polymer of glucose units and is the single most common organic chemical in nature. It accounts for roughly 40 to 50% of the wood by weight. Hemicellulose is a modified form of cellulose comprising approximately 30% of the cell wall whose structure can vary depending upon the exact type of wood. Lignin is a complex three-dimensional phenolic polymer which composes 20 to 30% of the structure of the wood. The rest of the weight of the wood is composed primarily of extraneous extractive substances which reside within the cellular structure and affect properties such as specific gravity, moisture absorption, and durability.

Variations in the compositions, structures, and volumes of these four components can have dramatic effects on the properties of the wood. These properties are relatively constant within a species, although growing conditions can have a significant influence.

Mechanical Properties

The properties of wood can vary substantially depending upon moisture content. "Green" wood, wood taken directly from a living tree with associated high moisture level, is significantly weaker (lower Young's modulus, tensile strength, and compressive strength) than oven-dried wood. Typical ratios of dry to green wood strength properties vary from 1.2 to 1.8.

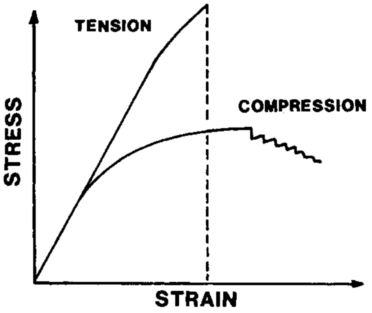

FIGURE 12.4.1 Stress–strain behavior of wood in tension and compression. Stress–strain curves for wood in tension and compression parallel to grain. Signs of stress and strain have been ignored so that both may be plotted together. Note particularly the difference in strength and in the extent of the nonlinear deformation prior to maximum stress. (From Wangaard, F.F., Ed., *Wood: Its Structure and Properties,* The Pennsylvania State University, University Park, 1981, 250.)

The failure modes of wood are more complex than one might expect. Because wood is essentially a composite material, it does not follow Hooke's law at high stresses but instead exhibits viscoelastic behavior. Figure 12.4.1 shows typical stress–strain curves for wood in tension and compression. At very high stresses, creep can occur. Wood is strongest in tension parallel to the grain, on the order of 100 MPa for a typical softwood. Perpendicular to the grain this value drops to about 4 MPa. In compression the strength values are approximately half the tension values, due to the collapse of the cellular structure and buckling of the wood fibers.

There are three principal shear failure modes in wood, six if one distinguishes between the radial and tangential directions. These modes are shear perpendicular to grain, shear parallel to grain, and rolling shear. Rolling shear occurs when the failure plane is parallel to the grain but the sliding direction is perpendicular to the grain, hence the fibers "roll" over each other. Wood is strongest when the shear is perpendicular to the grain, and weakest in rolling shear.

Decay Resistance

Totally dry wood does not decay. Furthermore, wood kept completely submerged will not decay significantly. Wood decays most rapidly in warm, humid, low-altitude areas. Some species of wood are more decay resistant than others as a result of the presence of extractives. White oak, walnut, cherry, cedar, and yew are examples of highly decay-resistant woods. Pines, willows, elms, beeches, and spruces are examples of low decay-resistant woods.

Composites

By gluing wood plies, chips, fibers, or pulp together a composite material can be formed which has more isotropic and homogenous properties than regular timber. In addition, this technique creates a strong and durable product out of wood unsuitable for timber. In general, wood composites homogenize the extreme anisotropy of timber into a nearly isotropic material whose properties are an average of the properties in each direction of the original timber. Table 12.4.1 classifies the various wood composites based upon the constitutive particle and the binder.

The most common wood composite is paper. Paper is made from pulped and chemically treated cellulose fibers, which is then rolled into sheets, pressed, and dried. There is no glue involved, as the microfibrils of the cellulose interlock and form hydrogen bonds. Fiberboard is similar to paper, only thicker (by an arbitrary value, typically 0.012 in.) and with larger fiber bundles. *Hardboard* simply refers to a high-density fiberboard.

TABLE 12.4.1 Allowable Stresses for Plywood (Stresses in MPa)

Type of Stress	Species Group of Face Ply	Grade Stress Level S-1 Wet	S-1 Dry	S-2 Wet	S-2 Dry	S-3 Dry Only
Tension in plane of plies (at 45° to face use 1/6 value)	1	9.86	13.79	8.20	11.38	11.38
	2,3	6.76	9.65	5.65	8.27	8.27
	4	6.48	9.17	5.38	7.65	7.65
Compression in plane of plies (at 45° to face use 1/3 value)	1	6.69	11.31	6.21	10.62	10.62
	2	5.03	8.27	4.69	7.58	7.58
	3	4.21	7.31	4.00	6.83	6.83
	4	4.21	6.89	4.00	6.55	6.55
Shear in plane perpendicular to plies (45° use 2 × value)	1	1.41	1.72	1.41	1.72	1.45
	2,3	1.10	1.28	1.10	1.28	1.10
	4	1.00	1.21	1.00	1.21	1.07
Shear, rolling, in the plane of plies (at 45° to face grain use $1\frac{1}{3}$ value)	Marine and Structural I	0.43	0.52	0.43	0.52	—
	Structural II and 2.4.1	0.34	0.39	0.34	0.39	0.38
	All Other	0.30	0.37	0.30	0.37	0.33
Modulus of rigidity (shear in plane perpendicular to plies)	1	480	620	480	620	570
	2	410	520	410	520	470
	3	350	410	350	410	380
	4	310	350	310	350	310
Bearing (on face) (perpendicular to plane of plies)	1	1.45	2.34	1.45	2.34	2.34
	2,3	0.93	1.45	0.93	1.45	1.45
	4	0.72	1.10	0.72	1.10	1.10
Modulus of elasticity in bending in plane of plies (face grain parallel or ⊥ to span)	1	10,300	12,400	10,300	12,400	12,400
	2	9,000	10,300	9,000	10,300	10,300
	3	7,600	8,300	7,600	8,300	8,300
	4	6,200	6,900	6,200	6,900	6,900

Adapted from American Plywood Association, Plywood Design Specifications, 1976.

Wood chips and/or sawdust pressed and glued together is referred to as *particleboard*. Typically, the chips range in size from 10 to 300 mm long and are in the form of flakes or fibers. Particleboard is effectively isotropic, easily machineable, and inexpensive. It is often used in furniture and for floor underlayment. When larger wood chips are used the product is referred to as *flakeboard*.

Plywood is created by layering plies of radial-cut wood. Typically, the plies are oriented at 90° to each other, which results in a strong material when the stress in parallel or perpendicular to the grain of the face plies, but a lesser strength at any other angle. Some design strength specifications of plywood are given in Table 12.4.2. Plywood makes efficient use of timber due to its radial cut, minimizes the effects of imperfections, resists warping, and can be formed into large sheets. Plywood is also less expensive than clear lumber.

TABLE 12.4.2 Classification of Wood Composites

Material	Constitutive Particle	Binder
Wood flour molding	Wood flour	Plastic; synthetic resin
Fiber-reinforced plastic	Fiber	Plastic
Paper	Fiber segment; fiber	Cellulose; hemicellulose; synthetic resin
Fiberboard	Fiber segment; fiber; fiber bundle	Lignin; synthetic resin
Particleboard	Splinter; chip; flake; planer shaving	Synthetic resin
Plywood	Veneer	Synthetic resin; natural glue
Laminated wood	Lumber	Synthetic resin; natural glue; mechanical connector
Solid wood	Single fiber or earlywood–latewood and wood ray, etc.	Lignin; hemicellulose

The reader is referred to Table C.14 in the Appendix for an overview of the physical properties and uses of American woods. The table also contains recommendations for appropriate applications. Table E.1 in the Appendix gives nominal sizes for lumber and timber, as well as allowable stresses in tension and compression and moduli of elasticity of various kinds of woods.

12.5 Portland Cement Concrete

Steven H. Kosmatka

Introduction

Portland cement concrete is a simple material in appearance with a very complex internal nature. In contrast to its internal complexity, versatility, durability, and economy of concrete have made it the most-used construction material in the world. This can be seen in the variety of structures it is used in, from highways and bridges to buildings and dams.

Concrete is a mixture of portland cement, water, and aggregates, with or without admixtures. The portland cement and water form a paste that hardens as a result of a chemical reaction between the cement and water. The paste acts as a glue, binding the aggregates (sand and gravel or crushed stone) into a solid rocklike mass. The quality of the paste and the aggregates dictate the engineering properties of this construction material. Paste qualities are directly related to the amount of water used in relation to the amount of cement. The less water that is used, the better the quality of the concrete. Reduced water content results in improved strength and durability and in reduced permeability and shrinkage. As the fine and coarse aggregates make up 60 to 75% of the total volume of the concrete (Figure 12.5.1), their selection is important. The aggregates must have adequate strength and resistance to exposure conditions and must be durable.

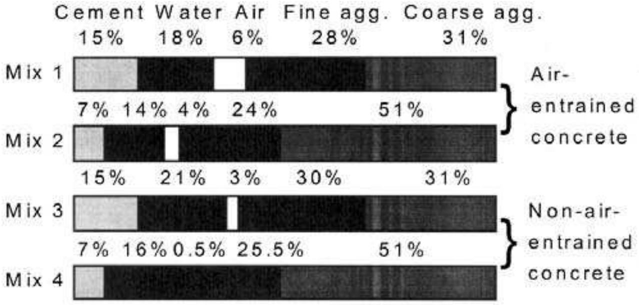

FIGURE 12.5.1 Range of proportions of materials used in concrete. (From *Design and Control of Concrete Mixtures,* EB001, Portland Cement Association, Skokie, IL, 1992. With permission.)

Fresh Concrete Properties

Freshly mixed concrete should be in a semifluid state capable of being molded by hand or mechanical means. All the particles of sand and coarse aggregate are encased and held in suspension. The ingredients should not segregate or separate during transport or handling. After the concrete hardens, it becomes a homogeneous mixture of all the components. Concrete of plastic consistency should not crumble, but flow sluggishly without segregation.

Concrete must be consolidated to form a homogeneous mass without the presence of large voids to achieve the desired strength and durability of the construction material. Internal and external vibration of concrete using vibrators allows stiff, slow-slump mixtures to be properly densified. The use of mechanical vibration provides an economical, practical method to quickly consolidate concrete without detrimentally affecting its properties.

Hardened Concrete Properties

Strength

Concrete gains strength by the reaction between cement and water — called hydration. Portland cement is primarily a calcium silicate cement. The calcium silicate combines with water and forms calcium silicate hydrate, which is responsible for the primary engineering properties of concrete, such as setting, hardening, strength, and dimensional stability. The compressive strength of concrete increases with age as long as an appropriate moisture content and temperature are available. This is illustrated in Figure 12.5.2. Compressive strength is usually specified at the age of 28 days; however, depending on the project, ages of 3 and 7 days can also be specified. For general-use concrete, a 28-day compressive strength between 20 and 40 MPa (3000 and 6000 psi) is used. 28 MPa (4000 psi) is most common. Higher-strength concrete, 50 to 140 MPa (7000 to 20,000 psi), is used in special applications to minimize structural dimensions, increase abrasion resistance and durability, and minimize creep (long-term deformation).

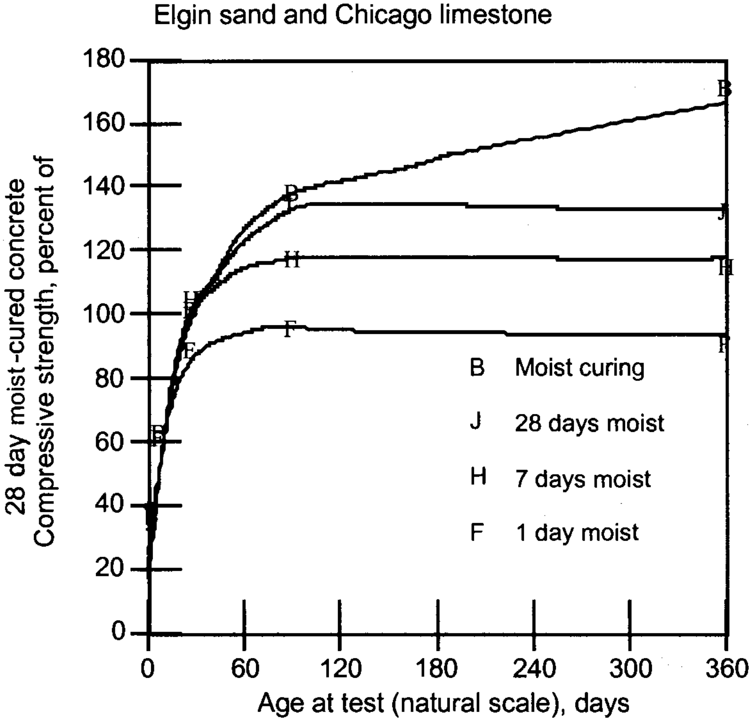

FIGURE 12.5.2 Concrete strength increases with age as long as moisture and a favorable temperature are present.

TABLE 12.5.1 Typical Properties of Normal-Strength Portland Cement Concrete

Compressive strength	20–40 MPa (3000–6000 psi)
Flexural strength	3–5 MPa (400–700 psi)
Tensile strength	2–5 MPa (300–700 psi)
Modulus of elasticity	14,000–41,000 MPa (2–6 million psi)
Permeability	1×10^{-10} cm/sec
Coefficient of thermal expansion	10^{-5}/°C (5.5×10^{-6}/°F)
Drying shrinkage	$4–8 \times 10^{-4}$
Drying shrinkage of reinforced concrete	$2–3 \times 10^{-4}$
Poisson's ratio	0.20–0.21
Shear strain	6000–17,000 MPa (1–3 million psi)
Density	2240–2400 kg/m^3 (140–150 lb/ft^3)

Increase in strength with age continues as long as any unhydrated cement is still present, the relative humidity in the concrete is approximately 80% or higher, and the concrete temperature is favorable. In order to maintain this increase in strength, concrete must be properly cured. Curing means that not only will a favorable temperature be present, but also moisture loss will not be permitted or extra water will be provided at the surface.

The compressive strength of concrete is directly related to the water/cement ratio. A decrease in water/cement ratio results in higher strength. Concrete achieves about 70 to 75% of its 28-day strength in 7 days. Although concrete is very strong in compression, it is weak in tensile strength. Tensile strength is about 8 to 12% of the compressive strength. Flexural strength is 0.7 to 0.8 times (for English units 5 to 7.5 times) the square root of the compressive strength. Shear strength is about 20% of the compressive strength. Modulus of elasticity ranges from 14,000 to 41,000 MPa and can be estimated as 5000 times the square root of the compressive strength (2 to 6 million psi or 57,000 times the square root of the compressive strength in English units). Refer to Table 12.5.1 to Table 12.5.3.

Density

Normal-weight concrete has a density of 2240 to 2400 kg/m^3 (140 to 150 lb/ft^3). The density of concrete varies with the relative density of the aggregate, the amount of air present in the paste, and the amount of water and cement in the mixture.

Permeability

Concrete permeability is a function of the permeability of the paste and aggregate and the interface between them. Decreased permeability improves the resistance of concrete to saturation, sulfate attack, chemical attack, and chloride penetration. Paste permeability has the greatest influence on concrete permeability. Paste permeability is directly related to the water/cement ratio and the degree of hydration or length of moist curing. A low water cement ratio and an adequate moist-curing period result in concrete with low permeability (Figure 12.5.3). The water permeability of mature, good-quality concrete, is approximately 1×10^{-10} cm/sec.

Abrasion Resistance

Abrasion resistance is directly related to the compressive strength of the concrete. The type of aggregate and the surface finish also have a strong influence on abrasion resistance. A hard aggregate, such as a granite, would provide more abrasion resistance than a soft limestone aggregate.

Volume Change and Crack Control

Concrete changes slightly in volume for various reasons. Understanding the nature of these changes is useful in planning concrete work and preventing cracks from forming. If concrete is free to move, normal volume changes would have very little consequence; but since concrete in service is usually restrained by foundations, subgrades, reinforcement, or connecting elements, significant stresses can develop. As the concrete shrinks, tensile stresses develop that can exceed the tensile strength of the concrete, resulting in crack formation.

The primary factors affecting volume change are temperature and moisture changes. Concrete expands slightly as temperature rises and contracts as temperature falls. The average value for the coefficient of thermal expansion of concrete is about 1.0×10^{-5}/°C (5.5×10^{-6}/°F). This amounts to a length change of 5 mm for a 10-m length (0.66 in. for 100 ft) of concrete subjected to a rise or fall of 50°C (100°F). The thermal coefficient of expansion for steel is about 1.2×10^{-5} per degree Celsius (6.5×10^{-6}/°F), comparable to that of concrete. The coefficient for reinforced concrete can be assumed as 1.1×10^{-5}/°C (6×10^{-6}/°F).

Concrete expands slightly with a gain in moisture and contracts with a loss in moisture. The drying-shrinkage of concrete specimens ranges from 4 to 8×10^{-4} when exposed to air at a 50% relative humidity. Concrete with a unit shrinkage of 5.5×10^{-4} shortens about the same amount as a thermal contraction caused by a decrease in temperature of 55°C (100°F). The shrinkage of reinforced concrete is less than that for plain concrete because of restraint offered by the reinforcement. Reinforced concrete structures with normal amounts of reinforcement have a drying-shrinkage in the range of 2 to 3×10^{-4}. The amount of shrinkage is directly related to the amount of water in the concrete. Higher water content results in higher shrinkage. Specimen size also has an effect. Larger specimens shrink less than small specimens.

Drying-shrinkage is an inherent and unavoidable property of concrete; therefore, properly positioned reinforcing steel is used to reduce crack widths or joints are used to predetermine or control the location of cracks. Shrinkage control joints should be spaced about 25 to 30 times the thickness of a concrete slab on ground.

Deformation and Creep

Concrete will deform a small amount when a load is placed on it. When concrete is loaded, the deformation caused by the load can be divided into two parts: a deformation that occurs immediately, such as elastic strain, and a time-dependent deformation that begins immediately but continues at a decreasing rate for as long as the concrete is loaded (Figure 12.5.4). This latter deformation is called creep. The amount of creep is dependent on the magnitude of the stress, the age and strength of the concrete when the stress is applied, and the length of time the concrete is stressed. Creep is of little concern for normal concrete pavements, bridges, and small buildings; however, creep should be considered in design for very tall buildings or very long bridges.

Concrete Ingredients

Portland Cements

Portland cements are hydraulic cements; that is, they set and harden by reacting with water. This reaction, called hydration, combines water and cement to form a stonelike mass. Portland cement was invented in 1824 by an English mason, Joseph Aspdin, who named his product portland cement because it produced a concrete that was of the same color as natural stone on the Isle of Portland in the English Channel.

Portland cement is produced by combining appropriate proportions of lime, iron, silica, and alumina and heating them. These raw ingredients are fed into a kiln that heats the ingredients to temperatures of 1450 to 1650°C (2600 to 3000°F) and changes the raw materials chemically into cement clinker. The

clinker is cooled and then pulverized. During this operation a small amount of gypsum is added to control the setting of the cement. The finished pulverized product is portland cement. Portland cement is essentially a calcium silicate cement.

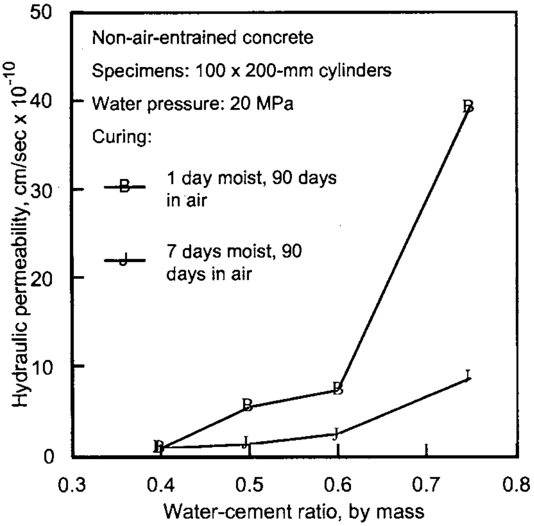

FIGURE 12.5.3 Water permeability of concrete as affected by water/cement ratio and curing. (From *Design and Control of Concrete Mixtures,* EB001, Portland Cement Association, Skokie, IL, 1992. With permission.)

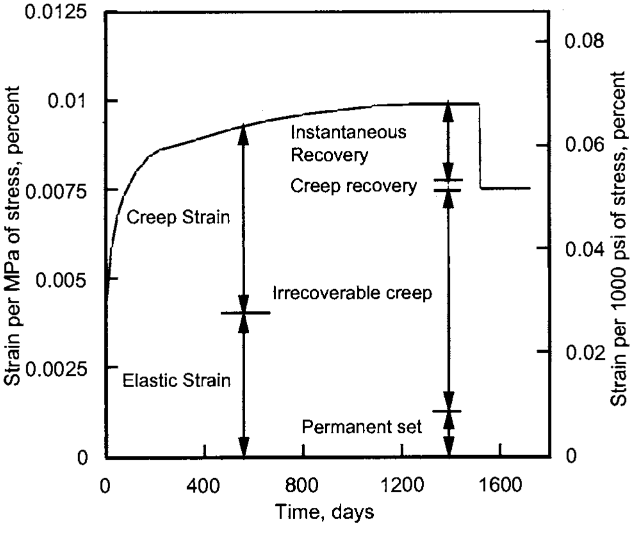

FIGURE 12.5.4 Combined curve of elastic and creep strains showing amount of recovery. (From *Design and Control of Concrete Mixtures,* EB001, Portland Cement Association, Skokie, IL, 1992. With permission.)

The American Society for Testing and Materials (ASTM) Standard C 150, Specification for Portland Cement, provides for the following types of portland cement:

Type I	General portland cement
Type II	Moderate-sulfate-resistant cement
Type III	High-early-strength cement
Type IV	Low–heat-of-hydration cement
Type V	High-sulfate-resistant cement

Types I, II, and III may also be designated as being air entraining. Type I portland cement is a general cement suitable for all uses where special properties of other cements are not required. It is commonly used in pavements, building, bridges, and precast concrete products.

Type II portland cement is used where precaution against moderate sulfate attack is important where sulfate concentrations in groundwater or soil are higher than normal, but not severe. Type II cement can also be specified to generate less heat than Type I cement. This moderate heat of hydration requirement is helpful when placing massive structures, such as piers, heavy abutments, and retaining walls. Type II cement may be specified when water-soluble sulfate in soil is between 0.1 and 0.2%, or when the sulfate content in water is between 150 and 1500 ppm. Types I and II are the most common cements available.

Type III portland cement provides strength at an early age. It is chemically similar to Type I cement except that the particles have been ground finer to increase the rate of hydration. It is commonly used in fast-track paving or when the concrete structure must be put into service as soon as possible, such as in bridge deck repair.

Type IV portland cement is used where the rate and amount of heat generated from hydration must be minimized. This low heat of hydration cement is intended for large, massive structures, such as gravity dams. Type IV cement is rarely available.

Type V portland cement is used in concrete exposed to very severe sulfate exposures. Type V cement would be used when concrete is exposed to soil with a water-soluble sulfate content of 0.2% and higher or to water with over 1500 ppm of sulfate. The high sulfate resistance of Type V cement is attributed to its low tricalcium aluminate content.

Blended Hydraulic Cements

Blended hydraulic cements are produced by intimately blending two or more types of cementitious material. Primary blending materials are portland cement, ground granulated blast-furnace slag, fly ash, natural pozzolans, and silica fume. These cements are commonly used in the same manner as portland cements. Blended hydraulic cements conform to the requirements of ASTM C 595 or C 1157. ASTM C 5195 cements are as follows: Type IS — portland blast-furnace slag cement, Type IP and Type P — portland–pozzolan cement, Type S — slag cement, Type I (PM) — pozzolan-modified portland cement, and Type I (SM) — slag-modified portland cement. The most common blended cements available are Types IP and IS.

ASTM C 1157 blended hydraulic cements include the following: Type GU — blended hydraulic cement for general construction, Type HE — high-early-strength cement, Type MS — moderate-sulfate-resistant cement, Type HS — high-sulfate-resistant cement, Type MH — moderate-heat-of-hydration cement, and Type LH — low-heat-of-hydration cement.

Supplementary Cementing Materials (Mineral Admixtures)

Supplementary cementing materials, also called mineral admixtures, are sometimes added to concrete mixtures. They contribute to the properties of hardened concrete through hydraulic or pozzolanic activity. Typical examples are natural pozzolans, fly ash, ground granulated blast-furnace slag, and silica fume. These materials react chemically with calcium hydroxide released from the hydration of portland cement to form cement compounds.

Below is a summary of the specifications and classes of supplementary cementing materials:

1. Ground granulated iron blast-furnace slag—ASTM C 989
   - Grade 80 — Slags with a low activity index
   - Grade 100 — Slags with a moderate activity index
   - Grade 120 — Slags with a high activity index
2. Fly ash and natural pozzolans — ASTM C 618
3. Class N — Raw or calcined natural pozzolans including diatomaceous earth, opaline cherts, shales, tuffs, volcanic ashes, and some calcined clays and shales
4. Class F — Fly ash with pozzolanic properties
5. Class C — Fly ash with pozzolanic and cementitious properties
6. Silica fume — ASTM C 1240

Mixing Water for Concrete

Almost any natural water that is drinkable can be used as mixing water for making concrete. However, some waters that are not fit for drinking may be suitable for concrete. Reference 1 provides guidance concerning the use of waters containing alkali carbonates, chlorides, sulfates, acids, oils, and other materials, and provides guidance as to allowable levels of contamination.

Aggregates for Concrete

The importance of using the right type and quality of aggregates cannot be overemphasized since the fine coarse aggregates occupy between 60 to 75% of the concrete volume and strongly influence the freshly mixed and hardened properties, mix proportions, and economy of the concrete. Fine aggregates consist of natural sand or crushed rock with particles smaller than 5 mm (0.2 in). Coarse aggregates consist of a combination of gravel or crushed aggregate with particles predominately larger than 5 mm (0.2 in.) and generally between 10 and 13 mm ($^3/_8$ and $^1/_2$ in.). The most common coarse aggregate size is 19 and 25 mm ($^3/_4$ and 1 in.) aggregate.

Normal weight aggregates should meet the requirements of ASTM C 33. This specification limits the amounts of harmful substances and states the requirements for aggregate characteristics, such as grading. The grading and maximum size of the aggregate affect the relative aggregate proportions as well as cement and water requirements, workability, pumpability, economy, shrinkage, and durability of the concrete.

Chemical Admixtures for Concrete

Admixtures are ingredients in concrete other than portland cement, water, and aggregates that are added to the mixture immediately before or during mixing. Common chemical admixtures include air-entraining, water-reducing, retarding, accelerating, and superplasticizing admixtures. The major reasons for using admixtures are to reduce the cost of concrete construction, achieve certain properties in concrete more effectively than by other means, or to ensure the quality of concrete during the states of mixing, transporting, placing, or curing in adverse weather conditions. Refer to Table 12.5.4.

Air-entraining admixtures are used purposely to entrain microscopic air bubbles in concrete. Air entrainment will dramatically improve the durability of concrete exposed to moisture during freezing and thawing. Air-entraining admixtures are commonly used to provide between 5 and 8% air content in concrete.

Water-reducing admixtures are used to reduce the quantity of mixing water required to produce concrete of a certain slump, reduce water/cement ratio, reduce cement content, or increase slump. Typical water-reducing admixtures reduce the water content by approximately 5 to 10%. High-range water reducers (superplasticizers) reduce the water content by approximately 12 to 30% and they can produce a highly fluid concrete.

Retarding admixtures are used to retard the rate of setting of concrete. An accelerating admixture is used to accelerate strength development of concrete at an early age.

Proportioning Normal Concrete Mixtures

The objective in proportioning concrete mixtures is to determine the most economical and practical combination of readily available materials to produce a concrete that will satisfy the performance requirements under particular conditions of use. To fulfill these objectives a properly proportioned concrete mix should possess these qualities: (1) acceptable workability of freshly mixed concrete, (2) durability, strength, and uniform appearance of hardened concrete, and (3) economy. Only with proper selection of materials and mixture characteristics can the above qualities be obtained in concrete production.

The key to designing a concrete mixture is to be fully aware of the relationship between the water/cement ratio and its effect on strength and durability. The specified compressive strength at 28 days and durability concerns dictate the water/cement ratio established for a concrete mixture. The water/cement ratio is simply the weight of water divided by the weight of cement. If pozzolans or slags are used, it would include their weights and would be referred to as the water/cementitious material

TABLE 12.5.4 Concrete Admixtures by Classification

Type of Admixture	Desired Effect	Material
Accelerators (ASTM C 494, Type C)	Accelerate setting and early-strength development	Calcium chloride (ASTM D 98) Triethanolamine, sodium thiocyanate, calcium formate, calcium nitrite, calcium nitrate
Air detrainers	Decrease air content	Tributyl phosphate, dibutyl phthalate, octyl alcohol, water-insoluble esters of carbonic and boric acid, silicones
Air-entrained admixtures (ASTM C 260)	Improve durability in environments of freeze-thaw, deicers, sulfate, and alkali reactivity Improve workability	Salts of wood resins (Vinsol resin) Some synethic detergents Salts of sulfonated lignin Salts of petroleum acids Salts of proteinaceous material Fatty and resinous acids and their salts Alkylbenzene sulfonates Salts of sulfonated hydrocarbons
Alkali-reactivity reducers	Reduce alkali-reactivity expansion	Natural pozzolans, fly ash, silica fume, blast-furnace slag, salts of lithium and barium
Bonding admixtures	Increase bond strength	Rubber, polyvinyl chloride, polyvinyl acetate, acrylics, butadiene-styrene copolymers
Coloring agents	Colored concrete	Modified carbon black, iron oxide, phthalocyanine, umber, chromium oxide, titanium oxide, cobalt blue (ASTM C 979)
Corrosion inhibitors	Reduce steel corrosion activity in a chloride environment	Calcium nitrite, sodium nitrite, sodium benzoate, certain phosphates or fluorosilicates, fluoroaluminates
Dampproofing admixtures	Retard moisture penetration into dry concrete	Soaps of calcium or ammonium stearate or eleate Butyl stearate Petroleum products
Finely divided mineral admixtures		
Cementitious	Hydraulic properties Partial cement replacement	Ground granulated blast-furnace slag (ASTM C 989) Natural cement Hydraulic hydrated lime (ASTM C 141)
Pozzolans	Pozzolanic activity Improve workability, plasticity, sulfate resistance; reduce alkali reactivity, permeability, heat of hydration Partial cement replacement Filler	Diatomaceous earth, opaline cherts, clays, shales, volcanic tufts, pumicites (ASTM C 618, Class N); fly ash (ASTM C 618, Classes F and C), silica fume
Pozzolanic and cementitious	Same as cementitious and pozzolan categories	High calcium fly ash (ASTM C 618, Class C) Ground granulated blast-furnace slag (ASTM C 989)
Nominally inert	Improve workability Filler	Marble, dolomite, quartz, granite
Fungicides, germicides, and insecticides	Inhibit or control bacterial and fungal growth	Polyhalogenated phenols Dieldrin emulsions Copper compounds
Gas formers	Cause expansion before setting	Aluminum powder Resin soap and vegetables or animal glue Saponin Hydrolized protein
Grouting agents	Adjust grout properties for specific applications	See Air-entraining admixtures, Accelerators, Retarders, Workability agents
Permeability reducers	Decrease permeability	Silica fume (ASTM C 1240) Fly ash (ASTM C 618) Ground slag (ASTM C 989) Natural pozzolans (ASTM C 618) Water reducers Latex

TABLE 12.5.4 (continued) Concrete Admixtures by Classification

Type of Admixture	Desired Effect	Material
Pumping aids	Imnprove pumpability	Organic and synthetic polymers Organic flocculents Organic emulsions of paraffin, coal tar, asphalt, acrylics Bentonite and pyrogenic silicas Natural pozzolans (ASTM C 618, Class N) Fly ash (ASTM C 618, Classes F and C) Hydrated lime (ASTM C 141)
Retarders (ASTM C 494, Type B)	Retard setting time	Lignin Borax Sugars Tartaric acid and salts
Superplasticizers[a] (ASTM C 1017, Type 1)	Flowing concrete Reduce water/cement ratio	Sulfonated melamine formaldehyde condensates Sulfonated napthalene formaldehyde condensates Ligonsulfonates
Superplasticizer[a] and retarder (ASTM C 1017, Type 2)	Flowing concrete with retarded set Reduce water	See Superplasticizers and also Water reducers
Water reducer (ASTM C 494, Type A)	Reduce water demand at least 5%	Lignosulfonates Hydroxylated carboxylic acids Carbohydrates (Also tend to retard set so accelerator is often added)
Water reducer and accelerator (ASTM C 494, Type E)	Reduce water (minimum 5%) and accelerate set	See Water reducer, Type A (Accelerator is added)
Water reducer and retarder (ASTM C 494, Type D)	Reduce water (minimum 5%) and retard	See Water reducer, Type A
Water reducer — high range (ASTM C 494, Type F)	Reduce water demand (miniumum 12%)	See Superplasticizers
Water reducer — high range — and retarder (ASTM C 494, Type G)	Reduce water demand (miniumum 12%) and retard set	See Superplasticizers and also Water reducers
Workability agents	Improve workability	Air-entraining admixtures Finely divided admixtures, except silica fume Water reducers

[a] Superplasticizers are also referred to as high-range water reducers or plasticizers. These admixtures often meet both ASTM C 494 and C 1017 specifications simultaneously.

ratio. The water/cement ratio can be established by a known relationship to strength or by durability requirements. For example, a concrete structure may require only 20 MPa (3000 psi) compressive strength, which would relate to a water/cement ratio of about 0.6; however, if the concrete is exposed to deicers, the maximum water/cement ratio should be 0.45 (Table 12.5.5). For corrosion protection or reinforced concrete exposed to deicers, the maximum water/cement ratio should be 0.40. When designing concrete mixtures, remember that where durability is concerned, water/cement ratio should be as low as practical. Entrained air must be used in all concrete that will be exposed to freezing and thawing and the presence of deicing chemicals. A typical air content for concrete would range from 5 to 8%. Reference 1 provides step-by-step procedures for proportioning concrete. Refer to Table 12.5.6 to Table 12.5.8.

Mixing, Transporting, and Placing Concrete

All concrete should be mixed thoroughly until it is uniform in appearance with all ingredients evenly distributed. If concrete has been adequately mixed, samples taken from different portions of a batch will

TABLE 12.5.5 Relationships Between Water Cement Ratio and Compressive Strength of Concrete

Compressive Strength at 28 days, MPa (psi)	Water-Portland Cement Ratio, by Mass: Non-Air-Entrained Concrete	Air-Entrained Concrete
40 (5800)	0.42	—
35 (5100)	0.47	0.39
30 (4400)	0.54	0.45
25 (3600)	0.61	0.52
20 (2900)	0.69	0.60
15 (2200)	0.79	0.70

Note: Strength is based on 150 × 300-mm cylinders moist cured 28 days at 23 ± 2°C. Relationship assumes maximum size of aggregate about 25 mm.

Adapted from *Design and Control of Concrete Mixtures,* EBDD1, Portland Cement Association, Skokie, IL, 1992. With permission.

have essentially the same unit weight, air content, slump, and strength. Concrete is sometimes mixed at a job site at a stationary mixer or paving mixer, and other times it is mixed in central mixers at ready-mix plants (ASTM C 94). Once concrete is transported to a job site it is then conveyed by a variety of methods including belt conveyors, buckets, shoots, cranes, pumps, wheelbarrows, and other equipment. Concrete should be conveyed in a manner in which the concrete is not allowed to dry out, be delayed, or allowed to segregate before it is placed.

Curing

All concrete must be properly cured. Curing is the maintenance of a satisfactory moisture content and temperature in concrete during some definite time period immediately following placing and finishing so that the desired properties of strength and durability may develop. Concrete should be moist cured for 7 days at a temperature between 10 and 27°C (50 and 80°F). Common methods of curing include ponding, spraying, or fogging; use of wet covers, impervious paper, plastic sheets, and membrane-forming curing compounds; or a combination of these.

Durability

Freeze-Thaw and Deicer Scaling Resistance

As water freezes in wet concrete, it expands 9%, producing hydraulic pressures in the cement paste and aggregate. Accumulated effects of successive freeze-thaw cycles and disruption of the paste and aggregate eventually cause significant expansion and extensive deterioration of the concrete. The deterioration is visible in the form of cracking, scaling, and crumbling.

The resistance of hardened concrete to freezing and thawing in a moist condition, with or without the presence of deicers, is significantly improved by the use of entrained air. Air entrainment prevents frost damage and scaling and is required for all concretes exposed to freezing and thawing or deicer chemicals. An air content of between 5 and 8% should be specified. Air-entrained concrete should be composed of durable materials and have a low water/cement ratio (maximum 0.45), a minimum cement content of 335 kg/m^3 (564 lb/yd^3) or move, proper finishing after bleed water has evaporated from the surface, adequate drainage, a minimum of 7-days moist curing at or above 10°C (50°F), a minimum compressive strength of 28 MPa (4000 psi), and a minimum 30-day drying period after moist curing. Sealers may also be applied to provide additional protection against the effects of freezing and thawing and deicers. However, a sealer should not be necessary for properly proportioned and placed concrete.

Sulfate-Resistant Concrete

Excessive amounts of sulfates in soil or water can, over 5 to 30 years, attack and destroy concrete that is not properly designed. Sulfates attack concrete by reacting with hydrated compounds in the hardened

cement paste. Due to crystallization growth, these expansive reactions can induce sufficient pressure to disrupt the cement paste, resulting in cracking and disintegration of the concrete. The first defense against sulfate attack is to use a low water/cement ratio (0.45 or preferably less), and to select a Type II or V cement (see the section on cement).

Corrosion Protection

Concrete protects embedded steel from corrosion through its highly alkaline nature. The high-pH environment (usually greater than 12.5) causes a passive and noncorroding protective oxide film to form on steel. However, carbonation or the presence of chloride ions from deicers or seawater can destroy or penetrate the film, causing rusting of the reinforcing steel. In addition to using a water/cement ratio of 0.40 or less, the following protective strategies can be used individually or in combination to reduce the risk of corrosion:

1. Cover thickness of 90 mm (3.5 in.) or more of concrete over top, reinforcing steel of compression zones. [*Note:* Excessive cover in tension zones exacerbates surface crack width.]
2. Low-slump dense concrete overlay
3. Latex-modified concrete overlay
4. Interlayer membrane/asphaltic concrete systems
5. Epoxy-coated reinforcing steel
6. Corrosion-inhibiting admixtures in concrete
7. Sealers with or without overlay
8. Silica-fume or other pozzolans that significantly reduce concrete permeability
9. Low water/cement ratio (<0.35) superplasticized concrete
10. Cathodic protection
11. Polymer concrete overlay
12. Galvanized reinforcing steel

13. Polymer impregnation
14. Lateral and longitudinal prestressing for crack control
15. Blended cements containing silica fume or other pozzolans to reduce permeability

Alkali–Silica Reaction

Most aggregates are chemically stable in hydraulic cement concrete, without deleterious interaction with other concrete ingredients. However, this is not the case for aggregates containing certain siliceous substances that react with soluble alkalis in concrete. Alkali–silica reactivity (ASR) is an expansive reaction between reactive forms of silica in aggregate and alkali hydroxides in concrete. Very reactive aggregates can induce cracks within a year, whereas slowly reactive aggregates can take over 20 years to induce noticeable cracks. ASR is best controlled through the use of fly ash, slag, silica fume, natural pozzolans, or blended hydraulic cement. With proper care in analyzing aggregates and selecting appropriate concrete ingredients, ASR can be effectively minimized using available materials. Reference 2 provides guidance on ASR.

Introduction

A *composite material* is defined as a combination of two or more components that yields unique characteristics in the final material. The selection of the materials and processes in developing and manufacturing composite structures depends on the end-use application. The development of new processes for making fibrous structures from polymers, metals, ceramics, and other precursors and the combination of those materials in various forms have allowed these materials to be used in a variety of applications. In other words, composites have been developed to satisfy the desired properties where no single quasi-continuous material would satisfy the need. Composites are usually made by combining a one-phase continuous material called a *matrix* with a second discontinuous component, usually termed *reinforcement*. The second component can be in the particulate form, that is, as *filler*, chopped fibers, continuous filaments or bundles of filaments, or continuous sheet materials in a two- or three-dimensional textile architecture. The nature of the architecture and the type of filler material will determine whether it will yield a high-, medium-, or low-performance end product. One method of configuration of composites may be based on the matrix-filler concept. Based on this concept, the composites can be divided into major categories, such as *ceramic matrix* (CMC) *metal matrix* and *polymer (plastics) matrix* (PMC) composites. Composites are further subdivided according to the shape and configuration of the reinforcing material. Table 12.6.1 shows the various forms (architecture) of reinforcements. When the reinforcing material is either ceramic or glass in the form of particulate, similar in all dimensions, it is called *particulate-reinforced* composite; and if it consists of short, needle-shaped single crystals, it is called *whisker-reinforced*. If fibers are of the order of a few millimeters in length, the reinforcing material is called *chopped fiber-reinforced*; and if it is a bundle of continuous filaments, it is called *fiber-reinforced composite*. Fiber-reinforced composites are further subdivided according to the configuration or the architecture of the reinforcement. Filaments aligned in one direction are classified as *uniaxial fiber composites*, and if the filaments are arranged in layers, such as filament-wound net shape or layered fabrics, then they are called *laminar composites*. Filaments that can be knitted or woven in a three-dimensional near-net shape form or deposited on a mandrel during extrusion are called *three-dimensional knitted* or *three-dimensional woven*, or *three-dimensional nonwoven composites*, respectively. Combination and lamination of knitted, woven, and braided structures to form three-dimensional forms can be further divided by the structure.

Wood, a natural composite of cellulose fibers bonded together with a matrix of lignin, has been used as an engineering material since time immemorial. But the first known important engineering material, dating back thousands of years, was husk or straw, employed as a reinforcement in clay or mud to make sun-dried bricks for use in adobe structures. Sawdust mixed with clay is an example of particulate composite. Lamination of wood has been used to make bows since prehistorical times. The earlier techniques used were very sophisticated. For example, the Mongols constructed the bows from composite of bull's tendon, wood and silk bonded together with adhesive derived from animal by products. Laminated wood has been found at Thebes dating back to 1500 B.C., and similar laminates based on shellac resin have been known and used in India for over 3000 years. Phoenicians used glass fibers as fillers in the making of bottles, but it was not until 1713 that it was rediscovered. The use of polymers as a doping agent started only after the development of synthetic chemistry, when the first polyester resin was prepared by Swedish chemist Jöns Jacob Berzelius. But the commercial use of doped fabrics, for aircraft wings, was seen in the early 1900s. Bakelite resin, a composite of phenol-formaldehyde, though discovered years earlier, was first marketed in 1909, with paper or cloth.

Glass fabric–reinforced/polymer (plastics) were first developed in the 1940s. Since then, with the development of various polymers, much attention has been paid to the making of reinforced structures from carbon and ceramic-based fibers, such as boron, developed in the 1960s. With the development of very high tenacity aramid polymeric fibers, for example, Kevlar® in the 1970s, and hydrocarbon-based fibers, for example, an ultrahigh molecular weight polyethylene, Spectra®, in the 1980s, the field of high-performance polymer-based composites has exploded.

In the last three decades of the twentieth century, there were phenomenal advances in both fiber and matrices, especially in the growth of lightweight aerospace metal matrix composites (MMCs), carbon-carbon composites, and high-temperature ceramic fiber matrix composites (CMCs). The properties of some of the engineering composites are shown in Table 12.6.2. Ceramic fiber polymer matrix composites have also been developed for personal protection, in addition to the damage protection of equipment from projectiles. In addition to the major advances in the development of lightweight and high-temperature composite for aerospace applications, the use of glass-reinforced polymer composites has achieved phenomenal growth in the past two decades.

The use of chopped-glass fibers and *tows* (large bundles of filaments) of glass fibers — in such applications as automobiles, pleasure boats, blades for windmills, and the frame structure for an entire cooling tower for power plants — accounts for increased use of polymer matrix composites (PMCs) in terms of volume and value. Glass fiber, both chopped and in tow forms, offers the low-cost composites made with polymer or plastic as a matrix. However, most of the polymer fiber matrices have low thermal

stability with operating temperatures of less than 100°C. Some polymers, such as polyetheretherketone (PEEK) and epoxy, can withstand temperatures of up to ~200°C before losing some mechanical properties. However, the PMCs do show improved strength (resistance to failure), higher stiffness (resistance to bending), and better structural integrity. Although metals inherently have high stiffness, strength, thermal stability, and thermal and electrical conductivity, the incorporation of metal or ceramic fibers (MMCs) offer high hardness, maintenance of hardness at elevated temperatures, and precise tolerance in the final product. The metal matrix imparts some ductility to the material, thus avoiding the catastrophic failure in solely ceramic material. The incorporation of ceramic fibers in CMCs allows better reliable failure predictability, though it may or may not increase the strength of the composite.

Reinforcement with carbon or graphite and other high-technology fibers such as aramids (Kevlar®) with epoxy have become the composite materials of choice in the aerospace industry. Carbon epoxy composite laminates can be designed to give a zero coefficient of thermal expansion. In 2002 the aerospace industry consumed nearly 25 million pounds of composite materials. Composites made from carbon and other advanced technology fibers are also being used with increased frequency in biomedical, automotive, and high-performance/high-cost consumer products such as sporting goods and civil engineering applications.

The mechanical behavior of a composite is a reflection of the interaction between the interface of the matrix and the reinforcement. In short, if there is no binding between the two, for small strain at least, there will be failure in mutual stress transfer. At higher strain the deforming matrix may impose itself on the more rigid filler, thereby producing mechanical friction, which will make the filler to determine the response of the material. If there is adhesion between the matrix and the reinforcement, then even at low strains the stress transfer will take place across the interface and the two phases will share the stress. The quality of the bond between the matrix and the reinforcement is an important consideration in the production of composites. The mechanical properties of MMCs and PMCs are decided and

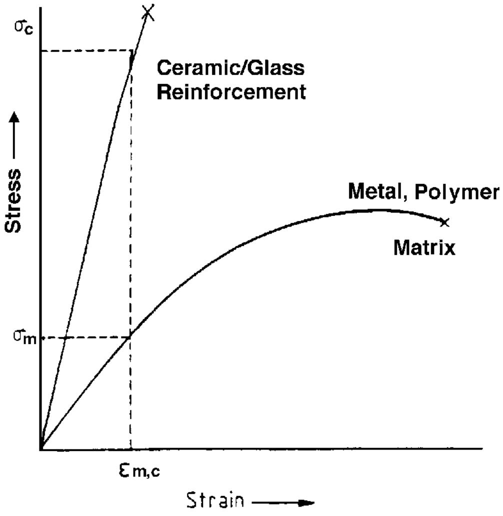

FIGURE 12.6.1 In a composite with good bonding between high-modulus ceramic and low-modulus metal or polymer matrix, the interfacial strain must be the same. Thus, the high-strength ceramic fiber bears most of the load (stress).

maximized by the efficient load transfer from the matrix (Figure 12.6.1) to the relatively high-strength, high-elastic modulus ceramic, carbon, or glass.

In light of the considerable importance of the interfacial bonding between the matrix and reinforcement, it is not surprising that a lot of research effort has gone into practical and theoretical understanding of the interface. But it is by no means an easy problem to study experimentally as it is a two-dimensional domain rather than a three-dimensional bulk phase, which is much easier to study. For best results there must be no relative sliding or interface failure, so the strain at the matrix-to-reinforcement area can be maximum and equal ($\varepsilon_{\text{matrix}} = \varepsilon_{\text{reinforcement}} = \varepsilon_{m,c}$). In other words, the reinforcements bear the major portion of the road, σ_c, while the weaker matrix bears a lower load, σ_m, because it has lower modulus. There are two aspects of relevance — wetting and adhesion on the one hand, and polymer adsorption on the other — in achieving the load transfer. The bond interface must be engineered because metals and polymers do not show intrinsic binding to ceramic reinforcement. This is accomplished by using a *coupling agent*, often xylene, which is applied to the ceramic or glass to promote bonding to a polymer; for metals, a metal matrix often has to be selected because it will bond to metals and some selected ceramics when molten or sintering during fabrication. To achieve a strong metal-to-ceramic bond, a controlled "forming gas" atmosphere must be used in the manufacture of MMC composites. Ceramics bond to ceramics easily, and materials form strong bonds during fabrication of CMCs. The implication of the nature and the quality of bonds in CMCs, MMCs, and PMCs for high-performance applications and the mechanics of these structures are discussed in the subsequent sections. Some recent publications for further readings on the manufacturing processes and properties of three-dimensional fiber-reinforced composites are listed at the end of the section on composites.

Polymer Matrix Composites

Weiping Wang, R. Allan Ridilla, and Mathew B. Buczek

Introduction

PMCs are used extensively as commodity and specialty engineering materials and constitute the largest class of composite materials on a dollar basis. The enormous success of PMCs arises from the wide range of properties that can be obtained and the low cost of low-end materials, such as fiberglass-reinforced

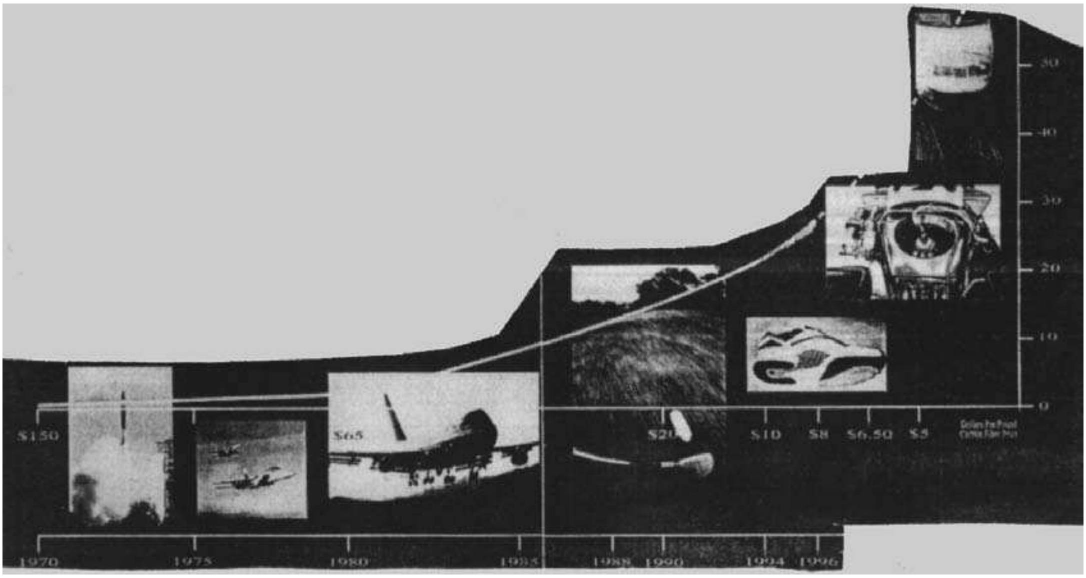

FIGURE 12.6.2 The evolution of carbon fiber composite applications since 1970, with fiber price and industry volume illustrated. (Source: Zoltek Co. Inc.)

polyester. Furthermore, the combination of high-strength/high-stiffness fibers in commodity polymer matrices offers an outstanding example of the composite principle — taking the best properties of both materials. The result is a strong, tough, stiff material, which, depending on the matrix and reinforcement type, provides value in applications as diverse as consumer products, construction, and aerospace.

A distinction must be made between reinforced plastics and advanced composites. The term *reinforced plastics* generally refers to plastic materials fabricated with a relatively low percentage of discontinuous, randomly oriented fibers, with rather moderate properties, and used in commodity applications. *Advanced composites*, on the other hand, refers to a class of materials where a high percentage of continuous, highly oriented fibers are combined with a suitable polymeric matrix to produce articles of high specific strength and specific stiffness. At present, composites are widely used in the aerospace and sporting goods industries for their superior performance. Figure 12.6.2 illustrates the evolution of applications for carbon fibers.

Polymers are also often "filled" with particulate reinforcements to increase certain properties, such as deflection temperature under load (DTUL). Although these materials are formally composites, they are usually regarded as filled polymers and not composites and thus will not be discussed explicitly in this section. Refer to Section 12.2.

Architecture

Each of the constituent materials in advanced composites must act synergistically to provide aggregate properties that are superior to the materials individually. The functional effectiveness of composites is principally due to the anisotropy of the materials and the laminate concept, where materials are bonded together in multiple layers. This allows the properties to be tailored to the applied load so that the structure can be theoretically more efficient than if isotropic materials were used. The reinforcements come in a variety of forms. Unidirectional tapes with all fibers along a common axis, woven fabrics constructed with fibers along both axes in the x–y plane, and three-dimensional architectures with reinforcements in more than two axial directions are just a few of the building blocks of composite structures.

The concept of laminate is illustrated in Figure 12.6.3. On the left is the unidirectional composite, where all reinforcements are aligned in one direction. This construction provides excellent properties in

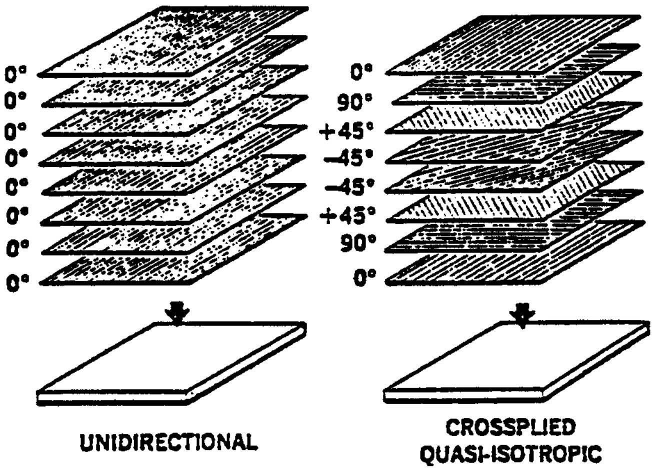

FIGURE 12.6.3 The basic concept of composite laminate (From Brandt, A.M. and Marshall, I.H., Eds., *Brittle Matrix Composites I*, Elsevier Applied Science, New York, 1986. With permission.)

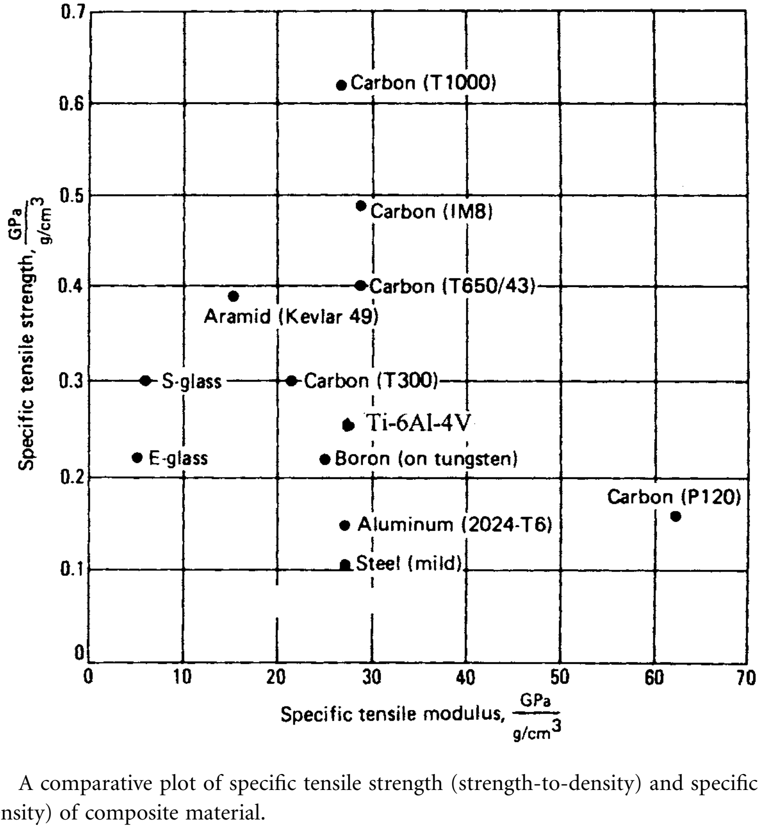

FIGURE 12.6.4 A comparative plot of specific tensile strength (strength-to-density) and specific tensile modulus (modulus-to-density) of composite material.

the fiber direction but is limited to the properties of the resin in the transverse direction. The cross-plied construction on the right creates a structure that has common properties in the x- and y-direction but is limited to the characteristics of the resin in the z-direction. A large number of variations exist, allowing the designer to tailor the properties of the structure by varying the type of fibers and fiber orientations. Shown in Figure 12.6.4 are typical values of specific tensile strength (strength-to-density ratio) and specific

TABLE 12.6.3 Advantages and Limitations of Polymer Matrix Composites

Potential Advantages	Potential Limitations
High strength-to-density ratio	Low–volume production methods
High stiffness-to-density ratio	High raw material cost
Excellent corrosion resistance	Poor impact resistance
Good fatigue resistance	Poor high-temperature performance
Low thermal expansion	Delamination/out-of-plane loading

tensile modulus (modulus-to-density ratio) for 65% volume fraction, cross-plied quasi-isotropic composites. Also included in the plot for comparison are properties of mild steel, titanium (Ti-6A1-4V), and aluminum (2024-T6). The actual properties of a composite will vary significantly due to flaws created during processing.

In selecting polymer composite materials for design, one should consider both the potential advantages and concerns typical to composites, as illustrated in Table 12.6.3. Clearly, the advantages of materials should be put into use to achieve higher levels of performance in many kinds of products. On the other hand, potential issues in higher raw material cost and lower production volume and yield should also be weighed.

Fiber

Introduction. The most common reinforcement in polymer composites are fibers. Fibrous reinforcements come from compounds of light elements, (e.g., B, C, Si, O). These compounds typically contain stable covalent bonds, which impart greater strength and stiffness compared with metallic or ionic bonds. The compounds are processed to the final usable form of a fiber or filament with a highly aligned and directional microstructure so that the strength and stiffness properties are optimized along the fiber axis. Glass, graphite/carbon, aramid, and boron are among most notable fibers currently used in polymer composites.

Glass Fiber. Glass-fiber reinforcements represent the largest volume used in the composites industry. These fibers are characterized by their low cost, clear to white color, good mechanical and electrical properties, high moisture and chemical resistance, and excellent dimensional stability with operational service to 550°C. Manufacturing of the fibers begins with molten glass, which is drawn through a furnace into a fibrous form of final diameter of about 10 mm and then quenched to secure the final amorphous microstructure prior to applying final coatings or sizing. Common types of commercially available glass fiber are E-glass and S-glass, both of which are low-alkali boro-alumino-silicate glasses. E-glass fiber, the workhorse of glass-fiber applications, is the lower-cost fiber and is used in both structural and electrical applications. S-glass provides higher tensile properties and increased temperature resistance needed for aerospace and aircraft applications with a price premium. Representative properties for the glass fibers are shown in Table 12.6.4.

TABLE 12.6.4 Fibers Used in Polymer Composites — Mechanical Properties

	E-Glass	S-Glass	AS4 PAN-Based Carbon	IM7 PAN-Based Carbon	P120 Pitch-Based Graphite	Kevlar-49	Boron

Carbon Fiber. Graphite/carbon fibers are the reinforcement of industrial choice for advanced composite applications where stiffness and performance are critical. Typical attributes of these fibers are excellent tensile strength and elastic modulus, ease of handling, black color, and a wide range of properties and cost. Graphite fibers are initially formed from polymer precursor compounds such as polyacrylonitrile (PAN) or rayon and pitch, an amorphous, aromatic by-product of petroleum distillation. PAN-based graphite fiber, the predominant commercial fiber, starts with the liquid PAN polymer, which is spun into a fiber and stretched to align the microstructure. It is then stabilized and the microstructure is aligned at 400 to 500°F in an oxidizing atmosphere under tension. Next, carbonization occurs in an inert atmosphere at 1800 to 2300°F to remove most noncarbon elements. Finally, the graphitization step is performed on the carbon fiber by applying tension to the fiber in an inert atmosphere at 3600 to 6500°F. The result is a highly aligned, highly graphitic fiber with preferred graphite orientation along the fiber axis. The temperature and tension fabrication parameters of the graphitization step, along with the purity of the initial PAN polymer, are the variables that are modified to differentiate "low-end" (low strength, modulus, cost) from the "high-end" fiber (high strength, modulus, cost) and all of the grades in between. Typical properties of several commercial grades of carbon/graphite fiber are listed in Table 12.6.2.

Aramid Fibers. The aramid fiber derives its properties from long, rodlike aromatic polyamides. These fibers are characterized by low density, white yellow color, extremely high tensile properties, poor compressive strength, and high toughness, and they are difficult to cut mechanically. The manufacturing process for these fibers involves complex polymerization steps as the liquid polymer in acid is extruded or spun into a fiber form, water-washed, dried, and finally heat-treated under tension. The result is a highly aligned radial system of axially pleated lamellae in the microstructure. Aramid fibers have proved extremely useful in tension-critical applications where the intrinsic compressive weaknesses of the fiber cannot be exploited. Commercially known as Kevlar, the most notable applications for aramid fibers are bulletproof vests (without matrix) and various high-pressure composite vessels. Typical properties for Kevlar 49 are listed in Table 12.6.2.

Boron Fibers. Boron reinforcements are referred to as filaments rather than fibers since they are made by the chemical vapor deposition of boron onto a fine tungsten wire. This fabrication process produces a large-diameter, stiff, and expensive reinforcement that is somewhat difficult to handle and produce into subsequent product forms such as fabrics and contoured structures. Although boron filaments possess the combination of high strength and high specific modulus that glass could not achieve, their use has been reduced to a minuscule level. Carbon/graphite fiber varieties have supplanted boron where high specific modulus is a requirement. A small volume of boron filaments still remain in a handful of military aircraft as well as in some recreational products, such as golf club shafts. Typical properties of boron filaments are shown in Table 12.6.2.

Polymer Matrix Materials

Introduction. While fibers provide much of the strength and stiffness in advanced composites, equally important is the matrix resin. The matrix holds the fiber network together, to protect the structure from environmental attack and to support the fibers so that loads can be transferred throughout the structure through a shear mechanism. Polymeric matrices can either be thermoset or thermoplastic resins.

Thermosets cannot be reformed or thermally reworked after polymerization (curing). They are subdivided into categories based on their chemical reactions. The first are addition-type polymers, generally considered easier to process, where two (or more) reactants combine to form the final cured product. The second is the condensation type, in which the reactants combine to form products in addition to water and other volatile constituents. These systems are more difficult to process due to the required management of the volatile to minimize process defects such as porosity.

Thermoplastic materials, on the other hand, are polymers that can be softened and melted with the application of heat. Although they can be recycled, thermoplastic matrices have found more-limited applications in the advanced composite applications since they are particularly susceptible to attack by fluids and to creep at high stresses, and are relatively difficult to handle in laminate or structural form prior to final consolidation. The remainder of this discussion will focus on thermoset matrices, which account for more than 90% of present-day advanced composite applications. Three principal organic matrix materials will be discussed: polyesters, epoxies, and polyimides.

Polyester Matrix. Low-cost polyester resins constitute the highest volume usage for the general composite industry. There are many resins, formulations, curatives, and other additive constituents that provide a wide array of properties and performance characteristics, such as mechanical strength, toughness, and heat resistance. The vast majority of applications utilize glass since its interfacial adhesion to these resins has been optimized by the development of silane surface treatments. These resins when combined with glass have found wide application in chemical processing construction and in marine industries where cured properties and low cost are tailor-made for design requirements. Applications with carbon/graphite and aramid fibers are far less frequent since adhesion to these fibers is generally poor and cure shrinkage on these resins is quite high. Additionally, structures requiring the high performance of carbon/graphite can often justify the use of more-expensive epoxy resins.

Epoxy Matrix. Epoxy resins are the prevalent polymer used with advanced composites. Their extensive use is primarily due to their superior mechanical properties, excellent adhesion, good processibility utilizing addition-type reactions, low cure shrinkage, and low cost. When choosing epoxy resins, two elements are crucial: the base resin and the curing agent or hardener. Since there are many base resins and curing agents, we present the following general relationships to provide a practical framework when utilizing epoxy compounds:

- *Chemistry*: Aromatic compounds are more thermally stable, stronger, and more resistant to fluids than are aliphatics.
- *Cross-link density*: Higher-temperature cures and longer cure times will increase cross-link density and therefore strength/modulus, service temperature, and chemical resistance.
- *Curing agents*: Amine-cured systems have better chemical resistance and superior thermal stability but are more brittle than anhydride-cured systems.

Epoxies are categorized by the cure temperature. The “250 F epoxies” are those that cure at 250°F and are suitable for service up to 250°F. The “350 F epoxies” are those with higher processing and service temperatures. One of the design concerns with epoxies is moisture absorption. The effects of moisture often require design stresses to be reduced in applications where moisture is a concern. Modern epoxy formulations include lower cost, higher toughness, and other properties, which continue to make epoxies attractive to the end user.

Polyimide resins span the temperature spectrum from 350 to 600°F. There are three general types of polyimides:

1. *Addition-reaction* polyimides, such as bismaleimides (BMIs)
2. *Condensation-reaction* polyimides, such as commercial Monsanto Skybond resin
3. *Combination* condensation/addition-reaction polyimides, such as PMR-15

BMIs are similar to epoxies in that they undergo addition reactions, are easy to process, and share many of the handling characteristics that make epoxies desirable. These materials are the composite resins of choice for temperatures in the range of 350 to 450°F to bridge the temperature gap between epoxies and other polyimides. They are more expensive and tend to be more brittle than epoxies. Condensation polyimides are used for composite applications from 450 to 520°F. These materials are difficult to process and tend to be quite brittle so their application is limited to adhesive bonding with some structural composite hardware. Combination-reaction polyimides have the highest thermal and oxidative stability and are used at service temperatures to 600°F. These resins are considerably more complicated because of their reaction mechanisms and the handling difficulties of the chemicals. Their application is principally restricted to aerospace composite structures where the performance needs to justify the difficult processing and high cost.

Processing

Continuous-fiber composites are manufactured in two steps: preform fabrication and consolidation/curing. The material comes in either the dry-fiber (without resin) form or with resin included called *prepreg*. Dry fibers are used in filament winding, pultrusion, weaving, and braiding. In the case of filament winding and pultrusion, resin is introduced at the same time fibers are during the time of winding and pultrusion. Resin can also be introduced to the fiber later by resin-transfer molding (RTM). Prepreg, at a higher material cost, eliminates the step of resin addition and provides the adhesion to hold the material together. Lay-up of prepreg, a time-consuming process, is a common method used in the aerospace industry where complex contoured surfaces are present.

Consolidation and curing consist of compacting the material to remove entrapped air, volatile, and excess resins while developing the structural properties by increasing the polymer chain length and cross-linking. Thermosetting polymer matrices must be cured *in situ* with the fibers to form composites. The goals of a successful cure are good consolidation with low porosity and high conversion of initial monomeric constituents to polymer (degree of cure).

The cure cycle of an epoxy resin composite is shown in Figure 12.6.5. At the start of the cure cycle, the material is normally under vacuum to remove residual volatile. The temperature is then ramped to the point where the polymer is melted. The ramp rates on heating must be slow enough as not to cause unnecessary thermal gradients and to avoid dangerous exotherm (runaway reactions) but not so slow as to cause excessive process time or premature cross-linking. Normal ramp rates are generally in the 1 to

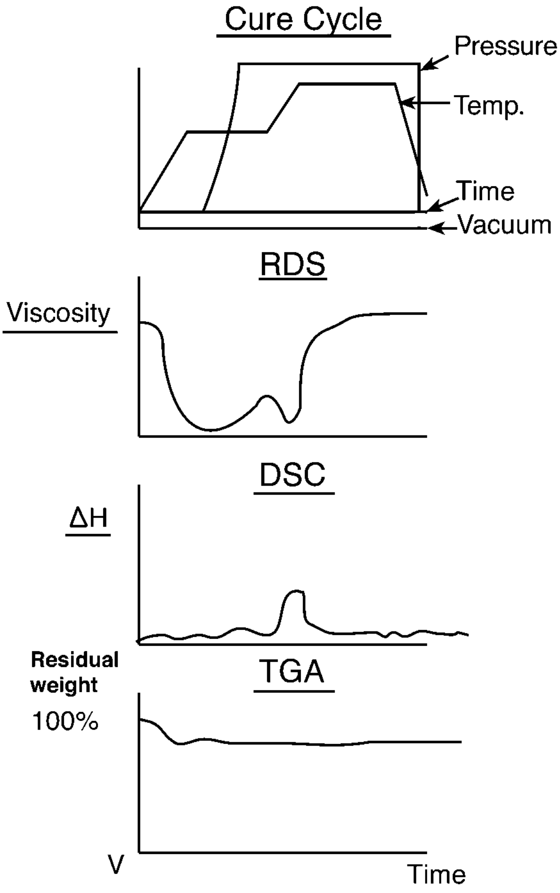

FIGURE 12.6.5 A typical curing cycle of epoxy composite with corresponding Rheometric Dynamic Spectroscopy (RDS), Differential Scanning Calorimetry (DSC), and Thermogravimetric Analysis (TGA) curves

5°F/min range. An isothermal hold of about 30 to 60 min is performed at the point where the resin reaches its minimum in viscosity, during which pressure is applied and the polymer is allowed to flow, thus consolidating the laminate. Following consolidation, the temperature is increased to the point where cross-linking occurs (350°F for this example). An additional hold of about 30 to 90 min is performed at this temperature to allow for the material to complete cross-linking. This event is shown as the end of the exothermic peak in the DSC curve as well as the asymptotic high-viscosity region.

Epoxies cure via additional reactions, where no volatile is generated during the cross-linking process. However, many other matrix materials (e.g., phenolics and many polyimides) cure via condensation reactions.

Mechanical Properties

Mechanical properties of polymer composites depend substantially on the processing and fabrication methods used, as well as on the fiber orientation. Thus, standard materials do not exist and it is difficult to generalize regarding properties. The three most significant factors in determining properties are the type of fiber, the volume fraction of fiber, and the orientation of the fiber. High-strength high-modulus graphitic carbon fibers will, of course, produce stronger, stiffer composites than those produced from fiberglass. Similarly, 60 vol% fiber composites will be stronger and stiffer than 30 vol%, and uniaxially aligned fiber composites will have maximum properties along the alignment axis, but will be highly anisotropic and will have poor properties in off-axis orientations. Cross-ply and laminated structures were standard approaches to reducing anisotropy during the early developments of composites, especially for aerospace applications. Since the early developments in cross-plying and lamination of two-dimensional woven, knitted, or stitched fabrics, composite structures made from three-dimensional woven, three-dimensional knits, and three-dimensional braided are being deployed in the field. Although tensile properties and failure mechanisms have been investigated since the 1980s, it is only recently that an understanding and modeling of the tensile behavior of such structures has become available. The reason for the slow progress has been the complexity of the geometry of the structure and the failure mechanism of fibers in these structures. The deformation behavior of two-dimensional laminates differs from that of the three-dimensional woven fabrics, as shown in Figure 12.6.6. Some structural features of a three-dimensional orthogonal woven fabric are shown in Figure 12.6.7. On the other hand, three-dimensional woven fabrics perform better in impact damage, as shown in Figure 12.6.6. Braid angle influences the mechanical properties, and some mechanical properties of carbon/epoxy, multilayer interlock three-dimensional braids are shown in Table 12.6.8.

Cross-ply and laminated structures are standard approaches to reducing anisotropy. Composite stiffness, E_c, can be approximated for polymer composites by application of the rule of mixtures:

$$E_c = E_f V_f + E_m(1 - V_f)$$

previously. Expected properties of such advanced polymer composites can only be approximated once the component and material variables are determined during the design stage. The recommended approach is to work with a composite fabricator during the design phase to establish the expected mechanical properties.

Metal Matrix Composites

Introduction

The term *metal matrix composites* is usually reserved for fiber-reinforced materials, although technically it applies to particulate-reinforced systems as well. The general term for particulate-, whisker-, and chopped-fiber-reinforced systems is *cermet*. A majority of commonly used systems are based on particulate reinforcements.

Cermets and Cemented Carbides — Particulate-Reinforced MMCs

The term *cemented carbide* is applied to particulate composites based on tungsten carbide in a cobalt matrix. This distinction is largely historical, not technical. The tungsten carbide–cobalt-based materials were first developed in Germany, while development of other cermets (including noncarbide-, oxide-, and nitride-based systems) occurred in the U.S. during and immediately after World War II. Thus, a

Notes: Most nylon resins listed in this table are used for injection molding, and test values are determined from standard injection-molded specimens. In these cases a single typical value is listed. Exceptions are MoS2-filled nylon and direct-polymerized (castable) nylon, which are sold principally in semifinished stock shapes. Ranges of values listed are based on tests on various forms and sizes produced under varying processing conditions.

Because single values apply only to standard molded specimens, and properties vary in finished parts of different sizes and forms produced by various processes, these values should be used for comparison and preliminary design considerations only. For final design purposes the manufacturer should be consulted for test experience with the form being considered. Listed values should not be used for specification purposes.

distinguishing nomenclature was developed both because "carbide" was no longer completely appropriate with oxide systems available and for geopolitical reasons. This nomenclature confusion between the most common cermets, the cemented carbides, and other materials still survives. The structure consists of a continuous metal alloy functioning as cement, which holds together particles of carbide, oxide, or nitride ceramic. These materials provide strength, high hardness, wear (abrasion) resistance, low sliding friction, and precise tolerance even at quite high temperatures. Cermets and cemented carbides derive their usefulness when the compressive strength, hardness, and thermal resistance of the ceramic reinforcement is coupled with the ductility, toughness, adhesion, and lubricity provided by the metal. Common applications include metal and rock cutting and grinding tools, high-temperature containers, and pouring spouts, rocket nozzles, turbine parts, flame nozzles, friction and glide parts, seals, magnetron tube cathodes, flame nozzles, and ballpoint pen tips.

A cermet is usually fabricated by mixing the ceramic and metal powders together with a binder. This often requires high-energy mixing because of density differences with tooling made of the same cermet to avoid contamination. Subsequently, the part is formed, commonly by unidirectional or isostatic pressing, to final shape (accounting for shrinkage) with a wear-resistant die and with the formed object, then in the liquid phase is sintered in a controlled-atmosphere furnace. The chemistry is often quite complex in order to control the structure and the interfacial bond between metal and ceramic. Molybdenum promotes wetting of titanium carbide by molten nickel. Tantalum and titanium carbides are usually added to tungsten carbide-cobalt cemented carbides. Some cermets are prepared by slip casting, liquid metal infiltration, hot pressing, or solid-state sintering of parts. In some cases the material is "deficient" in metal to provide porosity for the passage of ink (pen tips) or incorporation of lubricant.

As indicated in the introduction to this section, a good bond between ceramic grain and metal "cement" is required for proper load transfer and to provide a homogeneous structure for good load bearing and uniform deformation. This normally requires a good wetting between liquid metal and ceramic grains. This is affected by minor alloying additions to the metal and the firing atmosphere.

The distribution, stability, and composition of phases have profound effects on properties. The production of WC–6 w/o Co is a good example of the need for strict compositional control. The tertiary-phase diagram shows that the composition range from 6.00 to 6.12 w/o must be adhered to in order to prevent formation of phases other than WC and Co — a composition range of less than 0.12 w/o! Embrittlement by graphite occurs at higher carbon content and by eta phase (h–WCl-x) at lower carbon levels. Precise formulation and furnace atmosphere control is required, usually assisted by using a

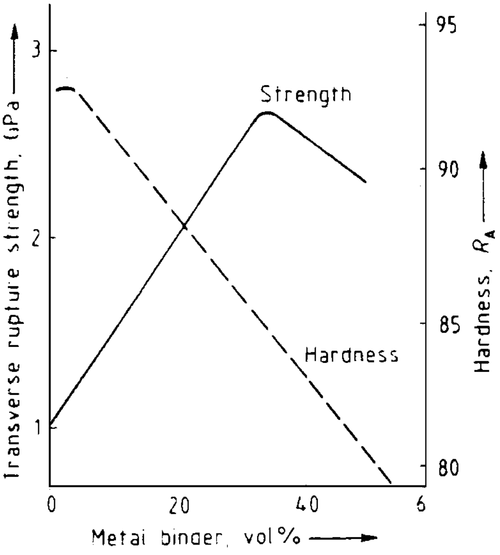

FIGURE 12.6.8 Effect of increased binder on strength and hardness of a TiC-Ni-Mo cermet with a 1 µm average carbide particle size

graphite-lined furnace. About 0.1% outside the acceptable composition range there is a drop of about 25% from the optimum strength.

It is important to engineer the microstructure of cermets in order to optimize properties. A uniform dispersion of round oxide, carbide, or nitride grains in the matrix of metal binder is desired. Inhomogeneity and sharp grain corners can act as failure origins. Round grains result from powder preparation and/or partial dissolution of sharp contours in the molten metal. As the amount of binder increases (Figure 12.6.8), the indentation hardness of the composite decreases, because metal, compared with ceramic, has a lower elastic modulus and will deform more easily. Fracture strength increases with binder because the metal phase confers fracture toughness. Generally, as ceramic grain size decreases, hardness and resistance to deformation increase for a fixed relative amount of ceramic. However, if the surface area increases sufficiently because of small grain size, there may not be enough metal to wet all the grain.

With these diverse factors a simplified way of looking at microstructural features and adjusting them for optimum performance is the mean free path, the average distance between neighboring ceramic grains (the average thickness of the binder phase). The mean free path depends on the size and shape of the grains and the amount of metal matrix available. Hardness, elevated-temperature hardness, strength, and toughness depend on the mean free path because it is the zone for absorption of crack energy and the medium for load transfer from grain-to-grain. Figure 12.6.9 shows that hardness varies with mean free path for a variety of cobalt contents and tungsten carbide grain sizes in cemented carbide. The curve does not continue below 0.1 mm because the metal binder becomes discontinuous.

Table 12.6.9 presents data for selected metal matrix systems with particulate reinforcement, including strength values at elevated temperatures. A section of Table 12.6.10 provides stiffness values for cobalt and nickel strengthened with sintered carbides.

Fiber-Reinforced MMCs

Fiber-reinforced MMCs may still be classed as an emerging materials area. A number of applications have been practiced, driven by the need for a lightweight, high-stiffness material and/or for elevated-temperature resistance in structures. These applications are typically for aerospace and similar advanced applications, which can use a premium material. The limited scope of current practical application and the limitations placed on technology disclosure by the Export Control Act and International Traffic-in-Arms Regulations make this section brief.

four times that of high-strength structural metals. The specific strength may be substantially higher than the metal. These properties are maintained to many hundreds of degrees above ambient, whereas those of many advanced structural metals deteriorate both in immediate heating and long-term creep. Some systems have been shown to have considerable fatigue resistance, showing several times the stress for equivalent cycle lifetimes. These properties are important for structural shapes in which lightweight and elevated-temperature resistance can afford a premium. Some applications have been struts and tubes for space structures, bicycle frames, turbine parts, propellers, and engine components. The fiber may be incorporated unidirectionally, as a woven two-dimensional laminate or a three-dimensional structure. Fabrication methods include diffusion bonding, pultrusion (hot isostatic drawing), hot rolling, molten metal infiltration, and casting.

Table 12.6.10 gives metal matrix strengthening values for fiber reinforcements added in volume percentages from 8 to 60%.

Ceramic Matrix Composites

Richard L. Lehman and Daniel J. Strange

CMCs are ceramic matrix materials, either oxide, carbide, nitride, boride, or similar material, reinforced with particulates, whiskers, or continuous fibers. The reinforcing phase may be of any material, but most interest is directed toward ceramic reinforcement media. The following sections address fiber- and whisker-reinforced ceramic composites, the materials that offer the greatest potential for ameliorating the brittleness of ceramics and for developing exceptional mechanical and structural properties.

TABLE 12.6.11 Ceramic Matrix Composites: Fiber and Matrix Properties

Ceramic Matrix Fiber Composites

Introduction. Ceramic matrix fiber composites (CMFCs) are the focus of substantial research but of limited commercial application as of this writing. The research enthusiasm is stimulated by the potential of high strength and toughness, mechanical and chemical durability, hardness, and oxidation resistance, all at elevated temperatures in the range 1000 to 1400°C. The limited commercialization, which is principally in military and aerospace applications, stems from the substantial cost of the fabricated materials, often in the range of thousands of dollars per kilogram. Fiber and matrix materials and properties used in CMFCs are presented in Table 12.6.11.

Mechanical Behavior. The primary goal of reinforcing a ceramic material with ceramic fibers is to increase the fracture toughness of otherwise brittle ceramic materials. In a monolithic ceramic, a flaw will propagate through the material under tension due to stress concentration at the crack tip. CMCs are designed with $E_f/E_m > 1$ so that the reinforcing fiber absorbs stresses, which tend to open and propagate cracks. Thus, the stress at the crack tip is reduced. Fiber debonding at the crack front, sliding, crack deflection, and other mechanisms also contribute to toughness. Often this is referred to as "rising R-curve" behavior, indicating that the strength of the ceramic at a crack tip increases with increasing crack length, stopping or slowing further crack growth. The most significant feature of CMFCs is the extensive fiber pullout, which occurs during failure. The fiber pullout results from low interfacial shear strengths, τ, which is designed into the composite by modifying interfacial properties and by using fibers with a *low* Weibull modulus. Loading is characterized by an initial elastic region followed by progressive failure of the matrix. The behavior is illustrated in Figure 12.6.10. During this matrix failure region, monotonically increasing loads are supported by the fibers. Ultimately, the fibers begin to fail according to bundle theory, and the remaining load support is provided by the frictional resistance to fiber pullout, a highly significant effect that absorbs large amounts of energy and contributes a high strain-to-failure performance previously unknown in ceramics. This "graceful" failure allows for a less catastrophic failure than normally

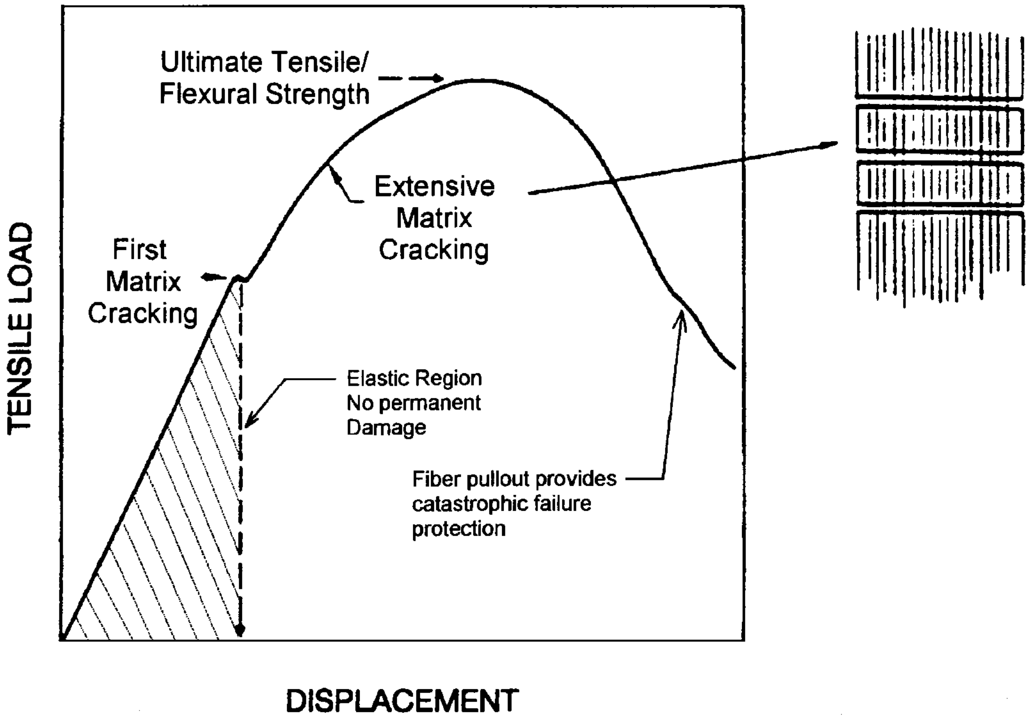

FIGURE 12.6.10 Load deflection behavior of CMFCs illustrating regions of fracture behavior

encountered in ceramics and is of great significance in the design of such materials as turbine blades, where the consequences of catastrophic failure are severe.

Continuous and Chopped Fiber Composites. The use of a continuous fiber reinforcement can have several advantages over the use of chopped fibers. There is a larger strain to pullout due to the increased fiber length, and the continuous fibers do not have stress-concentrating "flaws," as do the exposed ends of chopped fibers. Also, the prearrangement of the fibers allows very careful control of the properties in each direction, and the properties parallel to the fiber orientation will more closely mirror those of the fibers themselves than of the matrix. However, this type of composite is much more difficult to fabricate because of the problems of fiber weaving and forming, resistance to matrix infiltration, and resistance to densification, which necessitates expensive densification techniques, such as hot pressing, chemical vapor infiltration, polymer pyrolysis, directed metal oxidation, or sol-gel infiltration.

Glass Matrix CMFCs. A broad class of CMFCs has been developed and commercialized based on glassy matrix materials. The incentive for using a glassy matrix is the ease with which the matrix can be densified at low temperatures by vitreous sintering as opposed to the high-temperature solid-state sintering required for crystalline matrices. The low-temperature processing, in addition to being lower cost, preserves the high-strength properties of the fibers, which can easily be degraded at high temperatures. Unfortunately, the useful temperature of a glass-based CMC is limited to the Tg of the matrix, or slightly above, which prohibits traditional glass matrix CMCs from being used in extreme temperature applications (above approximately 1000°C). Newer glass and glass-ceramic compositions in the $CaO\text{-}Al_2O_3\text{-}SiO_2$ system are pushing this limit to the region of 1300°C. Two commercial glass matrix composites are Compglas™ and Blackglas™, both glass and glass/ceramic matrix materials reinforced with SiC fibers.

Polycrystalline matrix CMCs achieve higher temperature stability than the glass matrix composites, allow a wider choice of matrix materials, and generally have fewer problems with matrix reactivity. Typical

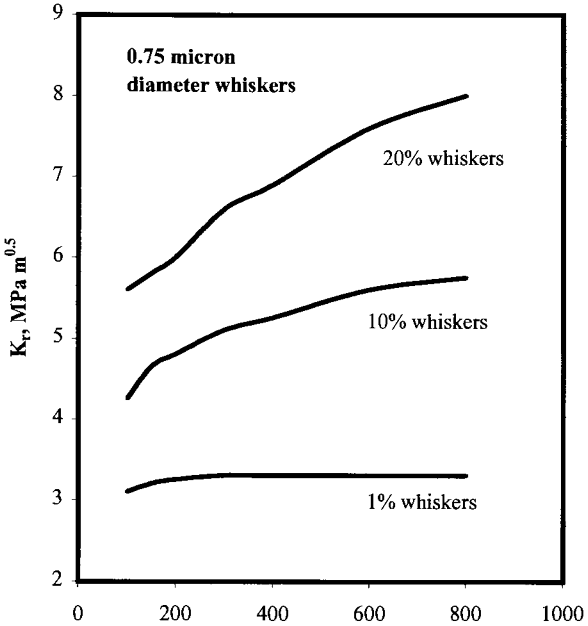

FIGURE 12.6.11 Fracture toughness and R-curve behavior of ceramic matrix whisker composites

crystalline matrix materials are the SiC, Si_3N_4, Al_2O_3, ZrO_2, and mixed silicates. Unfortunately, it is extremely difficult to sinter a CMC with a polycrystalline matrix to full density because of the interference of the fibers. This is particularly true with the nonoxide matrix materials. Pressureless sintering is ineffective for these materials, which necessitates the use of hot pressing or other exotic forming processes, which raise material costs considerably.

Ceramic Matrix Whisker Composites (CMWCs)

Whisker reinforcement of ceramic matrices, while not as exotic, can dramatically increase toughness while preserving relatively inexpensive forming techniques. Figure 12.6.11 illustrates the "rising R-curve" behavior of alumina with the addition of SiC whiskers, while Figure 12.6.12 shows the increase in fracture strength. The composites can generally be fully densified with hot pressing or hot isostatic pressing (HIP). Unfortunately, the toughness values achieved to date with whisker reinforcement are not as high as those for continuous-fiber reinforcement, although the lower cost of whisker composites has stimulated industrial applications. Cutting tool inserts, which must withstand high stresses at elevated temperatures (1200°C), are fabricated commercially from SiC-whisker-reinforced Al_2O_3 (SiC/Al_2O_3). These composite inserts have been a commercial product for a decade and are an excellent example of cost-effective CMCs, that is, high-value-added material applied to a small part exposed to extreme conditions. Health concerns regarding highly durable ceramic whiskers produced from SiC or Si_3N_4 have severely limited development and commercialization of these composites in the U.S. and Europe.

Carbon–Carbon Composites

Introduction

Carbon–carbon composites were originally developed for rocket nose cones in the 1960s because of their high specific strength, fracture toughness, thermal shock, and erosion resistance. Today, carbon–carbon composites are used in a broader range of applications, including brake components, fasteners, heaters, crucibles, and other assorted high-strength/high-temperature products.

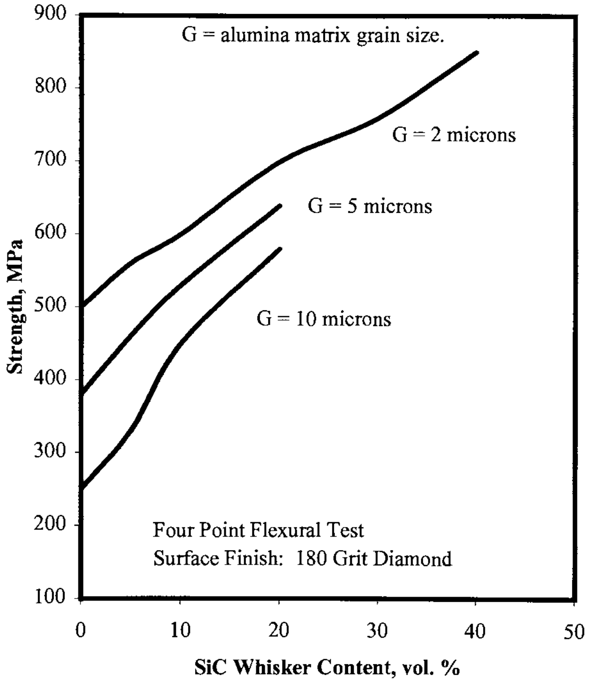

FIGURE 12.6.12 Strength behavior of SiC whisker-reinforced alumina matrix ceramic composite

High-Temperature Oxidation

Perhaps the greatest obstacle to the use of carbon–carbon composites as an engineering material, aside from high cost, is low oxidation resistance above 500°C. Although carbon–carbon maintains its mechanical properties to very high temperatures (>2000°C), it must be protected from oxidizing atmospheres at these temperatures or it will quickly degrade. Generally this is accomplished with SiC coatings with varying degrees of success. For most high-temperature oxidizing applications, carbon–carbon composite components are simply replaced when erosion reaches specified limits.

Fabrication

Most carbon–carbon composites are fabricated by polymer pyrolysis, the process of soaking carbon fiber yarns in a solution of a suitable polymer, then winding or laminating the fibers into the desired shape. Coal tar–based pitches, phenolics, and polyimides are also used as precursors.

The resulting green composite is then pressed, cured, and heated to 800 to 1200°C in an inert atmosphere, carbonizing the precursor. Some structures are heated to 2500°C to graphitize the matrix. The matrix after carbonization will contain a high porosity, typically 30%. This porosity is reduced by infiltrating the matrix with the precursor again and repeating the carbonization cycle. The densification cycle is repeated until the desired density is reached.

Carbon–carbon composites can be formed in random, unidirectional, two-dimensional, two-and-a-half-dimensional, and three-dimensional weaves. Unidirectional weaves provide the highest strength along the fiber axis but much lower strength in other directions. Unidirectional weaves are generally only used in laboratory investigations, as they have little technical value. Two-dimensional weaves (fabrics) are by far the most common due to the relative ease of manufacture and good mechanical properties in the plane of the fabric. Two-and-a-half-dimensional and three-dimensional weaves allow the weaving of very complex structures with good properties in any desired direction, yet the weaving costs can be prohibitive and unnecessary for most industrial applications.

Mechanical Properties

Properties of some carbon–carbon composite materials are given in Table 12.6.12. The properties can vary considerably, however, depending on factors such as the weave, tow diameter, precursor, pressing pressure, heat-treatment temperature, and number of densification cycles.

Under cyclical loading, carbon–carbon withstands 70 to 80% of its ultimate tensile strength. Carbon–carbon composites also have large strains to failure, exhibiting pseudoplastic behavior. This is unusual for a high-temperature ceramic material and is one of its prime attractions. The responsibility for this behavior lies with the low fiber–matrix interfacial bond strength and matrix microcracking. Unlike most high-temperature materials, the mechanical properties of carbon–carbon do not degrade at high temperatures. In fact, in inert atmospheres the strength of carbon–carbon composites increases by 40 to 50% up to a temperature of 1600°C.

Thermal conduction, electrical conduction, and thermal expansion are all much greater along the direction of the weave than perpendicular to it. Interestingly, thermal expansion is negative in two-dimensional weaves perpendicular to the fibers. It is therefore possible to use the fiber architecture to achieve near-zero thermal expansion in some directions.

12.7 Ceramics and Glass

Richard L. Lehman, Daniel J. Strange, and William F. Fischer, III

Traditional Ceramics

Traditional ceramics encompass many materials, not simply pottery, dinnerware, tile, and sanitaryware, but also technical whitewares, structural clay products, refractories, glazes, and enamels. The product and processing technology of these materials has advanced substantially in recent years which has improved products, reduced costs, and expanded application. Refer to Table 12.7.1 for properties of selected ceramics in this group.

Whitewares

Whitewares are principally comprised of traditional ceramic bodies that are white, cream, ivory, or light gray in appearance. Most whiteware materials are formulated from clay, flint, and feldspar (triaxial compositions) although other additives may be incorporated. The engineering properties of whitewares are strongly affected by porosity, a characteristic that reduces frost resistance and cleanability but is essential for certain aesthetic effects.

Vitreous. Vitreous whiteware bodies are translucent and have no open porosity, while earthenware and wall tile, for example, have substantial porosity, and semivitreous bodies bridge the gap in both porosity and translucency. The firing temperature is largely responsible for the differences in properties of the bodies by affecting the degree of vitrification. The general categories of products within the whiteware group are given in Table 12.7.2.

TABLE 12.7.1 (PART I) Physical Properties of Selected Ceramics

Material	Porcelain	Cordierite Refractory	Alumina, Alumina Silicate Refractories	Magnesium Silicate
Specific gravity	2.2–2.4	1.6–2.1	2.2–2.4	2.3–2.8
Coefficient of linear thermal expansion, ppm/°C, 20–700°	5.0–6.5 × 10^6	2.5–3.0 × 10^6	5.0–7.0 × 10^6	11.5 × 10^6

TABLE 12.7.2 Whiteware Materials

Class and Subclass	Percent Water Absorption	Example Product Type
Earthenware		
Natural clay	>15	Artware and tableware
Fine earthenware	10–15	Tableware, kitchenware, and artware
Semivitreous Earthenware	4–9	Tableware and artware
Talc earthenware	10–20	Ovenware and artware
Stoneware		
Natural stoneware	<5	Kitchware, artware, and drainage pipes
Fine stoneware	<5	Cookware, tableware and artware
Jasper stoneware	<1	Artware
Basalt stoneware	<1	Artware
Technical vitreous stoneware	<0.2	Chemicalware
China		
Vitreous china	0.1–0.3	Sanitaryware
Hotel china	0.1–0.3	Tableware
Cookware	1–5	Ovenware and stoveware
Technical china	<0.5	Chemicalware and ball mill jars and media
Fine china	<0.5	Tableware and artware
Porcelains		
Technical porcelains	<0.2	Chemicalware
Triaxial electrical porcelains	<0.2	Low-frequency insulators
High-strength electrical porcelains	<0.2	Low-frequency insulators
Dental porcelains	<0.1	Dental fixtures

Earthenware. Earthenware materials are defined as a nonvitreous clay-based ceramic ware of medium porosity (4 to 20%). They can be glazed or unglazed in their finished form. There are four primary subclasses of earthenware, natural clay, fine, semivitreous, and talc earthenware. Natural clay earthenware is derived from a single, unbeneficiated clay, whereas fine earthenware possesses beneficiated clays, as well as nonplastic materials, to comprise a triaxial body. Semivitreous earthenware is also a triaxial body, but it is fired to a higher temperature to form a more glassy phase, thereby creating a body with the lowest porosity of the earthenware group, usually between 4 and 9%. The final earthenware body is talc earthenware, produced principally from raw talc, with porosity ranging up to 20%. Earthenware bodies range in color from white for the talc and triaxial bodies, to tan and brown for many artware bodies, to a rusty red for terra-cotta.

Stoneware. Stoneware bodies can be either vitreous or semivitreous. They are primarily composed of nonrefractory fireclays or a combination of triaxial materials that matches the forming, firing, and finished properties of a natural stoneware body, bodies made from a single, naturally occurring, largely unbeneficiated clay-bearing material. Fine stonewares incorporate beneficiated clays, as well as nonplastics. Jasper stonewares are composed primarily from barium-containing compounds, while basalt stonewares contain large amounts of iron oxide.

Vitreous stoneware bodies are made from blends of a variety of beneficiated materials that are fired to higher temperatures to achieve low porosity levels (0 to 5%) necessary for many applications. Stoneware bodies are usually quite durable and resistant to chipping. However, translucency is less than that of china and the colors are not as white because of the presence of iron and other impurities.

China and Porcelain. China and porcelain are nearly synonymous terms which refer to fully vitreous (no porosity) clay, flint, feldspar compositions which are typically glazed, fired to high temperatures, and exhibit strength, hardness, and chemical durability. The term *china* is used to describe exceptionally fine materials prepared from low-impurity raw materials and used in artware and dinnerware. In modern times there has been a trend toward highly vitreous and highly translucent china compositions. Porcelain is used to describe mostly technical ceramics of the triaxial composition which are used as electrical insulators, sanitaryware, and chemical ware.

Subclassifications of china exist, such as vitreous china, hotel china, cookware, technical ceramics, fine chinas, and porcelains. Body formulations are usually based on the triaxial body, clays, flint/silica and fluxing agents, most usually feldspathic materials. However, there are a large number of bodies that are composed of a large fraction of other materials. Inclusive of these are alumina, bone ash, cordierite, other fluxes, and/or lithium compounds. Vitreous china is a category of traditional ceramics referring to the various sanitaryware plumbing fixtures and accompaniments. Hotel chinas, as the name implies, are generally used in commercial food establishments. Both bodies are glazed in a single firing operation in which both the body and glaze mature at the same time.

Technical whitewares account for a wide variety of vitreous ceramics used in the chemical, dental, refractory, mechanical, electrical, and structural areas. The compositions of most of these materials are similar to that used in the hotel chinas, with the possible substitution of alumina and zircon for some or all of the silica. These materials can be either glazed or unglazed with water absorption less than 0.5%.

Fine china bodies, including bone china, are highly vitrified and translucent materials that are usually fired in two or more separate operations. The first, higher-temperature firing matures the body and a second, lower-temperature firing matures the newly applied glaze. The separate firing conditions allow for the use of high-gloss glazes. Subsequent firings are used to apply decals and metallic decorations.

Porcelain ceramics are mostly used in technical applications. The typical body is triaxial (Table 12.7.2), although some or all of the silica can be replaced with alumina to increase the mechanical properties. Aside from triaxial porcelains, compositions in the $MgO \cdot Al_2O_3 \cdot SiO_2$ composition range are popular for electronic applications due to the absence of mobile alkali ions.

Refractories

Introduction. Refractory ceramic materials are by nature inert, high-melting-point compounds that are resistant to corrosion throughout the temperature range of use. Refractories must also withstand thermal cycling, thermal shock, mechanical fatigue, and a range of chemical attack from the elevated-temperature environments typical of most applications. Refractory materials are used in the processing of metals (75% of all refractories), glass, cement, and in the processing of nearly all ceramics.

Temperature Tolerance. A quality refractory must be stable at the intended use temperature. Refractoriness is a measure of the highest use temperature the material can withstand and is limited by the softening or melting point of the constituent oxides. Most refractories are a mixture of phases, and, as such, do not display a distinct melting point, but have a range of temperatures where the material starts to soften or melt. Most frequently, a refractory is categorized by an upper use temperature, but sometimes the refractoriness is quantified by the PCE or pyrometric cone equivalent. The PCE is a measure of the heat content that the refractory can withstand before beginning to soften, which is determined by the slumping of pyrometric cones during thermal cycle testing. This value may correspond to different temperatures under different environments or atmospheres and is thus a good indicator of maximum-use conditions. Refractory suppliers can provide PCEs for specific products. Another measure of a refractory quality is the failure under load temperature. The temperature where a refractory sags or deforms is part of all refractory specifications and is related to the amount and composition of the glassy phase within the material.

Dimensional Stability and Spalling. Dimensional stability and resistance to spalling are important performance criteria for most refractories. Spalling is the cracking or flaking of the refractory which usually results from thermal cycling, thermal gradients within the refractory, or compression effects due to differing thermal expansion of the different system materials. Spalling reduces the effectiveness and lifetime of the refractory. The dimensional stability of the refractory is also important. Since the refractory is subjected to both heating and cooling cycles, as well as thermal gradients in use, the expansion of the material is very important when choosing a refractory. Large changes in the size of a refractory set up stresses that can reduce the effectiveness of the refractory and may result in its failure..

Porosity. Refractory porosity is closely controlled in manufacturing since it leads to a reduction in the mechanical strength of the material and allows for the penetration and chemical attack of liquids or gases to the internal surface of the refractory. However, on the positive side, the presence of internal pores reduces the thermal conductivity of the material and increases fracture toughness, K_{IC}.

Fireclay Refractories. Fireclay refractories are composed of hydrated aluminosilicates with silica content of up to 75% or more with alumina and other minor contents of less than 40%, although alumina-fortified fireclay refractories are made with considerably higher alumina contents. Properties vary greatly over this wide range of compositions — generally, the higher the alumina content, the higher the performance. Fireclay refractories based on kaolin have a high refractoriness and high load resistance. Resistance to chemical attack and thermal conductivity decrease with increasing porosity, whereas spalling resistance increases. Increased alumina content raises the resistance of the material to attack in molten environments. Fireclay refractories are the most widely used refractory and find application in many industries.

Alumina Refractories. High-alumina refractories contain 80 to 99% or more aluminum oxide. As with fireclay materials, the higher the alumina content, the higher the refractoriness and the higher the load-bearing capacity. The chemical resistance of alumina refractories is greater than that of the fireclay refractories. Alumina brick is used to replace fireclay brick in more severe applications in the steel industry. Alumina bricks with phosphate bonding are used in the production of aluminum because of their refractoriness and the resistance of the phosphate bonding to chemical attack by the molten aluminum. Mullite ($3Al_2O_3 \cdot 2SiO_2$) refractories are similar to alumuna refractories in performance, but are cheaper and more resistant to thermal shock at the expense of some temperature capability.

Silica. Silica brick refractories, used in the glassmaking industry, range in composition from almost pure silica to mixtures containing lime, iron oxide, and alumina, depending on the degree of beneficiation of the raw materials. These refractories show a high degree of volume stability below 650°C (1200°F) and a lower degree of spalling than the fireclay bricks, largely because of the low thermal expansion of the silica.

Basic Refractories. Basic refractories are constituted from magnesite (MgO), calcia (CaO), and chrome (Cr_2O_3) and are used widely in metallurgical industries where basic slags predominate. They are not suitable in acid, or high-silica, environments. Refractories in this group, such as pure magnesite, dolomite (CaO-MgO), and chrome magnesite materials, have high refractoriness, volume stability, and are very resistant to chemical attack. Magnesite refractories have between 80 and 95% MgO content, a level at which the refractoriness and resistance to chemical attack is extremely high. Chromite refractories also have excellent chemical resistance in basic environments, with moderate resistance in acidic environments. The chrome content in these refractories ranges between 30 and 45%. Chrome–magnesite refractories are composed of over 60% MgO. Compositions and properties of selected basic and high-duty refractories are given in Table 12.7.3.

Glazes and Enamels

A glaze is a continuous glassy layer that is bonded to the surface of a ceramic. The glaze is typically hard, impervious to moisture, and easily cleaned. An enamel is similar in properties to a glaze, but the substrate is metallic. The surface finish of either can be altered from glossy to matte by varying the composition or the firing conditions. A glaze is usually composed of an aqueous suspension of ceramic particles that is applied to the surface of a material, dried, and fired. During firing, the materials within the glaze react and melt, forming a thin glassy layer on the surface of the ceramic material. Some materials are prefired and then the glaze is applied, or, as is becoming more common, the glaze can be fired along with the body. The maturing temperature of most glazes is on the order of 500 to 1500°C, or 930 to 2730°F. Glazes

TABLE 12.7.3 Compositions and Properties of Selected Basic and High-Duty Refractories

		Maximum Use Temperature in O_2		Thermal Conductivity		
Refractory	Composition	(°C)	(°F)	100°C/212°F	500°C/930°F	100°C/1830°F
Basic Refractories						
Silica	93–96% SiO_2	1700	3090	0.8–1.0	1.2–1.4	1.5–1.7
Fireclay	55–80% SiO_2 and 15–45% Al_2O_3	1300–1450	1370–2640	0.8–0.9	0.9–1.1	2.4–2.6
Magnesite	80–95% MgO Fe_2O_3 Al_2O_3	1800	3270	3.8–9.7	2.7–4.7	2.2–2.6
Chromite	30–45% Cr_2O_3, 14–19% MgO, 10–17% Fe_2O_3, 15–33% Al_2O_3	1700	3090	1.3	1.5	1.7
Chromite–magnesite	60+% Fe_2O_3 Al_2O_3	1800	3270	1.9–3.5	1.2–2.3	1.6
High-Duty Refractory						
Alumina	100% Al_2O_3	1950	3540	26	9.4	5.3
Magnesia	100% MgO	2400	4350	31	12	6
Silica	100% SiO_2	1200	2190	0.8	1.4	1.8
Mullite	72% Al_2O_3, 28% SiO_2	1850	3360	5.3	3.8	3.4

can be either clear, transparent, or opaque. Some glazes are formulated to form crystals within the glaze for a variety of optical effects, such as opalescence.

There are three main types of glazes used. The first of these are the raw glazes. Raw glazes can be further broken down into leaded, leadless, zinc-containing, slip, and porcelain glazes. Lead promotes the processing of the glaze via low viscosity and surface tension and imparts a high refractive index to the finished glaze. However, due to the health hazards associated with free lead, there has been a movement toward lead-free glazes in certain applications. Lead-free glazes require an increase in the firing temperature of approximately 150°C, from 1030 to around 1190°C. Porcelain glazes mature at temperatures in the same regime as the underlying body from which they get their name. Zinc-containing glazes are similar to porcelain glazes except that they mature at lower temperatures. Slip glazes are used in artware glazing and high-tension electrical insulators. Fritted glazes are in the form of prereacted glass which has been ground to form a powder. Special glazes offer special optical properties in the finished surface. Salt glazes are formed by injecting salts into the firing kiln, with the resulting glaze having a complex pattern of crystalline and glassy phases. Crystalline glazes are often zinc based and produce crystals within the glaze, again for artistic value. Luster glazes form a metallic coating on the glaze.

Structural Clay Products

Ceramic materials are used in a wide variety of applications in the construction industry, ranging from concrete and cement for buildings and highways, to structural clay materials for use in piping and roofing. For a discussion of concrete materials refer to Section 12.5.

Structural clay products have been used for millennia. Original uses included tile and clay brick for building construction, as well as pipes in water supply and sewer applications. These materials are still used today because of their high compressive strength and imperviousness to water. Structural ceramics are coarse-grained materials with the one exception of ceramic tile. Typical raw material compositions for these bodies are 35 to 55% clay, 25 to 45% filler, usually silica, and 25 to 55% fluxing material. Colors range from white for the kaolinitic clay products, to a buff for the fireclay materials, to red for the illitic materials. Properties vary widely between the different materials. Most concern is placed on the water absorption, which relates to freeze/thaw durability and compressive strength.

TABLE 12.7.4 Selected Properties of Crystalline Phases Used in Engineered Ceramics

Crystalline Phases	Formula	Melting Temperature (C)	Thermal Expansion α (ppm/°C)	Dielectric Constant κ
Magnesia	MgO	2852	14	5.5
Magnesia spinel	$MgO \cdot Al_2O_3$	2135	8	8.0
Alumina	Al_2O_3	2072	9	10.0
Mullite	$3Al_2O_3 \cdot 2SiO_2$	1920	5.5	4.5
Silica	SiO_2	1723	—	3.8
Protoenstatite	$MgO \cdot SiO_2$	1557	8.0	6.0
Forsterite	$2MgO \cdot SiO_2$	1910	12.0	6.0
Cordierite	$2MgO \cdot 2Al_2O_3 \cdot 5SiO_2$	1450	2.0	5.0

Zinc ferrite	$ZnO \cdot Fe_2O_3$	—	—	—

Advanced Ceramics

Classes of Advanced Ceramics

Advanced ceramic materials are materials which have been engineered to possess exceptional levels of mechanical, optical, thermal, or other property. Most often the materials possess high strength, high stiffness, or are chemically inert. Typical materials contain oxides, nitrides, or carbides which may be monolithic structures or reinforced with various particulate and/or fibrous materials. Refer to Section 12.6 for a detailed discussion of composites. The reinforcement phase usually, but not necessarily, differs from the matrix material. Phases used in designing engineered ceramics are listed in Table 12.7.4 with specific property characteristics as indicated. Advanced ceramic materials are currently much more varied and less standardized than metals, and materials from different manufacturers, or even from different production lots, will have varied properties.

Structural Ceramics

Required Properties. Structural applications involve the use of ceramic materials in load-bearing situations. Material properties required for these conditions include strength over a wide temperature range, often as high as 1400°C, stiffness, creep resistance, resistance to corrosion and oxidation, and, ideally, damage tolerance or toughness. The major difficulty in the use of ceramics for structural applications is their low fracture toughness compared with metals. Conversely, ceramics excel at high-temperature behavior, have low density/weight ratios, high stiffness, and chemical inertness. At the present level of technology, there is a trade-off between high strength and high toughness. To get a high-strength material usually requires a fine-grain-sized ceramic, while a tough ceramic material often has elongated grains or reinforcement phases that are usually quite large.

Applications. Existing and potential applications include automotive, biomedical, power generation, heat exchangers, wear materials, aerospace and military applications, cutting tools, and various other technologies. Table 12.7.5 provides the mechanical properties of selected advanced ceramics. The property

TABLE 12.7.5 Mechanical Properties of Selected Advanced Ceramic Materials

Material	Composition	Density (g/cc)	Elastic Modulus (GPa)	Fracture Strength (MPa)	Fracture Toughness K_{IC} (MPa · $m^{0.5}$)	Hardness (Vickers)
Alumina	Al_2O_3	3.9	380	Up to 400	4–9	2000
Beryllia	BeO	2.8–2.9	340	125	5	1100–1400

Zirconia	ZrO_2 stabilized with MgO	5.5	200	500	Up to 13	1200–1500
Zirconia	ZrO_2 stabilized with Y_2O_3	5.6	200	500–600	Up to 13	1200–1500
Zirconia (tetragonal)	ZrO_2	6.0	200	750	Up to 13	—
Zirconia (monoclinic)	ZrO_2	5.5	200	450	Up to 10	—
Reaction-bonded silicon nitride (RBSN)	Si_3N_4	1.9–2.8	150–250	300–400	Up to 12	750
Silicon nitride (hot pressed)	Si_3N_4	3.1–3.2	310	400–700	5–9	1600–2800
Silicon carbide (sintered)	SiC	3.0–3.2	400	400–500	6–9	2400–2800
Silicon carbide (hot pressed)	SiC	3.0–3.2	440	550–650	7–9	2500
Silicon carbide (RBSC)	SiC	3.0–3.15	350–400	300–400	4–8	2000
Boron carbide	B_4C	2.3–2.5	450	400–600	—	2800–3200
Boron nitride	BN	2.0–2.1	20–100[a]	—	—	Soft anisotropic
Graphite	C	1.9	3–15[a]	<50	—	Soft
Tungsten carbide	WC	15	600	450–750	Up to 20[b]	1300–1600
Titanium nitride	TiN	4.9	—	—	—	—
Titanium carbide	TiC	4.9	—	—	—	2800–3700

[a] Anisotropic.

[b] With Co additions.

values listed are guidelines; exact properties are difficult to specify since the exact properties depend largely on processing. Material selection is governed by the environmental conditions of each application.

Electronic and Magnetic Ceramics

Electronic and magnetic ceramic materials have a variety of useful functions. Alumina, alumina titanate, and aluminum nitride are used as substrate materials, zirconia is used in oxygen sensors, lead zirconate titanate (PZT) and lead magnesium niobate are common actuator and transducer materials, and barium titanate and related materials are used in capacitors. Ceramic materials are used not only in military and aerospace applications, but also in consumer electronics, computers, automotive and transportation systems, and power generation systems. Electronic/magnetic ceramics are useful as a result of a variety of properties. Refer to Table 12.7.1 for dielectric property data of selected compositions.

Optical Ceramics

Zirconia and transparent alumina, or sapphire, are often used as high-temperature windows, due to their high melting points, chemical inertness, and high transparency. They are also used as watch crystals, due to their high scratch resistance. Mirrors made from silicon carbide are being evaluated because of the higher strength-to-weight ratio compared with glass materials and the relatively low coefficient of thermal expansion of SiC. Laser crystals are a group of materials which are often based on doped crystals — yttrium aluminum garnet (YAG) is representative, Infrared (IR) transparent windows and shields are used principally in military and aerospace applications to protect IR sensors from damage. Missile nose cones, or randomes, must possess high mechanical strength and be resistant to mechanical erosion and thermal shock. Typical materials include aluminum oxynitride, spinel, zinc sulfide, calcium fluoride, yttria, and sapphire. Refer to Table 12.7.6 for IR absorption ranges of important ceramic materials.

Effect of Finishing and Machining on Properties

Final finishing of many advanced ceramics is required to obtain the optimum mechanical properties or to meet design tolerances. Since sharp corners act as stress concentrators and are not associated with good design, they are usually machined to a several-millimeter radius if they occur in the as-manufactured product. Other operations include surface grinding, polishing, or lapping operations. Ceramics are very hard materials, which makes final matching machining extremely time-consuming and expensive. Every effort should be made to fabricate components to close to net shape tolerances, or to machine the piece as much as possible prior to final firing.

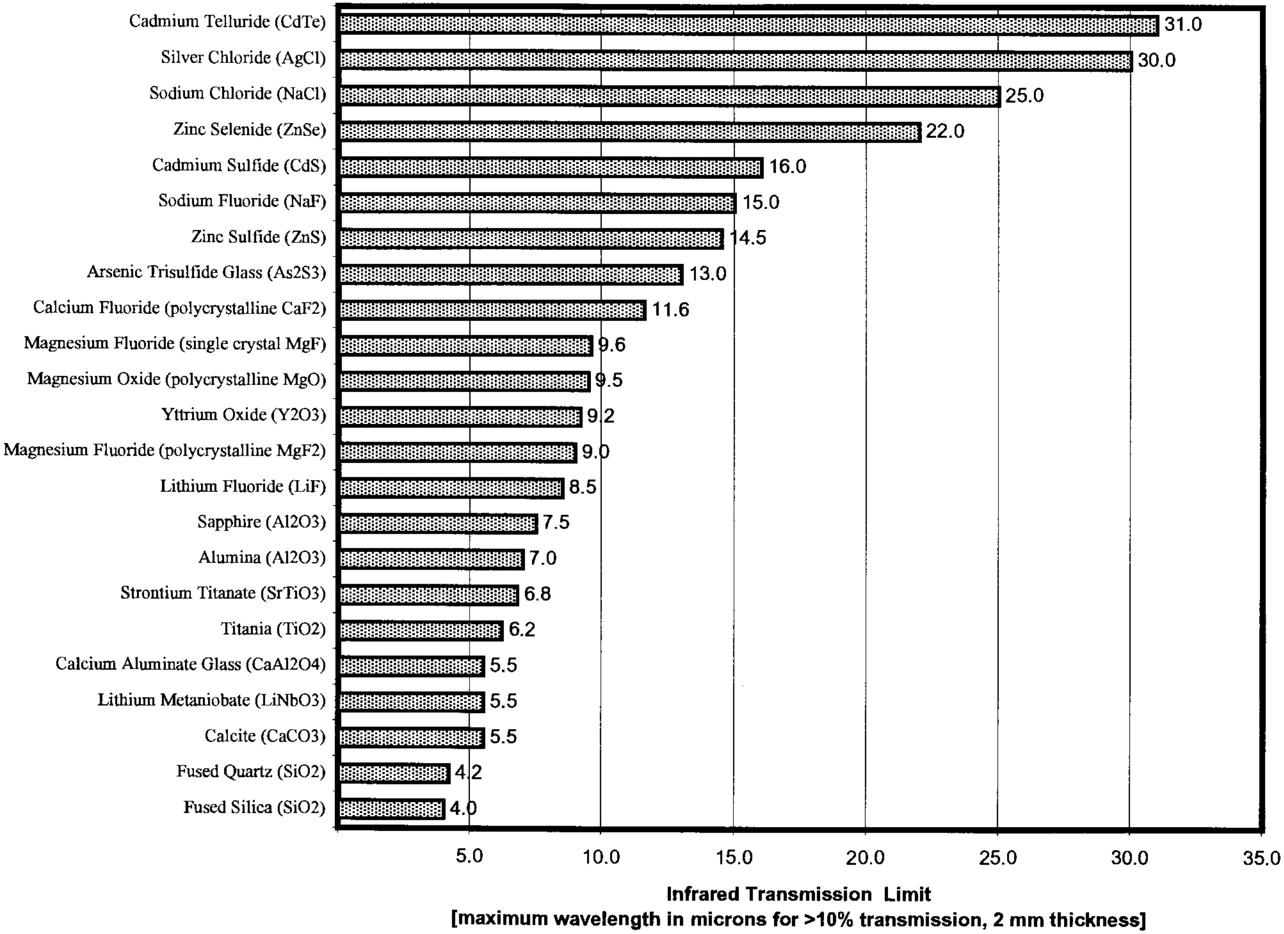
Traditional Glasses

Definition and Introduction

Traditionally, glass is defined as an inorganic product of fusion which has cooled to a rigid state without crystallizing. This broad definition says nothing about the chemistry of the glass but rather refers to the traditional concept of cooling liquid melts below the melting point to form substances which are rigid elastic mechanical solids but which have not crystallized. The historical model for this process is the melting of soda–lime silicate glass by fusing the raw materials at high temperature and cooling quickly to form the well-known window and container glass still in wide use today. Although this definition is still generally valid, processes exist today in which glass is made without fusion. Chemical and physical vapor deposition, and sol–gel processes are examples. Many organic and metallic materials form glasses and are in commercial use today, thus rendering the “inorganic” part of the historical definition inappropriate.

A more applicable definition of glass is an X-ray diffraction amorphous material which exhibits a glass transition. A glass transition is the temperature point at which the amorphous solid exhibits a continuous change in thermodynamic quantities such as heat capacity and expansion coefficient. Because the structure of the glass is frozen before it reaches equilibrium, a glass is metastable with respect to its corresponding

TABLE 12.7.6 IR Transmission Limits for Selected Materials



crystalline phase. Unlike the crystalline phase, the glass can have a range of physical properties depending upon the rate of cooling (thermal history) and these properties are universally isotropic.

Although glass can be made from an enormous range of polymers, oxides, metals, and inorganic and organic salts, the principle glasses of interest to a mechanical engineer will be glasses with oxide network formers such as SiO_2, B_2O_3, P_2O_5. These oxides, among others, are known as glass formers. They are capable of forming the three-dimensional network essential to the existence of the glassy state. Other oxides, such as alkalis, alkaline earths, and various transition elements simply serve to modify the basic network to produce varying properties.

The most common glass in use today is the very old soda–lime–silicate glass composition based on the weight composition: 74% SiO_2, 16% Na_2O, and 10% CaO. In this composition the silica is the network former, the sodium breaks up the silicate network to permit melting and fabrication at reasonable temperatures, and the calcia provides ionic bonding within the network to provide chemical durability. This composition is used today, with minor variations, for early all container, window, and tableware glass articles.

Composition/Properties

Traditional glasses are silicate glasses, i.e., glass which contain SiO_2 as the principal network-forming oxide. Table 12.7.7 give compositions for a representative range of commercial glasses, and Table 12.7.8 lists properties for flat glass. All glasses in Table 12.7.7 contain at least 50% SiO_2 and many are quite close to the traditional 74/16/10 composition mentioned above. The types and amount of modifier oxides are determined by the properties required in use. A more specific list of technical glass compositions from Corning, Inc., and identified by Corning glass codes, is given in Table 12.7.9. Principal glass types are discussed in the following sections.

Pure Silica Glass. Pure silica glass (fused silica) has excellent thermal, mechanical, chemical, and optical properties. Thermal expansion is 5.5×10^{-7}°C^{-1}, use temperature is above 1000°C, and it has excellent visible and ultraviolet (UV) transmission. However, the melting point is greater than 2000°C, which makes manufacture extremely difficult and expensive. Therefore, fused silica is used primarily for such demanding applications as optical fibers, semiconductor process equipment, UV lamps, optics, and space shuttle windows. If 7 wt% titanium dioxide (TiO_2) is added, the thermal expansion coefficient is reduced to zero in normal temperature ranges. This glass (ULE, or ultra low expansion) is used in applications which require exceptional dimensional stability. Telescope mirrors are an example.

High-Silica Glass. The high melting temperatures needed to produce pure SiO_2 glass can be avoided by first melting a special sodium borosilicate glass which can be formed into the desired shape. This glass (Vycor®) phase separates and after acid leaching results in a high (>96%) silica glass with nearly the same properties as pure vitreous silica.

Soda Silica. In order to lower the melting point, a flux is added. The most common flux is sodium oxide (Na_2O), which makes a low-melting glass that is soluble in water and is called water glass. Dissolved glass is used to seal or bond materials such as low-speed grinding wheels.

Soda–Lime–Silica. This is the most common glass and accounts for more than 90% of all the glasses made today. In this glass, lime (CaO) has been added to improve the durability of simple soda–silica glass. Small amounts of other oxides such as alumina (Al_2O_3), magnesium oxide (MgO), and potassium oxide (K_2O) are also added to further enhance the desired properties. The lime is usually obtained from limestone, and the sodium monoxide is obtained from any number of sodium compounds, notably sodium bicarbonate or common baking soda.

Aluminosilicate Glass. Aluminosilicate glass is produced by adding up to 20% Al_2O_3 to soda–lime glass. Aluminosilicate glasses are resistant to thermal shock and high temperatures, and they are not as difficult to produce as silica glass. They find wide use in electronics and in high-temperature laboratory equipment.

Hardness (Moh's)	5–6
Softening point, °C	729
Refractive index, sodium D-line	1.52
Modulus of elasticity, GPa	70
Tensile strength, MPa	45
Poisson's ratio	0.23
Coefficient of linear expansion, ppm/°C	8.8
Dielectric constant, 1 Mhz	7.1

Borosilicate Glass. In borosilicate glass much of the soda and lime of ordinary glass is replaced by boric oxide. The result is a glass that has a low thermal expansion and is thus resistant to heat and to sudden changes in temperature. The first borosilicate glass was developed by the Corning Glass Works under the trade name Pyrex. Borosilicate glasses are used in laboratory glassware, as well as in home ovenware. Because of their low thermal expansion they are suitable for applications requiring dimensional stability.

Lead Silicates. Lead silicate glass has a higher index of refraction and also a higher dispersion than soda–lime–silicate glass and thus finds use in optical applications. The high gloss resulting from high Fresnel reflection makes lead glasses of 24 to 35% PbO popular for consumer products in the form of artware and lead crystal glass. Lead glasses of different compositions are used widely in electronic applications since low-melting sealing glasses can be formed with little or no alkali, a constituent which promotes high electrical loss.

Strength of Glass

Theoretical Strength. Glass below the glass transition temperature (T_g) is a brittle solid, with failure originating at flaws (scratches, defects, minute compositional differences) which act as stress concentrators. Without flaws of any kind the strength of glass approaches theoretical levels of about 17 GPa (2.5×10^6 psi). Unfortunately, unless glass is processed under the utmost pristine conditions and then immediately coated to prevent surface abrasion by dust or other environmental agents, the glass will contain flaws which decrease the strength by several orders of magnitude from theoretical levels. Synthetic silica glass optical fibers, prepared under meticulous conditions and tested at 77 K, are among the few glass materials which exhibit nearly theoretical strength.

Nominal and Design Strength. The exact failure stress for a specific piece of glass will depend upon the configuration and size of the defect at the crack origin. Since these defects vary in size over a wide range, the standard deviation in the strength of glass will also be large. The glass design engineer must allow large safety factors, often 20 to 50%, to account for the statistical variation. For most types of glass a nominal strength of 70 MPa and a design stress of 7 MPa are typical. Table 12.7.10 summarizes strength and variability in the strength of glasses.

Strengthening and Tempering. Glass can be substantially strengthened, or tempered, either by rapid cooling or by ion-exchange of the surface to develop compressive stresses. Fast, uniform cooling of glass plates heated to the softening point will introduce surface compressive stresses on the glass (with corresponding tensile stress in the center) which become permanently frozen into place upon cooling to room temperature. These compressive stresses, typically 70 to 200 MPa, will resist externally applied tensile stresses and help to prevent crack propagation. Tempering will increase the strength of glass by as much as three to six times. Tempered glass will shatter violently when it fails as a result of the sudden release of stored elastic energy, although the broken pieces will not be sharp. Generally, only simple shapes can safely be thermally tempered.

Ion-exchange tempering also improves the strength of the glass by introducing surface compression. In the ion-exchange process large ions are “stuffed” into the interstices in the glass structure previously occupied by smaller ions. This is done by immersing the glass in a molten bath of the alkali salt (typically KNO_3 for a sodium-containing glass) at an elevated temperature. The larger ions will introduce a compressive strain as they force their way into the glass network. The strains obtainable are much higher than those from thermal tempering, generating stresses as high as 700 MPa, although the surface compressive layer is quite shallow and subject to penetration. Ion-exchanged glasses can be more than 10 to 20 times as strong as normal glass and are used, for example, in aircraft windshields to resist bird impacts.

TABLE 12.7.10 Ideal and Practical Strengths of Glass, Glass Fibers, and Glass–Ceramics

Type of Glass	Tensile Strength, psi	Strength/Weight Ratio, psi/lb per cu. in.
Untreated Glass		
Theoretical strength	1,000,000–4,000,000	45,000,000
Fibers, protected in vacuum	Up to 2,000,000	—
Fibers, in air, commercially available	250,000 average	6,000,000 average

Chemically Strengthened Glass–Ceramics		
Bulk material, abraded	200,000 and more	—

Compiled from several sources.

Behavior at Elevated Temperatures

Glasses do not have a clearly defined melting temperature. Instead, there is a temperature range where the viscosity of the glass changes smoothly from solid (greater than 10^{14} Pa · sec) to liquid (less than 10 Pa · sec). It is useful to define some points on the viscosity–temperature curve to create a clearer picture of the viscosity behavior of a glass. The strain point is defined as the temperature at which a glass will release 95% of its stresses within a period of 6 hr. This occurs at a viscosity of approximately $10^{13.5}$ Pa · sec. The annealing point occurs at 10^{12} Pa · sec a viscosity at which 95% of stresses will be released in 15 min. At $10^{6.6}$ Pa · sec, the softening point, the glass will deform under its own weight. The working point is defined as 10^3 Pa · sec, and is a typical minimum viscosity for machine working during forming. Refer to Table C.12 in the Appendix, Properties of Silicate Glasses. Many properties of glasses are presented in this comprehensive table, including maximum application temperatures (upper working temperature) and viscosity data for most common glasses. Generally, the extreme upper working temperature corresponds to the strain point of the glass. Normal service conditions are typically 50 to 60% of the strain point on the Kelvin temperature scale. Under normal service conditions glass is a brittle, mechanical solid, it possesses no mechanical characteristics of a liquid, and it will not flow. Specific heat and thermal conductivity data are presented in Table 12.7.11. Below the glass transition, glass is not a supercooled liquid, it is a glass. Old windows are not thicker at the bottom because of viscous flow.

Chemical Durability

Although glass is often considered an extraordinarily inert material, even the most durable glasses undergo some environmental degradation and many glasses are rapidly attacked by strong acid or basic solutions. Corrosive aqueous environments can cause the ions in the glass to be extracted by a leaching process. Chemical durability behavior is difficult to generalize and trial-and-error testing is usually required for each application. The most severe attack is experienced at extreme high and low pH values; neutral pH solutions rarely attack glass at significant rates. Glasses high in SiO_2, Al_2O_3, and CaO are generally most durable. Glasses high in alkali, such as Na_2O or K_2O, are less durable. B_2O_3 and PbO are intermediate.

TABLE 12.7.11 Thermal Properties of Several Glass Types

	Specific Heat			Thermal Conductivity, cal/cm sec°C × 10^{4a}			
Material	25°C	500°C	1000°C	–100°C	0°C	100°C	400°C
Fused silica	0.173	0.268	0.292	25.0	31.5	35.4	—
7900	0.18	0.24	0.29	24	30	34	—
7740	0.17	0.28	—	21	26	30	—
1723	0.18	0.26	—	—	29	33	—
0311 (chemically strengthened)	0.21	0.28	—	—	27	29	35
Soda–lime window glass	0.190	0.300	0.333	19	24	27	—
Heavy flint, 80% PbO, 20% SiO_2	—	—	—	10	12	14	—
Foamglass insulation	0.20	—	—	(0.97)	1.3	1.73	(2.81)
Fibrous glass	—	—	—	—	(0.8)	—	—
9606 glass–ceramic	0.185	0.267	0.311	—	90	86	75
9608 low-expansion glass–ceramic	0.195	0.286	—	—	48	51	55

Notes: Parentheses indicate extrapolated values. Specific heat increases with temperature and approaches zero at 0° K. There are no critical temperatures or phase changes. Thermal conductivity increases with temperature and is very high for glass ceramics.

[a] To convert to SI units, 1 cal/cm sec °C = 418.6 w/mk.

A notable form of chemical degradation which occurs under simple, apparently benign, conditions is weathering. Standard soda–lime–silicate window glass can be permanently damaged in a short time (~30 days) if held under high humidity with a means to retain adsorbed moisture on the surface. Such a means can be a dirt film or perhaps a sheet of newspaper. The moisture ion-exchanges with sodium ions in the glass, which form a high-pH surface film which accelerates the attack on the glass. Pitting and adherent surface deposits can quickly form, making the glass unusable.

For container applications requiring extremely high purity, it is common to use a durable glass such as a borosilicate or to increase the chemical resistance of the glass using surface treatments of SO_2, SnO_2, or TiO_2.

Optical Properties

Traditional glasses are principally used because they are transparent in the visible region of the spectrum; windows, containers, and precision optics are examples. Although pure silica is highly transmissive overt the entire visible spectrum, impurities impart coloration which detract from the performance of some glasses but which can also be used to produce beautiful and useful colored glasses. Table 12.7.12 lists impurity ions and their resulting colors. Iron is the most common impurity, imparting a blue-green-yellow tint depending on the oxidation state. It is possible to neutralize but not bleach impurity colors by "decolorization," the addition of complementary coloring oxides to produce an overall neutral gray absorption. Traditional glasses do not transmit well in the UV or IR range, with the exception of certain specialty glasses. Pure silica is the best example, enabling high transmission levels (>10%, 2 mm thickness) from 160 nm to 4 μm.

The refractive index of common silicate glasses are in the range of 1.5 to 1.7 and specific values are given in Table C.12 in the Appendix, *Properties of Silicate Glasses.*

Specialty Glasses

Non-Silica-Oxide Glasses

Glasses made from B_2O_3 and P_2O_3 glass formers rather than SiO_2 possess some special thermal, optical, and chemical properties which make them of interest in certain narrow engineering fields. Borate glasses, often in combination with PbO, are useful solder and sealing glasses for electronic applications; phosphate glasses have special optical properties and are also used as water-soluble chemicals in industry. Tellurite

TABLE 12.7.12 Coloring Additives to Glass

Color	Additive
Red	Colloidal Au or Cu, Cd-Se (S, Te)
Pink	$MnO_2 \cdot CeO_2$, Se^{2-}
Orange	CdS (Se)
Amber	FeS_x, $Fe_2O_3 \cdot TiO_2$
Yellow	UO_2, $CeO_2 \cdot TiO_2$, CdS
Green	Cr_2O_3, Fe_2O_3, CuO, U_2O_3
Blue	CoO, FeO, CuO
Violet	NiO, Mn_2O_3
Gray	$Co_3O_4 \cdot NiO$
Black	$Mn_2O_3 \cdot Cr_2O_3$, PbS, FeS, $CoSe_x$
UV absorption	CeO_2, TiO_2, Fe_2O_3, V_2O_5, CrO_3
IR absorption	FeO, CuO
Decolorization, i.e., mask Fe_2O_3 color	MnO, Se^{2-}, NiO, Co_3O_4
Opacification, i.e., white opals	CaF_2, NaF, ZnS, $Ca_2(PO_4)_3$
Solarization	Cerium, arsenic

glasses have high refractive indexes and, hence, are used in some demanding refractive optic applications. Glasses based on Bi_2O_3, Sb_2O_3, TeO_2, or V_2O_5 have very low melting points, suggesting their use as low-temperature electrical seals. Boro-aluminates have very high electrical resistivities. Alkaline earth aluminates have excellent IR transmitting properties and make excellent high-temperature lamp seals. Despite their unique properties, non-silica-oxide glasses are costly and make up only a very small percentage of the glass produced annually.

Chalcogenide Glasses

A class of excellent IR-transmitting glasses, the chalcogenides, are obtained by combining group VI elements with group V and IV elements. Glasses in this group also exhibit photoconductivity and semiconductivity. Applications for these glasses consist of IR-transmitting optical waveguides (to 20 μm), high-performance IR optical applications, and specialty applications which utilize their photoconductivity properties. Most notable of these applications is the photosensitive coating applied to photocopy drums. Purity issues have limited applications in optical fibers as of this writing.

Heavy Metal Fluoride Glasses

Heavy metal fluoride glasses (HMFG) are an important new (1975) composition group because of their extremely low theoretical optical attenuation (10^{-3} dB/km at 3.5 μm), which makes them candidates for repeaterless transoceanic communication links. Unfortunately, this magnitude of transmission has not been obtained in practice because of problems with high oxygen impurities and crystallization. Furthermore, HMFGs are readily attacked by water, and current development efforts are aimed at improving chemical durability. At present, HMFGs are limited to short transmission distance IR optical applications.

Amorphous Metals

Certain metal compositions can be fabricated as glasses by subjecting streams of the molten metal to extremely rapid quenching rates (10^5 to 10^8°C/sec). The resulting glasses possess intriguing properties. Strengths approach theoretical limits, and electrical resistivities are greater than their crystalline counterparts yet decrease with temperature. Most importantly, they have extremely low B–H hysteresis curves. For this reason they are used commercially as power transformer core laminations.

Amorphous Semiconductors

Many elements and compounds which exhibit semiconducting properties in the crystalline state are also semiconductors in the amorphous state. Si, Ge, P, As, $CdGe_xAs_2$ ($x = 0$ to 1.2), $Si_{1-x}H_x$ ($x = 0.1$ to 0.2) are important examples. These materials are use in fabrication of inexpensive vapor deposition fabrication of photovoltaic cells.

Glass Ceramics

A useful group of materials is made by batching, melting, and forming a product as a glass followed by heat treatment to nucleate and grow crystalline phases from the glass to produce a ceramic with up to 99% crystalline phase content. The microstructure contains crystals of about 1 μm size, a glassy matrix, and no porosity. The processing route is a principal advantage since high-speed glass-forming methods can be used, no porosity exists, the formed shape can be inspected as a transparent glass, and rejects at the forming stage can be recycled.

Glass ceramics are typically stronger than most ceramics as a result of zero porosity, and they are tougher than glass because of the deflection of crack fronts around the crystals. High-temperature properties are generally not good due to the glassy phase and the nature of the process, thus limiting most glass ceramics to low- and intermediate-temperature applications (<1000°C). A wide range of products has been made from glass ceramics, from home cookware to industrial bearings and aerospace radomes.

13.1 Introduction

Scott Smith

The dictionary entry for the word "manufacture" indicates that it comes from the Latin words *manu factus*, which literally mean "hand made." Manufacturing is an activity that has been with humankind from the beginning, and which has been present throughout recorded history. Indeed, the one activity that clearly distinguishes early human beings in the archeological record is their creation of handmade artifacts, such as tools, weapons, artworks, and jewelry, from the raw materials found in nature.

It is interesting then to look at the title of this chapter and find the word "Modern," meaning "involving recent techniques, methods, or ideas," next to "Manufacturing," one of the oldest known human endeavors. From the earliest arrows (created of wood, flint, feathers, and sinew) to aircraft (created of aluminum, titanium, steel, nickel, and their alloys, polymers, ceramics, composites, cloth, and many other materials), human minds have struggled to efficiently create products that meet the demands of consumers and improve the quality of life. Surely all of that effort must have long since explored and exhausted the entire spectrum of possible manufacturing techniques and processes. Nothing could be further from the truth! In fact, even though many manufacturing processes are thousands of years old, the pace of process improvement, and the pace of development of new manufacturing processes, continues to rapidly increase. Many examples of the latest developments and technologies of manufacturing are presented here.

Wealth and prosperity in human society is created by mining and agricultural activities (the means by which natural resources are extracted from the environment), and by manufacturing (the means by which those natural resources are transformed into products that meet the needs and wants of consumers). In 2001, approximately 14% of the U.S. gross domestic product resulted from production of durable and nondurable goods. Approximately 71% of total U.S. exports were manufactured goods. The manufacturing sector accounted for 95% of industrial research and development spending, and manufacturing industries employed a workforce of over 16 million people in over 300,000 companies. In the modern economy, manufacturing success requires the development and application of manufacturing processes capable of economically producing high-quality products in an environmentally acceptable manner.

In the broadest sense, manufacturing refers to the entire range of activities that together transform those natural resources into products. The scope of activities and infrastructure required to manufacture even the simplest products in everyday life is staggering. The industrial capability of a nation and of the world is an intricately woven interaction of the best efforts of millions of creative individuals. The process begins with the recognition of a need or want, and the development of a design to fulfill that need or want. During the design phase, alternative solutions are considered and judgments are made concerning component geometry, tolerances, material choices, and so on. Then the resources required to produce the part are acquired. Among these are financial resources, capital equipment, skilled workers, raw materials, energy, and distribution means. Increasingly, the manufacturing function extends throughout the life cycle of the product, including its use, service, and recycling or safe disposal.

Product quality and reliability, responsiveness to customer demands, increased labor productivity, and efficient use of capital continue to be areas that manufacturing companies must emphasize to respond to the challenge of global competitiveness. Leading manufacturing organizations must be able to adapt management and labor practices to the changing competitive climate, must develop and produce virtually defect-free products quickly in response to opportunities, must employ smaller adaptive workforces, and must provide worldwide service and support. Manufacturing practices must be continually evaluated and improved. New materials, new processes, creative use of existing resources, and the pervasive deployment of information technology play an indispensable role maintaining a competitive edge in the face of lower-wage competition from developing economies. A skilled, educated workforce can adapt and improve, and it is a critical component of a state-of-the-art manufacturing capability. Training and education are essential, not only as preparation before the start of a career, but continually throughout an entire career.

The practice of manufacturing has artisan-craftsman roots. Many manufacturing trades were learned in the past by trial and error or apprenticeship. This process is no longer sufficient. Modern manufacturing is rapidly evolving from an art into a science. Scientific and technical understanding of the individual manufacturing processes and of the manufacturing enterprise as a whole is needed to most effectively apply existing capabilities, quickly incorporate new developments, and identify the best available solutions to solve problems.

13.2 Unit Manufacturing and Assembly Processes

Robert E. Schafrik

There are a tremendous number of manufacturing processes able to impart physical shape and structure to a workpiece. However, if these processes are broken down into their basic elements and then examined for commonality, only a few fundamental processes remain. These are the building blocks, or unit processes, from which even the most complicated manufacturing system is constructed. This section describes these unit processes in sufficient detail that a technically trained person, such as a design engineer serving as a member of an integrated product and process design team consisting of members from other specialties, could become generally knowledgeable regarding the essential aspects of manufacturing processes. Also, the information presented in this section will aid such an individual in pursuing further information from more specialized manufacturing handbooks, publications, and equipment/tool catalogs.

Considering the effect that a manufacturing process has on workpiece configuration and structure, the following five general types of unit manufacturing process can be identified (Altan et al. 1983; NRC 1995):

Material removal processes — Geometry is generated by changing the mass of the incoming material in a controlled and well-defined manner, e.g., milling, turning, electrodischarge machining, and polishing.

Deformation processes — The shape of a solid workpiece is altered by plastic deformation without changing its mass or composition, e.g., rolling, forging, and stamping.

Primary shaping processes — A well-defined geometry is established by bulk forming material that initially had no shape, e.g., casting, injection molding, die casting, and consolidation of powders.

Structure-change processes — The microstructure, properties, or appearance of the workpiece are altered without changing the original shape of the workpiece, e.g., heat treatment and surface hardening.

Joining and assembly processes — Smaller objects are put together to achieve a desired geometry, structure, and/or property. There are two general types: (1) consolidation processes that use mechanical, chemical, or thermal energy to bond the objects (e.g., welding and diffusion bonding), and (2) strictly mechanical joining (e.g., riveting, shrink fitting, and conventional assembly).

Each component being manufactured has a well-defined geometry and a set of requirements that it must meet. These typically include

- Shape and size
- Bill-of-material
- Accuracy and tolerances
- Appearance and surface finish
- Physical (including mechanical) properties
- Production quantity
- Cost of manufacture

In order to satisfy these criteria, more than one solution is usually possible and trade-off analyses should be conducted to compare the different approaches that could be used to produce a particular part.

Every unit process must be controlled or directed in some way. The need for improved accuracy, speed, and manufacturing productivity has spurred the incorporation of automation into unit processes regarding both the translation of part design details into machine instructions, and the operation of the unit process itself and as a subsystem of the overall production environment. The section of this chapter on computer-aided design/computer-aided manufacturing (CAD/CAM) discusses the technology involved in creating and storing CAD files and their use in CAM. The expectations of precision are continuing to change, as indicated in Figure 13.2.1. This drive for ever-tighter tolerances is helping spur interest in continual improvements in design and manufacturing processes.

Modern machine tool controls are emphasizing two areas: adaptive control and communication. For *adaptive control* the controller must adapt its control gains so that the overall system remains at or near the optimal condition in spite of varying process dynamics. Expanded *communication* links the data collected by a unit process controller to other segments of the manufacturing operation. Data regarding production time and quantity of parts produced can be stored in an accessible database for use by inventory control and quality monitoring. This same database can then be used by production schedulers to avoid problems and costs associated with redundant databases.

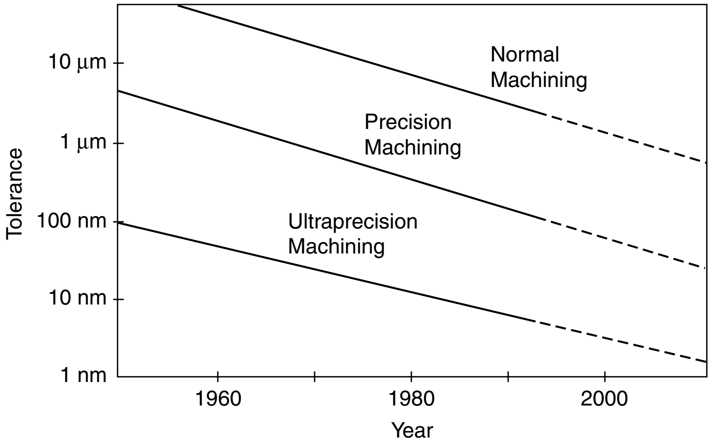

FIGURE 13.2.1 Precision machining domains. (From NRC, *Unit Manufacturing Processes*, National Academy Press, Washington, DC, 1995, 169. With permission.)

At the factory level, machining operations employing two or more numerically controlled (NC) machine tools may use a separate mainframe computer that controls several machine tools or an entire shop. The system is often referred to as *distributed numerical control* (DNC).

Today many factories are implementing *flexible manufacturing systems* (FMS), an evolution of DNC. An FMS consists of several NC unit processes (not necessarily only machine tools) that are interconnected by an automated materials-handling system and that employ industrial robots for a variety of tasks requiring flexibility, such as loading/unloading the unit process queues. A single computer serves as master controller for the system, and each process may utilize a computer to direct the lower-order tasks. Advantages of FMS include

- A wide range of parts can be produced with a high degree of automation.
- Overall production lead times are shortened and inventory levels reduced.
- Productivity of production employees is increased.
- Production cost is reduced.
- The system can easily adapt to changes in products and production levels.

In the following discussion, a number of unit processes are discussed, organized by the effect that they have on workpiece configuration and structure. Many of the examples deal with processing of metals, since that is the most likely material that users of this handbook will encounter. However, other materials are readily processed with the unit processes described in this chapter, albeit with suitable modifications or variations.

Mechanical assembly and material handling are also discussed in this section. On average, mechanical assembly accounts for half of the manufacturing time, and processes have been developed to improve the automation and flexibility of this very difficult task. Material handling provides the integrating link between the different processes — material-handling systems ensure that the required material arrives at the proper place at the right time for the various unit processes and assembly operations.

The section ends with a case study that demonstrates how understanding of the different unit processes can be used to make engineering decisions.

- Material removal (machining) processes
  - Traditional machining
    - Drill and reaming
    - Turning and boring
    - Planing and shaping
    - Milling
    - Broaching
    - Grinding
  - Nontraditional machining
    - Electrical discharge machining
    - Electrical chemical machining
    - Laser beam machining
    - Jet machining (water and abrasive)
    - Ultrasonic machining
- Phase-change processes
  - Green sand casting
  - Investment casting
- Structure-change processes
  - Normalizing steel
  - Laser surface hardening
- Deformation processes
  - Die forging
  - Press-brake forming

- Consolidation processes
  - Polymer composite consolidation
  - Shielded metal-arc welding
  - Mechanical assembly
- Material handling
  - Case study: Manufacturing and inspection of precision recirculating ballscrews

Material Removal Processes

These processes, also known as machining, remove material by mechanical, electrical, laser, or chemical means to generate the desired shape and/or surface characteristic. Workpiece materials span the spectrum of metals, ceramics, polymers, and composites, but metals, and particularly iron and steel alloys, are by far the most common. Machining can also improve the tolerances and finish of workpieces previously shaped by other processes, such as forging. Machining is an essential element of many manufacturing systems (ASM 1989b; Bakerjian 1992).

Machining is important in manufacturing because

- It is precise. Machining is capable of creating geometric configurations, tolerances, and surface finishes that are often unobtainable by other methods. For example, generally achievable surface roughness for sand casting is 400 to 800 μin. (10 to 20 μm), for forging 200 to 400 μin. (5 to 10 μm), and for die casting 80 to 200 μin. (2 to 5 μm). Ultraprecision machining (i.e., super-finishing, lapping, diamond turning) can produce a surface finish of 0.4 μin (0.01 μm) or better. The achievable dimensional accuracy in casting is 1 to 3% (ratio of tolerance to dimension) depending on the thermal expansion coefficient, and in metal forming it is 0.05 to 0.30% depending on the elastic stiffness, but in machining the achievable tolerance can be 0.001%.
- It is flexible. The shape of the final machined product is programmed and therefore many different parts can be made on the same machine tool and just about any arbitrary shape can be machined. In machining, the product contour is created by the path, rather than the shape, of the cutter. By contrast, casting, molding, and forming processes require dedicated tools for each product geometry, thus restricting their flexibility.
- It can be economical. Small lots and large quantities of parts can be relatively inexpensively produced if matched to the proper machining process.

The dominating physical mechanism at the tool/workpiece interface in conventional machining is either plastic deformation or controlled fracture of the workpiece. Mechanical forces are imposed on the workpiece by the application of a tool with sharp edges and higher hardness than the workpiece. However, many new materials are either harder than conventional cutting tools or cannot withstand the high cutting forces involved in traditional machining. Nontraditional manufacturing (NTM) processes can produce precision components of these hard and high-strength materials. NTM processes remove material through thermal, chemical, electrochemical, and mechanical (with high-impact velocity) interactions.

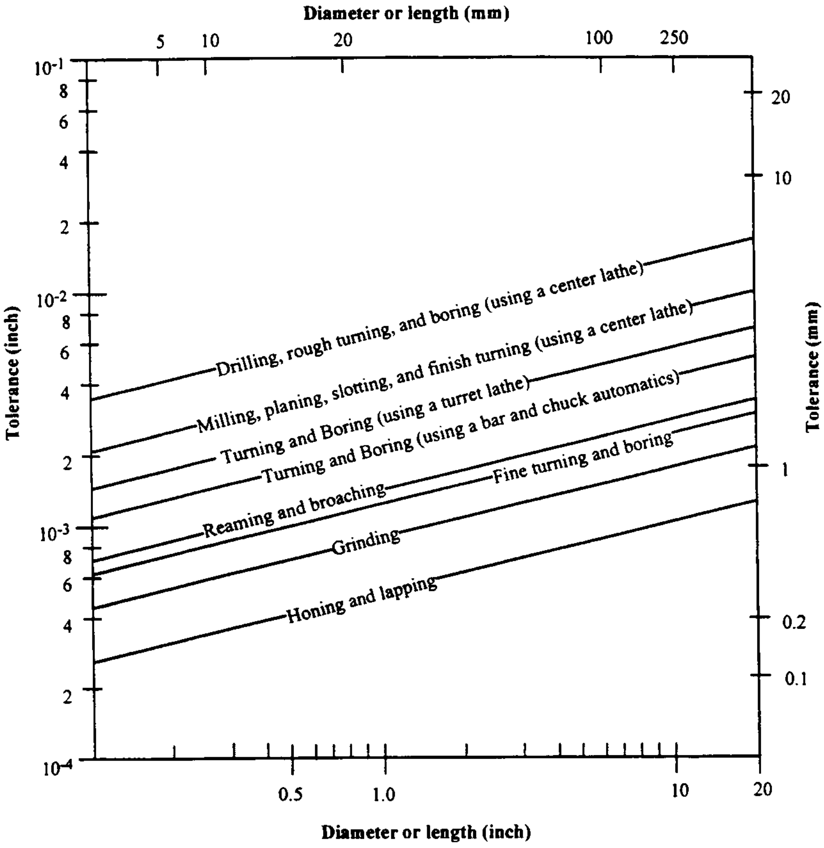

FIGURE 13.2.2 Tolerance vs. dimensional data for machining processes. (From NRC, *Unit Manufacturing Processes*, National Academy Press, Washington, DC, 1995, 168. With permission.)

Machinability is defined in terms of total tool life, power requirements, and resultant workpiece surface finish. To date, no fundamental relationship incorporates these three factors and thus machinability must be empirically determined by testing.

Machine tools can be grouped into two broad categories:

- Those that generate surfaces of rotation
- Those that generate flat or contoured surfaces by linear motion

Selection of equipment and machining procedures depends largely on these considerations:

- Size of workpiece
- Configuration of workpiece
- Equipment capacity (speed, feed, horsepower range)
- Dimensional accuracy
- Number of operations
- Required surface condition and product quality

For example, Figure 13.2.2 graphically indicates the various tolerance levels that can be typically achieved for common machining unit processes as a function of the size of the workpiece. Such data can help in identifying candidate unit processes that are capable of meeting product requirements.

Traditional Machining

Steven Y. Liang

Traditional machining processes remove material from a workpiece through plastic deformation. The process requires direct mechanical contact between the tool and workpiece, and it uses relative motion between the tool and the workpiece to develop the shear forces necessary to form machining chips. The tool must be harder than the workpiece to avoid excessive tool wear. The unit processes described here are a representative sample of the types most likely to be encountered. The reference list at the end of the section should be consulted for more detailed information on the unit processes discussed below, plus those that are not included here.

Process Kinematics in Traditional Machining. In all traditional machining processes, the surface is created by providing suitable relative motion between the cutting tool and the workpiece. There are two basic components of relative motion: primary motion and feed motion. Primary motion is the main motion provided by a machine tool to cause relative motion between the tool and workpiece. The feed motion, or the secondary motion, is a motion that, when added to the primary motion, leads to a repeated or continuous chip removal. It usually absorbs a small proportion of the total power required to perform a machining operation. The two motion components often take place simultaneously in orthogonal directions.

The functional definitions of turning, milling, drilling, and grinding are not distinctively different, but machining process specialists have developed terminology peculiar to a given combination of functions or machine configurations. Commonly used metal-cutting machine tools, however, can be divided into three groups, depending on the basic type of cutter used: single-point tools, multipoint tools, or abrasive grits.

Basic Machine Tool Components. Advances in machine-tool design and fabrication philosophy are quickly eliminating the differences between machine types. Fifty years ago, most machine tools performed a single function such as drilling or turning, and operated strictly stand-alone. The addition of automatic turrets, tool-changers, and computerized numerical control (CNC) systems allowed lathes to become *turning centers* and milling machines to become *machining centers*. These multiprocess centers can perform a range of standard machining functions: turning, milling, boring, drilling, and grinding (Green 1992).

The machine tool *frame* supports all the active and passive components of the tool: spindles, table, and controls. Factors governing the choice of frame materials are resistance to deformation (hardness), resistance to impact and fracture (toughness), limited expansion under heat (coefficient of thermal expansion), high absorption of vibrations (damping), resistance to shop floor environment (corrosion resistance), and low cost.

Guide ways carry the workpiece table or spindles. Each type of way consists of a *slide* moving along a track in the frame. The slide carries the workpiece table or a spindle. The oldest and simplest way is the *box way*. As a result of its large contact area, it has high stiffness, good damping characteristics, and high resistance to cutting forces and shock loads. Box slides can experience stick-slip motion as a result of the difference between dynamic and static friction coefficients in the ways. This condition introduces positioning and feed motion errors. A *linear way* also consists of a rail and a slide, but it uses a rolling-element bearing, eliminating stick-slip. Linear ways are lighter in weight and operate with less friction, so they can be positioned faster with less energy. However, they are less robust because of the limited surface contact area.

Slides are moved by hydraulics, rack-and-pinion systems, or screws. *Hydraulic pistons* are the least costly, most powerful, most difficult to maintain, and the least accurate option. Heat buildup often significantly reduces accuracy in these systems. Motor-driven *rack-and-pinion* actuators are easy to maintain and are used for large motion ranges, but they are not very accurate and require a lot of power to operate. Motor-driven screws are the most common actuation method. The screws can either be leadscrews or ballscrews, with the former being less expensive and the latter more accurate. The *recirculating ballscrew* has very tight backlash; thus, it is ideal for CNC machine tools since their tool trajectories are essentially continuous. A disadvantage of the ball-screw systems is the effective stiffness due to limited contact area between the balls and the thread. (*Note:* a case study at the end of this section discusses the manufacture of precision ballscrews.)

Electric motors are the prime movers for most machine tool functions. They are made in a variety of types to serve three general machine tool needs: spindle power, slide drives, and auxiliary power. Most of them use three-phase AC power supplied at 220 or 440 V. The design challenge with machine tools and motors has been achieving high torque throughout a range of speed settings. In recent years, the operational speed of the spindle has risen significantly. For example, conventional speeds 5 years ago were approximately 1600 rpm. Today, electric motors can turn at 12,000 rpm and higher. Higher speeds cause vibration, which makes use of a mechanical transmission difficult. By virtue of improvement in motor design and control technology, it is now possible to quickly adjust motor speed and torque. Spindle motors are rated by horsepower, which generally ranges from 5 to 150 hp (3.7 to 112 kW) with the average approximately 50 hp (37 kW). Positioning motors are usually designated by torque, which generally ranges from 0.5 to 85 lb-ft (0.2 to 115 Nm).

The *spindle* delivers torque to the cutting tool, so its precision is essential to machine tool operation. The key factors influencing precision are bearing type and placement, lubrication, and cooling.

Cutting-Tool Materials. The selection of cutting tool materials is one of the key factors in determining the effectiveness of the machining process (ASM 1989b). During cutting, the tool usually experiences high temperatures, high stresses, rubbing friction, sudden impact, and vibrations. Therefore, the two important issues in the selection of cutting-tool materials are hardness and toughness. *Hardness* is defined as the endurance to plastic deformation and wear; hardness at elevated temperatures is especially important. *Toughness* is a measure of resistance to impact and vibrations, which occur frequently in interrupted cutting operations such as milling and boring. Hardness and toughness do not generally increase together, and thus the selection of cutting tool often involves a trade-off between these two characteristics.

Cutting-tool materials are continuously being improved. Carbon steels of 0.9 to 1.3% carbon and tool steels with alloying elements such as molybdenum and chromium lose hardness at temperatures above 400°F (200°C) and have largely been replaced by *high-speed steels* (HSS). HSS typically contains 18% tungsten or 8% molybdenum and smaller amounts of cobalt and chromium. HSSs retain hardness up to 1100°F (600°C) and can operate at approximately double the cutting speed with equal life. Both tool steels and HSS are tough and resistive to fracture; therefore, they are ideal for processes involving interrupted engagements and machine tools with low stiffness that are subject to vibration and chatter.

Powder metallurgy (P/M) high-speed tool steels are a recent improvement over the conventionally cast HSS. Powder metallurgy processing produces a very fine microstructure that has a uniform distribution of hard particles. These steels are tougher and have better cutting performance than HSS. Milling cutters are becoming a significant application for these cutting-tool materials.

Cast cobalt alloys, popularly known as Stellite tools, were introduced in 1915. These alloys have 38 to 53% cobalt, 30 to 33% chromium, and 10 to 20% tungsten. Though comparable in room temperature hardness to HSS tools, cast cobalt alloy tools retain their hardness to a much higher temperature, and they can be used at 25% higher cutting speeds than HSS tools.

Cemented carbides offered a four- or fivefold increase in cutting speeds over conventional HSS. They are much harder, but more brittle and less tough. The first widely used cemented carbide was tungsten carbide (WC) cemented in a ductile cobalt binder. Most carbide tools in use now are a variation of the basic WC-Co material. For instance, WC may be present as single crystals or a solid solution mixture of WC-TiC or WC-TiC-TaC. These solid solution mixtures have a greater chemical stability in the cutting of steel. In general, cemented carbides are good for continuous roughing on rigid machines, but should avoid shallow cuts, interrupted cuts, and less rigid machines because of likely chipping.

A thin layer of TiC, TiN, or Al_2O_3 can be applied to HSS or carbide substrate to improve resistance to abrasion, temperature, friction, and chemical attacks. The *coated tools* were introduced in the early

1970s and have gained wide acceptance since. Coated tools have two or three times the wear resistance of the best uncoated tools and offer a 50 to 100% increase in speed for equivalent tool life.

Ceramic tools used for machining are based on alumina (Al_2O_3) or silicon nitride (Si_3N_4). They can be used for high-speed finishing operations and for machining of difficult-to-machine advanced materials, such as superalloys (Komanduri and Samanta 1989). The alumina-based materials contain particles of titanium carbide, zirconia, or silicon carbide whiskers to improve hardness and/or toughness. These materials are a major improvement over the older ceramic tools. Silicon nitride–based materials have excellent high-temperature mechanical properties and resistance to oxidation. These materials also have high thermal shock resistance, and thus can be used with cutting fluids to produce better surface finishes than the alumina tools.

These tools can be operated at two to three times the cutting speeds of tungsten carbide, usually require no coolant, and have about the same tool life at higher speeds as tungsten carbide does at lower speeds. However, ceramics lack toughness; therefore, interrupted cuts and intermittent application of coolants can lead to premature tool failure due to poor mechanical and thermal shock resistance.

Cermets are titanium carbide (TiC) or titanium carbonitride particles embedded in a nickel or nickel/molybdenum binder. These materials, produced by the powder metallurgy process, can be considered as a type of cemented carbide. They are somewhat more wear resistant, and thus can be used for higher cutting speeds. They also can be used for machining of ferrous materials without requiring a protective coating.

Cubic boron nitride (CBN) is the hardest material at present available except for diamond. Its cost is somewhat higher than either carbide or ceramic tools, but it can cut about five times as fast as carbide and can hold hardness up to 200°C. It is chemically very stable and can be used to machine ferrous materials.

Industrial *diamonds* are now available in the form of polycrystalline compacts for the machining of metals and plastics with greatly reduced cutting force, high hardness, good thermal conductivity, small cutting-edge radius, and low friction. Recently, diamond-coated tools are becoming available that promise longer-life cutting edges. Shortcomings with diamond tools are brittleness, cost, and the tendency to interact chemically with workpiece materials that form carbides, such as carbon steel, titanium, and nickel.

Wear of Cutting-Tool Materials. Cutting tools are subjected to large forces under conditions of high temperature and stress. There are many mechanisms that cause wear:

- Adhesion: The tool and chip can weld together; wear occurs as the welded joint fractures and removes part of the tool material, such as along a tool cutting edge.
- Abrasion: Small particles on the wear surface can be deformed and broken away by mechanical action due to the high localized contact stresses; these particles then abrade the cutting tool. Typically, this is the most common wear mode.
- Brittle fracture: Catastrophic failure of the tool can occur if the tool is overloaded by an excessive depth of cut and/or feed rate.
- Diffusion: Solid-state diffusion can occur between the tool and the workpiece at high temperatures and contact pressures, typically at an area on the tool tip that corresponds to the location of maximum temperature, e.g., cemented carbide tools used to machine steel. High-speed machining results in higher chip temperatures, making this an increasingly important wear mode.
- Edge chipping.
- Electrochemical: In the presence of a cutting fluid, an electrochemical reaction can occur between the tool and the workpiece, resulting in the loss of a small amount of tool material in every chip.
- Fatigue.
- Plastic deformation.

Single-Point Cutting-Tool Geometry. Figure 13.2.3 depicts the location of various angles of interest on a single-point cutting tool. The most significant angle is the cutting-edge angle, which directly affects the

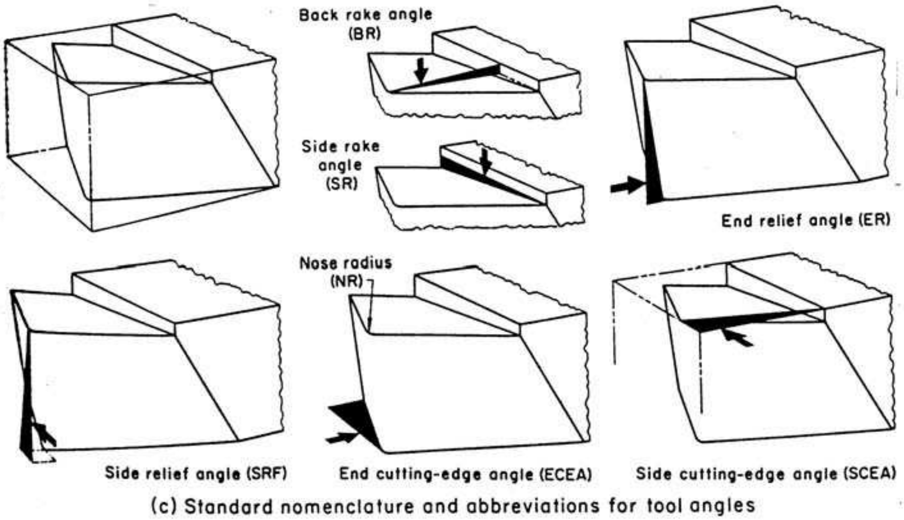

FIGURE 13.2.3 Standard nomenclature for single-point cutting-tool angles. (From *ASM Handbook*, *Machining*, vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 141. With permission.)

shear angle in the chip formation process, and therefore greatly influences tool force, power requirements, and temperature of the tool/workpiece interface (ASM 1989a). The larger the positive value of the cutting-edge angle, the lower the force, but the greater the load on the cutting tool. For machining higher-strength materials, negative rake angles are used. *Back rake* usually controls the direction of chip flow and is of less importance than the side rake. Zero back rake makes the tool spiral more tightly, whereas a positive back rake stretches the spiral into a longer helix. *Side rake* angle controls the thickness of the tool behind the cutting edge. A thick tool associated with a small rake angle provides maximum strength, but the small angle produces higher cutting forces than a larger angle; the large angle requires less motor horsepower.

The *end relief angle* provides clearance between the tool and the finished surface of the work. Wear reduces the angle. If the angle is too small, the tool rubs on the surface of the workpiece and mars the finish. If the angle is too large, the tool may dig into the workpiece and chatter, or show weakness and fail through chipping. The *side relief angle* provides clearance between the cut surface of the work and the flank of the tool. Tool wear reduces the effective portion of the angle closest to the workpiece. If this angle is too small, the cutter rubs and heats. If the angle is too large, the cutting edge is weak and the tool may dig into the workpiece. The *end cutting-edge angle* provides clearance between the cutter and the finished surface of the work. An angle too close to zero may cause chatter with heavy feeds, but for a smooth finish the angle on light finishing cuts should be small.

Machinability. Optimum speed and feed for machining depend on workpiece material, tool material, characteristics of the cut, cutting-tool configuration, rigidity of setup, tolerance, and cutting fluid. Consequently, it is not possible to recommend universally applicable speeds and feeds.

Drilling and Reaming. Drilling is the most widely used process for making circular holes of moderate accuracy. It is often a preliminary step to other processes such as tapping, boring, or reaming. *Reaming* is used to improve the accuracy of a hole while increasing its diameter. Holes to be reamed are drilled undersize.

Drills are classified by the material from which they are made, method of manufacture, length, shape, number and type of helix or flute, shank, point characteristics, and size series (Table 13.2.1). Selection of drill depends on several factors (ASM 1989b):

TABLE 13.2.1 Common Drill Types

Drill Type	Description	Application
Core	Has large clearance for chips	Roughing cuts; enlarging holes
General-purpose (jobber)	Conventional two-flute design; right-hand (standard) or left-hand helix. Available with flute modification to break up long chips	General-purpose use, wide range of sizes
Gun	Drill body has a tube for cutting fluid; drill has two cutting edges on one side and counter-balancing wear pads on the other side	Drill high-production quantities of holes without a subsequent finishing operation
High helix	Wide flutes and narrow lands to provide a large bearing surface	Soft materials, deep holes, high feed rates
Low helix	Deep flutes facilitate chip removal	Soft materials, shallow holes
Oil hole	Has holes through the drill body for pressurized fluid	Hard materials, deep holes, high feed rate
Screw-machine	Short length, short flutes, extremely rigid	Hard materials; nonflat surfaces
Step	Two or more drill diameters along the drill axis	Produce multiple-diameter holes, such as for drilling/countersinking
Straight flute	Flutes parallel to the drill axis minimize torquing of the workpiece	Soft materials; thin sheets

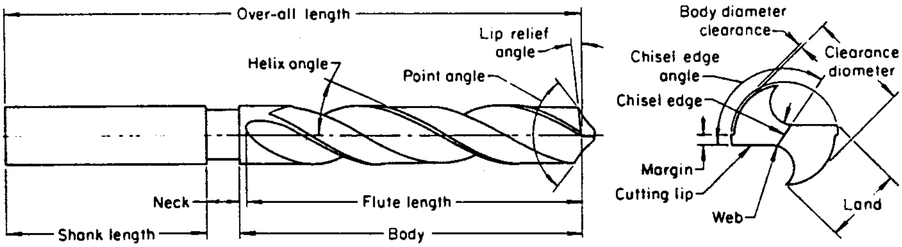

FIGURE 13.2.4 Design features of a typical straight-shank twist drill. (From *ASM Handbook*, *Machining*, vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 218. With permission.)

- Hardness and composition of the workpiece, with hardness being more important
- Rigidity of the tooling
- Hole dimensions
- Type of drilling machine
- Drill application — originating or enlarging holes
- Tolerances
- Cost

The most widely used drill is the general-purpose twist drill, which has many variations. The flutes on a twist drill are helical and are not designed for cutting but for removing chips from the hole. Typical twist drills are shown in Figure 13.2.4.

Machining forces during *reaming* operations are less than those of drilling, and hence reamers require less toughness than drills and often are more fragile. The reaming operation requires maximum rigidity in the machine, reamer, and workpiece.

Most *reamers* have two or more flutes, either parallel to the tool axis or in a helix, which provide teeth for cutting and grooves for chip removal. The selection of the number of flutes is critical: a reamer with too many flutes may become clogged with chips, while a reamer with too few flutes is likely to chatter (Table 13.2.2).

The optimal speed and feed for drilling depend on workpiece material, tool material, depth of hole, design of drill, rigidity of setup, tolerance, and cutting fluid. For *reaming* operations, hardness of the workpiece has the greatest effect on machinability. Other significant factors include hole diameter, hole

TABLE 13.2.2 Common Reamer Types

Reamer Type	Description	Application
Adjustable	Tool holder allows adjustment of the reamer diameter to compensate for tool wear, etc.	High-rate production
End-cutting	Cutting edges are at right angles to the tool axis	Finish blind holes, correct deviations in through-holes
Floating blade	Replaceable and adjustable cutting edges to maintain tight tolerances	High-speed production (workpiece rotated, tool stationary)
Gun	Hollow shank with a cutting edge (e.g., carbide) fastened to the end and cutting fluid fed through the stem	High-speed production (workpiece rotated, tool stationary)
Shell	Two-piece assemblies, mounted on arbors, can be adjusted to compensate for wear	Used for finishing operations (workpiece rotated, tool stationary)
Spiral flute	Flutes in a helix pattern, otherwise same as straight-flute reamer	Difficult to ream materials, and holes with irregularities
Straight flute	Flutes parallel to the tool axis, typically pointed with a 45° chamfer	General-purpose, solid reamer

configuration (e.g., hole having keyways or other irregularities), hole length, amount of stack removed, type of fixturing, accuracy and finish requirements, size of production run, and cost. Most reamers are more easily damaged than drills; therefore, the practice is to ream a hole at no more than two thirds of the speed at which it was drilled.

Most drilled holes are 1/8 to 1 in. (3.2 to 40 mm) in diameter. However, drills are available for holes as small as 0.001 in. (0.03 mm) (microdrilling), and special drills are available as large as 6 in. (150 mm) in diameter. The range of length-to-diameter (L/D) of holes that can be successfully drilled depends on the method of driving the drill and the straightness requirements. In the simplest form of drilling in which a rotating twist drill is fed into a fixed workpiece, best results are obtained when L/D is <3. But by using special tools, equipment, and techniques, straight holes can be drilled with L/D = 8 or somewhat greater. Nonconventional machining processes can also generate high-aspect-ratio holes in a wide variety of materials.

Reaming and boring are related operations. Hole diameter and length, amount of material to be removed, and required tolerance all influence which process would be most efficient for a given application (ASM 1989b). Most holes reamed are within the size range of 1/8 to 1 inch (3.2 to 40 mm), although larger and smaller holes have been successfully reamed. For most applications with standard reamers, the length of a hole that can be reamed to required accuracy ranges from slightly longer to much shorter than the cutting edges of the reamer, but there are many exceptions to this general rule of thumb. Tolerances of 0.001 to 0.003 in. (0.03 to 0.08 mm) with respect to the diameter are readily achievable in production reaming operations. Surface finish for annealed steels can be held within the range of 100 to 125 µin. (2.50 to 3.20 µm), but a surface as smooth as 40 µin. (1 µm) can be obtained under appropriate processing conditions (ASM 1989b).

Turning and Boring. Turning produces external cylindrical surfaces by removing material from a rotating workpiece, usually with a single-point cutting tool in a lathe. *Boring* is this same process applied for enlarging or finishing internal surfaces of revolution.

The basic equipment for turning is an *engine lathe* that consists of a bed, a headstock, a carriage slide, a cross slide, a tool holder mounted on the cross slide, and a source of power for rotating the workpiece (Table 13.2.3). Engine lathes are often modified to perform additional types of machining operations through the use of attachments. Most turning machines can also perform boring operations, but boring machines may not be able to perform turning operations. Sizes of lathes range from fractional horsepower to greater than 200 hp.

Machines used for boring are noted for their rigidity, adaptability, and ability to maintain a high degree of accuracy (Table 13.2.4). For extremely large workpieces, weighing thousands of pounds, the boring cutting tool is rotated and the workpiece is fixed.

TABLE 13.2.3 Typical Lathes Used for Turning

Lathe	Description	Applications
Bench lathe	An engine lathe that can be placed on a workbench	Small workpieces and prototype parts
Engine lathe	Has a leadscrew that moves the slide uniformly along the bed; available with chucking or centering headstock	Chucking type allows centering and clamping for rotation, e.g., holding castings or forgings Centering type secures workpiece between pointed centers, e.g., for turning long workpieces, such as shafts
Gap-frame lathe	Modified engine lathe for turning larger diameter parts	Workpieces requiring off-center mounting or irregular protuberances
Numerically controlled lathe	Uses a computer program to control the lathe to generate the desired shape	Produces consistent parts in a CAD/CAM environment
Tracer-controlled lathe	A duplicating lathe that uses a stylus moving over a template to control the cutting tool	Manufacture of prototype parts and low-rate production

TABLE 13.2.4 Typical Machines Used for Boring

Boring Machine	Description	Applications
Bar (screw) machine	Modified turret lathe to handle bars and tubes	Parts made from bars or tubes
Engine lathe	Versatile machine; essentially same machine as used for turning	Bores one hole at a time in a single part; limitations regarding workpiece size and configuration
Horizontal boring mill	Workpiece remains stationary and tool rotates	Wide variety of parts; cost-effective for a relatively high production volume
Precision boring machine	Vertical and horizontal models	Parts requiring extreme tolerances
Special-purpose machines	Boring machine modified for specialized application	Single-purpose applications with high production rates
Turret lathe	Has rotating turret on a lathe, tooled for multiple machining operations	More versatile than engine lathe; supports high production rates
Vertical boring mill	Same basic components as a lathe	Very large, heavy, or eccentric workpieces
Vertical turret lathe	Same features as vertical boring mill; may also have a second vertical head	Flexible machine, useful in CAD/CAM environment; simultaneous multiple machining operations possible

Machine Tool and Machining Parameters. In turning and boring operations, a single-point tool is traversed longitudinally along the axisymmetric workpiece axis parallel to the spindle. A tangential force is generated when the cutting tool engages the rotating work. This force is generally independent of the cutting speed and directly proportional to the depth of cut for a particular material, tool shape (particularly side rake angle), and feed rate. That force, when multiplied by the surface speed of the workpiece, estimates the net horsepower required to remove material. The extent to which workpiece material affects required machining power is illustrated in Figure 13.2.5. Moving the tool longitudinally requires much less power (ASM 1989b).

To minimize the number of cuts required, the depth of cut should be as great as possible, which is limited by the strength of the part and the fixturing, and the power output of the machine tool. The feed rate is a function of the finish desired and the strength and rigidity of the part and machine tool.

Components that range in size from those used in watches up to large steel propeller shafts more than 80 ft (24 m) long are regularly turned. Aluminum parts over 10 ft (3 m) in diameter have been turned. In practice, the weight of the workpiece per unit of volume determines the size of the workpiece that is practical to turn. Large, heavy parts can be turned in a vertical boring machine. Irregular-shaped parts,

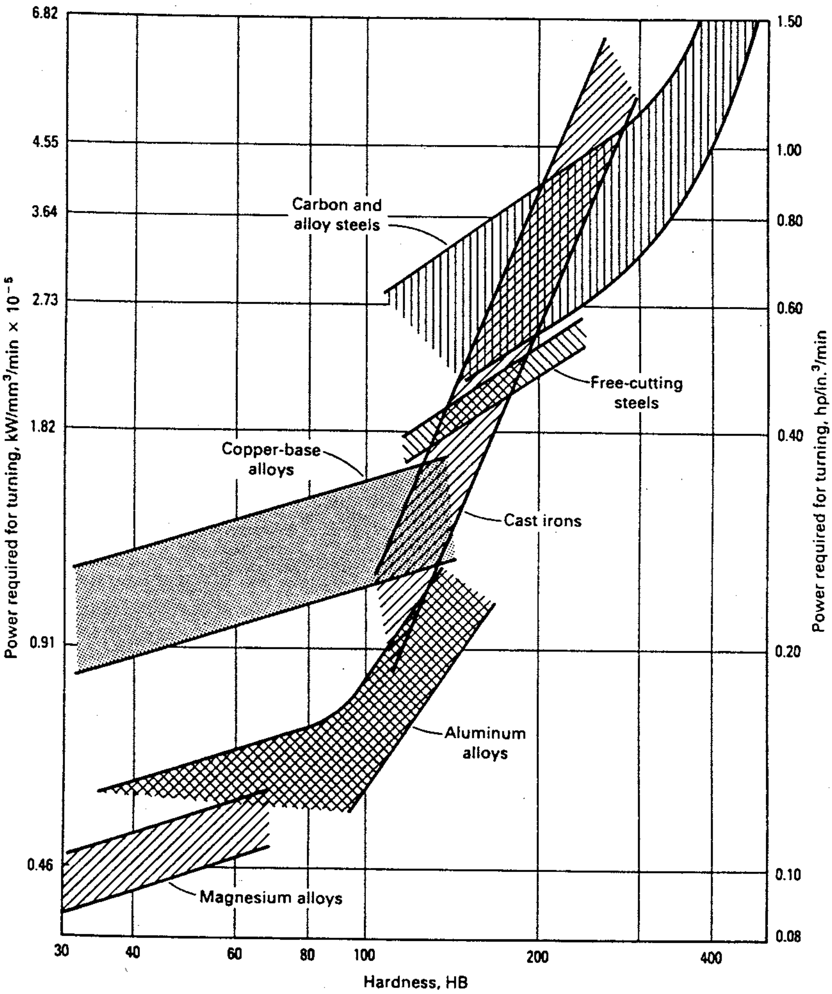

FIGURE 13.2.5 Effect of workpiece composition and hardness on power required for turning. (From *ASM Handbook*, *Machining*, vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 136. With permission.)

such as crankshafts, may require the use of counter-weighting to achieve dynamic balance for vibration-free turning.

For both turning and boring, the rotation speed, feed, and depth of cut determine the rate of material removal and resulting surface quality. Feed rate for most applications falls between 0.005 and 0.020 in./rev (0.13 and 0.51 mm/rev). Finishing cuts have a significantly lower feed rate (e.g., 0.001 in./rev, 0.03 mm/rev), and roughing cuts are made at a significantly higher feed rate (e.g., 0.25 in./rev, 6.35 mm/rev). Boring is not limited by the L/D ratio of a hole — this ratio can be as great as 50 if the tool bar and workpiece are adequately supported.

There are many potential sources of tolerance error in turning and boring operations. The more common errors are summarized in Table 13.2.5 and Table 13.2.6.

Planing and Shaping. Planing is a widely used process for producing flat, straight surfaces on large workpieces. A variety of contour operations and slots can be generated by use of special attachments. It is often possible to machine a few parts quicker by planing than by any other method. *Shaping* is a process for machining flat and contour surfaces, including grooves and slots.

TABLE 13.2.5 Factors Affecting Dimensional Accuracy in Turning

Quantity	Basic Cause of Inaccuracy	Corrective Actions
Diametrical roundness	Lathe spindle runout	Preload angular bearings to eliminate side and end movement
Diameter variation (taper)	Parallelism of spindle to longitudinal travel	Establish true parallelism between the axis of rotation of the workpiece and the longitudinal travel of the cutting tool
Face flatness	Lack of true normality of cross slide to axis of rotation	Precision align cross slide to axis of rotation
Length dimensions parallel to the axis of rotation	Improper positioning of longitudinal slide	Adjust positioning of longitudinal slide
Diameter accuracy	Inadequate gauging	Employ proper measurement technique

TABLE 13.2.6 Factors Affecting Dimensional Accuracy in Boring

Quantity	Basic Cause of Inaccuracy	Corrective Actions
Diameter accuracy	Inadequate gauging, or heat generated by the machining action	Employ proper measurement techniques; use cutting fluid to control temperature
Taper of the cylindrical bore	Deflection of the boring bar	Reduce the boring bar unsupported length; use a higher-stiffness material for the boring bar
Roundness, as determined by the variation in radius about a fixed axis	Finish cut is not concentric with the previous cut; or out-of-balance workpiece or holder	Begin with a semifinish cut, followed by a finish cut; carefully balance the initial setup
Concentricity of one surface with another	Too great a clamping force on the workpiece	Redesign clamping fixture, or use a precision boring machine
Squareness and parallelism of holes in relation to other features of the work	Dimensional changes in machine components	Maintain constant ambient temperature; maintain cutting fluid at constant temperature; or stabilize oil temperature

Planers develop cutting action from straight-line reciprocating motion between one or more single-point tools and the workpiece; the work is reciprocated longitudinally while the tools are fed sideways into the work. Planer tables are reciprocated by either mechanical or hydraulic drives, with mechanical drives predominating.

Shapers use a single-point tool that is supported by a ram, which reciprocates the tool in a linear motion against the workpiece. The workpiece rests on a flat bed and the cutting tool is driven toward it in small increments by ram strokes. Shapers are available with mechanical and hydraulic drives, with mechanical drives predominating.

Planing and shaping are rugged machining operations during which the workpiece is subjected to significant cutting forces. These operations require high clamping forces to secure the workpiece to the machine bed.

In general, it is advisable to plane steel with as heavy a feed and as high a speed as possible to promote good chip-formation conditions so that chip breakers are not needed. Carbide cutters allow cutting speed to be increased from 225 to 300 surface feet per minute (sfm) (70 to 90 m/min). For best results, uniform cutting speed and feed are maintained throughout the entire stoke (ASM 1989b).

In general, speeds are related to workpiece material characteristics and associated machinability. Feeds are influenced by the workpiece machinability, but also by ram speed, depth of cut, and required dimensional accuracy and surface finish. Common practice in shaping is to make roughing cuts at as high a feed and slow a speed as practical, and make finishing cuts at a low feed rate and high speed (ASM 1989b). For low carbon steel, a typical speed for a roughing cut is 50 sfm (15 m/min), while for a finishing cut it is 80 sfm (25 m/min) using a conventional cutting tool. Similarly for aluminum, a roughing cut of 150 sfm (45 m/min) is typically followed by a finishing cut of 200 sfm (60 m/min).

TABLE 13.2.7 Types of Planers

Planer Type	Description	Application
Double housing	Two vertical uprights support the crossrail which in turn supports the tools	Rigid machine; restricts the width of workpiece
Open side	A single upright column supports a cantilevered crossrail; less rigid than the double-housing type	Accommodates wide workpieces which can overhang one side of the table without interfering with the planer operation

TABLE 13.2.8 Types of Shapers

Shaper Type	Description	Application
Horizontal	The ram drives the tool in the horizontal direction; uses plane or universal table (rotates on three axes)	Gears, splined shafts, racks, and so on; not used for rate production
Vertical	The ram operates vertically, cutting on the downstroke	Slots, grooves, keyways; matching die sets, molds, fixtures; not used for rate production

There is a practical lower bound on minimum feed rate. Feed rates that are too low will cause the tool to chatter; feed rates less than 0.005 in. (0.125 mm) are seldom used in shaping. Similarly, shallow cuts (less than 0.015 in., 0.38 mm) will cause chatter during shaping.

Planers are available in a wide range of sizes (Table 13.2.7). Tools are available in a variety of configurations for undercutting, slotting, and straight planing of either horizontal or vertical surfaces (ASM 1989b).

Shapers are available in a large variety of sizes (Table 13.2.8), ranging from small models with a maximum stroke length of less than 6 in. (150 mm) to large machines with a maximum stroke of 36 in. (914 mm). On each machine, the length of stroke can be varied from its maximum to slightly less than 1 in. (25 mm) for the largest machine, and to 1/8 in. (3.2 mm) for the smallest machine.

Planing is a precision process in which flatness can be held within 0.0005 in. (0.013 mm) total indicated run out (TIR) on workpieces up to 4 ft^2 (0.4 m^2). Although planing is most widely used for machining large areas, it is also used for machining smaller parts, although 12 in. is about the minimum distance for a planing stoke. Size of the workpiece that can be planed is limited by the capacity of the planing equipment.

Shaping is a versatile process in which setup time is short and relatively inexpensive tools can be used. Under good conditions, a shaper can machine a square surface of 18 in. on a side (0.2 m^2) to a flatness within 0.001 in. (0.025 mm); under optimum conditions this can be improved to 0.0005 in. (0.013 mm). The size of the workpiece that can be shaped is limited by the length of the stoke, which is usually about 36 in. (914 mm). Shaping should be considered for machining flat surfaces in these instances:

- Required flatness cannot be achieved by another method.
- Production quantity is insufficient to justify the tooling costs of milling or broaching.

Planing and shaping are interrupted cutting processes, and are comparatively inefficient means of metal removal; for example, shaping costs five times that of milling, exclusive of the tooling and setup costs.

Milling. Milling is a versatile, efficient process for metal removal. It is used to generate planar and contour surfaces through the action of rotating multiple-tooth cutters. Surfaces having almost any orientation can be machined because both the workpiece and cutter can move in more than one direction at the same time.

Cutters with multiple cutting edges rotate in a spindle. The machining process is interrupted as the teeth of the milling cutter alternately engage and disengage from the workpiece.

TABLE 13.2.9 Types of Milling Machines

Milling Machine	Description	Application
Knee-and-column	Six basic components: • Base — the primary support • Column — houses spindle and drive • Overarm — provides support for the arbor-mounted cutting tools • Knee — supports the table, saddle, and workpiece; provides vertical movement • Saddle — provides 1° of horizontal motion • Table — directly supports the workpiece and provides a second degree of horizontal motion	Widely used for low production milling; provides three-axis movement; primary drawback is lack of rigidity due to the number of joints
Bed-type	Table and saddle mounted on a bed in fixed vertical position; vertical motion obtained by movement of the spindle carrier; available with horizontal or vertical spindle	Very rigid machine; permits deep machining cuts and close dimensional control
Planar-type (adjustable rail)	Can accommodate almost any type of spindle for driving cutters and boring bars; utilizes several milling heads	Use for mass-production milling; can perform simultaneous milling and boring operations
Special purpose	Many possible configurations involving major modifications or combinations of the basic types of milling machines; adapted for automated control	Optimized for high-volume production; includes profilers and machining centers; these machines are capable of performing multiple simultaneous machining operations

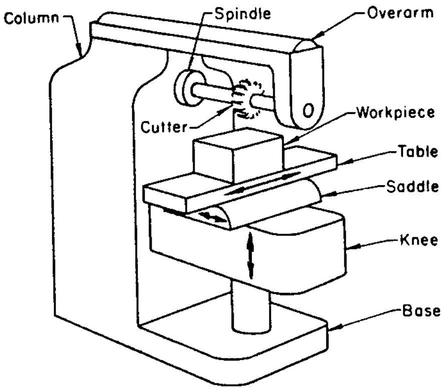

FIGURE 13.2.6 Principal components of a plain knee-and-column milling machine with a horizontal spindle. (From *ASM Handbook*, *Machining*, vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 304. With permission.)

Most milling is done in machines designed for milling (Table 13.2.9). Milling can also be done by any machine tool that can rigidly hold and rotate a cutter while feeding a workpiece into the cutter. Milling machines are usually classified in terms of their appearance: knee-and-column, bed-type, planar-type, and special purpose. The knee-and-column configuration is the simplest milling machine design. The workpiece is fixed to a bed on the knee and the tool spindle is mounted on a column, as depicted in Figure 13.2.6. For very large workpieces, gantry or bridge-type milling machines are used. Machines having two columns can provide greater stability to the cutting spindle(s). Special-purpose machines are modifications of the three basic models.

The usual power range for knee-and-column machines is 1 to 50 hp (0.75 to 37 kW). Bed-type machines are available in a wide range of sizes, up to 300 hp (225 kW). Planar-type machines are available from 30 to 100 hp (22 to 75 kW).

TABLE 13.2.10 Types of Milling Cutters

Milling Cutters	Description	Application
Peripheral mills	Cutting is primarily done by teeth on the periphery of the cutting tool; mounted on an arbor having its axis parallel to the machined surface	Removing metal from simple flat surfaces; milling contoured surfaces and surfaces having two or more angles or complex forms
Face mills	Machining action is accomplished by the bevel cutting edge located along the circumference of the mill; driven by a spindle on an axis perpendicular to the surfaced being milled	Can be more efficient at removing material than peripheral milling; very rigid tool setup possible; can achieve tight tolerances
End mills	Incorporate cutting edges on both the face and the periphery; can be used for face cuts and periphery cuts	Allow multiple operations without changing cutters; cutters can have difficulty in maintaining dimensional accuracy due to long unsupported length
Special mills	Can be almost any design	Optimized for a particular task

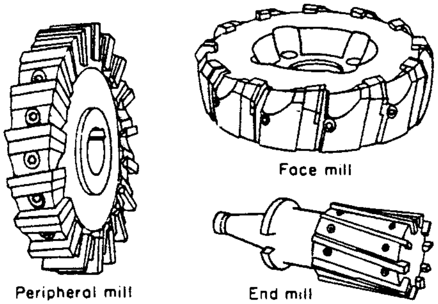

FIGURE 13.2.7 Three typical milling cutters. (From *ASM Handbook*, *Machining*, vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 311. With permission.)

A wide variety of milling cutters are available, using the full range of cutting-tool materials; there are three basic constructions (ASM 1989b):

Solid — Made from a single piece of HSS or carbide. Cutters can be tipped with a harder material; teeth can be designed for specific cutting conditions; the initial cost is low.

Inserted blade — Usually made from HSS, carbide, or cast alloy. Individual blades can be replaced as they wear out, saving replacement cost; they are ideal for close-tolerance finishing.

Indexable insert — Cutter inserts are made from carbide, coated carbide, ceramic, or ultrahard material such as diamond; each insert has one or more cutting edges; as inserts wear, they are repositioned to expose new cutting surface or indexed to bring another cutting insert on line. These inserts, widely used in computer-controlled machines due to their performance and flexibility, can produce a rougher surface than the other tool constructions and require somewhat higher cutting forces to remove metal.

Milling cutters are also described by the location of the cutting edges, as described in Table 13.2.10. Several cutters are depicted in Figure 13.2.7.

The angular relationships of the cutting edge greatly influence cutting efficiency, analogous to single-point cutting tools. A milling cutter should have enough teeth to ensure uninterrupted contact with the workpiece, yet not so many so as to provide too little space between the teeth to make chip removal difficult.

Milling speed varies greatly depending on workpiece material composition, speed, feed, tool material, tool design, and cutting fluid. Speeds as low as 20 sfm (6.1 m/min) are employed for milling low machinability alloys, while speeds as high as 20,000 sfm (6100 m/min) have been reported for milling aluminum (ASM 1989b). If the setup is sufficiently rigid, carbide or carbide-tipped cutters can be operated three to ten times faster than HSS cutters; top speed is usually constrained by onset of tool chatter.

For highest efficiency in removing metal while minimizing chatter conditions, the feed per tooth should be as high as possible. The optimum feed rate is influenced by a number of factors (ASM 1989b): type of cutter, number of teeth on the cutter, cutter material, workpiece machinability, depth of cut, width of cut, speed, rigidity of the setup, and machine power. The surface finish obtainable by milling can be quite good. A finish of 125 μin. (3.2 μm) can be readily achieved under normal circumstances with HSS mills, and finishes of 63 μin. (1.6 μm) are common if carbide tools are used. With careful selection of cutters and stringent control of process conditions, a finish of 10 min (0.25 mm) can be produced.

The initial cost of a milling machine is considerably greater than that of a planar or a shaper that can machine workpieces of similar size to similar finishes. Milling tools usually cost up to 50 times as much as tools for planers and shapers, and the setup time is usually longer. However, milling is far more efficient in removing material, and milling machines are commonly highly automated. Therefore, milling is preferred for production operations.

Grinding is often preferred to milling when the amount of metal to be removed is small and the dimensional accuracy and surface finish are critical. Milling and grinding are frequently used in combination.

Broaching. Broaching is a precision machining process. It is very efficient since both roughing cuts and finishing cuts are made during a single pass of the broach tool to produce a smooth surface, and further finishing is usually not necessary. Consequently, close tolerances can be readily achieved at a reasonable cost for high rates of production.

Broaches are expensive multi-toothed cutting tools. Thus, the process is usually employed for low or high production when broaching is the only practical method to produce the required dimensional tolerance and surface quality. An example of the latter case is the dovetail slots in jet engine turbine disks.

Broaching is a machining process similar to planing. A broach is essentially a tapered bar into which teeth are cut, with the finishing teeth engaging last on the end with the larger diameter. A single broach has teeth for rough cutting, semifinishing, and finishing. Broaching involves pushing or pulling a broach in a single pass through a hole or across a surface. As the broach moves along the workpiece, cutting is gradual as each successive tooth engages the workpiece, removing a small amount of material. Overall machining forces are much greater than that of other machining methods, and consequently broaching is considered to be the most severe of all machining operations.

Broaching machines are categorized as horizontal or vertical, depending on the direction of broach travel. Industry usage is almost evenly divided between these two categories. The selection of machine type depends heavily on the configuration of the workpiece and available space in the factory, considering both floor space and vertical clearance requirements.

Broaches can be categorized by the method through which they are actuated (push or pull), by type of cut (internal or external), and by the construction of the broach body. Figure 13.2.8 depicts typical internal and external broaching operations. Table 13.2.11 describes broaches according to their construction.

Length and depth of cut have the most influence on determining the required broaching tool length. For internal cutting operations, as the cut length increases, more chip storage capacity must be provided between the cutting edges for the same amount of tooth advance. Cutting fluids are useful in preventing the work metal from adhering to the broach, and thus result in higher-quality surface finishes and increased broach life.

The primary consideration in the selection of optimum broaching speed is the trade-off between speed and wear rate. In general, steels are broached at 10 to 30 sfm (3 to 9 m/min); the harder the steel, the slower the broach speed (ASM 1989b).

Broaching can maintain tight tolerances during long production runs since metal-cutting operations are distributed among the different roughing and finishing teeth. Also, broach teeth can be repeatedly sharpened, allowing cutting efficiency and accuracy to be maintained.

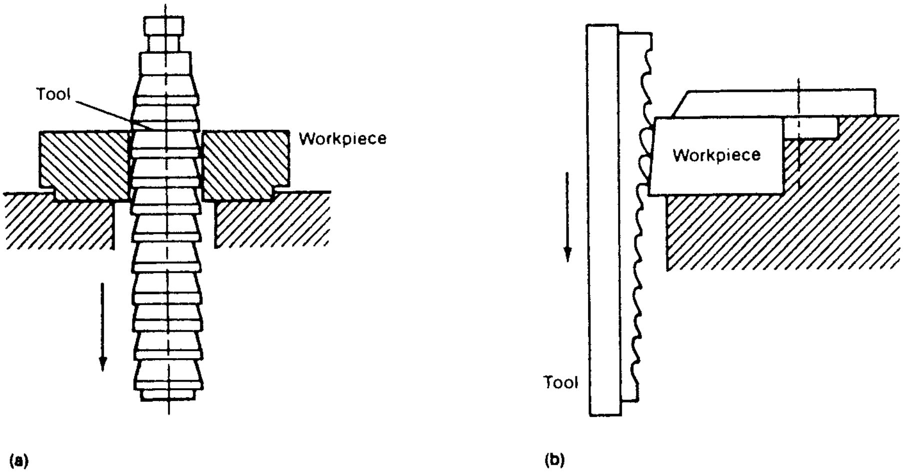

FIGURE 13.2.8 Internal (a) and external (b) broaching. (From *ASM Handbook*, *Machining*, vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 195. With permission.)

TABLE 13.2.11 Types of Broaches

Broaches	Description	Application
Solid	One-piece broach produced from tapered bar stock; repair of broken teeth is difficult	Parts which require high dimensional accuracy and concentricity
Shell	Multipiece broach consisting of a main body, an arbor section over which a removable shell fits, and a removable shell containing the cutting edges; worn or damaged sections can be replaced	Internal and selected external broaching; sacrifices some accuracy and concentricity as the tool is not as stiff as a solid broach
Insert-type	Effectively a tool holder with inserts to perform the actual cutting; inserts are typically made from HSS or carbides; worn or damaged inserts can be readily replaced	Broaching large, flat surfaces

Broaching is an extremely fast, precise machining operation. It is applicable to many workpiece materials over a wide range of machinability, can be accomplished in seconds, is readily automated, and can easily be done manually. For example, for low-carbon steels, tolerances of 0.002 in. (0.05 mm) can be readily attained with a surface finish of 60 μin. (1.55 μm); if desired, tighter tolerances and surface finishes of 30 μin. (0.8 μm) are possible without much additional effort. For difficult-to-machine superalloys, tolerances of 0.001 in. (0.025 mm) and surface finishes of 30 μin. (0.8 μm) are commonly achieved in production (ASM 1989b).

Broaching is rarely used for removing large amounts of material since the power required would be excessive. It is almost always more effective to use another machining method to remove the bulk of material and use broaching for finishing.

Since a broach moves forward in a straight line, all surface elements along the broach line must be parallel to the direction of travel. Consequently, the entire surface of a tapered hole cannot be broached. Also, cutting is done sequentially with the finishing teeth engaging last. Therefore, a blind hole can be broached only if a sufficiently long recess is provided to permit full travel of the broach.

The direction of travel of the broach cannot realistically be changed during a broaching stroke, except for rotating the tool. Thus, surfaces having compound curves cannot be broached in a single operation. On external surfaces, it is impossible to broach to a shoulder that is perpendicular to the direction of broach movement.

Grinding

Trevor D. Howes, John Webster, and Ioan Marinescu

Grinding, or abrasive machining, refers to processes for removing material in the form of small chips by the mechanical action of irregularly shaped abrasive grains that are held in place by a bonding material on a moving wheel or abrasive belt (Green 1992). In surface-finishing operations (e.g., lapping and honing) these grains are suspended in a slurry and then are embedded in a roll-on or reference surface to form the cutting tool. Although the methods of abrasion may vary, grinding and surface-finishing processes are used in manufacturing when the accuracy of workpiece dimensions and surface requirements are stringent and the material is too hard for conventional machining.

Grinding is also used in cutoff work and cleaning of rough surfaces, and some methods offer high material-removal rates suitable for shaping, an area in which milling traditionally has been used.

Grinding is applied mainly in metalworking because abrasive grains are harder than any metal and can shape the toughest of alloys. In addition, grinding wheels are available for machining plastics, glass, ceramics, and stone. Conventional precision metal and ceramic components and ultraprecision electronic and optical components are produced using grinding.

Three types of energy are involved in grinding (Andrew et al. 1985). Rubbing energy is expended when the grains (cutting edges) of the grinding wheel wear down. As they wear, they cut less and produce increasing friction, which consumes power but removes less material. Plowing energy is used when the abrasive does not remove all of the material but instead plows some of it aside plastically, leaving a groove behind. *Chip-formation energy* is consumed in removing material from the workpiece as the sharp abrasive grain cuts away the material (or chip) and pushes it ahead until the chip leaves the wheel.

The grinding wheel experiences *attritious wear* as the abrasive grains develop wear flats from rubbing on the workpiece, or when grains break free from the bond material. Attritious wear gives rise to rubbing energy resulting from friction, and thus can lead to thermal damage as power consumption increases without an increase in material removal rate. The wheel can wear through *fracture*, predominating at relatively high in-feed rates. In this case, pieces of the abrasive grain break free and expose a new, sharp surface.

Materials can be classified as either easy to grind or difficult to grind. For easy-to-grind materials, most of the power consumption becomes invested in chip formation; thus, rubbing and plowing energy are minimal. *Difficult-to-grind materials* involve considerable rubbing and plowing energy since the force required to remove chips is comparatively high.

In *surface grinding*, the grinding wheel traverses back and forth across the workpiece. Grinding can take place by using either the periphery or side face of the wheel. The table holding the part may also reciprocate. Surface grinding is done most commonly on flat surfaces and surfaces with shapes formed of parallel lines, e.g., slots.

Creep-feed grinding is a form of surface grinding in which the wheel feeds into the workpiece at a low rate (0.4 to 40 in./min, 10 to 1000 mm/min) while grinding at a large depth of cut (0.04 to 0.4 in., 1 to 10 mm, or deeper). A large amount of material can be removed with one pass of the wheel, compared with conventional surface grinding in which the wheel makes many quick passes over the workpiece at slight depths of cut. This process is limited by the large amount of heat generated at the grinding arc, which can result in thermal damage (grinding "burn"). Application of coolant is critical in creep-feed operations. CBN wheels, with their good heat transfer property, can also reduce the severity of burn (King and Hahn 1986).

Cylindrical grinding produces round workpieces, such as bearing rings, although some machines can also grind tapered parts. The workpiece is mounted to a spindle and rotates as the wheel grinds it. The workpiece spindle has it own drive motor so that the speed of rotation can be selected. Both inner surfaces (internal cylindrical grinding) and outer (external cylindrical grinding) can be worked, although usually the same machine cannot do both.

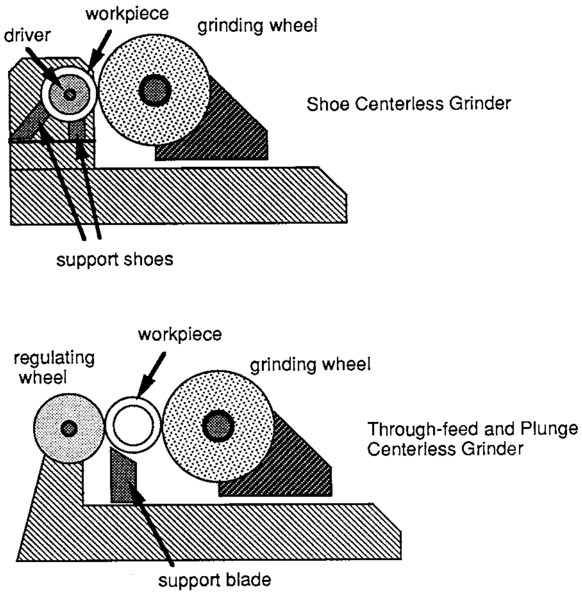

FIGURE 13.2.9 Through-feed and plunge centerless grinding. (Courtesy of T.D. Howes, J. Webster, and I. Marinescu.)

There are three variants for *external grinding*:

Plain grinding — The wheel carriage is brought to the workpiece on its spindle and in-feeds until the desired dimensions are reached.
Traverse grinding — The rotating workpiece is mounted on a table that reciprocates under the wheel; the grinding wheel is stationary except for its downward feed into the workpiece.
Plunge grinding — The table with the rotating workpiece is locked while the wheel moves into the workpiece until the desired dimensions are attained.

Centerless grinding is a form of cylindrical grinding. In this method workpieces are not held in a centering chuck but instead rotate freely between a support, regulating wheel, and the grinding wheel. The force of the rotating grinding wheel holds the workpiece against the support. The supports are usually stationary and so a flow of lubricant is required to reduce friction between workpiece and support. An example of centerless grinding is shown in Figure 13.2.9.

Abrasive belt machines use a flexible fabric coated with an abrasive stretched between two rollers, one of which is driven by a motor. Usually, the abrasive coating is aluminum oxide for steels and bronzes and silicon carbide for hard or brittle materials. In the metal industries, common use of such machines is for dry grinding of metal burrs and flash and polishing of surfaces. However, some fabrics permit use of grinding fluids to enhance chip removal and provide cooling and lubrication, which results in better cutting action and longer belt life.

Honing, lapping, and polishing use abrasives to improve the accuracy of the form of a workpiece or the surface finish beyond the capabilities of grinding.

- *Honing* is a low-surface-speed operation, usually performed on an internal, cylindrical surface but possible also on external ones. Stock is removed by the shearing action of abrasive grains: a simultaneous rotary and reciprocating motion of fixed abrasive in the form of a stone or stick. Finishes range from under 1 to 50 μin. (0.025 to 1.3 μm). The development of CBN has revolutionized the honing process because this material easily outperforms conventional abrasives such as aluminum oxide, lasting up to 100 times longer.

TABLE 13.2.12 Common Grinding Wheel Abrasives

Abrasive	Characteristic	Grinding Application
Aluminum oxide	Friable	Steel: soft or hardened, plain or alloyed
Seeded gel aluminum oxide	More friable and expensive than aluminum oxide	Steel: soft or hardened, plain or alloyed; use at higher stock removal rates
CBN	Tough; increased life at higher speeds; high accuracy and finish	Hardened steels; tough superalloys
Synthetic diamond	Hardest of all abrasives; can be friable; seldom need dressing/truing	Grinding hardened tool steels, cemented carbides, ceramics, and glass; cutting and slicing of silicon and germanium wafers
Silicon carbide	Friable	Cast iron; nonferrous metals; nonmetallics

- *Superfinishing*, like honing, uses fixed abrasives in the form of a stone. Unlike honing, which has a helical motion inside a bore, superfinishing uses high-speed, axial reciprocation combined with slow rotation of the outside diameter of the cylindrical component being processed. The geometry produced by a previous operation generally is not improved.
- *Lapping* is a fine-finishing, abrasive machining process used to obtain superior finish and dimensional accuracy. Lapping is unlike other finishing processes because some of the abrasive is loose rather than bonded. In general, lapping occurs when abrasive grains in a liquid vehicle (called a slurry) are guided across a workpiece by means of a rotating plate.
- *Polishing* uses free abrasive, as in lapping, but requires a soft support unlike the relatively hard support used in lapping. The total depth of cut during polishing can be as little as nanometers where chemical interactions will play a stronger role than mechanical or physical interactions. When the depth of cut is greater than 1 μin. (0.025 μm), the interactions are usually of a mechanical nature. Many industrial components, especially electronic and optical, required highly polished surfaces.

A *grinding wheel* consists of thousands of small, hard grains of abrasive material held on the surface in a matrix of bond material (Table 13.2.12). The bond material is matched to the characteristics of the grain to retain the grain sufficiently to maximize its use before shedding it. The structure of the wheel formed by specific types of grains and bonds determines its characteristics. The grains are spaced apart depending on the cutting required. Widely spaced grains (open structure) cut aggressively, which is useful for hard materials or high rates of material removal, but which tends to produce coarse finishes. Closely packed grains (dense structure) make fine and precise cuts for finish grinding.

Grain spacing is also important for temporary storage of chips of material removed from the workpiece. An open structure is best for storing chips between the grains, which are then released after wheel rotation moves the grains away from the workpiece. An open structure also permits more coolant to enter the spaces to dissipate heat.

The bonding material is important to grinding performance. This material is weaker than the cutting grains so that ideally, during grinding, the grain is shed from the wheel surface when it becomes dull, exposing new sharp grains. For instance, wheels with friable abrasives that fracture to expose new, sharp grains must retain the grains longer to maximize the use of the abrasive; these wheels use stronger bonding materials. The four types of bond material are vitrified, resinoid, rubber, and metal. Table 13.2.13 shows their properties and uses.

Grinding wheels must be resharpened on occasion. *Dressing*, not always required, sharpens the grains before grinding. *Truing* operations ensure the wheel conforms to the required cutting shape and will rotate concentrically to its spindle.

Because grinding wheels have relatively high mass and high operating speed, they must be *precisely balanced*. Imbalance causes vibrations that reduce the quality of the workpiece, hasten the wear of the spindle and bearings of the machine, affect other devices mounted on the grinder, and possibly transmit vibration from the grinder through the shop floor to other machines. Mounting of the wheel on the

TABLE 13.2.13 Characteristics of Grinding Wheel Bonds

Bond Type	Characteristic	Application
Rubber	Relatively flexible	Wet cut-off wheels; high-finish work; regulating wheels for centerless grinding
Resinoid (thermoplastic)	Relatively flexible	Rough grinding; portable grinders
Vitrified (glasslike)	Endure high temperatures; resist chemical effects of coolants; sensitive to impacts	Most widely used of all bonding materials
Metal	Electrodeposited nickel or sintered metal powder often used to bond CBN and diamond abrasives; has long wheel life; electrically conductive	Aggressive cutting operations such as creep-feed and deep grinding; electrically conductive grinding (e.g., electrochemical methods)

spindle and subsequent wheel wear can degrade the balance of the rotating system. Wheels are balanced by moving counterweights on balancing flanges. Some machines have an automatic balancer that shifts internal counterbalance masses.

Coolants are usually sprayed on the grinding zone to cool the wheel and workpiece, lubricate the surface to reduce grinding power, and flush away the chips. Excessive heat can damage both the wheel and workpiece by inducing undesirable physical changes in materials, such as metallurgical phase changes or residual stresses, or softening of the bond material in the grinding wheel. Coolant application is especially important in creep-feed grinding where the wheel-to-workpiece contact arc is long, heat generation is high, and the chips produced and abrasive lost from the wheel must be flushed away.

Selecting the type of *coolant system* depends on many factors, including the grinding wheel speed, material removal rate, depth of cut, and wheel/workpiece materials. The type of fluids used in this system requires consideration of both physical and environmental issues. Use of oil fluids can favor the formation of preferred residual stress patterns and better surface finish, and these oils can be recycled for long periods. However, oils present health risks, potential for groundwater contamination, and fire risks (especially with high-sparking superalloys). Water-based fluids offer far fewer environmental problems. Disadvantages of water-based fluids lie in their limited life expectancy of 3 to 12 months. Also, the relatively low viscosity of a water-based fluid at high velocity promotes a dispersed jet, which reduces cooling capacity.

Surface grinding can be a cheaper, faster, and more precise method than milling and planing operations. For profiled shapes, the grinding wheel can be dressed with less cost and inconvenience than changing milling setups for different parts. Grinding can be used as a high-stock-removal process; for example, creep-feed grinding has a depth of cut more typical of milling operations (0.1 in., 2.54 mm, and deeper). Creep-feed grinding is used for machining materials that are too difficult to work by other machining methods.

High-speed grinding can be extremely efficient. CBN abrasive allows high rates of material removal because CBN transfers heat away from the grinding zone due to its relatively high thermal conductivity, and CBN does not react with steel.

Considerable effort has been expended on modeling and testing the thermal limitations of grinding (Malkin 1989). Nearly all models depend on a fundamental model that relies on sliding contact theory. All models confirm the following guidelines for grinding with conventional abrasives when burn is a limitation: decrease wheel speed, increase workpiece speed, use softer-grade wheels.

Dynamic Stability and Chatter

Scott Smith

In all of the material removal processes just described, the achievable material removal rate may be limited by dynamic interactions between the cutting process and the structure of the machine-tool-workpiece system (Tlusty 1985).The resulting vibrations between the tool and workpiece cause excessive variations of the cutting force, resulting in poor surface quality and reduced life of the cutting tool (Welboum 1970). The vibrations encountered can be classified in three broad categories:

- *Free vibrations.* There is an initial input of energy, which results in a vibration at a damped natural frequency of the system. In a machine tool, such a vibration might occur at the start or end of an axis motion. The decay rate of the vibration is directly related to the amount of damping present. Solutions to free vibration problems typically include elimination of the source or an increase in the damping.
- *Forced vibrations.* These vibrations occur as the result of a period force. They have the frequency of the exciting force, and they persist as long as the excitation force persists. They are particularly problematic if the excitation force is near a natural frequency of the system (the case of "resonance"), in which case the amplitude of the vibration may become quite large. Forced vibrations in material removal might result, for example, from an unbalanced grinding wheel or milling cutter. Solutions to forced vibration problems typically include lowering the excitation force (for example, by balancing the tool) or moving it away from a resonance frequency.
- *Self-excited vibrations.* These vibrations result from an instable feedback mechanism between the cutting process and the structure. Any small vibration causes a wavy surface, which then leads to a variable cutting force, which leaves a wavy surface. If the vibration decreases, then the machining is stable. If it grows, this is the condition referred to as *chatter.* The resulting vibration can easily be large enough to cause the tool to lose contact with the workpiece, damage the workpiece, or break the cutter. Figure 13.2.10 illustrates the surface that may result.

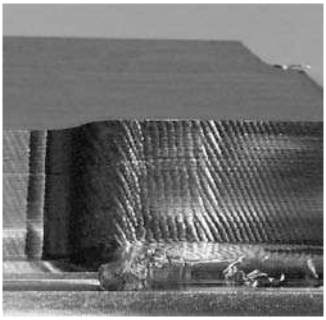

FIGURE 13.2.10 Surface resulting from chatter during milling. (Courtesy of S. Smith.)

Whether or not chatter occurs depends on a complex interaction between the dynamic characteristics of the structure (as represented by a *Frequency Response Function*, or *FRF*), the workpiece material, the cutting depths, and the spindle speed. Some speeds are favorable for stable material removal, while others are not. This chatter relationship is often expressed as a *stability lobe diagram*, as shown in Figure 13.2.11.

In this figure, the horizontal axis shows spindle speed, and the vertical axis shows axial depth of cut for a given radial depth of cut. Conditions above the line indicate chatter, and those below the line result in stable milling. It is clear from the figure that in milling, it is particularly important to exploit a

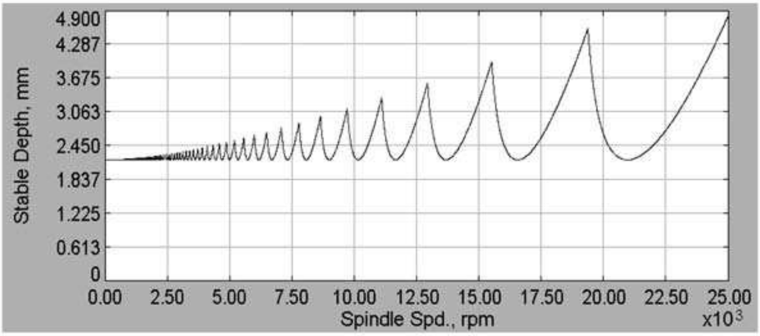

FIGURE 13.2.11 Typical stability lobe diagram for milling in aluminum. (Courtesy of Manufacturing Laboratories Inc.)

knowledge of the stability lobes as the spindle speed becomes high. In this case, milling at 25,000 rpm is substantially more advantageous than milling at 21,000 rpm. It is particularly important to respect the dynamic limitations during NC programming, so that first articles will be chatter-free. Software and hardware tools are continuing to be rapidly developed and deployed to help machine tool users make the required measurements (Delio et al. 1992).

Nontraditional Machining

K. P. Rajurkar and W. M. Wang

The processes described in this section are representative of the types most likely to be encountered. The references listed at the end of the section contain detailed information on these processes, plus those that are not described here.

Electrical Discharge Machining (EDM)

The electrical discharge machining (EDM) process machines hard materials into complicated shapes with accurate dimensions. EDM requires an electrically conductive workpiece. Process performance is unaffected by the hardness, toughness, and strength of the material. However, process performance is a function of the melting temperature and thermal conductivity. EDM is currently widely used in aerospace, machinery, and die and mold industries.

There are two types of EDM processes:

- Die-sinking EDM uses a preshaped tool electrode to generate an inverted image of the tool on the workpiece; commonly used to generate complex-shaped cavities and to drill holes in different geometric shapes and sizes on hard and high-strength materials.
- Wire EDM (WEDM) uses a metal wire as the tool electrode; it can generate two- or three-dimensional shapes on the workpiece for making punch dies and other mechanical parts.

EDM removes workpiece materials by harnessing thermal energy produced by pulsed spark discharges across a gap between tool and workpiece. A spark discharge generates a very small plasma channel having a high energy density and a very high temperature (up to 10,000°C) that melts and evaporates a small amount of workpiece material. The spark discharges always occur at the highest electrical potential point that moves randomly over the machining gap during machining. With continuous discrete spark discharges, the workpiece material is uniformly removed around the tool electrode. The gap size in EDM is in the range of 400 μin. to 0.02 in. (0.01 to 0.5 mm), and is determined by the pulse peak voltage, the peak discharge current, and the type of dielectric fluid.

The discharge energy during EDM is provided by a direct current pulse power generator. The EDM power system can be classified into RC, LC, RLC, and transistorized types. The transistorized EDM power systems provide square waveform pulses with the pulse on-time usually ranging from 1 to 2000 msec, peak voltage ranging from 40 to 400V, and peak discharge current ranging from 0.5 to 500 A. With the RC, LC, or RLC type power system, the discharge energy comes from a capacitor that is connected in parallel with the machining gap. As a result of the low impedance of plasma channel, the discharge duration is very short (less than 5 msec), and the discharge current is very high, up to 1000 A. The peak voltage is in the same range of transistorized power systems.

The transistorized power systems are usually used in die-sinking EDM operations because of their lower tool wear. Capacitive power systems are used for small hole drilling, machining of advanced materials, and micro-EDM because of higher material removal rate and better process stability. The WEDM power generator usually is a transistor-controlled capacitive power system that reduces the wire rupture risk. In this power system, the discharge frequency can be controlled by adjusting the on-time and off-time of the transistors that control the charging pulse for the capacitor connected in parallel with the machining gap.

The machining gap between tool and workpiece during EDM must be submerged in an electrically nonconductive *dielectric fluid*. In die-sinking EDM, kerosene is often used as a dielectric fluid because it provides lower tool wear, higher accuracy, and better surface quality. Deionized water is always used as a dielectric fluid in WEDM to provide a larger gap size and lower wire temperature in order to reduce the wire rupture risk. This fluid also serves to flush debris from the gap and thus helps maintain surface quality.

Copper and graphite are commonly used as die-sinking *EDM tool materials* because of the high electrical conductivity and high melting temperature and the ease of being fabricated into complicated shapes. The wire electrode for WEDM is usually made of copper, brass, or molybdenum in a diameter ranging from 0.01 to 0.5 mm. Stratified copper wire coated with zinc brass with diameter of 0.25 mm is often used.

In the traditional *die-sinking EDM process*, the tool is fabricated into a required shape and mounted on a ram that moves vertically. The spark discharges can only occur under a particular gap size that determines the strength of electric field to break down the dielectric. A servo control mechanism is equipped to monitor the gap voltage and to drive the machine ram moving up or down to obtain a dischargeable gap size and maintain continuous sparking. Because the average gap voltage is approximately proportional to the gap size, the servo system controls the ram position to keep the average gap voltage as close as possible to a preset voltage, known as the *servo reference voltage.*

In a WED machine, the wire electrode is held vertically by two wire guides located separately above and beneath the workpiece, with the wire traveling longitudinally during machining. The workpiece is usually mounted on an *x-y* table. The trajectory of the relative movement between wire and workpiece in the *x-y* coordinate space is controlled by a CNC servo system according to a preprogrammed cutting passage. The CNC servo system also adjusts the machining gap size in real time, similar to the die-sinking EDM operation. The dielectric fluid is sprayed from above and beneath the workpiece into the machining gap with two nozzles.

The power generators in WED machines usually are transistor-controlled RC or RLC systems that provide higher machining rate and larger gap size to reduce wire rupture risks. In some WED machines, the machining gap is submerged into the dielectric fluid to avoid wire vibration to obtain a better accuracy.

The upper wire guide is also controlled by the CNC system in many WED machines. During machining, the upper wire guide and the *x-y* table simultaneously move along their own preprogrammed trajectories to produce a taper and/or twist surface on the workpiece.

The polarity of tool and workpiece in EDM is determined in accordance with the machining parameters. When the discharge duration is less than 20 μsec, more material is removed on the anode than that on the cathode. However, if the discharge duration is longer than 30 μsec, the material-removal rate on the cathode is higher than that on the anode. Therefore, with a transistorized power system, if the pulse on-time is longer than 30 μsec, the tool is connected as anode and the workpiece is connected as cathode. When the on-time is less than about 20 μsec, the polarity must be reversed. With an RC, LC, or RLC power system, since the discharge duration is always shorter than 20 μsec, the reversed polarity is used.

With transistorized EDM power systems, the machining rate and surface finish are primarily influenced by the peak current. The machining rate increases with the peak current. The relationship between the machining rate and pulse on-time is nonlinear, and an optimal pulse on-time exists. Reducing peak current improves the surface finish but decreases the machining rate.

Die-sinking ED machines with transistorized power systems under good gap-flushing conditions can attain a material-removal rate as high as 12 mm^3/min/amp (for a steel workpiece). The wire cut EDM process can cut ferrous materials at a rate over 100 mm^2/min. A surface roughness value of 0.01 in. (0.2 mm) can be obtained with a very low discharge current. The tool wear ratio can be controlled within 1% during rough machining and semifinishing with the transistorized power generator. Dimensional tolerance of ±118 μin. (3 μm) and taper accuracy of 20 to 40 μin. (0.5 to 1 μm/mm) with both die-sinking and WEDM can be obtained.

EDM can machine materials having electrical conductivity of 10^{-2} W^{-1} cm^{-1} or higher. An average current density more than 4 A/cm^2 tends to cause substantial tool wear and unstable machining, and may lead to dielectric fire. This factor largely limits the productivity of EDM. During machining a deep cavity using die-sinking EDM under difficult flush condition, arc discharges occur, and the resultant thermal damage on workpiece substantially limits the productivity and the machined surface quality. Dielectric properties also impose additional constraints.

Electrical Chemical Machining (ECM)

The ECM process uses the electrochemical anodic dissolution effect to remove workpiece material. Like die-sinking EDM, the tool electrode of ECM is preshaped according to the requirements of the workpiece. During machining, the inverted shape of the tool is gradually generated on the workpiece. ECM machines complex contours, irregular shapes, slots, and small, deep, and/or noncircular holes. Typical applications of ECM include machining nickel-based superalloy turbine blade dovetails, slots in superalloy turbine disks, engine castings, gun barrel rifles, and forging dies. ECM is also used for deburring, surface etching, and marking.

Electrolyte fluid is forced through the gap between tool and workpiece during ECM. A low-voltage and high-current DC power system supplies the machining energy to the gap. The tool electrode of ECM must be connected as cathode and the workpiece must be connected as anode. The electrochemical anodic dissolution phenomenon dissolves workpiece surface material into metal ions. The electrolyte fluid flushes the metal ions and removes heat energy generated by the deplating actions. The gap size in ECM is in the range of 0.004 to 0.04 in. (0.1 to 1 mm). ECM process performance is independent of the strength, hardness, and thermal behavior of workpiece and tool materials.

Copper, brass, stainless steel, and titanium are commonly used as *ECM tool electrode materials* due to their good electrical conductivity, resistance to chemical erosion, and ease of being machined into desired shapes. The geometric dimensions of the machined surface generated by ECM depend on the shape of tool and the gap size distribution.

The structure of an EC machine varies with the specific applications. An ECM must have a tool feed system to maintain the machining gap, a power system to supply the power energy, and a fluid-circulating system to supply the electrolyte and to flush the machining gap. The power system used in ECM is a DC power source with the voltage ranging from 8 to 30 V and a high current in the range of 50 to 50,000 A, depending on the specific design of the power system.

The *electrolyte* is the medium enabling the reaction of electrochemical dissolution occurring on the anode. The electrolyte can be classified into categories of aqueous and nonaqueous, organic and nonorganic, alkaline and neutral, mixed and nonmixed, and passivating and nonpassivating, and acidic. The electrolyte is selected according to the type of workpiece material, the desired accuracy, surface finish requirements, and the machining rate. Neutral salts are used in most cases. Acid electrolytes are used only for small hole drilling when the reaction products must be dissolved in the electrolyte.

ECM performance is mainly influenced by electrical parameters, electrolyte, and geometry of tool and workpiece. The electrical parameters include machining current, current density, and voltage. ECM systems with 50 to 50,000 A and 5 to 30 V DC are available, and the current density can be in the range of 10 to 500 A/cm^2. Key electrolyte parameters consist of flow rate, pressure, temperature, and concentration. Important parameters of tool and workpiece geometry are contour gradient, radii, flow path, and flow cross section. When the tool feed rate equals the machining rate, an equilibrium gap size is obtained; this is critical to maintaining shaping accuracy.

The electrolyte selection also plays an important role in ECM dimension control. In this regard, the sodium nitrate solution is preferable because the metal-removal rate at smaller gap size locations is higher than at other places. Therefore, the characteristics of current efficiency in ECM influence the uniformity of the gap size distribution. ECM accuracy has recently been shown to improve with pulsed voltage (instead of continuous voltage) and an appropriate set of pulse parameters (on-time, off-time, etc.).

ECM is capable of machining any electrically conductive metallic material, and the process is generally unaffected by the hardness, strength, and thermal behaviors of materials. This process can be used to machine parts with low rigidity such as parts with thin walls. Machining rates of 2 to 2.5 cm^3/min/1000 A current, surface roughness of 4 to 50 μin. (0.1 to 1.2 μm), and accuracy of 400 μin. to 0.01 in. (10 to 300 μm) can be achieved with ECM. The available ECM equipment can machine a 0.04 to 80 in. (1 to 2000 mm) long workpiece. The typical energy consumption is 300 to 600 J/mm^3.

The machining rate and surface finish with ECM are much higher than that with EDM due to higher allowable current density and the molecular level of material removal. The machining accuracy, however, is substantially lower than EDM and is much more difficult to control.

The gap size distribution is influenced by many factors including the type of electrolyte, electrolyte flow rate and flow pattern, electrolyte temperature, current density of machining, and so forth. Therefore, the gap size distribution is not uniform in most cases and is difficult to determine analytically. The shape of machined surface by ECM will not be a perfect mirror image of the tool electrode. In order to achieve an acceptable accuracy, the tool shape must be modified by using trial-and-error method in test machining before machining of actual workpieces.

ECM cannot machine materials with electrical conductivity less than 103 W^{-1} cm^{-1}. ECM cannot produce very sharp corners (less than 800 μin., 0.02 mm, radius). The machining rate is limited by the electrolytic pressure (less than 5 MPa) and boiling point as well as the applied current (less than 50,000 A). The gap size that determines the final shape and accuracy is limited to 800 μin. to 0.004 in. (0.02 to 0.1 mm).

ECM generates a large amount of sludge and spent electrolyte. This waste requires significant processing before it can be safely disposed of.

Water and Abrasive Jet Machining

Water-jet machining (WJM) and *abrasive water-jet machining* (AWJM) are used in many applications. In the WJM process, relatively soft workpiece materials are cut by a high-velocity water jet; for example, food, wood, paper, plastic, cloth, rubber, and so forth. The AWJM process uses the fine abrasive particles mixed in the water jet to machine harder workpiece materials. The AWJM is used for drilling, contour cutting, milling, and deburring operations on metal workpieces, as well as for producing cavities with controlled depths using multipass and non-through-cutting methods. The cutting path of the WJM and AWJM can be controlled by a CNC system according to a preprogrammed program.

During WJM, the workpiece material is removed by the mechanical energy generated by the impact of a high-velocity water jet. In a water-jet machine, a high-pressure pumping system increases the pressure of water in the pipe system, and the pressurized water is sprayed from a nozzle with a small diameter to generate a high-velocity water jet.

In the AWJM process, pressurized water is sprayed from an orifice in the nozzle body into a mixing chamber to generate a negative pressure that absorbs the abrasive particles (supplied by an abrasive feed hose) into the water jet. The water jet/abrasive grain mixture is then sprayed through a tungsten carbide nozzle. The abrasive grains in the high-velocity water jet provide small cutting edges that remove material. The relative distance between water jet nozzle and workpiece is controlled by a two- or three-dimensional CNC system. This process can be used to generate a complicated shape.

The key parameters are the water and/or abrasive flow velocity, abrasive grain size, and mixing tube (nozzle) length and diameter. The typical water flow velocity is in the range of 2000 to 3000 ft/sec (600 to 900 m/sec) as determined by the water pressure. The water pressure in WJM and AWJM is very high, up to 2.7×10^6 psi (400 MPa), and the nozzle diameter is in the range of 0.003 to 0.08 in. (0.8 to 2 mm). The abrasive flow rate is governed by the water flow rate and the mixing density, and can be controlled up to 10 g/sec. Abrasive particles are usually in the range of 60 to 150 mesh size. Increasing water-jet flow velocity increases cutting depth. The taper error of cutting is determined by the traverse rate that describes the ratio between the material removal and the cutting depth and width. This parameter is influenced by the water and abrasive velocity and cutting speed. Proper selection of AWJ parameters is essential for the elimination of burrs, delaminations, and cracks.

Limitations of the process include stray cutting and surface waviness, high equipment costs, hazard from the rebounding abrasive, high noise levels, and short nozzle lifetimes due to wear and abrasion.

Ultrasonic Machining

Ultrasonic machining (USM) is a process that uses the high velocity and alternating impact of abrasive particles on the workpiece to remove material. The abrasive particles are mixed in a slurry that fills the machining gap between the tool and workpiece. The alternating movement of abrasive particles is driven by the vibration of the frontal surface of the tool at an ultrasonic frequency. The ultrasonic machining process can machine hard and brittle materials.

USM is often used for machining of cavities and drilling of holes on hard and brittle materials including hardened steels, glasses, and ceramics. Rotary ultrasonic machining (RUM) is a new application that uses a diamond grinding wheel as the tool for drilling, milling, and threading operations. During RUM, the tool is rotating at a high speed up to 5000 rpm and vibrating axially at ultrasonic frequency. This process is able to drill holes with diameters from 0.02 to 1.6 in. (0.5 to 40 mm) at depths up to 12 in. (300 mm). The material removal rate of 6 mm^3/sec can be obtained with the RUM process. The tolerance of ±300 µin. (±0.007 mm) can be easily achieved with both conventional and rotary ultrasonic processes.

In the USM process, the machining gap between tool and workpiece is filled with an abrasive slurry composed of an oil mixed with abrasive particles, with the frontal surface of the tool vibrating at ultrasonic frequency to provide the machining energy. The inverted shape of the tool is gradually generated on the workpiece. Material removal by the USM process is very complex. When the machining gap is small, the material may be removed as the frontal surface of the tool moves toward the workpiece, hitting an abrasive particle that impacts the workpiece surface. Material can also be removed by the impact of the abrasive particles when the machining gap is relatively large. In this case, the abrasive particles are accelerated by the pressure of slurry due to the ultrasonic vibration of the frontal surface of the tool. Also, ultrasonic-induced alternating pressure and cavitation in the slurry assist material removal.

The ultrasonic vibration in USM is generated by an *ultrasonic generator*. The ultrasonic generator consists of a signal generator, a transducer, and a concentrator. The signal generator produces an electrical signal whose voltage and/or current is changing at an ultrasonic frequency to drive the transducer. The frequency of the electrical signal can be adjusted in the range of 10 to 40 kHz.

The transducer converts the electrical voltage or current into the mechanical vibration. Two types of transducers are commonly used in USM:

- The *magnetostrictive transducer* was extensively used prior to 1970. This transducer is constructed by surrounding a number of sheets of magnetostrictive material with a coil. When the strength of the electric current in the coil changes at an ultrasonic frequency, a mechanical ultrasonic vibration is generated in the magnetostrictive material. This transducer has a low energy conversion efficiency, usually less than 30%.
- The *piezoelectric ultrasonic transducer* is commonly used today. The geometrical dimensions of this transducer vary with the change in the applied electric field. A mechanical ultrasonic vibration is generated when the strength of the electric voltage applied across the transducer material changes at an ultrasonic frequency. This transducer has an extremely high energy conversion efficiency, up to 95%. The amplitude of the ultrasonic vibration generated directly by the transducer is very small, about 400 μin. (0.01 mm). A concentrator is used for amplifying the amplitude into a level that is acceptable for USM. The transducer is mounted on the larger end of the concentrator; the tool is mounted on the smaller end.

In the ultrasonic machine, the ultrasonic generator is held vertically on the ram that moves vertically, and the workpiece is mounted on an *x-y* table that determines the relative position between tool and workpiece. During machining, a force providing pressure between the tool and workpiece is added through the ram mechanism.

The material-removal rate during USM increases with an increase in the amplitude of ultrasonic vibration, grain size of the abrasive particles, and pressure between the tool and workpiece. The surface finish is essentially determined by the grain size for a given workpiece material; that is, the smaller the grain size, the better surface finish. The abrasive grains used in USM are usually in the range of 100 to 900 mesh number.

The USM process is limited by the softness of the material. Workpiece materials softer than Rockwell C40 result in prohibitively long cycles. The best machining rate can be obtained on materials harder than Rockwell C60.

Phase-Change Processes

Phase-change processes produce parts from materials originally in the liquid or vapor phase. These include processes such as metal casting and injection molding of polymers. The two most commonly used metal-casting processes are described in this section. The references listed at the end of the section contain detailed information on all phase-change unit processes.

Metal casting is one of the primary methods of producing bulk shapes. Very complex shapes can be cast from nearly every metal, making casting an extremely versatile process. Castings are made in sizes that range from fractions of an ounce to hundreds of tons.

The selection of the best molding and casting process for an application can be complex, and is governed by many factors, which include casting size, variation in thickness of the casting sections, required mold strength, required surface finish and dimensional accuracy, production rates, environmental factors (e.g., reclamation of the sand and type of sand binder), and cost. Casting processes fall into five categories (Kanicki 1988):

Conventional molding processes — Green sand, shell, flaskless
Precision molding and casting processes — Investment, permanent mold, die casting

Special molding and casting processes — Vacuum molding, evaporative pattern casting, centrifugal casting
Chemically bonded self-setting sand molding — No-bake, sodium silicate
Innovative molding and casting processes — Unbonded sand molding (Patz and Piwonka 1988), rheocasting, squeeze casting, electroslag casting

This section discusses the most widely used conventional molding process, green sand, and the most widely used precision molding and casting process, investment casting. The reference list at the end of the section should be consulted for detailed information on all casting processes.

Properly designed and manufactured castings provide many advantages, and are competitive with other unit process methods. Success with casting processes, as with every process, requires design and process engineers knowledgeable regarding the advantages and limitations of casting processes so that appropriate design and process choices can be made that avoid or minimize the occurrence of defects.

Table 13.2.14 summarizes the most common defects that occur during casting and suggests design and process changes that can avoid or reduce the effect of the defects. However, the suggested mitigation strategies may introduce different casting defects or the evolution of other problems, so each change should be carefully evaluated with regard to the system as a whole.

Green Sand Casting Processes

Sand-mold casting is adaptable to a very wide range of alloys, shapes, sizes, and production quantities. Hollow shapes can be produced in these castings through the use of cores. Sand-mold casting is by far the most common casting process used in industry; some estimates are that as many as 90% of industrial castings use the sand-mold casting process (O'Meara et al. 1988). Green sand molding is currently the most widely used of all sand casting methods, although dry sand methods are preferred for very large castings. "Green" sand refers to the fact that water is added to activate the clay binder. In dry sand molding, the moisture is removed prior to casting.

Green sand-mold casting involves mixing sand with a suitable clay binder (usually a bentonite clay) and other additives, and packing the sand mixture tightly around a pattern that is constructed from the part design. However, the pattern is not an exact replica of the part since various dimensional allowances must be made to accommodate certain physical effects. After extracting the pattern from the sand mold, a cavity is left behind that corresponds to the shape of the pattern. Next, molten metal is poured into this cavity and solidifies into a cast replica of the desired part. After the casting cools, the sand is readily removed from the casting and may be reclaimed for further use.

A *mold pattern* is constructed from the casting design with suitable modifications. Depending on the complexity of the part, CAD/CAM programs are able to design patterns that require very little adjustment to achieve desired solidification control and dimensional accuracy in the resulting casting (Berry and Pehlke 1988). The computation is complex and cannot be easily done for complex shapes. The principal adjustments that must be made to translate a part design to a mold design result from many considerations (ASM 1988). One needs to

- Compensate for shrinkage of the sand during the drying/curing operations.
- Compensate for expansion of the sand caused by the rapid introduction of the molten metal into the mold.
- Compensate for contraction of the liquid metal during freezing.
- Allow easy extraction of the pattern from the packed sand through a taper on the vertical sides of the pattern.
- Add a gating network to allow molten metal to smoothly flow into the cavity.
- Add risers (including size), as required in key locations to continue feeding molten metal into the solidifying casting.
- Add provisions for core prints, as required, to anchor cores that produce internal cavities that could not be directly molded from the pattern.

There are basically three types of molding methods, which are categorized by the resulting hardness or density of the sand mold (O'Meara et al. 1988; Brown 1988):

TABLE 13.2.14 Typical Casting Defects and Mitigation Strategy

Casting Defect	Description and Cause	Mitigation Strategy
Cold shuts	Appear as folds in the metal — occurs when two streams of cold molten metal meet and do not completely weld Possible causes: • Interruption in the pouring operation • Too slow a pouring rate • Improperly design gating	Pour as quickly as possible Design gating system to fill entire mold quickly without an interruption Preheat the mold Modify part design Avoid excessively long thin sections
Hot tears and cracks	Hot tears are cracklike defects that occur during solidification due to overstressing of the solidifying metal as thermal gradients develop Cracks occur during the cooldown of the casting after solidification is complete due to uneven contraction	Fill mold as quickly as possible Change gating system; e.g., use several smaller gates in place of one large gate Apply thermal management techniques within the mold (e.g., chills or exothermic material) to control solidification direction and rate Insulate the mold to reduce its cooling rate Modify casting design: • Avoid sharp transitions between thin and thick sections • Taper thin sections to facilitate establishment of appropriate solidification gradients • Strengthen the weak section with additional material, ribs, etc.
Inclusions	Presence of foreign material in the microstructure of the casting Typical sources: • Furnace slag • Mold and core material	Modify gating system to include a strainer core to filter out slag Avoid metal flow turbulence in the gating system that could cause erosion of the mold Improve hardness of the mold and core
Misruns	Incomplete filling of the mold cavity Causes: • Too low a pouring temperature • Too slow a pouring rate • Too low a mold temperature • High backpressure from gases combined with low mold permeability • Inadequate gating	Control mold and metal temperature Increase the pouring rate Increase the pouring pressure Modify gating system to direct metal to thinner and difficult-to-feed sections quicker
Porosity	Holes in the cast material Causes: • Dissolved or entrained gases in the liquid metal • Gas generation resulting from a reaction between molten metal and the mold material	Pour metal at lowest possible temperature Design gating system for rapid but uniform filling of the mold, providing an escape path for any gas that is generated Select a mold material with higher gas permeability
Microshrinkage	Liquid metal does not fill all the dendritic interstices, causing the appearance of solidification micro-shrinkage	Control direction of solidification • Design gating system to fill mold cavity so that solidification begins at the extremities and progresses toward the feed gate • Lower the mold temperature and increase the pouring temperature • Add risers, use exothermic toppings to maintain temperature longer • Control cooling rate using chills, insulators, etc. in selected portions of the mold

Low-density molding

- *Hand-ramming* is the oldest, slowest, and most variable method for packing sand around the pattern. It is rarely used for production, but it can be employed for prototypes or very limited production runs.
- *Jolt* machines operate with the pattern mounted on a table, which is attached to the top of an air piston. Typically, a flask is placed on the table with the pattern centered in the flask cavity. The flask is filled with sand. Compressed air lifts the piston, and then the air is released, allowing the entire assembly to fall with a sharp jolt. The sequence can be repeated. The sand is compacted by its own weight and is densest at the pattern plate.
- *Jolt-squeeze* molding machines employ the same pattern equipment as the jolt machines, but after the jolting operation, the sand is squeezed by hydraulic pressure to improve the packing uniformity in the mold.

Medium-density molding

- *Rap-jolt machines* are improved versions of the low-pressure machines, capable of exerting higher pressure to compact the sand.
- *Sand slingers* direct sand into a mold from a rotating impeller. Sand-packing density is a function of the centrifugal velocity of the impeller. This method is particularly useful for large molds.

High-pressure molding

- *Pressure wave* methods allow the sand to gravity fill the mold. Then, the top of the mold is sealed and a high-pressure wave is created by a controlled explosion of a combustible gas or by the rapid release of air pressure.
- *Horizontal flaskless molding* utilizes a pattern carrier to support the top half (cope) and bottom half (drag) of the mold pattern. The cope and drag are spaced apart in the carrier, and the space is evacuated. The molding setup is depicted in Figure 13.2.12. Vents in the pattern cause sand to be drawn into the mold. When the mold is filled, it is tightly squeezed.

The details of the *metal pouring* operation vary quite a bit depending on the metal, the material specification, the furnace type, and the foundry layout. A ladling method using gravity pressure is commonly used to transfer the molten metal, which may be alloyed, degassed, and so forth immediately before it is discharged into the poring basin that feeds the gating system of the castings.

A *gating system* must allow complete fill of a mold cavity without causing flow turbulence that can entrap loose sand or slag and feed shrinkage as the liquid metal within the mold cools. The gating system

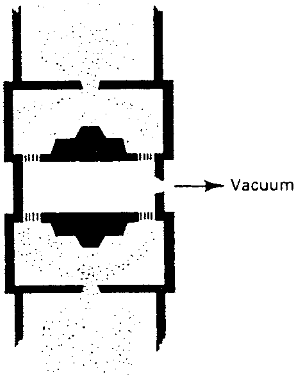

FIGURE 13.2.12 High-pressure vacuum-fill squeeze machine. (From *ASM Handbook*, *Machining*, vol. 15, 9th ed., ASM International, Metals Park, OH, 1989, 343. With permission.)

should be designed to promote progressive solidification from the point most distant from the gate toward the gate.

A *riser* is a reservoir of molten metal that is attached to the casting. It feeds the voids that develop within the casting as the liquid metal cools and begins to solidify. A thin skin of frozen metal first forms in a shell around the outer part of the mold cavity immediately after the metal is poured. This rigid shell serves as a mold for the remainder of the casting. The volume lost by the shrinkage of the metal as it solidifies within this shell must be replaced from a liquid metal source, such as a riser or a feeding gate, to prevent internal porosity. Risers are subsequently removed from the casting.

Management of thermal gradients within the solidifying casting is essential to minimize shrinkage. The solidification of risers can be slowed by the use of an *exothermic material* placed on top of a riser. The heat generated by this material can allow the riser to continue to feed the casting until it is solidified. *Chills* can be used to reduce the local temperature at the mold-casting interface, and thus accelerate freezing in selected locations, thereby establishing the solidification direction. Chills are usually metal inserts strategically placed in the mold. The mold can also be *insulated* to reduce the overall cooling rate of the casting if necessary to reduce residual stresses, but the metallurgical effect must be carefully considered.

In most cases, *electric furnaces* are used for melting, and pouring is nonpressurized.

Properly designed gating systems and risers should produce completely solid castings. A number of design rules for the gating and risering system have been developed for casting various metals to achieve continuous feeding of the solidifying casting. These rules are embedded in computer programs that aid design of casting molds and layouts.

It may be less expensive and easier to change the design than to develop a complex thermal management system within the mold. Typical design changes to evaluate include

- Thickening thin sections that feed heavier, more remote sections
- Reducing the mass of the remote thick section
- Adding a riser to feed separately the remote thick section

Each production step contributes to *dimensional variations* in a sand casting. For instance, dimensions are affected by the sand-packing density, by the process of withdrawing the pattern from the sand, by the moisture content of the sand, and by both the temperature of the molten metal and the speed with which it enters the mold cavity. The result is that sand casting is not inherently a precision process.

The surface finishes of sand castings are controllable only within rather wide limits (ASM 1988). Normally, the maximum allowable surface roughness is specified, and any smoother surface is acceptable. For instance, casting steel in green sand can have a surface roughness varying from 500 to 2000 μin. (12 to 50 μm), and aluminum from 125 to 750 μin. (3 to 20 μm). These values can be improved in certain instances through the application of coatings on the sand mold.

Porosity cannot be prevented in all cases. Changes to the part design and postcasting processing, such as hot isostatic pressing (HIP), should be considered.

Investment Casting

Investment castings are noted for their ability to reproduce extremely fine details and conform to very tight tolerances. As a result, these castings are used in critical, demanding structural applications, such as superalloy turbine airfoils and works of art.

The investment casting process employs a mold produced by enclosing an expendable pattern with a refractory slurry that is then hardened. The pattern, usually made from wax or plastic, is subsequently removed (e.g., by melting, dissolving, or burning), creating the desired mold cavity. The expendable patterns are themselves cast in a permanent pattern die. Ceramic cores can create internal passages within the casting.

Shell investment and solid investment processes are used in the production of investment castings (Horton 1988). The two processes differ in the method of mold preparation, not in pattern preparation or pattern assembly. In the shell investment process, the pattern assembly is precoated, dipped in a coating slurry, and covered with granulated refractory until the shell is built up to desired thickness, usually less than 0.5 in. (20 μmm); the thickness depends on the casting size and weight, cluster size, and type of ceramic and binder. As thin a shell as possible is specified to maximize mold permeability. Ceramic shell molds are used for the investment casting of carbon and alloy steels, stainless steels, heat-resistant alloys, and other alloys with melting points above 1100°C (2000°F).

The *ceramic material* used in shell investments is often silica, zircon (zirconium orthosilicate), an aluminum silicate, or alumina (Horton 1988). *Silica glass* (fused silica) is desirable because it is readily available, but it has a high coefficient of thermal expansion and an abrupt phase transition, and it cannot be used in vacuum casting because the silica decomposes at low vapor pressures, leading to severe metal-mold reaction. *Zircon* is readily available, is resistant to wetting by molten metal, and has a high refractoriness. Its use is limited to prime coats, though, because it is not available in large grain sizes. *Aluminum silicates*, such as mullite, can be manufactured to a range of pellet sizes and over a range of compositions. *Alumina* is more refractory than silica or mullite and is not very reactive with many metals.

The *binders* most often employed in shell investments are colloidal silica, ethyl silicate, and sodium silicate. *Colloidal silica* is an excellent general-purpose binder, and is the most widely used binder. Its primary disadvantage is that it is slow to dry. *Ethyl silicate* produces a bond between the refractory material that is very similar to that of colloidal silica. It dries much faster, but it poses a fire hazard and is more expensive. Liquid *sodium silicate* forms a strong, glassy bond. The material is inexpensive but its refractoriness is poor, and the bond deteriorates in the presence of steam used to remove the wax pattern.

In the *solid investment process*, the pattern assembly is placed in a flask, which is filled with a refractory mold slurry. This slurry hardens in air, forming a solid mass in which the pattern assembly is encased. The types of bonding materials and refractories differ depending on the pouring temperature of the metal. For nonferrous alloys, pouring temperature is usually below 2000°F (1100°C). In these cases, *alpha gypsum* is commonly used as both the refractory and the binder, with other refractories such as silica added to improve mold permeability. The process is primarily used for making dental and jewelry castings.

For extremely limited production and for the development of production process parameters, investment mold patterns can be directly machined from an expendable material, such as plastic. For production-level investment casting, however, the patterns are produced by injecting wax or plastic into *permanent pattern molding dies*. The dimensional tolerance of these permanent dies must be closely controlled.

A mixture of paraffin and microcrystalline wax is widely used for making investment casting patterns (Horton 1988). Waxes are strong, stiff, and provide adequate dimensional control during pattern making. They are easy to remove with pressurized saturated steam or elevated temperatures. *Plastic* patterns have several advantages compared with wax: higher strength, less subject to handling damage, can withstand automatic ejection from the pattern mold, and can reproduce thinner sections, finer definition, sharper corners, and better surface finish. But a major disadvantage is that certain plastics, such as polystyrene, expand during burnout and can crack ceramic shell molds.

Some investment castings require complex internal cavities (e.g., holes and air passages). For complicated shapes, the pattern-die *cores* are used to form portions of the pattern that cannot be withdrawn after the pattern is made. The cores must subsequently be dissolved or etched out from the casting.

As much *gating* as possible is included in the wax patterns. This allows use of standard methods of joining patterns together so that a number of investment castings can be produced during one pouring operation.

Investment casting is done in air and in vacuum. *Gravity pouring* fills the pouring basin from a ladle or directly from a furnace. This method requires low equipment investment but highly skilled operators. In pressure pouring the molds are filled from the furnace with an assist from a pressurized gas to fill rapidly thin sections. With *vacuum-assisted pouring*, a vacuum pump evacuates air from a mold ahead of the stream of molten metal to minimize flow resistance. *Centrifugal casting* uses a spinning mold assembly to develop added pressure to fill the mold.

Investment castings do the following:

- Produce complex shapes that are difficult to make by other means.
- Reproduce fine detail, high dimensional accuracy, and smooth surfaces requiring only minimal finishing.
- Adapt to most metal alloys.
- Allow control of metallurgical properties, such as grain size and grain orientation.

A tolerance of ±0.002 in. (0.05 mm) can be held on investment castings for each inch in its maximum dimension; however, a tolerance of ±0.005 in. (0.13 mm) is more typical (Horton 1988). A surface finish of 125 min. (3 mm) can be readily achieved, and surface finishes as smooth as 30 to 40 min. (0.8 to 1.0 mm) can be produced with suitable process control.

The size and weight of castings that can be investment cast are usually limited by physical and economic considerations. Generally, the process can be applied cost-effectively to casting weighing up to 10 lb (4.5 kg); investment castings weighing 50 lb (22.5 kg) are not unusual, and castings as large as 1000 lb (450 kg) are feasible. The initial tooling costs of investment casting can be high.

Structure-Change Processes

Structure-change processes alter the microstructure of a workpiece. These changes can be achieved through thermal treatment involving heating and cooling (quenching) under controlled conditions, sometimes in combination with mechanical forces, in order to effect desired solid-state phase transformations. These processes include those that diffuse selected species into a surface layer to modify its composition or to create a thin layer of material that does not increase the dimensions of the workpiece.

The two structure-change processes described here are representative examples. *Normalization of steel* is a process that changes bulk properties of a workpiece. *Laser surface hardening* of steel only changes its surface properties; it does not affect the bulk properties. Even though both examples relate to ferrous materials, structure-change processes are used to impart desired properties to many material systems; for example, age hardening of aluminum alloys. The references listed at the end of this section contain detailed information on structure-change processes.

Normalizing Steel

Normalizing is a heat-treating process that results in a relatively uniform steel microstructure. Essentially all the standard carbon steels can be normalized. The resulting phases and their size/distribution depend heavily on the carbon content of the steel. Normalization treatments are performed for a variety of reasons (Ruglic 1991):

- Refines the dendritic grain structure remaining from casting
- Eliminates severe texture (and hence anisotropic properties) that results from forging and rolling operations
- Reduces residual stresses
- Improves the response of a steel to further processing, such as machining or surface hardening
- Improves mechanical properties by precipitating desirable phases

The steel workpiece must be heated sufficiently high to transform the entire structure to austenite, a face-centered cubic phase that essentially solutionizes all the carbon (at room temperature iron exists as ferrite, a body-centered cubic phase that has a very low carbon solubility). Diffusion-controlled solid-state phase transformations require time at temperature to occur. Therefore, the workpiece must be held at temperature long enough for austenite to dissolve the carbon.

The workpiece is then cooled slowly enough to avoid trapping the carbon in a supersaturated solution as the iron transforms back from austenite to ferrite. A time–temperature-transformation curve depicts which phase transformations will occur for different cooling gradients. A typical T-T-T curve is shown in Figure 13.2.13, which depicts the difference between a normalizing cool rate and that for annealing. For the normalization treatment to be successful, the regions in the microstructure with a carbon content of 0.8% carbon precipitate fine lamellae of ferrite and iron carbide (Fe_3C) on cooling, known as pearlite. Those areas low in carbon content should precipitate ferrite grains during the initial phase of the cooling cycle, followed by pearlite precipitation. The regions high in carbon should precipitate iron carbide in the austenite grain boundaries, followed by pearlite precipitation (Ruglic 1991).

The end result of normalization is a microstructure, and hence the mechanical properties characteristic of the composition of the steel (primarily governed by carbon content) as opposed to a microstructure that was principally shaped by its previous thermomechanical processing.

Conventional heat-treating furnaces are used for normalization, such as batch or continuous furnaces (Ruglic 1991). The rate of heating is not critical. The furnaces must be able to heat the component to about 100°F (55°C) into the austenitizing region — this temperature depends on the composition of the steel.

Control of the cooling rate is critical. In the usual case, a workpiece can be removed from the furnace and allowed to air cool uniformly until the diffusion-controlled phase transformations are completed.

The ability to normalize the microstructure of steel is governed by thermodynamics. Phase stability and kinetics of the phase transformations are crucial. But heat transfer considerations also play a major role. For instance, it may not be possible to achieve the desired cooling gradient in the center of a thick section, and hence the properties of such sections will not be uniform.

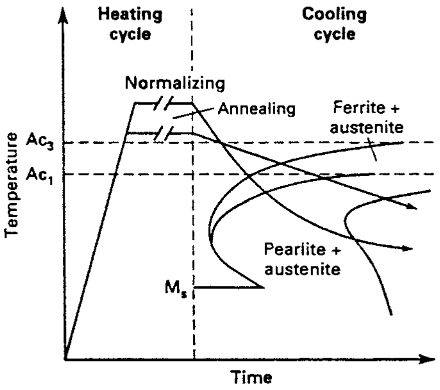

FIGURE 13.2.13 Time–temperature-transformation curve for normalizing compared to annealing. (From *ASM Handbook*, *Heat Treating*, vol. 4, 10th ed., ASM International, Metals Park, OH, 1991, 35. With permission.)

For complex shapes or for those workpieces having a high degree of residual stresses, some distortion will occur during the normalization process. The extent of distortion can be reduced by appropriate fixturing, but it cannot be eliminated. Hence, some tolerance allowance must be made.

Laser Surface Hardening

Laser surface hardening is used as an alternative to flame hardening and induction hardening ferrous materials. The rapid heating rate achievable by the laser minimizes part distortion and can impart surface hardness to low-carbon steels. The ability to locate the laser some distance from the workpiece can also be advantageous. The entire operation can be performed in air. This process is used to harden selected areas of machine components, such as gears, cylinders, bearings, and shafts.

Laser surface hardening imparts wear resistance and strength to the surface of a component without affecting its overall dimensions or changing its bulk properties. It is applied to selected areas that can be accessed by a laser beam. The process relies on rapid laser heating, followed by rapid quenching, to effect the necessary degree of hardening through phase transformation. The result is a very fine grain structure that is extremely hard. Typical case depth is a function of the composition of the ferrous material, but it will usually not exceed 0.1 in. (0.25 cm). For low- and medium-carbon steels, the case depth will range from 0.01 to 0.05 in. (0.03 to 0.13 cm), with the case depth increasing as the carbon content increases (Sandven 1991).

An industrial laser rapidly heats a thin surface layer into the austenite phase region (austenite is a face-centered cubic allotropic phase of iron that has a high solubility for carbon). The interior of the workpiece is unaffected. When the laser beam is moved, the heated surface quickly cools. Consequently, the carbon does not have time to diffuse as the iron attempts to transform back to its ferrite (body-centered cubic) structure. The resulting microstructure is extremely hard since the trapped carbon atoms distort the iron crystal structure into a highly strained body-centered tetragonal form, known as martensite.

The majority of *industrial metalworking lasers* are either solid-state Nd:YAG or carbon dioxide type. Either pulsed or continuous mode can be used for surface treatment. The power output range for YAG lasers is 50 to 500 W. Carbon dioxide lasers are available in much higher power levels, up to 25 kW.

The surface to be hardened is usually *coated* to improve its ability to absorb laser radiation. A typical coating is manganese phosphate. *Paints* containing graphite, silicon, and carbon are also used. These coatings/paints can increase the absorption of laser energy to 80% to 90% (Sandven 1991).

The output beam of the laser must be shaped and directed by an *optical system* to generate a laser spot of desired shape and size at the correct location on the workpiece surface. Reflective optical components are used since they are sturdy and easily adapted to an industrial environment.

Many factors affect the end result of laser surface hardening. Important is the hardenability of the workpiece material, which is affected by its composition and prior thermomechanical history. For the laser process, the key parameters are beam power density, uniformity of the beam, and processing speed. Following are some general processing guidelines (Sandven 1991):

- The range of usable power densities for laser surface hardening is 3200 W/in.^{2} (500 W/cm^2) to 32,000 W/in.^{2} (5000 W/cm^2) with beam dwell times ranging from 0.1 to 10 sec; higher power levels would melt the surface.
- Alloys with high hardenability can be processed at low speed with low power density to produce relatively thick cases.
- Alloys with low hardenability should be processed at high speed with high power density; the result is a shallow case.
- Beam configuration can be rectangular, square, or round; uniform energy density within the beam is very important.
- Maximum achievable surface temperature is proportional to the square root of the processing speed; thus, doubling the beam power density requires the processing speed to be increased by a factor of four to maintain the equivalent maximum surface temperature.
- Smaller workpieces are not as effective a heat sink as larger workpieces, and hence self-quenching may have to be assisted by quenching media.

The depth of hardness that can be practically achieved is limited by the surface melting point. Because of the high beam energy density, heat flow on complex-shaped surfaces, particularly those involving sharp corners or edges, can cause unexpected surface melting. Therefore, power density and process conditions must be carefully controlled.

It may be necessary to overlap passes of the laser beam, such as at the end of a complete pass around a cylinder. As a result, some tempering of the area already hardened occurs. The slower the processing speed, the greater the degree of tempering.

Deformation Processes

Deformation processes change the shape of an object by forcing material to flow plastically from one shape into another shape without changing mass or composition (Table 13.2.15). The initial shape is usually simple. This shape is plastically deformed between tools or dies to obtain the final desired geometry, properties, and tolerances. A sequence of such processes is generally used to progressively form material. Deformation processes, along with casting and machining, have been the backbone of modern mass production.

In addition to shape change, forming processes alter the microstructure of the workpiece and can improve material properties. Deformation processes are normally considered when (Semiatin 1988)

- Part geometry is moderately complex.
- Component properties and structural integrity are important.
- Sufficient production volume can amortize tooling costs.

Deformation processes can be classified (Semiatin 1988) as bulk forming processes and sheet forming processes.

Bulk forming processes (e.g., rolling, extrusion, and forging) are characterized by

- Input material form is a billet, rod, or slab.
- Workpiece undergoes a significant change in cross section during forming.

TABLE 13.2.15 Significant Factors in Modeling a Deformation Process

Process Component	Characteristics
Input material	Flow stress; workability; surface condition
Output material	Geometry; mechanical properties; dimensional accuracy and tolerances; surface finish
Deformation zone	Deformation mechanics; stress state; temperature
Tooling	Material and geometry; surface conditions; temperature
Tool/material interface	Friction and lubrication; heat transfer
Process equipment	Speed and production rate; power range; precision

Sheet metal forming processes (e.g., stretching, flanging, and drawing) are characterized by

- Input material is a sheet blank.
- Workpiece is deformed into a complex three-dimensional form without appreciably changing the cross section.

The key to attaining desired shape and properties is controlling metal deformation (Altan et al. 1983). The direction of the metal flow, the magnitude of the deformation, the rate of deformation, and the processing temperatures greatly affect the properties of the formed part. Design of the end product and the required deformation process consists of these steps:

- Predicting metal flow by analyzing kinematic relationships (e.g., shape, velocities, strain rates, and strains) between the deformed and undeformed part configurations
- Establishing producibility limits
- Selecting the process equipment and tooling capable of operating within the producibility limits

A bulk forming process (forging) and a sheet forming process (bending) are described next as representative examples of deformation processes. The references listed at the end of the section should be consulted for further information on these unit processes.

Die Forging

Talyan Altan

Forging involves the controlled plastic deformation of metals into useful shapes (ASM 1988c). Deformation may be accomplished by means of pressure, impact blows, or a combination. To reduce the flow stress, forging is usually accomplished at an elevated temperature. Forging refines the microstructure of a metal and can improve its mechanical properties, especially in preferred directions. Forging can also be used for other purposes, such as to consolidate powder preforms by welding grains, eliminate porosity in castings, break up long inclusions in forgings, and demolish the dendritic structure resulting from casting (Altan 1988a).

Forgings are generally considered when strength, reliability, fracture toughness, and fatigue resistance are important. Forgings are used in critical, high-load applications, such as connecting rods, crankshafts, transmission shafts and gears, wheel spindles, and axles. Military and commercial aircraft are major users of forgings for numerous critical items, such as bulkheads, beams, shafts, landing gear cylinders and struts, wheels, wing spars, and engine mounts. Similarly, jet engines depend on forgings for disks, blades, manifolds, and rings.

There are two broad categories of forging processes: closed-die forging and open-die forging. *Closed-die forging*, also known as *impression die forging*, employs precision-machined, matching die blocks to forge material to close dimensional tolerances. Large production runs are generally required to justify these expensive dies. During forging, the die cavity must be completely filled. To ensure this, a slight excess of material is forged. Consequently, as the dies close, the excess metal squirts out of the cavity in a thin ribbon of metal, called flashing, which must be trimmed.

Isothermal forging in heated superalloy dies minimizes the die quenching effect, preventing the rapid cooling of the workpiece in cold dies. This allows complete die fill and the achievement of close dimensional tolerances for difficult to process materials, such as superalloys.

Open-die forgings are the least refined in shape, being made with little or no tooling (Klare 1988). These forgings are large, relatively simple shapes that are formed between simple dies in a large hydraulic press or power hammer. Examples are ship propeller shafts, rings, gun tubes, and pressure vessels. Since the workpiece is always larger than the tool, deformation is confined to a small portion of the workpiece at any point in time. The chief deformation mode is compression, accompanied by considerable spreading in the lateral directions.

There are two major classes of forging equipment as determined by their principle of operation: forging hammer, or drop hammer, which delivers rapid impact blows to the surface of the metal, and forging press, which subjects the metal to controlled compressive force. Each of these classes of forging equipment needs to be examined with respect to load and energy characteristics, its time-dependent characteristics, and its capability for producing parts to dimension with high accuracy.

Forging hammers generate force through a falling weight or ram (Altan 1988b). These machines are energy restricted since the deformation results from dissipating the kinetic energy of the ram. The forging hammer is an inexpensive way to generate high forging loads. It also provides the shortest contact time under pressure, ranging from 1 to 10 msec. Hammers generally do not provide the forging accuracy obtainable in presses.

Forging presses are either mechanical or hydraulic (Altan 1988c). *Mechanical forging presses* are stroke-restricted machines since the length of the press stroke and the available load at various positions of the stroke represent their capacity. Most mechanical presses utilize an eccentric crank to translate rotary motion into reciprocating linear motion of the press slide. The blow of the press is more like a squeeze than an impact of a hammer. Because of this, dies can be less massive and die life is longer than with a hammer. *Hydraulic presses* are load-restricted machines in which hydraulic pressure actuates a piston that squeezes the die blocks together. Full press load is available at any point during the stroke of the ram. A hydraulic press is relatively slow, resulting in longer process time; this may cause undesirable heat loss and die deterioration.

Preform design is the most difficult and critical step in forging design. Proper preform design assures defect-free flow, complete die fill, and minimum flash loss. Although metal flow consists only of two basic types, extrusion (flow parallel to die motion) and upsetting (flow perpendicular to the direction of die motion), in most forgings both types of flow occur simultaneously, leading to a very complex flow field. An important step in understanding metal flow is to identify the neutral surfaces. Metal flows away from the neutral surface in a direction perpendicular to the die motion. Ideally, flow in the finishing step should be lateral toward the die cavity without additional shear at the die-workpiece interface. This type of flow minimizes forging load and die wear. A milestone in metalworking is the use of CAD in establishing the proper design for preforming and finishing dies in closed-die forging (Gegel and Malas 1988). Figure 13.2.14 illustrates the relationships between forging process variables and those of a forging press that must be understood in order to estimate process performance for a hot-forging operation.

Designing a mechanical component that is to be made by forging together with the optimum geometry for the forging dies requires analysis of many factors (Altan 1988a), including

- Design rules
- Workpiece material specification and its critical temperatures
- Flow stress of the material at the process conditions (e.g., temperature, temperature gradient, strain rate, total strain)
- Workpiece volume and weight
- Frictional conditions in the die
- Flash dimensions
- Number of preforming steps and their configuration (flow field for the material)
- Load and energy requirements for each forging operation
- Equipment capability

In closed-die forging, it is particularly difficult to produce parts with sharp fillets, wide thin webs, and high ribs. Moreover, dies must be tapered to facilitate removal of the finished piece; draft allowance is approximately 5° for steel forgings (see Table 13.2.16).

Press-Brake Forming

Press-brake forming is a process used for bending sheet metal; the workpiece is placed over an open die and then pressed into the die by a punch that is actuated by a ram known as a press brake (ASM 1988b). The main advantages of press brakes are versatility, ease and speed with which new setups can be made, and low tooling costs.

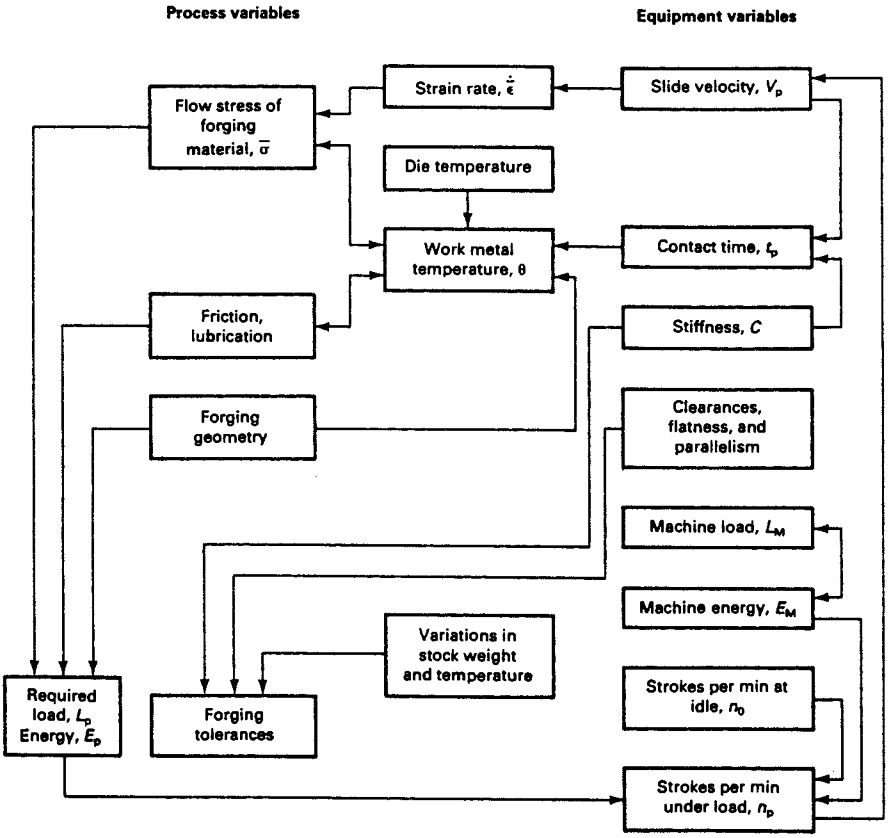

FIGURE 13.2.14 Relationships between process and machine variables in hot-forging processes conducted in presses. (From *ASM Handbook*, *Forming and Forging*, vol. 14, 9th ed., ASM International, Metals Park, OH, 1988, 36. With permission.)

Press-brake forming is widely used for producing shapes from ferrous and nonferrous metal sheet and plate. Although sheet or plate 0.250 in. (10 mm) thick or less is commonly formed, metals up to 1 in. (25 mm) thick are regularly formed in a press brake. The length of a sheet is limited only by the size of the press brake. Forming can be done at room or elevated temperature. Low-carbon steels, high-strength low-alloy steels, stainless steels, aluminum alloys, and copper alloys are commonly formed in a press brake. Press-brake forming is applicable to any metal that can be formed by other methods, such as press forming and roll forming.

Press-brake forming is considered for bending sheet metal parts when the production quantities are small, dimensional control is not critical, or the parts are relatively long. In contrast, press forming would be considered when production quantities are large, tolerances are tight, or parts are relatively small. Contour roll forming would be another option for high-rate production applications (ASM 1988c).

Bending is a method of forming sheet metal by stressing a material beyond its yield strength while remaining below its ultimate strength so that cracking is avoided. In press-brake forming the tooling and setup are relatively simple. A workpiece is placed over a die, typically having a V-shape. The bend angle is determined by the distance the workpiece is pressed into the die by the punch. The width of the die opening (the top of the V) affects the force needed to bend the workpiece. The minimum width is determined by the thickness of the workpiece and the radius of the punch nose.

A *press brake* is basically a slow-speed punch press that has a long, relatively narrow bed and a ram mounted between end housings. Rams are mechanically or hydraulically actuated. Figure 13.2.15 depicts a typical setup for press-brake forming.

TABLE 13.2.16 Typical Forging Defects and Mitigation Strategies

Defect	Description and Cause	Mitigation Strategy
Surface cracking	Fine cracks in the surface of the forging Possible causes: • Excessive working of the surface at too low a temperature • Brittle or low melting phases in the grain boundaries • Cracking at the die parting line	Increase the amount of preheating of the forging billet and forging die Change material specification Change furnace atmosphere to avoid diffusion of unwanted elements Increase the flash thickness Relocate the die parting line to a less critical location Stress relieve the forging prior to flash removal
Cold shut	Appears as a fold; occurs when two surfaces of metal fold against each other without welding Possible causes: • Poor metal flow in the die • Excessive chilling during forging • Poor die lubrication	Redesign forging die and/or forging preform to improve plastic flow of the metal during the forging operation Redesign the forging to avoid areas which are difficult to fill Increase the amount of preheating of the forging billet and forging die Improve die lubrication
Underfill	Incomplete forging in which all details are not produced Possible causes: • Debris residue in die • Scale on forging billet • Billet too small to completely fill die	Clean die thoroughly Completely descale the billet Redesign preform
Internal cracks	Cracks not visible from the surface, but detected during inspection and/or exposed during metal removal Possible causes: • Scale embedded in the internal structure of the forging • High residual tensile stresses	Completely descale the billet For open-die forgings, use concave dies Redesign for closed-die forging Use a hydraulic press and heated dies to avoid formation of excessive tensile stresses during forging

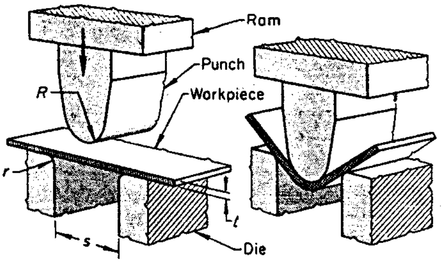

FIGURE 13.2.15 Typical setup for press-brake forming. (From *ASM Handbook*, *Forming and Forging*, vol. 14, 9th ed., ASM International, Metals Park, OH, 1988, 533. With permission.)

V-bending dies and their corresponding punches are the tools most commonly used in press-brake forming. The width of the die opening is usually a minimum of eight times the sheet thickness.

Capacities of commercial press brakes range from 8 to 2500 tons. Required capacity is governed by the size and bending characteristics of the work metal and by the type of bend to be made (ASM 1988b).

The nose radius of the punch should not be less than the work-metal thickness for bending low-carbon steel, and must be increased as the formability of the workpiece material decreases. The radius of the V-bending die must be greater than the nose radius of the punch by an amount at least equal to the workpiece thickness to allow for the bottoming of the punch in the V.

It is preferable to orient a bend so that it is made across the rolling direction rather than parallel to it. Sharper bends can be made across the rolling direction without increasing the probability of cracking the material. If bends must be made in two or more directions, the workpiece should be oriented on the sheet layout such that none of the bends will be parallel to the rolling direction.

Springback after press-brake bending is considered only when close dimensional control is needed. It can be readily compensated for by overbending. Factors that affect springback include the mechanical properties of the work material, the ratio of the bend radius to stock thickness, the angle of bend, the method of bending, and the amount of compression in the bend zone. A greater amount of overbending is needed to correct for springback on small bend angles than on large bend angles.

The generally accepted tolerance for dimensions resulting from bending of metal sheet in the press brake is ±0.016 in. (±0.4 mm) up to and including 0.125 in. (3 mm) thickness (ASM 1988b). For heavier gauges, the tolerance must be increased accordingly. Achievable tolerances are influenced by the part design, stock tolerances, sheet metal blank preparation, the condition of the machine and its tooling, and operator skill.

In press-brake forming, as in other forming processes, the metal on the inside portion of the bend is compressed or shrunk, and the metal on the outside portion is stretched. This results in a strain gradient across the thickness of the workpiece in the area of the bend with tensile strain on the outside and compressive strain inside. These residual strains (and resulting stresses) can lead to distortion of the part under loading conditions, heating, or cooling.

The formability of metals decreases as the yield strength approaches the ultimate strength. In press-brake forming, as the yield strength of the work metal increases, power requirements and springback problems also increase, and the degree of bending that is practical decreases.

There are several factors that will make it difficult to establish or maintain accurate placement of a bend line in a press brake. Corrective action may require a design change or change in processing sequence:

- Bends or holes that are located in close proximity to the required bend line can cause the position of the bend line to wander.
- Notches and cutouts located directly on the bend line make it difficult to maintain an accurate bend location.
- Offset bends will shift location unless the distance between bends in the offset is at least six times the thickness of the workpiece material.

If multiple bends must be made on a workpiece, it may not be possible to avoid a bend that is parallel to the rolling direction. Depending on the degree of texture in the sheet and the anisotropy of the material, a change to a higher-strength material may be necessary to achieve the desired geometry.

Consolidation Processes

Consolidation processes fuse smaller objects such as particles, filaments, or solid sections into a single solid part or component to achieve desired geometry, structure, and/or property. These processes use either mechanical, chemical, or thermal energy to bond the objects. Interaction between the material and the energy that produces the consolidation is a key feature of the process.

Consolidation processes are employed throughout manufacturing, from the initial production of the raw materials to final assembly. One group of processes involves the production of parts from powders of metals, ceramics, or composite mixtures. The resultant consolidated products are typically semifinished and require further processing. For instance, the consolidation of powders produces bar, rod, wire, plate, or sheet for upstream processes.

The consolidation of net shape composite structures (i.e., require minimal finishing work) is an increasingly important area. The design of the structural geometry, selection of material, and choice of consolidation processes all act together to provide the required level of performance. There are two types of matrix materials used: themosetting and thermoplastic. The consolidation process of each of these types of resins is different. A unit process described in this section addresses the consolidation of composites using polymeric thermosetting resins.

An important family of consolidation processes includes welding and joining processes used to permanently assemble subcomponents. Historically, welding and joining processes are developed empirically and quickly evaluated for benefit in manufacturing applications, driven by the promise of significant potential benefits. The need for welding and joining is substantial since only monolithic parts can be made without joining. The ideal joint would be indistinguishable from the base material and inexpensive to produce (Eagar 1993). However, experience indicates that no universal joining process exists that can entirely satisfy the wide range of application needs, and thus design engineers must select the most appropriate joining methods that meet requirements. Shielded metal-arc welding, the most widely used welding process, is described in this section.

The unit processes described here are a representative sample of the types most likely to be encountered. The references listed at the end of the section should be consulted for detailed information on these unit processes.

Polymer Composite Consolidation

Weiping Wang, Alan Ridilla, and Matthew Buczek

A composite material consists of two or more discrete materials whose combination results in enhanced properties. In its simplest form, it consists of a reinforcement phase, usually of high modulus and strength, surrounded by a matrix phase. The properties of the reinforcement, its arrangement, and volume fraction typically define the principal mechanical properties of a composite material. The matrix keeps the fibers in the correct orientation and transfers loads to the fibers.

Continuous-fiber-reinforced materials offer the highest specific strengths and moduli among engineering materials. For example, a carbon fiber/epoxy structural part in tensile loading has only about 20% of the weight of a steel structure of equal stiffness. Composite parts can integrate component piece parts, such as molded-in rib stiffeners, without the need for subsequent assembly operations and fasteners.

Many types of polymer composites are in use. Composities are usually identified by their fiber material and matrix material. Fiber materials are necessarily strong, stable materials that can be processed into fiber formats. Typcial fibers are glass, graphite/carbon, aramid, and boron. *Glass* fibers represent the largest volume usage since they have excellent properties and are low cost. *Graphite/carbon* fibers are widely used for advanced composite applications in which stiffness and high performance are critical. These fibers are also expensive. *Aramid* fibers, a type of polyamide, have proved useful in applications where its performance in axial tension can be exploited without incurring too severe a penalty by the material's poor performance under compressive loading. *Boron* filaments have high strength and high modulus, but most applications requiring high performance, such as military aircraft structures, are now using carbon fibers.

Low-cost *polyester* resins are the most widely used matrix material for the general composite industry; the majority of these applications use glass as the fiber. Many applications are found in the chemical process, construction, and marine industry. The most widely used polymers are *epoxy* resins, which are used with carbon, aramid, and boron fibers for many advanced applications, such as in aircraft structure and rocket motor fuel tanks. *Polyimides* are polymer resins that provide more temperature performance than is possible from the epoxy-based material, and they are used in advanced aircraft structures and jet engine components where heating of the structure will occur.

Each of the constituent materials in advanced composites acts synergistically to provide aggregate properties that are superior to the materials individually. The functional effectiveness of composites is principally due to the anisotropy of the materials and the laminate concept, where materials are bonded together in multiple layers. This allows the properties to be tailored to the applied load so that the structure can be theoretically more efficient than if isotropic materials were used. The reinforcements come in a variety of formats. Unidirectional tapes with all fibers along a common axis, woven fabrics constructed with fibers along both axes in the *x-y* plane, and multidimensional architectures with reinforcements in more than one axial direction are just a few of the available formats.

Consolidation in composites can be considered to occur at two levels: the fibers are infiltrated with the matrix to form a lamina or ply, and the individual laminae are consolidated together to form the final structure. In the prepreg process, these two levels are distinctly separated, since the fiber/matrix consolidation process forms the prepreg, which is then laid up to form the laminate or final component. In other processes, such as resin transfer molding, fiber/matrix infiltration and the consolidation of the final part are done in a single stage. Single-stage consolidation processes are attractive because they eliminate the additional cost associated with prepreg production; however, two-stage consolidation processes have major advantages that often outweigh the benefits of single-stage consolidation. These include flexibility in part geometry, high fiber content, excellent fiber wet-out, and better control of fiber volume fraction distribution. Because of these advantages, prepreg processing is firmly entrenched in high-value products, such as aerospace applications, in spite of its high cost.

Typical steps in manufacturing continuous-fiber composites involve *preform fabrication* and consolidation/curing (Advani 1994). Preform fabrication creates the structure by positioning material close to the final part shape (Table 13.2.17). The material comes in either the *dry fiber* (without resin) form or with resin included, called prepreg. Dry fibers are used in filament winding, weaving, braiding, and pultrusion. The resin can be introduced in the operation or downstream molding. *Prepreg*, at a higher material cost, eliminates the step of resin addition and provides the adhesion to hold the material together. Consolidation/curing involves compacting the preform to remove entrapped air, volatiles, and excess resins while developing the structural properties by increasing the polymer chain length and cross-linking.

Thermosetting polymeric materials will not soften and flow upon reheating after polymerization because of the formation of a cross-linked polymer network. Therefore, thermosetting polymer matrices must be cured *in situ* with the fibers to form the composite structure. The goals of a successful cure are good consolidation with low porosity and high conversion of initial monomeric constituents to polymer.

The challenge of the cure process is to manage the interactions of temperature distribution, degree of cure, laminate thickness, and void content by manipulating the applied temperature, pressure (or displacement), and vacuum. Temperature must be controlled so that resin temperature stays within limits.

TABLE 13.2.17 Methods of Composite Preform Fabrication

Method	Description	Application
Weaving	Process of interlacing yarns to form a stable fabric construction that is flexible Less frequent interlacing results in better composite strength	Closely conforms to surfaces with compound curvature
Braiding	Intertwines parallel strands of fiber A tubular braid consists of two sets of yarn which are intertwined in "maypole dance" fashion; produced with varying diameter or circumferential size	Sporting equipment Good torsional stability for composite shafts and couplings Geometric versatility and manufacturing simplicity
Pultrusion	Reinforcing fibers pulled from a series of creels through a resin impregnating tank; preformed to the shape of the profile to be produced; enters a heated die and is cured to final shape	Produce constant cross-section pieces at high production rates
Filament winding	Pulling roving (unlisted bundles of fibers) over a mandrel by rotating the mandrel about a spindle axis; can cure on the mandrel	Cylindrical parts Can be low cost
Tube rolling	Material cut from prepreg tapes and laid on a flat surface; plies of different orientations joined together; a cylindrical mandrel is rolled on the material; curing is typically done on the mandrel	Low-cost method for making tubular structures or tapered tubes, e.g., golf shafts
Manual layup	Plies of different fiber orientations are cut from flat sheets of the prepreg material and laid up on a tool; bagging materials are applied and sealed to the tool for subsequent consolidation Flexible in producing complicated features at low start-up/tooling cost; building a curved, variable-thickness part can be complicated	Most common method used in the aerospace industry
Automatic tape layup	Computer-controlled machine tools or robots with a material delivery system • Automated tape layup machine uses prepreg tape, typically 3 to 12 in. wide, suitable for large surface of gentle contours • Fiber placement employs multiple tows for more complex surfaces	Provides lower cost and variability over manual layup, but requires higher capital investment

Both the duration and the magnitude of pressure application are important as excessive resin flow results in a resin-starved laminate. Similarly, pressure application too soon in the process can entrap volatiles in the material. Materials can also exhibit lot-to-lot variability. The problem is further complicated when processing a complex-shaped part or multiple parts of different geometry.

Composite cure processes are typically performed in an autoclave or in a heated press. An *autoclave* is essentially a heated pressure vessel. Nitrogen gas is normally used for pressurization. The temperature, pressure, and vacuum are controlled vs. time to effect the cure. Recent advancements in *intelligent processing* use sensors to determine the state of cure in real time, and make appropriate control adjustments to optimize the cure cycle (NRC 1995). Figure 13.2.16, which plots data from an actual implementation, depicts the potential that intelligent processing has in reducing autoclave processing time and cost.

Press molding uses a high-pressure press and matched metal tools to form a part. The main components of a press-molding system include the tools, the ram, and the heated platens. Again, release materials must be applied to the tools to avoid laminate adhesion. Advantages of press molding include improved surface finish (since both sides are tooled) and the elimination of the vacuum bagging systems. However, the pressure inside the mold is not necessarily uniform and volatiles are not easily removed. Consequently, press molding is generally suitable for composite systems that do not generate a significant amount of volatiles.

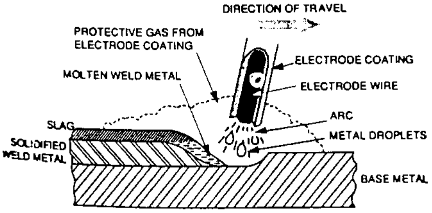

FIGURE 13.2.17 Shielded-metal arc-welding process. (From *ASM Handbook*, *Welding, Brazing, and Soldering*, vol. 6, 10th ed., ASM International, Metals Park, OH, 1993, 175. With permission.)

Shielded-Metal Arc Welding

Bonding is achieved in fusion welding by interposing a liquid of substantially similar composition as the base metal between the surfaces to be joined (Eagar 1993). The need for welding and joining is substantial since only monolithic parts can be made without joining. Traditional welding processes have unique advantages, which make them the processes of choice for a large number of applications. For example, in the fabrication of heavy structures, arc welding will dominate other assembly processes because of the inherent flexibility and economy of welding.

In the majority of arc-welding methods, the workpiece is made part of the electric welding circuit, which has as its power source a welding generator or transformer. To start a weld, an arc is struck by touching the workpiece with the tip of the electrode. The welder guides the electrode by hand in welding a joint, and controls its direction and traveling speed. The welder maintains arc voltage by controlling arc length (the distance between the end of the electrode and the work surface). Because an electric arc is one of the hottest sources of heat, melting occurs instantaneously as the arc touches the metal. Arc welding is a highly popular process because of its flexibility and relatively low cost (ASM 1993).

In shielded-metal arc welding, an arc is struck between the workpiece and a covered (or coated) metal electrode. Filler metal is provided by the consumable electrode. Combustion and decomposition of the electrode covering from the heat of the welding arc produce a gaseous shield that excludes the oxygen and nitrogen in the atmosphere from the weld area; these gases would otherwise cause excessive porosity and poor ductility in the weld. Welds by this method are of very high quality (Juers 1993). Figure 13.2.17 depicts the components of the shielded-metal arc welding process.

For shielded-metal arc welding, the metallurgical properties of a weld depend greatly on the type of electrode and its covering. The *electrode coverings* contain shielding gas formers that exclude atmospheric gases from the weld area. Electrode coverings offer additional capabilities (Juers 1993):

- Deoxidizers and nitrogen absorbers to purify the depositing metal
- Slag formers to protect the weld from oxidation
- Ionizing elements to stabilize the arc

- Alloying elements to produce higher-strength welds
- Iron powder to increase metal deposition rate

Selection of the proper electrode is based on many considerations (Juers 1993):

- Base metal strength
- Base metal composition
- Welding attitude (position)
- Welding current
- Joint design and fit
- Base metal thickness and shape
- Service conditions
- Production efficiency and conditions

Many types and sizes of *power supplies* are used. Supplies can be either direct current (DC) or alternating current (AC) types; combination AC/DC power supplies are widely used. In general, power supplies are required that produce controllable levels of constant-current output. The rate of metal deposition is determined by the output current from the power supply.

Shielded-metal arc welding is the most widely used welding process for joining metal parts, principally because of its versatility. Also, the welding equipment is less complex, more portable, and less costly than for other arc-welding processes.

Shielded-metal arc welding is generally very useful in joining components of complex structural assemblies. Joints in virtually any position that can be reached with an electrode can be welded, even if directly overhead. Joints in blind areas can be welded using bent electrodes. Welding in positions other than flat require the use of manipulative techniques and electrodes that cause faster freezing of the molten metal to counteract gravity. Shielded-metal arc welding can be done indoors or outdoors.

Metals welded most easily by the shielded-metal arc process are carbon and low-alloy steels, stainless steels, and heat-resistant alloys. Cast iron and high-strength steels can also be welded, but preheating and postheating may be required. Shielded-metal arc-welding electrode materials are available for matching the properties of most base metals; thus, the properties of a joint can match those of the metals joined.

Joint design (shape and dimension) is determined by the design of the workpiece, metallurgical considerations, and established codes or specifications.

Welds should preferably be located away from areas of maximum stress. Poorly placed welds can result in undesirable, and unplanned, stress concentrations that can cause early failure of the joint.

Poor joint fit-up increases welding time and is often the cause of poor welds. Metals with a low melting point, such as zinc, lead, and tin, cannot be welded by electric arc methods.

Limitations of shielded-metal arc welding compared with other arc-welding methods are related to metal deposition rate and deposition efficiency. Consumable electrodes have a fixed length, usually 18 in. (460 mm), and hence welding must be stopped periodically to replace the electrode. Another limitation is the requirement to remove the slag covering that forms on the weld after each welding pass.

There is a minimum gauge of sheet that can be successfully welded without burn-through. Generally 0.060 in. (1.5 mm) is the minimum practical sheet thickness for low-carbon steel sheet that can be welded by a welder possessing average skill (Juers 1993).

Special techniques are required when welding pieces of unequal thickness because of their different heat dissipation characteristics. Solutions include

- Placing a copper backing plate against the thinner section to match the heat dissipation from the thick section
- Redesigning the component so that the thick and thin sections taper at the joint to approximately the same size

Distortion is unavoidable in welding because of residual stresses that arise from nonuniform heating and cooling. Various procedures can be used to minimize distortion, such as clamping the workpieces. But straightening of the workpiece may be required to achieve the required dimensional accuracy.

Mechanical Assembly

S. H. Cho

Total labor involved in the assembly processes in the U.S. varies from 20% (farm machinery) to almost 60% (telecommunications equipment). On average, assembly tasks occupy 53% of manufacturing time, and 10% to 30% of total production cost of most industrial products. Use of improved assembly methods and technologies is essential to reduce overall manufacturing costs.

Assembly Methods and Systems

Assembly systems are classified in several different ways (Table 3.2.18). Figure 13.2.18 indicates the types of automated systems that could be cost-effective based on assembly part count and production volume.

Generally, *automatic assembly systems* consist of three major components:

- *Transfer system* to move work carriers with in-process subassemblies between workstations
- *Parts feeding device* to supply parts to be assembled into the appropriate position, where the parts are loaded by the handling/placing mechanism
- *Parts handling/placing mechanisms* to pick parts and perform assigned assembly tasks such as placing, inserting, and screwing

The *transfer system* can be continuous or intermittent according to the transfer method. In the *intermittent transfer system*, assembly tasks in a workstation are performed during a stationary period of the work carriers, which are transferred to the subsequent workstation after completion of the assembly tasks. *Continuous transfer systems* have a problem of not being able to assure positioning accuracy between an in-process subassembly and the tools of a workstation; thus, the intermittent type is usually used (Boothroyd 1992).

There are two modes of *intermittent transfer*: in-line and rotary. For the *in-line* mechanisms, the walking beam, the shunting work carrier, and the chain-driven work carrier are commonly used. The *rotary* type

TABLE 13.2.18 Classification of Assembly Systems

Type of Assembly System	Classification Basis	Description
Manual	Level of automation	Assembly tasks completed manually
Automatic	Level of automation	Adopts mechanized devices or industrial robots with supplementary equipment for handling and assembling parts
Semiautomatic system	Level of automation	Manual workers and mechanized devices cooperate to complete assembly tasks
Cell-type system	Configuration	Very flexible integrated assembly workstation; assembly completed by various equipment, such as robots or pick-and-place units, parts feeders, parts tray, magazines, automatic tool changer, and auxiliary jig/fixtures
Line-type system	Configuration	Assembly tasks divided into subtasks which are completed at workstations connected by transfer systems; handles large parts, cycle-time variation, and gripper change
Dedicated system	Degree of flexibility	Not flexible — can assemble only one product of a single model; generally economical for large production volumes
Flexible system	Degree of flexibility	Accommodates different products; economical for medium-size and mixed-model production

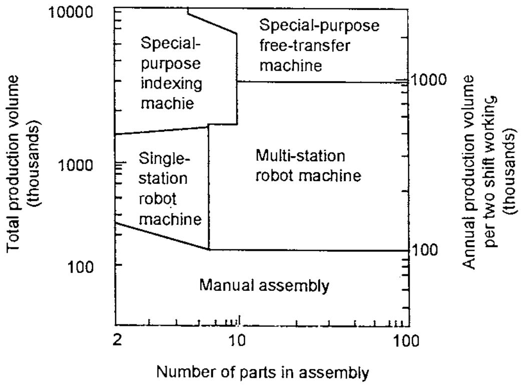

FIGURE 13.2.18 Conditions for economic application of various assemby systems (Courtesy of S. H. Cho)

employs mechanisms such as rack and pinion, ratchet and pawl, Geneva mechanism, and mechanical cam drives. Currently, free-transfer conveyors with stopping and positioning mechanisms are widely used in flexible assembly lines.

Most *feeding systems* have devices to orient parts supplied by the following means (Yeong and Vries 1994):

- *Bulk supply*, for parts that are easily separated, fed, and oriented automatically. Bulk supply usually adopts various part feeders, e.g., vibratory bowl feeders and various nonvibratory mechanical feeders for small parts. These feeders usually only handle one type of part and cannot be applied to assembly systems that require flexible part-feeding devices.
- *Organized supply*, which uses special pallets such as a kit or a magazine for parts that cannot easily be separated, fed, and oriented.

Parts-handling/placing mechanisms include pick-and-place units and various types of industrial robots. To load and assemble parts, the mechanism usually employs various assembly wrists: jaw-type gripper, vacuum suction pad, magnetic chuck, screwdriver, nut runner, and others. A number of different wrists are required when automatically assembling different parts in a workstation. To accommodate this assembly situation, a multifunctional gripper, a tool-changing system, and a universal gripper have been developed and widely used in robotic assembly systems.

FIGURE 13.2.19 Various assembly wrists. (Courtesy of S. H. Cho.)

Selection of Assembly Systems

The placement of a part in its assembled position and part mating impose tight constraints on the positioning mechanism and on part properties such as clearances and geometry. These constraints are more severe for assembly systems mating a variety of precision products that must adapt to frequent design changes. The assembly systems of this type must possess the adaptability to changing assembly environments, thus requiring *flexible automatic assembly* (Boothroyd 1984).

A typical *flexible robotic assembly* system uses an industrial robot for part handling, part positioning, and part mating. These systems are limited by positioning and orientation misalignment caused by the low positioning accuracy of robots, uncertainty in part handling, and variation in the location of parts.

Various approaches are available that take into consideration uncertainty in orientation and parts properties variation. Figure 13.2.19 depicts various types of assembly wrists that are in use. In general, wrists can be classified into three basic configurations:

- Passive accommodation
- Active accommodation
- Passive-active accommodation

There are two types of *passive wrist methods*:

- The wrist accommodates misalignments by deforming its structure elastically under the influence of the contact forces generated during the assembly of the misaligned parts. A *mechanically compliant structure* is needed for either the robot wrist or the assembly worktable, which can be deformable according to the reaction force acting on the mating parts. Remote center compliant wrist is one of such typical wrists; this method usually requires part chamfering (Cho et al. 1987).
- The wrist corrects misalignment by *applying external forces* or torques to the misaligned parts in a prescribed manner or a random way. For instance, a vibratory wrist utilizes pneumatic actuators controlled by a pulse width modulation controller to generate desirable vibration; this method does not require part chamfering.

Active wrist methods employ sensor-controlled wrists and compensate misalignments by controlling the fine motion of the assembly wrist or the work table based on sensory feedback. Advances have been made in the area of sensing technique, gripper and actuating mechanism design, and the related control algorithms. Sensors for these wrists are needed prior to contact (vision, range, displacement, proximity), during contact (touch, slip), and after contact (force, moment). Based on the force sensor signals and the associated algorithms, the wrist motion can be corrected to reduce misalignment.

The *passive-active accommodation method* is achieved by combination of the "passive and active" techniques. The basic strategy is that the part mating is continued within some allowable forced moments, while beyond this the insertion method is switched from the passive to active to reduce the mating force by using sensors with compliant structures.

The *sensor-based assembly* is similar to the method employing the active wrist. Both rely on sensory information for fine-motion control. The principal difference is that the former utilizes robot motion, while the latter relies on wrist motion.

Reaction forces (*force/torque information*) that occur during part mating can represent the status of the contact between mating parts. Among the approaches are pattern classifiers that determine the contact state at which the assembly parts are contacting each other, position error recovery via fuzzy logic, heuristic search with fuzzy pattern matching, and learning of nonlinear compliance using neural network.

Visual/optical information is critical to compensate for positioning and orientation error occurring due to misalignment. Visual information is often combined with other data, such as force/torque, pressure, and displacement, because a rather longer time is required for image processing, object recognition, and error calculation and because visual information is sensitive to external environmental conditions such as illumination.

Assembly Line

An assembly line usually consists of a set of workstations that perform distinct tasks linked together by a transfer mechanism. Each task is an assembly operation, and each workstation represents a location along the line where the tasks are processed. A buffer storage is placed between workstations for reducing the effect of a workstation failure on the throughput.

Line balancing is essential for designing a cost-effective assembly system (Groover 1980). The time required for the completion of a task is known as the *process time*, and the sum of the process times of the tasks assigned to a station is the *station time*. The total task processing times for assembling all the parts is the *work content*. When *assembly sequences* are generated without considering line balancing, the sequences may not guarantee the minimum number of workstations. Therefore, line balancing must be concurrently considered in defining the assembly sequences.

Design for Assembly

Approximately 80% of manufacturing cost is determined at the conceptual design stage. Design for assembly (DFA) is crucial during early design. The objective of the DFA is to facilitate the manufacturing and assembly of a product. DFA applies to all the assembly operations, such as parts feeding, separating, orienting, handling, and insertion for automatic or manual assembly (Ghosh and Gagnon 1989).

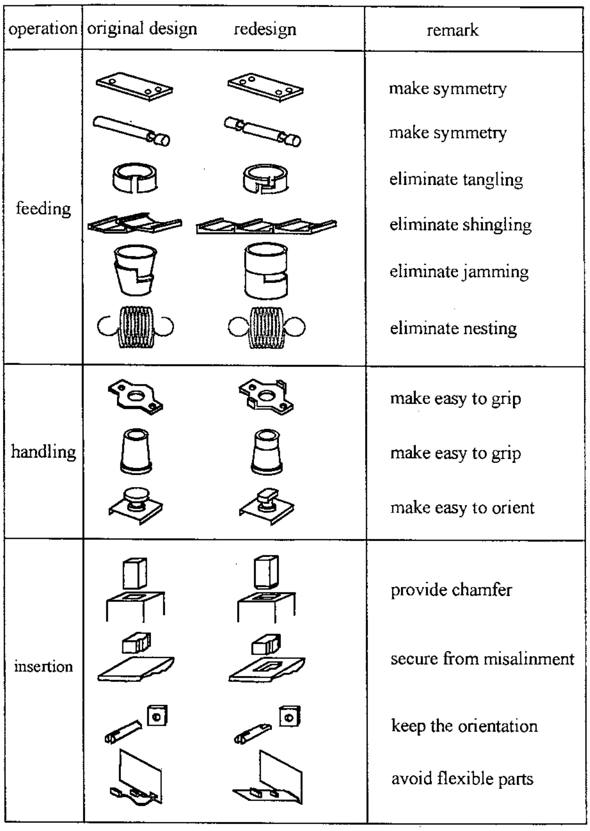

FIGURE 13.2.20 Results of DFA analysis. (Courtesy of S. H. Cho.)

DFA is directed toward

- Reducing the number of parts by modularization
- Easing feeding and minimizing reorientation
- Easing insertion by self-aligning, self-locating, elimination of part interference, and efficient fastening

Axiomatic DFA uses design guidelines based on experience of product designs and assembly operations. *Procedural DFA* evaluates the design efficiency based on the production cost.

Figure 13.2.20 shows results that were obtained using DFA rules to evaluate part designs in consideration of feeding and insertion. Such analysis has great potential in improving assembly operations.

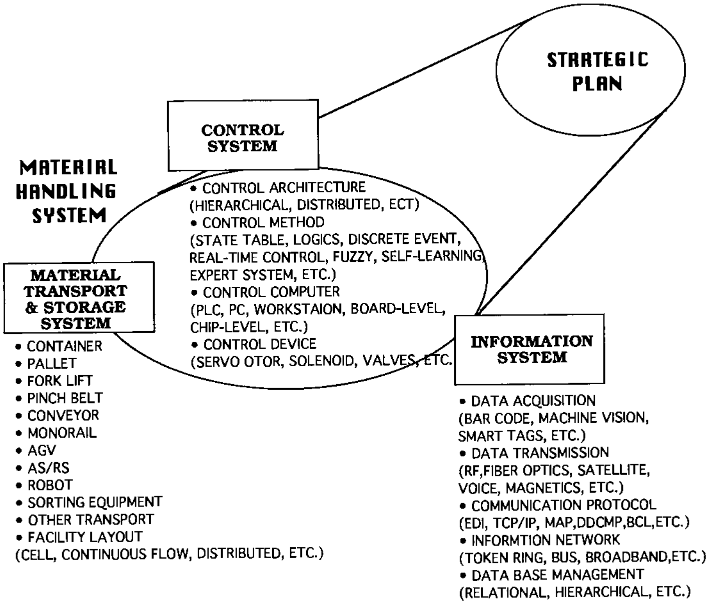

FIGURE 13.2.21 Modern material-handling system. (Courtesy of J. Lee.)

Material Handling

Ira Pence

Material handling provides the right amount of all the required materials at the right place and time to support manufacturing. Properly designed, the material-handling system provides for the acquisition, transportation, and delivery of material so that the minimum cost is incurred considering capital, labor, and expenses. It focuses on obtaining material and supplies, moving them between process steps, and delivering the finished product to the customer. Figure 13.2.21 depicts the elements of a modern materials-handling system, which reaches beyond the factory floor, serving as an integrating force for production operations.

The material-handling system should be analyzed as a single entity so trade-offs in expense in various elements can be made to minimize the total cost. Often, however, the activities are broken into purchasing, transportation, warehousing, and distribution functions, which operate independently. Such divisions are arbitrary because the material-handling system is an unbroken chain of activities that start when the suppliers complete their last value-added operation and extend until the product is delivered. Minimum-cost material handling will not be achieved if the partitioning of material flow into subelements leads to optimization of each subelement at the expense of the entire system.

Planning is crucial to the design of a smoothly functioning materials operation. Planning should be consistent with the strategic plan for the entire manufacturing operation. In formulating the plan, a realistic assessment of the problems and opportunities associated with arranging, controlling, and implementing the material flow must be used. Specific tactics, such as just-in-time delivery, should support the strategic plan. Expensive automation should not be used unless the volume and stability of the product justify its use.

Logistics

The movement of material in a manufacturing enterprise is usually broken into two broad categories, inside the plant and external to it. External movement is generally referred to as "logistics," while the internal flow is known by many different names. Material movement considered logistics is generally marked by a wide geographic scope, diversity of equipment and technology, and some uncertainty in delivery time. But the basic goals are identical to in-plant movement, and most of the analysis tools are applicable to both categories.

For large manufacturing enterprises the number of individual components involved in the production of the product, often referred to as SKUs (stock-keeping units), can be very large. In the past, it was helpful to treat items of similar size, weight, storage requirements, and delivery times as a single commodity. This simplified manual analysis and was sometimes done by computer programs that analyze logistical information. However, current computer systems make it practical to treat each item individually.

Basic Elements

The basic activities associated with material handling are *moving*, *storing*, and *controlling* material. These activities are interrelated with production scheduling and information must flow both ways.

Movement may be over short distances, as from one machining center to another, or long, from one plant to another. In all cases the basic information that must accompany the move includes the part identity, timing, quantity, source, and destination. Each move should be planned and scheduled, taking into account the speed of the basic mechanism as well as allowance for loading, unloading, logging, counting, and so forth.

Movement can be continuous or in batches, synchronous or asynchronous, horizontal or vertical. Each move should be examined for the characteristics of urgency, safety, size, weight, and similar factors before selecting the technology to be used to perform the move. Singular instances should be accommodated in the most expeditious manner, and repetitive moves must be made in the most efficient and effective manner.

One of the basic tenets of material handling is to retain *control* of the material. Inventory control generally maintains up-to-date records on the quantity and location of material on hand. However, in a *virtual warehouse*, it is important to know what material has been ordered and the status. Control includes procedures and equipment to properly handle the material.

The *storage* of material should be minimized. Materials are typically stored to compensate for uncertainty in delivery systems and to allow ordering of economic quantities.

Occasionally unexpected changes in production will result in delaying the release of material to the factory floor and that material must be stored until needed. *Just-in-time delivery*, where parts are delivered directly from local suppliers to the assembly line several times a day, has been proved in several industries. Thus, the need for storage due to uncertainty of delivery has been reduced. At the same time, global sourcing has increased. As supply lines lengthen, the uncertainty of delivery increases. The more complex the supply system, the more likely the occurrence of an unexpected delay. In designing a storage system, the trade-off of higher transportation cost but less inventory vs. volume discounts on purchases and transportation, but with storage costs, must be evaluated.

Further Information

The Material Handling Industry (MHI) produces two catalogs each year. One provides information on the publications available from the MHI, including all the educational material; standards and specifications; operating, maintenance, and safety manuals; and reference works. The other provides a directory of member companies and the products they manufacture. Both are available from the MHI Literature Department.

Case Study: Manufacturing and Inspection of Precision Recirculating Ballscrews

Toskiaki Yamaguchi, Yashitsugu Taketomi, and Carl J. Kempf

The precision and quality of the components of mechanical devices used in both industrial and consumer products must meet high performance and durability requirements. The manufacturing challenges that apply to ballscrews, in general, are representative of other components such as gears, shafts, and bearings.

This case study on precision ballscrews illustrates how the different unit manufacturing processes presented in this chapter apply to a particular application, and how design and manufacturing engineering decisions are affected by quality and cost considerations.

Many of the processing steps and fundamental techniques discussed in this case apply to the manufacture of many other precision components. The case study also illustrates the rationale for continuously improving production processes and discusses strategies for improvement that benefit from past experience.

Overview of Ballscrew Design and Manufacturing Considerations

Ballscrews convert rotary motion into linear motion. Ballscrews have low friction compared with standard leadscrews, and have enabled precise control of mechanical systems at a relatively low cost. They are used extensively in production machinery, such as milling machines, and are being applied in other fields, such as robotics, inspection equipment, and office automation equipment.

The key components of a ball-screw system consist of a screw shaft with a spiral groove, a nut with a corresponding spiral groove that rides along the shaft, and balls that are captured between the shaft and the nut. A recircultation tube provides a return path for the balls from the end of the nut. Components in this assembly are typically made from steel alloys, chosen to provide a good combination of toughness, surface hardness, and ease of manufacture.

Ballscrews are applied in a variety of ways, but the most common configuration is one in which a rotational input of the shaft imparts a translational motion to the nut. The shaft is normally supported by rotating bearings at both ends, and the translating element attached to the nut is supported by linear guide bearings. Ballscrews range in size from very small units with a shaft diameter on the order of 0.08 in. (2 mm) and a length of about 4 in. (100 mm) to very large units with a shaft diameter on the order of 12 in. (300 mm) and a length of up to 50 ft (16 m). Key dimensional features that are controlled to a high degree of precision for an assembled ball-screw system are shown in Figure 13.2.22.

The main factors in ballscrew performance are accuracy and lifetime. *Accuracy* is determined primarily by the precision of the screw lead, that is, the linear displacement of the nut that is produced by rotary displacement of the shaft. The measurements used to assess the *precision* of the lead are discussed later. To obtain a long *lifetime*, the shaft must have high surface hardness in order to withstand loads at the shaft/ball and nut/ball interfaces. Since ballscrews may be subject to a variety of loading conditions, the ballscrew must possess good impact strength and toughness.

Secondary design factors include low audible noise, low static and dynamic friction, low friction variation, minimal backlash, high mechanical stiffness, and resistance to dirt and contaminants. Ballscrews are often used in specialized applications, such as operation in vacuum or ultraclean environments, in corrosive or dirty environments, in a thermally controlled environment, and in environments where vibrations must be minimized. To meet these demands, basic ballscrew designs are adapted to use

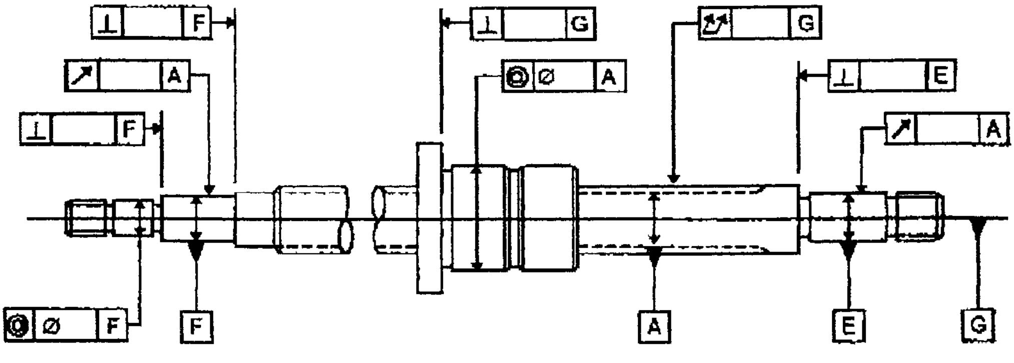

FIGURE 13.2.22 Key ballscrew dimensions. (Courtesy of T. Yamaguchi, Y. Taketomi, and C. J. Kempf.)

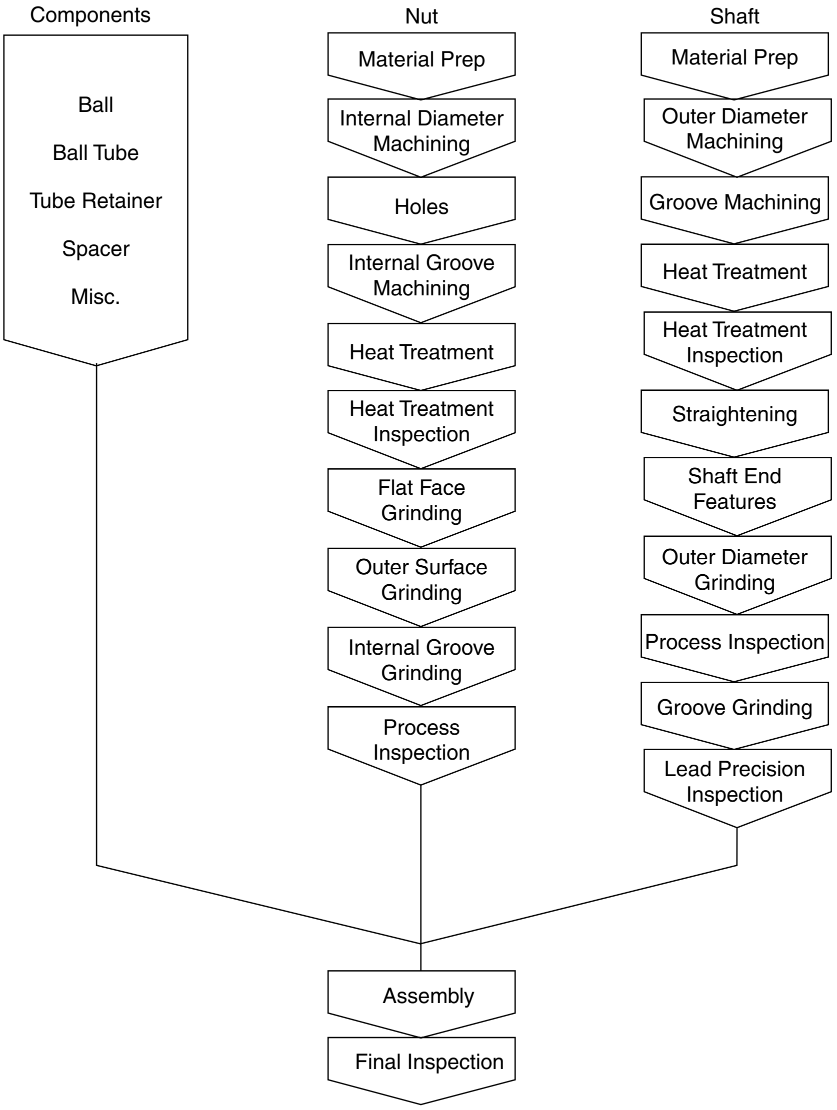

FIGURE 13.2.23 Ballscrew processing flowchart. (Courtesy of T. Yamaguchi, Y. Taketomi, and C. J. Kempf.)

special materials, surface treatments, and to provide features such as hollow shafts for coolant flow or damping materials.

The major steps in production and assembly of traditional ground ballscrews are summarized as a flowchart in Figure 13.2.23.

Initial Machining Operations

A lathe is used to establish the outer diameter of the shaft and cut the groove. In both operations, an allowance is made for material that will be removed in the final grinding operations. For short shafts, the support is provided from the shaft centers and a single cutting tool can be used with multiple passes to produce the desired outside diameter and groove. For long ballscrews, the lateral deflection of the shaft during cutting operations is significant and workpiece supports are necessary to prevent deflection of the shaft.

For long ballscrews, the total processing time can become extremely long using multiple passes with a single-point cutting tool. In such cases, a multiple-point tool that can remove more material on a single cutting pass is more efficient to use. But a multipoint cutter requires more time for setup and adjustment. Thus, there is an economic trade-off between single-point and multipoint cutting techniques.

Because of subsequent heat-treat operations, the shaft will undergo dimensional changes. The design must allow for these dimensional changes. This is an area in which production experience is critical. Statistical analysis of previous manufacturing results, together with modeling of material behavior, is critical to continued design and process improvement.

Surface Treatments

In order to withstand the loads at contact points, a very high surface hardness is necessary. A surface hardness of Rockwell C 58-62 with a depth on the order of 0.8 to 1.2 mm is required. For short ballscrews, *carburization* is used to develop the necessary surface hardness. For longer shafts, carburization is impractical because of the size of carburizing furnaces. In this case, an induction hardening process is used.

Electrically heated gas furnaces are used in the carburizing process. The immersion in the carburizing furnace is followed by quenching and tempering. During carburizing, key parameters such as temperature and gas concentrations are continuously monitored and adjusted by a process control system. Because high hardness is needed only in the ball groove, areas of the shaft and nut that will be subject to subsequent machining operations are coated before carburizing. This coating, which is applied like paint, prevents the diffusion of carbon into the material surface.

For longer shafts, a different steel is chosen and an induction hardening process is used. The general trend within the industry is toward induction hardening since it has the advantage of being a continuous process. When using induction hardening, single shafts can be processed immediately after machining. Induction hardening machines require less initial capital than for a carburizing system.

The shaft undergoes dimensional changes as a result of the surface heating, and a *straightening* operation is necessary. Prior to straightening, the shaft is chilled in a carefully controlled manner to subzero temperatures to ensure that the solid-state transformations are completed; the result is a more stable microstructure. For straightening, a *specialized press* is used to measure automatically the deviation from perfect straightness; it automatically applies loads along the shaft as necessary to restore the shaft to near-perfect straightness.

Grinding and Finishing Operations

After surface treatment, chilling, and straightening, the outside diameter of the shaft is ground to the final dimensions. Except for very short ballscrews, the grinding cutting forces will cause lateral deflection of the shaft, and thus the centers in the shaft ends cannot be used as datums for final machining operations. Consequently, the outside diameter of the shaft is ground to precise tolerances. Although the outer diameter of the shaft is not a functional part of the finished ballscrew, it is used as a datum surface when the final grinding of the shaft groove is performed.

Grinding of the shaft can be done on either centerless grinders or cylindrical grinders. Since centerless grinders take a long time to set up, they are generally used for large production runs of shafts having the same diameter. For the case of cylindrical grinders, the shaft is supported at the centers in the shaft ends as well as at workpiece supports along the length of the shaft. By adjusting the work rests, minor variations in taper and bending of the shafts can be corrected. This processing step requires considerable operator skill and experience in order to minimize variations in the outer diameter and residual bending of the shaft.

To maintain precision and finish of the outer diameter, automatic balancing of the grinding wheel is necessary. CBN grinding wheels are used although they are more expensive than traditional abrasive wheels; their long life and low wear rates make them economical.

After turning the external diameter to final size, shaft end features are produced. These features include bearing seats, keyways, flats, and locknut threads. The final finishing operation for the ballscrew generates the ball groove. This is the key processing step in assuring that the ballscrew possesses the required lead accuracy. If this process is not carefully controlled, there will be variation in the lead, depth of the groove, and smoothness of the groove, causing subsequent problems with accuracy, stiffness, running force and noise, and lifetime.

Removal of the outer layer of hardened material during outer diameter grinding can cause minor bending of the shaft as the net residual stresses in the material change. Prior to final cutting of the ball groove, the straightness of the shafts is checked and minor corrections made.

To maintain very high lead precision, the final groove grinding is done in a specially temperature-controlled environment of 68 ± 2°F (20 ± 1°C). Cutting oil is applied liberally to the shaft to minimize thermal effects due to cutting and deviations between the grinding machine and shaft temperature. As in the case of external diameter grinding, automatic balancing is used to minimize vibrations. To further reduce vibrations, each grinding machine is mounted on an individual base to minimize vibration coupling between various machines. The isolation properties of the machine bases are adjusted when a new machine is placed in service and undergo periodic inspection and adjustment during operation.

Because the size and lead of the groove varies from ballscrew to ballscrew, the grinding wheel must be matched to the groove shape. Thus, an inventory of several types of wheels is necessary; traditional abrasives are used since the costs of CBN wheels would quickly become prohibitive.

In general, accuracy in the groove-grinding process requires a combination of modeling and statistical analysis. As in the case of surface treatment, the collection and analysis of past production data allows continuous refinement of the manufacturing process.

Assembly and Inspection

The main factor in ballscrew accuracy is the lead. To facilitate a quantitative measurement of the lead, four fundamental parameters are used. To measure the lead error, precision measurements over a long travel range are made using computer-controlled laser interferometry.

Unacceptable variations in friction, increased running noise, and a reduction in life result from poorly formed grooves. Thus, the depth and cross-sectional profile of the groove must fall within allowable tolerances. Direct measurement of the groove cross section is quickly performed on an optical profile projector. Precise measurement of groove depth can be made on selected samples. The screw shaft is supported between two centers and rotated at a fixed speed. A table carrying a contact probe moves along the screw shaft in the axial direction synchronously with the screw rotation. The probe is placed in contact with the groove to measure variations in the groove depth over the entire length of the shaft. By performing a frequency analysis on the groove depth errors and accounting for the rotational speed of the ballscrew during the measurement process, frequencies of unwanted vibrations occurring in the production machinery can be detected and the source of the anomaly eliminated to improve the production process.

Even with good control of the screw shaft and nut groove diameters during production, additional steps are necessary to obtain the desired amount of axial play or preload in the assembled ballscrew. By selecting slightly different ball sizes, required axial play or preload can be achieved. For a given nominal ball diameter, balls usually are grouped in steps of 20 to 40 μin. (0.5 or 1.0 μm). To increase production efficiency, assembly jigs are used.

The majority of precision ballscrews are preloaded in order to remove backlash and achieve the desired axial stiffness. Two methods of achieving the desired preload are used. The first preloading method increases the ball size until the desired preload is achieved. The second method uses double-nut preloading in which a spacer is inserted between the two nuts to take up the axial play and achieve the desired preload.

The preloaded ballscrew has some running torque when the screw is rotated. The relation between this running torque and the preload has been determined based on both theoretical and experimental studies. Since preload cannot be measured directly, it is estimated based on measurements of the running torque in a specialized torque-measuring machine.

A special machine is used for direct measurement of axial stiffness. In this process, the screw shaft is clamped and an axial load is applied to the nut. A displacement sensor is fixed to the shaft close to the nut and the relative displacement of the nut can be measured when force is applied. The measurements of force and displacement can be plotted on an X-Y recorder to depict the stiffness characteristics of the ballscrew assembly.

13.3 Essential Elements in Manufacturing Processes and Equipment

Sensors for Manufacturing

John Fildes

Introduction

A good modern definition for a sensor must capture the diversity of these devices. A sensor is a device that detects or measures the state or value of a physical or chemical variable and provides the result in a useful way. At the minimum, a sensor contains a transducer that converts the detected or measured quantity to another form of representation. For example, a very simple sensor is an indicator whose color changes upon reaction with a minimum amount of a chemical species. Nonetheless, the sensors that are normally encountered are more complex, containing a transducer, an output display, and possibly supporting electronics for signal conditioning, communications, and logic functions.

Sensor technology is undergoing rapid change because of three developments. One development is the emergence of integrated and smart sensors, wherein transducers have been miniaturized, usually through the use of silicon micromachining, and integrated with electronics for signal conditioning, communications, and logic functions. The second development is the ongoing adaptation of nondestructive evaluation (NDE) measurements and laboratory measurements for online use in supervisory and intelligent process control systems. These NDE and laboratory-type measurements require rather complex systems, with extensive signal conditioning and data analysis. The third development is also related to the emergence of supervisory control systems. The data from multiple sensors are comparatively analyzed in a process called data fusion to better identify the state of the system and the occurrence of process faults. Thus, the topic of sensors and sensory systems now encompasses transducers, integration with supporting electronics for communications and logic functions, data-analysis techniques, and data-fusion methods.

Classification of Sensors

A good taxonomy for sensors is provided by the requirements for different degrees of process control, which is shown in Figure 13.3.1. This taxonomy contains three classes: sensors used in regulatory feedback control loops, process analyzers, and product quality analyzers. In Figure 13.3.2, the basic element of control is the regulatory feedback loop that maintains controllable processing parameters at the desired values. These types of sensors, which usually provide a single value and are relatively generic in their applicability, are used for monitoring variables such as temperature, pressure, flow, level, displacement, proximity, and velocity. For use of sensors in regulatory control, sensitivity, selectivity, simplicity, speed, reliability, and low cost are the critical attributes. Historically, sensors were almost solely used in this function, but this is no longer the case. Sensors, or more properly sensory systems, are now also used as process analyzers and product quality monitors. Sensors of this type, which are used for feedback in supervisory control, are more complex and application specific, and their output tends to be a matrix of values (e.g., a video image or a spectrum). Sensors of this type provide a representation of the process

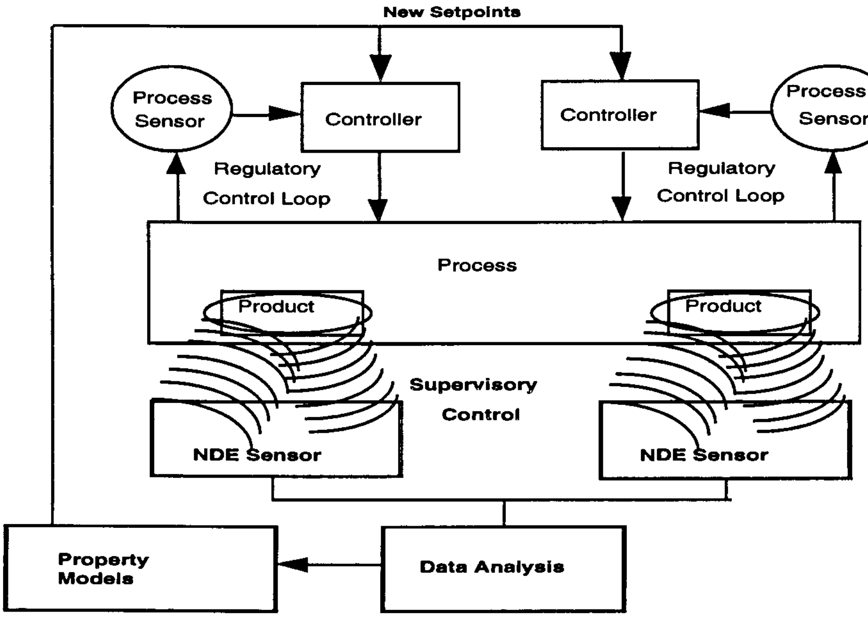

FIGURE 13.3.1 Regulatory and intelligent control.

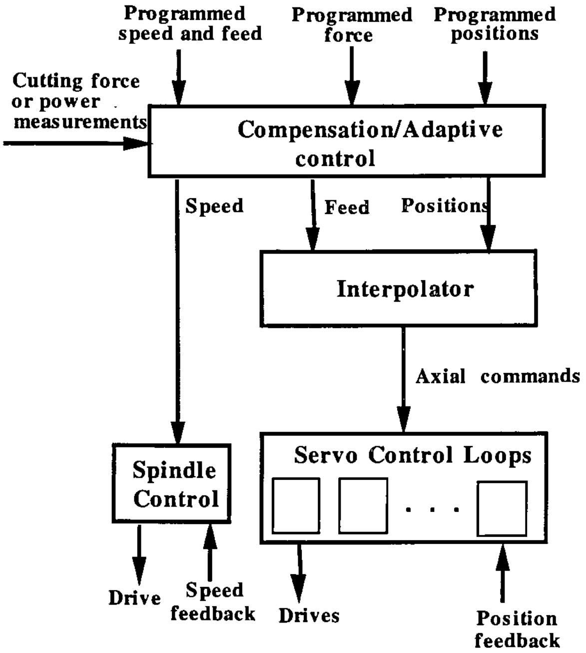

FIGURE 13.3.2 Typical CNC architecture.

or product that has greater information content but that is more abstract than the representation provided by sensors used in regulatory control. Thus, extensive computations and modeling are needed for process analyzers and product quality sensors, but there is also more ability to correct for deficiencies in sensitivity and selectivity through computational means. In this case, measurement speed is usually less demanding. These differences in the three types of sensors are summarized in Table 13.3.1.

TABLE 13.3.1 Characteristics of Regulatory and Intelligent Process Control Sensors

Characteristic	Regulatory Feedback Sensors	Process and Product Sensors
Speed of response	Very fast	Slow
Type of output	Single value	Matrix of values
Relationship of output to system parameter	Simple and direct	Abstract representation
Amount of computation	Little or none	Extensive
Sensitivity	Inherently high	Can be improved by computation and modeling
Selectivity	Inherently high	Can be improved by computation and modeling
Cost	Very low to moderate	High
Size	Small	Large
Applicability	Broad	Application specific

TABLE 13.3.2 Regulatory Processing Variables

Controllable Variable	Influenced Processing Factors
Temperature	Rates of chemical reactions; degree of cure of polymers; degree of softening and viscosity; cooking times; drying times; annealing times; degree of carborization
Pressure	Consolidation density; porosity; concentration of gaseous chemical reactants; forging; bending; injection times in molding
Flow	Mix ratios; quenching time; concentration of chemical reactants; color; pH; humidity
Level	Capacity; mix ratio; concentration of chemical reagents
Humidity	Drying of paper and grains; cooking
Position	Parts handling and placement; machining accuracy
Motion	Assembly; machining accuracy

TABLE 13.3.3 Sensor Technologies for Regulatory Control

Variable	Major Sensor Technologies
Temperature	Thermocouples, thermistors, resistance thermometers, infrared pyrometers, acoustic pyrometers
Pressure	Manometers, bellows and diaphragms, strain gauges, piezoresistive, piezoelectric, capacitive, thermocouple, ionization
Flow	Differential pressure (orifice plate, Venturi, pitot tube); velocity (turbine, vortex, electromagnetic, Doppler ultrasonic, time-of-flight ultrasonic); positive displacement (rotary sliding vane, gear, impeller); mass flow (thermal, coriolis); variable area (rotameters)
Level	Floats, pressure, radio frequency, ultrasonic, microwave, resistance tape, optical
Humidity	Dew point, length of hair, conductivity, capacitive, resonate
Position	Rotary encoder, linear variable differential transformer, potentiometers, magnetostrictive, magnetic, inductive proximity, magnetic, ultrasonic
Motion	Tachometers, pitot tube, anemometers

The typical regulatory variables are temperature, pressure, flow, level, humidity, position, and motion. These variables form the basis for many process factors as summarized in Table 13.3.2; the major sensor technologies for these variables are summarized in Table 13.3.3.

Integration refers to inclusion of signal conditioning on the same substrate as the transducer. One of the major advantages of integration is that the integrated sensor can operate with a very small transducer output, which results in significantly smaller sensors. With the advent in telecommunications and the microelectrical-mechanical systems (MEMS) technologies, we can integrate software, hardware, power source, and communications on the same chip. Table 13.3.4 lists the advantages and disadvantages of integrated sensors.

Smart sensors are defined as those that also include logic functions, rather than just signal-conditioning electronics. Smart sensors may also include communications circuitry, diagnostics, and sometimes control outputs so that they can be directly connected to actuators, and documentation and trending functions.

TABLE 13.3.4 Characteristics of Integrated Microsensors

Characteristic	Advantage/Disadvantage
Batch fabrication	Excellent control, low cost, sensor arrays
Loss of modularity	Difficult to package and limitations on materials
On-chip amplification	Better signal-to-noise ratio
On-chip compensation	Better accuracy through compensation for interferences
On-chip feedback	Better linearity
On-chip scaling and conversion	Standardized output
On-chip multiplexing	Sensor arrays, bus addressable

Conventional pressure sensors have rather broad accuracy limits, such as 0.25% of span. High-end smart pressure sensors have an accuracy of less than 0.1% of span, and midrange smart pressure sensors approach this accuracy. Smart pressure transmitters are already available with built-in proportional-integral-derivative control functions, and fuzzy logic capabilities will soon be available. Multivariate measurement is not yet available but will become so soon. Most likely, pressure and temperature will be the two measurements. Smart sensors are also available for presence detection, positioning, infrared photodetection with triangulation, and flow meters, specifically magnetic meters, Coriolis mass flow meters, and ultrasonic flow meters. Integrated and smart sensor technology is also improving accelerometers, proximity detectors, and tactile sensors. The use of integrated and smart sensors will increase because of the overloading of shared resources and the use of distributed control schemes to solve this problem.

Use of Sensors in Supervisory and Intelligent Control Systems

As shown in Figure 13.3.1, supervisory control augments regulatory control by using process analyzers to better characterize the state of the process and sensors of product characteristics to assess the outcome of the process and to determine corrections for unacceptable deviations. These corrections are then implemented by the regulatory controllers. There are many ways in which supervisory control can be implemented. A common way is to measure important aspects of the process and the product performance, and to use a model to relate variations in processing parameters to variations in product performance.

Process analyzers are central to enabling supervisory control because they allow a more accurate, but abstract, representation of the state of the process. These devices augment regulatory control by monitoring other important variables in the process, but ones that are generally not directly controllable. The use of process analyzers provides improved reliability, flexibility, predictive diagnostics, ease of use, and central data collection with process documentation; trending; recipe handling; and statistical quality assurance. Process analyzers are now used for monitoring important process gases such as oxygen, carbon monoxide and dioxide, oxides of nitrogen and sulfur, and hydrocarbons. For liquids, process analyzers are available for pH, conductivity, redox potential, dissolved oxygen, ozone, turbidity, specific ions, and many organic compounds. The measurement techniques are summarized in Table 13.3.5.

TABLE 13.3.5 Process Analyzers

Process Analyzer Technology	Typical Uses
Electrochemical (potentiometric, amperometric)	Gases such as carbon monoxide and dioxide, oxides of nitrogen and sulfur, and hydrocarbons; species in liquids such as dissolved oxygen, pH, redox potential, specific ions, organic compounds, inorganic compounds
Chromatography (gas and liquid)	Gases such as CO and CO_2; species in liquids such as alcohols, flavors, lipids, polymers, and other organic compounds
Infrared spectroscopy	Near infrared — web processes for thickness, composition, solvent, coating Mid-infrared — chemical and petrochemical processes, polymers, food processes
Ultraviolet/visible	Gases and liquids including all elemental halogens, other inorganics, aromatics, carbonyls, many salts of transition metals

TABLE 13.3.6 Product Quality Sensors

Sensor	Applications
Time-of-flight ultrasound	Either thickness or elastic constants, if the other is known
Electromagnetic acoustic transducer (EMAT)	Either temperature or elastic constants, if the other is known
Eddy currents	Electrical conductivity, magnetic permeability, thickness, temperature, presence of flaws
NMR (high resolution for liquids, low resolution for solids)	Composition of chemicals, petroleum, foods, polymers, fibers
Infrared and Raman spectroscopy	Degree of cure of polymers

Traditionally, process analyzers have been stand-alone devices with a single sensor and a dedicated operator interface. The trend is toward modularity, multiple sensors, and digital communications so that process analyzers can be incorporated into distributed control systems in an open architecture control environment. Smart sensor technology is also turning conventional sensors into process analyzers. A good example is provided by smart infrared temperature sensors. These sensors provide sample and hold, correction for reflected radiation when the emissivity of the target is less than one and its temperature is lower than ambient, analog outputs for control, digital outputs, trend analysis, and area sampling with line scanners. This functionality has made temperature mapping of surfaces in furnaces practical and is used in annealing of aluminum, steel reheating, and oven drying of webs such as paper.

Another trend is the use of sensor fusion, where information from multiple sensors is combined to improve the representation of the process. Sensor-fusion techniques can use mechanistic models, statistical models, or artificial intelligence techniques, such as neural networks, fuzzy logic, and expert systems. Sensor fusion provides more reliability because the validity of the data of each sensor can be assessed from the other sensors, and if a sensor is faulty, its value can be predicted from the other sensors. Sensor fusion provides a better representation of the process because it captures the interrelationships that often exist between processing variables, which are treated independently without sensor fusion.

As shown in Figure 13.3.1, intelligent control involves the use of product quality sensors. Of the three classes of sensors discussed in this section, these sensors tend to be the most complex and provide the most complete, but abstract, representation of the state of the product. In some cases, the same technologies are used for product quality sensors as for process analyzers. An obvious example would be where chemicals undergo reaction without a change of state. In other cases, specialized product quality sensors have emerged. Table 13.3.6 lists some of the product quality sensors that are either being used or evaluated experimentally.

Computer Control and Motion Control in Manufacturing

Yoram Koren and M. Tomizuka

Computerized Numerical Control Architecture

A typical architecture of a CNC system consists of three levels, as shown in Figure 13.3.2. At the lowest level are the axial servocontrol loops and the spindle controller. These servoloops are closed at a high sampling rate. The interpolator that supplies the axial position commands to the control loops is at the intermediate level of this architecture. At the highest level are the compensation algorithms for the errors of mechanical hardware deficiencies, such as machine geometry errors and thermal deformation of the machine structure. This level also includes adaptive control algorithms that adapt the machine feed and speed to the cutting tool and workpiece material to maximize machine productivity at rough cutting and maintain precision at fine cutting.

CNC Part Programs

The CNC software consists of a control program and part programs. The numerical data that are required for producing a specific part by a CNC machine make up the part program. The *part program* is arranged

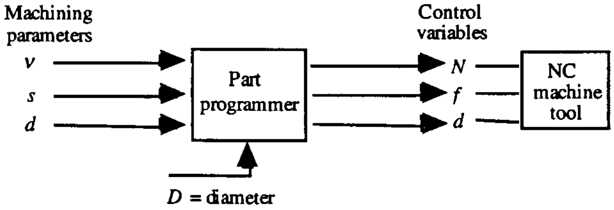

FIGURE 13.3.3 Conversion of machining parameters to control variables.

in the form of *blocks* of information, where each block contains the numerical data required to produce one segment of the workpiece. Each block contains, in coded form, all the information needed for processing a segment of the workpiece: the segment shape and length, its cutting speed, feed, and so forth. Dimensional information (length, width, and radii of circles) and the contour shape (linear, circular, or other) are taken from an engineering drawing. In NC, dimensions are given separately for each axis of motion (X, Y, etc.). Cutting conditions such as cutting speed, feed rate, and auxiliary functions (coolant on and off, spindle direction, clamp, gear changes, etc.) are programmed according to surface finish and tolerance requirements.

The part program contains the required positions of each axis, its direction of motion and velocity, and auxiliary control signals to relays. The controller generates an internal signal indicating that the previous segment is completed and that the new block of the part program should be read. The controller also operates the drives attached to the machine leadscrews and receives feedback signals on the actual position and velocity of each one of the axes.

In CNC systems the part dimensions are expressed in the part programs by integers. Each unit corresponds to the position resolution of the axes of motion and is referred to as the *basic length-unit* (BLU). The BLU is also known as the "increment size" or "bit-weight," and in practice it corresponds approximately to the accuracy of the system. To calculate the position command that the computer sends to the CNC machine, the actual length is divided by the BLU value. For example, in order to move 0.7 in. in the positive X direction in a system with BLU = 0.001 in., the position command is $X + 700$.

In the first generations of CNC systems, dimensions were given in part programs by BLUs, as in NC. In new CNCs, however, dimensions, or desired cutter positions, are given in a normal way, as to a regular computer. The command $X – 0.705$, for example, will move the X-axis in the negative direction by 0.705 in. The resolution by which the dimension commands are given depends on the system BLU.

In addition to cutter positions, the part programmer must program the machining parameters such as tool diameter, cutting speed (n), feed (s), and depth of cut (d). The task of the part programmer is to convert the machining parameters n and s to NC control variables — spindle speed (N) and feed rate (f), as shown in Figure 13.3.3.

Point-to-Point and Contouring Axes of Motion

CNC systems consist of two functional types: point to point (e.g., drilling machine) and contouring, or continuous path (e.g., milling machine).

Point-to-Point Systems. The simplest example of a point-to-point (PTP) CNC machine tool is a drilling machine. In a drilling machine the workpiece is moved along the axes of motion until the center of the hole to be drilled is exactly beneath the drill. Then the drill is automatically moved toward the workpiece (with a spindle speed and feed that can be controlled or fixed), the hole is drilled, and the drill moves out in a rapid traverse feed. The workpiece moves to a new point, and the above sequence of actions is repeated.

In a PTP system, this system requires only position counters for controlling the final position of the tool upon reaching the point to be drilled. The path from the starting point to the final position is not controlled. The data for each desired position are given by coordinate values. However, in high-speed drilling applications, such as the task of single-spindle drilling of an engine block, a control loop is needed to control the acceleration and deceleration of the motion. The digital signal processing technique has been used to control the settling time of the motion system for very fast PTP motion profile (1 to 4 g) so that the spindle could perform drilling operations without breaking the drill. A linear motor-based machine tool has been built and demonstrated by Anorad Corp. (Hauppauge, New York) for Ford Motor's engine machining line.

Contouring Systems. In contouring, or continuous-path, systems, the tool is cutting while the axes of motion are moving, as, for example, in a milling machine. All axes of motion might move simultaneously, each at a different velocity. When a nonlinear path is required, the axial velocity changes, even within the segment. For example, cutting a circular contour requires a sine-rate velocity change in one axis, while the velocity of the other axis is changed at a cosine rate.

In contouring machines, the position of the cutting tool at the end of each segment together with the ratio between the axial velocities determines the desired contour of the part, and at the same time the resultant feed also affects the surface finish. Since, in this case, a velocity error in one axis causes a cutter path position error, the system has to contain continuous-position control loops in addition to the endpoint position counters. Consequently, each axis of motion is equipped with both a position loop and a position counter. Dimensional information is given in the part program separately for each axis and is fed to the appropriate position counter. Then, an *interpolator*, in the controller, determines the proper velocity commands for each axis in order to obtain the desired tool feed rate.

Interpolators. In contouring systems the machining path is usually constructed from a combination of linear and circular segments. It is only necessary to specify in the part program the coordinates of the initial and final points of each segment and the feed rate. The operation of producing the required shape based on this information is termed *interpolation*, and the corresponding software algorithm in CNC is the *interpolator.* The interpolator coordinates the motion along the machine axes, which are separately driven, to generate the required machining path. The two most common types of interpolators are linear and circular. Parabolic interpolators are also available in a few CNC systems that are used in the aircraft industry.

Linear interpolator: The ability to control the movement along a straight line between given initial and final coordinates is termed *linear interpolation*. Linear interpolation can be performed in a plane (two dimensional), using two axes of motion, or in space (three dimensional), where the combined motion of three axes is required. In this chapter only two-dimensional linear interpolators are discussed. To illustrate the interpolator function, consider a two-axis system, where a straight cut is to be made. Assume that the X axis must move p units at the same time that the Y axis moves q units. The contour formed by the axis movement has to be cut with a feed rate of V length-units per second (e.g., mm/sec). The numerical data of p, q, and V are contained in the part program and are fed into the interpolator. The interpolator then generates two velocity signals V_x and V_y, where

$$V_x = \frac{pV}{\sqrt{p^2 + q^2}} \tag{13.3.1}$$

and

$$V_y = \frac{qV}{\sqrt{p^2 + q^2}} \tag{13.3.2}$$

The position reference inputs to the axial control loops are

$$R_x = V_x t \tag{13.3.3}$$

and

$$R_y = V_y t \tag{13.3.4}$$

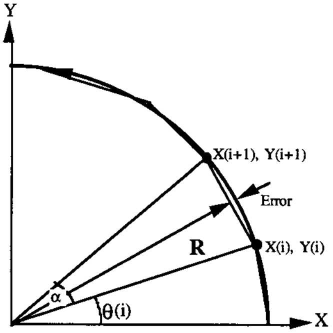

FIGURE 13.3.4 A circular interpolator divides the arc into straight lines.

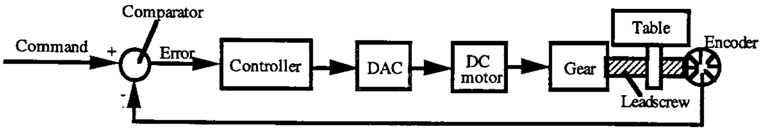

FIGURE 13.3.5 Closed loop of CNC.

As seen, the two-dimensional linear interpolator supplies velocity commands simultaneously to the two machine axes and maintains the ratio between the required incremental distances.

Circular Interpolator: The two most common interpolators in CNC systems are linear and circular. The *circular interpolator* eliminates the need to define many points along a circular arc. Only the initial and final points and the radius are required to generate the arc. The circular interpolator divides the arc into straight lines with a contour error smaller than one BLU. It operates on an iterative basis, where for a given point, $x(i),Y(i)$, a small incremental angle is added to calculate the next point, as shown in Figure 13.3.4.

Both the linear and circular interpolators are based on generating incremental positions every T seconds, where T is the sampling period of the CNC system. Typically, CNC systems operate on one common sampling period for both the interpolator and the control loops. In these systems a typical T may be between 1 and 10 msec. Some other CNC systems utilize a separate computer for the interpolation and another one or several microprocessors for closing the control loops.

Motion Control Systems

A typical closed loop of a CNC machine is shown in Figure 13.3.5. The computer compares the command and the feedback signals and gives, by means of a digital-to-analog converter, a signal representing the position error of the system, which is used to drive the DC servomotor. The feedback device, which is an incremental encoder in Figure 13.3.5, is mounted on the leadscrew and supplies a pulsating output. The incremental encoder consists of a rotating disk divided into segments, which are alternately opaque and transparent. A photocell and a lamp are placed on both sides of the disk. When the disk rotates, each change in light intensity falling on the photocell provides an output pulse. The rate of pulses per minute provided by the encoder is proportional to the revolutions per minute of the leadscrew.

Normally, the motor is mechanically coupled to the load via a drive mechanism. For example, robot links and positioning tables are loads. It is usually a good assumption to ignore the dynamics in the current feedback loop and regard the command current as the actual current, which sets the torque input to the mechanical portion of the system. Notice that the inertia and bearing friction of the motor must be considered as a part of the mechanical portion of the motion control system, which strongly influences the design of the velocity and position loop feedback controllers. These controllers can be implemented in either analog or digital form. In recent years, digital implementation on microprocessors and/or DSPs has become popular, and digital velocity and position controls are often referred to as *digital servo.* The current feedback is usually built into the "drive" (power amplification system). While feedback signals for the velocity and position controllers are usually obtained from the motor, the velocity and position of the load, for example, a positioning table, at the opposite end of the drive mechanism are the quantities of our ultimate concern. Closed-loop control schemes based on the motor velocity and position are sometimes called semi-closed-loop control schemes. The velocity and position of the load must be fed back for full closed-loop control. Typical drive mechanisms are ballscrews and various types of gears. Several manufacturers provide so-called direct drive (DD) motors, which are capable of delivering large torques but with a significantly reduced maximum speed. DD motors may eliminate drive mechanisms. However, they are heavy and may not always be the best solution depending on applications. Common sensors for positions are potentiometers and shaft encoders, and those for velocities are tachogenerators and frequency-to-voltage convertors (FVC), the input to which is encoder pulses. In digital servos, encoders are popular for measuring positions, and velocities are either estimated from encoder pulses or are obtained from FVCs.

Traditional velocity and position loop feedback controllers are of PID (proportional plus integral plus derivative) type. The output of a PID controller is

$$u(t) = k_p e(t) + k_i \int_0^t e(\tau)\, d\tau + k_d \frac{de(t)}{dt} \tag{13.3.5}$$

where $e(t)$ is the error, $u(t)$ is the controlling input, and k_p, k_i, and k_d are, respectively, proportional, integral, and derivative control gains. Equation 13.3.5 represents the PID control law in the continuous-time (analog) form. In digital control, the PID control law

$$u(k) = k_p e(k) + k_i T \sum_{j=0}^{k} e(j) + \left(\frac{k_d}{T}\right)\left[e(k) - e(k-1)\right] \tag{13.3.6}$$

where k denotes the kth sampling instance and T is the sampling period. In position loop feedback control, e and u correspond to the positioning error and the velocity command, respectively. For the velocity loop controller, they are the velocity error and the current command. Another popular linear controller is the lead/lag compensator. Input-output (I/O) interfaces include analog-to-digital convertors (A/D), decoders for processing encoder pulses, and digital-to-analog convertors (D/A). Motion control systems can be built from components and programmed with custom software, they can be purchased as plug-in boards for various buses, or they can be purchased as packaged systems.

PID and lead/lag compensators are simple and utilized in many applications. However, they alone might not be adequate for problems where the performance requirements are stringent. Extreme care must be taken during the design of a closed-loop control system. By increasing the magnitude of the feedback signal (e.g., more pulses per one revolution of the leadscrew), the loop is made more sensitive. That is known as increasing the open-loop gain. Increasing the open-loop gain excessively may cause the closed-loop system to become unstable, which obviously should be avoided.

The basic nature of "feedback" control is that the control action is based on the error. When the reference input for the position loop is fixed, the integral action may assure zero errors at the steady state. In tracking control, however, the position command is continuously varying, which combined with the dynamics of the closed-loop system makes tracking errors always occur. For example, in contouring of a circular arc in machining, the command position signal for each motion control axis is sinusoidal. Such an operation is essentially a test of the frequency response of the motion control axis. The controller is normally tuned so that the frequency response gain is close to but not exactly 1 in the operating range. In high-speed contouring operations, corresponding frequencies are high, and the gain is normally below unity. Then, the actual diameter is slightly smaller than the desired diameter. This consequence is often called the radial reduction error. Such errors may be reduced by applying the disturbance observer scheme to the position loop. However, the disturbance observer is still a feedback controller, and one sampling time delay in digital implementation further diminishes its effectiveness.

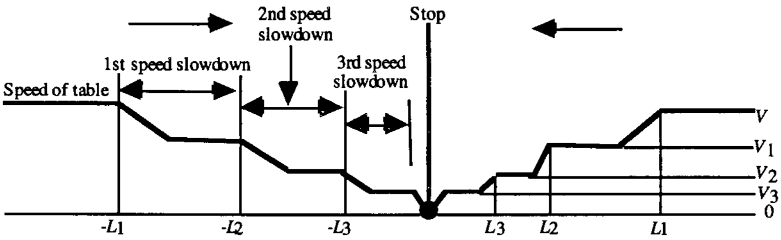

FIGURE 13.3.6 Deceleration procedure in a PTP system.

The following discussion describes some principles of motion control systems for PTP machines and contouring machines.

The control loops of PTP systems are designed to control the position of the machine tool axes. Each axis is *separately* driven and should follow the command signal. The system design starts by selecting the type of control: open loop or closed loop, a decision that depends on the required specifications of the NC system and economy. Open-loop controls use stepping motors as the drive devices of the machine table. The drive units of the stepping motors are directly fed by the controller output pulses. The selection of the appropriate motor depends on the maximum torque, required velocity, and step size in the system. Stepping motors can be implemented on small-sized PTP systems in which the load torque is small and constant. Larger PTP machines and contouring systems utilize closed-loop control systems.

In PTP systems each axis is driven separately at the maximum allowable velocity. This velocity depends on the drive type and on the mechanical structure of the particular machined or manufacturing system. In order to avoid large overshoots, the velocity is decelerated before the target point in which the tool starts to operate (e.g., to drill). Since the path between the points is insignificant, *the deceleration is accomplished in each axis separately.*

In practical systems the deceleration is accomplished by three stages. A typical three-stage deceleration diagram of one axis of the table is given in Figure 13.3.6. The table moves at rapid velocity V until reaching a distance L_1 from the target point, where the table is instructed to move at smaller velocity V_1. After a time delay, which depends on the system inertia, the table moves at a new velocity V_1 until reaching a distance of L_2 units from the target point, where again the velocity is reduced to V_2. When the table is at a distance of L_3 units before the target point, the velocity is reduced once more and the table "creeps" toward the final point at very low velocity V_3, and subsequently stops.

The control in CNC contouring systems operates in closed loops, which compare the command pulses from the interpolator with the feedback signal from the encoder or the resolver. The most sophisticated design applies to the closed-loop control of contouring systems. In the design of these loops, the transfer function of each element must first be determined; the system is then set up in block diagram form, and finally the loop gain is established based on performance analysis. The transfer function of each element is based on its mathematical model. In establishing the mathematical model the engineer is faced with a compromise between *accuracy* and *complexity*, on one hand, and *approximation* and *simplicity*, on the other. In this section we discuss simple models, in which the principles of design can be readily illustrated.

The control loops of contouring systems are usually of the closed-loop type, as shown in Figure 13.3.7. They use two feedback devices: a tachometer that measures the motor speed and is included in the drive unit, and a position feedback transducer, which is capable of also measuring the axis velocity (such as an encoder, resolver, or inductosyn). In encoder-based systems the encoder is mounted on the leadscrew and emits pulses; each pulse indicates a motion of 1 BLU of axis travel. Therefore, the number of pulses represents position and the encoder pulse frequency is proportional to the axis velocity.

Error Sources in CNC Systems

Despite the high precision of CNC equipment, it still has position and contour errors. Error sources in CNC machines are classified into three categories:

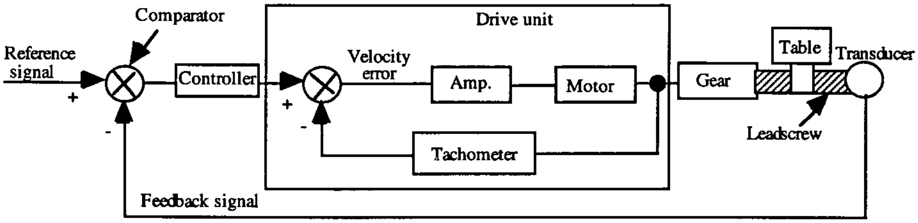

FIGURE 13.3.7 Control loop of contouring system.

1. Mechanical hardware deficiencies
    - Orthogonality of machine axes
    - Straightness of the machine axes
    - Thermal deformation of the machine structure
    - Backlash in the gears and leadscrew nuts
    - Uneven leadscrew pitch
    - Friction in moving components (leadscrews, guideways, etc.)
2. Cutting process effects
    - Tool deflection due to cutting forces
    - Large vibrations and chatter
    - Tool wear
    - Workpiece thermal deformations
    - Workpiece deformations due to cutting forces
3. Controller and drive dynamics
    - Disturbances due to cutting forces
    - Disturbance due to friction forces in the machine guideways
    - Contour errors caused by tracking errors of nonlinear contours (e.g., circles)
    - Contour errors caused by mismatch of equivalent parameters in the axial controllers
    - Corner errors in contouring operations

In general, errors of the first type, such as machine geometry errors and thermal deformation of the machine structure, can be compensated for by the machine controller. To further understand the measurement of errors, the next section will examine the metrology for precision engineering.

Metrology and Precision Engineering

Kam Lau

Introduction

Precision engineering in manufacturing generally refers to the engineering processes of achieving tighter tolerances or dimensional accuracy of a design. The process of precision engineering consists of the part *design*, part fabrication, and, finally, part *inspection*. This section addresses some of today's precision engineering considerations in fabrication and inspection.

Factors in Precision Engineering

The fabrication process is a material transformation process that determines the final part dimensions through material forming, removal, or insertion. Precision in the fabrication generally refers to the dimensional "repeatability and accuracy" of a part transformed under such a process. The factors to be considered to ensure good "precision" are (1) errors of the *machine* system(s), (2) the *environment* in which the machining is being performed, (3) the *manufacturing process*, and (4) the *instrumentation* to verify the performance of the factors.

Machine Errors. Machine errors can be classified into geometric, thermal-induced, dynamic, and structural errors. Geometric errors are errors related to the undesirable machine geometry caused by nonorthogonality (squareness error) of axes, linear positioning (or scale) error, reversal (or backlash) error, straightness error, pitch, yaw, and roll errors of a machine axis during a linear move. If the machine is equipped with a rotary table, geometric error would include axis wobble, rotational positioning error, eccentricity, and parallelism errors.

Geometric Errors: Geometric errors are much better understood in the machine industry than the thermal, dynamic, and structural errors. The techniques and instruments to check for the geometric error are very well established and are commonly applied in the machine tool industry. However, for small to medium-size machines, geometric errors constitute only about 25% or less of the total manufacturing error. For larger machines, the percentage can go as high as 50%. As such, just knowing the geometric errors of a machine system may not be adequate in the realization of the total manufacturing error.

Traditional devices for measuring different types of geometric errors are the mechanical square, straightedge, autocollimator, electronic level, step gauge, optical polygon, and dial indicator. In some instances, a combination of these devices is needed. Newer instruments that can offer faster and more precise measurements are the laser interferometer system, the 5-D laser interferometer system, and the telescopic ball bar.

Thermal Errors: Thermally induced machine error is considered one of the key factors affecting the accuracy of a machine tool. Thermally induced errors arise as a result of nonuniform heat generation within the machine such as in motors, bearings, and guideways; heat generated during the cutting process; and the coolant effect as well as the environmental effect resulting in the uneven growth of the machine structure. Thermal error can contribute as much as 50% of the total manufacturing error in small to medium-size machines. However, this effect has been largely unrecognized or often ignored by the machine tool industry until recently.

There are basically two alternatives to monitor the thermally induced errors — intermittent and continuous monitorings. Intermittent monitoring generally involves the use of a touch probe or dial indicator(s) to periodically measure against one or multiple fixed positions as the machine is going through a thermal exercise. In the case of the dynamic spindle thermal study, an artifact such as a sphere or a rod can be mounted on the spindle while it is running at a certain speed. At some elapsed time (e.g., 1-min intervals), the spindle will stop momentarily and the machine will reposition the artifact to the dial indicator(s) to check for the repeatability. Any deviations from the initial position (i.e., cold-start position) are considered as thermal growth due to the spindle warm-up. A typical spindle thermal test takes about 4 to 8 hr to complete. A similar procedure can be applied for the environmental and servomotion-related thermal growth measurements.

The continuous thermal growth monitoring generally involves the use of some noncontact sensors such as capacitance gauges, optical sensors, or inductance sensors arranged in the similar fashion as above. The benefits of continuous monitoring are that there is no interruption of the spindle dynamic and that the machine positioning repeatability does not necessarily interfere with the results. Furthermore, the noncontact nature generally allows the spindle to operate at any speeds, thus giving a much broader range of thermal assessment.

Laser interferometer systems are also used occasionally to monitor thermal growth effects. Because of its ability to identify the growth along the entire axis, the laser measurement is better suited for monitoring the growth of a linear-scale system caused by internal or external heat sources. Linear-scale error caused by axis movement is about one fifth that of the spindle thermal in medium to small machines. It is even less in larger machines since the heat dissipation effect in larger machines is much more effective.

Dynamic Errors: Dynamic errors here refer to those caused by the motions of a CNC machining center. These include the servo-gain mismatch, servo-stick-slip, servo-oscillation, and controller error. Errors pertaining to tool chattering, structural deformation (caused by machine carriage acceleration and deceleration), machine/part deadweight, and so forth are considered structural errors and are discussed later in this chapter.

Servo-gain mismatch is often caused by the electrical (or computer) gain setting of one axis not matching the other. The problem is not severe when the machine is primarily used for static positioning purposes, such as drill, boring; however, it can be a problem in precision contour milling when two or more axes are to be used in synchronization with each other. The magnified elliptical error is caused by one axis responding faster than the other in reaching the commanded positions. Servo-gain mismatch can easily be corrected in a routine machine maintenance.

Structural Errors: Structural errors include tool-chattering error and structural deformation error (due to acceleration and deceleration of the machine carriage, the deadweight distribution, and the cutting force, among other factors).

Tool chattering generally affects the machinability and surface finish of the workpiece, not the dimensional accuracy. Structural deformation caused by the acceleration and deceleration of the machine carriage and workpiece is rather insignificant for quasi-static positioning and slow-speed contouring. However, the error can be significant if the contouring speed is high. Another major contributor to the structural error is the cutting force. An excessive amount of cutting force can cause the spindle axis, the tool, the fixture, and the part to deform.

A good device to gauge the potential structural error is a compliance system. A basic compliance system consists of a load cell and a dial indicator, which are set up between the machine table and the spindle. The table is programmed to move in small increments (e.g., 5 mm) in either directions of the load cell. The readings from the load cell (force) and the indicator (actual displacement of the table) are then recorded at every increment. A compliance chart can then be obtained by plotting the forces (F) against the differences between the actual and commanded displacements (DD) of the table (i.e., F vs. DD).

Another type of structural error for large machines is from the machine foundation error. Most large machine bases are built in sections. These sections are then aligned, assembled, and anchored together to a common reinforced concrete foundation. As such, the foundation becomes part of the machine structure and the accuracy and repeatability of the machine are therefore heavily dependent on the stability of the foundation. It is not unusual to find the performance of the machine degraded as a result of floods and earthquakes, and loosening of anchor supports due to prolonged use or lack of maintenance.

Errors Introduced by Environmental Effects. For manufacturing plants that have little or no control of the plant environment, environmental effects can be very significant sources of errors. Two of the most dominant environmental effects are thermal and vibration effects.

Thermal Errors: For many nontemperature-controlled manufacturing plants, it is not unusual to observe a total temperature swing of 20°F throughout a day of operation. This wide fluctuation of environmental temperature can cause significant accuracy and repeatability problems to the machining systems as well as the workpieces. Even in a somewhat controlled environment, thermal errors can still be a major problem. For instance, if the machine is located in the vicinity of a frequently operated bay door, where there is a substantial temperature difference between the plant temperature and the outdoor temperature, or if it is placed next to a heat source such as a welder, an electric blower or exhaust, or a hydraulic pump, or under direct sunlight, the heat source can still cause tremendous localized thermal distortion of the machining system.

In most cases, one can reduce the localized environmental thermal effect by isolating the heat sources with simple panel shielding or by relocating the machines. If an overall plant temperature control is unachievable or impractical for economic reasons, one may consider (1) applying localized thermal control of certain key machining systems, or (2) implementing computer thermal compensation techniques.

Vibration Errors: Environmental vibration error is a result of one or more external vibration sources affecting the structural stability of the machine system. This type of error can be significant if the machining system is located next to a heavy punch press operation or where frequent forklifting operation is present. Using a spindle analyzer or a laser interferometer system to access the amount of the environmental vibration error is common.

Other Errors: Other types of environmental errors are the interference or instability of the electric power source, the factory-supplied pneumatic and hydraulic pressures, air pressure, and humidity. These types of errors may be of lesser magnitude than the ones mentioned earlier; however, it is always good practice not to underestimate their potential effects in any precision manufacturing considerations.

Errors Introduced by the Manufacturing Process. The magnitude of these types of errors depends heavily on the process control and manufacturing practices implemented by each individual plant. In general, the concerns in this area are the effects of the coolant on the workpiece and the machine structure, the pallet and the fixture, the repeatability of the pallet and tool changer, and the tool deflection in manufacturing.

Coolant Effects: Eighty percent of machining uses coolant, sometimes referred to as *wet machining*. In most cases, the coolant temperature is not controlled. For smaller machining systems, a small coolant tank can be found next to the machine. For larger machines, a large coolant tank can be found underneath the ground. The main purposes of the coolant in machining are (1) for lowering the cutting temperature, and (2) for chip removal. As the coolant is being recycled during the machining process, its temperature gradually warms up. This significant increase in temperature affects the workpiece dimensions since the workpiece temperature before machining is generally room temperature. Similarly, the pallet dimensions are also affected.

Tool and Fixture: The conditions of the pallets, tools, and fixtures often govern the repeatability of a manufacturing system. These components should be checked routinely for wear and chipping. Fixtures and clamping devices should be routinely checked to ensure that proper clamping forces can be applied and that contact surfaces are in good condition. Many of these checks can be accomplished visually or by performing dial indicator repeatability checks.

When excessive cutting force is expected, it is necessary to consider the maximum possible amount of the tool, workpiece, and fixture deflections resulting from the force. The amount, if it exceeds the manufacturing tolerance, should be reduced by either decreasing the depth of cut or the feed rate or by strengthening the tool and fixture. A compliance system is a good qualifier to measure the tool deflection under load.

Instrumentation and Inspection in Precision Engineering

The American National Standards Institute developed *ANSI B5.54 Standards for CNC Machining Center Performance Evaluation* for the purpose of providing detailed guidelines for machine tool users and developers to evaluate and compare the performances of CNC machining systems. The *standards* delineate procedures for the measurements of the machine and environmental errors as stated earlier, as well as choices of conventional and state-of-the-art instruments used in doing the measurements. Experience indicates that these measurements are useful not only for performance evaluation but also for better understanding of the sources of errors. This information is crucial for preventive maintenance and for accuracy enhancement of CNC machine systems.

Some of the key techniques introduced by the *B5.54 Standards* are the telescopic ball-bar measurement, spindle dynamic and thermal drift measurement, laser diagonal measurement, and the one-day test.

Instrumentation and Metrology

Telescopic Ball Bar. The telescopic ball-bar test is gradually becoming one of the most powerful and convenient tests for CNC machining center evaluations. As is shown in Figure 13.3.8, a telescopic ball bar consists of a spring-suspended reed having two spheres attached to both ends. The spheres are allowed

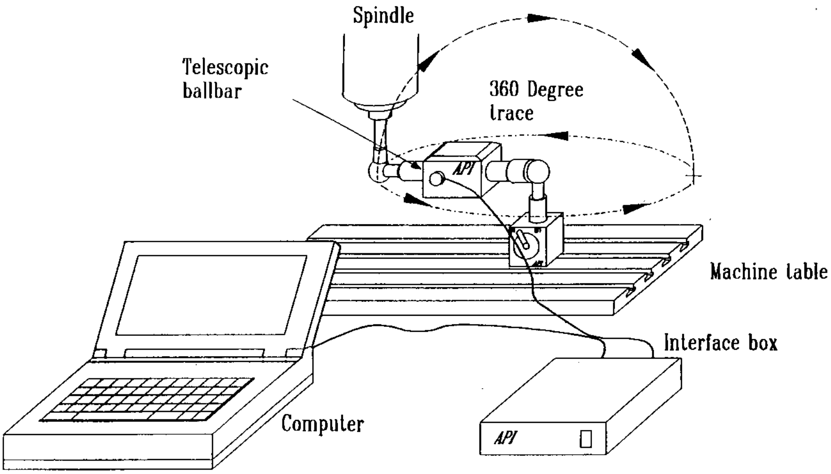

FIGURE 13.3.8 The telescopic ball bar.

to move relative to each other with a limited travel, for example, 3 to 4 mm. Inside the reed is a displacement sensor, known as a linearly variable displacement transducer (LVDT), that measures the relative move of the spheres. The output of the LVDT is connected to a computer.

To use the telescopic ball bar, one of spheres is magnetically attached to the magnetic socket that is installed on the machine spindle; the other is magnetically attached to a second magnetic socket mounted on the table. The machine is then programmed to contour in a circle in the *X-Y*, *X-Z*, or *Y-Z* plane, as shown in Figure 13.3.8. As the contouring proceeds, any errors of the machine in contouring will be translated into relative moves picked up by the LVDT and instantaneously recorded by the computer. After the machine has stopped, the computer then plots the errors on a chart for analysis. Errors such as backlash, axes nonsquareness, scale mismatch, servo-gain mismatch, cyclic motion, stick-slip, and certain straightness errors can be readily detected by using a telescopic ball bar.

Laser Interferometer. A laser interferometer system can produce measurements pertaining to the linear, angular, straightness, and squareness errors of a machine system. To many in the manufacturing industry, laser interferometer measurements are considered as the primary calibration standards. However, it is important that when using a laser interferometer, the proper procedures are followed. Precautions should be taken when using a laser interferometer system: avoid setting up the laser in areas where large air turbulence is present; set up the laser to minimize the cosine error and Abbe error; beware of the environmental effects (i.e., temperature, pressure, and humidity) to the laser accuracy; and understand the material parameters (i.e., material temperature, coefficient of expansion, etc.) to the measuring accuracy. In the event that these effects are significant, it is necessary to compensate for them in the final results.

Setting up a laser interferometer system for machine measurement can be very tedious and sometimes frustrating. It is not unusual to take 2 to 3 days to measure all linear, straightness, angular, and squareness of a mid-size 3-axis CNC machine (referred to as 21 parameters measurement). A new laser system known as the 5-D laser interferometer system, developed by Automated Precision Inc. (Gaithersburg, Maryland), has the capability of measuring 5 degrees of freedom (i.e., *X*-, *dY*, *dZ*, pitch, and yaw) simultaneously in one single setup. In contrast, the 5-D system is able to cut down the measuring time to 3 to 4 hr.

A laser interferometer system should not be confused with an alignment laser system. A laser interferometer system works on the polarized light interference principle and can produce precision to within a tenth (or better) of a wavelength of light (i.e., 630 nm for an HeNe laser). By using the same measuring principle, a laser interferometer system can also generate angle measurements to within 0.1 arc-sec. An alignment laser works on beam-pointing effects and combines the measurements with a photodetector for straightness and angle measurements (not linear measurement). In this case, the laser beam is used as a straightedge. Unless the electro-optics elements are used carefully, the accuracy is much lower than that of a laser interferometer system. Although alignment lasers are commonly used in machine alignment, it should not be construed as a precision calibration standard.

Spindle Analyzer. A spindle analyzer can be used to measure several important parameters of a machining system. These include thermal growth of a machine resulting from environmental variations (i.e., temperature, vibration) and internal heat sources (i.e., motors, spindle bearings, hydraulic systems), spindle dynamic errors resulting from a worn or contaminated bearing, and machine axis repeatability.

For advanced applications, it is recommended that the sensors be of noncontact nature since contact sensors can create problems when measuring a high-speed spindle in motion. The noncontact sensors can be optical, capacitive, or inductive. They all have their advantages and disadvantages dependent on their applications. Users should consult with the manufacturers before making their selections.

Other Metrology Instruments. The above-mentioned metrology instruments represent some of the latest and most commonly used instruments in the manufacturing industry. Other instruments that are also used frequently are electronic autocollimators, electronic levels, force gauges, temperature sensors, vibration sensors, dial indicators, proximity sensors, mechanical straightedges, step gauges, and precision-indexing tables. One should not, however, overlook the benefits offered by some of the latest data acquisition and data analysis software packages such as statistical process control (SPC). Of course, the proper selection and use of any instrument are key to a better understanding of the factors in precision manufacturing.

Inspection System and Metrology

The direct-computer-controlled coordinate measuring machine (DCC-CMM) has been the dominating means for final workpiece dimensional inspection in the manufacturing industry since the early 1980s. Since then, several advanced dimensional measuring devices have also been developed and are gaining wide acceptance in industry. These are the high-speed laser tracking systems and the manually operated measuring robots. There is also a growing interest in the manufacturing industry to reduce the off-line inspection process (i.e., CMM-type applications) by performing some of the inspections on the CNC machining system. This is referred to as on-machine gauging. This section will discuss some of the key considerations related to the use of these advanced inspection systems.

Laser Tracking Interferometer Systems. The laser tracking interferometer system (LTS) was developed at the National Institute of Standards and Technology (NIST) in the mid-1980s for medium- to large-dimensional inspections. It was then commercialized and introduced to the industry in late 1989. Since then, the LTS has been gaining popularity and is becoming one of the dimensional measuring standards.

Through the combination of a precision dual-axis gimbal, a laser interferometer system and an optical target (i.e., a retroreflector), the laser beam is precisely directed to the target through the manipulation of the gimballed mirror via the control computer. As the beam is sent back to the laser by the target, it is partially deflected to a dual-axis photodetector. The beam position is then interpreted by the computer. As the target moves, the photodetector immediately generates an error signal to the computer that drives the mirror to ensure the beam stays locked onto the target. While it is tracking, the computer acquires the laser measurement and the two angle measurements (a and b angles) of the mirror and computes for the three-dimensional position of the target.

The advantages of the LTS are that (1) it is considered one of the most accurate large-dimensional coordinate measuring devices with an accuracy of better than 10 ppm (i.e., 100 mm at 10 m); (2) it has a very measurable envelope — 25 m × 360°; (3) it can track a target moving at a speed of 4 m/sec; (4) it can sample up to 1000 samples/sec; and (5) it is compact, portable, and fully automatic. It is well suited for rapid surface scanning, jigs and fixture alignment, replacement of conventional CMMs for large structural measurements, and large CMMs, robotic devices, or CNC machining center calibrations.

The disadvantages are that (1) when used in areas where significant air turbulence is present, the system becomes less reliable; (2) the accuracy may be reduced when used in areas where heavy forklifting activities are present (since the floor foundation is part of the measuring frame); and (3) the system needs zero referencing if the interferometer beam is interrupted during measurement.

On-Machine Gauging. On-machine gauging (or in-process gauging) refers to the dimensional inspection process implemented during or after a machining cycle right on the machining system. In other words, the machining system, retrofitted with a sensor (i.e., a touch probe), is used to serve as a coordinate measuring machine while the workpiece is still on the machine. This concept certainly has merit since most CNC machining systems have control, scale, and structural integrity equal to or better than many DCC-CMMs.

The advantages of performing dimensional inspections on the same machining system are obvious: (1) it eliminates the need of moving the workpiece to a CMM; (2) it reduces the inspection cycle time; and (3) it eliminates realignment error should reworking the workpiece become necessary. The disadvantages, however, are (1) since the same machine frame is used for machining and inspection, if the machining system has any inherent errors (such as geometric errors) that affect the workpiece accuracy, it is incapable of detecting those errors in the inspection, and (2) the machine will experience a large degree of thermal distortion caused by the internal heats.

In order to implement on-machine inspection, it is therefore necessary to first perform geometric accuracy evaluation of the machining system according to B5.54 Standards. All effort should be made to ensure that the accuracy is maintained. Second, a machine thermal growth analysis should be performed to ascertain the limitation of the thermal distortion in inspection. In either case, a minimum rule of thumb of four times the accuracy tolerance should be applied. New techniques of thermal and geometric modeling and compensation of the machining system can be considered in order to achieve the inspection goals.

Other Inspection Systems. Other emerging inspection machines, such as the manually operated robotic measuring device, stereotriangulation measuring systems, and photogrammetry systems, are also gaining popularity in manufacturing. Although they may not offer the same types of accuracy and versatility as the previously mentioned system, they feature a new trend of inspection requirements — portability, agility, shop-floor hardiness, high-speed data acquisition, low cost, and powerful software capability.

13.4 Design and Analysis Tools in Manufacturing

Computer-Aided Design Tools for Manufacturing

David C. Anderson

Introduction

Computer-aided design (CAD) tools for manufacturing are computer programs that evaluate producibility of a product under development using computer models of the product and simulation models for manufacturing processes. Examples of such processes are assembly, casting, molding, stamping, forming, and inspection. The early stages of design are critical to the success of the final product since most of the final cost of a product is committed through decisions about the product's geometry and the materials that lead to the selection and planning of manufacturing processes and production facilities.

Concurrent engineering (CE) is a methodology for product development processes in which the tasks are performed simultaneously based on "what if" decision-making processes. CE is a driving force behind the development of CAD tools for manufacturing.

CAD System and Manufacturing

One of the first and most prominent manufacturing applications of the CAD system was the automated programming of numerically controlled (NC) machine tools. NC machines were developed in the 1950s, but their widespread use was hindered by the difficulty in writing the requisite NC programs, lists of coded cutting tool motions that directed the machine to cut the desired part. Computer programs that facilitated the generation of NC programs were among the first CAD tools for manufacturing. Early systems focused on profile cutting, generating cutter location data that described the two-dimensional coordinates of the paths of cutting tools that would remove the material to create the final part. Three-dimensional NC programming capabilities are available in most CAD systems today. The user guides the generation of NC data by interactively selecting each surface to be machined and answering questions about tools, approach directions, and machining preferences.

Solid Models and Manufacturing

A key element of virtually all CAD tools for manufacturing is the need to interpret the CAD data according to manufacturing capabilities, requirements, and constraints. Generally, this interpretation involves determining the characteristic shapes in the CAD data related to the manufacturing process of interest and applying knowledge about the process to determine the manufacturing operations and parameters. Solid models are rigorous computer data structures that contain a complete, unambiguous representation of the nominal geometry of an object. Solid models and solid modeling operations, like the Boolean union, difference, and intersection of solids, enabled geometric computations about the design that were not possible with earlier CAD data. With solid modeling, the emphasis in CAD shifted from data for visual communication to product data models that could be used for more sophisticated computer analyses with more automation.

In solid models, geometric features can be described in a form more suitable for engineering and manufacturing applications. As a result, feature-recognition algorithms have become an important element of many CAD tools for manufacturing for translating CAD models into usable geometric data for design evaluations.

However, feature recognition has limitations because it is not possible to translate every solid model into a given set of features. Also, some applications of feature recognition require additional, nongeometric information. This information must be added to the CAD data before, during, or after the feature-recognition process. For example, part tolerance data are required for machining process planning but are not available in current CAD data. Feature-based design (FBD) was developed to overcome some of the limitations of feature recognition. Instead of deriving a features model from a solid model, FBD systems create the product model with features during the design process. Many FBD applications have been demonstrated in the area of machining, and some commercial CAD vendors have incorporated these features into their systems.

FBD also has limitations. The features that are useful for one manufacturing process may not be useful for another. For example, a model made with cavity features, such as holes, slots, and pockets, provides ready-to-use data for machining planning. However, this model is inappropriate for sheet metal bending or welding processes that require an understanding of the bends and protrusions on a part, not its cavities.

Product Data Standards and Manufacturing

The International Standards Organization (ISO) has developed the Standard for the Exchange of Product (STEP) model data. In the U.S., the Integrated Graphics Exchange Specification (IGES)/PDES Organization

(IPO) developed the Product Data Exchange Specification (PDES). These efforts merged and PDES was renamed Product Data Exchange using STEP, which is now the American National Standard for STEP. STEP became the international standard (ISO 10303) in March 1994.

STEP is organized as a series of "parts" that are developed and published separately. The parts are organized into numerical series: description methods (parts 11 to 20), integrated resources (parts 41 to 200), application protocols (parts 201 to 1200), abstract test suites (parts 1201 to 2200), implementation methods (parts 21 to 30), and conformance testing (parts 31 to 40). The product information is specified in a formal specification language, EXPRESS, which is documented in Part 11. Part 1 is an overview of the entire standard.

The STEP application protocols (APs) are important to CAD tools for manufacturing. These are the implementable portion of the STEP standard. Each AP draws on integrated resources and adds specific constraints, relationships, and attributes to meet the information requirements of a particular application. It is expected that several hundred APs may be developed for many different industrial applications.

Design for "X" Tools

Many CAD tools for manufacturing belong to a class of programs described as "design for x," where "x" signifies an application area, such as design for assembly or design for castability. The phrase *design for manufacturability (DFM)* can be considered as a specialization of design for x in which all the applications are manufacturing. Generally, DFM applications are computer programs that perform computations to analyze the producibility of a product with respect to a specific manufacturing process or set of processes. The format of the design data representing the product required by the program varies greatly. The program then provides an evaluation of the suitability of the design according to this domain. The form of this evaluation also varies with each program.

DFM programs act as "manufacturing experts" that provide qualitative, and perhaps quantitative, information about potential problems in a design based on predefined knowledge about a manufacturing process. The programs emulate the process done by human experts, examining the design data and reporting any problems based on experience. Many efforts are based on expert systems technology from the field of artificial intelligence (AI). The searching is performed through the facilities of an AI language, such as PROLOG or LISP, or using an expert system "shell," a preprogrammed generic expert system. Design data are first translated into a knowledge base, the AI version of a database, containing facts and rules. In a sense, the detailed design data are made into logical data that can be processed using AI methods. The program computationally searches the design data for data patterns that match problem conditions represented in the knowledge base of the program. The problem conditions are computer representations of design data that are known to cause manufacturing difficulties for a given process. For example, a "design for injection molding" program may report that an internal corner radius in a geometric model of a part is too small and may cause problems in the mold. In some cases, the program provides a quantitative evaluation of the design, or producibility index. This provides a convenient numerical comparison between two competing designs.

Tools for Manufacturing Process Planning

Tien-Chien Chang

Introduction

Process planning prepares a production documentation that specifies the operations and operation sequence necessary to manufacture a product. Process planning is defined as an act that determines the manufacturing operations, operation sequence, and resources required to make a product. The process domain includes machining process planning, welding process planning, EDM process planning, forming process planning, and so forth. The product domain includes mechanical part process planning, mechanical assembly process planning, and electronics assembly process planning. The input to a process planning system (or a human process planner) can be an engineering drawing, a CAD model, or a three-dimensional solid model. While most human planners prefer an engineering drawing on paper or in electronic form, process planning systems usually use CAD models.

The result of the process-planning activity is a "process plan" (see Figure 13.4.1), also called route sheet, operation sheet, or operation planning summary. It can be as aggregate as a list of work center identification numbers or as elaborate as a 50-page document with setup drawings, tool specifications, and operation time estimates.

Since the information on the process plan is used in scheduling the production and controlling the machine, the production efficiency and the product quality are affected.

Manual Process Planning

Process planning involves several or all of the following activities:

- Selection of machining operations
- Sequencing of machining operations
- Selection of cutting tools
- Selection of machine tools
- Determination of setup requirements
- Calculations of cutting parameters
- Planning tool path and generation of NC part programs
- Design of jigs and fixtures

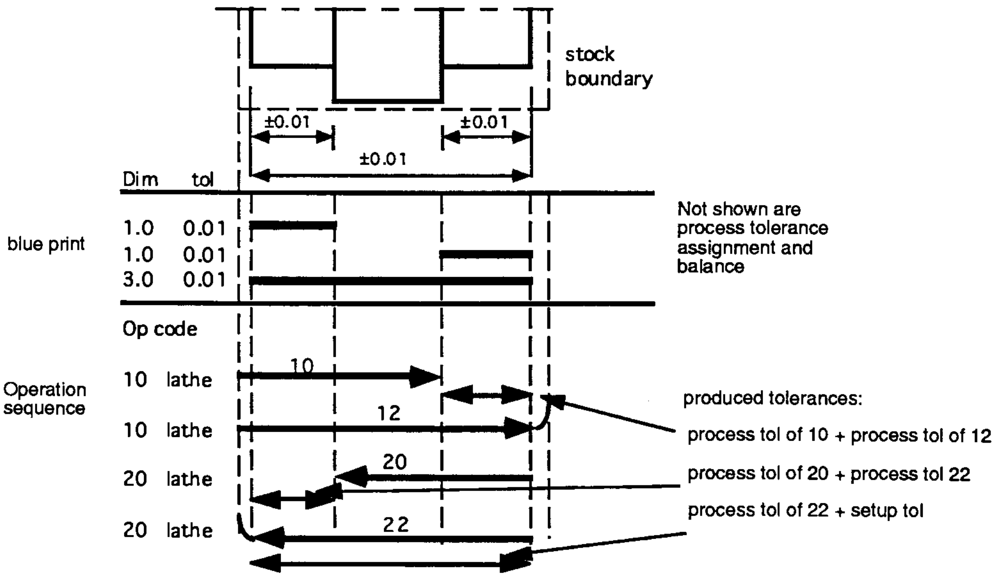

FIGURE 13.4.2 A tolerance chart.

The details incorporated in a typical process plan usually vary from industry to industry. It depends on the type of parts, production methods, and documentation needs. A process plan for a tool room–type manufacturing environment typically relies on the experience of the machinist and does not have to be written in any great detail. In fact, the instruction "make as per part print" may suffice. In typical mass-production-type industries, the process-planning activity is embodied in the transfer and flow lines used for manufacturing component parts and assembly. For metal-forming-type manufacturing activities, such as forging, stamping, die casting, sand casting, or injection molding, the process-planning requirements are embedded directly into the design of the die/mold used, where most process-planning activity is fairly simple. A process planner must

- Be able to understand and analyze part requirements
- Have extensive knowledge of machine tools, cutting tools, and their capabilities
- Understand the interactions between the part, manufacturing, quality, and cost
- Possess analytical capabilities

Tolerance Charting

During process planning it is important to ensure that the setup and operation sequence will yield a satisfactory part. Tolerancing charting (Figure 13.4.2) has been used to help in allocating process tolerances and verifying the operation sequence. A tolerance chart analyzes one dimension at a time. In a tolerance chart, the top is the part drawing. Dimensions and tolerances are presented with the geometry. Dashed lines show the stock boundary. From the features of the part and the stock, extension lines are drawn to the body of the chart. The section below the drawing shows the critical dimensions and tolerances. These dimensions and tolerances must be satisfied after the processes are complete. Following the process sequence, each operation is listed in the third section of the chart. A line is drawn from the reference surface of a setup to the cut surface. For example, in operation 10, the raw stock boundary at the left is the reference surface. The second surface from the right-hand side is created by this operation. From the chart, one can calculate the resultant tolerances. The results are compared with the blueprint tolerance.

Although traditionally a tolerance chart is implemented on paper and through a fixed procedure, it can also be implemented in a computer. The process tolerance stack-up may be used to verify the design specification and select the appropriate processes and sequences.

Computer-Aided Process Planning

There are two basic approaches to computer-aided process planning — variant and generative. The *variant* approach is signified by the terminology used by the computer to retrieve plans for similar components using table lookup procedures. The human process planner then edits the plan to create a "variant" to suit the specific requirements of the component being planned. Creation and modification of standard plans are the process planner's responsibility. The *generative* approach generates a plan for each component without referring to existing plans. Generative-type systems can perform many functions in a generative manner, while the remaining functions are performed with the use of humans in the planning loop.

Variant Process Planning

The variant approach to process planning was the first approach used to computerize the planning techniques. It is based on the concept that similar parts will have similar process plans. The computer can be used as a tool to assist in the identification of similar plans, retrieving them and editing the plans to suit the requirements for specific parts.

In order to implement such a concept, part coding and classification based on group technology is used as a foundation. Individual parts are coded based on several characteristics and attributes. Part families are created of like parts having sufficiently common attributes to group them into a family. This family formation is determined by analyzing the codes of the part spectrum. A "standard" plan consisting of a process plan to manufacture the entire family is created and stored for each part family. The development of a variant-process-planning system has two stages: the preparatory stage and the production stage (Figure 13.4.3).

During the preparatory stage, existing components are coded, classified, and later grouped into families. The part family formation can be performed in several ways. Families can be formed based on geometric shapes or process similarities. Several methods can be used to form these groupings. A simple approach would be to compare the similarity of the part code with other part codes. Since similar parts will have similar code characteristics, a logic that compares part of the code or the entire code can be used to determine similarity between parts.

Families can often be described by a set of family matrices. Each family has a binary matrix with a column for each digit in the code and a row for each value a code digit can have. A nonzero entry in the matrix indicates that the particular digit can have the value of that row, for example, entry (3,2) equals one implies that a code x3xxx can be a member of the family. Because the processes of all family members are similar, a standard plan can be assigned to the family. The standard plan is structured and stored in a coded manner using operation codes (OP-codes). An OP-code represents a series of operations on one machine/workstation. For example, an OP-code DRL10 may represent the sequence center drill, change drill, drill hole, change to reamer, and ream hole. A series of OP-codes constitute the representation of the standard process plan.

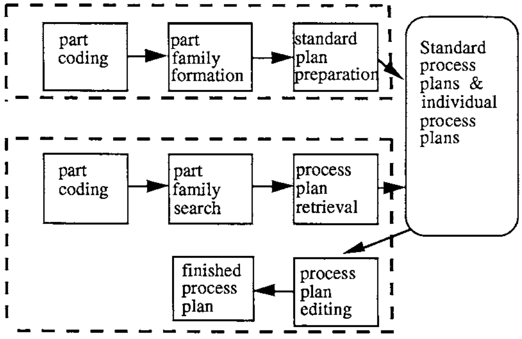

FIGURE 13.4.3 Variant-process-planning approach.

Before the system can be of any use, coding, classification, family formation, and standard plan preparation must be completed. The effectiveness and performance of the variant-process-planning system depend to a large extent on the effort put forth at this stage. The preparatory stage is a time-consuming process.

The production stage occurs when the system is ready for production. New components can be planned in this stage. An incoming component is first coded. The code is then sent to a part family search routine to find the family to which it belongs. Since the standard plan is indexed by family number, the standard plan can be easily retrieved from the database. The standard plan is designed for the entire family rather than for a specific component; thus, editing the plan is unavoidable.

Variant-process-planning systems are relatively easy to build. However, several problems are associated with them:

- The components to be planned are limited to previously planned similar components.
- Experienced process planners are still required to modify the standard plan for the specific component.
- Details of the plan cannot be generated.
- Variant planning cannot be used in an entirely automated manufacturing system, without additional process planning.

Despite these problems, the variant approach is an effective method, especially when the primary objective is to improve the current practice of process planning. In most batch-manufacturing industries, where similar components are produced repetitively, a variant system can improve the planning efficiency dramatically. Some other advantages of variant process planning are

- Once a standard plan has been written, a variety of components can be planned.
- Programming and installation are comparatively simple.
- The system is understandable, and the planner has control of the final plan.
- It is easy to learn and easy to use.

The Generative Approach

Generative process planning is the second type of computer-aided process planning. It can be concisely defined as a system that automatically synthesizes a process plan for a new component. The generative approach envisions the creation of a process plan from information available in a manufacturing database without human intervention. Upon receiving the design model, the system is able to generate the required operations and operation sequence for the component.

Knowledge of manufacturing has to be captured and encoded into computer programs. By applying decision logic, a process planner's decision-making process can be imitated. Other planning functions, such as machine selection, tool selection, and process optimization, can also be automated using generative planning techniques.

A generative-process-planning system consists of three main components:

- Part description
- Manufacturing databases
- Decision-making logic and algorithms

The definition of generative process planning used in industry today is somewhat relaxed. Thus, systems that contain some decision-making capability on process selection are called generative systems. Some of the so-called generative systems use a decision tree to retrieve a standard plan. Generative process planning is regarded as more advanced than variant process planning. Ideally, a generative-process-planning system is a turnkey system with all the decision logic built in. However, due to the differences among manufacturing shops, decision logics have to be customized for each shop.

The generative-process-planning approach has the following advantages:

- Consistent process plans can be generated rapidly.
- New components can be planned as easily as existing components.
- It has potential for integrating with an automated manufacturing facility to provide detailed control information.

There is no fixed representation or procedure that can be identified with generative process planning. The general trend is to use a solid model CAD-based input and expert system or an object-oriented planner construct. Most of the research systems are of this type. A few commercial products can also be classified as generative.

Process Plan Standardization

In the past two decades CAD has became the primary tool for engineering design. CAD data became the driving information for all downstream applications. The international standard. STEP, which began as an electronic product model information standard, has grown to be the information model standard for industrial automation and integration. Process planning model is part of this standard (ISO 10303 Part 224). The standards allow software vendors and machine tool builders to seamlessly interface their products. A computer-aided process planning system can read product definition information through a standard front end, and output process plans in a standard format as well. Presently this feature is still being implemented in CAD/CAM systems.

Conclusions

Process planning is a critical function in design and manufacturing. The quality of the product and the cost of production are affected by the process plan. A process plan incorporates information on the shop capability, resource requirement, and best routing. In order to produce a good process plan, a planner must be knowledgeable in both the manufacturing practices and the current shop status and capabilities. At this moment most computerized planners are still based on data retrieval and database lookup. As the information technology is further developed and we have a better understanding of process capabilities, integrated planning systems will evolve.

Simulation Tools for Manufacturing

Hank Grant

Introduction

Digital simulation uses a mathematical model to represent a real or hypothetical physical system. A computer simulation model of a physical system provides a laboratory in which alternative designs can be explored and analyzed. The model, executed on the computer, is a software replica of the manufacturing system and is controlled so that the behavior of the system can be studied and analyzed. Decisions can be made concerning production alternatives. For example, adding a new lathe can be considered without disrupting the actual physical system.

Simulation depends on describing a system in terms acceptable to the computer language used. To do this, it is necessary to have a *system-state description*, which is typically characterized by a set of state variables included in the computer program that make up the simulation model.

Types of Simulation Models

Simulation models are typically classified into three types: discrete event, continuous, and combined. Simulation software has been designed to address each of these types of models.

Discrete Event. Discrete event simulation is used to model systems when there are specific events in time when the variables of the system may change in values. The mechanics of those changes must be well known and easily characterized. The behavior of the system is represented by the behavior of individual objects of interest called *entities*. The simulation model characterizes the behavior of these entities as they move through the system in simulated time.

Discrete events are points in time where the characteristics of an entity may change and where the state variables of the system may change. For example, when a customer arrives for service, the state of the system may change (number in the system, status of the server, etc.). The modeling of systems using this approach consists of developing descriptions of the events and how they cause the state variables to change and the entities to be manipulated.

The individual events may not always be predictable, and stochastic elements may be present in the operation of the system. For example, the time between arrivals of customers to the system may be a random variable. Simulation languages have many tools to support random variation in models.

A special kind of discrete event model is a *network model*. Network models use a standard set of symbols to represent the flow of entities in the system. They are graphical in nature, and are useful communication vehicles as well as powerful in building simulation models quickly and easily. Several languages are available that include network modeling capabilities, and they are described later.

Continuous. Continuous simulation is an approach that is popular among engineers and economists. The main building blocks of this approach are as follows (Pidd 1994).

Aggregated variables: Instead of a concern with individual entities, the main concern is with the aggregated behavior of populations (e.g., the changing sales of a product through time).

Smooth changes in continuous time rather than focusing on individual events, where the stress is on the gradual changes that happen as time progresses: Thus, just as the graph of a variable might be smooth, the aim is to model the smooth changes of the variable by developing the suitable continuous equations.

Differential or difference equations: The model consists mainly of a set of equations that define how behavior varies through time; thus, these tend to be differential equations or, in simpler cases such as system dynamics, difference equations.

Nature does not present itself labeled neatly as discrete or continuous; both elements occur in reality. Modeling, however, as mentioned earlier, involves approximation, and the modeler must decide which of these approaches is most useful in achieving the desired aim of the simulation.

Combined Discrete Event/Continuous. In some cases, both approaches are needed and the result is a mixed discrete-continuous simulation. An example of this might be a factory in which there is a cooking process controlled by known physics that is modeled by continuous equations. Also in the factory is a packing line from which discrete pallets of products emerge. To model the factory will require a mixed ap3proach.

Modeling Languages

Specifically designed computer simulation languages provide many features for managing the updating of the state variables and advancing time. They also provide features for recording system performance statistics and for generating random numbers to introduce system randomness.

The lowest level of computer language typically used is FORTRAN or BASIC. This requires that the entire simulation model be coded, which is labor intensive. High-level languages, such as SLAM, SIMSCRIPT, and GPSS, facilitate simulation because they provide subroutines for time advancement, entity maintenance, and statistic collections. Higher-level simulation languages are designed for special purposes; MAP/1, SPEED, and MAST are three designed for the simulation of manufacturing systems.

Some simulation languages can produce animations. This permits the simulation to be illustrated graphically on a computer terminal so that the analyst can see the system in action and observe its interactions and behavior, a visual function beyond the scope of standard reporting technique. For example, TESS (a software program) provides animation, as well as model-building and output analysis capabilities, for the SLAM simulation language.

The following discussion by Banks (1994) provides an overview of the primary languages available.

Applications of simulation exist in many arenas such as manufacturing, material handling, health services, military decision support, natural resources, public services, transportation, and communications, to mention a few.

These simulation applications are usually accomplished with the use of specially developed simulation software. This tutorial describes the software in two categories. The first of these is software for general purposes. This type of software can solve almost any discrete simulation problem. In this section, five products, GPSS/H™, GPSS/World™, SIMSCRIPT II.5©, SIMAN V©, and SLAMSYSTEM©, will be discussed to provide a feel for this type of software.

GPSS/H. GPSS/H is a product of Wolverine Software Corp., Annandale, VA (Smith and Crain 1993). It is a flexible yet powerful tool for simulation. It provides improvements over GPSS V that had been released by IBM many years earlier. These enhancements include built-in file and screen input/output (I/O), use of an arithmetic expression as a block operand, interactive debugger, faster execution, expanded control statement availability, and ampervariables that allow the arithmetic combinations of values used in the simulation. The latest release of GPSS/H is version 2.0. It added a floating-point clock, built-in math functions, and built-in random variate generators. Options available include Student GPSS/H, Personal GPSS/H within the 640K memory limit, and GPSS/H 386, providing unlimited model size.

GPSS World. GPSS World, from Minuteman Software, is a complete redesign of GPSS/PC™ (Cox 1992). It is designed as a high-power environment for simulation professionals. It provides both discrete and continuous simulation. Its features include interactivity, visualizability, and configuration flexibility. It utilizes 32-bit computing, virtual memory, preemptive multitasking, symmetric multiprocessing, and distributed simulation. Highlights include drag-and-drop model building, 512 MB of virtual memory for models, point-and-shoot debugging, an embedded programming language, built-in probability distributions, multiple data types, and many other improvements to GPSS/PC.

The GPSS World family is a set of three software products, including

- GPSS World is the center of the family. This self-contained modeling environment includes local Simulation Server™ capabilities.
- Simulation Server provides simulation services on a remote networked computer. It does not include a model-building user network.
- Simulation Studio provides hierarchical modeling and user-drawn simulation capabilities.

An enhanced memory version of GPSS/PC is also available. It allows access of up to 32 MB of memory.

SIMSCRIPT II.5. SIMSCRIPT II.5 from CACI Products Company is a language that allows models to be constructed that are either process oriented or event oriented (Russell 1993). The microcomputer and workstation version include the SIMGRAPHICS animation and graphics package. SIMSCRIPT can be used to produce both dynamic and static presentation-quality graphics such as histograms, pie charts, bar charts, levels of meters and dials, and time plots of variables. Animation of the simulation output is also constructed using SIMGRAPHICS. SIMGRAPHICS can be used also to produce interactive graphical front ends or forms for entering model input data. An input form may include such graphical elements as menu bars with pull-down menus, text or data boxes, and buttons that can be clicked to select an alternative. The graphical model front end allows for a certain set of modifications to the model to be made without programming, facilitating model use by those who are not programmers.

SIMAN V. SIMAN V from Systems Modeling Corporation is a general-purpose program for modeling discrete and/or continuous systems (Glavach and Sturrock 1993; Banks et al. 1995). The program distinguishes between the system model and the experiment frame. The system model defines components of the environment such as machines, queues, and transporters and their interrelationships. The experiment frame describes the conditions under which the simulation is conducted, including machine capacities and speeds and types of statistics to be collected. What-if questions can usually be asked through changing the experiment frame rather than by changing the model definition. Some important aspects of SIMAN V are as follows:

- Special features that are useful in modeling manufacturing systems, including the ability to describe environments as work centers (stations) and the ability to define a sequence for moving entities through the system.
- Constructs that enable the modeling of material-handling systems including accumulating and nonaccumulating conveyors, transporters, and guided vehicles.
- An interactive run controller that permits break points, watches, and other execution control procedures.
- The ARENA environment, which includes menu-driven point-and-click procedures for constructing the SIMAN V model and experiment; animation of the model using Cinema, the input processor that assists in fitting distributions to data; and the output processor that can be used to obtain confidence intervals, histograms, correlograms, and so on. (More aspects of the ARENA environment are discussed later.)
- Portability of the model to all types of computers.

SLAMSYSTEM. SLAMSYSTEM, from Pritsker Corp., is an integrated simulation system for PCs based on Microsoft® Windows® (Pritsker 1986; O'Reilly 1993). All features are accessible through pull-down menus and dialog boxes and are selected from the SLAMSYSTEM Executive Window. A SLAMSYSTEM project consists of one or more scenarios, each of which represents an alternative system configuration. A project maintainer examines the components of the current scenario to determine if any of them have been modified, indicates whether or not tasks such as model translation should be performed, and allows the user to accomplish these tasks before the next function is requested. SLAMSYSTEM allows multiple tasks to be performed in parallel while the simulation is operating in the background.

Some of the features of SLAMSYSTEM are as follows:

- Models may be built using a graphical network builder and a forms-oriented control builder, or text editor. When using the first method, a network symbol is selected with the mouse, then a form is completed specifying the parameters for that symbol. The clipboard allows many other operations, such as grouping one or more symbols and placing them elsewhere on the network.
- Output analysis includes a "report browser" that allows alternative text outputs to be compared side by side. Output may be viewed in the form of bar charts, histograms, pie charts, and plots. Output from multiple scenarios can be displayed at the same time in bar-chart form. By using the Windows environment, multiple output windows can be opened simultaneously.

- Animations are created under Windows using the facility builder to design the static background and the script builder to specify which animation actions should occur when a particular simulation event occurs. Animations can be performed either concurrently or in a postprocessing mode. Two screens can be updated simultaneously, and up to 225 screens can be swapped into memory during an animation.
- SLAMSYSTEM was designed to be used in an integrated manner. For example, historic data may be read to drive the simulation. CAD drawings may be loaded. Output charts and plots created by SLAMSYSTEM can be exported via the clipboard to other applications.

The newest release of SLAMSYSTEM is version 4.0. Some of its unique features include the following:

- Multiple networks in a single scenario: Networks can be constructed in sections and combined at runtime. The sections can be reused in future models.
- New output graphics: These graphics support three-dimensional X-Y grids and display of point plot data.
- Direct interface to SimStat (product of MC^2 Analysis Systems): These files may be loaded for advanced statistical analysis.
- OS/2 metafiles for graphics: The OS/2 metafile format can be read for animation backgrounds or icons.

Conclusion

Simulation is a powerful approach to modeling manufacturing systems in that many complex and diverse systems can be represented. Simulation can predict system performance measures that are difficult to assess without a model. It is a proven, successful tool and has been in use since the 1950s. The current languages take advantage of the capabilities of today's microprocessors and provide the user with the needed online support for model development, management, and analysis.

Tools for Intelligent Manufacturing Processes and Systems: Neural Networks, Fuzzy Logic, and Expert Systems

Tien-I. Liu

Introduction

Starting in the 1980s, researchers and practitioners became increasingly interested in intelligent machines and intelligent manufacturing. The goal of these systems and processes is to model the skills and expertise of professionals so that machines and manufacturing systems can possess some of the characteristics of human intelligence. Three techniques — neural networks, fuzzy logic, and expert systems — have been widely used in manufacturing. This section describes the principles and functions of these tools. Examples in applying these tools to manufacturing applications are highlighted as well.

Neural Networks

Neural networks consist of a set of nodes that are nonlinear computational elements. The pattern of connectivity between nodes, known as *weights*, can be modified according to some preset learning rule. The knowledge of the networks is stored in their interconnections (Kohonen 1986).

Since neural networks are parallel distributed processing, they have the following advantages:

- They are adaptive and can learn from experience.
- The network can be refined at any time with the addition of new training data.
- Various model architectures can be used.
- They can compute very quickly and thus are very suitable for real-time applications.
- They can be used for analyzing large amounts of data to determine patterns that may predict certain types of behavior.
- They can capture the complexities of the process, including nonlinearities, even if the dynamics of the process is unknown.
- They can make decisions based on incomplete and noisy information.
- They degrade gracefully even when parts of the structure have been destroyed.

Neural networks are best at performing the types of tasks which need human perception. These tasks do not have exact answers, for example, classification and trend analysis. A typical example of such problems is machine diagnosis. An experienced mechanic can point out what is wrong with an automobile by standing beside the car and listening to the sound of the running engine. Another example is character recognition. Any person who is familiar with alphabets can easily identify the letter “A” in any of various typefaces or handwritten scripts. In both cases it is practically impossible to develop a set of if-then rules to let a computer to do the job. These tasks are also difficult to program using standard computer techniques.

Many electronics and computer companies have put considerable effort into neural-network development. IBM has announced a neural-network development package for its computer; Intel Corp. has developed a microchip that supports this technology. Japanese companies such as Fujitsu, Hitachi, Mitsubishi, and Sumitomo Heavy Industries are also working in this field.

A bomb-detection machine that uses neural-network technology to detect plastic explosives hidden in baggage has been developed and installed in several airports. Neural networks have also been applied to ensure the operation of an industrial power distribution substation. It has replaced a conventional mechanical system and improved the performance by greater than an order of magnitude.

Integrating sensors with neural networks for monitoring and diagnostic purposes can enhance production reliability, prevent potential problems caused by abnormal conditions, and maintain high product quality in the factory (Liu and Iyer 1993). The applications of neural networks for monitoring and diagnostic purposes have been used with ball-and-roller bearings, turning processes, milling processes, drilling processes, tapping processes, and glass furnaces. The results are very successful (Liu and Anatharaman 1994).

Neural networks have also been used in the image processing for computer vision and speech-recognition systems (Badal 1993). They also are used for the control of machines and processes. The neural-network controller is capable of online learning of the system dynamics and then taking adequate action to achieve the predetermined goal. They also can be used to tune the gain of control systems.

Fuzzy Logic

The theory of fuzzy sets has been developed as a methodology for the formulation and solution of problems that are too complex or too ill defined to be solved by traditional techniques. In fuzzy logic, the membership in a set is not either 0 or 1; instead it is a value between 0 and 1. Membership functions span some problem domain, such as length or weight, and show the membership for each value of the problem domain. Membership functions are subjective evaluations and can be represented by many kinds of curves. However, the membership function cannot be assigned arbitrarily. The formulation of the membership function should be based on the professional feeling and physical understanding of the problem. Let $S = \{s\}$ represent a space of objects. Then a fuzzy set X in S is a set of ordered pairs

$$X = \left\{s, f_x(s)\right\}, \quad s \_ S(1)$$

where $f_x\ (s)$ is the grade of membership of s in X and $f_x\ (s)$ is a number in the interval (0,1).

Fuzzy mathematics, which consists of precise rules to combine vague expressions, such as "very high" and "somewhat heavy," has been developed (Kandel 1986). Generally speaking, fuzzy logic systems have the following advantages:

- They are inherently flexible.
- They are robust to noisy or missing data, unexpected disturbances, and errors in problem modeling.
- They are suitable to deal with problems for which knowledge is approximate or problems that are so complex that it is difficult to develop an adequate mathematical model.
- They usually are energy efficient.

Fuzzy mathematical techniques are very suitable for the control of machine tools, robots, and electronic systems (Mamdani 1993). They are also applicable to image understanding for computer vision and pattern classification for the monitoring and diagnosis of manufacturing processes (Du et al. 1992).

The very first application of fuzzy logic was the control of the fuel-intake rate and gas flow of a rotating kiln used to produce cement. Since then, it has been used to control many automated manufacturing processes. Fuzzy logic has resulted in significant improvements to many commercial products, such as cameras and air conditioners. Although fuzzy logic was developed in the U.S., most of the installed applications are still in Japan. The most impressive application is a subway system operated by a fuzzy computer. It was installed in the 1980s by Hitachi at Sendai, about 200 mi north of Tokyo. This system is more than 10% more energy efficient than the previous system, and it is so smooth that passengers do not need to hang onto straps.

At AT&T Bell Laboratories, Dr. M. Togai and Dr. H. Watanabe developed the very first fuzzy logic processing chip in 1985. NASA is developing fuzzy controllers to help astronauts pilot the space shuttle in earth orbit. In the U.S. the interest in applying fuzzy logic is growing continuously.

Expert Systems

An expert system is a computer system that possesses the capability of a human expert. An expert system has the following five essential parts (Figure 13.4.4):

1. *User interface:* This module is the interface between the user and other parts of the expert system.
2. *Knowledge base:* The knowledge about solving specific problems is stored in the knowledge base of an expert system. The process of building the knowledge base is called *knowledge engineering* and is done by a knowledge engineer (Figure 13.4.5). Knowledge engineering refers to the acquisition of knowledge from a human expert or other source and the coding of it into the expert

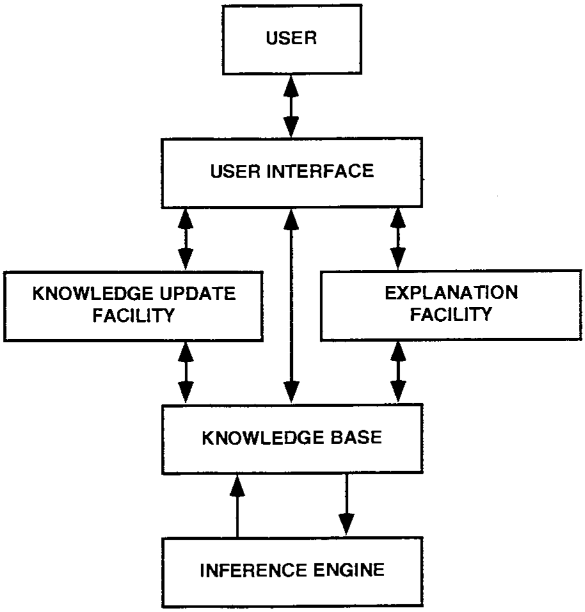

FIGURE 13.4.4 Typical expert system architecture.

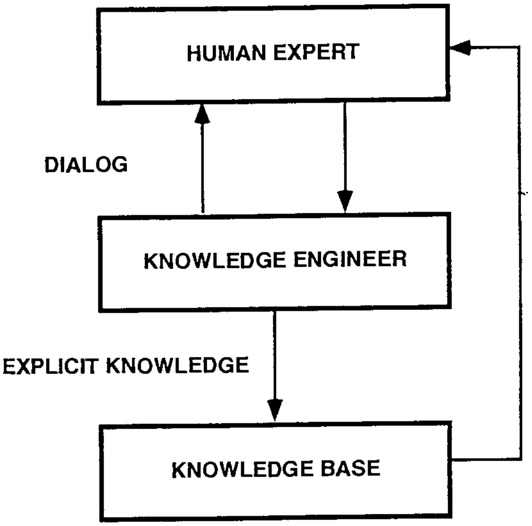

FIGURE 13.4.5 Knowledge engineering.

system. The knowledge base usually consists of rules and facts. Rules are made up of English-like sentences or clauses. Rules are often defined using an if-then syntax that logically connects one or more antecedent clauses with one or more consequent clauses as follows:

IF antecedent THEN consequent

A rule says that if the antecedent is true, then the consequent is also true. The antecedent and consequent of rules refer to a specific fact that describes the state of the world. On the other hand, each fact is a single sentence that describes some aspect of the state of the world.

3. *Inference engine:* The inference engine can infer new knowledge from existing knowledge stored in the knowledge base. Two general inference approaches are commonly used: forward chaining and backward chaining. Forward chaining is the reasoning from facts to conclusions resulting from those facts. Backward chaining involves reasoning in reverse from a hypothesis to the facts that support the hypothesis.
4. *Knowledge update facility:* The knowledge in many fields, including engineering and manufacturing, changes with time. The expert system can be updated through this facility.
5. *Explanation facility:* Just as a human expert can explain how a specific conclusion has been drawn, the explanation facility can explain its reasoning to enhance the credibility of an expert system.

Expert systems are quite different from conventional programs because the problems usually have no algorithmic solution and rely on inferences to achieve a reasonable solution. In other words, the expert system is very suitable to solve problems that require heuristic rules. These heuristic rules can be stored in the knowledge base.

Expert systems have the following advantages as compared with the human expert:

- They are steady and unemotional and have high reliability. Therefore, errors are reduced.
- They have high availability. Users can get answers at any time.
- The expert system can be installed and used at multiple sites.
- They can explain how a conclusion has been reached. Thus, the users feel comfortable working with expert systems.

Expert systems can help people solve problems. They can free the human expert from the routine job to do other work. Hence, they can increase efficiency and reduce cost.

Expert systems have been used in many fields. There are many commercialized expert systems running on different computer platforms that help professionals in various fields, enhancing efficiency and productivity greatly.

Manufacturing, assembly, quality, reliability, and cost need to be taken into consideration in the early stage of product design. Expert systems have been developed for DFM, design for assembly (DFA), design for quality and reliability, product cost estimation, and so forth. These expert systems can be integrated with the existing CAD/CAM systems (Liu et al. 1995). Many expert systems have also been built and used in the areas of facility design, production planning and control, computer-aided process planning, material handling, quality control, equipment maintenance and repair, and real-time control (Alto et al. 1994). Simply put, design and manufacturing work can be upgraded from an experience-based to a science-based function by using expert systems.

Conclusion

Neural networks, fuzzy logic, and expert systems are the trend of the future. They can make machines and manufacturing processes much smarter. Applying these techniques can lead to the realization of a fully automated factory in the future.

Tools for Manufacturing Facilities Planning

J. M. A. Tanchoco, Andrew C. Lee, and Su-Hsia Yang

Introduction

The main function of facility planning is the design of efficient flow of products from raw material to finished goods. It is one of the most important determinants of operating efficiency and production cost. Traditionally, the facility-planning problem is divided into three areas: group technology (GT), material handling, and facility layout (see Figure 13.4.6). GT, which is closely related to cellular manufacturing, is usually defined as the grouping of dissimilar machines in close vicinity. Each group or cell is dedicated to the production of one or more parts families. The parts in the family are similar in their processing requirements (Wemmerlov and Hyer 1989). Two of the most fundamental elements in facility planning are the facility layout and the material-handling system.

Facility layout positions the workstations around the fixed product based on the processing sequence. In a product layout, machines are arranged according to the processing sequence of the product, for example, the assembly of automobiles and certain electronic products. The machines are located so as to provide smooth and logical flow of material. In a group layout, also referred to as a cellular layout, products are grouped into logical product families. All machines that perform similar operations are grouped together in the process layout. A process layout is characterized by a high degree of flexibility and machine utilization. Regardless of the type of facility, a detailed layout should not be designed without giving serious consideration to material-handling requirements. The choice of material-handling methods and equipment is an integral part of the layout design. The facility layout design component performs two basic functions. The first function is to decide how to locate cells with respect to one another. The objective is to minimize either the total material flow distance or transportation time. The second function is to resolve the machine location and orientation relative to each other within the cell. The constraints in layout design or facility structure could prohibit the placement of the cells or machines in some locations, thus changing the machine compositions of the cells. The resolution from this design problem has a significant impact on the distance that material has to be moved.

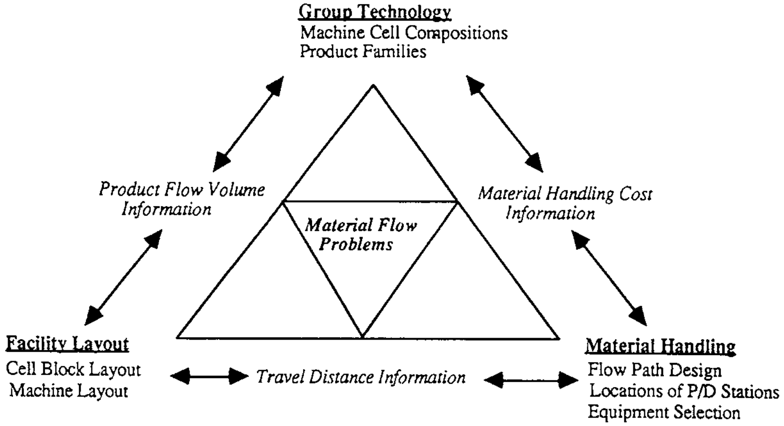

FIGURE 13.4.6 Facilities-planning framework components.

Material handling performs a critical function in modern dynamic manufacturing systems. The transportation of materials within a production system is often accomplished with limited resources, for example, conveyors, forklift trucks, or automated guided vehicles (AGVs). Such transfer mechanisms not only deliver material in a timely fashion but also provide temporary storage capacity. These limited resources require a capital investment, which increases the overall production costs. Excess transportation capability represents expenditures that are not accompanied by increased value. Insufficient capacity, on the other hand, can adversely affect production by delaying the delivery of material, thus reducing the total production volume. Material handling is generally considered as a non-value-adding activitiy. However, one can argue that material handling adds time and space value by making the material available and ready for processing.

The material handling has three functions. First, the flow path design selects the route that material transfers from cell to cell or from machine to machine. Limited by the cost of remodeling, the existing plant configuration (such as the aisle width) might not be able to accommodate the traffic flow. Therefore, considerations must be given to the overall facility layout and building structure. The second function is to locate the pickup and delivery stations along the flow path. Along with the facility layout and flow path design, it is one of the most important determinants of the operating cost of material handling. Finally, the best combination of material-handling equipment is determined. Because of the complex, ill-structured, and experience-based nature of the problem, the decisions for choosing material-handling equipment tend not to be based on rigorous criteria. However, the designers must recognize that there is an appropriate level of technology for every application that will meet the combined need for maximum handling efficiency and acceptable cost.

Decision Factors for Facilities Planning

The effectiveness of a facility-planning system depends on the careful integration of GT, facility layout, and the material-handling system.

Group Technology. Mitrofanov (1959) is recognized as the first person to introduce the concept of GT and machine grouping. Since then, a number of researchers have developed techniques for machine grouping and part family formation. In general, these techniques can be categorized as follows:

1. *Machine-Component Matrix* (McAuley 1972; King 1980; McCormick et al. 1972): The main idea behind this approach is to delineate cells by grouping binary entries of a machine-component incidence matrix into fuzzy blocks along the matrix diagonal.
2. *Mathematical Programming Formulation* (Kusiak et al. 1986; Askin and Standridge 1993): In this approach, a large, combinatorial mixed integer programming formulation is usually required to model the problem.
3. *Graph-Based Formulation/Partitioning* (Rajagopalan and Batra 1975; Faber and Carter 1986): In this approach, the machine-part matrix is represented by a bipartite, transition, or boundary graph. Then, it is solved using graph theoretic clustering methodology.

Facility Layout. The facility layout problem has been formulated as a quadratic assignment problem (QAP). The objective function for this type of formulation is to minimize the total material-handling cost. Given the complexity of the QAP formulation, the size of problems that could be solved by optimal methods is very limited. Thus, heuristic algorithms are more suitable. These heuristics can be classified into two major groups. The first group is called construction algorithms (Seehof and Evans 1967; Lee and Moore 1967; Foulds and Giffin 1985; Hassan and Hogg 1991). The main idea behind these methods is to build the layout by adding one more block (a cell or a department) to a partial block layout until all blocks have been located. The methodology requires two steps: a selection step and a placement step. The selection step determines the order by which the blocks enter the layout, while the placement step selects the location of the new block to enter the layout relative to the blocks that are already in the layout. The objective is to maximize some kinds of performance criteria, for example, total closeness rating. Graph theoretic methods have been applied as a solution methodology for this approach.

The second group of the layout heuristics is called improvement algorithms. This approach starts from an initial layout, and improvements are made by successive pairwise interchanges of blocks. The general form of an improvement algorithm consists of the following steps: (1) select a pair of activities, (2) estimate the cost of interchange, (3) exchange if the total cost is reduced, and (4) repeat until no more improvement can be made. This category of heuristics includes the computerized relative allocation of facilities technique (CRAFT) of Armour and Buffa (1963) and Buffa et al. (1964) and the methods of Hillier (1963), Fortenberry and Cox (1985), and Co et al. (1989).

Recognizing the weaknesses of both construction and improvement algorithms when applied separately, Golany and Rosenblatt (1989) proposed a hybrid method that takes advantages of both construction and improvement algorithms. They use the layout resulting from the construction algorithm as the initial layout and improve upon it using an improvement algorithm. Since most of the heuristics for facility layout are based on the "greedy approach," the solution is very sensitive to the initial layout. The final layout given by the algorithm may not be the best.

Material Handling. Material handling involves moving, storing, and controlling the flow of materials. Several components, such as the flow path design, the locations of pickup and delivery stations, and the material-handling equipment selected, have significant effects on the overall effectiveness of the material-handling system. The objective of flow path design is to determine the best "street network" that transporters pass through when parts are moved from one machine to the next. It is one of the major determinants in the calculations of travel times, operating expenses, and installation costs of the material-handling system. There are numerous types of flow path network configurations. The most widely adopted flow path design is the conventional flow network. It is usually a unidirectional flow network where any cell boundary is used as part of the flow path. In a unidirectional network, one has to determine the flow direction for each aisle. Its flexibility, reliability, and efficiency have made this type of network a popular choice especially when AGVs are used. In comparison, the potential of using a bidirectional flow network could make the system more efficient (Egbelu and Tanchoco 1986). The same authors also developed guidelines for the use of a single-lane bidirectional flow network. However, the advanced hardware requirements and complicated system controllers are viewed negatively.

A single-loop flow path network can be found in many flexible manufacturing systems. The entire flow path design is made up of a single loop. This type of network can potentially minimize some of the problems associated with a conventional flow network. Congestion is inherently low and the operating rules are simple. It also has relatively low initial investment and maintenance costs.

Recently, a new flow path network configuration, a segmented flow topology (SFT), was developed by Sinriech and Tanchoco (1994). It consists of one or more zones, each of which is separated into nonoverlapping segments. Each segment is serviced by a single bidirectional material-handling device. Transfer buffers are located at both ends of each segment. The flow structure in each zone is determined by the logical flow requirements and by the existing aisle network. The SFT provides a simple flow structure and control system. The research also suggested that it can achieve a higher throughput capability compared to other material flow path network configurations.

The locations of pickup and delivery stations have generally been considered as a secondary issue in the design phase of facility layout and a material-handling system. Yet it can have detrimental effects on the costs of material handling and the machine layout configuration. In a study by Warnecke et al. (1985), they confirmed that the actual pickup and delivery station flow distance is much more representative than taking the rectilinear distance between the centers of machine blocks. Since then, several design procedures have been proposed to find the optimal location of material-transfer stations. Montreuil and Ratliff (1988) suggested a systematic methodology for locating pickup and delivery stations within a facility layout using multifacility location theory. The objective function is to minimize the sum of the rectilinear distance traveled by all intercellular flows, given the boundary regions on station location. Luxhoj (1991) developed a two-phase design procedure that is suitable for the spine layout where the active flow lines are well defined.

In terms of material-handling equipment selection, a large variety of equipment types available are with their own special functions and characteristics. Each equipment type has its own capability and limitations. Some of these characteristics are difficult to quantify. The integrated nature of the manufacturing systems complicates the material-handling selection problem. The problem was first addressed by Webster and Reed (1971). The procedure they suggested initially assigns material-handling equipment to departmental moves based on cost alone. Then, move assignments are interchanged to seek improvement in equipment utilization and total cost. Hassan et al. (1985) reformulated Webster and Reed's model as an integer programming model with the objective of minimizing the total operating and capital costs of the selected equipment. Due to the combinatorial nature of the problem, it is solved using a construction heuristic that exploits some similarities to both knapsack and the loading problems. Material Handling Equipment Selection System (MATHES) was developed by Fisher et al. (1988). MATHES is a rule-based system for the selection from 24 different types of material-handling equipment.

Conclusion

The framework discussed in this section provides an alternative perspective from the material flow viewpoint. It integrates all of the important design factors associated with facilities planning. It incorporates most of the desired properties with respect to the overall plant operations. At the same time, the framework also summarizes the difficulties and complexities that confront the facility designer. The description of the framework is intended as a general exposition of the fundamental concepts and a direction for future research in facilities planning.

13.5 Rapid Prototyping

Takeo Nakagawa

Manufacturing Processes in Parts Production

The rapid progress of CAD technology for the design of machine parts has now made it easy to store three-dimensional shape data on computers. The application of these three-dimensional data has realized NC programming by CAM system, resulting in the remarkable advance of automated production. The increase in highly functional machine parts and advanced designs has led to the design of more and more complicated surfaces using CAD. To reduce the lead time and costs for the development of new industrial products, "rapid prototyping" has been recognized as a unique, layered manufacturing technique for making prototypes.

With this rapid prototyping, shapes of machine parts are created by building up layers and layers of materials, unlike the material-removal technique which shapes by gradual machining using a cutting tool. In this sense, rapid prototyping resembles the joining technique of small particles or thin layers. Various types of rapid prototyping methods have been born over the last couple of years. A common feature of these methods is that parts are directly shaped fully automatically according to CAD data. Specifically, in all of these methods, the three-dimensional CAD data are taken as composed of thin layers of two-dimensional data. The thin layers are formed using the two-dimensional data and built up to form an actual three-dimensional solid product. With the nature of the processing steps, this rapid prototyping technique is called *layered manufacturing*. Since the method can also be used in other applications than prototyping, it is also referred to as *free-form fabrication*. Because three-dimensional objects can be made from three-dimensional CAD data, this new rapid-prototyping method is also called three-dimensional plotting. At the present time, laser stereolithography is the most widespread rapid-prototyping method.

Rapid Prototyping by Laser Stereolithography

Laser stereolithography involves the use of a liquid photocurable resin, which cures instantaneously when scanned with a laser as a result of polymerization. As shown in Figure 13.5.1, the laser is scanned over this resin repeatedly to form thin layers of cured resin, which eventually build up to form a three-dimensional solid product. Specifically, the process involves first slicing a model based on three-dimensional CAD data stored on computer horizontally into equal thickness. Based on these slice data, the laser scans the thin liquid resin layer to form the first solid layer. Liquid resin is then poured over this cured layer of resin and again scanned by laser to form the next layer according to the next slice data. To ensure that the liquid resin on the cured resin is even, its surface is often swept by a blade. So, by repeating this process and forming layer over layer of cured resin, a solid object is formed.

Although the surface accuracy problems are resolved by making each layer extremely thin, a small amount of roughness of the surface eventually remains and subsequent polishing is often performed to achieve a smooth finish. For shapes that cannot be formed by building the layers upward, the resin is cured on a support. This support is also made of the same photocurable resin and is removed after the product has been formed. For some types of resins that do not cure completely with a laser alone, the whole product is cured by exposure to an ultraviolet lamp after it has been formed.

The photocurable resin is composed of photopolymerizing oligomer, reactive diluent, and photoinitiator. When a laser is irradiated onto this resin, the monomer undergoes a series of reactions to form a solid polymer that has a three-dimensional network structure. The resins used for laser stereolithography are the radical polymerization type, the cation polymerization type, or the hybrid type, which is a combination of the first two types. The curing properties and mechanical properties of the cured resin are important, because these affect the applications of the cured product formed by laser stereolithography. These resins are prepared minutely by adjusting the mixture rate of the resin components and the additives to suit laser stereolithography.

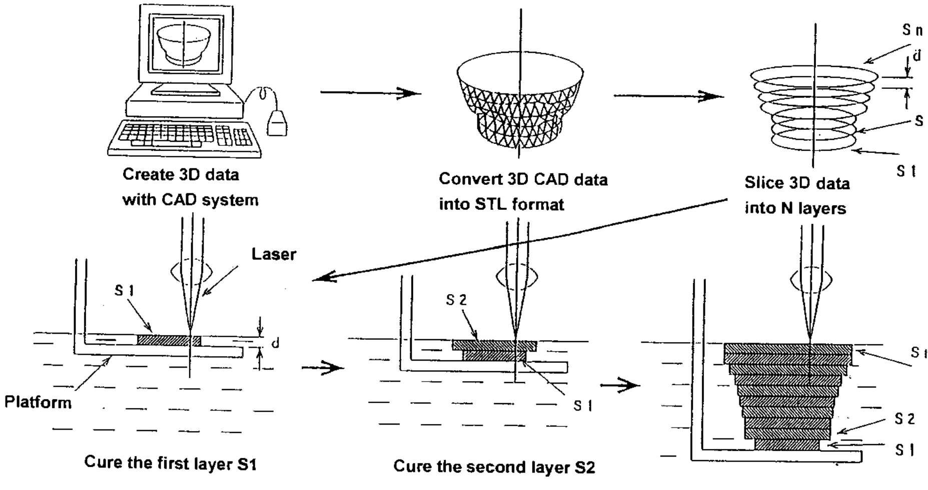

FIGURE 13.5.1 Principle of photocurable resin process.

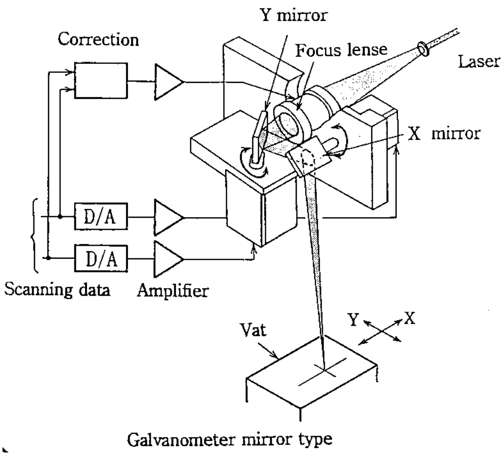

FIGURE 13.5.2 Scanning system of UV laser beam.

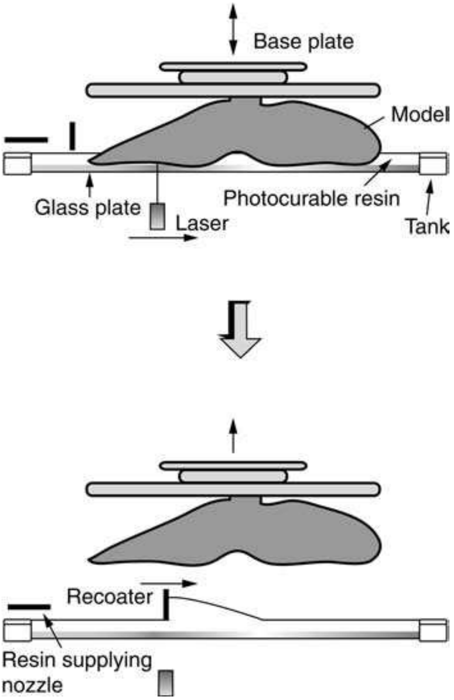

FIGURE 13.5.3 Laser beam radiation from below (Denken).

In most cases, the He-Cd laser with 325-mm wavelength or Ar laser with 364-mm wavelength is used as the light source. Higher-power lasers like Ar perform higher-speed beam scanning, resulting in the increase of modeling speed. As shown in Figure 13.5.2, these lasers scan at very high speed in the same way as the laser printer by rotating galvanomirrors. In some special machines, the laser beam is exposed from the bottom, as shown in Figure 13.5.3, by an *XY* plotter.

Laser stereolithography requires three-dimensional CAD data composed of surface or solid data in order to create solid models. Many types of CAD systems are now available on the market, and most of the CAD data they provide can be transmitted to laser stereolithography systems. At the same time, the

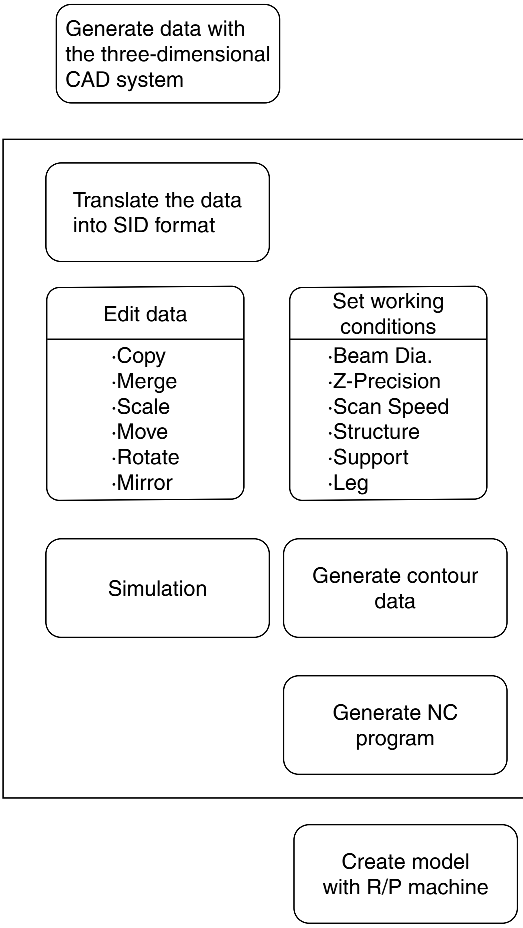

FIGURE 13.5.4 Software for R/P system (CMET).

laser stereolithography system is equipped with a scanning program, support and reinforcing rib design software, magnification/contraction functions, functions to determine the scanning and operating conditions, and simulation functions. Figure 13.5.4 shows a software flowchart in laser stereolithography.

The following shows the advantages of rapid prototyping over material-removing processes such as machining:

1. Deep holes and structures with complicated internal shapes that cannot be machined simply by cutting tools can be formed in a single process. Moreover, one rapid-prototyping machine is usually capable of fabricating any type of shape.
2. Rapid prototyping requires no complicated control programs such as tool path and repositioning of the workpiece. With the three-dimensional CAD data, there is no need for special knowledge of the cutting process, and operations from data input to actual fabrication are simple and short.
3. The rapid-prototyping systems produce no machining wastes. Because they do not vibrate and are silent, they can be used in offices like office business machines. They can also be operated fully automatically even at night since there is no need for the management of tooling.

The major shortcomings of laser stereolithography are that only photocurable resins can be used and the material strength of these materials is slightly worse than the common polymer. In addition, metal products cannot be manufactured directly by laser stereolithography.

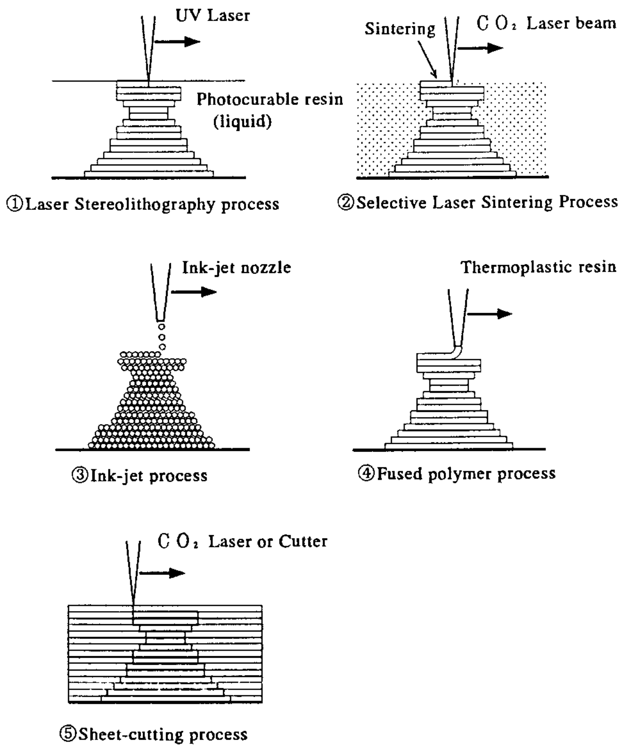

FIGURE 13.5.5 Schematic of various layer-additive fabrication processes.

Other Rapid-Prototyping Methods

The laser stereolithography method was developed in an early stage and is currently applied extensively. Besides laser stereolithography, many types of new rapid-prototyping methods have also emerged. As shown in Figure 13.5.5, rapid prototyping can broadly be classified into photopolymer, powder sintering, ink jetting, fused deposition, and sheet cutting. Figure 13.5.6 shows the history of these rapid-prototyping systems. Most of the methods were developed in the U.S., but the photopolymer process and sheet lamination were first proposed in Japan.

Another photopolymer process is the mask pattern-curing method shown in Figure 13.5.7. Similar to the photocopying process, a master pattern based on slice data is created, the pattern on the glass sheet is placed over a photocurable resin layer, and this layer is exposed to ultraviolet light. Although the machine is large, the exposing speed is faster than the laser beam method mentioned earlier, and the thickness of the product is very precise because each surface formed is cut by milling to obtain precise thin layers.

Three-dimensional objects can also be formed by powder sintering. In the process shown in Figure 13.5.8, powder is used instead of liquid photocurable resin. The powder is evened out using a roller, a CO_2 laser is beamed, and the powder is bonded by heat fusion. In this case, powder is heated up beforehand to the temperature just below the melting point in the antioxidation environment using N_2 gas. It is possible to create high-density polymer solid models as well as porous models.

Porous polycarbonate models are quite suitable for the investment casting model. With this method, metal and ceramic powders can also be used. Metal and ceramic powders used are coated by resin and each metal or ceramic powder is bonded by the coated resin. Sintered porous ceramic molds can be used for casting molds. Powder binding can be performed by spraying binding material on the loose powder layer through the ink jet nozzle, as shown in Figure 13.5.9. This is also used for making the sand mold

for casting. When wax or resin is sprayed from the jet nozzle, wax or resin models can be fabricated, as shown in Figure 13.5.10. In this case, the surface of the sprayed thin layer should be machined smoothly and flatly in order to obtain vertical accuracy.

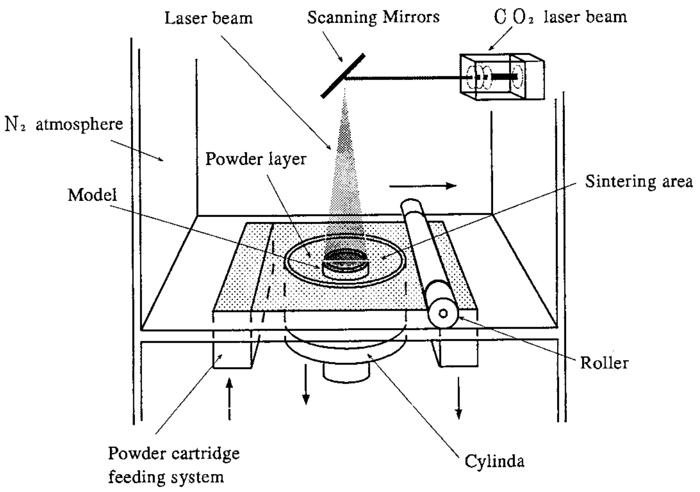

FIGURE 13.5.8 Selective laser sintering process (DTM, EOS).

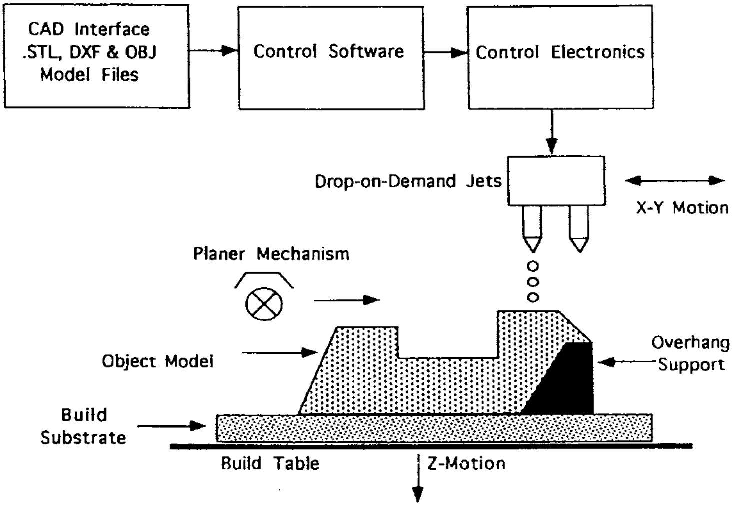

FIGURE 13.5.10 Ink-jet process (Sanders prototype).

Figure 13.5.11 shows the fused-deposition method. In this method, a fine nozzle deposits a layer of resin or wax. Wax is normally used to form lost wax models. Fused deposition systems, in which material is supplied by the pellet or wire, enable materials to be formed very similarly to general injection mold

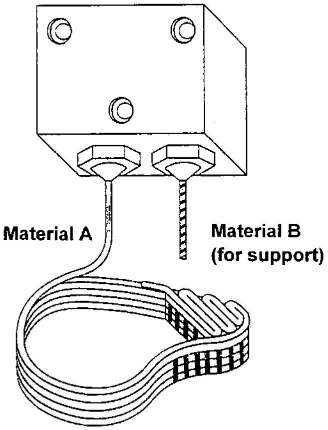

FIGURE 13.5.11 Fused deposition process (Stratasys).

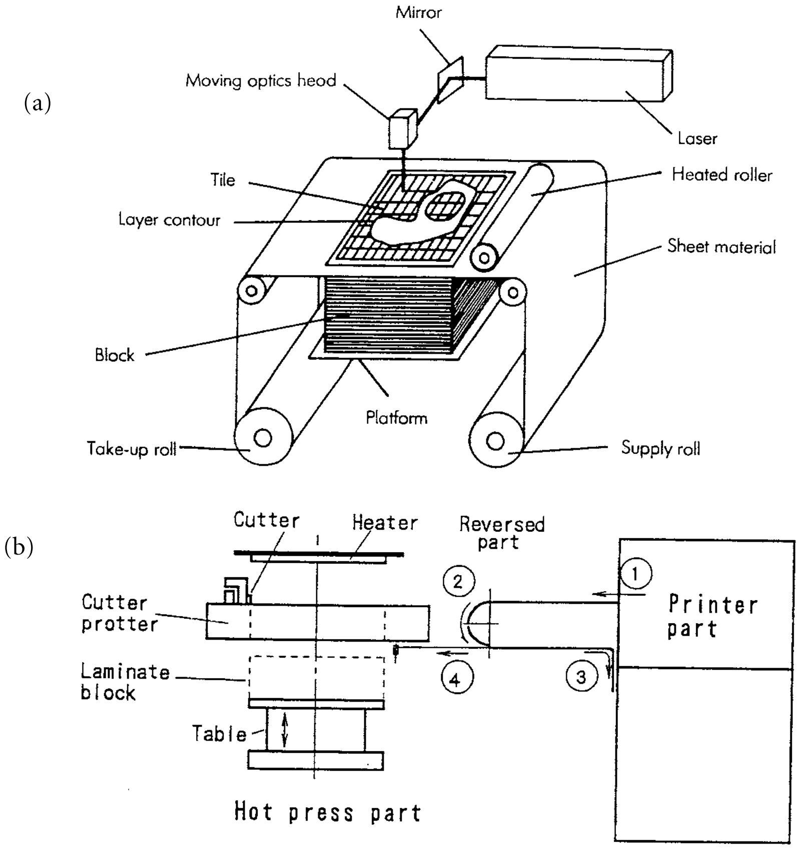

FIGURE 13.5.12 Sheet cutting process: (a) Laser (LOM), (b) Cutter (Kira).

materials like ABS and nylon. One of the two nozzles is used for making the support, where the support material is usually wax with lower melting points.

Figure 13.5.12 shows two methods that cut thin sheets according to slice data and laminate them to form three-dimensional objects. One method uses a laser to cut sheets applied with adhesive, which are then laminated by hot toll pressing, while the other uses a knife to cut the sheets. In the latter case, adhesive is applied to sheets of paper according to the desired shape by spraying the toner using a dry Xerox-type copy machine. Due to the use of paper in these sheet-lamination methods, the model formed should be immediately coated to prevent the absorption of moisture. Although there is a limit to the shapes that can be made, the method is nevertheless used for making wood models for casting, because it is inexpensive and enables large-sized models to be made and the model material is similar to wood.

The common feature of all of these methods is that slice data is obtained from three-dimensional CAD data and these slice data are used to laminate thin layers of material, which means that the same software can be used for all of these methods. Another feature is that all rapid-prototyping machines use the modified printing technology.

Although many of these rapid-prototyping machines tend to be costly, inexpensive models are also now available. Machine cost reduction has been achieved by proper utilization of key parts, which are used for the printer. New and improved methods should continue to be developed with the introduction of printing technology.

Application of Rapid Prototyping

Figure 13.5.13 shows the applications of three-dimensional models made by rapid prototyping. They are mainly intended for verifying CAD data, checking the designs, functional checks of prototypes, wax models for investment casting, master models for die and model making, mold making for prototype manufacturing, casting models, and medical use CT and MRI data. Although dimensional accuracy was given little importance in the verification stage of CAD data and design, high dimensional accuracy is now demanded of the functional check of prototypes. Because photocurable resins contract in the solidification process, slight distortions are generated in the fabricated product. Among the various rapid-prototyping machines, the photocurable resin process is most suitable for making complicated shapes and obtaining the highest accuracy.

Even in laser stereolithography, accuracy has improved to a considerable extent with the enhancement of the resin and scanning method and the accumulation of know-how for positioning the reinforcing rib. It should also be possible to attain the same accuracy as injection molds by measuring formed products, correcting the data, or predicting errors.

In general, photocurable resins are generally weak and brittle as compared with conventional polymer parts produced by injection molds. Urethane resin, which is typically used for vacuum casting with a silicon rubber mold reversely copied from a rapid-prototyping model, also lacks the required strength. In order to carry out the functional check of the prototypes created, other processes that can use normal thermoplastic should be used.

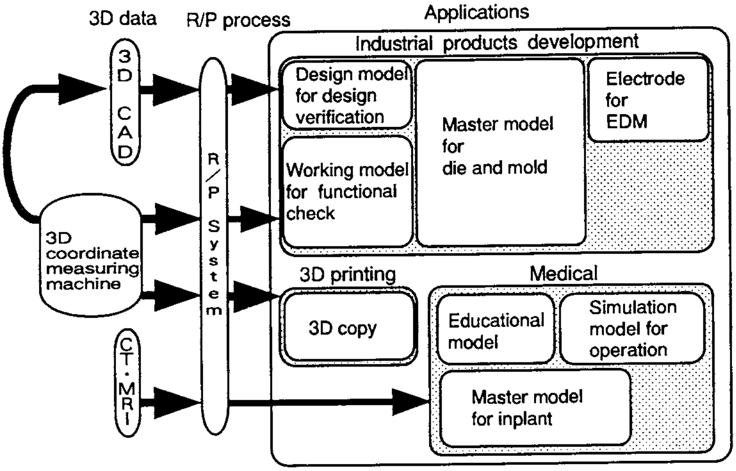

FIGURE 13.5.13 Application of rapid prototyping (Source: CMET).

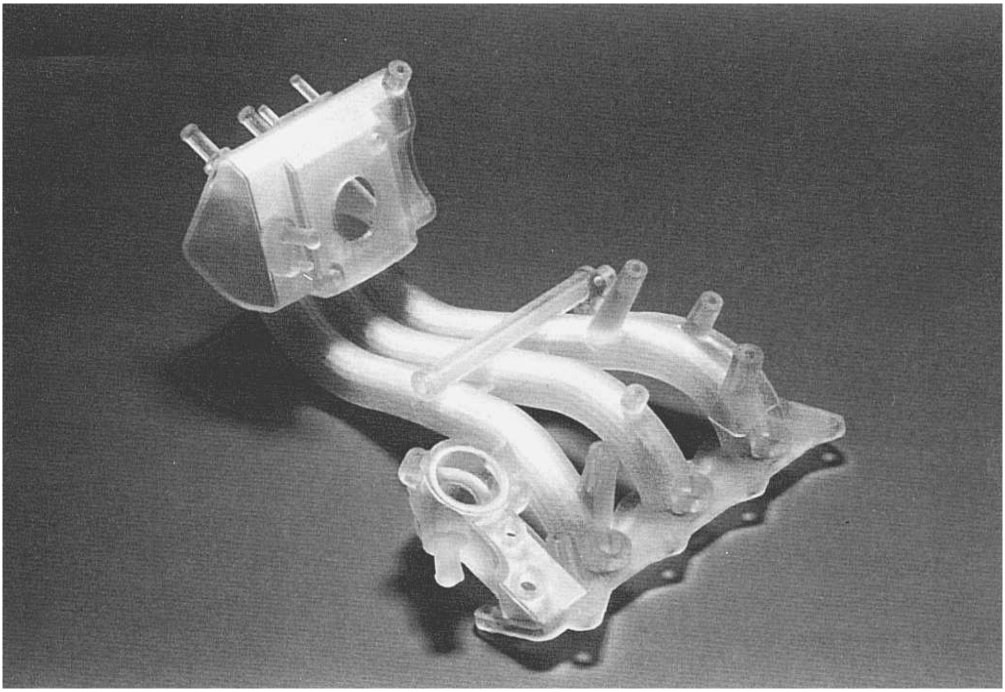

FIGURE 13.5.14 Sample for fluid dynamic analysis.

Figure 13.5.14 shows an intake manifold for car engines made by laser stereolithography. This serves as a test model for checking fluid performance of air. For such purposes, current photocurable resins available prove relatively satisfactory.

Although the powder sintering process can apply some metals, there is no suitable rapid-prototyping technique that can directly form products from metal materials at the moment. Research activities are under way to study the feasibility of producing molds from metal materials directly using a three-dimensional printing technique. In a general application, the lost wax models are first made by rapid prototyping and then used for creating metal prototypes by investment casting.

Rapid prototyping is still a relatively new technology, and therefore considerable opportunities for technical improvements exist.

General Rapid Prototyping in Production

For rapid prototyping to be carried out, three-dimensional CAD data must be available. Creating the CAD data takes far more time than creating the three-dimensional models based on the CAD data. By realizing efficient concurrent engineering, rapid prototyping will no doubt become a very important tool. In general, many other types of production systems can be included in the list of systems currently termed general rapid prototyping (casting and machining, etc.).

Casting methods that are able to produce green sand molds satisfy the conditions of rapid prototyping. Expendable pattern casting is also suitable for rapid manufacturing. In this case, a three-dimensional polystyrene foam model is made by machining or binding. Most of the industrial products around us are produced with dies and molds. Because they are expensive to manufacture, dies and molds are unsuitable for making prototypes and for small-lot production. This may be a reason why rapid prototyping was developed; however, some prototype production methods do involve the use of dies and molds. Flexible prototype production has been carried out in sheet metal forming with the use of the turret punch press, laser beam cutting machine, and NC press brakes. Producing dies and molds rapidly and manufacturing using such dies and molds also fit into the category of general rapid prototyping in the broad sense. Examples include what is known as the low-cost blanking dies using steel rule, deep drawing die made of zinc alloy, and bismuth alloy.

Among the many general rapid-prototyping systems that exist, the newly developed rapid-prototyping methods we discussed are gradually becoming methods for creating complicated products accurately with the use of three-dimensional CAD data. In terms of the total cost, applications of these new methods are still limited, but the spread of three-dimensional CAD data and technological progress of rapid prototyping should make them one of the common manufacturing techniques in the near future.

13.6 Underlying Paradigms in Manufacturing Systems and Enterprise Management for the 21st Century

Quality Systems

H. E. Cook

Introduction

Quality engineering has been described as the process of minimizing the sum of the total costs and the functional losses of manufactured products. Total costs include variable costs, investment, maintenance/repair costs, environmental losses, and costs of disposal or recycling. Functional losses arise from deviations from ideal performance. A subset of total quality management, quality engineering, focuses on parameter and tolerance design after the target specifications for the product have been developed as part of system design.

In contrast to quality engineering, *total quality management* embraces the entire product realization process. Its objective should be to maximize the net value of the product to society, which includes buyer, seller, and the rest of society. Product value is determined solely by the customer and can be set equal to the maximum amount the customer would be willing to pay for the product. For a product to be purchased, its price must be less than its perceived value to the customer at the time of purchase. Consumer surplus is the difference between value and price.

The true value of a product is formed by the customer after assessing the product's performance over the complete time period that he or she used it. Functional quality loss is also known as the cost of inferior quality that is equal to the loss of value incurred by a product as a result of its attributes being off their ideal specification points (Figure 13.6.1). When manufacturing costs are added to value, the resulting sum (equal to total quality less environmental losses) is maximized when the attribute is off its ideal specification because of the impossibly high costs required to make a product perfect.

Requirements Flow

The systems viewpoint, as expressed by the flow of requirements shown in Figure 13.6.2, is helpful in considering the full ramifications of total quality management. Every system can be divided into subsystems, and every system is but a subsystem of a larger system. Each task receives input requirements from its customer (either internal or external) and sends output requirements to its suppliers.

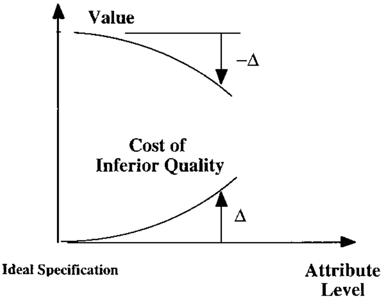

FIGURE 13.6.1 The relation of product value to the cost of inferior quality.

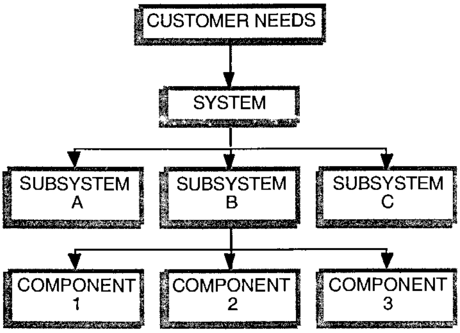

FIGURE 13.6.2 Flow of requirements from the customer through the enterprise.

Task Objectives

A major objective of the system task is to assess customer needs, to translate those needs into a complete set of system-level specifications for the product, and to send a key (but partial) set of subsystem requirements to those responsible for the subsystem tasks. The system specifications and subsystem requirements developed by the system task should be such that (1) customers will want to purchase the product in a competitive marketplace and, with use, find that the product meets or exceeds their expectations, (2) the product will meet the profitability objectives of the enterprise, and (3) all environmental rules and regulations are met. The system task also has the responsibility of resolving conflicts that arise between subsystem tasks.

The subsystem task receives the key requirements from its internal customer, translates them into a complete set of subsystem requirements, and sends a key (but partial) set of component requirements to those responsible for the component tasks. In turn, those responsible for each component task translate the requirements received into a complete set of component requirements and a partial (but key) set of raw material requirements. Requirements set at each level include controls on variable costs, investment, performance, reliability, durability, service, disposal, environmental quality, package, assembly, and timing for both production and prototype parts. Synchronization is very important to total quality management since parts should be received exactly when needed with minimal inventory.

Parts Flow

The response to the requirements flow is a parts flow in the opposite direction that begins with the conversion of raw materials into components. This is followed by the assembly of components into subsystems, which are shipped to the system task for final assembly. The process is completed by shipping the finished product to the customer. Thus, each task shown in Figure 13.6.1 has both a planning or design function as well as other functions, including manufacturing, assembly, purchasing, marketing,

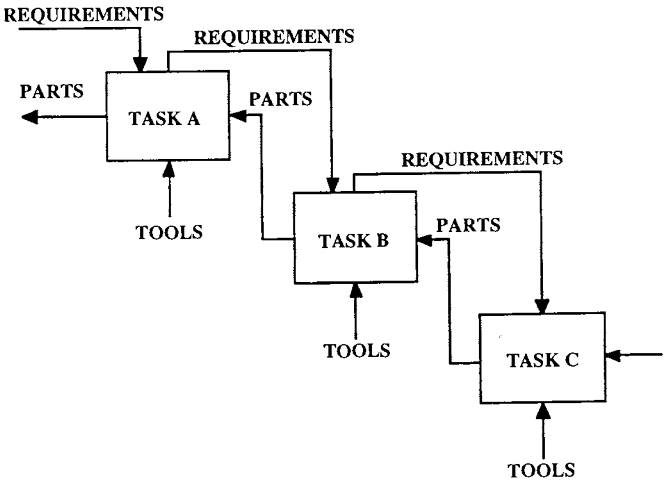

FIGURE 13.6.3 The flow of requirements and parts in a modified IDEF0 (function model) representation.

service, accounting, and finance. The actions taken to meet customer needs should be traceable as the requirements flow through the enterprise. With the systems viewpoint, all parameters are measured or computed at the full system level, including value, costs, and investment.

Task Management

Within each task shown in Figure 13.6.2 are subtasks. The combined flow of requirements and parts between several subtasks is shown in Figure 13.6.3 using a modified IDEF representation. Requirements are shown as controls that flow from left to right, and parts, in response, are shown as flowing from right to left.

Each task is accomplished by exercising its authority, responsibility, and capability. Authority to set requirements on parts should rest fully and undiluted with the task receiving the parts. The task that ships the parts should possess the full authority, responsibility, and capability to manufacture the parts for its customer. Before sourcing of parts, demonstration of capability by the manufacturer is a vital element of sound quality engineering. Capability is ultimately determined by the set of tools that the task has at its disposal and includes the skills and experience of the people as well as the hardware and software used by them.

Because a broad range of skills is needed, the required expertise is generated by forming a team to carry out the task. Quality tools used by the teams include structured methodologies such as Taguchi methods (design of experiments), quality function deployment, failure mode effects and criticality analysis, statistical process control, cost analysis, and value analysis. It is highly recommended that final authority and responsibility for each task rest with one person.

Fundamental and Bottom-Line Metrics

A variety of parameters can be used to measure the progress of quality improvements. These include such factors as the degree of customer satisfaction expressed for the product, the frequency of repair, and the variance found in product dimensions and performance levels that directly affect value to the customer. Repair and operating costs borne by the customer subtract from value if they are greater than what was anticipated by the customer. Likewise, resale price subtracts form value if it is below what the customer expected. Performance degradation of the product over its lifetime of use diminishes its value. Noise and atmospheric pollution caused by the manufacture and use of the product lower the net value of the product to society. The costs to manufacture and develop the product subtract from the net value received by the manufacturer. Moreover, products that are not improved in value and reduced in costs at the pace of competing products will likely be eliminated from the market in time.

These metrics can be grouped into one of three categories — value, cost, and the pace of innovation. They represent the fundamental metrics for the product because they determine what the bottom-line metrics of profitability and market share will be. Management of the fundamental metrics is the management of total quality and, likewise, the management of the total enterprise. The level of sustained profitability is the best measure of how well total quality is being managed in competitive markets.

Electronic Data Interchange

Chris Wang

Introduction

Electronic data interchange (EDI) is a method for exchanging business information between computer systems. In a traditional purchasing environment, buyers, when placing computer-generated orders, will mail them to suppliers, and it could take days before the suppliers receive them and then rekey the orders into their computer systems. Using EDI, the buyer's computer system can generate an EDI standard order transaction and transmit it directly to the supplier's inventory system for material pickup. It happens instantly. The benefit of EDI is quite obvious in this case since it reduces material lead time dramatically. Consequently, the objectives of EDI implementation should not be limited to just reducing paperwork and clerical work; instead, it should be used as a methodology to streamline company processes and allow the company to become competitive in the marketplace.

EDI Elements

EDI consists of the following elements:

- Trading partners — The parties, such as a manufacturer and a supplier, who agree to exchange information.
- Standards — The industry-supplied national or international formats to which information is converted, allowing disparate computer systems and applications to interchange it. This will be discussed in more detail later.
- Applications — The programs that process business information. For example, an orders application can communicate with an order-entry application of the trading partner.
- Translation — The process of converting business information, usually from a format used by an application, to a standard format, and vice versa.
- Electronic transmission — The means by which the information is delivered, such as a public network. Some companies may choose to build their own transmission facilities. For others, a value-added network (VAN) seems to be a good choice since companies do not have to invest heavily in communication equipment and personnel to support it. The VAN provider can handle disparate communication hardware and software and provide wide-area network access at a reasonable cost.

EDI in Manufacturing

In the present-day business environment, many companies are turning to just-in-time (JIT) and other techniques to compete as effectively as possible. EDI can make an important contribution to the success of JIT by ensuring that information exchanged between business partners is also just in time.

In traditional manufacturing, material is stored in quantities much larger than required because of faulty components and possible waste in the production process. To solve problems of carrying safety stock and still producing high-quality product, JIT seems to be an effective technology.

JIT systems are designed to pull raw materials and subassemblies through the manufacturing process only when they are needed and exactly when they are needed. Also, with rapidly changing production needs, orders are getting smaller and are issued more frequently. The traditional paperwork environment simply cannot effectively cope with this change. This is why EDI comes in to play a key role to provide fast, accurate information to achieve these JIT goals. In other words, EDI can provide JIT information in manufacturing processes.

- EDI cuts order delivery and lead time — The more control points you have in a process, the greater the number of potential problems. EDI eliminates "control points" for the order process. It eliminates the need to mail orders and rekey order information at the receiving end. It reduces the material lead time for production use.
- Connect applications and processes — With EDI capability, information, such as scheduling, orders, advance delivery notice, statistical process control data, and material safety data sheets can pass quickly and accurately from the supplier's computer application to the customer's computer application, so that arriving material can be put to production use with confidence. This meets one of the important goals of JIT, that is, to turn the supplier's entire production line into a vast stockroom so a company does not have to maintain a huge warehouse and the working capital tied to excess inventory.
- Improve relationship with customers and suppliers — In the supply chain environment, the quicker the chain moves, the better the customers' needs can be met. With quicker orders, acknowledgments, order changes, and invoices, EDI can satisfy customers' needs more quickly. Also, the time spent on order tracking and error recovery can now be used in a more productive way and can improve customer/supplier relationships. Companies deeply involved in EDI may see the number of suppliers reduced. This is because through the EDI process, a company can weed out many suppliers who are not efficient and reliable.

EDI Standards

When two organizations exchange business forms electronically, information is encoded and decoded by the computer software of both parties. Therefore, the information must be unambiguous, in order to avoid different interpretations. This relates to the meaning of the terms used, the representation of data used, the codes to be used for data, and the sequence in which data are to be transmitted. All these parameters must be arranged between the two parties on a detailed level.

There are many standard types of exchange — it can be based on bilateral agreement, imposed by a dominating party in a certain marketplace, or jointly developed by an industrial group. Some standards have been ratified by international organizations.

The pioneer of EDI standard development was the transportation industry. The Transportation Data Coordinating Committee (TDCC) developed sets of standards for transportation mode — air, ocean, motor, and rail. Later, the U.S. grocery industry developed a set of standards, the Uniform Communication Standard (UCS), based on the TDCC structure.

The TDCC and UCS are more geared toward the business forms exchanged by shipper/carrier, for example, bills of lading. Not until the American National Standards Institute (ANSI) got involved did a general-use standard for all industries start to develop, leading to the birth of ANSI X12 standards.

The ANSI X12 is popular in the U.S. Although ANSI X12 is intended for all industries, different user groups still come up with their own conventions to address their specific needs but remain under the X12 umbrella. To name a few, there are the Automotive Industry Action Group (AIAG) for the auto industry, CIDX for the chemical industry, and EIDC for the electronic industry.

In Europe, at approximately the same time period, under the leadership of the U.K., the Trade Data Interchange (TDI) was developed. The TDI syntax and structure are quite different from the ANSI X12. To resolve the incompatibility, the U.N. organization UNJEDI was formed to develop an EDI international standard containing features from both TDI and ANSI X12. The result was the EDI for Administrative, Commerce, and Transport (EDIFACT). This is the standard to which the world is trying to convert.

EDI Implementation

Before implementation of EDI, planning is critical to success. First, get all the right people involved in planning and implementation of EDI. Ensure that every employee gets EDI education on how to use EDI as a business tool to manage his or her job. Prepare a strategic plan to get approval and support from top management. Managers should be aware of the significant benefits of EDI and should appreciate the potential of EDI as a business methodology to improve the bottom line.

As part of a strategic plan, it is crucial to perform an operational evaluation. This evaluation details how the internal departments of the company function. For each paper document under evaluation, information flow is tracked, processing procedures are scrutinized, time is measured, and costs are calculated. This will provide top management with valuable information as important as industry trends and competition information. The operational evaluation provides the company with detailed documentation about how it does business in a paper-based environment. This information then serves as a benchmark against which to measure projected costs and benefits of the EDI model.

Once the strategic plan is in place, available resources must be allocated to the departments that will generate the most benefits for the company. Once EDI is implemented in the company, the next step is to sell it to trading partners to maximize the EDI investment.

Summary

EDI is on a fast-growing path. EDI software and communication services are available and not expensive. It will not be too long before EDI becomes mandatory as a business practice. If a company is determined to implement EDI, it should look beyond just connecting two computer systems. To achieve the best return on the EDI investment, one should try to use EDI to improve the existing processes within the organization and the relationship with customers and suppliers.

13.7 Electronics Manufacturing: Processes, Optimization, and Control

Roop L. Mahajan

Introduction

We live in the information age, and electronics technology is an important part of it. Since the invention of the transistor in 1947, and the introduction of integrated circuits (ICs) in 1958, the electronics industry has grown rapidly as evidenced by the intrinsic pervasiveness of electronic products in our lives. The sale of these products has been steadily on the rise over the last seven decades, as shown in Figure 13.7.1. In the U.S., starting from an industry-wide sales volume of approximately $210 billion in 1986, electronic sales in the year 2000 were close to $1 trillion.[1] A similar trend is seen in the sale of electronics worldwide. Figure 13.7.2 gives a snapshot view of total global sales in 1980, 1990, and 2000.[2] A breakdown of market share for several product groupings is also shown to indicate the increasing role played by electronic products in business, retail, and the computer industry. This impressive growth in the electronics industry has resulted in a significant change in the composition of the workforce in the U.S., as shown in Figure 13.7.3. About half of the workforce is now employed in the information industry that deals with gathering, creating, processing, disseminating, and using information. As we move into the next century, this fraction is expected to get even larger. It is needless to say that a healthy, competitive electronics industry is vital to the economic health of a nation.

As with other segments of the market, manufacturing is critical to the electronics industry. A classical definition of manufacturing is *an assemblage of all processes required to convert raw material into a finished product*. The raw material in electronics manufacturing is typically an IC, although in some subassembly operations, the starting material may be electronic components, modules, or subsystems. An IC is a collection of electronic circuits made by simultaneous formation of individual transistors, diodes, and resistors on a small chip of semiconductor material. These devices are interconnected to one another with a metal, such as aluminum, deposited on the chip surface. The semiconductor material is typically silicon (≈90% of the applications). For very high speed, high frequency, and optical applications, compound

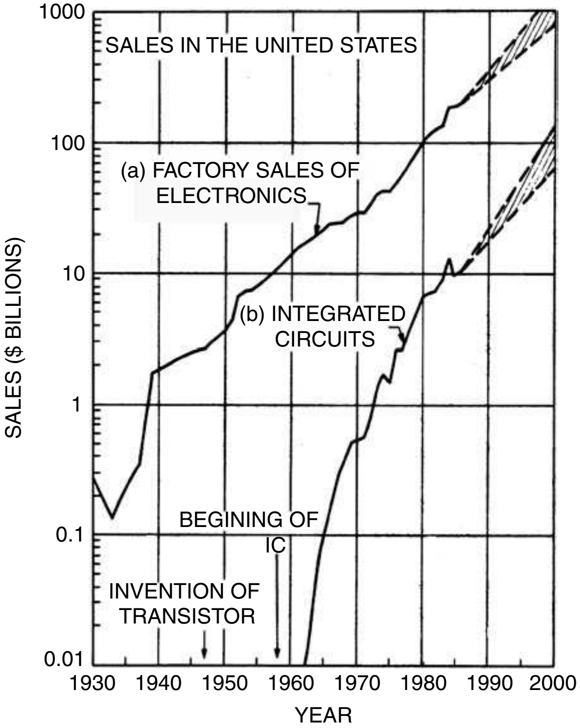

FIGURE 13.7.1 Factory sale of electronics and ICs in the U.S. (Source: Sze, S.M. 1988. *VLSI Technology*, McGraw-Hill, New York, 2.)

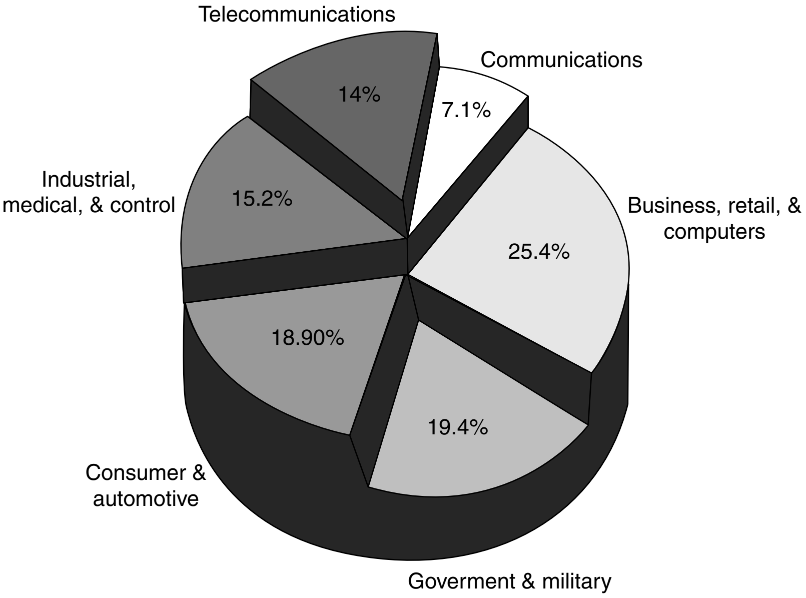
semiconductors gallium arsenide (GaAs) and indium phosphide (InP) are the materials of choice. In this chapter, our focus is on silicon ICs only.

IC fabrication is an extraordinary example of mass production and involves many complex manufacturing processes. Some of these are discussed to provide the reader an appreciation of the complexity of the tasks involved in modeling, optimizing, and controlling these processes.

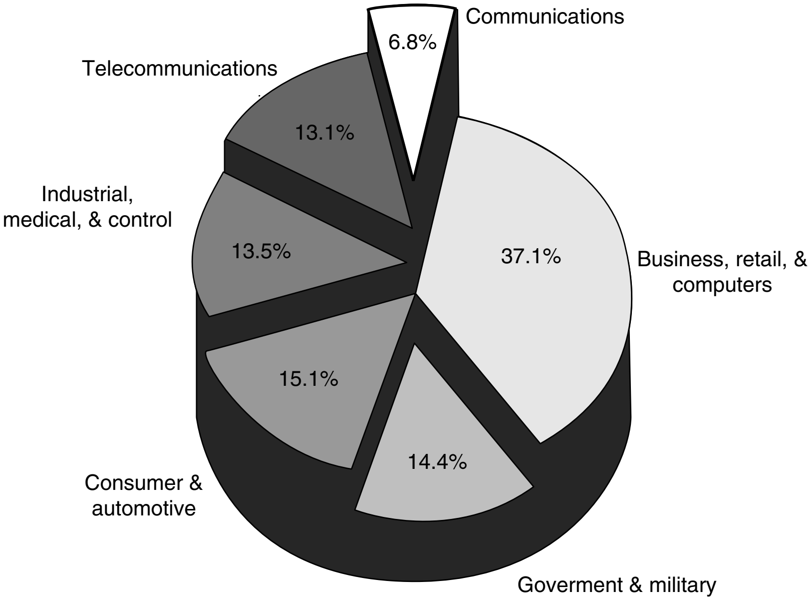
The final products cover an extremely wide range, from consumer electronics to supercomputers. The Semiconductor Industry Association (SIA) Technology Roadmap[3] categorizes these products by the following six market applications:

- *Commodity:* Consumer products, microcontrollers, disk drives, displays, costing less than $300
- *Handheld*: Battery-powered products, mobile products, handheld cellular telecommunications, other handheld products, costing less than $1000
- Cost performance: Notebooks, desktop personal computers, telecommunications, costing less than $3000
- High performance: High-end workstations, servers, avionics, supercomputers, costing $3000 and up
- Auto*motive:* Under-the-hood and other hostile requirements
- *Memory:* Dynamic random access memory (DRAM), standard RAM (SRAM)

A number of assembly processes are involved in converting an IC to any of the listed electronic products; see, for example, Figure 13.7.4, which shows the major stages in manufacturing of a desktop computer. Many of the manufacturing processes required in the production of desktop computers are common to most of the electronic products. These are introduced later in this chapter to give readers a feel for the complexity and diversity of the processes used.



1980 $220 billion



1990 $654 billion

FIGURE 13.7.2 Global electronics markets by product groups. (Source: Landers, T.L., Brown, W.D., Fant, E.N., Malstrom, E.M., and Schmitt, N.M. 1994. *Electronics Manufacturing Processes*, Prentice Hall, Englewood Cliffs, NJ, 8.)

The electronics market is extremely dynamic, highly competitive, and global in nature. There is a continuously increasing demand for higher performance at reduced costs. The industry has responded remarkably well by placing a larger number of devices (transistors, capacitors, resistors, and diodes) on a chip. This strategy has been made possible through a continuous shrinkage in minimum device

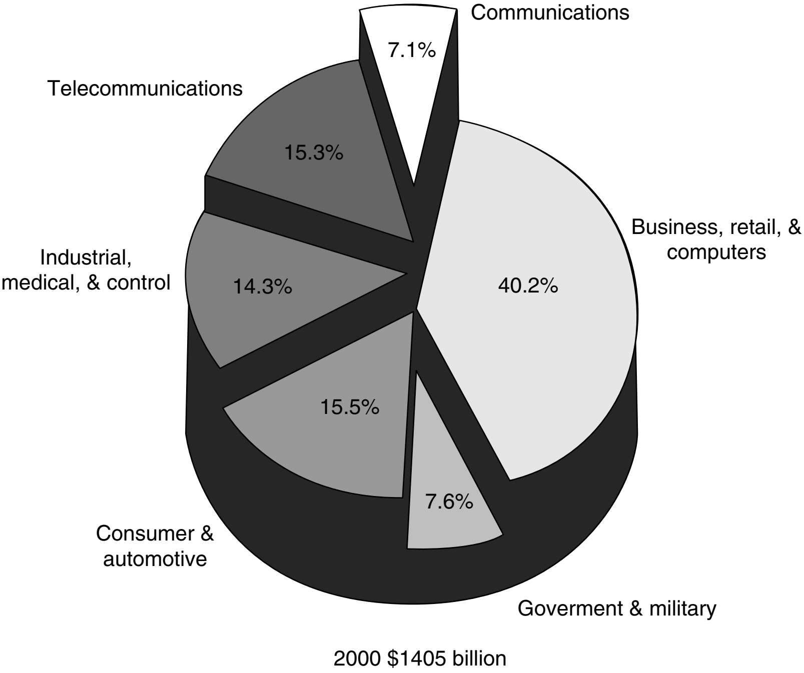


FIGURE 13.7.2 (continued)

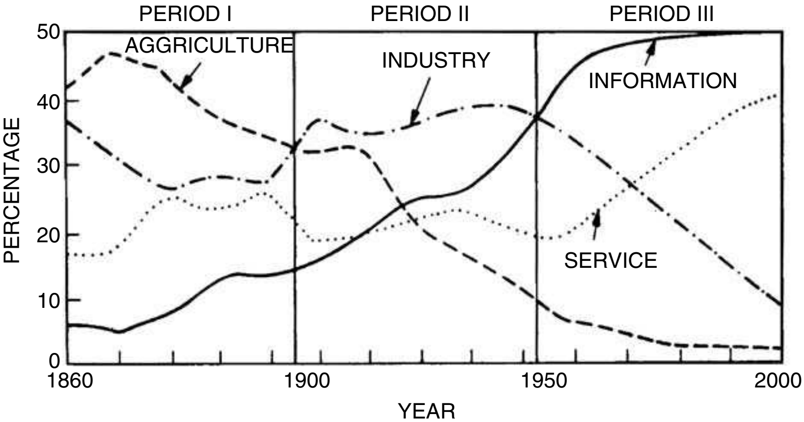

FIGURE 13.7.3 Changing composition of workforce in the U.S. (Source: Sze, S.M. 1988. *VLSI Technology*, McGraw-Hill, New York, 2.)

dimensions, as shown in Figure 13.7.5. Concomitantly, the cost per function has decreased by an average of 25%–30% per year. In 1999, the affordable packaged unit cost/bit for DRAM and microprocessors was 60 and 1735 microcents, respectively. These costs are expected to go down at an average of 29% for DRAM and 24% for microprocessors.[3]

To meet these aggressive goals and the fierce global competitive pressures, an electronic manufacturer has to ensure that each of the many processing steps involved is in control. The processes must be optimized for higher yields. Different strategies required for process optimization and control are the main focus of this chapter. Emphasis is on artificial neural networks that have evolved as a technique with considerable promise.

IC Fabrication

The structure of an IC is complex both in topography of its surface and its internal composition. The structure is made up of many layers, each of which is a detailed pattern. Some of the layers lie within the semiconductor wafer, and others are stacked on the top. The manufacturing process consists of forming this sequence of layers precisely to the design specifications.

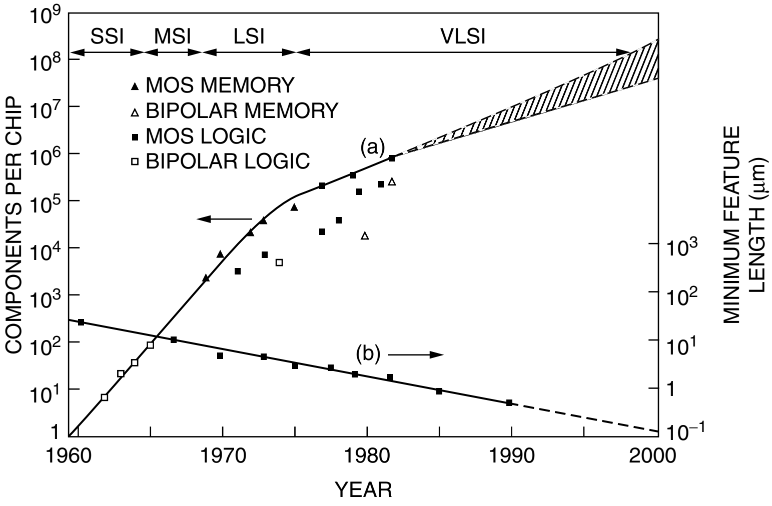

FIGURE 13.7.5 Evolution of minimum device dimension and number of components per IC chip. (Source: Sze, S.M. 1988. *VLSI Technology*, McGraw-Hill, New York, 2.)

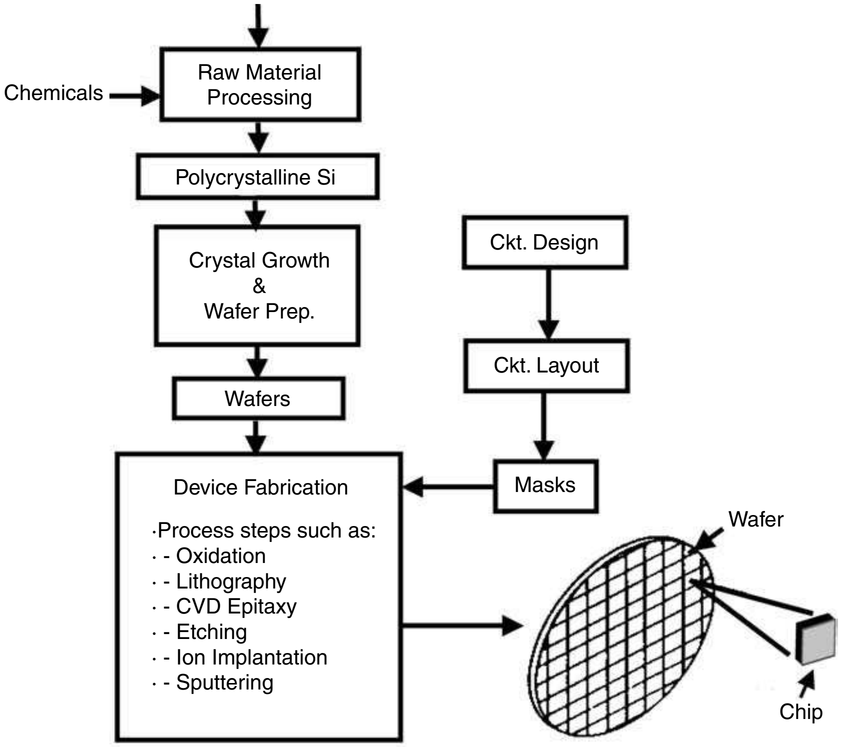

FIGURE 13.7.6 Fabrication sequence from raw material to chip.

A schematic of the device fabrication sequence is shown in Figure 13.7.6. The starting material for the device fabrication is a thin wafer of single crystal silicon doped with an appropriate impurity. The commonly used method to grow pure silicon crystals is the Czochralski method, in which polycrystalline silicon is melted in a quartz crucible (see Figure 13.7.7 for a schematic of this process). A small seed of monocrystalline silicon is dipped into the molten polycrystalline silicon to start the growth process. By

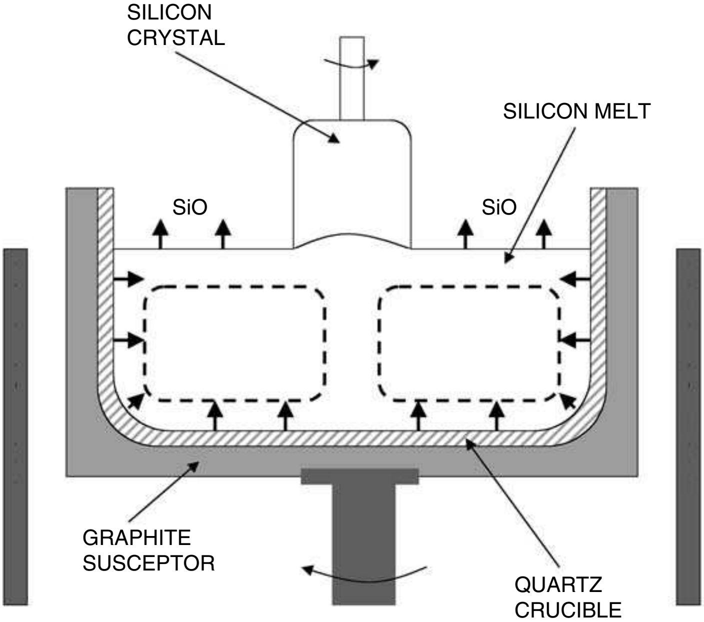

FIGURE 13.7.7 Schematic of Czochralski bulk growth of silicon.

a proper adjustment of the pull rate of the seed crystal and the amount of heat pumped into the crucible, a single crystal ingot of the desired diameter can be grown. As large as 300-mm diameter crystals are now grown, although 200-mm diameter crystals are still popular. The ingots are then sliced to thin wafers (to a thickness on the order of 0.5 mm), which are then polished and stacked in boxes.

It is noted that the polycrystalline material itself is produced using a number of complex manufacturing processes. The starting raw material there is either sand or metallurgical grade silicon. The latter may be available from ore processing, for example, iron refining. These processes include (1) melting silicon in an arc furnace, (2) generating silicon-containing gases (silanes and dichlorosilanes) in a fluidized bed reactor, (3) separation and purification, and (4) using a fluidized bed reactor or deposition chamber to produce polycrystalline silicon. All of these processes are lumped under "Raw Material Processing" in Figure 13.7.6. For more details on these, the reader is referred to Lee.[4]

Before the wafers can be processed in an IC fabrication facility, the circuit has to be designed to the given requirements and specifications, as shown in Figure 13.7.6. The design is generally carried out with the aid of a computer to arrive at the most space-conserving layout of the circuit's elements. The resulting layout is then converted into a set of oversized (generally tenfold) drawings with a schematic for each layer. After checking and correcting, a photographically reduced image of each layer is reproduced in a number of steps to yield a set of final-sized masks for different fabrication steps. Masks are made from emulsion-coated glass plates or glass covered with a hard surface material, such as silicon, iron oxide, chromium oxide, or chromium. A large number of working plates are copied from the final masks.

With the working copies ready, manufacturing can start to fabricate structures according to the design specifications. For illustration, consider the fabrication of a diode, shown in Figure 13.7.8. A diode is the simplest semiconductor device. In operation, it is similar to a one-way valve for fluid flow in that it conducts in one direction (forward) and blocks the flow of current in the opposite direction (reverse). Its role in IC fabrication is the electrical isolation of many different types of active components. The diode can be fabricated by forming a p-n junction either by forming a p-type region in an n-type semiconductor or vice versa, where an n-type semiconductor is formed by adding Group V elements (e.g., phosphorus) as an impurity (dopant) to silicon. A p-type semiconductor, on the other hand, is formed by adding Group III elements (e.g., aluminum) as dopant to silicon. The various steps involved

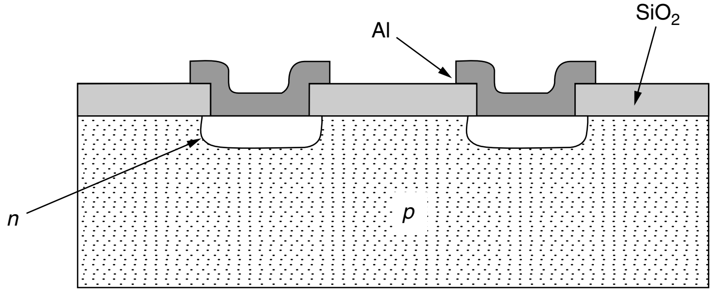

FIGURE 13.7.8 The p-n diode. (Source: Lee, H.H. 1990. *Fundamentals of Microelectronics Processing*, McGraw-Hill, New York, 42.)

in the fabrication of a p-n junction are shown in Figure 13.7.9. A brief description of the various fabrication processes involved is given next.

Oxidation (step 1 in Figure 13.7.9): Oxidation is a low-cost and accurately controlled process that is generally used to grow thin layers of silicon dioxide on silicon wafers. To accomplish this, silicon wafers are heated in an atmosphere of oxygen or water vapor at temperatures in the range between 900 and 1200°C. Oxygen arriving on the surface wafer surface combines with silicon to form silicon dioxide.

$$\mathrm{Si} + \mathrm{O_2} \Rightarrow \mathrm{SiO_2} \tag{13.7.1}$$

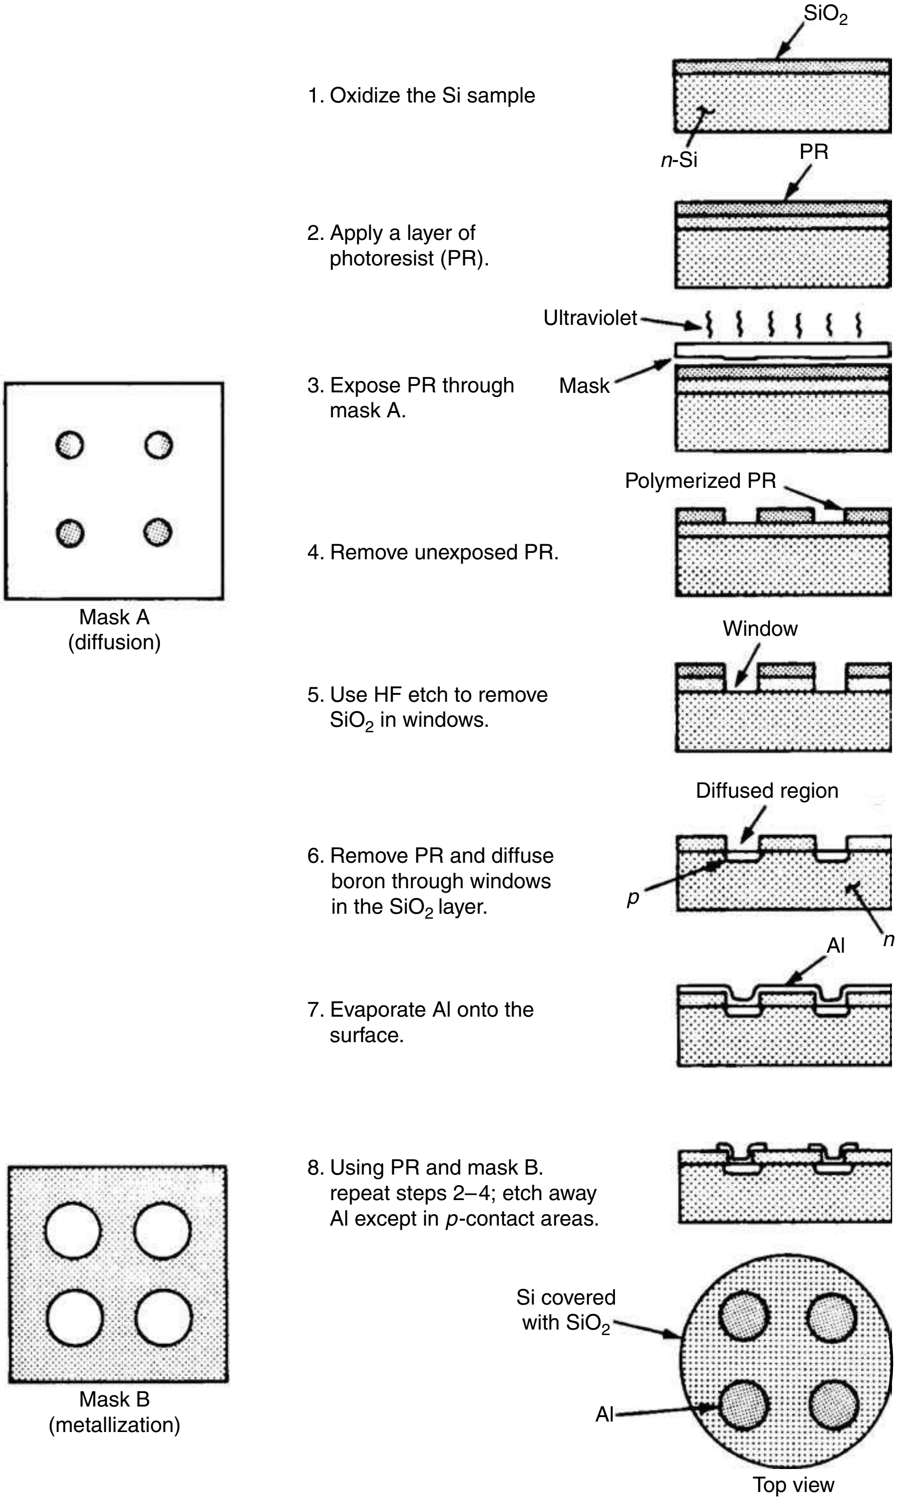
$$\mathrm{Si} + 2\mathrm{H_2O} \Rightarrow \mathrm{SiO_2} + 2\ \mathrm{H_2} \tag{13.7.2}$$

Selecting the appropriate time and temperature of oxidation can accurately control the exact thickness. The oxidation process is generally carried out in a high temperature furnace tube made of quartz, polycrystalline silicon, or silicon carbide. Up to several hundred wafers, separated by only a few millimeters, are loaded into slots in a quartz boat. Three zone resistance heated furnaces are used for precise temperature control.

Photolithography (steps 2 to 5 in Figure 13.7.9): This is a method for accurately forming patterns on the wafer and is probably the most important step in wafer fabrication. In operation, the oxidized surface is first coated with photoresist (PR) material that is generally a light-sensitive polymeric material. To accomplish this, a small amount of PR in a solvent is placed on the wafer. The wafer is held on a vacuum check and then spun rapidly at 1000 to 5000 rpm. The solvent evaporates, leaving behind a uniform layer of the polymeric film. A mild heat treatment dries the film thoroughly and enhances its adhesion to the silicon dioxide layer under it. Times range from 10 to 30 min in an oven at 80 to 90°C in an air or nitrogen atmosphere.

A photomask, a square glass plate with a patterned emulsion or metal film on one side, is placed over the wafer. The wafer is now exposed to ultraviolet radiation through the photomask. The photomask allows UV radiation to pass selectively on the wafer according to the preset pattern. The exposed PR material polymerizes and hardens. Following this, the PR is baked in an oven for 20 to 30 min. at 120 to 180°C to further harden the PR. Subsequent washing of the wafer in the selective solvent results in the removal of the unexposed PR film where the mask was opaque. The wafer, with its PR pattern, is now placed in a solution of buffered hydrofluoric acid that dissolves the oxide layer wherever it is unprotected. It is to be noted that the acid does not attack either the photoresist or the silicon wafer itself. After rinsing and drying, wafers are further exposed to another chemical treatment to strip the hardened PR material.

A net result of the steps described is the opening of windows in the wafer according to a preset pattern. These windows are now ready for the next fabrication step, which might be doping or deposition of a desired film.



1. Oxidize the Si sample
2. Apply a layer of photoresist (PR).
3. Expose PR through mask A.
4. Remove unexposed PR.
5. Use HF etch to remove SiO_2 in windows.
6. Remove PR and diffuse boron through windows in the SiO_2 layer.
7. Evaporate Al onto the surface.
8. Using PR and mask B. repeat steps 2–4; etch away Al except in *p*-contact areas.

FIGURE 13.7.9 Outline of steps in the fabrication of diodes. (Source: Lee, H.H. 1990. *Fundamentals of Microelectronics Processing*, McGraw-Hill, New York, 42.)

Doping (step 6 in Figure 13.7.9): To make a desired device, it is necessary to selectively induce impurities to create localized n-type or p-type regions. This can be accomplished either through diffusion or ion implantation. The former is similar to the oxidation process described earlier. Silicon wafers are heated to ~1000°C and dopants (boron, phosphorus, etc.) from a vapor or dopant-oxide source are introduced into the quartz tube carrying the wafers. Dopants diffuse through the exposed window in the silicon to form the desired n- or p-type regions.

In ion implantation, the dopant atoms are ionized and accelerated. The ion source operates at ≈25 kV and produces a plasma containing the dopant ions and some other undesired species. An analyzer magnet bends the ion beam through a right angle to select the desired dopant, which then passes through an aperture slit into the main accelerator column. Energy up to 175 KeV is added to the ions to accelerate them to their final velocity. These excited atoms strike the wafers and are embedded at various depths according to their mass and energy. The whole process takes place at room temperature.

The process provides more accurate control than diffusion. However, the wafers have to be annealed to minimize damage due to implantation.

Chemical Vapor Deposition (CVD): Chemical vapor deposition refers to the formation of a crystalline material on a substrate by the reactions of the chemicals from the vapor phase using an activation energy. CVD-deposited films are widely used in IC fabrication. These films provide conducting regions within the device, electrical insulation between metals, or protection from the environment. The material to be deposited is brought in a carrier gas in a reactor housing the heated wafers. The film material diffuses to the substrate wafer, where a chemical reaction takes place, resulting in deposition of the film over the wafers. For example, in epitaxial CVD deposition of silicon on silicon, silane (SiH_4) carried by hydrogen is brought over silicon wafers heated to ~1350°K. Silane decomposes to silicon, and hydrogen and silicon deposit on the wafers. Plasma or laser assisted CVD processes are also used when deposition is required at lower temperatures.

Three common CVD reactor configurations are shown in Figure 13.7.10. While the horizontal and vertical barrel reactors (Figure 13.10a and Figure 13.10b) are commonly used for silicon epitaxy, the tubular hot wall reactor (Figure 13.7.10c) is used for deposition of polysilicon and other dielectric films. Of these, the horizontal reactor (Figure 13.7.10a) is perhaps the oldest configuration. A silicon-coated graphite susceptor is housed in a quartz chamber, and is generally tilted by ≈3° to the horizontal. It has been shown, for example, by Ristorcelli and Mahajan[5] and Eversteyn et al.[6] that this tilt is necessary to ensure uniformity of deposition along the length of the susceptor. The wafers are heated through direct contact with the inductively heated graphite susceptor. The quartz chamber walls, in comparison, are cold. These reactors offer high throughput, but uniformity in deposition is difficult to achieve.

The IR (infrared) heated vertical barrel reactor is the workhorse of the industry for large-volume production of silicon epitaxial wafers. In a reactor of this design, silicon wafers rest in shallow pockets in a multifaceted, slightly tapered susceptor that is rotated inside a quartz bell jar. The most common mode of heating is through an array of IR lamps backed by reflectors. The mixture of appropriate gases enters through two nozzles at the top of the reactor and is exhausted through a central hole at the bottom. The ambient working pressure may be either atmospheric or about 0.1 atm.

In hot wall tubular reactors, Figure 13.7.10c, the quartz tube is heated from outside, and both reactor and wafers are assumed to be isothermal. Fifty to 200 wafers are stacked side by side with a constant small separation between them. The wafers are generally placed back to back, concentric to the tube x-sectional area so that the center of the wafer coincides with the axis of the tube. The total pressure in the heated zone varies from 0.1 to 10 torr, and the temperature ranges from 300 to 900°C.[4] The fluid distributes equally in the annular region between the periphery of the wafers and the inner wall of the reactor and provides the source gas to the inter-wafer region. The deposition is kinetically controlled and is affected mostly by the temperature distribution in the reactor.

Sputtering and evaporation (step 7 in Figure 13.7.9): In sputtering, the target material is bombarded by energetic ions to release (sputter) some atoms. These atoms are then condensed on the substrate to form a film. Evaporation is generally used to lay down the metallic conducting layers. The metallic charge

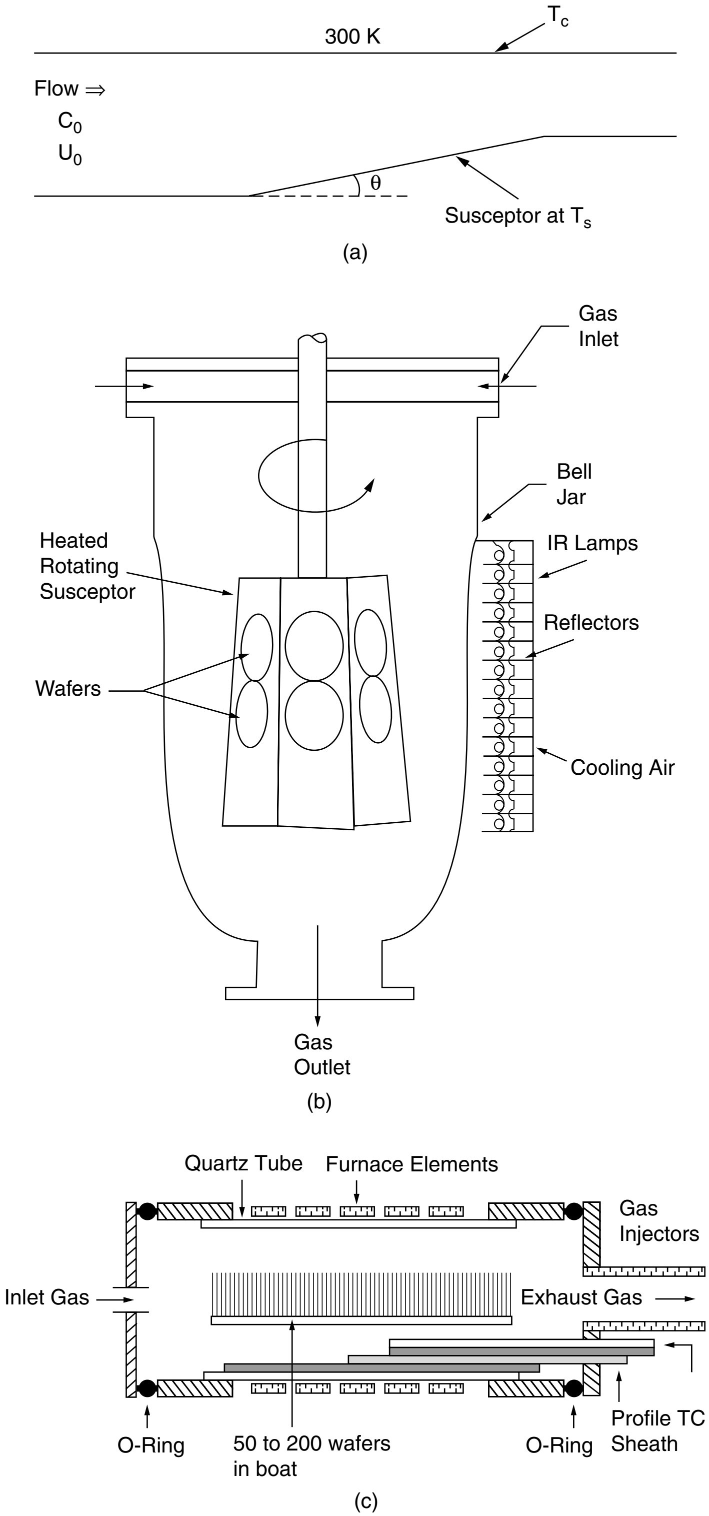


FIGURE 13.7.10 Three common CVD reactor configurations: (a) horizontal reactor; (b) vertical barrel reactor; (c) hot wall tubular reactor. (Source: Mahajan, R.L., Transport phenomena in chemical vapor deposition systems. *Advances in Heat Transfer*, 28, 339, 1996.)

(generally Al) is placed in a crucible, and the wafers are positioned above the charge in a movable fixture (planetary). A jar is lowered over the planetary and high vacuum is generated. Direct bombardment with high-energy electrons heats the metal charge. The charge evaporates and deposits on the wafers. Other forms of heating, for example, induction, resistance, or laser beam heating, can also be deployed.

Reactive plasma etching: The wet chemical etching described under photolithography can be replaced by dry etching, such as reactive plasma etching. In this technique, ionization and fragmentation of gases generated in plasma creates reactive species. These species bombard the substrate surface and remove or etch material from the surface regions not masked by lithographic patterns. Typical gases used are halogen compounds such as CF_4 and Cl_2. Additional gases such as H_2 or O_2 are included to provide desired selectivity and edge profile. For example, CF_4 in O_2 plasma gives rise to atomic fluorine, which then reacts with the surface and causes its removal.

It is noted that step 8 in Figure 13.7.9 is a repetition of steps 2 to 4. The fabrication steps for other semiconductor elements, such as transistors, are more numerous than those for the diode described here but essentially follow the same sequence. The structure is built layer by layer using photolithography to generate patterns according to the specified design for the next step, which could be doping or deposition. For more details on IC fabrication, the reader is referred to Sze,[1] Lee,[4] and Jaeger.[7]

From Chip to Final Product

The end product of the IC fabrication is a wafer with multiple chips on it (see Figure 13.7.6). Each IC (or die) on the wafer is probed to determine whether it functions properly. After testing, the wafer is sectioned to separate the individual chips. This is usually accomplished by scribing between the chips. Generally, a diamond-tipped scribe is used and scribing borders of 75 to 250 μm are formed around the periphery of the dice. Following scribing, the wafer is placed on a soft support and pressure is applied on the wafer using a roller. The wafer breaks along the scribe lines to give individual chips. As mentioned earlier, this good IC serves as the starting material for the final electronic product. Several subassembly processes, along with other feeder components, are encountered before the final finished product is out of the factory.

For example, consider the steps involved in the manufacture of a desktop computer. Referring to Figure 13.7.4, the first step in the assembly is housing the IC in a package called a chip carrier. The chip carriers protect the chips from the environment and provide connections from the chip pads to the circuit board. These are described next to facilitate an understanding of the various assembly steps involved.

Chip Carriers

Two types of chip carriers, through-hole and surface-mount components, are available. In the former (see Figure 13.7.11a), the components have leads that are connected to the pads on the chip. These leads are intended for pin in-hole mounting on the circuit board. The latter come in two categories: the leaded and the leadless. In the leaded surface-mount chip carriers, the leads are intended for attachment to the surface of the board (see Figure 13.7.11b). In the leadless, on the other hand, metallized pads are provided on the chip carrier to provide soldering surfaces for connection to the board (see Figure 13.7.11c). A brief description follows.

Through-Hole Chip Carriers

These come in a variety of configurations, as shown in Table 13.7.1. Of these, the plastic dual-inline package (DIP) is among the most commonly used. The manufacturing steps involved in its assembly are shown in Figure 13.7.12. Shown at the bottom of the figure is a lead frame, which is typically made of a copper alloy. It has a pad in the center to receive the IC and has leads that extend out of the package. As a first step in housing the IC, the dice bearing the finished circuits is first bonded to the central pad. Bonding methods vary depending on the quality of the chip carrier. For the metal lead frame, bonding can be performed using epoxies or polyimide adhesives with a metallic filler. The latter is needed to enhance the thermal conductivity of the epoxy and thus reduce the thermal resistance between the die and the package.

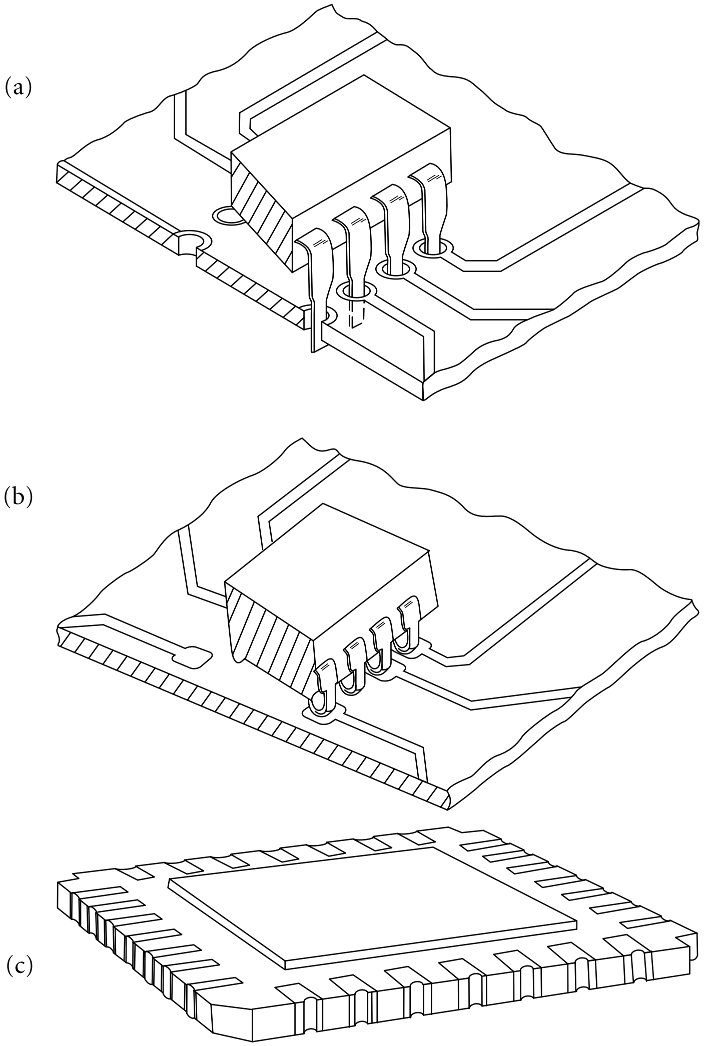

FIGURE 13.7.11 Through-hole and surface-mount chip carriers: (a) through-hole; (b) leaded surface-mount; (c) leadless surface-mount. (Sources: Landers, T.L., Brown, W.D., Fant, E.N., Malstrom, E.M., and Schmitt, N.M. 1994. *Electronics Manufacturing Processes*, Prentice Hall, Englewood Cliffs, NJ, 8. and Dally, J.W., *Packaging of Electronic Systems*, McGraw-Hill, New York, 1990.)

Fine wire leads are then connected from the aluminum bonding pads of the chip to the lead wires on the chip carrier using automatic wire bonding techniques. The protective housing is provided by injection molding of plastic over the frame. After separating individual packages, the leads are bent to produce the package.

Three commonly used automated wire bonding techniques are (1) thermocompression bonding, (2) ultrasonic bonding, and (3) thermosonic bonding. In the thermocompression bonding, a combination of pressure and temperature is used to weld fine gold wires (15 to 75 μm in diameter) to the chip pads and the package leads. Different steps used are shown schematically in Figure 13.7.13. The gold wire is fed from a spool through a heated capillary and a gold ball is formed using a hydrogen torch or electric spark (step a). The ball is positioned over the bonding pad, the capillary is lowered, and the ball deforms into a “nail head” as a result of the pressure and heat from the capillary (step b). Next, the capillary is raised and moved into position over the package (step c). A wedge bond is produced by deforming the wire with the edge of the capillary (step d). Finally, the capillary is raised and the wire is broken near

TABLE 13.7.1 Examples of Through-Hole Packages

PACKAGE NAME	OUTLINE	LEAD SPACING
S-DIP (SHRINK DIP)		1.78 mm
SKINNY DIP (OR SLIM DIP)		2.54 mm CERAMIC WIDTH 2/3 OR 1/2
SIP (SINGLE INLINE)		2.54 mm

QUIP (QUAD INLINE)		1.27 mm

Source: Sze[1]

the edge of the bond (step e). During this operation, the substrate is typically maintained at a temperature between 150 and 200°C, while the temperature of the bonding interface ranges from 280 to 350°C.

In ultrasonic bonding, aluminum wire is used instead of gold wire and the bond is made through a combination of pressure and ultrasonic vibration in the range of 20 to 60 KHz. The vibration causes the metal to deform and flow easily under pressure at room temperature. Thermosonic bonding combines the features of thermocompression and ultrasonic bonding in that the substrate is maintained at ~150°C, and ultrasonic vibration is also deployed. Excellent bonds result.

The DIPs just described are low-cost packages and are available with as few as four leads to more than 80 leads. For higher pin densities, pin grid array carriers are used (see Table 13.7.1). The body of the package provides a cavity for the chip and the pins are placed in a regular x-y array in the space around the cavity. Wire bonding is still used to connect the die to the gold interconnection lines, which fan out to the array of pins. Other popular through-hole packages are listed in Table 13.7.1.

Most of the through-hole packages are also available in ceramic casings. In the ceramic DIP, for example, the die is mounted in a cavity on a gold-plated ceramic substrate and wire-bonded to gold-plate Kovar leads. A ceramic or metal lid is then used to seal the top of the cavity. Typically, these packages are also hermetically sealed. Compared to plastic packages, ceramic packages are designed for use over a wider range of temperatures but are also more expensive. They are generally used in military and high-end commercial products.

Surface-Mount Packages

These packages offer higher densities than the counterpart through-hole packages. Holes are not necessary in the printed wiring boards (PWBs) to receive the lead wires from the through-hole components. As a result, the leads can be placed on lower pitches. For comparison, the lead pitch for DIPs is 100 mils, while for the surface-mount packages, the lead pitch is 50 mils or less. The packages with pitches of less than 50 mils are referred to as fine-pitch packages and are available in pitches of 33, 25, and 20 mils. Ultra fine pitch (< 20 mils) are also available. Further, both sides of the board can be used to accommodate components. These advantages have made surface-mount the packages of choice, although many of the boards even today deploy both surface-mount and through-hole packages. Note that as in through-hole components, surface-mount packages are also available both in plastic and ceramic bodies.

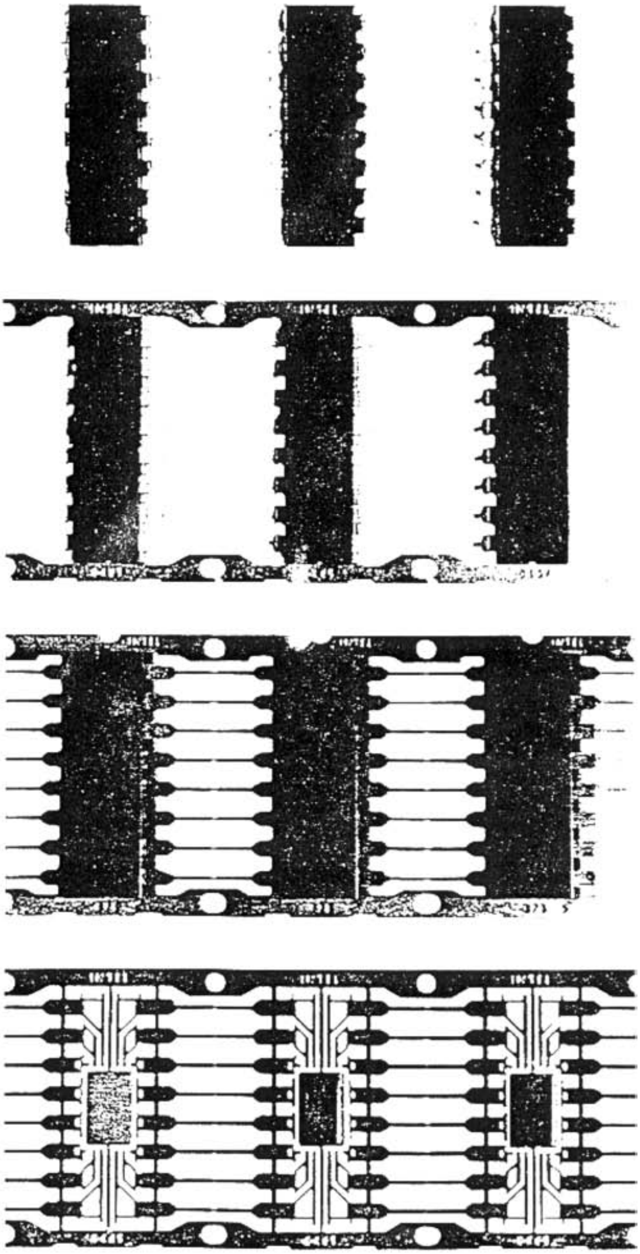

FIGURE 13.7.12 Steps involved in the manufacture of a DIP.

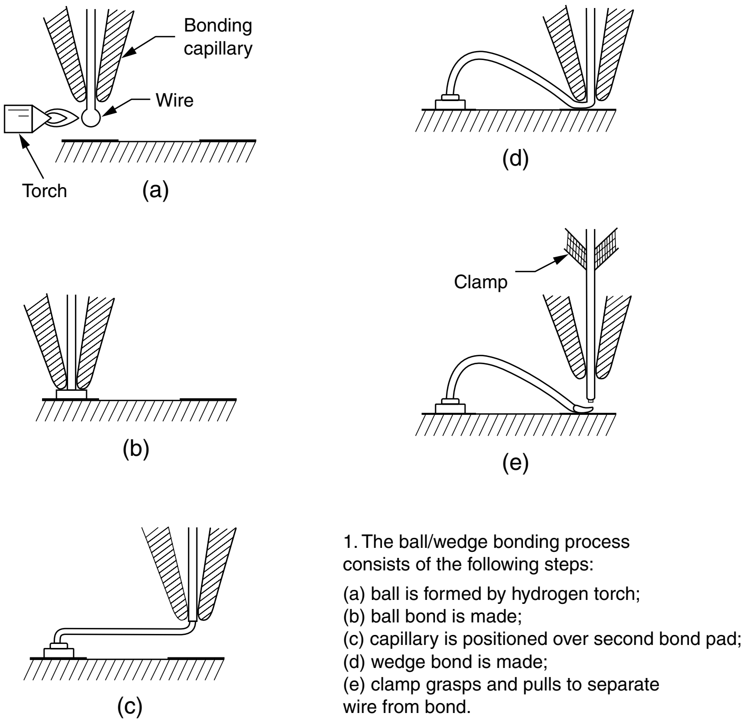
As mentioned earlier, the surface-mount components are available both in leaded and leadless configurations, as shown in Table 13.7.2. The types of leads used in the former are shown in Figure 13.7.14. All the styles permit soldering of the package directly to the board. Of the three, the gull-wing offers the advantage of visual inspection of the solder joint, but it takes more room on the PWB than the others. Also, the leads are more susceptible to damage during handling. The J-leads provide better protection against damage in handling, provide more clearance between the package and the PWB for easier cleaning, but are more expensive to make and inspect. The I-leads are simpler to manufacture than the J-leads, but care must be exercised to ensure coplanarity of the leads during shearing.



1. The ball/wedge bonding process consists of the following steps:
(a) ball is formed by hydrogen torch;
(b) ball bond is made;
(c) capillary is positioned over second bond pad;
(d) wedge bond is made;
(e) clamp grasps and pulls to separate wire from bond.

FIGURE 13.7.13 Thermosonic ball-wedge bonding of a gold wire. (Source: Dally, J.W., *Packaging of Electronic Systems*, McGraw-Hill, New York, 1990.)

In leadless chip carriers, the die is mounted in a cavity in the middle of the package and connections are made between the package and die using wire bonding. The cavity is then sealed with a cap of metal, ceramic or epoxy. All the leadless chip carriers have metallized pads around the perimeter of the package that allow the package to be soldered to a PWB.

Ball Grid Arrays

The surface-mount packages have progressively evolved toward finer pitches due to the continued demand for higher-density packages. However, at reduced pitches, the process window tightens, and the fine-pitch packages with their fragile leads pose serious handling problems. As a result, new packages called *ball grid arrays* have become very popular in recent years.

A ball grid array is an area array package like a pin grid array except that the leads are now replaced by solder balls. Two types of commonly used BGAs, ceramic ball grid arrays (CBGAs) and plastic ball grid arrays (PBGAs), are shown in Figure 13.7.15. The PBGA, also known as OMPAC (over molded plastic pad array) by Motorola, has a high-temperature laminate consisting of BT (bismaleimide triazene) resin. Other types of BGAs used in practice are ceramic column grid array and tape ball grid array. For more details, see Prasad.[9]

BGAs do not have the limitations of fine-pitch surface-mount packages since instead of fragile leads, they have robust solder balls at much higher pitches that permit higher density and their electrical performance is enhanced due to reduced inducatance and the resulting propagation delay. The additional price is in the increased layer count requirement on the board.

Attaching the Package to the Printed Wiring Board

The PWB is a type of substrate consisting of one or more layers of laminates and metal conductors that provide a mounting surface for electronic packages to be electrically connected and mechanically supported. Three common types of PWBs are the single-sided, double-sided, and multilayer boards. Their

TABLE 13.7.2 Examples of Surface-Mount Packages

Surface Mount	Shape	Material	Typical Features Lead Pitch	# of I/O Pins
Small Outline Package (SOP)		Plastic	• 1.27 mm (50 mil) • 2-direction lead	8–40
Quad Flat Package (QFP)		Plastic	• 1.0 mm • 0.8 mm • 0.65 mm • 4-direction lead	88–200
Flat Package of Glass (FPG)		Plastic	• 1.27 mm (50 mil) •.762 mm (30 mil) • 2-direction lead • 4-direction lead	20–80
Leadless Chip Carrier (LCC)		Plastic	• 1.27 mm (50 mil) • 1.016 mm (40 mil) •.762 mm (30 mil)	20–40
Plastic Leaded Chip Carrier (PLCC)		Plastic	• 1.27 mm (50 mil) • J-shaped bend • 4-direction lead	18–124
Very Small Quad Flat Package (VSQF)		Plastic	• 0.5 mm	32–100

fabrication involves a number of steps, including laminating, pressing, punching/drilling, image transfer, and soldering.

In the single-sided boards, base materials such as laminated layers of woven glass cloth impregnated with epoxy resin are joined together, treated, and cured to form "prepregs." A number of such prepregs are stacked to give the desired board thickness. The stack of prepregs is placed on top of copper foil, and the whole assembly is inserted into a press, which, through application of heat and pressure, binds the laminates together. The boards are then sized to the final dimensions. Following this, the circuit image is applied to the foil using photoresist and then etched so that all the wiring for the electronic components and attachment pods are aligned to match the corresponding leads or pads from the components. Holes are drilled or punched into these laminates for accommodating the through-hole components. Double-sided boards have circuit lines on both the top and bottom surfaces of the laminate. To accommodate any through-hole components, the circuits on the top and bottom sides are connected by drilling holes through the board whose inner surfaces are plated.

Multilayer boards, shown in Figure 13.7.16, are fabricated from several layers of laminates with pre-etched copper foils stacked together in a sandwich with pre-impregnated epoxy-glass sheets positioned between each layer. The assembly is then placed in a hot platen press to produce the finished product. As before, plated through-holes are incorporated in the board to provide connections to the interior planes. In some cases, the plated through-holes are filled with solder to act as thermal vias, which provide an additional thermal path for the heat to be dissipated away from the chip.

Different techniques are deployed for attaching through-hole and surface-mount packages to the board. For surface-mount components, stencil printing, followed by reflow soldering, is the common procedure. Simply stated, the stencil printing process, as shown schematically in Figure 13.7.17, is a process of pushing solder paste through the apertures in a thin metal stencil onto pads of a PWB. The

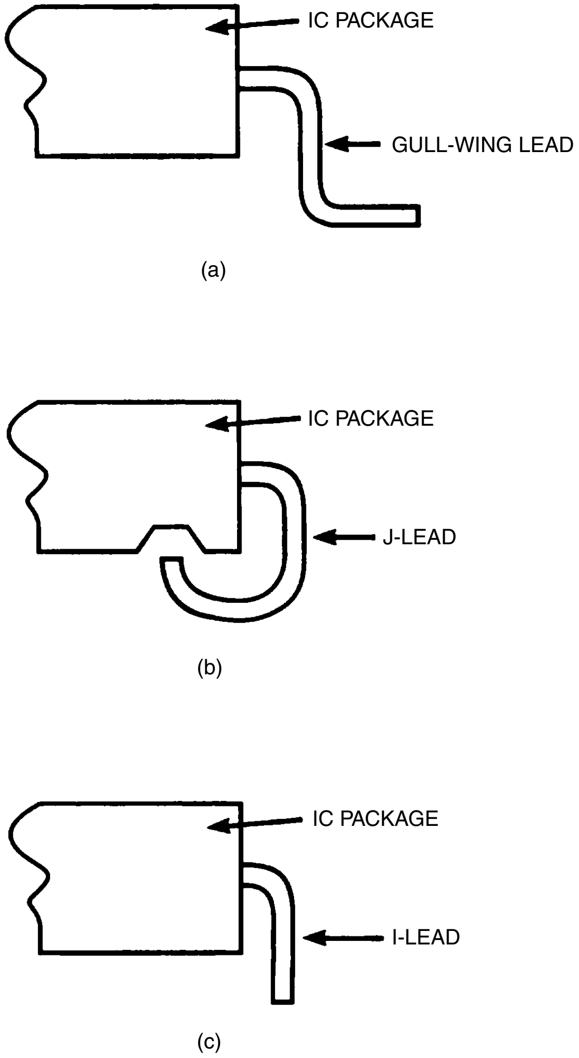


FIGURE 13.7.14 Lead configurations in leaded surface-mount packages.

stencil has openings that correspond to the solder pads on the board. The solder paste is first spread over the stencil, and the squeegee, during its travel over the stencil, forces the requisite amount of paste. The process is quite complex, and involves a large number of variables relating to solder paste, flux, stencil, squeegee, and environmental conditions. An empirical artificial neural network model relating these variables to the process output (the thickness of the solder paste dispensed) is developed later in this section and the optimum settings based on such a model are described.

With the solder paste in place, the surface-mount components are now positioned at the designated locations on the PWB using "pick and place" equipment. The pick and place machine, accompanied by part feeders, is an important part of a surface-mount assembly line. The line's throughput is primarily determined by the pick and place machine, and the majority of manufacturing defects that require rework arise from placement problems. As a result, careful selection of the equipment is important for quality production. For more details, the reader is referred to Prasad.[9]

The next step is reflow soldering using infrared (IR), vapor phase condensation, or convective air heating. Schematic diagrams of an IR oven, a vapor phase facility, and wave soldering machine are shown in Figure 13.7.18. The infrared oven, Figure 13.7.18a, consists of a series of IR panel heaters placed on

the top and bottom of the channel. Each of these heaters is maintained at a unique temperature. A conveyor carries the unsoldered PWB assemblies into the oven where the heaters provide the necessary thermal energy to remove volatiles from the solder paste, liquefy flux, and melt solder paste. In the cooler exit section of the oven, the solder solidifies to form the necessary bond between the modules and PWB. For more details on IR reflow soldering and modeling of the transport phenomena see Prasad,[9] Mahajan,[10] and Fernandes et al.[11]

Wave soldering (Figure 13.7.18b) deploys a pot of molten solder in which a pump produces a solder wave. The solder wave is adjusted to produce a flow of liquid solder that impinges on the underside of the circuit board that is traversed over the wave at an appropriate speed. As the board comes into contact with the wave, molten solder is supplied to all of the solder joints on the board. Several parameters, including wave temperature, the conveyor speed, the preheating temperature, and type of flux used, come into play in determining the assembly yield. The interactions between the various parameters are complex, and extensive experimentation is generally required to achieve optimum performance.[12]

Vapor phase condensation reflow-soldering, Figure 13.7.18c, is an attractive alternative to infrared reflow soldering, especially in those circumstances where accurate temperature control is desired. In principle, a body of hot saturated vapor at a temperature about 30°C above the melting temperature of the solder is generated in a container. As shown in Figure 13.7.18c, this is achieved by boiling the fluid in the container using immersion heaters and condensing them at the cooling coils placed at the top of the container. The fluid used is generally a Fluorinert fluid with a boiling temperature of ~215°C. The vapor is about 25 times heavier than air and is thus easy to confine. The PWB assembly, with the solder paste and components in place, is brought into the hot vapor zone by a conveyor. There, the vapors condense on the cooler part and transfer heat to the solder to reflow it. After the required residence time (typically on the order of one minute), the assembly is brought to rest in the exit region, where the solder solidifies. The maximum temperature attainable in this process is the boiling temperature of the fluid and the temperature everywhere in the assembly is uniform. For more details on this process, the reader is referred to Wenger and Mahajan[13–15] and Prasad.[9]

For attaching through-hole components to the PWB, the component leads are inserted into the plated through-holes in the PWB using automatic insertion tools. The PWB assembly is then passed over a wave soldering facility, as shown in Figure 13.7.18b, where molten solder wicks through the space between the component leads and the inner walls of the plated through-hole and forms a solder joint attaching the component to the board.

PWBs to Enclosure

The next stage in our journey to the finished product is the housing of the PWBs in an enclosure. (In Figure 13.7.4, the enclosure is the CPU chassis, which may be supplied by a contract manufacturer.) The enclosure supports the boards, provides a cooling medium (a small muffin fan in the CPU chassis), and provides protection from the environment. The PWBs are connected together with edge connectors that allow the boards to plug into a back panel, a wire wrap board, or cables.

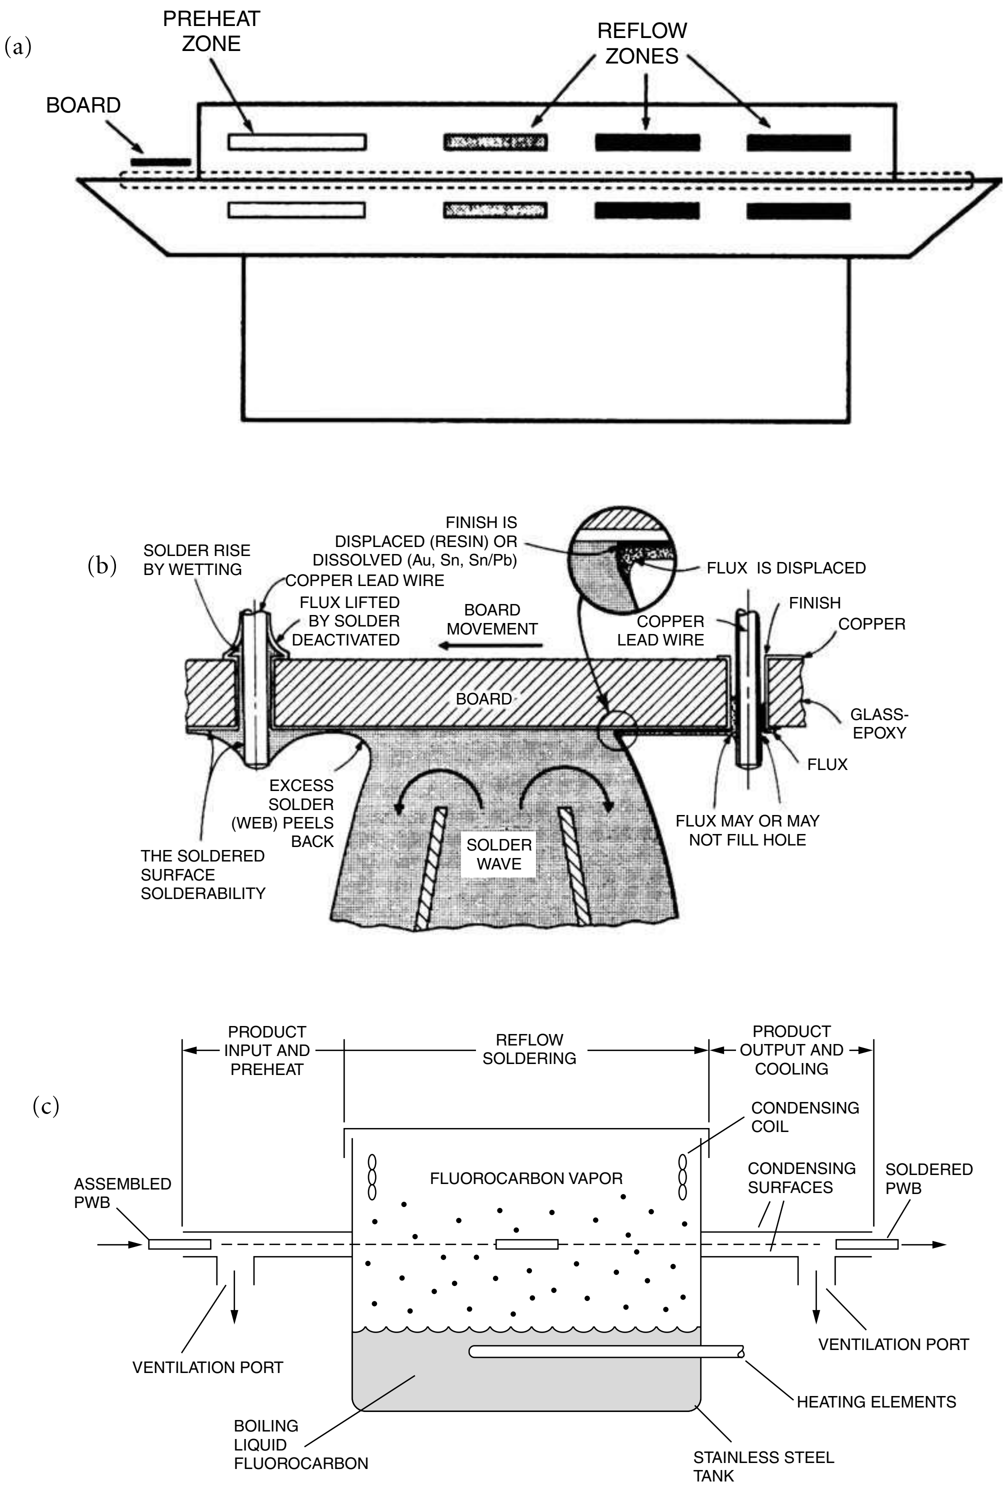

FIGURE 13.7.18 Three commonly used soldering (or reflow soldering) facilities. (a) an IR oven, (b) wave soldering, (c) vapor phase condensation soldering. (Sources: Dally, J.W., *Packaging of Electronic Systems*, McGraw-Hill, New York, 1990. and Prasad, R.P. 1997. *Surface Mount Technology*, Chapman & Hall, New York.)

The Finished Product

Finally, all the back panels, the circuit board, power supplies, and other accessories are housed in a cabinet. The other subassemblies, if any, are integrated to produce the complete electronic system. In Figure 13.7.4, the keyboard and monitor are fabricated and assembled separately and incorporated with the CPU chassis.

For further discussion of the different levels of packaging discussed, the reader is referred to Dally[8] and Landers et al.[2]

The Road to Process Optimization and Control

The goal of the first part of this section was to provide the reader with a feel for the basic nature of the electronics industry and the various processes involved in the manufacture of electronic products. The remainder of this section focuses on process modeling, optimization, and control.

The electronic markets are highly competitive and dynamic, and the processes are complex and diverse. As a result, attainment of higher yield at each manufacturing step is imperative and is the goal of every manufacturing organization. To achieve this, all the variables controlling the desired output in a given process need to be understood, optimized, and controlled to minimize variability and the attendant costs. In addition, the process controller must be quick to detect and correct any departures in the manufacturing process output from the optimum.

To meet these challenges, several tools and methodologies for control of electronic manufacturing processes have been developed over the years. These include conventional and multivariable response surface methodologies and artificial intelligence (artificial neural networks, fuzzy logic, expert system) based optimization and control algorithms. In most general terms, these are designed to address one of the following functions: (1) identifying robust settings for optimum performance, (2) determining whether a process has shifted from its desired settings suggesting equipment and process problems, (3) run-to-run control based on postprocess measurements, and (4) real-time control based on *in-situ* measurements (see Mahajan[16]). We discuss each of these functions and methodologies in some detail. Definitions of a "process," a process "in control," the causes of process variation, and statistical process control are introduced to set the stage for our discussion.

Process

Following the AT&T Statistical Quality Control Handbook,[17] a process is defined as "… any set of conditions, or set of causes, which work together to produce a given result." When applied to manufacturing, this generic definition of the term process may be defined as "a combination of labor, machines, tools, and methods used in a specific environment to manufacture a given product."

Process Variation

The ingredients comprising a manufacturing process — labor, machines, tools, methods — contribute to its variation. These, following Shehwart,[18] can be divided into two major components: (1) assignable causes of variation, and (2) inherent or random variation. While the former can be generally discovered and removed from the process, the latter, an aggregate of causes such as the routine variation of the incoming material, floor vibration, environmental changes, and operator influences, cannot be economically discovered and removed from the process without basic changes in the process. In general, random causes are the reasons behind the run-to-run variability of a process.

To understand quantitatively the structure or underlying patterns, if any, of these variations probability distributions are used. A probability distribution is a mathematical tool that gives the probability of occurrence of the value of a variable in the population. When the variable being measured is expressed on a continuous scale, the distribution is called a continuous distribution. On the other hand, when the variable takes on only discrete values, the probability distribution is called a discrete distribution. The commonly used discrete distributions are the hypergeometric distribution, the Binomial distribution, the Poisson distribution, and the Pascal distributions. For more details, the reader is referred to Montgomery.[42]

Examples of the continuous probability distributions include perhaps the most commonly used normal distribution, the exponential distribution, the gamma distribution, and the Weibull distribution.[42] A brief description of the characteristics of the normal distribution is given below. For the other distributions, the reader is referred to Montgomery.[42]

For a normal random variable, x, the probability distribution is mathematically given by

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2} \quad -\infty < x < \infty \tag{13.7.3}$$

where μ is the mean, σ is the standard deviation, and σ^2 is the variance. A normal distribution is shown graphically in Figure 13.7.19(a). The areas under the curves for the variable lying between $\mu \pm \sigma$, $\mu \pm 2\sigma$, and $\mu \pm 3\sigma$ are shown. For example, for a 3σ process, 99.73% of the values fall between the limits defined by the mean plus or minus three standard deviations.

The normal distribution is often assumed as the appropriate probability model for a random variable. The basis for this assumption is the central limit theorem which states that the sum of n independently distributed random variables is approximately normal, regardless of the distributions of the individual variables.[42] Mathematically, if $x_1, x_2 \ldots x_n$ are independent random variables with mean μ, and variance σ_i, and $y = x_1 + x_2 + x_3 + \ldots x_n$, then the distribution of

$$\frac{y - \sum_{i=1}^{n} \mu_i}{\sqrt{\sum_{i=1}^{n} \sigma_i^2}} \tag{13.7.4}$$

approaches the standard normal distribution N(0,1) distribution as $n \to \infty$ where 0 and 1 refer to the mean and standard deviation, respectively. The value of n for which the approximation may hold varies depending on the distribution of each x_i. If the distribution of each x_i does not depart radically from the normal, $n \geq 4$ may be sufficient for the applicability of the central limit theorem.[42]

These variations lead to deviation of the quality characteristic of the product to be manufactured from the target value, which in turn leads to degradation of quality and higher losses. Taguchi's[19] loss function is a recognized way of quantifying these losses and provides a strong motivation for tighter process control. Some of the commonly used measures of variation around the target are the process capability indices, C_p, C_{pu}, C_{pl}, and C_{pk}, where

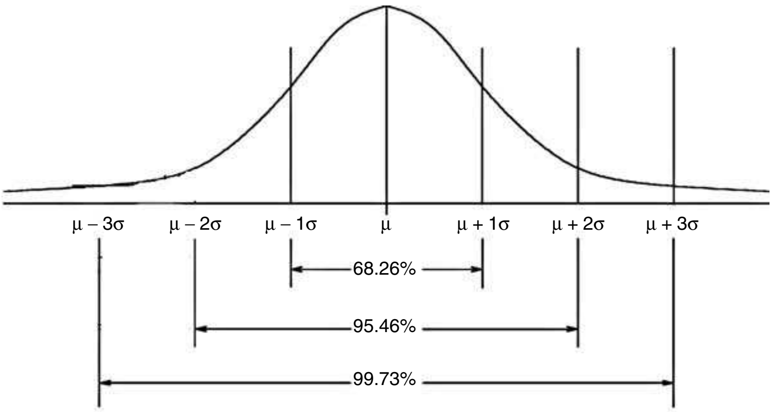
$$C_p = \frac{USL - LSL}{6\sigma} \tag{13.7.5}$$

$$C_{pu} = \frac{USL - \bar{x}}{3\sigma} \tag{13.7.6}$$

$$C_{pl} = \frac{\bar{x} - LSL}{3\sigma} \tag{13.7.7}$$

$$C_{pk} = \min\left(C_{pu}, C_{pl}\right) \tag{13.7.8}$$

where USL, LSL, $\bar{x}$ and σ refer to the upper specifications limit, the lower specification limit, the process average, and the standard deviation, respectively. C_p is a measure of the potential process performance that can be obtained if the process average is on the nominal of the specification limits for such a normally



(a) Normal distribution

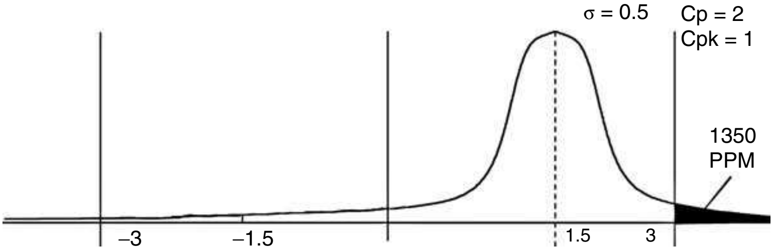
(c) 6σ Process, process mean centered around the nominal



(d) 3σ Process, process mean shifted off the nominal by 3σ.

FIGURE 13.7.19 Normal probability distributions with different values of C_p, C_{pk}.

distributed, ±3σ process, $C_p = 1$ (Figure 13.7.19b) and the associated defect rate is 2700 PPM. For $C_p = 2$ (Figure 13.7.19c), the process is much tighter and the fall out rate drops to 1.7 PPB. Since in actual practice it is common for the process average to shift from its nominal value, C_p does not truly reflect the process performance. C_{pk}, on the other hand, takes this shift into account and is probably a truer measure of the process performance. For example, consider Figure 13.7.19d. The process has $C_p = 2$, but its mean has shifted from its nominal value by 1/2 (USB-LSL). Its $C_{pk} = 1.0$. It is clear from the figure that the defect rate is 1350 PPM, which corresponds to one half of that for $C_p = 1$. Thus, both C_p and C_{pk}, used together, provide a good gage in measuring success of the process control efforts.

Statistical Process Control (SPC)

Introduced by Shehwart around 1930, SPC is a well-established tool used in production for process capability studies, process monitoring, and process improvement. Briefly, a process is in statistical control when it displays only random variations, as discussed earlier, and it is out of statistical control if there are unnatural patterns associated with assignable causes. Classical Shehwart control charts ($\overline{X} - R$, $\overline{X} - S$ and $X - R$) are tools that indicate whether the process is operating as consistently as possible. Here, $\overline{X}$, R, S and X are the sample average, the range, the sample standard deviation, and the individual sample value, respectively. Any unnatural variation suggests an assignable cause and the need for an alarm to take corrective action to bring the process under control. Some other control charts used in practice include the cumulative sum (CUSUM) control charts,[20] control charts with modified control limits,[21] and the moving average control charts, and multivariate charts.[22]

There are several electronic manufacturing processes where the simultaneous control of two or more related quality characteristics is necessary. Use of conventional SPC requires that these parameters be identically, independently, and normally distributed (IIND). However, typically these parameters are statistically correlated with each other, and controlling them using conventional SPC methodology can lead to error. This error increases with an increase in the number of quality characteristics. To allow SPC to be applied to such processes, several multivariate control schemes have been developed. Notable among these is a multivariable SPC scheme developed by Spanos et al.[23] and Spanos.[24] Under this scheme, using time series filters and multivariate statistics based on Hotelling's T^2 statistic, raw measurement signals are filtered to produce independent and normally distributed signals. These signals are combined into a single statistic that can be used to trigger an alarm. The scheme can be used both in a run-to-run and real-time mode. Note that the alarm generated is not based on product measurement but on process parameters that have no specified target value yet are related to how the equipment is functioning. A schematic of their real-time SPC scheme is shown in Figure 13.7.20.

Statistical process control tools allow us to monitor a process and raise a flag when the process exhibits "unnatural" shift due to assignable causes. The next logical step is to have the ability to make the process behave the way we want it to. The goal is to optimize the process and bring it back to the target value of its desired output characteristic. The first step to accomplish this task is to develop a model that captures the underlying relationship between input(s) and output(s). To this end, two kinds of models, physical and empirical, are generally used. These are described next.

Physical Models

These models are developed on the physical and chemical laws underlying a process. The governing equations based on these laws, along with the appropriate boundary conditions, are developed, which

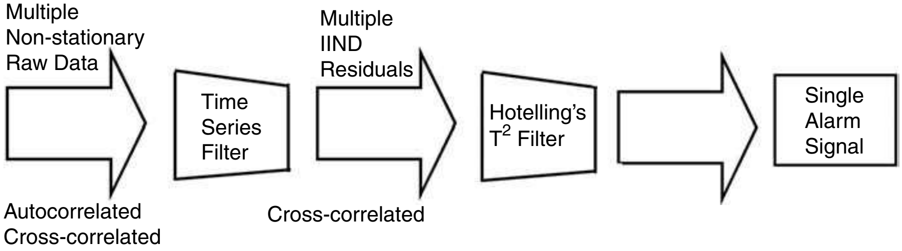


FIGURE 13.7.20 Schematic of the real-time SPC scheme. (Source: Spanos, C.J., Guo, H.F., Miller, A.,and Levine-Parrill, J., Real-time statistical process control using tool data. *IEEE Transactions on Semiconductor Manufacturing*, 5, 4, 308, 1992.)

are then solved analytically or numerically to provide the relationship between the governing parameters and the desired outputs. Consider, for example, the epitaxial growth of silicon by chemical vapor deposition in a horizontal reactor (see Figure 13.7.10a). The reactor consists of an entrance region, a deposition region, and an exit region. A carrier gas, typically H_2 with a small amount of silicon-bearing species, such as $SiCl_4$, SiH_4, $SiHCl_3$, or SiH_2Cl_2, and trace quantities of the desired dopant is passed over the hot wafers maintained at ~1350 K. As mentioned earlier, the silicon-bearing species diffuse from the bulk flow to the silicon substrate, where silicon is deposited by chemical reaction(s).

An important consideration in the epitaxial growth is the uniformity of layer thickness. To achieve this, a basic understanding of the various input parameters — (the inlet reactant concentration C_0, the flow rate U_0, the susceptor temperature Ts, and the downstream distance xy to the growth rate, $\dot{m}$ — is critical. Several analytical and experimental studies[5,6,25–28] on this subject have been reported. For a comprehensive review, see Mahajan.[29] A brief description of the analysis by Mahajan and Wei[28] is provided to give the readers a feel for the power of physical models.

The silicon deposition in the horizontal CVD reactor is diffusion controlled. That is, all the reactants that diffuse to the substrate are instantly consumed, leading to the deposition of a thin layer of silicon. Under these circumstances, the deposition is affected by the flow field in the reactor. Coupled equations of momentum, energy, and mass transport need to be solved to arrive at the deposition rate as a function of the input parameters. These equations for a two-dimensional, laminar flow were numerically solved by Mahajan and Wei.[28] Results were presented for both horizontal ($\theta = 0$), and tilted susceptors for different values of θ. A comparison with the experimental data of Eversteyn et al.[6] showed excellent agreement. It was also shown that the tilted susceptor, by increasing the flow velocity downstream, compensates for the depletion effect of the silicon-bearing species, and hence results in uniform deposition. The analysis suggested a value of $\theta = 2.5$ for optimum results. In actual practice, $\theta = 2.9°$. This agreement is excellent and indeed does point out the power of physical models.

The physical models are attractive since they provide a fundamental understanding of the relationships between the various input and output parameters. They are generally valid over a wide range of input parameters and can provide guidelines for the equipment design and process recipes. However, many a time, simplifying assumptions are made in developing these models to make the solutions tractable. The solutions then are approximate. As a result, their applicability for optimization and control is limited. Further, many of the electronics packaging and manufacturing processes tend to be complex, and hence, may not be amenable to accurate analytical or computational analysis. This difficulty in simulating complex assembly processes is one of the reasons for a general lack of enthusiasm for using physical models in real-life manufacturing.

Empirical Models

As opposed to physical models, empirical models, such as statistical regression, artificial neural networks (ANNs), and fuzzy logic (FL) models, are built from experimental data. Of these, statistical regression models are among those commonly deployed. Such models are accurate over the range in which they are developed. However, they do have their own limitations. They may require a large number of experimental points and may have poor predictive capabilities, especially when the number of input/output (I/O) variables is large. An attractive alternative is to use ANNs and FL techniques for building empirical models. These models can then form the basis for process optimization and control. In this chapter, our focus is on ANNs. However, the strategies discussed for process optimization and control also apply to FL modeling.[10]

Artificial Neural Networks

An artificial neural network is a parallel processing system of interconnected processing elements, *neurons*, which are connected together by weighted, directed interconnections. These interconnection weights are flexible parameters that are adjusted during the training procedure.

In a feed-forward neural network, such as the one shown in Figure 13.7.21, the neurons are organized in layers. There is an *input layer,* comprising input neurons that receive the input into the network; an

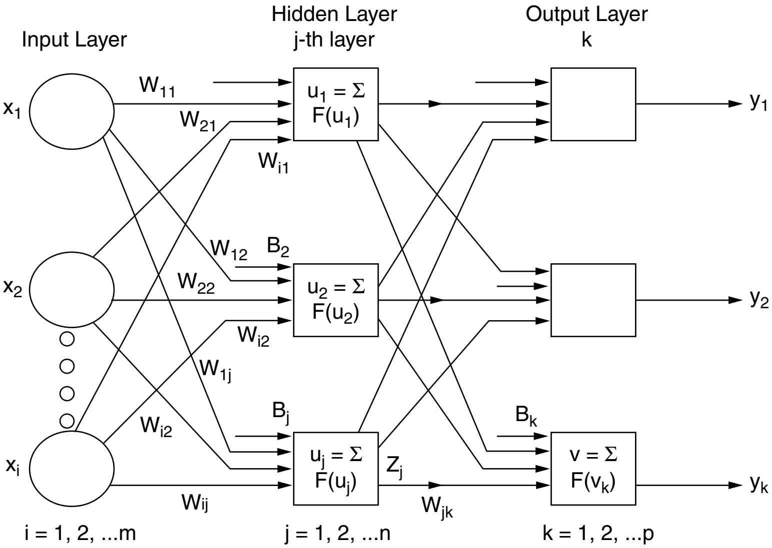

FIGURE 13.7.21 A typical artificial neural network structure. (Source: Marwah, M., Li, Y., and Mahajan, R.L., Integrated neural network modeling for electronic manufacturing. *J. Electronic Manufacturing*, 6, 2, 79, 1996.)

output layer, comprising output neurons that deliver the network's output; and one or several *hidden layers* sandwiched between the input and output layers. It is the neurons in the hidden layers that provide the processing. All interconnections are directed in the forward direction, which is defined as the direction from the input layer to the output layer. Thus, for example, a feed-forward neural network with a single hidden layer may be represented as

$$y_j^\ell = F\left(\sum_{i=1}^{N_{\ell-1}} W_{ij}^\ell y_i^{\ell-1} + B_j^\ell\right) \tag{13.7.9}$$

where y_j^ℓ is the output of the j-th neuron in the ℓ-th layer, W_{ij}^ℓ is the weight on the connection from the i-th neuron in the (ℓ -1)-th layer to the j-th neuron in the ℓ-th layer, B_j^ℓ is the bias connected to the j-th neuron in the ℓ-th neuron, and $N_{\ell-1}$ is the number of neurons in the $(\ell - 1)$-th layer. Note that $y_j^0 = x_i$, where x_i is the input and N_0 is the number of inputs, and F is an activation function that may be thought of as providing a nonlinear gain for the artificial neuron. Typically, F is the sigmoid function

$$F(u) = 1\big/(1 + e^{-u}) \tag{13.7.10}$$

It serves to bound the output from any neuron in the network and allows the network to handle both small and large signals.

Note that the weights (W_{ij} and B_j) are the adjustable variables in the above equation. The power of ANNs lies in the theorem that says that given sufficient hidden neurons the function represented by an ANN can approximate any function, however nonlinear, to arbitrary accuracy in a finite domain.[31] A neural network starts out with random weights, and the weights are adjusted until the required degree of accuracy is obtained. In the context of a neural network, this is *learning*. A powerful algorithm is available for training a neural network. This algorithm, called *back-propagation*, guarantees that a neural network will converge to the mapping underlying its training data. In fact, this algorithm is so relentless that care has to be taken to prevent overfitting of data when those training data are noisy. For a detailed description of neural networks and the back-propagation algorithm, refer to Werbos,[32] Haykin,[33] Smith,[34] and Wasserman.[35]

Source: Li et al.[39]

Recently, Marwah et al.[30] presented an integrated methodology to develop economical and predictive neural network models. The methodology includes data preprocessing, the simple-to-complex network structure approach, and simultaneous training and testing, where training and testing data are identified according to a statistical design of experiments (DOE) to capture the underlying I/O relationship. For some other approaches to determining the optimal neural network configuration, see references 36–38.

Some of the distinguishing features of neural networks are their learning and generalization abilities and nonlinearity. They are thus excellent candidates for modeling the nonlinear, complex, and noisy processes, such as those encountered in electronics manufacturing. A representative application to stencil printing, described earlier, is examined next.

Application to Stencil Printing

As mentioned earlier, the factors affecting solder paste printing are many (see Li et al.[39]). As many as 32 parameters relating to solder paste, stencil design, and machine process parameters were identified. Clearly, building reliable physical models for such a complex process is an extremely difficult task. Li et al. fixed the stencil design and solder paste parameters and built an ANN model relating the machine process parameters to the height of the solder paste dispensed. The six machine parameters listed in Table 13.7.3 were selected as the main effects requiring investigation.

To generate the training and testing data for an ANN model for the stencil printing process, a Taguchi array L27 was selected to set up the experiment. The experiments were conducted on a FUJI-GSP-II printer on one of the assembly lines. The stencil used was of stainless steel with the thickness stepped down to 8, 6, and 4 mils. The board material was FR-4. The solder paste's composition was 63 Sn/37 Pb with powered mesh –325/+500, and the metal load was 90% (w/w). The paste viscosity was 1000 ± 10% kpcs, and the pads on the board were of 20 mil, 25 mil, and 50 mil pitch. A total of 54 experimental runs, 27 for each direction of the printer, were made. The solder paste height on the three 20-mil pitch pads, four 25-mil pitch pads, and seven 50-mil pitch pads was measured on each board using a laser section microscope.

The experimental trials were randomized. The solder paste height on the three 20-mil pitch pads, four 25-mil pitch pads, and seven 50-mil pitch pads was measured on each board. The mean, $\bar{h}$, and the standard deviation (σ) were computed for each pattern for all the 27 trials using Equation 13.7.11 and Equation 13.7.12:

$$\bar{h} = \frac{1}{N} \sum_{i=1}^{1} h_i \tag{13.7.11}$$

$$\sigma = \sqrt{\frac{\sum_{i=1}^{N} \left(h_i - \bar{h}\right)^2}{N-1}} \tag{13.7.12}$$

where h_i is the solder paste height at site i and N is the number of sites measured for each pattern. Thus, a total of 27 data points were obtained. These were then used to develop the neural network models.

Following the neural network modeling approach described by Marwah et al.,[30] the optimum network structure for the mean paste height was found to be 6-4-3, where the three numbers represented the six input neurons corresponding to the six design parameters, four hidden neurons, and the three output neurons corresponding to the mean height for 20-, 25-, and 50-mil pitch pads. The testing relative error, ε_{rel}, for the 20-, 25-, and 50-mil pitch pads was found to be 4%, 4%, and 5%, respectively, where

$$\varepsilon_{rel} = \frac{1}{N}\sum_{i=1}^{N}\frac{\hat{y}_i - y_i}{y_i} \tag{13.7.13}$$

where $\hat{y}_i$ = the predicted output; y_i = the actual output and N is the total number of data points.

A neural network for the standard deviation σ was built to capture the relationship between the inputs and σ. The optimum network structure, in this case, was found to be 6-3-1. The testing relative error was 18%. Considering the relatively small values of σ and data points involved, this kind of relative error was considered to be reasonably good. The variation model formed the basis for determining the optimum settings for minimum variation.

ANN Models as Real-Time Process Analysis Tools

Once an ANN process model has been built to learn the input(s)-output(s) relationship, it can then be used in a predictive mode for providing very fast response to "what if" scenarios. In a reliability simulation study of solder joints, Subbarayan et al.[40] investigated the influence of manufacturing process-induced variations in four design parameters on the fatigue life of solder joints in the 72 I/O OMPAC BGA Package (Figure 13.7.15a). The four parameters were PWB pad size, solder volume, solder joint height, and substrate pad size. The finite element solutions were used to train an ANN. The CPU time taken by the ANN model on a DEC Alphastation 200 4/233 workstation was less than one second. In comparison, an average finite element simulation of the equations took a total of 175 minutes of CPU time. This significant advantage in the speed of analysis is due to the parallel computing process in the neural network. This capability is particularly important in complex electronic manufacturing processes where the process output tends to drift and shift with time. To bring the process back under control, the process technician/engineer, based on his or her past experience, may want to change the input parameters. Instead of conducting a test run and possibly incurring production losses, the technician/engineer can run the simulation on the ANN model that has been trained on the process, and obtain in almost real time an answer to whether the stipulated changes will occur.

Process Optimization

Process optimization may be viewed as an example of off-line process control, where the objective is to estimate the optimal operating point.[41] After fine-tuning, the initial settings provided by optimization may serve to provide guidelines for the local domain in which the process controller ensures that a product is produced to its targeted characteristics.

The most commonly used approach in process optimization is response surface methodology (RSM). RSM is a collection of mathematical and statistical techniques.[42] It uses a low-order polynomial in a local region constructed on the data obtained from the DOE. The gradient descent method is then used to search for the optimum.

Statistical RSM has proven to be effective in many applications. However, as mentioned earlier, when the process is influenced by a large number of variables, is highly nonlinear, and has multiple outputs, the conventional statistical RSM has some limitations. For example, the low-order polynomial cannot fit discrete data well.[43] As an improvement, Guo and Sachs[44] have proposed a "multiple response surfaces" methodology. They use multiple, low-order polynomials to model the output characteristics at each of

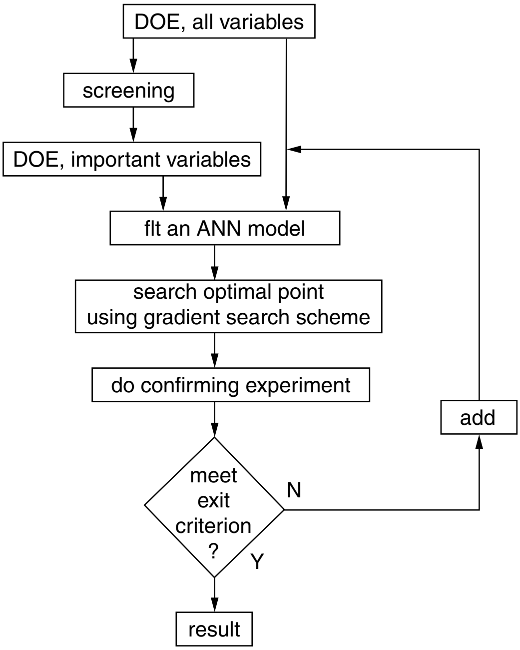

FIGURE 13.7.22 Process optimization using neural network model. (Source: Wang, X.A., and Mahajan, R.L., Artificial neural network model-based run-to-run process controller. *IEEE Transactions on CPMT — Part C*, 19, 19, 1996.)

the measurement sites within a batch of products. The general model is then obtained by manipulating these multiple models.

Since neural nets have excellent correlating capabilities, it is reasonable to expect that the replacement of statistical polynomial regression models by neural network models can lead to economy of experiments in locating the optimum. The methodology for arriving at the optimum settings is shown schematically in Figure 13.7.22. The neural network model, in conjunction with a search algorithm, such as steepest gradient, is used to determine the optimum settings for the desired output. If the predicted output is not satisfactorily confirmed by the experimental data, the indication is that the ANN model may not be that accurate in the region near the optimum. The strategy then is to add the new experimental data to retrain the model. The new model predicts the optimum settings, the accuracy of which is verified again. The process is iterated until the desired accuracy is achieved.

Li et al.[39] used this approach to identify the optimum settings for the stencil printing process described earlier. Based on the ANN model for σ, the optimum settings for the six factors given in Table 13.7.3 for minimum variation were determined, where σ is the standard deviation in the height of paste dispensed. These settings and results are given in Table 13.7.4, where m and c denote metal and bare copper for squeege and pad, respectively.

TABLE 13.7.4 Optimum Settings and Confirmation Results for Stencil Printing

A	B	C	D	E	F	Network Predicted σ	Confirmation Results (trial no.) σ
m	c	7	0.375	22	30	0.28	0.28 (1) 0.26 (2) 0.26 (3)

Source: Li et al.[39]

The actual values of the standard deviation, σ, for three production runs made at these optimum settings are also given in the table. The match between the prediction and the experiments is excellent.

Wang and Mahajan[43] used the algorithm shown in Figure 13.7.22 to demonstrate that ANN RSM outperformed the conventional statistical RSM in arriving at the optimum with fewer experimental data points. The test vehicle used was a production CVD silicon epitaxial barrel reactor (see Figure 13.7.10b). The conclusions were that both for the noise-free and noisy data, the ANN RSM outperformed the statistical RSM in providing more accurate settings with fewer data points. The difference was more significant for noisy data.

Fault Diagnosis

In manufacturing, a common experience is that a process drifts or shifts from its normal performance due to assignable or nonassignable causes. The first step in bringing the process back in control is to detect any significant deviation in the output from the target or norm. Artificial neural networks have traditionally been deployed in pattern recognition and have been shown to provide excellent performance.[46] This strength of ANNs can be exploited in fault diagnosis in manufacturing. The behavior of some characteristic output quantities associated with normal operation as well as certain events can be used to train a neural network to distinguish between normal and off-normal operation and to classify event signatures.

The concept of a spatial and temporal classifier is outlined in Mahajan et al.[47] The former relies on relations between spatially distributed data. These relations define the normality of the process, and sufficient deviation from them is used as a basis for alarms. This approach is useful when consecutive run data are not available. When enough run-by-run data are available, a time series (temporal) event classifier can be designed. Then, time variations in the data over consecutive runs are indicators of shifts and drifts.

Specific events cause characteristic variations in the data. For both spatial and temporal classifiers, neural network models can be trained for the spatial/temporal relations that exist for normal runs and for events.[48] When the operation data are fed into the classifier, the classifier matches the variation to the pre-learned patterns of the different neural networks for events and the normal operation of the process. This discrimination triggers the appropriate control action.

Run-by-Run and Real-Time Process Control

With the fault diagnosis completed, we now need to consider strategies to control a process. Two strategies, run-by-run and real-time control, are available. In the run-by-run controller, diagnosis and adjustment are achieved between runs based on the results of postprocess and *in-situ* measurements (if available) from the current process step and postprocess measurements from the previous steps.[41] In the real-time control, *in-situ* measurements form the basis for process adjustments during a run to bring a process as close to the target as possible.

A multitude of strategies have been developed over the years to achieve manufacturing process control. One way to describe these is to categorize them into two different paradigms: (a) analytical control theory paradigm, and (b) nonanalytical control paradigm. A spirited discussion of these two paradigms is given in Mamdani.[50]

The analytic control theory paradigm, based on the dynamic system theory, assumes that many dynamical systems can be mathematically modeled. System controllers using well-established mathematical techniques can then be analyzed and designed to achieve control. However, as mentioned earlier, there are many processes that may not be amenable to mathematical analysis. This is especially true for the more complex electronic manufacturing processes. This difficulty has led to nonanalytic controls that do away with the mathematical modeling requirement.

The nonanalytic control paradigm control strategy depends on the techniques in the fields of artificial intelligence and pattern recognition to develop diagnostic and control tools. The information about the process is obtained from the experimental data, which may be used in raw form or from I/O models based on the experimental data. The AI techniques used include, among others, rule-based systems, machine learning methods, protocol analysis, neural networks, and FL.

In conventional expert systems, rules to determine corrective actions are developed using a knowledge base (the knowledge gleaned from experts) and inference procedures. For complex manufacturing systems, however, one needs a large amount of knowledge and some means of accurately capturing the many years of experience of an expert or a team of experts.[51] As a result, conventional expert systems have not found a wider acceptance in the control of electronic manufacturing processes.

In one approach to overcome this difficulty, Irani et al.[52] utilize machine learning in extracting knowledge from data. Using their machine learning algorithm (GID3), a modified version of Quinlan's ID3 (1986), a decision tree can be induced from a given set of training data, which (the tree) can then be translated into a set of rules for use in expert systems.

In another approach, control is achieved through automatic process control (APC). In this strategy, variation is minimized not by removing its root cause but rather by transferring the variation into another variable, the manipulated variable.[53] Based on the feedback, the manipulated variable is adjusted to compensate for the process variation.

In integrated automatic-statistical process control (IASPC), the features of both SPC and APC are integrated to gain process control. Vander Weil et al.[54] used this approach (they termed it algorithmic statistical process control) to achieve quality improvement through appropriate process adjustment and elimination of root causes of variability signaled by statistical monitors. They used an autoregressive moving average function (ARMA) model to map the relationship between the off-normal deviation in the output for the current run and that in the input for the previous run. This model provided the compensatory adjustments from run to run. Simultaneously, a cumulative sum (CUSUM) chart was used to detect and provide statistical monitoring of any deviation of the closed-loop process from the estimated model and control algorithm. Application of this methodology to control and monitoring of viscosity in a polymerization process demonstrated success.

Mozumder and Barna[55] proposed applying Western Electric rules to determine an "out-of-control" or "out-of-specification" signal followed by adjustment of the process/equipment models to match the new state of the equipment.

Hu et al.[56] proposed a run-by-run controller that combined SPC and model-based feedback APC. This controller operates in three modes: gradual, rapid, and generalized SPC mode. In the gradual mode, the exponential weighted moving average (EWMA) is used to update a linear controller so that it can catch up with the changing process. Consider, for example, a simple process $y = a + bx$. Assuming that b is constant and only a shifts, a can be estimated at time t as follows:

$$a_t = y_t - bx_t \tag{13.7.14}$$

Applying the EWMA to at

$$a_{et} = wa_t + \left(1 - w\right) a_{e(t-1)} \tag{13.7.15}$$

where w is a weight factor of the EWMA and subscripts t and e_t refer to the time and the EWMA value at time t, respectively. Based on Equation 13.7.14 and Equation 13.7.15, the new setting for the next run is simply

$$x_t = \frac{y_t - a_{et}}{b} \tag{13.7.16}$$

The control adjustment is made every run.

In the rapid mode, the controller approximates the magnitude of the shift and assesses the probability of the shift. Based on this information, the control action is determined. For example, for a given estimated

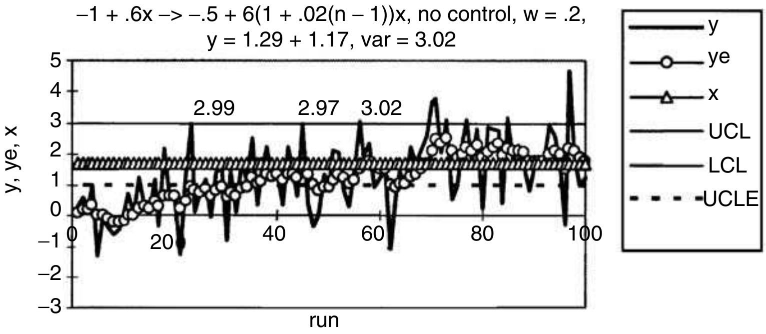

FIGURE 13.7.23 A shifting and drifting process without control (Source: Wang, X.A., and Mahajan, R.L., Artificial neural network model-based run-to-run process controller. *IEEE Transactions on CPMT — Part C*, 19, 19, 1996.)

magnitude, the controller action is smaller for small values of the estimated shift probability, and vice versa. The choice between the gradual and rapid mode is dictated by generalized SPC. For details, see Hu et al.[56]

Note that the EWMA acts as a filter for the process output noise. The smaller the w, the stronger the filter. As a limiting case of $w = 0$, the EWMA ignores the current Δy_t; then $\Delta y_{et} = \Delta y_{e(t-1)} = \Delta y_{e0} = 0$. It thus completely filters out all the noise and the signal changes. For $w = 1$, the EWMA does not filter out any noise, and the EWMA chart becomes the Shewhart chart. In addition to acting as a filter, the EWMA serves to detect process drift and small shifts.[42,57] Drift is generally associated with a slow change in the quality characteristic on the order of 1σ over a period of 100 to 1000 runs.[56] Shift, on the other hand, describes a sudden change in the output characteristic. It can occur, for example, after maintenance operations or specification changes and may be large, on the order of 2σ or larger. It occurs over a few runs. However, as pointed out in Montgomery,[42] the EWMA is not very effective in detecting large shifts. Further, the optimum value of w is a function of the magnitude of the shift. For small shifts, w = 0.2 is a typical value, and for a large shift of 4σ, for example, a value between 0.82 and 0.95 may be more appropriate.[57]

To understand the operation of EWMA, consider a one input-one output process $y = -1 + 0.6x + N(0,1)$ that shifts and drifts to $y = -0.5 + 0.6\ (1 + 0.02\ (n - 10))x + N(0,1)$ at run $n = 10$ (see Figure 13.7.23). Here $N(0,1)$ represents a normal distributed noise with zero mean and unit deviation. The process output mean shifts 0.5σ and the sensitivity drifts 2% per run. The target is zero, hence $\Delta y = y - T = y$. In the absence of any active control, the initial input x = 1.6667 does not change. For the 100 runs, the output mean then is 1.29 with a standard deviation of 1.17. As a result, the overall variance with respect to the original target is 3.02.

In Figure 13.7.23, *ye* is the EWMA of *y*. A nice feature of EWMA is that the standard deviation of the filtered signal, $\sigma_{\Delta ye}$, is less than that of the unfiltered signal, $\sigma_{\Delta y}$. As shown in Mongtomery,[42] if the sample number is moderately large, the standard deviation of Δ_{ye} converges to its asymptotic value as

$$\sigma_{\Delta ye} = \sqrt{\frac{w}{2-w}}\sigma_{\Delta y} \tag{13.7.17}$$

Taking the control limit for Δy as three for the process shown in Figure 13.7.23, and selecting $w = 0.2$, we have $\sigma_{\Delta ye} = \sigma_{\Delta y}/3 = 1$. The control limit for Δye is represented by a short horizontal dotted line legend as UCLE. From Figure 13.7.23, the first out-of-control signal given by the Shewhart chart is at run 56 when $\Delta y = 3.02$. However, examination of filtered data indicates an out-of-control at run 35, where Δye reaches 1.24. Recalling that the process deviation took place at run #10, the Shewhart chart thus gives an out-of-control signal at run 56, which is 46 runs after shift/drift. The EWMA chart, on the other

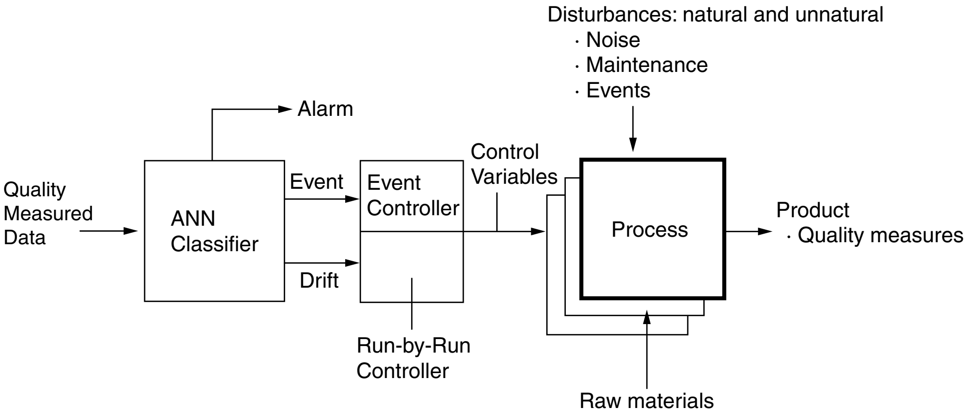

FIGURE 13.7.24 An ANN-based diagnostic/control strategy (Source: Mahajan, R.L., Hopper, P., and Atkins, W., Neural nets and fuzzy logic for semiconductor manufacturing: Part II: Process optimization and control. *Semiconductor Int.*, 111, 1995b and Mahajan, R.L., Hopper, P., and Atkins, W., Neural nets and fuzzy logic for semiconductor manufacturing: Part I: Basic concepts. *Semiconductor International*, 217, 1995a.)

hand, gives out-of-control signal at run 35, only 25 runs after shift/drift. This early detection is attractive since it allows the control action to be taken in advance of potentially bad runs.

Butler and Stefani[59] proposed a double exponential filter to forecast the error in the succeeding run, where one filter is used to estimate the true output and a second filter estimates the trend. The filter equations are as follows:

$$\Delta y_{et} = w_1 \Delta y_t + \left(1 - w_1\right) \Delta y_{e(t-1)} \tag{13.7.18}$$

$$(PE)_t = \Delta y_t - \Delta y_{e(t-1)} \tag{13.7.19}$$

$$(FPE)_t = w_2 (PE)_t + (1 - w_2)(FPE)_{(t-1)} \tag{13.7.20}$$

$$(\Delta y_t)_{\mathrm{Pr}\,ed} = \Delta y_{et} + (FPE)_t \tag{13.7.21}$$

where Δy_t is the current error (deviation from the target), Δy_{et} is the current smoothed error, $(PE)_t$ is the estimated trend at t, $(FPE)_t$ is the current smoothed trend, and $(\Delta y_t)_{\mathrm{Pr}\,ed}$ is greater than 1σ where σ, as usual, is the standard deviation of the process.

Mahajan et al.[42,60] proposed an ANN model-based classifier/controller strategy, shown schematically in Figure 13.7.24. According to this strategy, the product quality data are fed to a classifier that serves the following three functions: (1) to detect in the output data any significant deviation from the normal behavior, (2) to identify the significant deviation with an assignable event to trigger the corresponding control action, and (3) to initiate the appropriate run-by-run controller if the deviation is due to a nonassignable cause.

There are two subcontrollers in the controller module in Figure 13.7.24: an event controller and a run-by-run process controller. An event controller issues a control action specific to that event, whereas a run-by-run controller serves the function of modifying the settings to bring the process output back to the target between the runs. It takes care of the drifts and shifts that are not associated with any particular event.

Run-by-run controllers using neural networks have been used in a number of manufacturing processes.[61–64] A schematic of one such controller is shown in Figure 13.7.25. At the heart of the controller

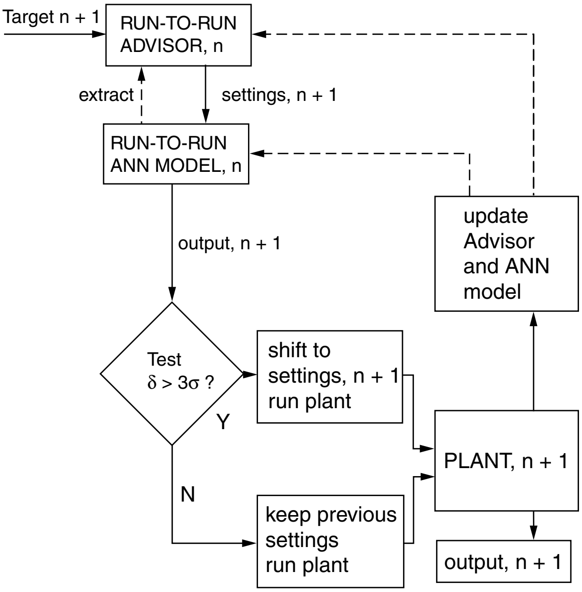

FIGURE 13.7.25 A schematic of a run-by-run controller (Source: Mahajan, R.L., Hopper, P., and Atkins, W., Neural nets and fuzzy logic for semiconductor manufacturing: Part II: Process optimization and control. *Semiconductor Int.*, 111, 1995b and Mahajan, R.L., Hopper, P., and Atkins, W., Neural nets and fuzzy logic for semiconductor manufacturing: Part I: Basic concepts. *Semiconductor International*, 217, 1995a.)

is a dynamic neural network model of the plant which is used to predict the output for a given run before the run is actually made. If the predicted plant output is within the desired specifications, the signal is passed on to the plant to continue the run. Otherwise, the difference between the predicted and the target outputs is fed to the controller, which then provides new input settings for the plant. Both the plant model and controller are updated after each run.

Several variations to the run-by-run process control strategy are possible; see, for example, references 41, 58, and 65–66. In reference 58, the authors proposed a neural network model–based IASPC controller. As a first step, the exponential weighted moving average is used to detect the process shift or drift. The control action is provided by an ANN-model based controller, which is extracted from the process model simply by Taylor expansion and inversion, as follows.

The Taylor expansion of the ANN process model, 17.7.7, $y = f(x_i)$, gives the sensitivities of the output change with respect to the input changes. That is,

$$y - T = \Delta y = \sum_{i=1}^{n} \frac{\partial f}{\partial x_i} \Delta x_i \tag{13.7.22}$$

where T is the control target, and $\partial f/\partial x_i$ is the process sensitivity of output deviation, Δy, to input deviation Δx_i. Note that Equation 13.7.22 is a plane in the n-dimensional space and $\sum_{i=1}^{n}(\partial f/\partial x_i)^2 > 0$. To minimize Δx_i, these were calculated based on the distance from the origin to the plane[67] as ΔS, given in

$$\Delta S = \frac{\Delta y}{\sqrt{\sum_{i=1}^{n} \left(\frac{\partial f}{\partial x_i} \right)^2}} \tag{13.7.23}$$

and Δx_i is the projection of ΔS in the direction of x_i, that is

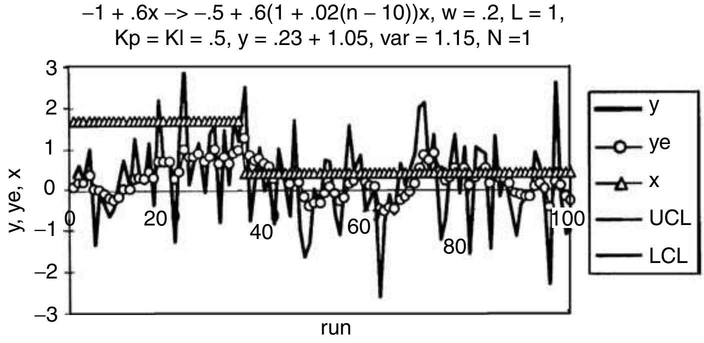

FIGURE 13.7.26 A shifting and drifting process controlled by a run-by-run controller (Source: Wang, X.A., and Mahajan, R.L., Artificial neural network model-based run-to-run process controller. *IEEE Transactions on CPMT — Part C*, 19, 19, 1996.)

$$\Delta x_i = \frac{\dfrac{\partial f}{\partial x_i}}{\displaystyle\sum_{i=1}^{n}\left(\frac{\partial f}{\partial x_i}\right)^2}\Delta y = c_i \Delta y \tag{13.7.24}$$

where c_i is the process sensitivity of input adjustments, Δx_i, to output deviation, Δy. Equation 13.7.24 is thus the controller model that provides the relationship between the controller's outputs Δx_i and its input Δy.

Wang and Mahajan[58] used this strategy and proposed a triple-mode operation for the controller; no action, gradual mode, and rapid mode. If the filtered output deviation is below a threshold limit, no control action is recommended. That is, if $|\Delta y_{et}| < L\sigma_{\Delta y}$ and $|\Delta y_t| < 3\sigma y$, then $|\Delta x_{it}| = 0$ where $L\sigma_{\Delta y}$ is the control action limit for Δy_e. For $w = 0.2$, nominal value of $L = 1$. The argument was that it is generally advisable to leave the process unattended rather than fine-tune it after every run. Generally, the cost of adjusting the input settings is high, and sometimes run-by-run adjustment may even deteriorate the overall performance of the process. This is particularly true for noisy processes. In the gradual mode, if

$$\left|\Delta y_{et}\right| \geq L\sigma_{\Delta y} \ and \left|\Delta y_{et}\right| \leq 3\sigma_{\Delta y} \tag{13.7.25}$$

then the controller issues gradual control action defined by

$$\Delta x_{it} = k_c c_i \Delta y_{et} + \frac{k_p}{M}\sum_{N=1}^{M} c_i \Delta y_{et(1-N)} \tag{13.7.26}$$

where k_c and k_p are weights for the current control action and the previous M runs' average control, respectively. Typically, $k_p = 1 - k_c$.

They used this approach for a simple one input-one output process shown in Figure 13.7.23. Using $k_c = k_p = 0.5$, $w = 0.2$, $L = 1$, and $M = 30$, they showed that only one control action was needed for this simple process at run number 35 (see Figure 13.7.26). The overall variance with respect to target was reduced to less than half of that in Figure 13.7.23.

When the output deviation is large, the controller works in a rapid control mode. Then, the control action is solely based on the current output deviation. The objective is to bring the output to the target rapidly. In other words, if

$$\left|\Delta y_t\right| > 3\sigma_{\Delta t} \tag{13.7.27}$$

then

$$\Delta x_{it} = c_i\,\Delta y_y \tag{13.7.28}$$

Figure 13.7.27 shows an uncontrolled process $y = -1 + 0.6x + N(0,1)$ which at run 10 undergoes a large shift of 6σ and becomes $y = 5 + 0.6x + N(0,1)$. For the 100 runs, the output mean is $y = 5.48$, and the overall variances is 34. Figure 13.7.28 shows the process behavior when it is controlled by a dual controller. At run 10, the output is beyond the upper control limit of three. This activates the rapid mode controller to issue a quick control action at run 11, in accordance with Equation 13.7.25, with $c_i = 1.667$, $\Delta x_i = 9.5$. The new x is 7.83 and the output is brought close to the target. This causes a takeover by the gradual mode controller. At run 71, the EWMA detects the output to be outside the control action limit of one σ, and the controller then issues a gradual correction action. Over 100 runs, the output mean is 0.163 and the overall variance is 1.43, which is much lower than that in Figure 13.7.28. The accompanying control actions are only two and the number of alarms is one.

Wang and Mahajan[58] also reported application of their control strategy to an experimental CVD barrel reactor and demonstrated its effectiveness.

Concluding Remarks

Electronics manufacturing is perhaps the best example of mass production. The manufacturing processes involved are diverse and complex. In this chapter, an attempt has been made to familiarize the reader with a majority of the manufacturing processes that are involved in fabricating an IC (the central element in electronics manufacturing), packaging an IC, and assembling the package on a printed wiring board that goes into the final product. It has been emphasized that process optimization and control are critical to the success of the electronics manufacturing industry.

The development of strategies to achieve optimum process operations, with minimum scrap, is an active area of research. Multidisciplinary solutions building on the existing techniques in classical control theory, advanced SPC tools, intelligent control techniques based on neural network and FL models, and integrated knowledge-based systems are being developed. In this chapter, some recent research in the use of ANNs for process modeling, optimization, fault diagnosis, and control was described in detail.

Given the complexity and variety of the electronic manufacturing process, it is the belief of this author that in the near future, research in process optimization and control will continue to build on several of the existing technology platforms discussed in this chapter. Integration of different approaches to arrive at elegant, self-adaptive, and comprehensive control solutions will remain an active area of research. Development of real-time controllers needs accelerated research. To this end, integration of *in-situ* sensors, including microelectromechanical systems (MEMS), needs to be explored.

15.1 Introduction

Mohamed Gad-el-Hak

The length-scale of man, at slightly more than 10^0 m, amazingly fits right in the middle of the smallest subatomic particle, which is approximately 10^{-26} m, and the extent of the observable universe, which is of the order of 10^{26} m. Toolmaking has always differentiated our species from all others on Earth. Aerodynamically correct wooden spears were carved by *archaic Homo sapiens* close to 400,000 years ago. Man builds things consistent with his size, typically in the range of two orders of magnitude larger or smaller than himself. But humans have always striven to explore, build, and control the extremes of length and time scales. In the voyages to Lilliput and Brobdingnag of *Gulliver's Travels*, Jonathan Swift speculates on the remarkable possibilities that diminution or magnification of physical dimensions provides. The Great Pyramid of Khufu was originally 147 m high when completed around 2600 B.C., while the Empire State Building constructed in 1931 is presently 449 m high. At the other end of the spectrum of man-made artifacts, a dime is slightly less than 2 cm in diameter. Watchmakers have practiced the art of miniaturization since the thirteenth century. The invention of the microscope in the seventeenth century opened the way for direct observation of microbes and plant and animal cells. Smaller things were man-made in the latter half of the twentieth century. The transistor in today's integrated circuits has a size of 0.18 micron in production and approaches 10 nanometers in research laboratories.

Microelectromechanical systems (MEMS) refer to devices that have characteristic length of less than 1 mm but more than 1 micron, that combine electrical and mechanical components, and that are fabricated using integrated circuit batch-processing technologies. Current manufacturing techniques for MEMS include surface silicon micromachining; bulk silicon micromachining; lithography, electrodeposition, and plastic molding; and electrodischarge machining. The multidisciplinary field has witnessed explosive growth during the last decade, and the technology is progressing at a rate that far exceeds that of our understanding of the physics involved. Electrostatic, magnetic, electromagnetic, pneumatic and thermal actuators, motors, valves, gears, cantilevers, diaphragms, and tweezers of less than 100-micron size have been fabricated. These have been used as sensors for pressure, temperature, mass flow, velocity, sound, and chemical composition; as actuators for linear and angular motions; and as simple components for complex systems such as robots, micro-heat-engines, and micro-heat-pumps. Worldwide market projections for MEMS devices tend to be optimistic, reaching $30 billion by the year 2006.

In this chapter, we breifly introduce MEMS technology. Readers are referred to more specialized books such as those by Kovacs (1998), Gad-el-Hak (2002), Karniadakis and Beskok (2002), and Madou (2002) for more detailed treatment of the subject. The present chapter consists of seven sections. Following these introductory remarks, MEMS technology and its applications are broadly introduced in the second section. The third section describes the various techniques used to fabricate microelectromechanical systems. Packaging and reliability issues are outlined in the following two sections. The physical modeling of fluid flows and solid mechanics of microdevices are discussed in Sections 6 and 7, respectively.

15.2 MEMS Technology and Its Applications

Mohamed Gad-el-Hak

Tool making has always differentiated our species from all others on Earth. Aerodynamically correct wooden spears were carved by archaic Homo sapiens close to 400,000 years ago. Man builds things consistent with his size, typically in the range of two orders of magnitude larger or smaller than himself, as indicated in Figure 15.2.1. Although the extremes of length-scale are outside the range of this figure, man, at slightly more than 10^0 m, amazingly fits right in the middle of the smallest subatomic particle, which is approximately 10^{-26} m, and the extent of the observable universe, which is of the order of 10^{26} m (15 billion light years); neither geocentric nor heliocentric but rather egocentric universe! But humans have always striven to explore, build, and control the extremes of length and time scales. In the voyages to Lilliput and Brobdingnag of *Gulliver's Travels*, Jonathan Swift (1726) speculates on the remarkable possibilities that diminution or magnification of physical dimensions provides. The Great Pyramid of Khufu was originally 147 m high when completed around 2600 B.C., while the Empire State Building constructed in 1931 is presently — after the addition of a television antenna mast in 1950 — 449 m high. At the other end of the spectrum of man-made artifacts, a dime is slightly less than 2 cm in diameter. Watchmakers have practiced the art of miniaturization since the thirteenth century. The invention of the microscope in the seventeenth century opened the way for direct observation of microbes and plant and animal cells. Smaller things were man-made in the latter half of the twentieth century. The transistor —

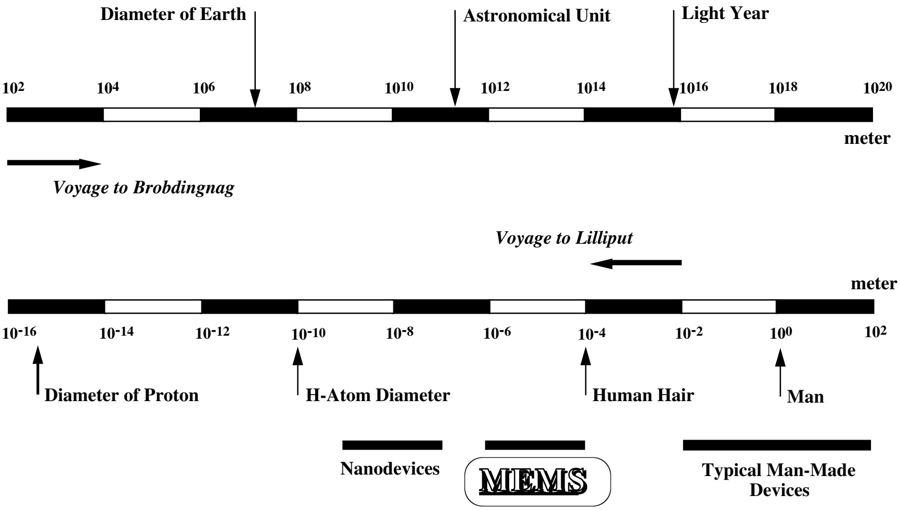

FIGURE 15.2.1 Scale of things, in meters. Lower scale continues in the upper bar from left to right. One meter is 10^6 microns, 10^9 nanometers, or 10^{10} Angstroms.

invented in 1947 — in today's integrated circuits has a size of 0.18 micron (180 nanometers) in production and approaches 10 nm in research laboratories using electron beams. But what about the miniaturization of mechanical parts — machines — envisioned by Feynman (1961) in a legendary speech?

Manufacturing processes that can create extremely small machines have been developed in recent years (Angell et al. 1983; Gabriel et al. 1988; 1992; O'Connor 1992; Gravesen et al. 1993; Bryzek et al. 1994; Gabriel 1995; Ashley 1996; Ho and Tai 1996, 1998; Hogan 1996; Ouellette 1996; Paula 1996; Robinson et al. 1996a, 1996b; Tien 1997; Amato 1998; Busch-Vishniac 1998; Kovacs 1998; Knight 1999; Epstein 2000; O'Connor and Hutchinson 2000; Goldin et al. 2000; Chalmers 2001; Tang and Lee 2001; Gad-el-Hak 2002; Karniadakis and Beskok 2002; Madou 2002). Electrostatic, magnetic, electromagnetic, pneumatic and thermal actuators, motors, valves, gears, cantilevers, diaphragms, and tweezers of less than 100-μm size have been fabricated. These have been used as sensors for pressure, temperature, mass flow, velocity, sound and chemical composition; as actuators for linear and angular motions; and as simple components for complex systems such as robots, micro-heat-engines and micro-heat-pumps (Lipkin 1993; Garcia and Sniegowski 1993, 1995; Sniegowski and Garcia 1996; Epstein and Senturia 1997; Epstein et al. 1997).

Microelectromechanical systems (MEMS) refer to devices that have characteristic length of less than 1 mm but more than 1 micron, that combine electrical and mechanical components, and that are fabricated using integrated circuit batch-processing technologies. The books by and Kovacs (1998), Gad-el-Hak (2002), and Madou (2002) provide excellent sources for microfabrication technology. Current manufacturing techniques for MEMS include surface silicon micromachining; bulk silicon micromachining; lithography, electrodeposition, and plastic molding (or, in its original German, Lithographie Galvanoformung Abformung, LIGA); and electrodischarge machining (EDM). As indicated in Figure 1, MEMS are more than four orders of magnitude larger than the diameter of the hydrogen atom, but about four orders of magnitude smaller than the traditional man-made artifacts. Microdevices can have characteristics length smaller than the diameter of a human hair. Nanodevices (some say NEMS) further push the envelope of electromechanical miniaturization (Roco 2001).

The famed physicist Richard P. Feynman delivered a mere two but profound lectures[†] on electromechanical miniaturization: "There's Plenty of Room at the Bottom," presented at the annual meeting of

---

[†] Both talks have been reprinted in the *Journal of Microelectromechanical Systems,* vol. 1, no. 1, pp. 60–66, 1992, and vol. 2, no. 1, pp. 414, 1993.

the American Physical Society, Pasadena, California, December 29, 1959, and “Infinitesimal Machinery,” presented at the Jet Propulsion Laboratory on February 23, 1983. He could not see a lot of use for micromachines, lamenting in 1959 “[Small but movable machines] may or may not be useful, but they surely would be fun to make,” and 24 years later “There is no use for these machines, so I still don’t understand why I’m fascinated by the question of making small machines with movable and controllable parts.” Despite Feynman’s demurring regarding the usefulness of small machines, MEMS are finding increased applications in a variety of industrial and medical fields, with a potential worldwide market in the billions of dollars ($30 billion by 2006). Accelerometers for automobile airbags, keyless entry systems, dense arrays of micromirrors for high-definition optical displays, scanning electron microscope tips to image single atoms, micro-heat-exchangers for cooling of electronic circuits, reactors for separating biological cells, blood analyzers, and pressure sensors for catheter tips are but a few examples of current usage. Microducts are used in infrared detectors, diode lasers, miniature gas chromatographs, and high-frequency fluidic control systems. Micropumps are used for ink-jet printing, environmental testing, and electronic cooling. Potential medical applications for small pumps include controlled delivery and monitoring of minute amounts of medication, manufacturing of nanoliters of chemicals, and development of an artificial pancreas.

The multidisciplinary field has witnessed explosive growth during the last decade. Several new journals are dedicated to the science and technology of MEMS, such as *Journal of Microelectromechanical Systems*, *Journal of Micromechanics and Microengineering*, and *Microscale Thermophysical Engineering*. Numerous professional meetings are devoted to micromachines, for example, *Solid-State Sensor and Actuator Workshop, International Conference on Solid-State Sensors and Actuators (Transducers), Micro Electro Mechanical Systems Workshop, Micro Total Analysis Systems, Eurosensors,* among others.

In this chapter, we briefly introduce MEMS technology. Readers are referred to more specialized books such as those by Kovacs (1998), Gad-el-Hak (2002), Karniadakis and Beskok (2002), and Madou (2002) for more detailed treatment of the subject. The present chapter contains sections on fabrication, packaging, and reliability of microelectromechanical systems. The physical modeling of fluid flows and solid mechanics of microdevices are also discussed.

15.3 Microscale Manufacturing Processes

A Comparison of Miniaturization Techniques: Top-Down and Bottom-Up Manufacturing

Marc J. Madou and Hong Zhou

Introduction

> Progress in science depends on new techniques, new discoveries and new ideas, probably in that order.
>
> **Sydney Brenner, 1980**

> A happy man is too satisfied with the present to dwell too much on the future.
>
> **Albert Einstein, "My Future Plans," September 18, 1896**

In manufacturing, forming and removing are the two primary processes. Forming creates an original shape from a molten mass, a gaseous state, or solid particles. During such processes, cohesion is created among individual particles; examples include plastic molding, thin film metal deposition by evaporation or sputtering, and electroforming. Removing processes destroy cohesion among particles as exemplified in wet chemical etching, electrodischarge machining (EDM), traditional mechanical turning, and laser drilling.[1] In this section, we are interested in those forming and removing processes enabling the manufacture of precision miniature machines.

"Precision machining," when used by mechanical engineers, has typically been reserved for removal processes only, whereas "micromachining," as used to describe integrated circuit (IC)-based fabrication technology, covers both removal and forming processes. Precision machining and Si micromachining are complementary; both strive to improve absolute and relative manufacturing tolerances, with Si-based technology better at obtaining smaller features (absolute tolerance) and traditional methods better at obtaining tighter relative tolerances. In this section, precision machining encompasses removal and forming processes, with micromachining as one of its newest disciplines.

Humans are still best at building structures they can grasp with their hands and see with their eyes, and have only relatively recently started to craft objects at the micro- and nanoscale level. The manufacture of miniature devices is still principally based on top-down manufacturing methods; starting from bigger building blocks, say a whole Si wafer, and reducing them into smaller and smaller pieces by cutting, etching, and slicing. Also, chunks of materials are bolted, riveted, glued, or welded onto the workpiece, or thin layers are deposited onto the substrate. Bottom-up manufacturing methods, in which small particles such as atoms, molecules, and atom clusters are added or removed for the construction of bigger functional structures, are seen by many as the next natural step in human manufacture (e.g., Drexler[2] and Whitesides[3]). Bottom-up methods are nature's way of growing things, and in biomimetics we study how, building bottom-up — that is, atom by atom — nature, through eons of time, developed manufacturing methods, materials, structures, and intelligence. An example of bottom-up manufacturing, or "nanochemistry," is the self-assembly of a monolayer from individual molecules on a gold surface.

Miniaturization science today is still predominantly practiced by electrical and mechanical engineers, but as applications are becoming more and more biological in nature, biologists, materials scientists, chemists, and physicists must work together with electrical and mechanical engineers to develop new miniaturization solutions. We hope that this contribution will further stimulate such collaborations and help bridge the gap between "dry" engineering, in air and with rigid materials, and "wet" engineering, with flexible materials in watery solutions.

Top-Down Manufacturing Methods

Shaping device contours in top-down manufacturing is either lithography based, for example in the fabrication of ICs, or non-lithography based, as in mechanical grinding. Accordingly, the method used results either in truly three-dimensional machines or in projected two-dimensional shapes. The methods may also be characterized according to the energy source involved in removal or addition of materials to the workpiece. The energy sources are chemical (including photochemical), thermal, electrochemical, electrothermal, and mechanical. Here, to illustrate top-down manufacturing, we will review IC processes (which encompass mostly chemical, electrochemical, and thermal processes), LIGA and replication techniques, femto-second laser machining (thermal), and ultraprecision computer numerical controlled (CNC) machining (mechanical) — four techniques most suitable for MEMS fabrication

IC Manufacturing Techniques Suitable for MEMS

Suitable IC techniques for batch manufacturing are applied today to a wide variety of non-IC products, and are also combined with traditional precision manufacturing methods. Undoubtedly, the merging of traditional precision engineering and IC manufacturing methodology will lead to many more interesting, new manufacturing processes. The IC processes of primary interest are lithography, wet and dry etching, and deposition techniques. In each short section we emphasize those features that distinguishes those processes in MEMS from those in IC fabrication.

Lithography

Lithography is a technique used to transfer copies of a master pattern onto the surface of a solid material, such as a silicon wafer. Here we review different forms of lithography, detailing those aspects that differ most from the miniaturization processes used to fashion ICs.

The most widely used form of lithography is photolithography. In photolithography, wavelengths of the light source used for exposure of the resist-coated wafer through a mask featuring the desired pattern, range from the very short wavelengths of extreme ultraviolet (EUV) — 10 to 14 nm, to deep ultraviolet (DUV) — 150 to 300 nm, to near ultraviolet (UV) — 350 to 500 nm. In near UV, one typically uses the g-line (435 nm) or i-line (365 nm) of a mercury lamp. Accurate registration and exposure of a series of successive patterns in a mask aligner lead to complex multilayered ICs. This essentially two-dimensional process has a limited tolerance for nonplanar topography, creating a major constraint for building non-IC miniaturized MEMS systems, which often exhibit extreme topographies. Photolithography has matured rapidly and constantly improved at resolving ever-smaller features. Research in high-aspect-ratio resists features, to satisfy needs of both IC and non-IC miniaturization (e.g., MEMS), is finally also improving photolithography's capacity to cover wide ranges of topography.

Photolithography and pattern transfer involves a set of process steps summarized in Figure 15.3.1. As an example we use an oxidized Si wafer and a negative photoresist system. An oxidized wafer (A) is coated with a 1-μm-thick negative photoresist layer (B). After exposure (C), the wafer is rinsed in a developing solution or sprayed with a spray developer, which removes the unexposed areas of photoresist and leaves a pattern of bare and photoresist-coated oxide on the wafer surface (D). The photoresist pattern is the negative image of the pattern on the photomask. In a typical next step after development, the wafer is placed in a solution of HF or HF + NH_4F, meant to attack the oxide but not the photoresist or the underlying silicon (E). The photoresist protects the oxide areas it covers. Once the exposed oxide has been etched away, the remaining photoresist can be stripped off with a strong acid such as H_2SO_4 or an acid-oxidant combination such as $H_2SO_4 - Cr_2O_3$, attacking the photoresist but not the oxide or the silicon (F). Other liquid strippers include organic solvent strippers and alkaline strippers (with or without oxidants). The oxidized Si wafer with the etched windows in the oxide (F) now awaits further processing. This might entail a wet anisotropic etch of the Si in the oxide windows with SiO_2 as the etch mask.

After near UV lithography has run its course, extreme ultraviolet lithography is one of the most promising next-generation lithography (NGL) options. Extreme ultraviolet lithography (EUVL), using wavelengths in the 10- to 14-nanometer (nm) range to carry out projection imaging, is perhaps the most natural extension of optical projection lithography as in principle it only differs in terms of the wavelength. This type of radiation is also referred to as soft-X-ray radiation and vacuum UV. Sources for this type of radiation are laser-produced plasmas and synchrotrons. The technique is capable of printing sub-100-nm features while maintaining a DOF (depth of focus) of 0.5 μm or larger. Unfortunately things are not that

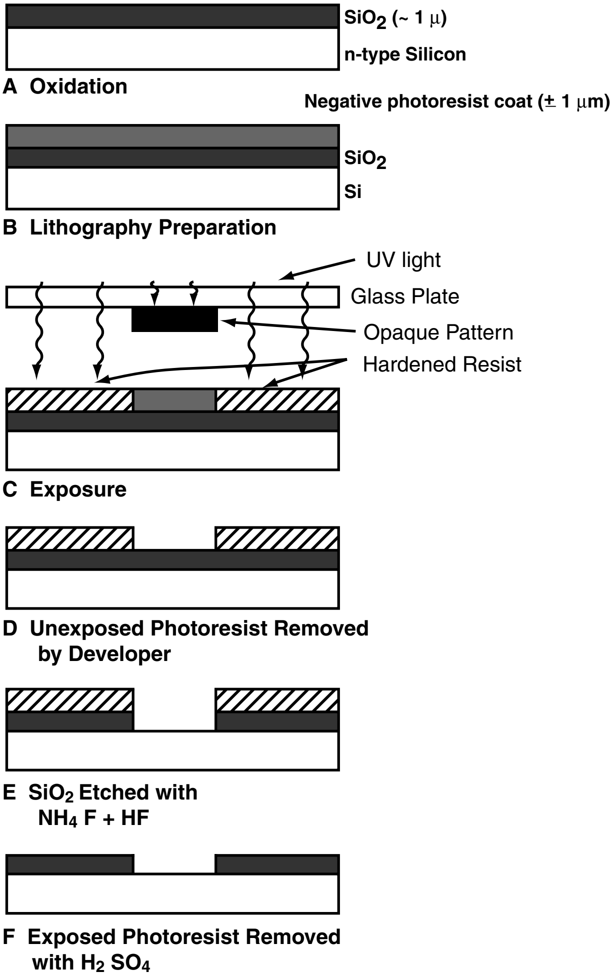

FIGURE 15.3.1 Basic photolithography and pattern transfer. Example uses an oxidized Si wafer and a negative photoresist system. Process steps include exposure, development, oxide etching, and resist stripping. Steps A to F are explained in the text.

simple — EUV is strongly absorbed in virtually all materials and consequently imaging must be carried out in vacuum; also, all camera optics as well as masks used must be reflective rather than refractive. New resists and processing techniques must be developed as well.

In Figure 15.3.2 we compare UV lithography, direct write electron- and ion-beam lithography, and X-ray lithography. Electron-beam and ion-beam lithography are slow, serial direct write techniques, and, since charged particles are involved, they must be held in a vacuum.[4] X-rays do not need to be kept in a vacuum, and another advantage is that one can use flood exposure of resist-coated wafers, ensuring higher throughput than when writing with a thin electron or ion beam. The method is also referred to as deep X-ray lithography (DXRL).

X-ray lithography is superior to optical lithography because of the use of shorter wavelengths and a very large DOF and because exposure time and development conditions are not as stringent. Reproducibility is high as results are independent of substrate type, surface reflections, and wafer topography. Another important benefit is that X-ray lithography is immune to low-atomic-number (Z) particle contamination (dust). With an X-ray wavelength on the order of 10 Å or less, diffraction effects generally are negligible and proximity masking can be used, increasing the lifetime of the mask. With a standard 50 μm proximity gap and using synchrotron X-rays, 0.25 μm patterns can be printed; by decreasing the

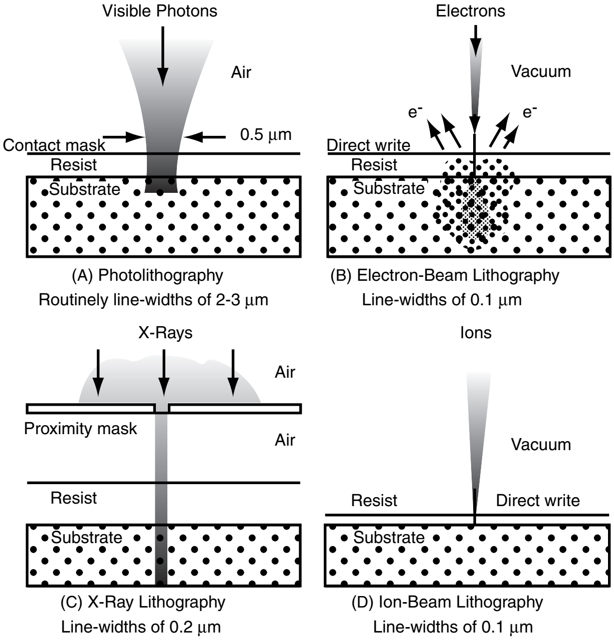

FIGURE 15.3.2 A comparison of photolithography, electron-beam, ion-beam, and X-ray lithography.

proximity gap to 25 µm, patterns of 0.15 µm can be resolved.[5] The obtainable aspect ratio, defined as the structural height or depth to the minimum lateral dimension, reaches more than 100. (With UV photolithography, under special conditions, an aspect ratio of about 25 is possible at most; e.g., by using SU-8 photoresist.) An aspect ratio of 100 corresponds to the aspect ratio attainable by wet chemical anisotropic etching of monocrystalline Si.

In X-ray lithography there are essentially no optics involved, and although this sounds like an advantage, it also presents one major disadvantage — one can only work with 1:1 shadow printing. No image reduction is possible so the mask fabrication process is very complicated.

IC and miniaturization science do have different preferred lithography strategies. The required very high throughput and finer geometries with ICs makes EUVL a good choice. In miniaturization science, modularity, large depth of focus, extending the z-direction, that is, the height of features (skyscraper-type structures), incorporating nontraditional materials (e.g., gas-sensitive ceramic layers, polymers) and replication methods catch the spotlight and very large batch fabrication is not always a prerequisite, making DXRL a better option here.

Wet and Dry Etching

Lithography steps are followed by a number of subtractive and additive processes. Materials are either removed from or added to a device, usually in a selective manner, transferring the lithography patterns onto ICs or three-dimensional micro- or nano-machines. Table 15.3.1 lists the most important subtractive processes encountered in miniaturization science, including wet and dry etching, focused ion-beam (FIB) milling, laser machining, ultrasonic drilling, electro discharge machining (EDM), and traditional precision machining. Applications, which mostly involve Si, typical material removal rates, relevant reference(s), and some remarks on the techniques supplement the list. Two of the most widely used subtractive techniques for micromachining listed in Table 15.3.1 are wet and dry etching. These two most popular techniques are detailed a bit more in what follows.

Wet etching is used for cleaning, shaping three-dimensional structures, removing surface damage, polishing, and characterizing structural and compositional features.[20] The materials etched include semiconductors, conductors, and insulators. The most important parameters in chemical etching are bias

TABLE 15.3.1 Partial List of Subtractive Processes Important in Micromachining

Subtractive Technique	Applications	Typical Etch Rate	Remark	References
Wet chem. etch.: iso.	Si spheres, domes, grooves	Si polishing at 50 μm/min with stirring (RT, acid)	Little control, simple	6
Wet chem. etch.: anis.	Si angled mesas, nozzles, diaphragms, cantilevers, bridges	etching at 1 μm/min on a (100) plane (90°C, alkaline)	With etch-stop more control, simple	6
Electrochem. etch.	Etches p-Si and stops at n-Si (in n-p junction), etches n-Si of highest doping (in n/n+)	p-Si etching 1.25–1.75 μm/min (100) plane, 105–115°C (alkaline)	Complex, requires electrodes	7, 8
Wet photoetch.	Etches p-type layers in p-n junctions	Etches p-Si up to 5 μm/min (acid)	No electrodes required	9
Photo-electrochem. etch.	Etches n-Si in p-n junctions, production of porous Si	Typical Si etch rate: 5 μm/min (acid)	Complex, requires electrodes and light	10
Dry chem. etch.	Resist stripping, isotropic features	Typical Si etch rate: 0.1μm/min (but with more recent methods up to 6 μm/min)	Resolution better than 0.1 μm, loading effects.	11, 12
Physical/chem. etch.	Very precise pattern transfer	Si etch rate: 0.1 to 1 μm/min (but with more recent methods up to 6μm/min)	Most important dry etching technique	12, 13
Physical dry etching, sputter etching, and ion milling	Si surface cleaning, unselective thin film removal	Typical Si etch rate: 300 Å/min.	Unselective and slow, plasma damage	13
Vapor phase etching with XeF$_2$ (and other interhalogens)	Isotropic Si etching in presence of Al and SiO$_2$	Typical Si etch rate: 1–3 μm/min	Very selective, fast, and very simple	14
Focused ion-beam (FIB) milling	Microholes, circuit repair, microstructures in arbitrary materials	Typical Si etch rate: 1 μm/min	Long fabrication time: >2 h including setup	15
Laser machining (with and without reactive gases)	Circuit repair, resistor trimming, hole drilling, labeling of Si wafers	Typical rate for drilling a hole in Si with a Nd:YAG (400W laser): 1 mm/sec (3.5 mm deep and 0.25 mm dia.)	Laser beams can focus to a 1 μm spot, etch with a resolution of 1 μm^3	16
Ultrasonic drilling	Holes in quartz, silicon nitride bearing rings	Typical removal rate of Si: 1.77 mm/min	Especially useful for hard, brittle materials	17
Electrostatic discharge machining (EDM)	Drilling holes and channels in hard brittle metals	Typical removal rate for metals: 0.3 cm^3/min	Poor resolution (>50 μm), only conductors, simple, wire discharge machining resolution much better	18
Mechanical turning, drilling and milling, grinding, honing, lapping, polishing, and sawing	Almost all machined objects surrounding us	Removal rates of turning and milling of most metals: 1 to 50 cm^3/min, for drilling: 0.001 to 0.01 cm^3/min	Prevalent machining technique	19

RT = room temperature, chem. etch. = chemical etching, iso. = isotropic, anis. = anistropic

(undercut), tolerance, etch rate, anisotropy and selectivity, over etch, feature size control, and loading effects. The emphasis in what follows is on Si, but the application is generic. Isotropic etchants, also polishing etchants, etch in all crystallographic directions at the same rate; they usually are acidic, such as HF/HNO$_3$/CH$_3$COOH (HNA), and lead to rounded isotropic features in single crystalline Si. The

HNA etch is also known as the "poly-etch" because in the early days of the integrated circuit industry it was used as an etchant for polysilicon.[21] Isotropic etchants are used at room temperature or slightly above (<50°C). Historically they were the first Si etchants introduced.[20,22–29] [Later it was discovered that some alkaline chemicals will etch anisotropically, that is, they etch away crystalline silicon at different rates depending on the orientation of the exposed crystal plane. Typically the pH stays above 12, while more elevated temperatures are used for these slower type etchants (>50°C). The latter type of etchants surged in importance in the late 1960s for the fabrication of dielectrically isolated structures in silicon.[30–44] These anisotropic etching procedures heralded the emergence of what is now called bulk micromachining. Anisotropic etching of Si also heralded the beginning of MEMS. Isotropic etchants typically show diffusion limitation, whereas anisotropic etchants are reaction rate limited. In both cases the two principal reactions are oxidation of the silicon followed by dissolution of the hydrated silicate.

Wet chemical etching of Si provides a higher degree of selectivity than dry-etching techniques (as we discuss in a moment). Wet etching usually is also faster; a few microns to tens of microns per minute for isotropic etchants and about 1 µm/min for anisotropic wet etchants vs. 0.1 µm/min or less in typical dry etching. More recently, though, with inductively coupled plasma (ICP) dry etching of Si, rates of up to 6 µm/min are achieved. Modification of wet etchant and/or temperature can alter the selectivity to silicon dopant concentration and type and, especially when using alkaline etchants, to crystallographic orientation.

A typical set of examples of wet etched isotropic and anistropic Si pieces is shown in Figure 15.3.3.

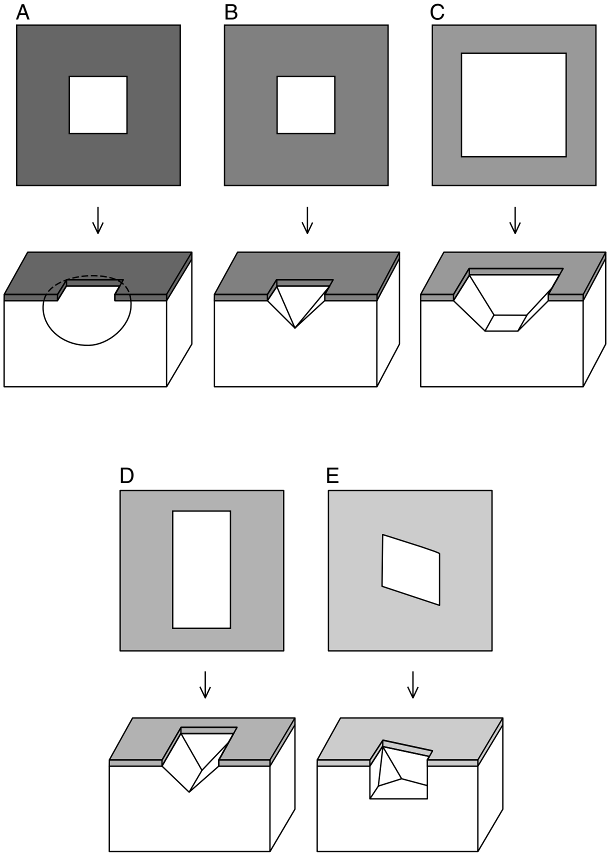

FIGURE 15.3.3 Isotropic and anisotropic wet etched features in [100] and [110] Si wafers. (A) isotropic etch; (B) through (E) anisotropic etch. (A) through (D): [100]-oriented wafers and [E]:[110]-oriented wafer.

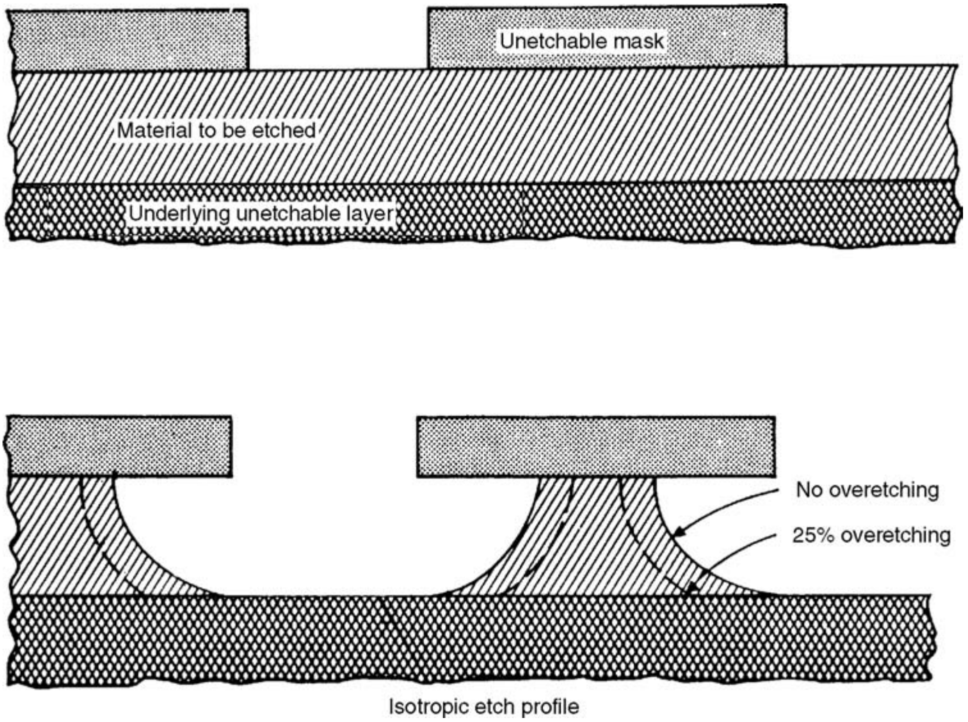

FIGURE 15.3.4 Example of various etch profiles obtained with dry etching in Si.

Dry etching covers a family of methods by which a solid surface is etched in the gas or vapor phase, physically by ion bombardment, chemically by a chemical reaction through a reactive species at the surface, or by combined physical and chemical mechanisms. Plasma-assisted dry etching is categorized according to the specific setup as either *glow discharge* (diode setup) or *ion beam* (triode setup). Using glow discharge techniques, plasma is generated in the same vacuum chamber where the substrate is located; when using ion-beam techniques, plasma is generated in a separate chamber from which ions are extracted and directed in a beam toward the substrate by a number of grids. It is also common to differentiate between (1) chemical plasma etching (PE), (2) synergetic reactive ion etching (RIE), and (3) physical ion-beam etching (IBE).[45] In sputter/ion etching and ion-beam milling, or IBE, etching occurs as a consequence of a physical effect, namely momentum transfer between energetic Ar^+ ions and the substrate surface. Some type of chemical reaction takes place in all the other dry-etching methods. In the case of physical/chemical RIE, impacting ions, electrons, or photons either induce chemical reactions or, in sidewall-protected ion-assisted etching, a passivating layer is cleared by the particle bombardment from horizontal surfaces only. As a result, in the latter case etching occurs almost exclusively on the cleared planar surfaces. In reactive PE, neutral chemical species such as chlorine or fluorine atoms generated in the plasma diffuse to the substrate where they react to form volatile products with the layer to be removed. The only role of the plasma is to supply gaseous, reactive etchant species.

In selecting a dry-etching process, the desired shape of the etch profile and the selectivity of the etching process require careful consideration. Figure 15.3.4 shows different possible etch profiles,[11] where, depending on the mechanism employed, isotropic, directional, or vertical etch profiles are obtained. In dry etching anisotropic etch profiles — directional or vertical — can be generated in single crystalline, polycrystalline, and amorphous materials. The anisotropy is not a result of anisotropy in the etching rate of single crystals as in the case of anisotropic wet chemical etching; rather, the degree of anisotropy is controlled by the plasma conditions. Selectivity of a dry etch refers to the difference in etch rate between the mask and the film to be etched, again controllable by plasma conditions.

TABLE 15.3.2 Comparison of Dry and Wet Thin Film Etching Processes

	Dry Etching		Wet Etching	
Etching Factors	Ion Etching	RIE	Chemical	Electrochemical
Driving force	Plasma	Reactive gases	Etching solution	External current
Environment	Vacuum	Vacuum	Acidic/Alkaline	Mostly neutral Salt solutions
Rate	~100 Å/min	~1000 Å/min	~1 μ/min	10 μ/min
Selectivity	Poor	High	Very High	Very high
Wall slope control	Directional	Anisotropic (flexible)	Isotropic	Better than chemical
Safety and environmental concerns	Low	Moderate/high	High	Low
Monitoring and control issues	Some	Some	Many	Few
Cost	High	High	Low	Moderate

Source: Based on Dr. M. Datta (http://www.research.ibm.com/journal/rd/425/datta.html)

The preference of dry stripping over wet stripping methods is based on a variety of advantages: fewer disposal problems; less corrosion of metal features in the structure, and less undercutting and broadening of photoresist features, that is, better CD control (nanometer dimensions); and, under the right circumstances, a cleaner resulting surface. Also, with the new generations of ICs, all with sub-quarter-micron geometries, surface tension might preclude a wet etchant from reaching down between photoresist features, whereas dry etching precludes any such problem. As in IC manufacture, dry etching has evolved into an indispensable technique in miniaturization science. After the success of wet etched Si micromachined products in the 1980s and early 1990s the maturation of flexible, generic, and fast anisotropic deep reactive ion etching (DRIE) techniques in the late 1990s spawned a second wave of Si miniaturized commercial products.

Different dry and wet thin film etching processes that are applicable in microfabrication are compared in Table 15.3.2 (based on http://www.research.ibm.com/journal/rd/425/datta.html). Dry-etching processes are particularly suitable for patterning very fine dimensions. Relatively low etching rates (at the very best 6 μm/min in DRIE) and high equipment cost restrict their application to precision etching of thin films involving very small amounts of material removal. Wet chemical etching methods, on the other hand, are used in microfabrication because of their selectivity and high etch rates. They are predominantly used in large-scale production of metallic parts involving bulk metal removal. Treatment and disposal of hazardous waste contribute significantly to the product cost in chemical wet-etching manufacturing processes but much less so in electrochemical machining.

Deposition Techniques

Solids can be deposited onto a substrate from a liquid, a plasma, a gas, or a solid state. These additive techniques are often accompanied or followed by thermal processing to obtain desired materials properties and substrate adhesion. Although deposition methods, especially in the thin film arena, are generally the same as in ICs, additive processes in miniaturization science span a much wider range from inorganic to organic materials. Besides the typical microelectronic elements — Si, Al, Au, Ti, W, Cu, Cr, O, N, and Ni-Fe alloys — miniaturization science involves deposition of several nontypical elements such as Zr, Ta, Ir, C, Pt, Pd, Ag, Zn, In, Nb, and Sn. Moreover a plethora of exotic compounds ranging from enzymes to shape memory alloys and from hydrogels to piezoelectrics are used. The number of materials and compounds involved in IC fabrication, in comparison, is very limited. In miniaturization science, particularly in chemical sensors and biomedical devices, modular, thick film technologies are more prevalent.

Table 15.3.3 presents additive processes; Table 15.3.4 lists MEMS materials, typical deposition techniques, and an example application for the deposit. The references in Table 15.3.3 are meant as a basis for further study of additive processes.

In the deposition methods from the gas phase listed in Table 15.3.3, two major categories can be distinguished: direct line-of-sight impingement deposition techniques called *physical vapor deposition*

TABLE 15.3.3 Additive Processes

Additive	Application Example	Reference
Bonding techniques	7740 glass to silicon	46
Casting	Thick resist (10-1000 μm)	
Chemical vapor deposition	Tungsten on metal	47
Dip coating	Wire type ion selective electrodes	
Droplet delivery systems	Epoxy, chemical sensor membranes	
Electrochemical deposition	Copper on steel	48
Electroless deposition	Vias	49
Electrophoresis	Coating of insulation on heater wires	
Electrostatic toning	Xerography	
Ion cluster deposition		50
Ion implantation and diffusion of dopants	Boron into silicon	51
Ion plating	Metal on insulators	50
Laser deposition	Superconductor compounds	52
Liquid phase epitaxy (CVD)	GaAs	53
Material transformation (oxidation, nitridation, etc.)	Growth of SiO_2 on silicon	54
Molecular beam epitaxy (PVD)	GaAs	55
Plastic coatings	Electronics packages	56
Screen printing	Planar ion selective electrodes (ISEs)	57
Silicon crystal growth	Primary process	58
Spin-on	Thin resist (0.1–2 μm)	58
Spray pyrolysis (CVD)	CdS on metal	59
Sputter deposition (PVD)	Gold on silicon	60
Thermal evaporation (PVD)	Aluminum on glass	60
Thermal spray deposition from plasmas or flames	Coatings for aircraft engine parts and ZrO_2 sensors	61
Thermomigration	Aluminum contacts through silicon	62

(PVD) and diffusive-convective mass transfer techniques, that is, *chemical vapor deposition* (CVD). See Figure 15.3.5 for an example of a PVD and a CVD reactor.

Evaporation, sputtering, molecular beam epitaxy (MBE), laser ablation deposition, ion plating, and cluster deposition represent PVD techniques. CVD techniques include plasma-enhanced (PECVD), atmospheric pressure (APCVD), low-pressure (LPCVD), very low pressure (VLPCVD), electron cyclotron resonance (ECRCVD), metallorganic (MOCVD), and spray pyrolysis. Epitaxial techniques have gained importance in ICs and mechanical sensor fabrication. A particulate deposition technique, such as plasma spraying, has potential for chemical sensor applications. Like spray-pyrolysis, plasma spraying does not have IC industry applications but might propel planar thick film chemical sensors into the realm of "batch" manufacturability.

With the growth of the BIOMEMS field, techniques for depositing organic materials for chemical and biological sensors, often arranged in some type of an array configuration, are gaining importance. Techniques with special merit for chemical and biological sensor manufacture include spin coating, dip coating, plastic spraying, casting, Doctors' blade or tape casting, silk-screening, plasma polymerization, and Langmuir-Blodgett deposition. For sensor array manufacture, lithography, ink jetting, mechanical microspotting, digital mirror deposition, and electrochemical deposition of functional chemistries are important.

Electrochemical and electroless metal deposition and micromolding are gaining renewed interest because of the emerging importance of replication methodologies in MEMS.

Surface micromachining constitutes a combination of CVD deposition of structural materials (e.g., poly-Si), dry etching to pattern the structural material and wet etching of sacrificial layers (e.g., SiO_2). A surface micromachining process sequence for the creation of a simple freestanding poly-Si bridge is illustrated in Figure 15.3.6.[64,65] A sacrificial layer, also called a spacer layer or base, is deposited on a silicon substrate coated with a dielectric layer as the buffer/isolation layer (Figure 15.3.6A). Phosphosilicate glass

TABLE 15.3.4 IC and MEMS Materials, Deposition Method, and Typical Application

Material	Deposition Technique	Function
Organic Thin Films		
Hydrogel	Silk screen	Internal electrolyte in chemical sensors
Photoresist	Spin-on	Masking, planarization
Polyimide	Spin-on	Electrical isolation, planarization, microstructures
Metal Oxides		
Aluminum oxide	CVD, sputtering, anodization	Electrical isolation
Indium oxide	Sputtering	Semiconductor
Tantalum oxide	CVD, sputtering, anodization	Electrical isolation
Tin oxide(SnO_2)	Sputtering	Semiconductor in gas sensors
Zinc oxide	Sputtering	Electrical isolation, piezoelectric
Non-Crystalline Silicon Compounds		
α-Si-H	CVD, sputtering, plasma CVD	Semiconductors
Polysilicon	CVD, sputtering, plasma CVD	Conductor, microstructures
Silicides	CVD, sputtering, plasma CVD, alloying of metal and silicon	Conductors
Metals (thin films) with ρ in $\mu\Omega\cdot$cm in ()		
Silver (Ag) (1.58)	Evaporation; sputtering	Electrochemistry electrode
Aluminum (Al) (2.7)	Evaporation, sputtering, plasma CVD	Electrical interconnects, limited to operations below 300°C
Chromium (Cr) (12.9)	Evaporation, sputtering, electroplating	Electrical conduction, adhesion layer (10–100 nm)
Gold (Au) (2.4)	Evaporation, sputtering, electroplating	Electrical interconnects for higher temperatures than Al, optical reflection in the IR
Iridium (Ir) (5.1)	Sputtering	Electrochemistry electrode, biopotential measurements
Molybdenum	Sputtering	Electrical conduction
Platinum(Pt) (10.6)	Sputtering	Electrochemistry electrode, biopotential measurements
Palladium (Pd) (10.8)	Sputtering	Electrical conduction, adhesion layer, electrochemistry electrode, solder wetting layer
Tungsten (W) (5.5)	Sputtering	Electrical interconnects at higher temperatures
Titanium(Ti) (42)	Sputtering	Adhesion layer
Copper(Cu) (1.7)	Sputtering	Low resistivity interconnects
Alloys		
Al-Si-Cu	Evaporation, sputtering	Electrical conduction
Nichrome(NiCr) (200–500)	Evaporation, sputtering	Thin film laser-trimmed resistor
Permalloy™ (Ni_xFe_y)	Sputtering	Magnetoresistor, thermistor
TiNi (80)	Sputtering	Shape memory alloy
Chemically/Physically Modified Silicon		
n/p type silicon	Implantation, diffusion, incorporation in the melt	Conduction modulation, etch stop
Porous silicon	Anodization	Electrical isolation, light-emitting structures, porous junctions
Silicon dioxide	Thermal oxidation, sputtering, anodization, implantation, CVD	Electrical and thermal isolation, masking, encapsulation
Silicon nitride	Plasma enhanced CVD (PECVD)	Electrical and thermal isolation, masking, encapsulation

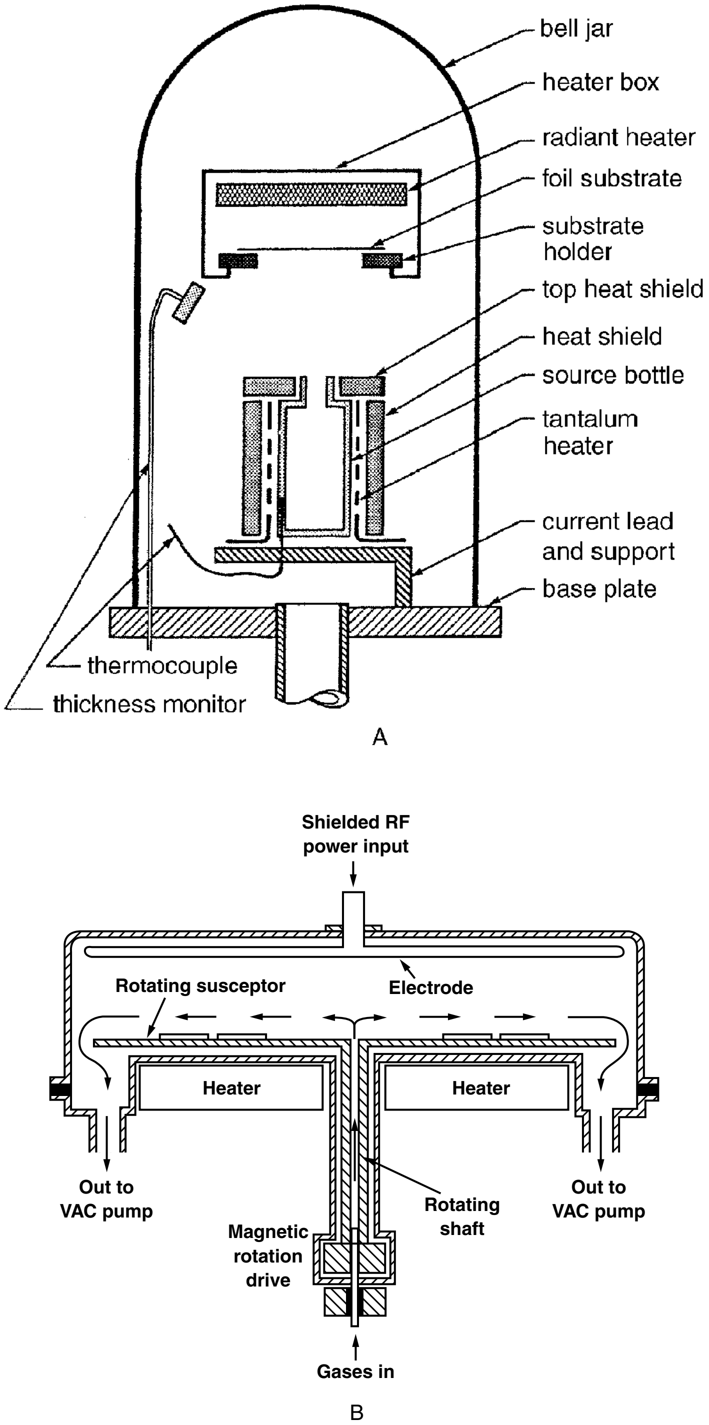

FIGURE 15.3.5 Example setup for PVD: (A) typical thin film deposition by evaporation setup; and (B) for CVD, cross section of a PECVD reactor from Applied Materials.

(PSG) deposited by LPCVD stands out as the best material for the sacrificial layer because it etches even more rapidly in HF than SiO_2. In order to obtain a uniform etch rate, the PSG film must be densified by heating the wafer to 950–1100°C in a furnace or a rapid thermal annealer (RTA).[65] With a first mask,

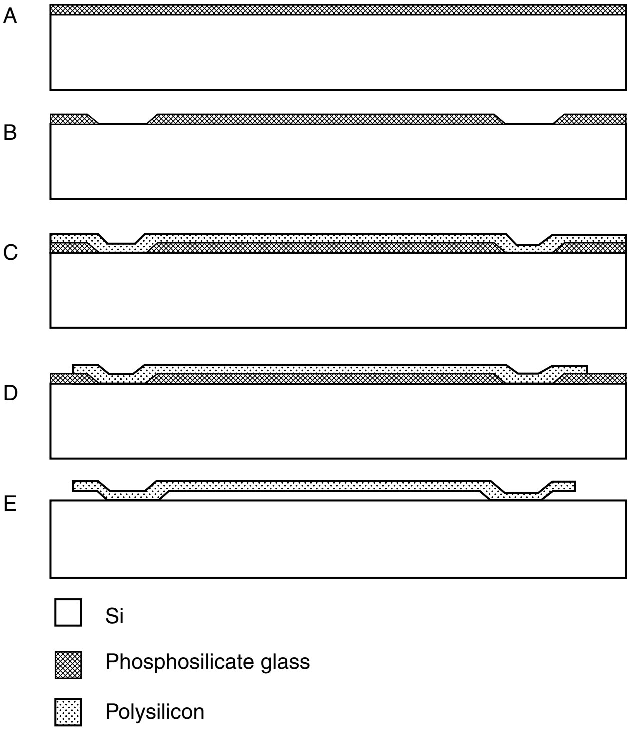

FIGURE 15.3.6 Basic surface micromachining process sequence. (A) Spacer layer deposition (the thin dielectric insulator layer is not shown). (B) Base patterning with mask 1. (C) Microstructure layer deposition. (D) Pattern microstructure with mask 2. (E) Selective etching of spacer layer.

the base is patterned as shown in Figure 15.3.6B. Windows are opened up in the sacrificial layer and a microstructural thin film, whether consisting of polysilicon, metal, alloy, or a dielectric material, is conformably deposited over the patterned sacrificial layer (Figure 15.3.6C). Furnace annealing, in the case of polysilicon at 1050°C in nitrogen for one hour, reduces stress stemming from thermal expansion coefficient mismatch and nucleation and growth of the film. Rapid thermal annealing has been found effective for reducing stress in polysilicon as well.[63] With a second mask, the microstructure layer is patterned, usually by dry etching in a CF_4 + O_2 or a CF_3Cl + Cl_2 plasma (Figure 15.2.6D).[66] Finally, selective wet etching of the sacrificial layer, say in 49% HF, leaves a freestanding micromechanical structure (Figure 15.3.6E). The surface micromachining technique is applicable to combinations of thin films and lateral dimensions where the sacrificial layer can be etched without significant etching or attack of the microstructure, the dielectric, or the substrate. Typically a surface micromachining stack may contain a total of four to five structural and sacrificial layers but more are possible; the poly-Si surface machining process at Sandia's SUMMIT, for example, stacks up to five polysilicon and five oxide layers.

LIGA and Replication Techniques

LIGA is the German acronym for X-ray lithography (X-ray *lithographie*), electrodeposition (*galvanoformung*), and molding (*abformtechnik*). The process involves a thick layer of X-ray resist — from microns to centimeters — high-energy X-ray radiation exposure, and development to arrive at a three-dimensional resist structure. Subsequent metal deposition fills the resist mold with a metal and, after resist removal, a freestanding metal structure results.[67] The metal shape may be a final product or serve as a mold insert for precision plastic molding. Molded plastic parts may in turn be final products or lost molds (see Figure 15.3.7). The plastic mold retains the same shape, size, and form as the original resist structure but is produced quickly and inexpensively as part of an infinite loop. The plastic lost mold may generate metal parts in a second electroforming process or generate ceramic parts in a slip casting process.

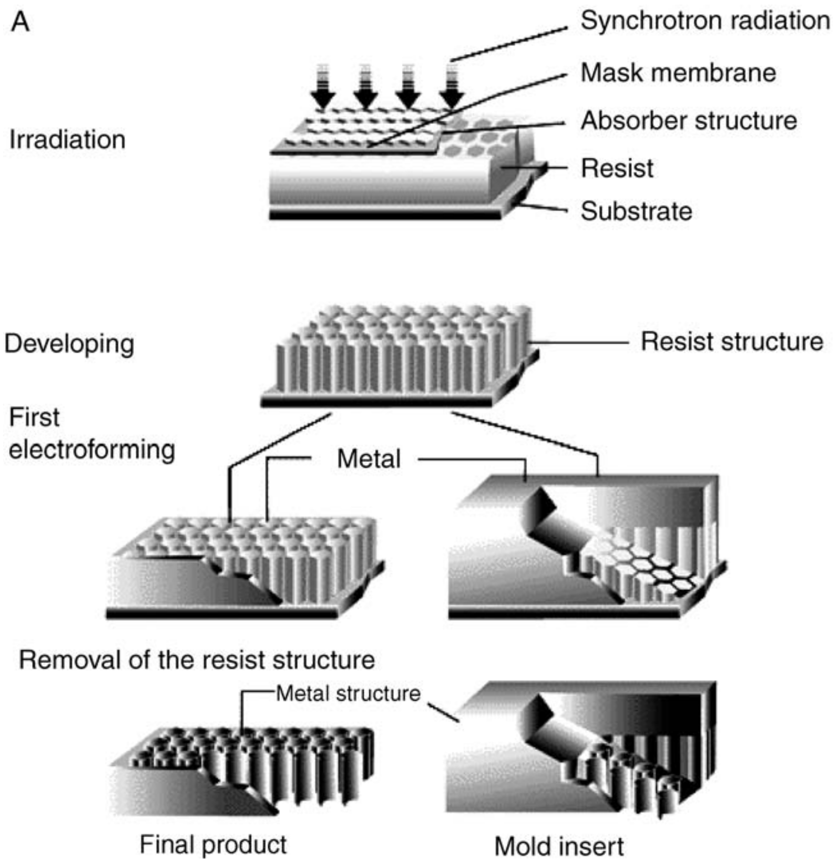

FIGURE 15.3.7 (A) The basic LIGA process steps X-ray deep-etch lithography and first electroforming. (B) Plastic molding and second electroforming/slip casting. (After H. Lehr and M. Schmidt, *The LIGA Technique*, commercial brochure, IMM GmbH, Mainz-Hechtsheim, 1995. With permission.)

The bandwidth of possible sizes in all three dimensions renders LIGA useful for manufacture of microstructures (micron and submicron dimensions), of packages for these microstructures (millimeter and centimeter dimensions), and even for the connectors from those packages to the "macro world" (electrical, e.g., through-vias or physical, e.g., gas in- and outlets).

Once LIGA was established in the research community, interest in other micro- and nano-replication methods became more pronounced. Given the cost of the LIGA equipment, various LIGA-like processes took center stage. These pseudo-LIGA methods involve replication of masters created by alternate means such as deep reactive ion etching (DRIE) and novel ultraviolet thick photoresists. This more generalized lithography and replication procedure is illustrated in Figure 15.3.8.

Micromachining techniques are reshaping manufacturing approaches for a wide variety of small parts. Frequently, IC-based batch microfabrication methods are considered together with more traditional, serial machining methods. In this evolution, LIGA and pseudo-LIGA processes constitute "handshake-technologies," bridging IC and classical manufacturing technologies. The capacity of LIGA and pseudo-LIGA for creating a wide variety of shapes from different materials makes these methods akin to classical machining with the added benefit of unprecedented aspect ratios and absolute tolerances rendered possible by lithography or other high-precision mold-fabrication techniques. The high cost of X-ray lithography caused many miniaturization engineers to search for alternate means for fabricating high-aspect-ratio metal or polymer micro-masters. Micromold inserts (or micro-masters) can be fabricated by a variety of alternate techniques, such as CNC machining, silicon wet bulk micromachining, precision

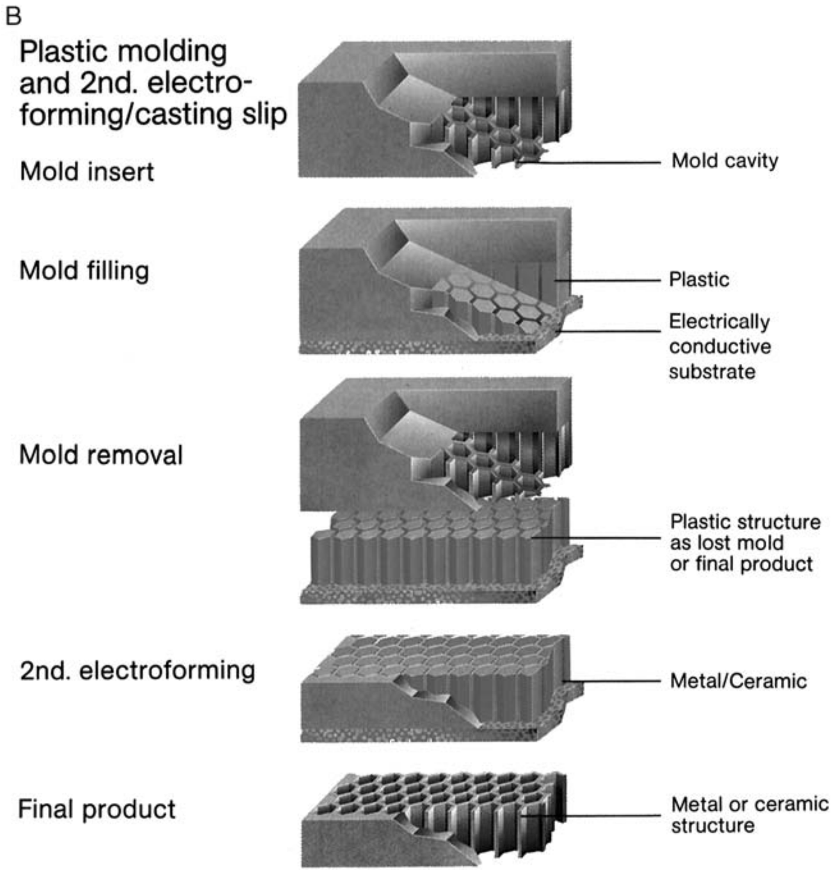

FIGURE 15.3.7 (continued).

EDM, thick deep UV resists, DRIE, excimer layer ablation, and e-beam writing. In Table 15.3.5 LIGA metal molds are compared with metal masters fabricated by other means. For example, comparing metal mold inserts made by spark erosive cutting and X-ray lithography, the latter proves far superior.[69] LIGA PMMA features as small as 0.1 μm are replicated in the metal shape with almost no defects. The electroformed structures have a superior surface quality with a surface roughness, R_{max}, of less than 0.02 μm.[70]

Deep reactive-ion etching (DRIE) and thick deep UV-sensitive resists (DUV) such as polyimides, AZ-4000, and SU-8 are recent contenders for micro-master mold fabrication. With respect to dry etching, higher and higher aspect ratio features are being achieved; especially when using highly anisotropic etching conditions as in cryogenic DRIE and in the Bosch process, remarkable results are obtained. Wall roughness, causing form locking, remains a problem with DRIE; the dry-etching process was optimized for speed, not for demolding. For small-quantity production, where the lifetime of mold inserts is not crucial, a silicon wafer etched by DRIE can be utilized directly as a mold insert for anywhere from 5 to 30 molding cycles.[72,73] Figure 15.3.9A shows such a Si mold for building a two-point calibration fluidic device on a compact disc. Wet etching of Si leads to much smoother surfaces than DRIE and is therefore the preferred method for making mastermolds out of Si. For much longer-lasting molds, metallizing the Si structure and using the metal as mold is preferred. Photoresist structures on a silicon substrate have also been tested as mold inserts in plastic molding because of the simplicity and low cost of the process. Figure 15.3.9B shows a SU-8 photoresist mold for the same lab CD platform shown in Figure 15.3.9A. In low-pressure molding processes, such mold inserts do work for a limited number of runs (applying a thin metal layer over the top of the resist may further extend the lifetime of the mold), but their applicability in high-pressure processes needs to be further verified. A better approach is to use deep UV-photosensitive resists for electroplating to yield a metal tool, usually nickel or nickel-cobalt. Figure 15.3.9C shows a nickel mold insert made using SU-8 in our lab for the two-point calibration microfluidic platform. Both DUV and DRIE are more accessible than LIGA and will continue to improve, taking more opportunities away from LIGA. Like LIGA, both alternative techniques can be coupled with plating, but neither technique can yet achieve the extreme low surface roughness and vertical walls of LIGA.

Other competing technologies for making metal masters are laser ablation methods and ultraprecision CNC machining. The latter methods are serial processes and rather slow, but since we are considering the production of a master only these technologies might well be competitive for certain applications.

Laser microablation produces minimum features of about 10 μm width and aspect ratios of 1:10. Challenges include taper and surface finish control. Recast layers around the laser drilled features cause form locking and infidelity in the replication. Femtosecond pulse lasers promise thinner or even the absence of recast layers and excellent resolution, and should be investigated further (see also below).[74]

For large features (>50 μm) with tolerances and repeatability in the range of about 10 μm, traditional CNC machining of materials like tool steel and stainless steel is often accurate enough for making metal mold inserts. The advantage of this technique is that the tool materials used are the same as those in conventional polymer molding, so their design, strength, and service life are well established. Complicated three-dimensional structures can also be machined easily. The main drawbacks are that it is difficult to

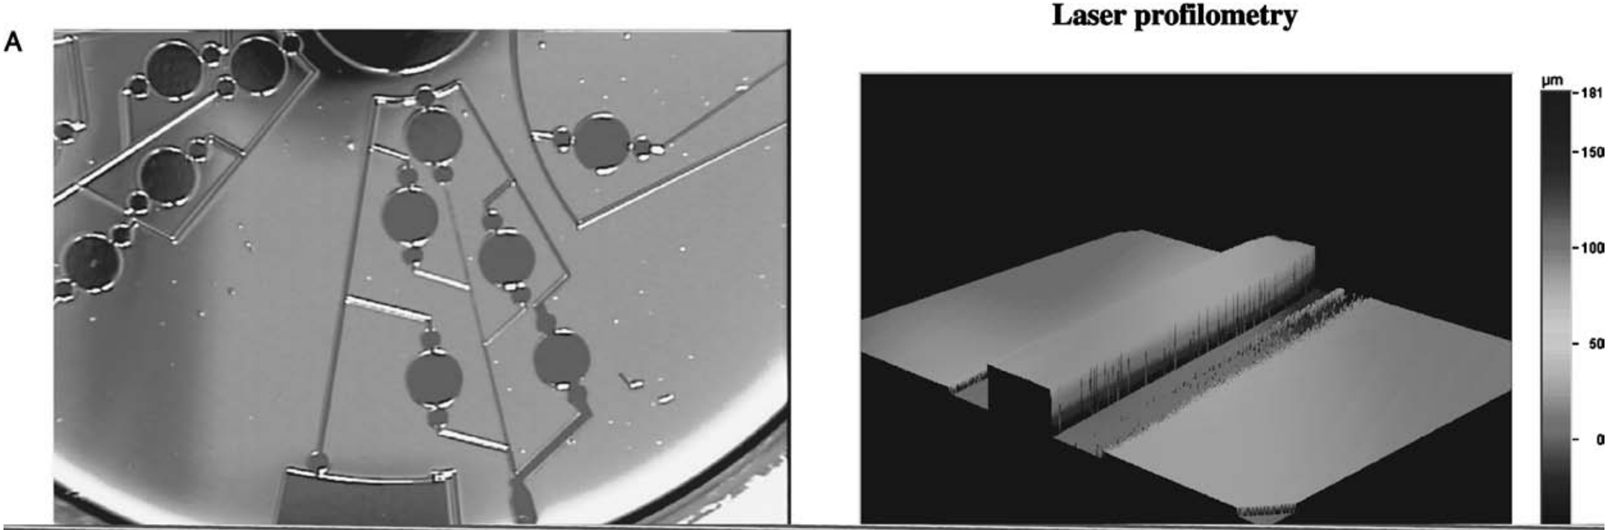

FIGURE 15.3.9A Silicon mold insert made by UV photolithography and deep reactive-ion etching (DRIE) at Burstein Technologies/UCLA/OSU.

make sharp corners or right angles, and the surface quality is usually poor (surface roughness is around several μm).[75] In contrast, lithographic methods can produce molds with excellent surface quality (surface quality < 0.1 μm), and sharp corners or right angles. However, they cannot be used on conventional tool materials like steel. Diamond-based micromilling and microdrilling[76] reduce the surface roughness to 1 μm or less.[77] While diamond-based methods can achieve features smaller than 10 μm, they are only applicable to "soft" metals such as nickel, aluminum, and copper.

From Table 15.3.5 a significant potential application of LIGA remains the fabrication of those metal molds that cannot be accomplished with other techniques because of the tight wall roughness tolerances, small size, and high-aspect-ratios. From the table it is obvious that LIGA micromolds excel in both very low surface roughness and excellent accuracy.

Summarizing, the requirements for an optimal mold insert fabrication technique are[78]

1. The master has to be removed from the molded structure, so the ease of release through wall inclination control is crucial (undercuts, for example, cannot be tolerated as they cause form locking).
2. The most important parameter, including master lifetime and achievable aspect ratios, depend strongly on the surface quality of the master.
3. The interface chemistry between master and polymer is a critical factor and must be controlled.

Laser Machining

Conventional lithographic techniques for making three-dimensional shapes are limited to unidirectional extensions of two-dimensional patterns. By using laser-beam removal processes, truly three-dimensional structures can be made without the need of masks. Three-dimensional structures are first constructed using a commercial solid-modeling software package. Then these structures are digitized into a stack of planar software masks, each comprising an array of pixels. In a laser machining setup, depth contouring is accomplished by dynamically refocusing the laser beam. Numerous different profiles (masks) can be stored in the laser positioning system and recalled as required. Laser machining is not always narrow beam based. In the case of excimer lasers, a quite broad beam of UV is produced and the shape of the micromachined structures may be controlled by using a chrome on quartz mask, like the masks produced for photolithography. In the simplest system, the mask is placed in contact with the material being machined, and the laser light is shone through it.

Like other thermal removing techniques, laser machining does leave a heat affected zone (HAZ) on the workpiece where molten material resolidified *in situ* or where material was sufficiently heated and cooled rapidly enough to result in embrittlement. This change in material properties can alter subsequent laser ablation and material performance.

Micromachining with laser ablation was first reported by R. Srinivasan and V. Mayne-Banton of IBM Research in 1982.[79] Initial studies by Srinivasan and co-workers showed that pulsed ultraviolet laser radiation at 193 nm can be used to etch organic polymers several micrometers in depth. To illustrate how fast things have been moving since but how little yet is known of the fundamental underlying processes in this field, consider that it was only recently recognized that femtosecond laser pulses interact with matter in a manner that is totally different from traditional lasers with longer pulses. During machining with femtosecond lasers, much less heat dissipates in the substrate, and as a consequence, ultrafast lasers present the potential for micromachined products of superior quality.

Based on pulse length there are three major laser machining operation modes; short, ultrashort, and long (or continuous wave [CW]). *Short* means that the pulse is longer than 10 picoseconds. *Ultrafast* or *ultrashort* means that the laser pulse has a duration that is somewhat less than 10 picoseconds — usually some fraction of a picosecond. *Long* or *CW* lasers are lasers that are operated in a continuous wave (pulse duration > 0.25s) rather than a pulsed mode. Each operation mode has its own micromachining applications. Short pulses of coherent light replace electrons from the electron beam vacuum technology as the cutting tool by vaporizing the substrate (subtractive process). No vacuum is required, but the removal rate is much slower than in electron-beam machining. With ultrashort pulses, so much energy is deposited

TABLE 15.3.6 Laser Parameter and Related Processing Parameters

Laser Parameter	Influence on Material Processing
Power (average)	Temperature (steady state) Process throughput
Wavelength (μm)	Optical absorption, reflection, transmission, resolution, and photochemical effects
Spectral linewidth (nm)	Temporal coherence Chromatic aberration

in the material at such a fast rate that the material is forced into a plasma state; the material goes from a solid to a gas phase without first going through a melt phase. This plasma then expands away from the material as a highly energetic gas, taking almost all the heat away with it. This newest operation mode promises to open up a new universe of very accurate micromachined parts unavailable with short laser pulsing. Long pulse or CW lasers can be used to melt the metal for welding (additive process).

Table 15.3.6 summarizes all the different laser parameters that can be controlled and their effect on materials processing.[80] For micromachining purposes, the wavelength, spot size (i.e., the minimum diameter of the focused laser beam), average laser beam intensity, depth of focus, and laser pulse length are the five most important parameters to control.

The most fundamental feature of laser/material interaction in the long pulse regime (e.g., pulse duration 8 ns, energy 0.5 mJ) is that the heat deposited by the laser in the material diffuses away during the pulse duration, that is, the laser pulse duration is longer than the heat diffusion time. This may be desirable for laser welding, but for most micromachining jobs heat diffusion into the surrounding material is undesirable and detrimental to the quality of the machining.

The various undesirable effects associated with long laser pulse etching are illustrated in Figure 15.3.10.

From this discussion it is obvious why we are interested in laser micromachining with short pulses, particularly femtosecond lasers with pulses more than a million times shorter than the several nanosecond duration pulses used in traditional industrial laser micromachining systems. The laser intensity easily reaches the hundreds of terawatts per square centimeter at the work spot itself. No material can withstand the ablation forces at work at these power densities. This means that with ultrafast laser pulses very hard materials (such as diamond) as well as materials with extremely high melting points (such as Molybdenum and Rhenium) can be machined. The most fundamental feature of laser-matter interaction in the very fast pulse regime is that the heat deposited by the laser into the material does not have time to move away from the work spot during the time of the laser pulse. The duration of the laser pulse is shorter than the heat diffusion time. This regime has numerous advantages:

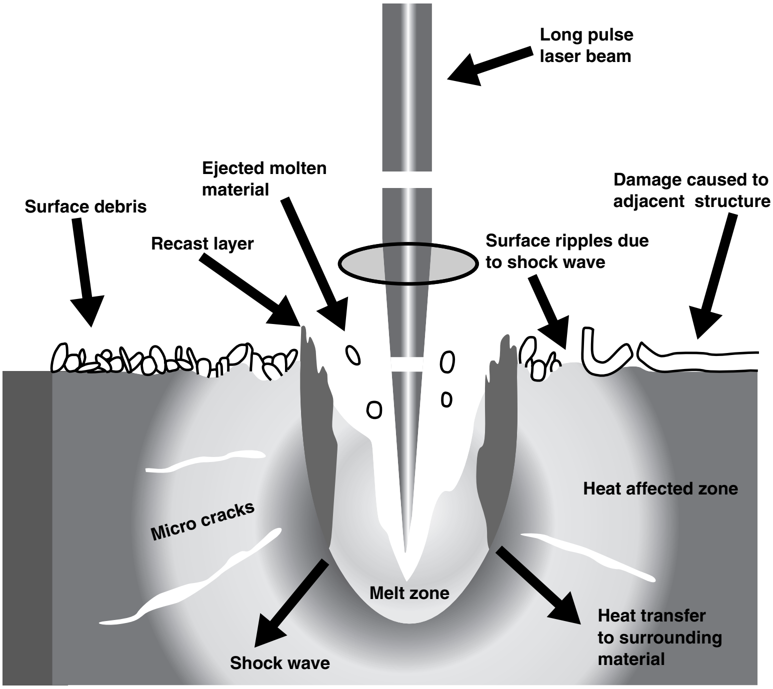

FIGURE 15.3.10 Various undesirable effects associated with laser pulses that are too long, for example, pulse duration 8 ns, energy 0.5 mJ.

- Because the energy does not have the time to diffuse away, the efficiency of the machining process is high. Laser energy piles up at the level of the working spot, whose temperature rises instantly past the melting point of the material and keeps on climbing into what is called the *plasma* regime.
- After the ultrafast laser pulse creates the plasma at the surface of the workpiece, the pressures created by the forces within it cause the material to expand outward from the surface in a highly energetic plume or gas. The internal forces that previously held the material together are vastly insufficient to contain this expansion of highly ionized atoms and electrons from the surface. Consequently, there are no droplets that condense onto the surrounding material. Additionally, since there is no melt phase, there is no splattering of material onto the surrounding surface.
- Heating of the surrounding area is significantly reduced and consequently all the negatives associated with a HAZ are no longer present — which means no melt zone, no micro cracks, no shock wave that can delaminate multilayer materials, no stress that can damage adjacent structures, and no recast layer.

The many advantages associated with working in the femtosecond pulse range are illustrated in Figure 15.3.11.

Mechanical Processes

Introduction

In mechanical precision machining, mechanical energy is the *modus operandi* behind every operation, from grinding and drilling to broaching (removing very thin slices) and milling.[†] In mechanical removing

---

[†] A useful glossary for terms used in metal removal and manufacturing processes in general can be found at http://instruct1.cit.cornell.edu/courses/orie310/mfgproc/mfgprocsummary.html and an introduction to machine tools can be found at http://me.mit.edu/2.70/machine/outline.html and at http://engide.bizland.com/mfg-5-machine.htm.

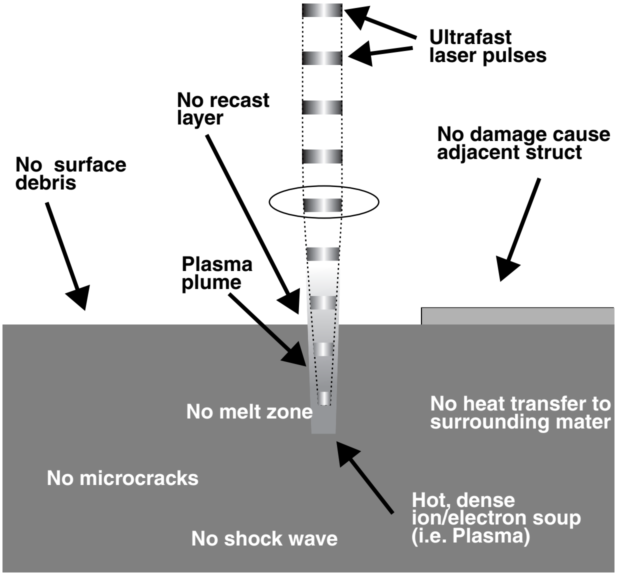

FIGURE 15.3.11 Advantages associated with working with very short laser pulses (<10 picoseconds).

(machining), stresses induced by a tool overcome the strength of the material. How well a part made from a given material holds its shape with time and stress is referred to as the *dimensional stability* of the part and the material. In order to maximize dimensional stability, the machine design engineer tries to minimize the ratios of applied and residual stress to yield strength of the material. A good rule of thumb is to keep the static stress below 10% to 20% of yield. Thermal errors are often the dominant type of error in a precision machine, and thermal characteristics such as thermal expansion coefficient and thermal conductivity deserve special attention.[81]

Precision Mechanical Machining vs. Si Micromachining

For over a hundred years, precise macromachines have been designed and built with mechanical removal techniques achieving part-per-million relative tolerances; recently macromechanical machines have entered the realm of 0.1 ppm relative tolerances.[82] In comparing Si micromachines with mechanically machined macrostructures, Slocum makes some important observations.[82] He notes that, while micromachines are impressive for their small size, their relative accuracy is two orders of magnitude worse than is typically achieved in macromachines, which, moreover, are much more complex. Typical micromachines today, Slocum points out, are comparable with the macromachines of the early 1700s with respect to complexity and accuracy. The surface roughness of micromachines looks high compared to the specular finishes of bearing surfaces. In reality, the absolute roughness is about the same, but in micromachines surface forces such as friction are relatively more important. Thermal errors in a micromachine are generally more relaxed; the small scale and fast thermal equilibrium of the smaller structures is their saving grace. Another key issue Slocum brings up is that of position measurement systems; verification of fabricated geometry and tolerances are much more difficult for micromachines since measurement of a displacement of one part in ten thousand will typically get one down to the nanometer level.

Higher-accuracy machining is needed to provide computer memory disks and optical mirrors and lenses with accuracies to a fraction of the wavelength of light. A better understanding of the limits of traditional and nontraditional machining methods would help the mechanical engineer make the best choice in machining tools. At the same time, as micromachine mechanical complexity increases, it seems appropriate for the designers of micromachines, who are typically electrical engineers, to study macromachine design.

Watanabe, N. Kawahara, Y. Ohtsuka, and T. Hattori, *J. Microelectromech. Syst*., 4, 76–80, 1995. With permission.)

Ultra-High Precision Mechanical Machining

In mechanical machining, various factors such as deformation of the workpiece and tool, vibration, thermal deformation, and inaccuracies of machine tools affect the machining accuracy. Ultra-high precision machines with sharp single-crystal diamond tools have made submicrometer precision machining possible. The first CNC machines became available in 1977. The smallest movement the machines could reproducibly make was 0.5 μm. By 1993, 0.05 μm became possible, and today there is equipment available featuring 0.01 μm and even nanometer step resolution.[83] The resolution of the steps a machine can make, of course, is a determining factor for the manufacturing accuracy of the workpiece. Ultraprecision manufacturing is still the commercially preferred technique for the production of computer hard disks, mirrors for X-ray applications, photocopier drums, commercial optics such as polygon mirrors for laser-beam printers, consumer electronics such as mold inserts for the production of CD reader heads and camcorder viewfinders, in addition to high-definition television (HDTV) projection lenses and VCR scanning heads.

Using a diamond tip and numerical control (NC), rice-grain-sized cars were machined at Nippondenso (one car was 4.5 mm long and another was 7.5 mm long) (Figure 15.2.12).[84] The shell of the car was made by the sacrificial mold technique.

The single-crystal diamond tool refinements are not the only reason for the high precision achieved today; submicron precision is also being achieved through high-stiffness machine beds, air bearings (air bearings with a rotational precision of 0.01 μm and better are available now), and measurement systems such as laser interferometry. Furthermore, highly precise instruments such as servomotors, feedback devices, and computers have been implemented, and many types of machine tools are now equipped for CNC, further improving precision and reproducibility of the manufactured parts.

The latest trend is toward flexible manufacturing. In response to the need for automation and the demands created by frequent design changes over a broad variety of products, flexible manufacturing systems (FMS) were developed. FMS is a combination of several technologies such as computers, CNC workstations, robots, transport bands, computer-aided design (CAD), and automatic storage. The technique was developed to produce many varieties of a certain product in smaller quantities rather than many devices of one type. CNC workstations are linked by automatic workpiece transfer and handling, with flexible routing and automatic workpiece loading and unloading.[85]

Fanuc's ROBOnano U_i is an ultraprecision micromachining station capable of making such high precision parts as the mold for diffraction gratings or aspheric lenses. This superprecision micromachining equipment consists of a diamond milling tool rotating at high speed on a superprecision positioning table with nanometer resolution. Using this setup, Fanuc succeeded in relief engraving a minute,

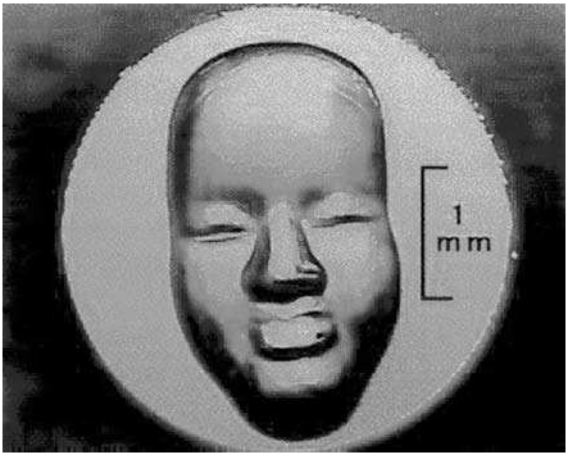

FIGURE 15.3.13 Japanese NOH mask. (*Source:* Fanuc).

mirror-surfaced Noh-mask in copper with a "diamond end mill," which results in a surface smoother than a mirror (see Figure 15.3.13). The roughness of the forehead (R_{max}) of the mask is 60 nm. Thus, Fanuc has realized a superprecision micromachining technique that allows mirror finishing in any direction except in a narrow groove.

Despite all of this progress, the fact that it often takes a 2-ton machine tool to fabricate micro parts where cutting forces are in the milli- to micro-Newton range is a clear indication that a complete machine tool redesign is required for the fabrication of micromachines.[86] Along this line, in Japan the concept for desktop flexible manufacturing systems (DFMS) for building micromachines was proposed in the early 1990s.[87] The manufacturing units would be tabletop size and include universal chuck modules to which workpieces would be continuously clamped through most of the manufacturing process. The miniature die press from Aoki and Takahashi is one of the first examples of progress in that direction.[88]

Bottom-Up Manufacturing

Introduction

At the beginning of the twenty-first century, the performance criteria for top-down manufacturing techniques, that is, Moore's law, which projects the progress in achievable transistor density on a chip, and Taniguchi's curves, which predicts improvements in accuracy for mechanical machining, have started to exhibit signs of a slowdown. Further miniaturization progress will most likely be based on methods originating in nanochemistry, that is, bottom-up methodologies as well as combinations of top-down nanofabrication using "traditional" IC methods and nanochemistry.

A Path to Bottom-Up Manufacturing

Over the next ten years, the size overlap of objects fabricated with either approach will become more significant. Consequently, molecular engineers and supramolecular chemists who are manipulating, with rapidly improving dexterity, nature's building blocks, such as atoms, molecules, proteins, and DNA, will, jointly with MEMS specialists who are now reaching the 0.1 μm lithography limits, find new ways to combine top-down nanofabricated components with bottom-up "natural" products. Previous manufacturing methods discussed in this section are all top-down technologies. In this decade, bottom-up manufacturing methods, in which small particles such as atoms, proteins, and atom clusters are added or removed for the construction of bigger functional structures, will become the most important research domain for the future of manufacturing. Bottom-up methods draw from work in supramolecular chemistry, protein engineering, molecular self-assembly, proximal probes such as STM, photon manipulation of individual atoms, carbon nanotubes, and so forth. For the next two decades, we expect the size of objects that can be built with top-down and bottom-up approaches to overlap more and more as we learn new ways to combine ever smaller components manufactured through nanofabrication with the products of molecular engineers and supramolecular chemists who manipulate nature's building blocks such as atoms, molecules, proteins, and DNA with increasing dexterity.

Guidance from Nature

Nature provides excellent examples in the design of efficient microsystems as it optimizes scaling laws in the micro-domain and even exploits the quantum-size effects of its components. In biological systems, the energy efficiency is approximately proportional to the 2/3 power of the linear dimension. This is because metabolism is proportional to the second power of the linear dimension (surface of the organism, 1^2), and energy uptake (feeding) is proportional to the body volume (1^3), so the smaller organism is, the higher its efficiency. As a consequence, smallness is the ancestral condition of life. Large organisms are built bottom-up from cells rather than divided into cells. Cells are, in turn, fabricated from yet smaller entities. A single *E. coli* bacterium, for example, is shaped like a cylinder about 1 μm across and 3 μm long. It contains at least 3000 different molecular parts and will divide every 20 minutes when nutrients are available. Human manufacturing technology works in the opposite direction; it builds top-down. Humans tend to start with larger building blocks and use stiff materials (e.g., Si or stainless steel), whereas nature prefers small building blocks and mostly soft, low Young's modulus materials (e.g., materials in muscle or skin). As an example of recent human engineering ingenuity, consider Si micromachining or MEMS. Si micromachining involves Si wafer slabs as thick as 500 μm, insulating layers up to a μm thick, Al and Au metal layers between a few hundred and few thousand Ås thick, and, in general, three-dimensional structures with dimensions anywhere between 1 and 500 μm. Although MEMS has led to major advances, the method still presents a limited choice of materials and works with building blocks that are large and crude compared to nature's arsenal.

Biomimetics is the study of how nature, building atom by atom, through eons of time, developed manufacturing methods, materials, structures, and intelligence. These studies are inspiring engineering and design of man-made miniature objects. As nanochemistry is currently inspiring a new wave of biomimetic efforts, caution is in order since, as the legend of Icarus so pointedly reminds us, most previous attempts at biomimetics have resulted in failure. However, we believe that past failures mostly pertain to macroengineering and will not hold true in nanoengineering. In macroengineering, as S. Vogel points out in *Cats' Paws and Catapults,*[89] human and natural technologies form a separate, well-integrated entity, operating in an internally coherent context. Nature, for example, does not use steel, nor does it favor the production of flat surfaces and sharp corners — all very useful in human manufacturing. Nature builds with proteins and produces mostly curved surfaces and rounded corners, resulting in such masterfully engineered objects as biological cells. In large-scale engineering projects, both natural and human manufacturing approaches have their merits within their own proper frame of reference. It is in the nano world that nature is way ahead of human engineering as it has learned to work with much smaller, more versatile building blocks and master the self-assembly of those building blocks. As humankind learns to build with the same construction set, we are bound to challenge nature in nano engineering. Because it uses relatively large building blocks, human manufacturing is rapid and the expectation is that nature, because it uses much smaller building blocks, for example, atoms with a diameter of 0.3 nm, must be very slow. To offset the time it takes to work with small, basic building blocks, nature, in growing an organism, relies on an additive process featuring massive parallelism and self-assembly.

A few of the guiding principles involved in the construction of living organisms are[90]

- The use of composites (rather than monolithic materials in human engineering)
- Several successive levels of organization (hierarchy)
- Soft flexible materials
- Self-assembly, self-organization, and self-replication all through weak bonds
- The use of templates (e.g., the reading of genes by messenger RNA [m-RNA] to build proteins in the cells' ribosomes)
- Compartmentalization

These principles provide inspiration for the implementation of human nanotechnology.

Nanocomposite materials, for example, are widespread in biological systems as in bone, cell walls, soft body tissue, and so forth. The nacre (mother-of-pearl) of abalone shell, an oriented coating composed of alternating layers of aragonite ($CaCO_3$) and a biopolymer, is an often studied example. The laminated structure provides strength, hardness, and toughness. Nacre is twice as hard and 1000 times as tough as its constituent phases. Humankind has accumulated plenty of experience with composite materials, but attempts to make "biomimetic" nanocomposite assemblies are quite recent. Along this line, Sellinger et al. reported on an efficient self-assembly process for preparing nanolaminated organic-inorganic coatings that mimic nacre.[91] New biomimetic materials, such as scaffolds for regrowth of tendons, tend to be composites too, although not on the nanoscale; in the case of tendon scaffolds, composites are made from carbon fibers and polylactic acid.[90]

Proteins, bone, and tissue fibers have a hierarchical organization much more complex than materials of the nonliving world (e.g., crystals). This organization bestows many benefits on living organisms, such as a high strength-to-density ratio and the ability to serve several functions simultaneously. The ability of humans to mimic this feat is still limited and will only improve if we become more adept at manipulating a wider variety of materials at the nanoscale, use smaller building blocks, and build in three dimensions with more dexterity. Traditional lithography is mostly limited to two-dimensional structures and is impractical for printing feature sizes below 0.1 μm.

Self-assembly is the lock-and-key[†][92] assembly of complex molecules, such as in the case of neurotransmitters assembling with molecular recognition sites on proteins that elicit chemical responses — for example, acetylcholine recognition at nerve-muscle junctions resulting in muscle contractions.[3] Self-assembly is taken advantage of, for example, in DNA probes and immunosensors but is not used much yet in human manufacturing. Some early attempts at self-assembly of larger components (e.g., GaAs diodes), include DNA mediated self-assembly.[93–95]

Self-organization leads to large supramolecular architectures such as molecular crystals, liquid crystals, colloids, micelles, spherical bilayer structures of cell walls, phase-separated polymers, and self-organized monolayers, which, to confuse students, are called self-assembled monolayers (SAMs). No chemist needs to specify the individual atom or molecule positions in these systems.[96] For example, after disintegration of ribosomes into their protein and RNA building blocks the molecules will reorganize into functional units in a test tube given the right conditions. Humankind is using self-organization in building SAMs, and in colloid chemistry, one can precipitate inorganic solids such as silver halide crystals with astonishing regularity in size and properties, comparable to what can be accomplished with microlithography. The latter has become one of several routes to build quantum structures.

In self-replication, molecules such as DNA encode the genetic information for cells and the resulting organisms, thus allowing the information to be passed on from cell to cell and from generation to generation.[97]

The use of templates in micromachining has become very extensive, but our templates are at the microscale, not at the nanoscale. Finally, compartmentalization corresponds to the principle of most biological events, and many chemical changes are presided over by nonequivalent bonding interactions in, between, and beyond molecules. Chemistry beyond the molecule has given rise to supramolecular chemistry — a new field of chemistry pioneered by researchers such as Nobel laureate Jean-Marie Lehn from the University of Strasbourg.[98,99] The fundamental concepts underpinning supramolecular science are processes in which atoms, molecules, aggregates of molecules, and components arrange themselves into ordered, functioning entities without human intervention.[100] The weak interactions typically involved are

---

[†] The "lock-and-key" concept of biochemical interactions has over the years been modified in favor of a "hand-in-a-glove" concept because there is some reorganization (conformational change) required to make two biomolecules complementary to each other.[91]

- Hydrogen bonds
- Electrostatic attractions
- van der Waals' forces
- Hydrophobic interactions
- Weak covalent bonds

Through supramolecular chemistry with weak ionic and hydrogen bonds and van der Waals interactions (0.1 to 5 kcal/mol), structures with dimensions of 1 to 100 nm are possible. For chemical synthesis, the largest of these dimensions is often too large and for microfabrication it is often too small. The different fundamental processes at work in supramolecular chemistry can be illustrated by examples from nature.

The Future

Most miniaturization, especially in ICs, over the next 10 to 15 years will be based on nanofabrication, and Moore's law will continue to run its course. In parallel, we will continue to adapt nanochemistry principles and combine them with nanofabrication. There is a significant gap between the scale of individual molecular structures of nanochemistry and the submicrometer structures of nanofabrication. It is exactly in that gap, from about one nanometer to several hundred nanometers, where fundamental materials properties are defined. It is also on the nanometer scale that quantum effects become significant.

There is little doubt that biotechnology analysis tools will keep on improving at an increasingly faster rate. Desktop DNA sequencers and three-dimensional protein readers will be a reality in the not-so-distant future. Genetic engineering will have the most profound impact, though, on how humankind looks at manufacturing. Since it is already possible to synthesize a virus bottom-up, given the sequence of the bases in its genes, it seems quite likely that we will be able to manufacture synthetic viruses designed to enter a cell and carry out diagnostic and therapeutic tasks. Venter has proposed building bottom-up a minimal gene setup required to sustain life in a test tube. Photovoltaic solar cells today have a high conversion efficiency of about 10% to 15% but are expensive to deploy and maintain. Crops grown for energy are also expensive, involve harvesting and are only 1% efficient. It is conceivable that genetic engineering will enable the production of energy crops that convert sunlight into fuel at a 10% efficiency.[101] Through nanochemistry, the current digital information technology (IT) revolution might well be followed by a new analog manufacturing revolution. Today, computers let us shape our digital environment, but by giving computers the means to manipulate the analog world of atoms as easily as they manipulate bits, the same kind of personalization may be brought to our physical three-dimensional environment. In this context Gershenfeld from the MIT Media Laboratory envisions a personal fabricator (PF) akin to the PC.[102]

A human society based on nanomachining will be a much more balanced one with a manufacturing approach based on how the species itself is made. Products will be based on a fundamental understanding of the assembly of their ultimate components, atoms, molecules and proteins, and on how to induce self-assembly into useful objects. Materials will be degradable, flexible, and fully reusable. The smaller building blocks used in manufacture will enable products of more variety and intelligence. There will be less emphasis on the traditional engineering materials such as steel, wood, stone, composites and carbon, and proteins will become much more important.

The transition toward a nano-society will require a major shift in workforce skill level as manipulating data and applying knowledge of bioengineering will be part of a manufacturing worker's daily duties. In academia, less hyper-specialization and better grounding in all the sciences and engineering will become a must as the traditional "dry engineering and sciences," such as electrical engineering and mechanical engineering, merge with the "wet sciences and engineering," such as biology and bioengineering.

15.4 MEMS Packaging

Liang-Yu Chen and Phillip J. Zulueta

Introduction

The functionality and capability of micro-devices (circuits) have been dramatically complemented and expanded by the emergence of microelectromechanical systems (MEMS). The basic function of conventional microelectronic circuits is to process and exchange electromagnetic signal/power. Thus, the interaction between conventional electronics and their environments is very much limited to electromagnetic exchanges. However, since microsystems composed of electronics and MEMS may have the capabilities to accept nonelectromagnetic signals and provide nonelectromagnetic actuation, the interactions between microsystems and their environments can be electromagnetic, mechanical, optical, thermal, chemical, and biological. Figure 15.4.1 shows the two-way interactions between a generalized MEMS and its

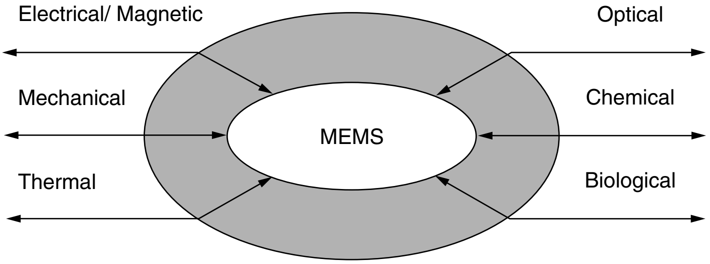

FIGURE 15.4.1 The function of MEMS chip-level packaging as an electrical/magnetic, mechanical, thermal, optical, chemical, and biological interface between a microsystem and its environment.

environment in various physical and chemical formats. Each intake arrow represents a type of possible signal that MEMS can accept, and each outgoing arrow represents a type of possible actuation that MEMS can provide. As the passive interfaces between the microsystems and the outside world, the packaging systems of microsystems may have to be capable of mediating electromagnetic, mechanical, optical, thermal, chemical, and biological interactions. These microsystem packaging functions can be far more complicated than those of conventional electronic packaging, and therefore generate new requirements and challenges to the device packaging field. Packaging requirements for MEMS devices can be device/system dependent; thus a microsystem package very likely must be specifically designed for a designated MEMS system. This is a significant difference between MEMS packaging and conventional electronics packaging, where one type of chip level package can be used for packaging many types of electronic devices/circuits.

Generally speaking, both functions and requirements of a microsystem package may need to be specified electromagnetically, mechanically, thermally, optically, chemically, and biologically. This section will discuss the thermomechanical aspects of microsystem packaging. The basic thermomechanical issues concerned in microsystem packaging include mechanical alignment, mechanical integrity, mechanical testing, stress/strain effects, and thermal mechanical environment durability. The last two issues are interrelated and are the major interest of this section, while other topics are briefly discussed next.

Mechanical alignment. Microsystems with optical MEMS are often connected to optical fibers. For example, MEMS mirror based multi-channel optical switches are connected to over dozens of optical fibers through chip level packaging. The light beams are usually focused down to a few microns diameter (Takshara et al. 2000) at both the fiber tip and chip mirror/photo diode sides. Therefore, mechanical alignment of the relative position of the chip with respect to the fiber(s) becomes one of the critical factors to overall system performance and reliability. Usually, passive alignment uses a relatively expensive expanded mode region of laser diodes. In recent years, passive alignment methods using a single-mode laser source have been reported. These methods provide low-cost, quick, and automated alignment (Owen 2000). The requirement of high-precision mechanical alignment also raises the compatibility issue of the materials used in packaging. The mismatch of thermal expansion of packaging materials can cause significant mechanical misalignment introducing thermal effects on the optical operation of the system when the environmental temperature changes (Takshara et al. 2000). Both mechanical alignment and calibration must be considered in chip-level packaging design.

Mechanical integrity. The MEMS accelerometer used in automobile safety airbag control is one of the first commercialized MEMS devices. Most of these MEMS accelerometers are silicon based. The mechanical environment for the MEMS accelerometer can be harsh. For example, the accelerometer and packaging systems used for many aerospace and military applications, such as spacecraft landing control, missile targeting, and ammunition triggering, can experience acceleration as high as ~10^3 g. Therefore, mechanical strength, mechanical rigidity, and resonant frequencies associated with the sensor package all become critical in packaging design and test.

Mechanical testing and qualification criteria. The core operation of a MEMS device is at least partially mechanical whether or not it is designed for direct mechanical function. Therefore, MEMS devices also need mechanical testing and mechanical qualification criteria in addition to the electrical test and qualification specifications. A MEMS resonator-based RF filter is a typical example: it is a device providing electronic functions with mechanical operations inside the device. Therefore, a complete performance and environment durability spec of this type of device also includes mechanical parameters, such as maximum environmental acceleration and vibration frequency. Mechanical testing of MEMS devices can be complicated and cost prohibitive.

Stress effects and thermal environment durability. The major wafer-level packaging processes include wafer bonding, wafer encapsulating, and solder/eutectics bumping. As discussed in the next section, most of these wafer-level processes are performed at elevated temperatures. The assembly is thermomechanically relaxed at an elevated processing temperature, so the processed (such as bonded) wafers are likely under significant stress because of material Coefficient of Thermal Expansion (CTE) mismatches when being operated or stored at lower temperatures. The material property mismatch at MEMS wafer-level packaging is a unique mechanical concern of MEMS packaging. Chip-level packaging (such as die-attach assembly) has a similar material property mismatch caused by thermal stress issues. Die-attach assembly is composed of a device die, packaging substrate, and a die-attaching layer. Thermomechanical stresses due to mismatch of CTE of packaging materials, such as the substrate, with the wafer material of MEMS devices (such as Si or SiC) is a common mechanical issue. CTE mismatch at the chip-level packaging can cause misalignment of optical MEMS upon environmental temperature change (Takshara et al. 2000). The CTE mismatch can also generate unwanted device thermal response to environmental temperature changes (Beranek 2000). In the extreme case, CTE mismatch can cause permanent mechanical damage, such as cracking of dies.

Piezoresistive MEMS sensors have been extensively used for both static and dynamic pressure measurements. The operation of these sensors depends on the mechanical deformation of a diaphragm on which piezoresistive strain sensors are built. Therefore, these sensors are sensitive to external forces applied on the devices. The most common but unwanted external force on the sensor diaphragm is the die-attach thermomechanical stress generated by mismatch of thermal expansions of die, attach, and substrate materials. The thermal stress may significantly change the thermomechanical configuration of the diaphragm. These stress effects are often neither reversible nor reproducible. Thus, packaging technology is one of the critical factors determining the reliability of packaged MEMS devices.

Packaging stress is especially important to MEMS for high-temperature applications. NASA is developing next-generation aerospace engines with self-monitoring and self-control capabilities. A microsystem that is capable of operation in a high-temperature combustion environment is essential to characterization and control of engine combustion processes in real time (Hunter 2003). Surface and atmospheric temperatures of Venus are about 500°C with a corrosive (acidic) atmosphere. Sensors and electronics for a diving or landing probe to Venus must be able to withstand high temperature and reactive chemical environments. For these high-temperature microsystems for aerospace applications, packaging thermal stress becomes a great concern because these devices may experience wide environmental temperature variation.

In order to discuss the basic MEMS packaging technology and analyze the mechanical stress sources in MEMS packaging at various levels, we will introduce some basic packaging concepts.

Fundamental Packaging Concepts

Four packaging levels. The wafer-level packaging provides micromechanical structures and electronic device structures (on a chip) with micro-level insulation and on-wafer electrical interconnection. It is realized prior to wafer dicing and usually considered as level-zero packaging. Chip-level packaging provides single- or multidevice chip(s) with macro-level insulation and electrical interconnections, so after packaging the device chips are ready to be handled in a macro way; it is considered as level-one packaging. Printed circuit board (PCB)–level packaging provides interconnections between (packaged) chips and passives; it is considered as level-two packaging. The instrument-level packaging provides

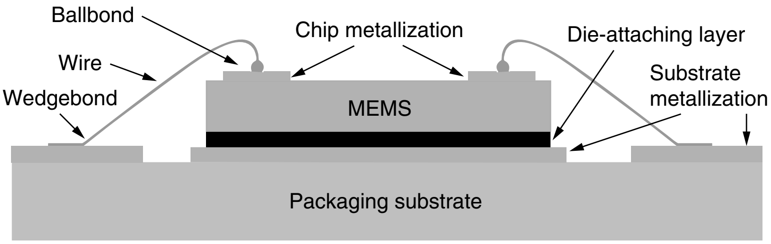

FIGURE 15.4.2 A schematic diagram of conventional chip-level packaging with wire-bond and die-attach.

interconnections between PCBs and other units; it is considered as level-three packaging. This section only addresses mechanical topics of level-0 and -1 packaging.

Substrate. Substrate is the packaging base on which a device die (chip) is mechanically attached and electrical interconnections are built. Substrate also refers to the base of a PCB. Very often, insulating materials such as ceramics and plastics are used for substrate. Coated metals can also be used as substrates. The important material properties of a substrate include electrical resistivity, dielectric constants, thermal expansion coefficient, thermal conductivity, mechanical and electrical strength, and chemical stability. Commonly used substrate materials are aluminum nitride, aluminum oxide, quartz, Kovar, molybdenum, and plastics.

Wire-bond. Wire-bond is one of the common methods for electrical interconnection between the microchip and the chip-level package. A complete wire-bond loop includes a metallization pad on the chip, a metallization pad or input/output (I/O) of the chip-level packaging substrate, and a thin metal wire bonded to both chip and packaging substrate. The wire materials include Au, Cu, Al, and Pd. The bonding methods used for wire-bond include ultrasonic, thermal ultrasonic, thermal compression, and parallel gap welding. The thermal ultrasonic bond is the most popular one for Au and Al wires. During the bonding process, wire and pad surfaces are brought into intimate contact. Heat and ultrasonic energies excite interfacial (atoms) inter-diffusion and electron sharing, resulting in bonding. There are two types of ultrasonic wire-bonds: ball-bond and wedge-bond. Ball-bond is more often used to bond wires onto metallization pads on chips. Ball-bond does not apply to Al wire because Al wire may oxidize during the process of ball formation. Au wire ball-bond is usually performed at elevated temperatures. Compared with wedge-bond the ball-bond provides a smaller footprint and therefore higher bonding density. Wedge-bond can apply to both Au and Al wires. Al wire wedge-bond is performed at room temperature. The disadvantage of wire-bond technology is that it can only apply to low-density interconnections because the pads on the chip have to be at the chip's edges; otherwise, wires may easily cause short circuits. Figure 15.4.2 shows a schematic diagram of the wire-bond-based packaging scheme.

Die-attach. Die-attach is basically the mechanical attachment of a device die to a packaging substrate providing mechanical and possibly electrical interconnection between the die and the packaging substrate. The common materials used for attaching dies include epoxy, solder, low-temperature eutectics, and glass. The physical processes of die attachment include polymerization, melting/condensation, and inter-diffusion (ultrasonic bonding). Traditionally, the active side of a die faces up and the die attachment is made to the backside of the die. Wire-bond is then used to electrically interconnect the chip to the packaging substrate.

Flip-chip. Flip-chip is a die-attach structure where the die active side faces (down) toward the packaging substrate, as shown in Figure 15.4.3. The die is both mechanically and electrically interconnected to a packaging substrate using low-temperature eutectics, solder, or Au(Al) bumps. The physical processes of flip-chip die attachment include melting/condensation and interdiffusion (ultrasonic bonding). Very often, an under-fill material is used to fill the space between the die and the substrate to reinforce the structure for better thermomechanical reliability. The flip-chip scheme provides much higher chip packaging density. Flip-chip technology has been further developed to chip-scale packages (CSP), three-dimensional stacks, three-dimensional hybrid, direct chip attach (DCA), and so forth.

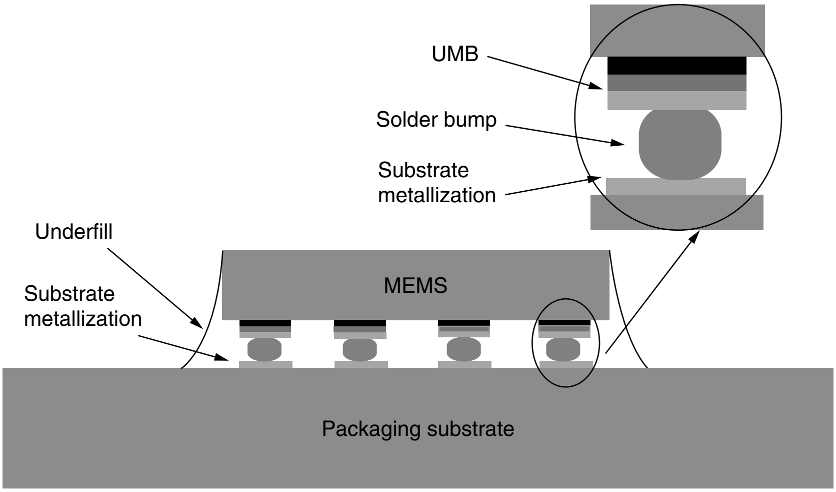

FIGURE 15.4.3 A schematic diagram of flip-chip packaging.

Sealing and Encapsulate. Usually an inert chemical environment is preferred for many MEMS and most electronic devices, so these devices are hermetically sealed into packages by glass, solder, brazing/metallization, and plastics/epoxy to reduce direct exposure to moisture and other reactive chemicals. Usually, sealing directly with glass or plastics without a package lid is considered an "encapsulate."

Harsh Environments. Harsh environments are the environments beyond those suitable for conventional silicon microelectronics and compatible packaging technology. High and extremely low temperatures, high radiation, very high acceleration, very high and dynamic pressure, chemically reactive and corrosive, and bio and medical *in vivo* environments are typical harsh environments for microsystems. Very often harsh environments generate significant challenges and additional requirements to both microsystems and packaging systems.

Wafer. Wafer is the base material on which MEMS devices and electronics are directly built. Single-crystal silicon (and other semiconductive materials such as III-V materials, silicon carbide, germanium, and SOI), poly-crystal silicon, silicon nitride, quartz, and alumina are examples of wafer materials used for fabrication of microsystems.

MEMS Packaging and Thermal Stress

Thermally induced stresses can cause undesired thermal response of MEMS device, irreproducibility of device operation and configuration, and drift of the device output. The thermal stress generated at both wafer bonding and die-attach levels must be suppressed in order to achieve precise and reliable device/system operation. To fully understand the sources of packaging stresses and resolve the issue of stresses generated at both wafer and die-attach levels, we will first discuss various wafer bonding and die-attach assembly methods. Following that, both analytical and numerical methods for packaging stress analysis will be examined.

Wafer-Level Packaging and Thermal Stress

Complicated wafer-level processes are extensively used in both MEMS device fabrication and wafer-level packaging. These wafer-level processes include wafer oxidizing, etching, thin-film deposition (metal, silicon, oxide, nitride, etc.), wafer bonding, sealing, and dicing. The materials used in wafer-level processes include oxides/nitrides, ceramics, metals/alloys, and plastics. Because of the limited space in this section, we concentrate on wafer bonding. Wafer bonding is one of the most important wafer-level packaging steps, and also the major thermal stress source of wafer-level packaging.

Si/Si and SiC/SiC Wafer Bonding

Si to Si wafer bonding is used with deep etching to create cavity-based MEMS devices such as Si capacitive pressure sensors (Ko and Wang 1999; Wang and Ko 1999; Young 2004). Wafer-level cavities are also used for packaging mechanical active components on MEMS chips. In the recent decade, wafer-bonding techniques have developed rapidly to satisfy MEMS fabrication and packaging needs. Si-Si or Si-SiO_2-Si bonding can be realized by fusion bonding at high temperatures. Generally, the process temperature required for Si wafer (without surface oxide) fusion bonding is above 1000°C, and the bonding can be conducted in vacuum to avoid wafer oxidation. The fusion bonding provides very good mechanical strength, but the disadvantage of using this method is the exposure of the wafer to high temperatures during the bonding process. Global high temperature exposure may damage prefabricated device structures and metallization. Chemical vapor deposition (CVD) and plasma-enhanced CVD (PECVD) are also often used to bond Si to Si without the surface oxide layer. These bonding methods are based on growing a thin material layer, such as poly Si, between Si wafers, to join them. Besides the exposure to high temperatures, the wafers are exposed to the CVD chemical environment. In parallel with CVD methods, sputter deposition is another choice for growth of a layer of bonding material. Special spatial geometry is necessary using this method, but the advantages gained over CVD are the control of the growth zone and less exposure to high temperature.

For bonding of Si wafers with a surface oxide layer (SiO_2/Si), usually the wafers are processed in acid first to form surface Si-O-H bonds. These hydrated wafer surfaces can be bonded directly to one another by intimate contact in a wide temperature range, from room temperature to ~1000°C. The bonding strength depends on the bonding temperature. The fact that higher bonding temperature provides better mechanical strength indicates different interfacial chemical reactions at different bonding temperatures (Madou 1997).

Low-temperature eutectics have been widely used to bond Si wafers in microfabrications. The most frequently used eutectics is $Au_{97}Si_3$ alloy, which has a low melting temperature of 363°C (Pecht et al. 1998). This eutectic bonding provides good mechanical strength. The bonding procedure is as follows: A thin SiO_2 layer is first grown on a Si wafer as an insulation layer. A chromium (Cr) thin-film layer with a thickness of 0.05 μm is deposited as an adhesion layer followed by a 0.5 μm Au layer. The second Si wafer is pressed onto the first Si wafer with an Au-coated surface, with ~MPa pressure. Heating the assembly slowly up to 410°C for 10 min provides a good $Au_{97}Si_3$ eutectic bonding.

It has been reported that Si-face 6H-SiC wafers on axis (0001) orientation and $3 \cdot 10^{18}/cm^3$ n-type doping have been fusion bonded at temperatures above 800°C (Yushin 2003). The wafer surface roughness was 1.5 nm (RMS). The samples were cleaned in JTB-111 solution, then 10% hydrofluoric acid and deionized water. Surface oxides were desorbed in ultra-high vacuum (UHV) at 1100°C for 30 min prior to fusion. The fusion bonding was performed in UHV at temperatures between 800 and 1100°C under a uniaxial stress of 20 MPa for 15 hrs. Examination by Transmission Electron Microscope (TEM) showed a 3 nm carbon interlayer at the bonding interface. The interface carbon might have resulted from high-temperature annealing (Bryant et al. 1999). The bonded SiC retained its crystalline quality. Electrical measurements showed that azimuthal orientation misalignment between the wafers had significant effects on interface states. It is important to note that many single-crystal structures of SiC, such as the hexagonal structures (6H and 4H), present polar characteristics, that is, Si terminates one side of a wafer and C terminates the other side of the wafer. The effects of polarity on SiC/SiC direct fusion bonding have not been reported. Except for the difference of the fabrication process for the surface silicon dioxide layer, the bonding process/mechanisms of SiC-SiO_2/SiO_2-SiC may be similar to that of the Si-SiO_2/SiO_2-Si system. However, it is of interest to know the effects of residual interfacial carbon, which usually accumulate at SiO_2/SiC interfaces, on the bonding quality.

Glass/Si and Glass/Metal Bonding

Glass can be bonded to many electrically conductive materials such as Si and metals at temperatures well below the glass-melting temperature with the assistance of a high electrical field (Go et al. 1998 and Madou 1997). The common experimental setup is as follows: The conductive component, such Si or

TABLE 15.4.1 Thermal and Mechanical Properties of Various Materials for MEMS Fabrication

Material	CTE (E-6/°C)	Elastic Modulus (GPa)	Poisson's Ratio	Processing Temperature (°C)
Si	2.49-4.44 (25–1027°C)	112.4	0.28	1000
SiO_2 fused quartz	0.4–0.7	70–78	0.17	1580–1730
SiC	4.5–4.7	459–476	0.14	>1250
Pyrex glass	3.25	62.75	0.2	1252
Al	24–27.4 (20–500°C)	68	0.33	<660.37
Ni	13.1 (20°C)	207	0.31	<1455 (melting)

metal, is connected to the anode, and a sharp cathode is placed on the glass side to generate a high electric field at the material interface. Usually, the anodic bonding is conducted between 200 and 450°C, and the voltage depends on the bonding materials and the thicknesses of the two materials, especially the glass. The bonding process typically starts from the area contacted by the sharp cathodes and proceeds toward the wafer edges. A typical process lasts less than 5 min. Pyrex glass (Dow Corning 7740) is one of the most commonly used glass materials for anodic bonding. The detailed mechanism of this relatively old technology has not yet been completely understood, but some works/literature on this aspect can be found. In order to use this bonding method, very smooth bonding surfaces are required. The advantage of anodic bonding is the relatively low temperature required for bonding. However, the disadvantage is that a high electrical field is used in the bonding process that might be harmful to some prefabricated device structures. The alkali metals in the glass may also migrate under high electrical potential, causing damage to the devices. Apparently, anodic bonding is limited to alkali metal rich glasses.

Thin-metal layers, such as 4 μm thick aluminum (Al), have been used as the bonding layer between Pyrex glass and a Si wafer with a silicon nitride surface layer. First, a 0.5 μm low-pressure CVD silicon nitride is grown on the Si wafer. A thin-film aluminum sealing layer is then deposited on the Pyrex glass. A rapid heating of the assembly to temperatures around 750°C provides a stable bond at the Al/silicon nitride interface. This type of bonding provides hermetic sealing to water.

Stress Issue in Wafer Bonding

Except for (same material) wafer-wafer fusion bonding, most other types of wafer-level bonding involve hetero-material(s) such as oxides/glass and eutectics, as the bonding layer. All these bonds are processed at elevated temperatures. Because of the CTE mismatch between the wafers and the bonding layer, significant thermal stress can be generated after the assembly cools down to room temperature. Table 15.4.1 shows the basic thermal and mechanical properties for some commonly used construction materials for MEMS. These residual thermal stresses generated at wafer-level bonding may have a significant impact on both the operation and performance of the device. In recent years various new/modified wafer bonding methods have been developed with reduced global temperature exposure to the wafer or assembly. These wafer-bonding techniques may have the potential to reduce the wafer-level stresses.

New Wafer Bonding Methods

Lin successfully demonstrated a local heating method to heat only the active/effective bonding areas of the wafer(s) (Lin 2000). Microfabricated polysilicon heaters were used for local heating. The heat spread area of a 1 μm line heater was typically about 1 μm, according to numerical modeling (Lin 2000). This local resistive heating method has been demonstrated for Si-Au eutectic bonding, Si-glass fusion bonding, solder bonding, and local plasma bonding/sealing. Mechanical tests of various wafer bonds using this local heating method showed that the results were comparable to wafer-wide heating methods. The disadvantage of local heating is the limited wafer-bonding area.

Microwave heating was proposed to perform wafer-level eutectic bonding (Budraa et al. 1999): A thin Au layer was first directly deposited on a Si wafer. The second Si wafer was pressed onto the Au coated Si wafer. The Au layer was used as the Au source, forming $Au_{97}Si_3$ eutectics as well as an effective energy-receiving antenna absorbing most of the microwave energy to heat the bonding assembly locally. The effectiveness of microwave heating made the necessary heating process as short as one min. Since the bonding/heating areas defined by Au thin-film were limited, the rest of the wafer could be kept at relatively lower temperatures. But if the bonding area is large, this method loses part of its advantage. Another disadvantage is that this method can only be used before device fabrication because the microwave radiation may also heat the metallization areas on the wafer and damage/change the device behavior.

Ultrasound bonding technology has been widely used for thin-wire bonding of electrical interconnection. Recently, an ultrasound wafer bonding method was developed to bond indium (In)-coated Si wafer to Au- or Al-coated Si wafer at room temperature under 10 ~ 40 MPa pressure. The ultrasound power needed to bond 1.6 ~ 2.1 mm^2 die ranged from 20 ~ 40 Watts. This bonding method turns ultrasound frequency mechanical vibration energy to localized thermal energy. Thus, it enables relatively low-temperature bonding between similar or dissimilar metal-coated wafers. Even though the local surface may be heated up to 200 ~ 300°C due to the friction of two contacting surfaces, the rest of the wafer is still at low temperature because of the rapid bonding process and limited bonding power. This technology was also demonstrated to join ceramic and metal plates (Kim et al. 2002). The disadvantage of this method is that the size of one of the "wafers" is likely limited, so it is suitable for bonding a small die to a wafer/die rather than a whole wafer to another. The ultrasound frequency must be away from the mechanical resonant frequencies of MEMS structures; otherwise the bonding process may damage the microfabricated mechanical structures on the wafer.

Continuous (Wild et al. 2001) and pulsed (Luo and Lin 2002) laser-beam methods have been demonstrated to bond glass to Si wafers. The continuous laser beam is transmitted through the transparent glass wafer to excite the Si/glass interface locally. The locally heated spot or line width is around 300μm or less with a laser beam power of 12 ~ 30-watts and a scanning rate of 50 ~ 500 mm/min. A nanosecond-pulsed YAG laser with a pulse duration of 4 ~ 6 ns and a wavelength of 355 nm has been used to demonstrate bonding glass to a Si wafer. The focal spot size of the laser beam is 1 mm, and a regular white paper with predefined patterns is used as the mask to select bonding areas. The temperature at the bonding spot drops from 2500 to 43°C in 2 ms. A thin indium layer is used as the bonding material. The mechanical strength of the bonded assemblies resulting from the pulsed mode method is limited by the mechanical strength of indium, 2.6 MPa, while the bond strength resulting from the continuous mode method can be as high as 5 ~ 10 MPa. The advantage of laser wafer bonding is localized heating and high selectivity of bonding area. The disadvantage of laser beam bonding is time consumption for large area bonding.

Room temperature wafer bonding between Si and ceramic wafers by means of surface activation using Ar ion-beam etching was reported recently (Takagi et al. 2001). Four-inch Si wafers with mesa structure have been bonded to 3- or 4-inch ceramic wafers in vacuum by intimately mating two wafer surfaces after removing wafer surface oxides and surface adsorbates (contaminations). Before Ar beam etching, the wafer surfaces must be polished. The bonding strength measured between Si wafers with 9 × 9 mm^2 mesas and ceramics materials such as single-crystal a-Al_2O_3, 128°Y-cut $LiNbO_3$, Z-cut $LiNbO_3$, 36°X-cut $LiTaO_3$, and Gd_3GaO_{12} were better than those resulting from conventional wafer bonding methods (Takagi et al. 2001). This is perhaps the "cleanest" wafer-joining method because Ar normally does not react to most elements/materials. But this method is likely only suitable for bonding wafers with a limited effective bonding area. Another disadvantage of this bonding method is that the wafer surfaces have to be exposed to an Ar ion beam, which may destroy any prefabricated MEMS or circuits on the surfaces.

Die Bonding

After wafer-level fabrication, including wafer bonding a die/chip bonding process will usually follow to interconnect the die/chip to the next level packages, such as chip-level packages or directly to the PCB. As discussed in Fundamental Packaging Concepts, there are two basic chip-level packaging schemes: one is die-attach/wire-bond and the other is the flip-chip scheme. The mechanical and electrical interconnections of the die are separated in the die-attach/wire-bond scheme while the mechanical and electrical interconnections are combined in the flip-chip scheme. The die-attach/wire-bond scheme is suitable to a chip-and-board packaging infrastructure. This packaging infrastructure provides a unique flexibility of chip-level packages — in other words, one of these types of chip packages can fit many device chips.

In the era when device yield was a significant concern, this type of single-chip-package and board infrastructure also provided flexibility of component selection and replacement. The wire-bond-based electrical interconnection system provides excellent thermomechanical reliability (Tummala 2001). The wire-bond scheme is the most frequently used electrical interconnection technology in chip-level packaging today. It is predicted that it will remain so in the foreseeable future. The flip-chip scheme is a relatively newer packaging scheme. It was introduced by IBM in 1962. The flip-chip scheme eliminates the space needed for wire-bonds, significantly reducing the package size, that is, increasing the packaging density (the number of packaged chips per unit area). Flip-chip is a favored assembly for high-frequency applications because the short bump interconnection reduces parasitic effects. Flip-chip has been successfully used for high-performance optoelectronics packaging using self-alignment. The flip-chip structure also allows three-dimensional stacking for multichip module and high-density memory chip packaging. The disadvantage of the flip-chip structure is the compromised reliability of the die bonding resulting from the merging of the mechanical and electrical interconnections between the chip and the packaging substrate. Usually the thermal reliability of flip-chip assembly can be improved by suitable underfill. The flip-chip packaging scheme has been further developed. Besides the initial chip-on-board infrastructure, new technologies have been generated based on the flip-chip technology for various applications.

Die-Attach and Wire-bond Scheme

Wire-bond and die-attach packaging is the most popular chip-level packaging scheme. In this approach, the chip/die is mounted to the package with the active die side facing up. The electrical interconnections between the chip/die and the package are then realized through thin-wire bonding, as discussed earlier. Both die-attaching materials and die-attaching processes will be discussed in this section.

Materials. The materials used to attach/bond the die include epoxy, glass, solder, and low-temperature eutectics. Recently, thick-film materials have been tested for high-temperature operable conductive die attachment. Besides the function of mechanical mounting, die-attach sometimes also provides electrical interconnection through the backside contact of the die/chip. Metallic particles are added to nonconductive die-attach materials, such as epoxy and glass, to make the materials electrically conductive.

- *Epoxy and polyimides:* These are two of the most popular low cost die-attach materials. These materials (either one component or two components) polymerize at either room temperature or elevated temperatures, ~125°C, in a few hours. Usually, metal particles such as silver are added to improve the electrical and thermal conductivities. The thermal stability of these materials is an issue for applications with high-reliability requirements. The CTE of epoxy materials ranges from 50 to 80 ppm/°C, which is significantly higher than the CTEs of chip materials (Si and SiC) and ceramic substrate materials. These materials are cured at temperatures up to 180°C. The maximum operating temperature is limited to the glass transition temperature of the epoxy or polyimide.
- *Solder/eutectics:* The melting temperatures of alloys composed of tin (Sn), lead (Pb), indium (In), cadmium (Cd), bismuth (Bi), gallium (Ga), silver (Ag), gold (Au), silicon (Si), and germanium (Ge) cover a wide temperature range from room temperature to 420°C (Tummala 2001, p. 374). The selection of solder materials depends on the processing temperature, temperature of operation, and the metallization materials on both the chip and substrate. AuSi and AuGe eutectics provide high melting temperatures and excellent fatigue/creep resistance. The disadvantage of this type of eutectic is a lack of plastic flow resulting in high-thermal stress due to mismatch of CTEs between the solder and chip/board materials. PbSnInAg-based alloy provides low melting temperatures and better plasticity. Solder/eutectics provide excellent thermal and electrical conductivities. The bonding process using solder and low-temperature eutectics is usually a melting solidification cycle. The maximum operating temperature of solder/eutectics is limited by material softening/melting temperature.
- *Glass:* Silver and other precious metal filled glasses are also used for die bonding. Glass bonding is basically a melting-solidification process so it usually requires high processing temperatures (>400°C). However, glasses provide excellent thermal and chemical stability. Glasses have very low

porosity and adhere/wet well to a large variety of materials. Melting (and solidifying) temperatures of glasses, which are determined by the glass components and additives, cover a broad temperature range; so do thermal expansions coefficients of glasses. In order to select an appropriate glass material for a specific die/substrate bond, we should consider both CTE match and processing temperature. Unlike solder and eutectics, the maximum operating temperature of glass-bonded die-attach can sometimes exceed the die-bonding temperature, the initial melting temperature of the glass, because the glass crystallizes during the solidification process (McCluskey et al. 1996).

- *Thick-Film:* Thick-film materials have been tested for high-temperature operable conductive die attaching/bonding in recent years. Thick-film metallization materials are usually composed of fine metal (for metal/alloy thick-films) or glass (encapsulate) powders, inorganic binder (such as metal oxides), and organic vehicle. Screen-printing techniques are used to provide patterned thick-film coatings with thickness control. During the initial drying process (at 100 ~150°C) the organic vehicle evaporates and the paste becomes a semisolid phase mixture of metal powder and binder. In the final curing process (~850°C recommended for most thick-film products), the inorganic binder molecules migrate to the metal film/substrate (e.g., Au/ceramic) interface and form reactive binding chains. Au thin wires can be bonded directly to Au thick-film metallization pads using commercialized wire-bond equipments to provide electrical interconnection in packaging. Some new thick-film materials may be applicable to various ceramic substrates such as alumina (Al_2O_3) (Keusseyan et al. 1996) and aluminum nitride (AlN) (Wang et al. 2002; Keusseyan et al. 1996; Chitale et al. 1994; Shaikh 1994). Compared with direct thin-film metallization on ceramic substrate, thick-film metallization provides lower cost, simpler processing, lower electrical resistance, and better adhesion, which is provided by the reactive binders at the metal/substrate interface.

  Both the electrical and mechanical properties of Au thick-film materials for applications in hybrid-packaging conventional ICs have been extensively validated at $T < 150°C$. An electrically conductive die-attach scheme using Au thick-film as die-attaching material for Ni metallized SiC devices has been tested for operation at temperatures up to 500°C (Chen et al. 2000). Au has a low elastic modulus and yield strength, and a very wide plastic deformation range. The excellent thermal and mechanical properties of Au make it a feasible die attaching/bonding material, especially for high-temperature and harsh-environment applications.

  A SiC test die with a Ni contact on the back was attached to a ceramic substrate using an optimized two-step Au thick-film process (Chen et al. 2000). A thick-film layer was first screen-printed on the substrate and cured at 850°C using a standard process (DuPont 1999). The SiC die was then attached to the cured thick-film pattern with a second layer of thick film. A sufficient drying process (120 to 350°C) was critical to keep the thick-film bonding layer uniform and the die parallel to the substrate after the curing process. Following the drying process, the attached die was cured at ~600°C. Curing at 600°C or above allowed sufficient diffusion to occur at the Au/Ni and Au/Au interfaces, and consequently established bonding (Chen et al. 2000).

Bonding Processes. A phase transition process from liquid or semiliquid to solid is typically involved in most die-bonding processes except for diffusion bonding. For example, the bonding process is a polymerization process for epoxy and a solidification process for solder, eutectics, and glass. This type of solidification often is enabled at elevated temperatures with a corresponding material volume change during the phase transition. Therefore, significant thermal stress can be generated because of the mismatch of thermochemical properties of materials. The basic structure of the die-attach/bond assembly for thermomechanical study is similar to that of the wafer bond, that is, a sandwich composed of two thicker layers (die and substrate) and a thin bonding layer.

Flip-Chip

In the flip-chip die-attach scheme, the die is interconnected to the packaging substrate both electrically and mechanically using the active side of the device/chip, so the die faces down. Flip-chip technology has been successfully used for MEMS packaging (Boustedt et al. 2002).

General Structure. As illustrated in Figure 15.4.3, the chip is first coated using electroplating and electroless deposition to form a multilayer under bump metallization (UBM) system on the electrical contact area of the chip. Before the deposition of UBM the electrical contact area(s) on the chip are often capped by an Al or Au thin film (Oppermann et al. 2000). The selection of UBM materials is made to match the bump material and bonding method. The bumps are usually deposited using electroplating or electroless deposition directly on UBM. Mature die attaching/bonding methods include thermal compression, low-temperature soldering, and adhesive paste joining. The metallization on the board (substrate) is also selected to be compatible to the bump material and die attaching/bonding method.

Material Systems. The UMB is generally composed of four layers: adhesion, diffusion barrier, wetting, and anti-oxidation/soldering layers. The function of the adhesion layer is to provide sufficient adhesion to the chip metallization surface. Chromium (Cr), titanium (Ti), zinc (Zn), and nickel (Ni) are often used as adhesion-layer materials. The function of the diffusion-barrier layer is to protect the metallization on the chip from the materials/elements of UBM and bump material. The candidate materials for the barrier layer include W, TiW, and Ni. A wetting layer is needed if the bump material does not sufficiently wet the barrier layer. Copper (Cu), Pd, and Ni are often used for this purpose. The anti-oxidation/soldering layer protects the UBM from oxidation, and a gold (Au) thin-film is usually used. For example, Ti/W/Ni/Au, Cr/CrCu/Cu/Au have been used for commercialized solder bumping. In many cases, some of these four layers can be combined to a certain extent so that the UBM is composed of fewer than four layers. For example, Ti/W/Cu UBM is coated on Cu/SnPb electroplated chips for PbSn solder bumps, while the metallization on the substrate/board is Cu/Ni/Au. Ti/W/Au is coated on Au electroplated (an additional Sn layer on top of the Au is needed for AuSn bumps) chips for Au or AuSn solder bumps, and Cu/Sn is used for substrate/board metallization. Ti/W/Au UBM is coated on Au electroplated chips for isotropic conductive adhesive (ICA) paste bonding, and Cu/Au or Cu/Ni/Au is used for substrate/board metallization. ICA paste is usually stencil printed.

Bonding Process. The electrical contacts on the chip are usually fabricated by thin-film deposition and plasma-etch (or lift-off) patterning technologies. In order to reduce the fabrication costs, the UBM layers are usually deposited by electroplating and electroless deposition onto the electrical contacts on the chip. The bumps are deposited by electroplating with a photoresist mask. After the deposition, the mask is etched off and the wafer undergoes a reflow procedure to shape the bumps using the surface tension of the liquefied bump material. There are two categories of die-bonding methods: soldering and thermal compression bonding. During the soldering process the solder bumps melt and wet the metallization pads of the substrate/board. During the thermal compression bonding process, the substrate/board is heated up and the solder/eutectic bumps are compressed and bonded to the metallization pads on the substrate/board. The bonding mechanism of this method is similar to that of thermal compression wire-bonding.

Stress Issues. Thermal compression and solder/eutectics die bonding are both processed at elevated temperatures, so local (the adjacent area surrounding a bump) thermal stress is generated after the assembly cools down because of the CTE mismatches of chip/metallization/UBM/bump/metallization/substrate. Further, global thermal stress is generated because of the mismatch of CTEs of the chip and substrate materials. Thermomechanically, if we consider the UBM, solder/eutectics bump, and the substrate metallization as one metallic layer possessing higher CTE in comparison to the die and substrate materials, a single bump flip-chip die bond presents a die/bonding layer/substrate sandwich structure. This sandwich structure is similar to those of wafer bonding and conventional die-attach. The thermomechanical stress/strain analysis of this sandwich structure, die/adhesive/substrate, is particularly important to MEMS packaging because the thermal stress/strain effects on the packaged devices have been expanded from permanent mechanical damages of package and packaged die(s) to the thermal stress effects on device operation/performance.

Boundary Value Problem and Analytical Methods

In this section a boundary value problem of thermal stress/strain of a generic square-shaped die-attach, as shown in Figure 15.4.4, is established. The major purpose of establishing the boundary value problem

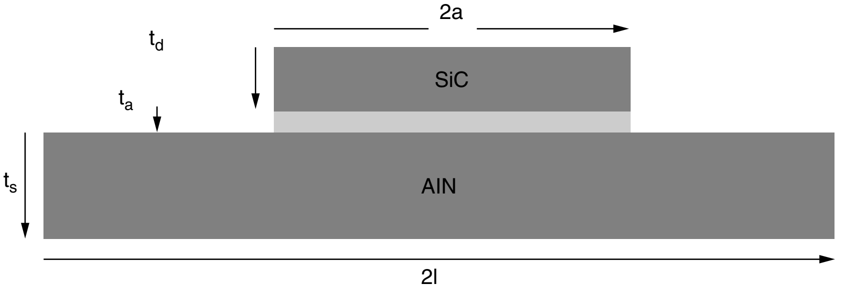

FIGURE 15.4.4 A schematic diagram of a generic SiC die-attach.

is not to directly lead readers to exact analytical solutions of the die-attach stress problem because of the mathematical complexity of the problem. Instead it helps us to understand: (1) the relations between thermomechanical variables, (2) constraints of stress/strain tensors, and (3) the dependences of the thermal configuration of a die-attach assembly on the physical properties of the die-attach materials, the geometric symmetry of the die-attach, the process temperature, and the boundary (and interface) conditions. All these form a base for discussion of approximate analytical methods and numerical solutions later.

Governing Equations of Displacements

Assuming that the temperature distribution in the die-attach is static ($\partial T/\partial t = 0$) and uniform ($\partial T/\partial x = \partial T/\partial y = \partial T/\partial z = 0$), and the external force on the die-attach structure is zero, the general thermal mechanical governing equations for the die-attach system are listed as

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 v}{\partial x \partial y} + \frac{\partial^2 w}{\partial x \partial z} + (1-2\upsilon)\nabla^2 u = 0 \tag{15.4.1a}$$

$$\frac{\partial^2 v}{\partial y^2} + \frac{\partial^2 u}{\partial x \partial y} + \frac{\partial^2 w}{\partial y \partial z} + (1-2\upsilon)\nabla^2 v = 0 \tag{15.4.1b}$$

$$\frac{\partial^2 w}{\partial z^2} + \frac{\partial^2 u}{\partial x \partial z} + \frac{\partial^2 v}{\partial y \partial z} + (1-2\upsilon)\nabla^2 w = 0 \tag{15.4.1c}$$

where

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

u, v, and w = the displacements in x-, y-, and z-directions, respectively

υ = Poisson's ratio of the material

The normal stress distributions are determined by the displacements, material properties, and the temperature (Lau et al. 1998):

$$\tau_{xx} = \frac{\lambda}{\upsilon}\left[(1-\upsilon)\frac{\partial u}{\partial x} + \left(\frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}\right)\right] - \beta(T - T_o) \tag{15.4.2a}$$

$$\tau_{yy} = \frac{\lambda}{\upsilon}\left[(1-\upsilon)\frac{\partial v}{\partial y} + \left(\frac{\partial w}{\partial z} + \frac{\partial u}{\partial x}\right)\right] - \beta(T - T_o) \tag{15.4.2b}$$

$$\tau_{zz} = \frac{\lambda}{\upsilon}\left[(1-\upsilon)\frac{\partial w}{\partial z} + \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right)\right] - \beta(T - T_o) \tag{15.4.2c}$$

Shear stresses are reduced from u, v, and w as

$$\tau_{xy} = \frac{E}{2+2\upsilon}\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) \tag{15.4.3a}$$

$$\tau_{yz} = \frac{E}{2+2\upsilon}\left(\frac{\partial v}{\partial z} + \frac{\partial w}{\partial y}\right) \tag{15.4.3b}$$

$$\tau_{zx} = \frac{E}{2+2\upsilon}\left(\frac{\partial w}{\partial x} + \frac{\partial u}{\partial z}\right) \tag{15.4.3c}$$

where

$\lambda = \dfrac{\upsilon E}{(1+\upsilon)(1-2\upsilon)}$
$\beta = \dfrac{\alpha E}{1-2\upsilon}$
E = Young's modulus
α = the coefficient of linear thermal expansion (CTE)

Material properties α, E, and υ generally are different for the die, attaching layer, and the substrate materials. The strain tensor components are also reduced directly from the displacements:

$$\varepsilon_{XX} = \frac{\partial u}{\partial x} \tag{15.4.4a}$$

$$\varepsilon_{YY} = \frac{\partial v}{\partial y} \tag{15.4.4b}$$

$$\varepsilon_{ZZ} = \frac{\partial w}{\partial z} \tag{15.4.4c}$$

$$\varepsilon_{xy} = \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \tag{15.4.4d}$$

$$\varepsilon_{yz} = \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} \tag{15.4.4e}$$

$$\varepsilon_{zx} = \frac{\partial w}{\partial x} + \frac{\partial u}{\partial z} \tag{15.4.4f}$$

where ε_{XX}, ε_{YY}, and ε_{ZZ} are the three normal strains, which are the diagonal elements of a nine-element strain tensor in the *X-Y-Z* coordinate system. The physical interpretation of a normal strain is one of relative longitudinal elongations under normal stresses. ε_{xy}, ε_{yz}, and ε_{zx} are shear strain components, which are nondiagonal tensor elements. They are usually diagonally (only with respect to the diagonal line along ε_{XX}, ε_{YY}, and ε_{ZZ}) commutable. The physical interpretation of a shear strain is a tangent of deformation of a right angle under the corresponding shear stress. Within the elastic deformation region of an isotropic media the stress and strain tensors have the following linear relations:

$$\varepsilon_{XX} = \frac{1}{E}\left[\tau_{XX} - \upsilon\left(\tau_{YY} + \tau_{ZZ}\right)\right] + \alpha\left(T - T_o\right) \tag{15.4.5a}$$

$$\varepsilon_{YY} = \frac{1}{E}\left[\tau_{YY} - \upsilon\left(\tau_{XX} + \tau_{ZZ}\right)\right] + \alpha\left(T - T_o\right) \tag{15.4.5b}$$

$$\varepsilon_{ZZ} = \frac{1}{E}\left[\tau_{ZZ} - \upsilon\left(\tau_{XX} + \tau_{YY}\right)\right] + \alpha\left(T - T_o\right) \tag{15.4.5c}$$

$$\varepsilon_{XY} = \frac{1}{G}\tau_{XY} \tag{15.4.5d}$$

$$\varepsilon_{YZ} = \frac{1}{G}\tau_{YZ} \tag{15.4.5e}$$

$$\varepsilon_{ZX} = \frac{1}{G}\tau_{ZX} \tag{15.4.5f}$$

G is shear modulus of the material. For an object of uniform and isotropic medium, in a uniform static temperature field, without external mechanical load, all stress components vanish. Consequently, all shear strain components vanish and the thermal strains contribute to three normal strain components only. If a stress is so high that it generates plastic (permanent) strain, then the stress and strain relations are no longer linear functions.

If there is no residual stress at a certain temperature, such as the die-attaching temperature, then the mismatch of CTEs of the die-attach assembly and the temperature deviation from the stress-free temperature (relaxing temperature) are the major sources of thermal mechanical stresses. This would become more apparent if the boundary value problem were listed for the die, the attaching layer, and the substrate separately. There would be an external force term at the boundaries, that is, the interface between the die and the attaching layer and the interface between the attaching layer and the substrate. These external force terms are generated by the mismatch of material CTEs or the residual stresses. In case there is neither residual stress nor CTE mismatch, these external force terms vanish and the solutions for the equations are trivial.

Constraints on Stress and Strain Tensors

For any static configuration, all stresses must meet the equilibrium conditions. We take an infinitesimal volume and consider a local static condition. A force equilibrium between the surface forces (stresses) and body force F must be reached (Sokolnikoff 1956). If the external body force is zero, the constraining conditions for the stress components are established:

$$\frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} + \frac{\partial \tau_{zx}}{\partial z} = -F_x = 0 \tag{15.4.6a}$$

$$\frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \tau_{yy}}{\partial y} + \frac{\partial \tau_{zy}}{\partial z} = -F_y = 0 \tag{15.4.6b}$$

$$\frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} + \frac{\partial \tau_{zz}}{\partial z} = -F_z = 0 \tag{15.4.6c}$$

Besides the constraints of these partial derivatives of stress tensor components, these equations also indicate the continuity of τ_{ii} in i-direction ($i = x, y, z$) and τ_{ij} in i- and j-directions ($i, j = x, y, z$ but $i \neq j$), where body force density is not unlimited, regardless of the media uniformity.

The equilibrium of moments in various directions leads to very important constraints on the nine element stress tensor (Sokolnikoff 1956, p. 42):

$$\tau_{ij} = \tau_{ji} \tag{15.4.7}$$

This indicates that the stress tensor is diagonally symmetric, so only six out of nine elements of the stress tensor are independent regardless of material properties.

The existence of single-valued continuous solutions of displacements would place the following derivative constraints on the strain tensor components (Sokolnikoff 1956):

$$\frac{\partial^2 \varepsilon_{xx}}{\partial y \partial z} = \frac{\partial}{\partial x}\left(-\frac{\partial \varepsilon_{yz}}{\partial x} + \frac{\partial \varepsilon_{zx}}{\partial y} + \frac{\partial \varepsilon_{xy}}{\partial z}\right) \tag{15.4.8a}$$

$$\frac{\partial^2 \varepsilon_{yy}}{\partial z \partial x} = \frac{\partial}{\partial y}\left(-\frac{\partial \varepsilon_{zx}}{\partial y} + \frac{\partial \varepsilon_{xy}}{\partial z} + \frac{\partial \varepsilon_{yz}}{\partial x}\right) \tag{15.4.8b}$$

$$\frac{\partial^2 \varepsilon_{zz}}{\partial x \partial y} = \frac{\partial}{\partial z}\left(-\frac{\partial \varepsilon_{xy}}{\partial z} + \frac{\partial \varepsilon_{yz}}{\partial x} + \frac{\partial \varepsilon_{zx}}{\partial y}\right) \tag{15.4.8c}$$

$$2\frac{\partial^2 \varepsilon_{xy}}{\partial x \partial y} = \frac{\partial^2 \varepsilon_{xx}}{\partial y^2} + \frac{\partial^2 \varepsilon_{yy}}{\partial x^2} \tag{15.4.8d}$$

$$2\frac{\partial^2 \varepsilon_{yz}}{\partial y \partial z} = \frac{\partial^2 \varepsilon_{yy}}{\partial z^2} + \frac{\partial^2 \varepsilon_{zz}}{\partial y^2} \tag{15.4.8e}$$

$$2\frac{\partial^2 \varepsilon_{zx}}{\partial z \partial x} = \frac{\partial^2 \varepsilon_{zz}}{\partial x^2} + \frac{\partial^2 \varepsilon_{xx}}{\partial z^2} \tag{15.4.8f}$$

Besides the constraints of partial derivatives of strain tensor elements, these equations also indicate continuity of ε_{ii} in j and k ($j, k \neq i$) directions and ε_{ij} ($i \neq j$) in all three directions. However, these equations do not directly apply any constraints on $\partial\varepsilon_{xx}/\partial x$, $\partial\varepsilon_{yy}/\partial y$, and $\partial\varepsilon_{zz}/\partial z$, indicating the possibility of discontinuity of normal strains in the strain orientation. These observations are useful, and it is important to analyze and understand normal and shear strain distributions in an inhomogeneous medium, such as interface areas of a die-attach assembly composed of die, die-attach, and substrate materials.

Boundary, Symmetry, and Interfacial Conditions

The dimensions of a square shaped die attached to a square shaped substrate with a thin die attaching layer are shown in Figure 15.4.4. Assuming there are no external mechanical loads applied on the die-attach (gravity is ignored), the boundary conditions of the die-attach assembly are basically natural boundary conditions: the assembly is free to expand such that all (both normal and shear) stress components on the assembly surfaces vanish at any temperature. Assuming that the distortions of the die-attach assembly are negligible compared with the dimensions of the die-attach, these boundary conditions are: at $x = \pm a$ and $z > t_s$, or $x = \pm l$ and $z < t_s$: $\tau_{xx} = 0$ and $\tau_{xy} = 0$ and $\tau_{xz} = 0$, at $y = \pm a$ and $z > t_s$, or $y = \pm l$ and $z < t_s$: $\tau_{yy} = 0$ and $\tau_{yx} = 0$ and $\tau_{yz} = 0$, at $z = 0$, $z = t_s$ and $|x| > a$ or $|y| > a$, or $z = t_s + t_a + t_d$: $\tau_{zz} = 0$, $\tau_{zx} = 0$, and $\tau_{zy} = 0$.

The symmetry conditions are: at $x = 0$: $u = 0$, $\tau_{yx} = 0$, and $\tau_{zx} = 0$, at $y = 0$: $v = 0$, $\tau_{xy} = 0$, and $\tau_{zy} = 0$. The symmetry conditions basically indicate that the transverse shear stress u and the displacements in the x- and y-directions vanish at the transverse central planes of the x- and y-directions correspondingly.

At the interfaces between the die and the die-attaching layer and between the die-attaching layer and the substrate, the bonding conditions are usually assumed to be ideal. This means all displacements are continuous at the interfaces: $u|_{S_s+} = u|_{S_s-}$, $v|_{S_s+} = v|_{S_s-}$, $w|_{S_s+} = w|_{S_s-}$, $u|_{S_a+} = u|_{S_a-}$, $v|_{S_a+} = v|_{S_a-}$, and $w|_{S_a+} = w|_{S_a-}$. S_s is the interface between the die and the attaching layer, and S_a is the interface between the attaching layer and the substrate, respectively.

The Relaxation Condition

At the die-attaching or wafer-bonding temperature, the attaching or bonding material usually either melts or becomes highly diffusive. So at this temperature, the assembly is thermomechanically relaxed, that is, the stress level of the assembly reaches zero or a minimum. This temperature is usually defined as the relaxation temperature in the following thermal stress/strain discussion. This minimum stress level depends on the physical properties of the assembly materials and the physical/chemical process of the attaching or bonding. For thermal compression of thermal-sonic-compression bonding, relaxation conditions (temperature) may not exist.

Analytical Methods

The thermomechanical boundary value problem of a die-attach with simple geometry is still complicated enough that a closed exact analytical solution has never been derived after decades of efforts. The thermal mechanical boundary value problem of a sandwich type structure is really not new. It has been identified and studied for decades for thermal expansion of bimetal thermostats and electronic packaging. No closed exact analytical solutions have been derived, even in a narrow temperature range in which the material properties, such as thermal expansion and Young's modulus, can be approximately treated as constants. Therefore, various approximations and assumptions have been used to obtain approximate analytical solutions.

Tomoshenko first established a two-dimensional analytic method for the bimetal thermostat using elastic theory. Assuming that the materials are uniform and isotropic, the temperature field is uniform, $t_{d,a,s}/a = \varepsilon \ll 1$, $t_d/t_s = O(1)$ (the thickness of die is at least an order lower than that of the substrate), and $t_a/t_{d,s} = O(\varepsilon)$, an asymptotic solution was derived based on the following assumptions: in the die and substrate, horizontal displacements are linear functions of z, the vertical displacements are a second-order function of z, and the displacements in the die-attaching layer are linear functions of z (Tomoshenko 1925).

Extending Tomoshenko's elastic theory of bi-metal thermostats, Suhir developed a practical one-dimensional model for horizontal distributions of lateral normal (tensile) stress, τ_N, shear stress, τ_S, and peeling (transverse normal) stress, τ_P, at the die/attaching layer interface using the condition of horizontal displacement compatibility at the interface (Suhir 1987):

$$\tau_S = \left[\frac{1-\upsilon_s^2}{E_s t_s} + \frac{1-\upsilon_d^2}{E_d t_d} + \frac{\left(t_d + t_s\right)^2}{4D}\right]^{-1/2} \left[\frac{t_d}{3D_d} + \frac{2t_a}{3G_a}\frac{t_s}{3D_S}\right]^{-1/2} \left(\alpha_s - \alpha_d\right)\left(T - T_R\right)\frac{\mathrm{Sinh}\left(Ax\right)}{\mathrm{Cosh}\left(Al\right)} \tag{15.4.9a}$$

$$\tau_N = \left[\frac{1-\upsilon_s^2}{E_s t_s} + \frac{1-\upsilon_d^2}{E_d t_d} + \frac{\left(t_d + t_s\right)^2}{4D}\right]^{-1} \left[\frac{1}{t_d} + \left(t_d + t_s\right)\frac{E_d t_d}{4D\left(1-\upsilon_d^2\right)}\right]\left(\alpha_s - \alpha_d\right)\left(T - T_R\right)\left(1 - \frac{\mathrm{Cosh}\left(Ax\right)}{\mathrm{Cosh}\left(Al\right)}\right) \tag{15.4.9b}$$

$$\tau_P = 6\left[\frac{t_s t_d^3 E_d}{12\left(1-\upsilon_d^2\right)} - \frac{t_d t_s^3 E_s}{12\left(1-\upsilon_s^2\right)}\right]\left[\frac{2t_a}{3G_a} + \frac{t_d}{3G_d} + \frac{2t_s}{3G_s}\right]^{-1}\left[\frac{E_d t_d^3}{\left(1-\upsilon_d^2\right)} + \frac{E_a t_a^3}{\left(1-\upsilon_a^2\right)} + \frac{E_s t_s^3}{\left(1-\upsilon_s^2\right)}\right]^{-1}$$
$$\frac{\left(\alpha_s - \alpha_d\right)\left(T - T_R\right)\mathrm{Cosh}(Ax)}{\mathrm{Cosh}(Al)} \tag{15.4.9c}$$

where $G_{d,a,s}$, $E_{d,a,s}$, $\upsilon_{d,a,s}$, and $\alpha_{d,a,s}$ are shear moduli, and tensile elastic moduli, Poisson's ratios, and coefficients of thermal expansions (CTE) of the die (*d*), attaching layer (*a*), and substrate (*s*) materials, respectively. Also

$$A=\left[\frac{1-\upsilon_s^2}{E_s t_s}+\frac{1-\upsilon_d^2}{E_d t_d}+\frac{\left(t_d+t_s\right)^2}{4D}\right]^{1/2}\left[\frac{t_d}{3G_d}+\frac{2t_a}{3G_a}+\frac{t_s}{3G_s}\right]^{-1/2} \tag{15.4.9d}$$

and

$$D=D_1+D_2+D_3=\frac{1}{12}\left[\frac{E_d t_d^3}{\left(1-\upsilon_d^2\right)}+\frac{E_a t_a^3}{\left(1-\upsilon_a^2\right)}+\frac{E_s t_s^3}{\left(1-\upsilon_s^2\right)}\right] \tag{15.4.9e}$$

These results indicate that the normal stress in the die is high at the central area and sharply decreases to zero in a narrow area at the die edges. Both shear and peeling stresses are high at die edge areas and decrease rapidly approaching the die central area. These formulae have been suggested for direct reliability assessment of die-attach for conventional electronic packaging through calculation of maximum normal stress in the die, the maximum shear stress at the interface, and the maximum peeling stress at the die/attaching layer interface to predict the failures of die material, attaching layer material, and the adhesion of die/attaching layer interface (Hu and Pecht 1993).

This engineering theory of thermally induced stresses in bimaterial assemblies was extended to a trimaterial assembly for interfacial thermal shear stresses based on the following assumptions: stresses and strains are in the materials' elastic regions, no singular stresses exist at the assembly edges, and the deflections of the assembly are small. The interfacial shear stresses and assembly deflection are determined without considering the effects of peeling stress (Suhir 2001):

$$\tau_{s1}=-kT_1^o\frac{\sinh(kx)}{\cosh(kl)} \tag{15.4.10a}$$

$$\tau_{s2}=-kT_3^o\frac{\sinh(kx)}{\cosh(kl)} \tag{15.4.10b}$$

τ_{s1} and τ_{s2} are shear stresses at the first-layer/second-layer (such as die/die-attaching layer) interface and the second-layer/third-layer (such as attaching layer/substrate) interface, respectively, where

$$k=\left\{\frac{k_1^{\,2}+k_2^{\,2}}{2}\left[1+\left(1-\gamma\left(\frac{2k_1k_2}{k_1^{\,2}+k_1^{\,2}}\right)^{1/2}\right)^2\right]\right\}^{1/2},\quad T_1^o=-\frac{\left(\alpha_3-\alpha_2\right)\lambda_{13}+\left(\alpha_1-\alpha_2\right)\lambda_{33}}{\gamma\lambda_{11}\lambda_{33}}\Delta T\ ,$$

$$T_3^o=-\frac{\left(\alpha_3-\alpha_2\right)\lambda_{11}+\left(\alpha_1-\alpha_2\right)\lambda_{13}}{\gamma\lambda_{11}\lambda_{33}}\Delta T\ ,\ k_1=\left(\lambda_{11}/k_{12}\right)^{1/2}\ ,\ k_2=\left(\lambda_{33}/k_{23}\right)^{1/2}\ ,\ \gamma=1-\frac{\lambda_{13}^{\,2}}{\lambda_{11}\lambda_{13}}\ ,$$

$$k_i=\frac{t_i}{3G_i}\quad (i=1,2,3)\ ,\ \lambda_{11}=\frac{\left(t_1+t_2\right)^2}{4D}+\lambda_1+\lambda_2\ ,\ \lambda_{33}=\frac{\left(t_2+t_3\right)^2}{4D}+\lambda_2+\lambda_3\ ,$$

$$\lambda_{13}=\frac{\left(t_1+t_2\right)\left(t_2+t_3\right)}{4D}-\lambda_2\ ,\ \lambda_i=\frac{1}{E_it_i}\quad (i=1,2,3)$$

E_i is the elastic modulus of the ith component, t_i is the thickness of ith component, and $\Delta T = T - T_o$ is the temperature deviation from the relaxing temperature at which the stresses and strains vanish.

The corresponding peeling stresses at the interfaces are

$$\tau_{Pj} = m_j\left[\chi_0(s,k)V_0(sx) + \chi_2(s,k)V_2(sx)\right] + C_j\frac{\cosh kx}{\cosh kl}\ ,\quad j = 1,2 \tag{15.4.11}$$

where

$$\chi_0(s,k) = \frac{s\sqrt{2}}{k}\frac{\left[V_0(sl)-1\right]\tanh kl + \frac{s\sqrt{2}}{k}V_3(sl)\left(1-1/\cosh kl\right)}{\left[V_0(sl)-1\right]V_1(sl) + V_2(sl)V_3(sl)}\ ,$$

$$\chi_2(s,k) = \frac{s\sqrt{2}}{k}\frac{[V_2(sl)-1]\tanh kl + \frac{s\sqrt{2}}{k}V_1(sl)(1-1/\cosh kl)}{[V_0(sl)-1]V_1(sl) + V_2(sl)V_3(sl)}\ ,\quad V_0(sx) = \cosh sx\cos sx\ ,$$

$$V_2 = \sinh sx\sin sx\ ,\quad s^4 = \frac{s_1^4 + s_2^4}{2}\left[1 + \sqrt{1 - \frac{\delta}{4\left(s_1^4 + s_s^4\right)}}\right],\quad s_1^4 = \frac{D_1 + D_2}{4D_1D_2\delta_{12}}\ ,\quad s_2^4 = \frac{D_2 + D_3}{4D_2D_3\delta_{23}}\ ,$$

$$\delta_{12} = \frac{t_1}{E_1^*} + \frac{t_2}{2E_2^*}\ ,\quad \delta_{23} = \frac{t_3}{E_3^*} + \frac{t_2}{E_2^*}\ ,\text{ and }\ \delta = \frac{D}{\delta_{12}\delta_{23}D_1D_2D_3}$$

where $j = 1$ refers the first-layer/second-layer interface and $j = 2$ refers to the second-layer/third-layer interface.

It is worthwhile to indicate that these interfacial shear, peeling, and normal stresses are derived from engineering theory. They were not mathematically solved from the displacement governing equations; they were derived from interfacial mechanical equilibrium equations of the die-attach assembly (Suhir 2001).

Recently, Ru (2002) developed a nonlocal model assuming that the longitudinal displacement at a bimaterial elastic beam interface also depends on both the shear stress and the second gradient of the interfacial shear stress. Ru's results satisfy both of the requirements of the zero-longitudinal force and zero shear stress at the free edges. The peeling stress calculated from this model is equilibrated at the interface (Ru 2002).

$$\tau_S = \alpha\Delta T\frac{\cosh\left(\rho_1 l\right)\sinh\left(\rho_2 l\right)\sinh\left(\rho_1 x\right)\cos\left(\rho_2 x\right) - \sinh\left(\rho_1 l\right)\cos\left(\rho_2 l\right)\cosh\left(\rho_1 x\right)\sin\left(\rho_2 x\right)}{\Sigma} \tag{15.4.12}$$

$$\begin{aligned}\tau_P = \alpha\Delta T\frac{t_1D_2 - D_1t_2}{2\left(D_1 + D_2\right)}\Bigg\{&\frac{\left[\rho_1\cosh\left(\rho_1 l\right)\sin\left(\rho_2 l\right) - \rho_2\sinh\left(\rho_1 l\right)\cos\left(\rho_2 l\right)\right]\cosh\left(\rho_1 x\right)\cos\left(\rho_2 x\right)}{\Sigma} - \\ &\frac{\left[\rho_1\sinh\left(\rho_1 l\right)\cos\left(\rho_2 l\right) + \rho_2\cosh\left(\rho_1 l\right)\sin\left(\rho_2 l\right)\right]\sinh\left(\rho_1 x\right)\sin\left(\rho_2 x\right)}{\Sigma}\Bigg\}\end{aligned} \tag{15.4.13}$$

where

$$\rho_1 = \left(\frac{\bar{A}}{4\bar{B}} + \frac{1}{2\bar{B}^{-1/2}} \right)^{1/2},$$

$$\rho_2 = \left(\frac{2\bar{B}^{1/2} - \bar{A}}{4\bar{B}} \right)^{1/2},$$

$$\bar{A} = \frac{t_1 K_1 / G_1 + t_2 K_2 / G_2}{\lambda_1 + \lambda_2 + \dfrac{\left(t_1/2 + t_2/2\right)^2}{D_1 + D_2}},$$

$$\bar{B} = \frac{t_1^3 d_1 K_1 / G_1 + t_2^3 d_2 K_2 / G_2}{\lambda_1 + \lambda_2 + \dfrac{\left(t_1/2 + t_2/2\right)^2}{D_1 + D_2}},$$

K_1, K_2, d_1, and d_2 material property related constants (Ru, 2002). The numerical results derived from these formulas are reasonably consistent with those of finite element analysis.

Approximate analytical solutions can provide quick and global stress/strains assessment. In the elastic region, limited parametric studies of the effects of materials, sizes, and process condition on stress/strain distributions can be analyzed using analytical results. However, as it has been noted, the analytical method has limitations as indicated in the following paragraph.

For conventional electronic packaging, material-level permanent damages are a critical concern for die-attach thermomechanical reliability. However, for MEMS packaging, especially high-temperature MEMS, we are interested in precise and quantitative three-dimensional stress/strain distributions in order to examine the mechanical effects of packaging stress/strain on device mechanical operation, before the stress/strain reaches the level causing permanent material damage. As indicated in the introduction of this section, various MEMS sensors for aerospace engine monitoring and combustion control operate in a wide range of high temperatures and pressures. Therefore, the stress formulae derived using constant material properties and zero external load may no longer be suitable. The temperature dependence of material properties makes the die-attach boundary value problem much more complicated, and elastic/plastic nonlinear material properties make the derivation of a closed analytical solution to this boundary value problem almost impossible.

In addition to the complexity caused by temperature dependent nonlinear material properties, the boundary geometry of the MEMS die may generate another obstacle to analytical solutions. As a simple example, a diaphragm-based piezoresistive MEMS sensor may have a round-shaped diaphragm at the center of a square die. Neither Cartesian nor cylindrical coordinates would fit the boundary geometry of this problem. Boundary geometries of MEMS devices can be much more complicated than those of the diaphragm-based sensor. Therefore, it becomes very difficult to derive an analytical solution of a boundary value problem for a high-temperature MEMS die-attach assembly.

Numerical analysis is a powerful method for solving thermomechanical boundary value problems, such as the stress/strain distribution of a die-attach assembly. Finite element analysis (FEA) is the most sophisticated numerical method that can deal with all the previously stated complexities, including the external mechanical load. Chang (2002) successfully used FEA to calculate deflection angles of a nickel-coated microplatform in static magnetic fields generated by a microfabricated DC coil (Chang 2002). Another advantage of FEA is its ability to solve coupled thermal and mechanical loads. The next subsection provides an example in which FEA is used to model stress/strain distributions of an Au thick-film based SiC die-attach over a wide temperature range. This example illustrates the application of FEA in MEMS packaging. In order to avoid possible redundancy the fundamentals of FEA are not covered in

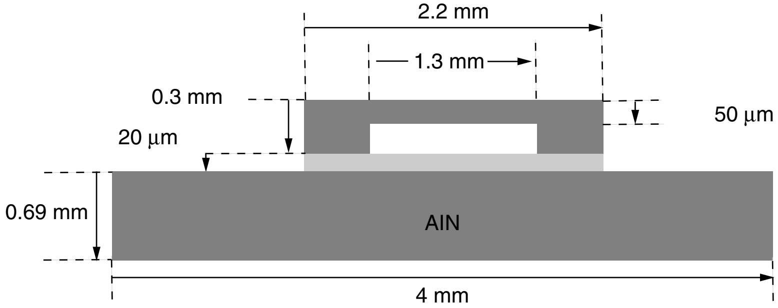

FIGURE 15.4.5 A schematic diagram of SiC pressure sensor die-attach using Au as attaching material for FEA simulation.

detail in this section. Readers can refer to other chapters of this handbook for both FEA fundamentals and practice.

Numerical Analysis of Die-attach Thermal Stresses and Strains

In this section, FEA simulation of stress/strain distributions of a SiC die-attach assembly over a wide temperature range is used to illustrate the application of numerical analysis for thermal stress/strain analysis in MEMS packaging. The SiC die includes a diaphragm structure. Diaphragm structures are used often in MEMS sensors and packaging, such as piezoresistive and capacitive acoustic (Chen et al. 2004) and pressure sensors (Beheim et al. 2001; Okojie et al. 2001).

As shown in Figure 15.4.5, a SiC die (2.2 mm × 2.2 mm × 0.30 mm) is attached to an AlN substrate (4 mm × 4 mm × 0.69 mm) with an Au thick-film layer (20 µm). The round diaphragm of the SiC die has a radius of 0.65 mm and a thickness of 50 microns. The die-attach is processed (cured) at 600°C and then cooled down to room temperature. It is assumed that the die-attach assembly is relaxed at 600°C before it is cooled down to room temperature, and that the cooling process is rapid enough such that the stress/strains caused by temperature deviation from the relaxing temperature are accumulated without relaxation/creeping. Because of the symmetry of the die-attach assembly, the stress/strain distributions of only a quarter of the assembly are simulated at room temperature. Within the ANSYS FEA software tool, the Geometric Non-linearity Option was enabled and Automatic Time-step Process was employed with 10% of the full temperature loading (temperature drops from 600 to 25°C) as the initial time-step. A line search was used with the Newton-Raphson iterative algorithm to improve and accelerate convergence.

The basic mechanical properties of materials included in the die-attach (Au, SiC, and AlN) and the temperature dependences of these material properties that were used in FEA simulation are listed in Table 15.4.2. The temperature dependence of the Young's modulus of AlN in a wide temperature range has not been reported, so it is extrapolated as a constant from the room temperature value. The Poisson's ratios of single-crystal 6H-SiC and AlN have not been published, so they are estimated from those of other carbides and nitrides, respectively. The thermal and mechanical properties of 6H-SiC are assumed to be isotropic. Material CTEs (mismatches) have the most significant effects on the die-attach assembly thermal stresses/strains. Temperature-dependent CTE data of both substrate and die materials (AlN and SiC), as listed in Table 15.4.2, were used for the FEA simulation.

The yield strength data of Au reported in the literature covers a wide range due to different heat-treatments applied to the materials used for these experimental tests. In this simulation, a low Au yield strength (250 psi) and temperature-dependent plasticity of Au are used. These simulation results should be close to stress/strain configurations of an Au thick-film based die-attach assembly sufficiently annealed (stored and operated) at 600°C. Plasticity of gold thick-film is a primary factor responsible for thermally induced stresses in a die-attach assembly. Only limited data of Au plasticity are available in published literature. Temperature dependent ultimate tensile strength of Au have been reported (King et al. 1988).

TABLE 15.4.2 Materials Properties of Au, AlN, Al_2O_3, and SiC Used for FEA

An elongation of 65% was reported for annealed gold (Suhir 1987). The yield strength of gold is 250 psi (King et al. 1988) at room temperature, and it is assumed to be independent of temperature in the calculation. Based on these material properties, approximations, and assumptions, temperature-dependent plasticity behavior of gold was constructed as shown in Figure 15.4.6 (Lin and Chen 2002).

Figure 15.4.7a and Figure 15.4.7b show the von-Mises stress (the second deviatoric stress invariant) contours for the SiC die from an SiC/Au/AlN die-attach assembly at room temperature with an assumed stress relaxing temperature of 600°C. Von-Mises stress is often used to determine if yielding or damage occurs. Since the maximum von-Mises stress of the die is much lower than the yield strength of SiC material, it is anticipated that there is no material level damage to the SiC die. The level of stress around the inner circle (etching wall) of the bottom of the die is high, whereas the stress level is lower towards the die edges and corners of the bottom of the die. The stress level also significantly decreases toward the top of the die. The level of stress in the diaphragm area is significantly higher than those in the areas surrounding the diaphragm. The stress level of the diaphragm area can be used to estimate the effects of die-attach thermal stress on operation and configuration of diaphragm-based MEMS devices. Figure 15.4.7(c) and Figure 15.4.7(d) show the distribution of peeling stress, which is the normal stress perpendicular to the die/attaching-layer interface, at the die/attaching layer interface. Positive peeling stress indicates that the stress is in tension, and the negative stress indicates the stress is compressive. The tension is relatively high around the inner circle of the bottom of the die. At the corner and edge areas, the peeling stress is negative, so it is compressive. Usually, tensile stress causes material damage/cracks.

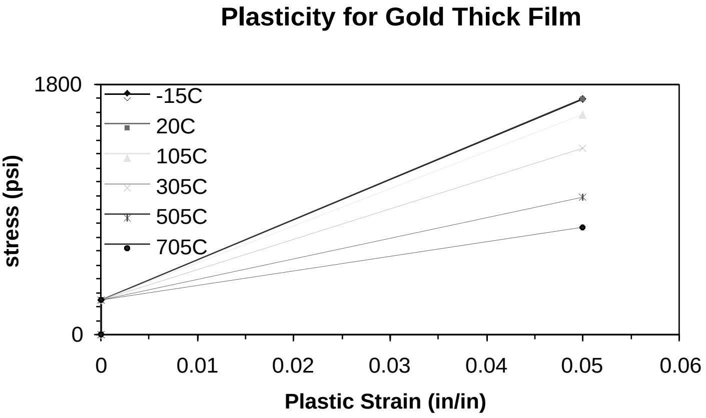

FIGURE 15.4.6 Temperature-dependent plasticity of gold thick film; –15°C and 20°C data overlap each other in the figure.

Compared with the mechanical strength of SiC material, the maximum tensile stress of the SiC die is still low, so no die material damage is anticipated. Figure 15.4.7(e) and Figure 15.4.7(f) show the die shear stress (τ_{zx}) distribution contour. The shear stress of the bottom of the die is high at the area close to the edge. Both peeling and shear stresses decrease rapidly toward the top of the die. The peeling and shear stresses in the diaphragm area are also higher than those outside the diaphragm. The peeling (tensile) stress at the die/attaching interface can be directly compared with the die-attach adhesion tensile strength data for reliability analysis and failure mode prediction. The shear stress at the die/attaching-layer interface can be directly compared to the shear strength of the die-attach material and the shear adhesion strength of the die/attaching layer interface for failure/reliability analysis.

Figure 15.4.7(g) and Figure 15.4.7(h) show von Mises stress contours on the top and bottom of the Au attaching layer. Von Mises stress is high at the corner region, illustrating that the shear component may dominate the von Mises stress at the die/attaching layer interface area. Figure 15.4.7(i–l) show peeling and shear stresses on the top and bottom of the die-attach layer. The peeling and shear stresses on the top of the attaching layer are exactly the same as those on the bottom of the die (the stress scale bars are in different scales). The peeling and shear stress contours on the bottom of the attaching layer are the same as those on the substrate. The strap structure of the shear stress indicates that τ_{zx} increases with the distance from the $x = 0$ neutral point. Because the die-attach assembly has 90° symmetry in the horizontal plane, the shear contour of τ_{zy} can be obtained with 90° rotation of that of τ_{zx}. Peeling and shear stresses at the attach layer/substrate interface can be compared with the experimental measurements of the adhesion strength of the attach layer/substrate interface for reliability assessment and failure-mechanism prediction. Figure 15.4.7(m) and Figure 15.4.7(n) show the equivalent plastic strain (EPS) distributions of the die-attaching layer after cooling to room temperature and heating back to 500°C (one thermal cycle).

The thermal stresses/strains on the diaphragm may cause changes in device configuration and operation. For example, thermal stress can directly generate thermal shift of the piezoresistance of diaphragm-based piezoresistive MEMS sensors such as pressure and acoustic sensors. A thermal shift of the capacitance of a diaphragm-based capacitive sensor due to the deformation of the diaphragm under thermal stress may also occur. These die-attach-related thermal stresses may have significant thermal effects on the packaged devices. In addition to the predications of packaging-related reliability and failure analysis, FEA results may also help MEMS packaging designers to simulate/predict packaging effects on devices. Using the FEA results may allow designers to reduce the parasitic packaging effects through materials selection and structure optimization. In order to study the effects of die-attach materials and die-attach geometries, single-parametric dependence of stress/strain on substrate material, die size, die-attaching layer thickness, and environment/processing temperature can be simulated using FEA (Lin and Chen 2002).

In these FEA simulations, the boundary conditions at both SiC/Au-thick-film and Au-thick-film/substrate interfaces are assumed to be ideal. This means that there is no slip at either interface under shear stress. Mathematically, this assumption implies that all three displacement components are continuous at the two interfaces. We made this assumption since limited interfacial thermomechanical properties of this material system are available. Further, it is difficult to either numerically model or experimentally measure the thermal and mechanical properties of interfaces, especially the temperature dependencies of these interfacial thermomechanical properties. This assumption may have limited applicability for those relatively “loosely” bonded interfaces, especially at elevated temperatures.

FIGURE 15.4.7 (continued).

The experimental measurement of three-dimensional die-attach stress/strain distributions and detection of the thermal mechanical failure of the Au attaching layer sandwiched between an SiC die and a ceramic substrate can be challenging, especially at elevated temperatures. Therefore, it is important and helpful to numerically validate the FEA results. First, the effect of mesh design/density on the numerical results can be examined by changing the three-dimensional FEA mesh. The convergence of the numerical results with increasing mesh density usually is a good indication of valid results. Second, the stability of the stress/strain dependence on the material properties, such as the CTE of the substrate, can also be used to examine the numerical stability with a small virtual perturbation (upward and downward shifts) of the CTE-temperature curve of the substrate material. Third, the numerical results should (approximately)

satisfy all the boundary/interface and symmetry conditions. This is a simple and quick way to physically validate the numerical results. Fourth, the trends of stress/strain can be compared with those predicted by approximate analytical results if they are available.

Low-Stress Die-Attach

Advanced low-stress die attach methods for MEMS packaging will be discussed in this section.

Low-Stress Die-Attach Materials

As discussed earlier, the die-attach stress/strain increases rapidly with the temperature deviation from T_R. T_R is the temperature at which the die-attach is thermomechanically relaxed (no stress or almost no stress). Usually, the physical/chemical process of die attaching determines T_R such that it is close to the die-attach process/curing temperature. Therefore, the die-attach process temperature is an important process parameter determining die-attach stress/strain and thermal reliability. The ideal situation is that T_R is at the center of the operating temperature range (Lin and Chen 2002). A process called low-temperature transient liquid phase (LTTLP) bonding allows die to be bonded at a relatively low temperature, from 60 to 160°C, yet the bonding layer will remelt only at a much higher temperature. The principle of this bonding process is that the metal(s) of the metallization on the substrate and/or the die dissolve into the melted alloy and form a new alloy that isothermally solidifies (Roman and Eagar 1992). In the mid-1960s it was demonstrated that indium, which melts at 156.7°C, forms In_xAu_y alloy with a melting temperature of ~300°C (Bernstein 1966). The research on LTTLP has been active again since the early 1990s because of the need for low-processing-temperature die-attach materials for reliable large-size high-power devices packaging. Various low-melting-temperature solders of indium, tin, bismuth, and cadmium have been tested for applications with base metals of gold, silver, and copper (Roman and Eagar 1992). Table 15.4.3 shows a recompiled table of melting temperature and tensile strength of these material systems. Low stress die-attach materials are attracting more attention because of the emerging needs of MEMS packaging.

Mechanically, most LTTLP bonds are as strong as an equivalent conventional solder bond (Roman and Eagar 1992). Typically, the remelting temperature and the mechanical strength of LTTLP bonds depend on the processing temperature and temperature profile (temperature vs. time).

Low-Stress Die-Attach Structures

Li and Tseng suggested a "four-dot" low stress die-attach approach for packaging of MEMS accelerometers that reduced die surface strains caused by CTE mismatches (Li 2001). FEA simulation results indicated that a significant stress reduction could be achieved when the area of die-bonding "dots" located at four die corners were small. This die-attach structure can dramatically reduce or eliminate the transverse

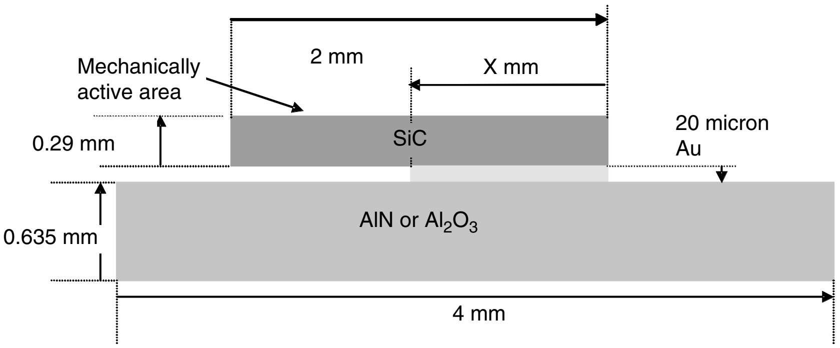

FIGURE 15.4.8 Partial die-attach structure.

normal stress in the central die area. However, it may not be optimized to reduce lateral normal stresses in the die, which is important to diaphragm-based piezoresistive MEMS sensors.

The thermal mechanical stress in the SiC die of the die-attach assembly shown in Figure 15.4.4 has been numerically simulated using FEA. The results show that the stress attenuates rapidly with increasing vertical distance to the interface of SiC and Au thick-film layer. Horizontally, the maximum thermal stress increases rapidly with the die size or die-attaching area (Chen and Lei 2002). Based on these results, an effective thermal stress attenuation method is suggested: lateral stress attenuation die attach (Chen and Lei 2002). This stress reduction die-attach structure requires that the die be partially attached to the substrate through the backside area of the nonmechanically active portion of the die, rather than fully attaching the die to the substrate. A side view of a partially bottom attached die-attach is illustrated in Figure 15.4.8. This die-attach structure allows a lateral distance on the device chip between the mechanically active area(s) and the direct attaching area. This die-attach structure allows the stress generated by thermal expansion mismatch at the die/attach/substrate bonding area to effectively attenuate along this lateral distance. The advantage of using this die-attach structure is the reduction of stress at mechanically active (unattached) areas of MEMS chips. Therefore, the requirement of matching the thermal expansion coefficients of die, attaching, and substrate materials is lessened. This low-stress die-attach technology is especially suitable for applications in high-temperature MEMS packaging for which thermal stress is a critical concern for both (packaged) device performance and reliability. Figure 15.4.9(a) through Figure 15.4.9(d) show various thermal stresses of die-attaches with attaching areas of 1 mm × 1 mm (Chen, 2003). The SiC die is 1 mm wide, 2 mm long, and 0.29 mm thick. The die is attached to an AlN substrate using 20 μm thick Au thick-film material. The substrate is 4 mm × 4 mm and 0.639 mm thick. Apparently, the stress levels in the majority area where the bottom of the chip is not directly attached to the substrate are very low.

Figure 15.4.10(a) and Figure 15.4.10(b) show two-dimensional FEA simulated stresses of a square die attached to a package wall through one of the die sides using Au thick-film material. The area near the far end of the die has low stresses.

Example of a MEMS Package

As discussed in the introduction, because of the nature of nonelectrical interactions between MEMS devices and their environment, the design of a MEMS package is much more complicated compared to a package for conventional electronics. Among the design considerations for MEMS packaging, mechanical design is one of the most important and critical factors for both functionality and reliability of packaged MEMS devices. The design of a multipurpose screw-in type high-temperature sensors package is used to illustrate the mechanical design that minimizes packaging thermal stress effects on MEMS device performance and reliability.

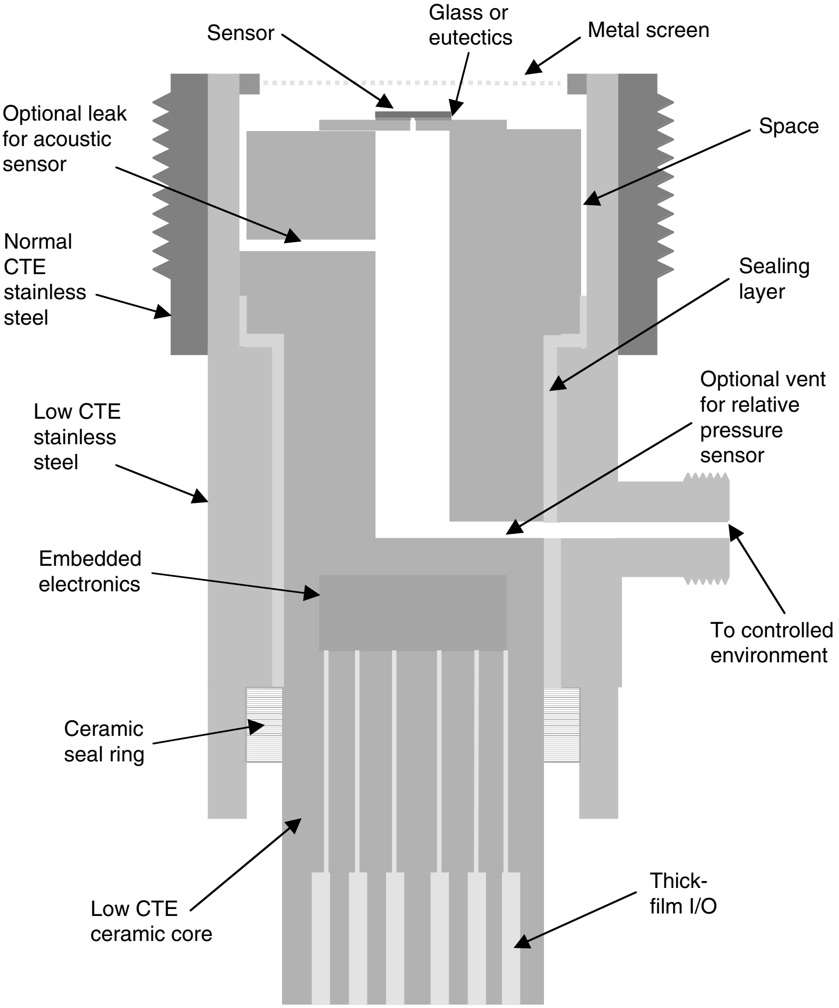

FIGURE 15.4.11 A multipurpose high-temperature MEMS package module for *in situ* characterization of aerospace engine combustion process (500°C). (Chen 2004.)

This multipurpose package is designed for real time *in situ* (500°C) characterization of combustion processes of aerospace engines (Chen 2004). As shown in Figure 15.4.11, the package base is made of a stainless steel material that has the same CTE as that of the engine body. The core of the package is made of a low CTE ceramic such as AlN. A glass material with a low curing temperature and low CTE is used to seal the ceramic core into the stainless steel base. Since the CTEs of stainless steels are usually higher than those of ceramics, the normal stresses at SS/glass and glass/ceramics interfaces are compressive at temperatures below the glass sealing/curing temperature. The upper part of the ceramic core is not directly sealed to the stainless steel base wall, so the compressive stress in the ceramic core attenuates rapidly toward the top of the ceramic core. Meanwhile the mounting stress generated at the thread area is also isolated from the top of the ceramic core where the sensor is mounted. The sensor is directly mounted on a piece of ceramic substrate, which is sealed onto the ceramic core. In order to minimize the die-attach thermal stress, a ceramic substrate with low CTE should be selected.

The static and dynamic pressures (Rossi 1988) in the chamber underneath the sensor are determined by the configuration of the package. The chamber pressure can be used as the reference point for differential measurements: The chamber can be sealed at vacuum so the chamber pressure is low with respect to the pressure in the measurement chamber. This configuration is suitable for absolute pressure measurement using a differential pressure sensor. The chamber can also be vented to atmosphere so the chamber pressure is a constant. This configuration is good for relative pressure measurement. The chamber can also be vented to the measuring chamber through a small leaking channel. Under this configuration the static pressure in the chamber is equal to that of the measuring chamber, but dynamically (above a certain frequency) the chamber can be isolated to the measuring chamber. This configuration is suitable for dynamic/acoustic pressure measurement. The dimensions of the chamber and vent affect both dynamic sensitivity and frequency response (the resonant frequency) of a diaphragm-based sensor through damping effects of the air in the chamber.

Electronics can be integrated into the ceramic core for signal conditioning and power management. For example, for a capacitive pressure sensor, the output signal very often is AC. Therefore, parasitic effects of electrical interconnections become an issue if the measuring electronics are far away from the sensor. The integrated electronics can also be used for *in situ* temperature compensation and output signal modulation and coding.

Discussion

MEMS devices operate mechanically (partially) so these devices can be sensitive to their mechanical environment. The mechanical functions of a MEMS packaging system become important to both device performance and reliability. These mechanical functions and requirements on the packaging system can be far beyond those developed for conventional electronics. Therefore, new research and development in packaging materials and processing are required. Currently, MEMS packaging is still in its initial development stage. Often a significant percentage of the cost of a MEMS product is from packaging, and packaging technology dominates product performance and reliability. The demands of a mature and systematic MEMS packaging technology opened another vivid area in device packaging.

Because of the limited space of this section, many mechanical issues other than thermal stress in MEMS packaging have not been addressed. One of these important issues is pre- and postpackaging mechanical testing and qualification criteria. Both the nature and function of MEMS devices determine that mechanical testing of MEMS can be much more complicated and expensive compared with those for conventional electronics. Establishing mechanical qualification criteria for a MEMS device is essential for a MEMS product.

Traditionally, device packaging is typically a macrofabrication process that has more material cost and less mechanical consistency and accuracy compared with the microfabrication process used for MEMS device fabrication. Because of these reasons and other technical requirements, there is a trend toward realizing more packaging functions at the wafer level, using microfabrication process, to replace chip-level and board-level packaging functions. This trend will likely push one-chip-system or one-module-system technology ahead. However, selection of a packaging scheme is not solely determined by technology suitability but also by cost and market demands.

Acknowledgments

The authors want to thank Drs. Lawrence G. Matus, Glenn M. Beheim, Gary W. Hunter, and Jih-Fen Lei at the NASA Glenn Research Center for their contributions. One of the authors (LC) would like to thank Dr. Carl W. Chang for his proofreading and helpful discussions on finite element analysis (FEA). The authors also would like to thank Dr. Robert S. Okojei for providing his design of SiC pressure sensor for FEA simulation. The FEA simulations were conducted by Dr. F. Patrick McCluskey and Mr. Karumbu Meyyappan at the University of Maryland at College Park, and by Dr. Shun-Tien Lin at United Technology Research Center, with the support of the NASA Electronic Parts and Packaging Program (NEPP) through the NASA Glenn Research Center. Part of this work was supported by Glennan Microsystems Initiatives (GMI).

15.5 Reliability and MEMS

Srihari Rajgopal, Christian A. Zorman, Darrin J. Young, and Mehran Mehregany

Introduction

Microelectromechanical Systems (MEMS) is an enabling technology with the potential to revolutionize a wide range of applications that could benefit from the insertion of highly functional, miniaturized electromechanical devices that can independently sense and act on the environments into which they are deployed. From a commercial perspective, MEMS is a particularly attractive technology because a wide range of MEMS devices can be fabricated using the batch-processing methods, techniques, and tools employed by the integrated circuit (IC) industry, thus creating at least the potential for low-cost manufacturing. Without question, research and development in MEMS have yielded devices with a level of complexity and functionality that could only have been imagined just a few years ago. Unfortunately, the pace of commercialization has lagged behind the advancement of the technology, in part because the reliability science of these micro-scale electromechanical devices has not matured. The penetration of MEMS technology into safety, navigation, health-care, and other mission-critical applications is further pushing the need to study, understand, and develop the subject of reliability as it pertains to MEMS.

The purpose of this chapter is to present a short overview of the concepts governing reliability science, and at the same time, to provide insight into the reliability issues pertinent to MEMS. Given the great diversity that exists in MEMS devices in terms of dimensions, materials, and operating environments, along with the fact that reliability is, in many respects, device and application specific, this chapter does not attempt to provide a comprehensive overview of reliability and MEMS. Instead, we present a review of the methods that were used by Texas Instruments to characterize and improve the reliability of the Digital Micromirror Device (DMD).[1] The DMD is one of the most recognizable MEMS-based products in the market today, due in part to the exhaustive reliability studies performed by Texas Instruments to field this product successfully. It is an excellent example for illustrating the importance of reliability analysis in MEMS product development.

Reliability as It Relates to MEMS

Reliability can be defined as the *probability* of a product to meet its design specifications without *failure* for a given period of *time* in a particular operating *environment*. Thus, statistical techniques are applied to analyze the data obtained from failure tests in order to estimate the average lifetime of a product. *Failure* refers to a predefined condition of nonoperation, and the *environment* refers to the operating conditions under which the failure tests were conducted. Operating conditions may replicate or exceed design specifications so as to accelerate product failure. For example, failure rates typically increase with increasing temperatures; therefore, accelerated failure tests are often performed at temperatures well above the specified operating temperature.

With respect to MEMS, the utilization of IC-based fabrication techniques and device interface electronics result in certain reliability issues that are similar to those encountered in the IC industry. However, reliability-related characteristics that are unique to MEMS include

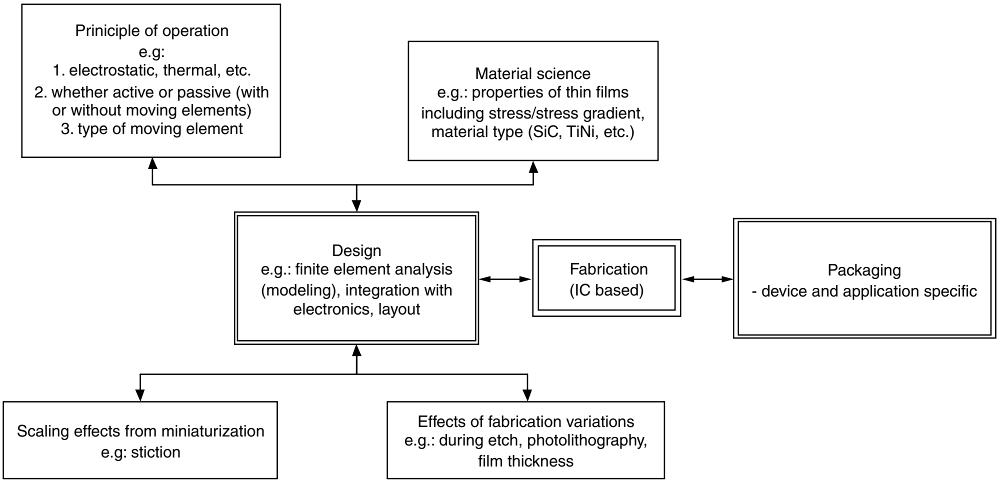

FIGURE 15.5.1 Factors defining the lifetime of a MEMS device.

- The presence of movable mechanical elements such as membranes, cantilevers, and rotating elements and the consequent effects from friction, wear, fatigue, and creep.
- Material characteristics such as
  - Thin film properties that may differ from bulk properties.
  - Thermal or crystallographic mismatch issues between different materials.
  - Film stress and its variation across film thickness (stress gradient).
- Surface interaction effects in mechanical contacts such as stiction and wear.
- Contradictions in packaging whereby the package is to protect the device from environmental factors while providing access to the environment for the desired sensing or actuation.
- Packaging considerations that are unique to a device and application. For example, the packaging requirements of a microvalve operating in a high-temperature environment differ substantially from that of a micromachined oscillator for wireless applications operating in a reduced pressure environment.

Reliability issues related to MEMS are illustrated schematically in Figure 15.5.1. In addition to device specifications and operating conditions, reliability considerations must take into account such factors as desired lifetime, safety concerns, cost, and manufacturability. These are represented schematically in Figure 15.5.2.

The schematic presented in Figure 15.5.1 suggests an integrated approach toward reliability with factors considered from the outset of device development. One such approach is known as the Failure Mode and Effect Analysis (FMEA) method.[1] The procedure begins with any new design and fabrication process, and involves a team of experts with backgrounds covering materials science, modeling, layout, interface electronics design, process technology, and packaging. The goals are to

1. Analyze design constraints, process issues, packaging limitations, and test methods.
2. Anticipate and identify potential failure modes (identifiable symptoms of failure), failure mechanisms, causes of failure, and potential means of acceleration.
3. Estimate the effects of these factors on lifetime.
4. Define appropriate verification tests.

A benefit of this approach is that device development time can be significantly shortened. Where new device technologies limit such analyses due to a lack of prior test data, a series of methodical characterization tests are usually conducted to create a knowledge database.

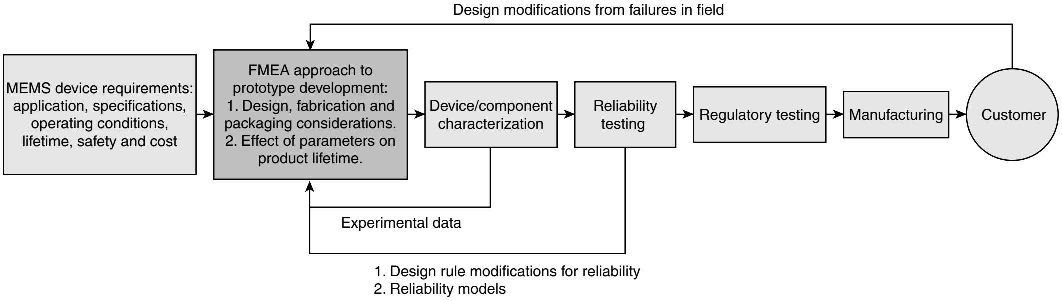

FIGURE 15.5.2 Typical sequence of events enabling final product reliability. (Adapted from Hnatek, E. 2003. Practical Reliability of Electronic Equipment and Products, Marcel Dekker, New York.)

Failure

Device failure is the primary focus of interest in reliability tests, the idea being to eliminate or postpone failure, thereby increasing useful life. This "useful life" is represented by region II in the life characteristic curve (Figure 15.5.3) that displays the failure (or hazard) rate as a function of time for an identical sample of devices under identical stress conditions. The life characteristic curve, otherwise known as the "bathtub curve"[2] is the combination of the other curves depicted, namely quality failures, stress-related failures, and wear-out failures.

The bathtub curve can be subdivided into three distinct regions that are largely based on the age of the device in question. Region I is known as the infant mortality region and encompasses the earliest stage of device life. Failures in this region are primarily related to issues in quality or manufacturing. In the case of microfabricated devices, these include processing defects, particles, and defective packaging. Failure mitigation is achieved primarily through increased quality control measures and improvements to manufacturing processes. To overcome high failure rates early in the lifetime, a "burn-in" procedure is typically used to screen out defective devices prior to product shipment. Depending on the device and application, this may include testing at increased stresses such as exposing devices to elevated or rapid fluctuations in temperature. Wear-out or application-oriented stress failures are usually minimized through design changes.

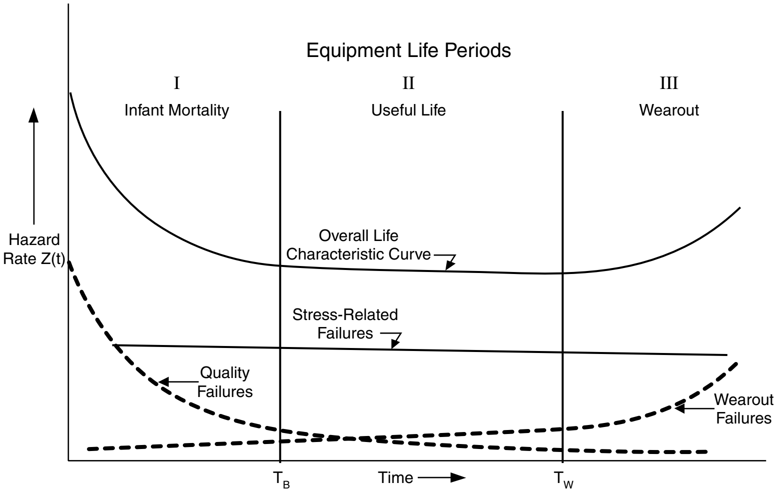

FIGURE 15.5.3 The bathtub curve. (*Source:* Hnatek, E. 2003. *Practical Reliability of Electronic Equipment and Products,* Marcel Dekker, New York.)

TABLE 15.5.1 Failure Regions in the Bathtub Curve and Mitigating Factors

Failure Region in the Bathtub Curve	Mitigation
Region I: Infant mortality	Quality control, improved manufacturing process, and design modification
Region II: Useful life/random failure	Design for reliability
Region III: Wear-out phase	Design for reliability (can only be delayed)

TABLE 15.5.2 Failure Mechanisms in MEMS and Potential Mitigation Methods

Failure Issues	Mitigation
Stiction	Fabrication (coatings), device design, packaging (hermetic)
Friction and wear	Material selection, device design (choice of motion, i.e., rotational, sliding), packaging (corrosive applications)
Creep	Material selection, packaging (such as improving thermal dissipation)
Fatigue/Fracture	Device design (in case of fracture caused by overstress effects), fabrication, and packaging
Shock/vibration	Device design
Dielectric breakdown (including ionizing radiation effects from space applications)	Design and/or packaging
Open/short circuits	Fabrication

Region II encompasses the useful life of the device. During this phase, the failure rate is reduced to an acceptable value and generally remains steady. Few failures are related to quality concerns. Wider device operating margins through design improvements mitigate stress-related failures.

Region III is known as the wear-out phase. Failure rates increase in this region as the device ages and latent defects develop over time. Proper design and adoption of robust technologies and materials help delay the onset of this phase. Table 15.5.1 presents a summary of the mitigation procedures used to minimize the effects of failure in each of the three regions of the bathtub curve.

Failure issues in MEMS that involve quality, stress, and wear-out failure profiles are listed in Table 15.5.2. Of these, stiction, friction/wear, creep and fatigue[3] are particularly important to MEMS owing to the incorporation of moving components in a large percentage of MEMS devices.

Stiction refers to the adhesion of adjacent microstructures and is particularly relevant to devices that rely on the mechanical contact of very smooth surfaces. It often occurs during the drying process (one of the final stages of device manufacturing) that follows a "wet" release step (which involves removal of the sacrificial layer beneath movable elements of the device to enable motion); however, it can also occur during field operation. Several strong adhesive forces, including capillary, electrostatic and van der Waals, result in "stuck" devices incapable of motion. Stiction is particularly troublesome for surface micromachined devices where the vertical distance between the substrate and a released component is often only a few micrometers and the contacting surfaces are very smooth.

Friction and wear are of interest in MEMS devices that incorporate sliding, rotational, or rubbing elements. With respect to silicon, adhesive wear has been found to be one of the most significant wear mechanisms.[3] In this case, the highest points of contact between the rubbing surfaces adhere. Break-off eventually occurs from one of the surfaces, resulting in particle generation. Some of these particles stick to one of the surfaces, forming sites for further particle accumulation. When reaching a certain size, these asperities break off, causing wear and also an accumulation of debris between the rubbing parts.

Humidity has been shown to be a key factor in wear of sliding micromachined polysilicon surfaces when operated in an air environment.[4] It has been observed that the volume of wear debris increases as the relative humidity decreases. Other forms of wear include abrasive wear observed in the presence of higher contacting and corrosive wear brought about by chemical reactions.

Creep has been observed in micromachined metal elements.[5] Creep is the slow change in the dimensions of a mechanical structure when it is exposed to prolonged loads that are below the yield stress of the material. The result is the degradation in performance of structural elements and ultimately a reduction in device lifetime. To better understand the effects of creep, consider the macro world where there is no evidence of creep at temperatures less than $0.3T_m$, where T_m is the melting temperature of the metal. At temperatures greater than $0.3T_m$ and/or high mechanical stress, creep may rapidly lead to fracture. While a corresponding quantitative relation has yet to be established for micro-scale devices, a similar qualitative behavior as a function of temperature may be expected.

Fatigue (progressive fracture under cyclic loading conditions) and fracture have both been explored in silicon and polysilicon, the primary structural materials in MEMS. Contrary to expectations, experimental results have shown that thin films of these "brittle" materials undergo time-dependent cracking (crack extension or crack initiation and growth) under monotonic and cyclic loading. Muhlstein et al.[6] suggested the cause was stress corrosion cracking (SCC) of the surface oxide on silicon and termed it "reaction-layer fatigue." (Stress corrosion cracking, or "static fatigue" in brittle materials like ceramics refers to the propogation of a small crack when subjected to stresses in a corrosive [e.g., humid] environment. Silicon reacts with the ambient to form the initial "native" oxide layer about 2 nm thick.[7]) In this study, micromechanical structures were subjected to environmentally assisted crack initiation, followed by sequential thickening (from continued chemical reactions with the ambient) and crack propagation until the structures suffered from final catastrophic failure. Kahn et al. showed that polysilicon is not susceptible to static SCC.[7] Low-cycle fatigue behavior was found to be dependent on the compressive stresses experienced during loading. It was postulated that microcracks originated from surface asperities created during processing. Fracture occurred from crack propagation during cyclic loading. The results were found to be independent of ambient conditions. In the case of high-cycle fatigue, additional "wedging" and crack extension were theorized from the growth of surface oxide in crack surfaces due to exposure to ambient air. Thus, a corrosive environment was found to exacerbate high-cycle fatigue.

Fatigue predictions based on bulk models have been found to be inconsistent with observations from micromechanical structures made from thin metal films. For instance, it has been reported that the aluminum hinges in the DMD do not experience fatigue.[8] Macroscopic fatigue models are based on the accumulation of dislocations that move to the metal surface, causing fatigue cracks, further accumulation of dislocations, increased mechanical stresses, and eventual breakage. In the case of a thin film, the material is only one or a few grains thick. As a result, a dislocation density sufficient to form fatigue cracks does not accumulate.

Failure resolution at the device level requires that the manifestation, mode, mechanism, and cause of each failure be addressed. *Failure manifestation* is the identification and definition of failure including, but not limited to, such aspects as whether the failure can be reversed, is permanent, or requires customer intervention. *Failure mode* is the measurable characteristic or symptom of failure. *Failure mechanism* is the actual effect observed in the device, and the *cause* is the actual source or initiator of the failure. The analysis process concerns itself with aspects such as whether the failure was random or preordained, catastrophic or gradual, and its time of occurrence. As shown schematically in Figure 15.5.4, every failure characteristic is represented at the infant stage and is consistent with quality, manufacturing, and design issues. Failures in the midlife region are predominantly random catastrophic failures as a result of such events as electrostatic discharge, particles, and processing defects. These failures correspond to the flat midlife region of the bathtub curve. In the wear-out phase, gradual and preordained failures reappear as a function of design, materials, and technology.

Mathematics of Reliability

The previous discussion centered on failure from a cause-and-effect perspective. The current topic focuses on the mathematical methods employed to quantify reliability and is based on detailed discussions presented in References 2, 9, and 10.

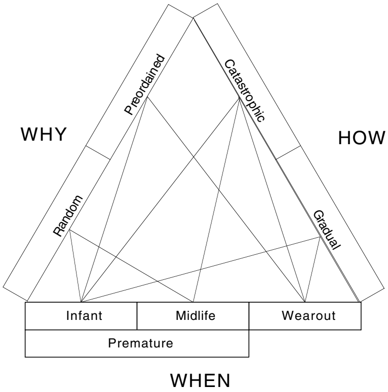

FIGURE 15.5.4 Failure analysis concepts as related to the three regions of the bathtub curve. (*Source:* Ohring, M. 1998. *Reliability and Failure of Electronic Materials and Devices*, Academic Press, San Diego, CA..)

Reliability essentially deals with assessing the failure rate and the service life of products. Thus failure data obtained from laboratory tests and field observations are analyzed using statistics and probability theory to obtain failure rates and project lifetimes of devices. Typical reliability metrics include failures in time (FIT) typically expressed as failures per one billion device hours, mean time between failure (MTBF) for repairable systems, mean time to failure (MTTF) for nonrepairable items, and percent failure per thousand hours.

If the probability density function (PDF) of failure is denoted by $f(t)$, then the cumulative distribution function (CDF), $F(t)$, representing the fraction of devices that fail up to time t can be written as

$$F(t) = \int_{-\infty}^{t} f(v)dv \tag{15.5.1}$$

Thus, the PDF can alternatively be written as

$$f(t) = \frac{d}{dt}F(t) \tag{15.5.2}$$

$F(t)$ may also be referred to as the *unreliability* probability.

The reliability function, $R(t)$, or the probability that the remaining fraction has survived for length of time t, is given by

$$R(t) = 1 - F(t) \tag{15.5.3}$$

therefore

$$f(t) = -\frac{d}{dt}R(t) \tag{15.5.4}$$

The failure rate (also known as the hazard or mortality rate), $\lambda(t)$, is defined as the ratio of the number of devices failing in the next time interval Δt to those that survived up to time t. Mathematically, the failure rate can be written as

$$\lambda(t) = \frac{F(t+\Delta t) - F(t)}{\Delta t\big(1 - F(t)\big)} = \frac{f(t)}{1 - F(t)} = \frac{f(t)}{R(t)} \tag{15.5.5}$$

The mean-time-to-failure (MTTF), the most frequently used reliability unit, is

$$MTTF = \frac{\sum_{j=1}^{n} t_j}{n} \tag{15.5.6}$$

where t_n represents the sum of the failure time of the nth device.

Consider $nf(t)$ as the number of devices that fail in the short interval between t and $t + \Delta t$. Given $nf(t)$ devices with lifetime t, the MTTF can be written as

$$MTTF = \frac{1}{n}\int_0^\infty t\left[nf(t)\right]dt = \int_0^\infty tf(t)dt \tag{15.5.7}$$

Substituting for $f(t)$ from Equation 15.5.4 and simplifying results in

$$MTTF = \int_0^\infty R(t)dt \tag{15.5.8}$$

Table 15.5.3 summarizes these basic reliability parameters.

Various models or life distributions exist to characterize failure rate and reliability, and to facilitate lifetime predictions beyond the range of data obtained through experiment and field observations. The choice of distribution type is based on the properties of these models, an understanding of the failure physics, and prior experience. Table 15.5.4 lists a few of the life distributions. The exponential life

TABLE 15.5.3 Basic Reliability Parameters

	Parameter	Expression	Meaning
1	Probability density function (PDF) $f(t)$	$f(t)\Delta t = P\{t \le T \le t + \Delta t\}$	Probability that failure occurs at time T between t and $t + \Delta t$
2	Cumulative distribution function (CDF) $F(t)$	$F(t) = P\{T \le t\}$	Probability that failure occurs at time T less than or equal to t
3	Reliability $R(t)$	$R(t) = P\{T > t\}$	Probability that failure does not occur by time t
4	Failure rate $\lambda(t)$	$\lambda(t)\Delta t = P\{T < t + \Delta t \mid T > t\}$	Probability that failure occurs at time $T < t + \Delta t$ provided that no failure has occurred at $T = t$
5	Mean time to failure (MTTF)	$MTTF = \int_0^\infty R(t)dt$	

Adapted from Hnatek, E. 2003. *Practical Reliability of Electronic Equipment and Products,* Marcel Dekker, New York.

TABLE 15.5.4 Commonly Used Reliability Distributions

	Distribution Type	Properties	Application	Examples
1	Exponential	Constant failure rate	For devices with minimal infant mortality failures	Random failures such as those caused by external shocks, i.e., failure processes independent of past history
2	Lognormal	time dependent failure rate	For wear-out failures	Failures caused by gradual degradation such as fatigue, and diffusion effects, i.e., failures that are the result of numerous small effects
3	Weibull	time dependent failure rate	Used to describe all three regions of the bathtub curve, i.e., decreasing and increasing failure rates.	Time to failure of individual system components, corrosion effects

distribution is used to model random failures and the lognormal distribution for wear-out failures. The Weibull distribution,[2,9,10] on the other hand, is flexible enough to model all three regions of the bathtub curve (as will become apparent later), and thus is the most commonly used model. We, therefore, will limit our discussion to the Weibull distribution.

For the two-parameter Weibull distribution, the CDF is given by

$$F(t) = 1 - e^{-\left(t/\tau\right)^{\gamma}} \tag{15.5.9}$$

Then, the PDF, failure rate, and reliability become

$$f(t) = \frac{\gamma}{\tau}\left(\frac{t}{\tau}\right)^{\gamma-1} e^{-\left(t/\tau\right)^{\gamma}}, \tag{15.5.10}$$

$$\lambda(t) = \frac{\gamma}{\tau}\left(\frac{t}{\tau}\right)^{\gamma-1}, \tag{15.5.11}$$

$$R(t) = e^{-\left(t/\tau\right)^{\gamma}} \tag{15.5.12}$$

where γ is the shape function and τ is the characteristic time or the scale parameter. The characteristic time occurs when 63.2% of the population fails and is defined to be when $t = \tau$ in Equation 15.5.9. Depending on the shape function, γ, the distribution can represent each of the region of the bathtub curve. Thus, $\gamma < 1$ represents decreasing failure rates in the infant mortality region, $\gamma = 1$ represents constant failure rate in the useful life region, and $\gamma > 1$ represents increasing failure rates in the wear-out region. By appropriately varying the two parameters, the model can be made to fit a wide range of experimental data.

It is common to come across linear plots of data based on the appropriate distribution. Such a plot allows easy derivation of reliability parameters from the slopes and intercepts as well as well a quantitative estimate of the fit. In the case of the Weibull distribution, from Equation 15.5.9,

$$F(t) = 1 - e^{-\left(t/\tau\right)^{\gamma}}$$

Rearranging and performing successive logarithmic operations yields

$$\ln\left[-\ln\left\{1 - F(t)\right\}\right] = \gamma \ln(t) - \gamma \ln(\tau) \tag{15.5.13}$$

Comparing this to the equation $y = mx + c$ results in

$$y = \ln\left[-\ln\left\{1 - F(t)\right\}\right], \quad m = \gamma \quad \text{and} \quad c = -\gamma \ln(\tau)$$

The Weibull probability plot is obtained by plotting $\ln[-\ln\{1 - F(t)\}]$ vs. $\ln(t)$, where F values may be obtained from sample failure data using the following equation:

$$F(t_i) = \frac{i - 0.3}{n + 0.4} \tag{15.5.14}$$

where γ and τ are obtained from the line fitted to the data.[9]

Accelerated Stress Testing

To reduce the development and test time facilitating a rapid deployment to market, accelerated life testing is commonly used to force products to fail more quickly than they would under normal operating conditions, the assumption being that the failure mechanism remains the same and failures in time under normal and accelerated conditions scale only by time. Thus, for true acceleration

$$F_a(t) = F(AF.t)$$

where $F_a(t)$ and $F(t)$ are the failure CDF's under accelerated stress and normal operating conditions, respectively, and $AF > 1$ is the acceleration factor.[10]

Where an empirical relationship cannot be defined directly from the tests, existing mathematical models governing similar stress acceleration modes or reactions are made to determine the acceleration factor. For example, the Arrhenius model based on the well-known reaction rate equation is used when stress testing involves raising the temperature to hasten the aging process. The Arrhenius rate reaction equation is given by

$$R = Ae^{-\frac{E_a}{K_b T}} \tag{15.5.15}$$

where R is the reaction rate, A is a constant, E_a is the activation energy, K_b is Boltzmann's constant, and T is the absolute temperature.[11] To formulate the stress model, from Equation 15.5.12 we define

$$L = Be^{\frac{E_a}{K_b T}} \tag{15.5.16}$$

where L is a life measure such as characteristic time, mean time, median life, etc., B is a model parameter, and T is the temperature (stress) in Kelvin.[11]

Thus the acceleration factor AF, defined as the ratio of the life during use to that at an increased stress, may be given as[11]

$$AF = \frac{L_{use}}{L_{accl}} = \frac{Be^{\frac{E_a}{T_{use}}}}{Be^{\frac{E_a}{T_{accl}}}} = e^{\left[\frac{E_a}{K_b}\left(\frac{1}{T_{use}} - \frac{1}{T_{accl}}\right)\right]} \tag{15.5.17}$$

Models also exist that represent other stress acceleration modes.

Accelerated tests also help define the operational and destruct limits of a device and clarify the effects of prolonged operating and nonoperating times on devices. Figure 15.5.5 shows a schematic plot of stress vs. the number of failures for an arbitrary device.[1] The stress limits for a device are also denoted. The operational limits represent the stress needed to cause the device to malfunction. The device, however, must be able to return to its normal mode on the removal of this stress. The destruct limits represent irreversible failure. The curves about each of these limits represent the failure distributions caused by the specific stresses.

The Digital Micromirror Device (DMD)

The DMD is one of the first commercialized MEMS devices and possesses "typical" microsystem characteristics, namely, moving parts, contact-type motion, and integrated electronics. It is used to digitally redirect light for visual display applications. In comparison to other display technologies, the DMD is more efficient in providing increased brightness, higher contrast ratio, and better reliability in conjunction with simpler optics in a compact form factor.[12]

The device consists of an array of square, aluminum alloy reflective mirrors with each square mirror being ~14 micron on a side.[1] Each mirror is mounted on an aluminum hinge and is capable of tilting

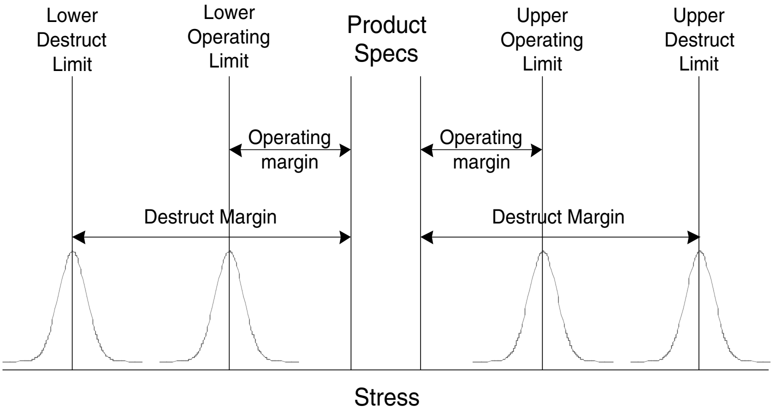

FIGURE 15.5.5 Accelerated test-to-failure methodology to determine operational and destruct parameters. (*Source:* Douglass, M.R. 2003. DMD reliability: a MEMS success story, *Proc. of Int. Society for Optical Eng. (SPIE)*, 4980,1–11.)

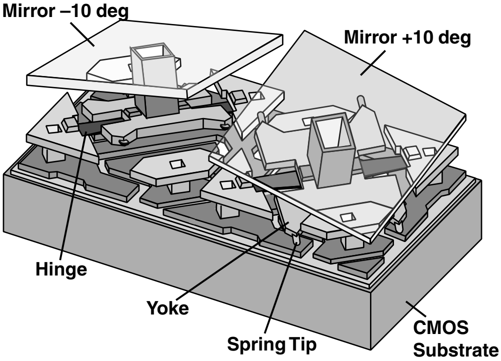

FIGURE 15.5.6 Schematic diagram of two DMD pixels with the mirrors made transparent in order to highlight the underlying device architecture. (*Source:* Sontheimer, A.B. 2002. Digital micromirror device (DMD) hinge memory lifetime reliability modeling, *IEEE Int. Reliability Physics Symposium Proc.*, Dallas, TX, April 7–11, 118–121.)

back and forth from +10° to –10° corresponding to the "on" and "off" positions of the mirror.[5] Mirror rotation is accomplished by tilting the yoke (Figure 15.5.6) using electrostatic attraction. The "on-mirrors" reflect light toward a projection lens to create an on-screen image, and the "off-mirrors" reflect light toward an absorber. The frequency of operation of each mirror during each video frame determines the light intensity. Color images are obtained using either a color wheel or a three-chip setup. Each mechanical structure rests on top of a standard static random access memory (SRAM) cell and is thus individually addressable. Integration with electronics is achieved using CMOS-compatible surface micromachining technology. The close packing density obtained by positioning the electronics and mechanical support structures under the mirrors avoids light diffraction and improves the contrast ratio. Highlights of the technology are shown in Table 15.5.5.[5]

Reliability testing of the DMD technology followed the approach shown schematically in Figure 15.5.7.[1] Failure mechanisms were investigated based on the Failure Modes and Effects Analysis method, as well as characterization tests performed on the fabricated devices. Table 15.5.6 summarizes the failure mechanisms investigated specific to the DMD MEMS superstructure and the methods adopted where necessary to mitigate such failures.

The primary lifetime-limiting parameter in the DMD was found to be hinge memory. What follows is a review of the still ongoing reliability modeling approach to characterize this failure mechanism.[13] Characterization methods and lifetime estimates are also summarized.

TABLE 15.5.5 DMD Technology Details

Device Highlights	Moving Parts: >0.5 Million
Motion	Discrete, contact type; ~ $900*10^9$ contacts/moving part
Process	Low temperature; dry-etched wafer level removal of sacrificial layer
Packaging	Die separation after sacrificial layer removal; hermetic welded lid package
Testing	Electro-optical, prior to die separation

TABLE 15.5.6 DMD Failure Mechanisms Investigated During Reliability Testing

Failure Mechanism Investigated	Failure Cause	Effects on Lifetime	Mitigation
Hinge fatigue	Material	No	N/A
Hinge memory[a]	High temperature; metal creep; high-duty cycle (on-side to off-side ratio)	Yes	Improved hinge material; reversed duty cycle actuation
Stuck mirrors	Particles; stiction; UV light exposure	Yes	Improved packaging and fabrication methods; spring tip design innovation, dry etch release, passivation layer, hermetic sealing UV filter (<400 nm)
Damage from environment	Shock, vibration, acceleration, temperature shock, cycling, and storage	No	N/A

[a] The inability of the mirror to return to its null (or flat) position after the removal of the applied bias voltage (shown in Figure 15.5.8). This occurs when the mirror is continually operated in the same state over a long period.

Based on References 1, 5, 8, and 13.

Hinge Memory

Hinge memory is the residual twist in the torsional hinge that supports a mirror. The twist is expressed as a residual tilt in the mirror following the removal of the actuation (bias) voltage. The tilt is caused from prolonged actuation of a mirror to one side compared to the other. Thus, the tilt is directed toward the side experiencing the greater number of landings. Failure is stated to occur when, beyond a residual tilt angle, the mirror is unable to overcome the electrostatic force of the applied bias voltage and land on the opposite side, causing it to be nonfunctional. A series of DMD micromirrors suffering from the hinge memory effect is shown in the SEM micrograph in Figure 15.5.8.

Parameters to Characterize Hinge Memory Failure — The parameters needed to characterize the hinge memory effect are[13,14]

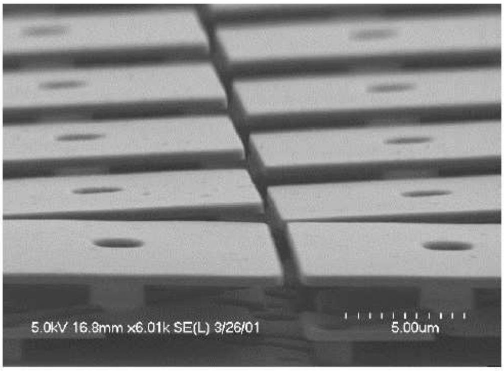

FIGURE 15.5.8 Scanning electron micrograph highlighting the flat mirrors in an unbiased condition (front row) and tilted mirrors after extended operation. (*Source:* Sontheimer, A.B. 2002. Digital micromirror device (DMD) hinge memory lifetime reliability modeling, *IEEE Int. Reliability Physics Symposium Proc.*, Dallas, TX, April 7–11, 118–121.)

Vb50 ±: The difference in DC voltage required to land (half the mirrors) on the plus side vs. the minus side

Vb50 shift%: The change between the voltage required to land a mirror in the direction of tilt and the initial value

To obtain the Vb50±, a DC voltage was applied to the mirrors and stepped up from 11 to 22 V. At each voltage step, the number of landed mirrors was measured using optical techniques for a 5/95 duty cycle, that is, 5 landings on the plus side followed by 95 landings on the minus side. The 5/95 duty cycle was chosen as an extreme scenario representing a less common mode of operation. The decreasing DC voltages required to land the mirrors on the minus side with increasing test time and increasing voltages on the plus side are shown in Figure 15.5.9 and Figure 15.5.10, respectively. The difference in the voltages required to land half of the mirrors on either side was termed Vb50± as derived from Figure 15.5.11. A change in this value is a direct indication of hinge memory.

Accelerated Testing — Figure 15.5.12 shows the results of tests conducted at temperatures of 85°C and 95°C to accelerate hinge memory failure. At these temperatures, nonfunctional mirrors were observed to begin to occur at a Vb50± of –14V. Thus, –14V was considered the conservative limit of device operation. Note the lack of failures at 65°C at the end of 2700 hrs.

Lifetime Estimates — Lifetime estimates were based on two approaches. In the first case, the curve fit to the Vb50± data at 65°C in Figure 15.5.13 was linearly extrapolated to –14V. This corresponded to a

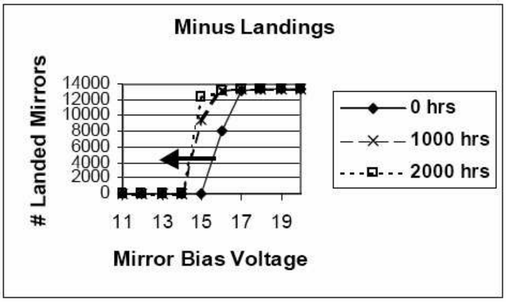

FIGURE 15.5.9 Reduction of bias voltage for minus-side landings as a function of time. (*Source:* Sontheimer, A.B. 2002. Digital micromirror device (DMD) hinge memory lifetime reliability modeling, *IEEE Int. Reliability Physics Symposium Proc.*, Dallas, TX, April 7–11, 118–121.)

pessimistic lifetime estimate of 11,000 hours. In the second case, the linear Weibull plot shown in Figure 15.5.14 was constructed following tests conducted at temperatures of 85°C and 95°C with the same sampling size and otherwise identical conditions. Nonfunctional mirrors were set as a metric for measuring lifetimes. To obtain lifetime estimates at in-use operating temperatures, an acceleration factor based on the Arrhenius model was used to model the temperature-stress acceleration.

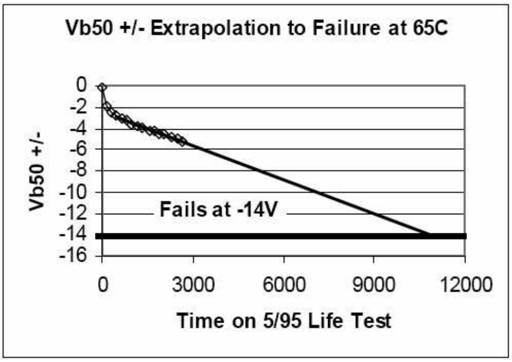

FIGURE 15.5.13 Average lifetime determination at 65°C. (*Source:* Sontheimer, A.B. 2002. Digital micromirror device (DMD) hinge memory lifetime reliability modeling, *IEEE Int. Reliability Physics Symposium Proc.*, Dallas, TX, April 7–11, 118–121.)

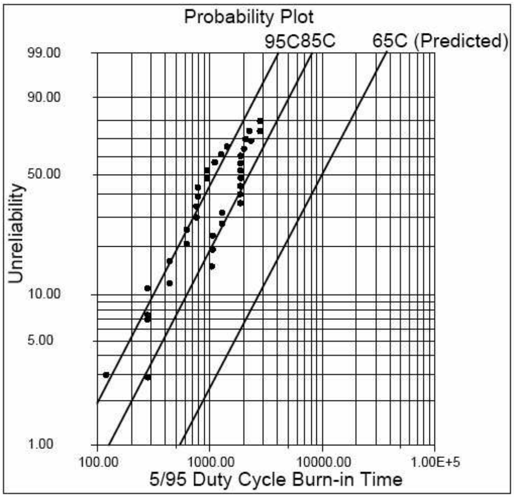

FIGURE 15.5.14 A Weibull distribution charting device failure data at temperatures of 85°C and 95°C. (*Source:* Sontheimer, A.B. 2002. Digital micromirror device (DMD) hinge memory lifetime reliability modeling, *IEEE Int. Reliability Physics Symposium Proc.*, Dallas, TX, April 7–11, 118–121.)

Using these models, conservative estimates assuming a normal operating temperature range of 25°C to 45°C and continuous operation at an aggressive 5/95 duty cycle indicated lifetimes in excess of 100,000 hours (Figure 15.5.15), which corresponds to 100 years of operation at 1000 hours/year. Estimates based on the most recent field data from third-generation DMDs (1999–2001) have indicated failure rates of less than 1000 FIT (failures per 10^9 operating hours), which correspond to a mean time between failures (MTBF) of 1,000,000 hours!

Conclusions

Without question, reliability science and testing are critical to the development of commercially viable MEMS devices. From the MEMS perspective, reliability analysis is multidisciplinary, ranging from fundamental material science on individual device layers to statistical analysis of performance data from system-level device testing under operating conditions. For the successful development of highly complex MEMS devices, reliability analysis needs to be an integral part of the entire effort involving all aspects of device manufacturing, from design and layout to packaging. As the successful commercialization of

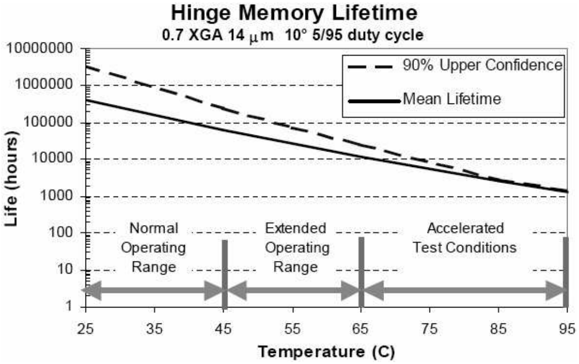

FIGURE 15.5.15 Predicted hinge memory lifetime as a function of temperature. (*Source:* Sontheimer, A.B. 2002. Digital micromirror device (DMD) hinge memory lifetime reliability modeling, *IEEE Int. Reliability Physics Symposium Proc.*, Dallas, TX, April 7–11, 118–121.)

the DMD has shown, proper use of reliability analysis techniques can greatly aid the development of highly sophisticated microchip arrays that integrate micro-scale electrical and mechanical components.

15.6 Fluid Flow in Microdevices

Mohamed Gad-el-Hak

Introduction

In this section, we review the status of our understanding of fluid flow physics particular to microdevices. The section is excerpted from an earlier publication by the same author (Gad-el-Hak 1999). Not all MEMS devices involve fluid flows, of course, but the present section will focus on the ones that do. Microducts, micronozzles, micropumps, microturbines, and microvalves are examples of small devices involving the flow of liquids and gases. MEMS can also be related to fluid flows in an indirect way. The availability of inexpensive, batch-processing-produced microsensors and microactuators provides opportunities for targeting small-scale coherent structures in macroscopic turbulent shear flows. Flow control using MEMS promises a quantum leap in control system performance (Gad-el-Hak 2000). Additionally, the extremely small sensors made possible by microfabrication technology allow measurements with spatial and temporal resolutions not achievable before. For example, high-Reynolds-number turbulent flow diagnoses are now feasible down to the Kolmogorov scales (Löfdahl and Gad-el-Hak 1999).

Flow Physics

The rapid progress in fabricating and utilizing microelectromechanical systems during the last decade has not been matched by corresponding advances in our understanding of the unconventional physics involved in the manufacture and operation of small devices (Kovacs 1998; Knight 1999; Gad-el-Hak 1999, 2002; Karniadakis and Beskok 2002; Madou 2002). Providing such understanding is crucial to designing, optimizing, fabricating, and utilizing improved MEMS devices. This section focuses on the physics of fluid flows in microdevices.

Fluid flows in small devices differ from those in macroscopic machines. The operation of MEMS-based ducts, nozzles, valves, bearings, turbomachines, and so forth cannot always be predicted from conventional flow models such as the Navier-Stokes equations with no-slip boundary condition at a fluid-solid interface, as routinely and successfully applied for larger flow devices. Many questions have been raised when the results of experiments with microdevices could not be explained via traditional flow modeling. The pressure gradient in a long microduct was observed to be nonconstant and the measured flow rate was higher than that predicted from the conventional continuum flow model. Load capacities of microbearings were diminished, and electric currents needed to move micromotors were extraordinarily high. The dynamic response of micromachined accelerometers operating at atmospheric conditions was observed to be overdamped.

In the early stages of development of this exciting new field, the objective was to build MEMS devices as productively as possible. Microsensors were reading something, but not many researchers seemed to know exactly what. Microactuators were moving, but conventional modeling could not precisely predict their motion. After a decade of unprecedented progress in MEMS technology, perhaps the time is now ripe to take stock, slow down a bit, and answer the many questions that arose. The ultimate aim of this long-term exercise is to achieve rational-design capability for useful microdevices and to be able to characterize definitively and with as little empiricism as possible the operations of microsensors and microactuators.

In dealing with fluid flow through microdevices, one is faced with the question of which model to use, which boundary condition to apply, and how to proceed to obtain solutions to the problem at hand. Obviously surface effects dominate in small devices. The surface-to-volume ratio for a machine with a characteristic length of 1 m is 1 m^{-1}, while that for a MEMS device having a size of 1 μm is 10^6 m^{-1}. The million-fold increase in surface area relative to the mass of the minute device substantially affects the transport of mass, momentum, and energy through the surface. The small length-scale of microdevices may invalidate the continuum approximation altogether. Slip flow, thermal creep, rarefaction, viscous dissipation, compressibility, intermolecular forces, and other unconventional effects may have to be taken into account, preferably using only first principles such as conservation of mass, Newton's second law, and conservation of energy.

In this section, we discuss continuum as well as molecular-based flow models, and the choices to be made. Computing typical Reynolds, Mach, and Knudsen numbers for the flow through a particular device is a good start to characterize the flow. For gases, microfluid mechanics has been studied by incorporating slip boundary conditions, thermal creep, and viscous dissipation, as well as compressibility effects, into the continuum equations of motion. Molecular-based models have also been attempted for certain ranges of the operating parameters. Use is made of the well-developed kinetic theory of gases, embodied in the Boltzmann equation, and direct simulation methods such as Monte Carlo. Microfluid mechanics of liquids is more complicated. The molecules are much more closely packed at normal pressures and temperatures, and the attractive or cohesive potential between the liquid molecules as well as between the liquid and solid ones plays a dominant role if the characteristic length of the flow is sufficiently small. In cases when the traditional continuum model fails to provide accurate predictions or postdictions, expensive molecular dynamics simulations seem to be the only first-principle approach available to rationally characterize liquid flows in microdevices. Such simulations are not yet feasible for realistic flow extent or number of molecules. As a consequence, the microfluid mechanics of liquids is much less developed than that for gases.

Fluid Modeling

There are basically two ways of modeling a flow field: either as the fluid really is — a collection of molecules — or as a continuum where the matter is assumed continuous and indefinitely divisible. The former modeling is subdivided into deterministic methods and probabilistic ones, while in the latter approach the velocity, density, pressure, and other factors are defined at every point in space and time, and conservation of mass, energy, and momentum leads to a set of nonlinear partial differential equations (Euler, Navier-Stokes, Burnett, among others). Fluid modeling classification is depicted schematically in Figure 15.6.1.

The continuum model, embodied in the Navier-Stokes equations, is applicable to numerous flow situations. The model ignores the molecular nature of gases and liquids and regards the fluid as a continuous medium describable in terms of the spatial and temporal variations of density, velocity, pressure, temperature, and other macroscopic flow quantities. For dilute gas flows near equilibrium, the

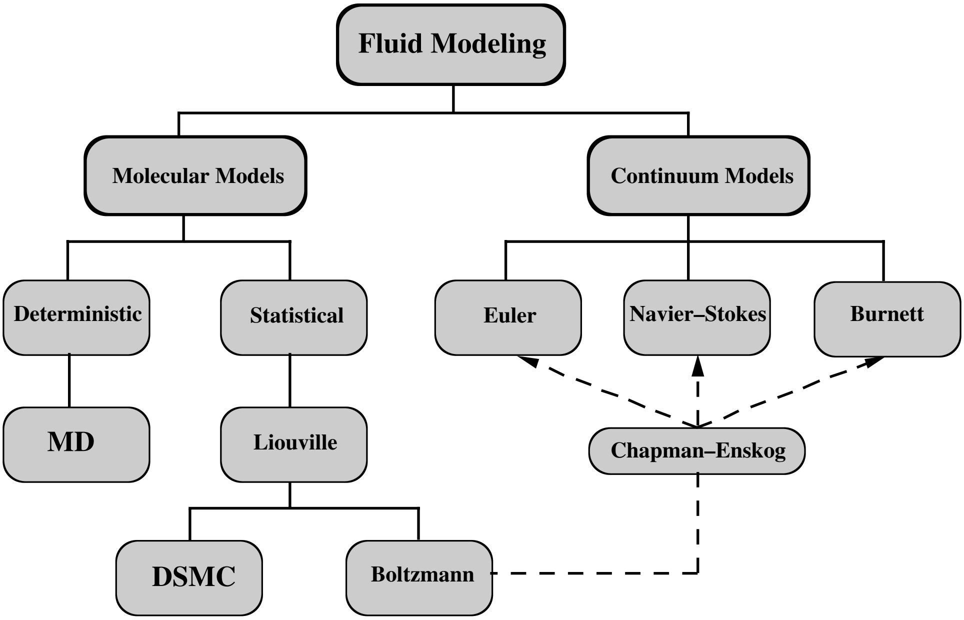

FIGURE 15.6.1 Molecular and continuum flow models.

Navier-Stokes equations are derivable from the molecularly based Boltzmann equation, but can also be derived independently of that for both liquids and gases. In the case of direct derivation, some empiricism is necessary to close the resulting indeterminate set of equations. The continuum model is easier to handle mathematically (and is also more familiar to most fluid dynamicists) than the alternative molecular models. Continuum models should therefore be used as long as they are applicable. Thus, careful considerations of the validity of the Navier-Stokes equations and the like are in order.

Basically, the continuum model leads to fairly accurate predictions as long as local properties such as density and velocity can be defined as averages over elements large compared with the microscopic structure of the fluid but small enough in comparison with the scale of the macroscopic phenomena to permit the use of differential calculus to describe them. Additionally, the flow must not be too far from thermodynamic equilibrium. The former condition is almost always satisfied, but it is the latter that usually restricts the validity of the continuum equations. As will be seen in the following subsection, the continuum flow equations do not form a determinate set. The shear stress and heat flux must be expressed in terms of lower-order macroscopic quantities such as velocity and temperature, and the simplest (i.e., linear) relations are valid only when the flow is near thermodynamic equilibrium. Worse yet, the traditional no-slip boundary condition at a solid-fluid interface breaks down even before the linear stress-strain relation becomes invalid.

To be more specific, we temporarily restrict the discussion to gases where the concept of mean free path is well defined. Liquids are more problematic, and we defer their discussion to a later subsection. For gases, the mean free path L is the average distance traveled by molecules between collisions. For an ideal gas modeled as rigid spheres, the mean free path is related to temperature T and pressure p as follows:

$$L = \frac{1}{\sqrt{2}\,\pi\, n\, \sigma^2} = \frac{k\,T}{\sqrt{2}\,\pi\, p\, \sigma^2} \tag{15.6.1}$$

where n is the number density (number of molecules per unit volume), σ is the molecular diameter, and k is the Boltzmann constant (1.38×10^{-23} J/K.molecule).

The continuum model is valid when L is much smaller than a characteristic flow dimension L. As this condition is violated, the flow is no longer near equilibrium, and the linear relation between stress and rate of strain and the no-slip velocity condition are no longer valid. Similarly, the linear relation between heat flux and temperature gradient and the no-jump temperature condition at a solid-fluid interface are no longer accurate when L is not much smaller than L.

The length-scale L can be some overall dimension of the flow, but a more precise choice is the scale of the gradient of a macroscopic quantity, as, for example, the density ρ:

$$L = \frac{\rho}{\left|\dfrac{\partial \rho}{\partial y}\right|} \tag{15.6.2}$$

The ratio between the mean free path and the characteristic length is known as the Knudsen number:

$$Kn = \frac{L}{L} \tag{15.6.3}$$

and generally the traditional continuum approach is valid, albeit with modified boundary conditions, as long as $Kn < 0.1$.

There are two more important dimensionless parameters in fluid mechanics, and the Knudsen number can be expressed in terms of those two. The Reynolds number is the ratio of inertial forces to viscous ones:

$$\mathrm{Re} = \frac{v_o\ L}{\nu} \tag{15.6.4}$$

where v_o is a characteristic velocity, and ν is the kinematic viscosity of the fluid. The Mach number is the ratio of flow velocity to the speed of sound:

$$Ma = \frac{v_o}{a_o} \tag{15.6.5}$$

The Mach number is a dynamic measure of fluid compressibility and may be considered as the ratio of inertial forces to elastic ones. From the kinetic theory of gases, the mean free path is related to the viscosity as follows:

$$\nu = \frac{\mu}{\rho} = \tfrac{1}{2} L \, \bar{v}_m \tag{15.6.6}$$

where μ is the dynamic viscosity, and $\bar{v}_m$ is the mean molecular speed, which is somewhat higher than the sound speed a_o:

$$\bar{v}_m = \sqrt{\frac{8}{\pi \gamma}} \, a_o \tag{15.6.7}$$

where γ is the specific heat ratio (i.e., the isentropic exponent). Combining Equation 15.6.3 through Equation 15.6.7, we reach the required relation:

$$Kn = \sqrt{\frac{\pi \gamma}{2}} \, \frac{Ma}{\mathrm{Re}} \tag{15.6.8}$$

In boundary layers, the relevant length-scale is the shear-layer thickness δ, and for laminar flows

$$\frac{\delta}{L} \sim \frac{1}{\sqrt{\mathrm{Re}}} \tag{15.6.9}$$

$$Kn \sim \frac{Ma}{\mathrm{Re}_\delta} \sim \frac{Ma}{\sqrt{\mathrm{Re}}} \tag{15.6.10}$$

where Re_δ is the Reynolds number based on the freestream velocity v_o and the boundary layer thickness δ, and Re is based on v_o and the streamwise length-scale L.

Rarefied gas flows are in general encountered in flows in small geometries such as MEMS devices and in low-pressure applications such as high-altitude flying and high-vacuum gadgets. The local value of Knudsen number in a particular flow determines the degree of rarefaction and the degree of validity of the continuum model. The different Knudsen number regimes are determined empirically and are therefore only approximate for a particular flow geometry. The pioneering experiments in rarefied gas dynamics were conducted by Knudsen in 1909. In the limit of zero Knudsen number, the transport terms in the continuum momentum and energy equations are negligible, and the Navier-Stokes equations then reduce to the inviscid Euler equations. Both heat conduction and viscous diffusion and dissipation are negligible, and the flow is then approximately isentropic (i.e., adiabatic and reversible) from the continuum viewpoint, while the equivalent molecular viewpoint is that the velocity distribution function is everywhere of the local equilibrium or Maxwellian form. As Kn increases, rarefaction effects become more important, and eventually the continuum approach breaks down altogether. The different Knudsen number regimes are depicted in Figure 15.6.2, and can be summarized as follows.

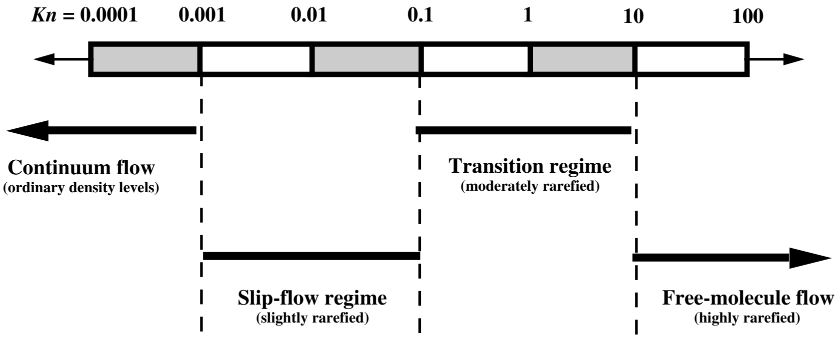

FIGURE 15.6.2 Knudsen number regimes.

Euler equations (neglect molecular diffusion):

$$Kn \to 0 \ (\mathrm{Re} \to \infty)$$

Navier-Stokes equations with no-slip boundary conditions:

$$Kn < 10^{-3}$$

Navier-Stokes equations with slip boundary conditions:

$$10^{-3} \le Kn < 10^{-1}$$

Transition regime:

$$10^{-1} \le Kn < 10$$

Free-molecule flow:

$$Kn \ge 10$$

As an example, consider air at standard temperature ($T = 288$ K) and pressure ($p = 1.01 \times 10^5$ N/m^2). A cube one micron on a side contains 2.54×10^7 molecules separated by an average distance of 0.0034 micron. The gas is considered dilute if the ratio of this distance to the molecular diameter exceeds 7, and in the present example this ratio is 9, barely satisfying the dilute gas assumption. The mean free path computed from Equation 15.6.1 is L =0.065 μm. A microdevice with characteristic length of 1 μm would have $Kn = 0.065$, which is in the slip-flow regime. At lower pressures, the Knudsen number increases. For example, if the pressure is 0.1 atm and the temperature remains the same, $Kn = 0.65$ for the same 1 μm device, and the flow is then in the transition regime. There would still be over 2 million molecules in the same one-micron cube, and the average distance between them would be 0.0074 μm. The same device at 100 km altitude would have $Kn = 3 \times 10^4$, well into the free-molecule flow regime. The Knudsen number for the flow of a light gas like helium is about three times larger than that for airflow at otherwise the same conditions.

Consider a long microchannel where the entrance pressure is atmospheric and the exit conditions are near vacuum. As air goes down the duct, the pressure and density decrease while the velocity, Mach number, and Knudsen number increase. The pressure drops to overcome viscous forces in the channel. If isothermal conditions prevail,[†] density also drops, and conservation of mass requires the flow to

---

[†] More likely the flow will be somewhere in between isothermal and adiabatic, Fanno flow. In that case both density and temperature decrease downstream, the former not as fast as in the isothermal case. None of that changes the qualitative arguments made in the example.

accelerate down the constant-area tube. The fluid acceleration in turn affects the pressure gradient, resulting in a nonlinear pressure drop along the channel. The Mach number increases down the tube, limited only by choked-flow condition $Ma = 1$. Additionally, the normal component of velocity is no longer zero. With lower density, the mean free path increases and Kn correspondingly increases. All flow regimes depicted in Figure 15.6.2 may occur in the same tube: continuum with no-slip boundary conditions, slip-flow regime, transition regime, and free-molecule flow. The airflow may also change from incompressible to compressible as it moves down the microduct. A similar scenario may take place if the entrance pressure is, say, 5 atm, while the exit is atmospheric. This deceivingly simple duct flow may in fact manifest every single complexity discussed in this subsection. In the following six subsections, we discuss in turn the Navier-Stokes equations, compressibility effects, boundary conditions, molecular-based models, liquid flows, and surface phenomena.

The Continuum Model

We recall in this subsection the traditional conservation relations in fluid mechanics. A concise derivation of these equations can be found in Gad-el-Hak (2000). Here, we reemphasize the precise assumptions needed to obtain a particular form of the equations. A continuum fluid implies that the derivatives of all the dependent variables exist in some reasonable sense. In other words, local properties such as density and velocity are defined as averages over elements large compared with the microscopic structure of the fluid but small enough in comparison with the scale of the macroscopic phenomena to permit the use of differential calculus to describe them. As mentioned earlier, such conditions are almost always met. For such fluids, and assuming the laws of nonrelativistic mechanics hold, the conservation of mass, momentum, and energy can be expressed at every point in space and time as a set of partial differential equations as follows:

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_k}\left(\rho\, u_k\right) = 0 \tag{15.6.11}$$

$$\rho\left(\frac{\partial u_i}{\partial t} + u_k \frac{\partial u_i}{\partial x_k}\right) = \frac{\partial \Sigma_{ki}}{\partial x_k} + \rho\, g_i \tag{15.6.12}$$

$$\rho\left(\frac{\partial e}{\partial t} + u_k \frac{\partial e}{\partial x_k}\right) = -\frac{\partial q_k}{\partial x_k} + \Sigma_{ki}\frac{\partial u_i}{\partial x_k} \tag{15.6.13}$$

where ρ is the fluid density, u_k is an instantaneous velocity component (u,v,w), Σ_{ki} is the second-order stress tensor (surface force per unit area), g_i is the body force per unit mass, e is the internal energy, and q_k is the sum of heat flux vectors due to conduction and radiation. The independent variables are time t and the three spatial coordinates x_1, x_2, and x_3 or (x,y,z).

Equation 15.6.11, Equation 15.6.12, and Equation 15.6.13 constitute five differential equations for the 17 unknowns ρ, u_i, Σ_{ki}, e, and q_k. Absent any body couples, the stress tensor is symmetric having only six independent components, which reduces the number of unknowns to 14. Obviously, the continuum flow equations do not form a determinate set. To close the conservation equations, the relation between the stress tensor and deformation rate, the relation between the heat flux vector and the temperature field, and appropriate equations of state relating the different thermodynamic properties are needed. The stress-rate of strain relation and the heat flux-temperature gradient relation are approximately linear if the flow is not too far from thermodynamic equilibrium. This is a phenomenological result but can be rigorously derived from the Boltzmann equation for a dilute gas assuming the flow is near equilibrium. For a Newtonian, isotropic, Fourier, ideal gas, for example, those relations read

$$\Sigma_{ki} = -p\,\delta_{ki} + \mu\left(\frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i}\right) + \lambda\left(\frac{\partial u_j}{\partial x_j}\right)\delta_{ki} \tag{15.6.14}$$

$$q_i = -\kappa\,\frac{\partial T}{\partial x_i} + \text{Heat flux due to radiation} \tag{15.6.15}$$

$$de = c_v\,dT \quad \text{and} \quad p = \rho R T \tag{15.6.16}$$

where p is the thermodynamic pressure; μ and λ are the first and second coefficients of viscosity, respectively; δ_{ki} is the unit second-order tensor (Kronecker delta); κ is the thermal conductivity; T is the temperature field; c_v is the specific heat at constant volume; and R is the gas constant, which is given by the Boltzmann constant divided by the mass of an individual molecule $k = mR$. The Stokes' hypothesis relates the first and second coefficients of viscosity, thus $\lambda + \frac{2}{3}\mu = 0$, although the validity of this assumption for other than dilute, monatomic gases has occasionally been questioned (Gad-el-Hak 1995). With the above constitutive relations and neglecting radiative heat transfer, Equation 15.6.11, Equation 15.6.12, and Equation 15.6.13, respectively, read

$$\frac{\partial\rho}{\partial t} + \frac{\partial}{\partial x_k}(\rho\,u_k) = 0 \tag{15.6.17}$$

$$\rho\left(\frac{\partial u_i}{\partial t} + u_k\,\frac{\partial u_i}{\partial x_k}\right) = -\,\frac{\partial p}{\partial x_i} + \rho\,g_i + \frac{\partial}{\partial x_k}\left[\mu\left(\frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i}\right) + \delta_{ki}\,\lambda\,\frac{\partial u_j}{\partial x_j}\right] \tag{15.6.18}$$

$$\rho\left(\frac{\partial e}{\partial t} + u_k\frac{\partial e}{\partial x_k}\right) = \frac{\partial}{\partial x_k}\left(\kappa\,\frac{\partial T}{\partial x_k}\right) - p\,\frac{\partial u_k}{\partial x_k} + \phi \tag{15.6.19}$$

The three components of the vector equation (Equation 15.6.18) are the Navier-Stokes equations expressing the conservation of momentum for a Newtonian fluid. In the thermal energy equation (Equation 15.6.198), ϕ is the always positive dissipation function expressing the irreversible conversion of mechanical energy to internal energy as a result of the deformation of a fluid element. The second term on the right-hand side of Equation 15.6.19 is the reversible work done (per unit time) by the pressure as the volume of a fluid material element changes. For a Newtonian, isotropic fluid, the viscous dissipation rate is given by

$$\phi = \tfrac{1}{2}\,\mu\left(\frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i}\right)^2 + \lambda\left(\frac{\partial u_j}{\partial x_j}\right)^2 \tag{15.6.20}$$

There are now six unknowns, ρ, u_i, p, and T, and the five coupled equations (Equation 15.6.17, Equation 15.6.18, and Equation 15.6.19) plus the equation of state relating pressure, density, and temperature. These six equations together with sufficient number of initial and boundary conditions constitute a well-posed, albeit formidable, problem. The system of Equation 15.6.17, Equation 15.6.18, and Equation 15.6.19 is an excellent model for the laminar or turbulent flow of most fluids such as air and water under many circumstances, including high-speed gas flows for which the shock waves are thick relative to the mean free path of the molecules.

Considerable simplification is achieved if the flow is assumed incompressible, usually a reasonable assumption provided that the characteristic flow speed is less than 0.3 of the speed of sound. The incompressibility assumption is readily satisfied for almost all liquid flows and many gas flows. In such cases, the density is assumed either a constant or a given function of temperature (or species concentration). The governing equations for such flow are

$$\frac{\partial u_k}{\partial x_k} = 0 \tag{15.6.21}$$

$$\rho\left(\frac{\partial u_i}{\partial t} + u_k\,\frac{\partial u_i}{\partial x_k}\right) = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_k}\left[\mu\left(\frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i}\right)\right] + \rho g_i \tag{15.6.22}$$

$$\rho\, c_p\left(\frac{\partial T}{\partial t} + u_k\,\frac{\partial T}{\partial x_k}\right) = \frac{\partial}{\partial x_k}\left(\kappa\,\frac{\partial T}{\partial x_k}\right) + \phi_{\text{incomp}} \tag{15.6.23}$$

where ϕ_{incomp} is the incompressible limit of Equation 15.6.20. These are now five equations for the five dependent variables u_i, p and T. Note that the left-hand side of Equation 15.6.23 has the specific heat at constant pressure c_p and not c_v. It is the convection of enthalpy — and not internal energy — that is balanced by heat conduction and viscous dissipation. This is the correct incompressible-flow limit — of a compressible fluid — as discussed in detail in Section 10.9 of Panton (1996); a subtle point perhaps but one that is frequently missed in textbooks.

For both the compressible and the incompressible equations of motion, the transport terms are neglected away from solid walls in the limit of infinite Reynolds number ($Kn \rightarrow 0$). The fluid is then approximated as inviscid and nonconducting, and the corresponding equations read (for the compressible case)

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_k}\left(\rho\, u_k\right) = 0 \tag{15.6.24}$$

$$\rho\left(\frac{\partial u_i}{\partial t} + u_k\,\frac{\partial u_i}{\partial x_k}\right) = -\frac{\partial p}{\partial x_i} + \rho\, g_i \tag{15.6.25}$$

$$\rho\, c_v\left(\frac{\partial T}{\partial t} + u_k\,\frac{\partial T}{\partial x_k}\right) = -p\,\frac{\partial u_k}{\partial x_k} \tag{15.6.26}$$

The Euler equation (Equation 15.6.25) can be integrated along a streamline, and the resulting Bernoulli's equation provides a direct relation between the velocity and pressure.

Compressibility

The issue of whether to consider the continuum flow compressible or incompressible seems to be rather straightforward, but is in fact full of potential pitfalls. If the local Mach number is less than 0.3, then the flow of a compressible fluid like air can — according to the conventional wisdom — be treated as incompressible. But the well-known $Ma < 0.3$ criterion is only a necessary and not a sufficient one to allow a treatment of the flow as approximately incompressible. In other words, there are situations where the Mach number can be exceedingly small while the flow is compressible. As is well documented in heat transfer textbooks, strong wall heating or cooling may cause the density to change sufficiently and the incompressible approximation to break down, even at low speeds. Less known is the situation encountered in some microdevices where the pressure may strongly change due to viscous effects even though the speeds may not be high enough for the Mach number to go above the traditional threshold of 0.3. Corresponding to the pressure changes would be strong density changes that must be taken into account when writing the continuum equations of motion. In this subsection, we systematically explain all situations where compressibility effects must be considered. Let us rewrite the full continuity equation (Equation 15.6.11) as follows

$$\frac{D\rho}{Dt}+\rho\,\frac{\partial u_k}{\partial x_k}=0 \tag{15.6.27}$$

where $\frac{D\rho}{Dt}$ is the substantial derivative $\left(\frac{\partial}{\partial t}+u_k\frac{\partial}{\partial x_k}\right)$, expressing changes following a fluid element. The proper criterion for the Incompressible approximation to hold is that $\left(\frac{1}{\rho}\frac{D\rho}{Dt}\right)$ is vanishingly small. In other words, if density changes following a fluid particle are small, the flow is approximately incompressible. Density may change arbitrarily from one particle to another without violating the incompressible flow assumption. This is the case for example in the stratified atmosphere and ocean, where the variable-density/temperature/salinity flow is often treated as incompressible.

From the state principle of thermodynamics, we can express the density changes of a simple system in terms of changes in pressure and temperature:

$$\rho = \rho(p,T) \tag{15.6.28}$$

Using the chain rule of calculus:

$$\tfrac{1}{\rho}\,\frac{D\rho}{Dt} = \alpha\,\frac{Dp}{Dt} - \beta\,\frac{DT}{Dt} \tag{15.6.29}$$

where α and β are, respectively, the isothermal compressibility coefficient and the bulk expansion coefficient — two thermodynamic variables that characterize the fluid susceptibility to change of volume — which are defined by the following relations

$$\alpha(p,T)\equiv\frac{1}{\rho}\left.\frac{\partial\rho}{\partial p}\right|_T \tag{15.6.30}$$

$$\beta(p,T)\equiv-\frac{1}{\rho}\left.\frac{\partial\rho}{\partial T}\right|_p \tag{15.6.31}$$

For ideal gases, $\alpha = 1/p$ and $\beta = 1/T$. Note, however, that in the following arguments it will not be necessary to invoke the ideal gas assumption. The flow must be treated as compressible if pressure and/or temperature changes — following a fluid element — are sufficiently strong. Equation 15.6.29 must of course be properly nondimensionalized before deciding whether a term is large or small. In here, we follow closely the procedure detailed in Panton (1996).

Consider first the case of adiabatic walls. Density is normalized with a reference value ρ_o; velocities with a reference speed v_o; spatial coordinates and time with L and L/v_o, respectively; and the isothermal compressibility coefficient and bulk expansion coefficient with reference values α_o and β_o. The pressure is nondimensionalized with the inertial pressure-scale $\rho_o\, v_o^2$. This scale is twice the dynamic pressure, that is, the pressure change as an inviscid fluid moving at the reference speed is brought to rest.

Temperature changes for the case of adiabatic walls can only result from the irreversible conversion of mechanical energy into internal energy via viscous dissipation. Temperature is therefore nondimensionalized as follows:

$$T^* = \frac{T - T_o}{\left(\dfrac{\mu_o\, v_o^2}{\kappa_o}\right)} = \frac{T - T_o}{\mathrm{Pr}\left(\dfrac{v_o^2}{c_{p_o}}\right)} \tag{15.6.32}$$

where T_o is a reference temperature; μ_o, κ_o, and c_{p_o} are, respectively, reference viscosity, thermal conductivity, and specific heat at constant pressure; and Pr is the reference Prandtl number, $(\mu_o\, c_{p_o})/\kappa_o$.

In the present formulation, the scaling used for pressure is based on the Bernoulli's equation and therefore neglects viscous effects. This particular scaling guarantees that the pressure term in the momentum equation will be of the same order as the inertia term. The temperature scaling assumes that the conduction, convection, and dissipation terms in the energy equation have the same order of magnitude. The resulting dimensionless form of Equation 15.6.29 reads

$$\frac{1}{\rho^*}\,\frac{D\rho^*}{Dt^*} = \gamma_o\, Ma^2 \left\{\alpha^*\,\frac{Dp^*}{Dt^*} - \frac{\mathrm{Pr}\, B\, \beta^*}{A}\,\frac{DT^*}{Dt^*}\right\} \tag{15.6.33}$$

where the superscript * indicates a nondimensional quantity, Ma is the reference Mach number (v_o/a_o, where a_o is the reference speed of sound), and A and B are dimensionless constants defined by $A \equiv \alpha_o \rho_o c_{p_o} T_o$ and $B \equiv \beta_o\, T_o$. If the scaling is properly chosen, the terms having the * superscript in the right-hand side should be of order one, and the relative importance of such terms in the equations of motion is determined by the magnitude of the dimensionless parameter(s) appearing to their left, for example, Ma, Pr, and so forth. Therefore, as $Ma^2 \to 0$, temperature changes due to viscous dissipation are neglected (unless Pr is very large, as for example in the case of highly viscous polymers and oils). Within the same order of approximation, all thermodynamic properties of the fluid are assumed constant.

Pressure changes are also neglected in the limit of zero Mach number. Hence, for $Ma < 0.3$ (i.e., $Ma^2 < 0.09$), density changes following a fluid particle can be neglected and the flow can then be approximated as incompressible.[†] However, there is a caveat in this argument. Pressure changes due to inertia can indeed be neglected at small Mach numbers, and this is consistent with the way we nondimensionalized the pressure term above. If on the other hand pressure changes are mostly due to viscous effects, as is the case for example in a long microduct or a micro-gas-bearing, pressure changes may be significant even at low speeds (low Ma). In that case the term Dp^*/dt in Equation 15.6.33 is no longer of order one, and may be large regardless of the value of Ma. Density then may change significantly and the flow must be treated as compressible. Had pressure been nondimensionalized using the viscous scale ($\mu_o v_o/L$) instead of the inertial one ($\rho_o\, v_o^2$), the revised Equation 15.6.33 would have Re^{-1} appearing explicitly in the first term in the right-hand side, accentuating the importance of this term when viscous forces dominate.

A similar result can be gleaned when the Mach number is interpreted as follows:

$$Ma^2 = \frac{v_o^2}{a_o^2} = v_o^2\, \left.\frac{\partial\rho}{\partial p}\right|_s = \frac{\rho_o\, v_o^2}{\rho_o}\, \left.\frac{\partial\rho}{\partial p}\right|_s \sim \frac{\Delta p}{\rho_o}\,\frac{\Delta\rho}{\Delta p} = \frac{\Delta\rho}{\rho_o} \tag{15.6.34}$$

where s is the entropy. Again, the above equation assumes that pressure changes are inviscid, and therefore a small Mach number means negligible pressure and density changes. In a flow dominated by viscous

---

[†] With an error of about 10% at $Ma = 0.3$, 4% at $Ma = 0.2$, 1% at $Ma = 0.1$, and so on.

effects — such as that inside a microduct — density changes may be significant even in the limit of zero Mach number.

Identical arguments can be made in the case of isothermal walls. Here strong temperature changes may be the result of wall heating or cooling, even if viscous dissipation is negligible. The proper temperature scale in this case is given in terms of the wall temperature T_w and the reference temperature T_o as follows:

$$\widehat{T} = \frac{T - T_o}{T_w - T_o} \tag{15.6.35}$$

where $\widehat{T}$ is the new dimensionless temperature. The nondimensional form of Equation 15.6.29 now reads

$$\frac{1}{\rho^*}\frac{D\rho^*}{Dt^*} = \gamma_o\, Ma^2\, \alpha^*\, \frac{Dp^*}{Dt^*} - \beta^*\, B\left(\frac{T_w - T_o}{T_o}\right)\frac{D\widehat{T}}{Dt^*} \tag{15.6.36}$$

Here we notice that the temperature term is different from that in Equation 15.6.33. *Ma* is no longer appearing in this term, and strong temperature changes, that is, large $(T_w - T_o)/T_o$, may cause strong density changes regardless of the value of the Mach number. Additionally, the thermodynamic properties of the fluid are not constant but depend on temperature, and as a result the continuity, momentum and energy equations all couple. The pressure term in Equation 15.6.36, on the other hand, is exactly as it was in the adiabatic case and the same arguments made before apply: the flow should be considered compressible if $Ma > 0.3$, or if pressure changes due to viscous forces are sufficiently large.

Experiments in gaseous microducts confirm the above arguments. For both low- and high-Mach-number flows, pressure gradients in long microchannels are nonconstant, consistent with the compressible flow equations. Such experiments were conducted by, among others, Prud'homme et al. (1986), Pfahler et al. (1991), van den Berg et al. (1993), Liu et al. (1993; 1995), Pong et al. (1994), Harley et al. (1995), Piekos and Breuer (1996), Arkilic (1997), and Arkilic et al. (1995; 1997a; 1997b). Sample results will be presented in the following subsection.

There are three additional scenarios in which significant pressure and density changes may take place without inertial, viscous, or thermal effects. First is the case of quasi-static compression/expansion of a gas in, for example, a piston-cylinder arrangement. The resulting compressibility effects are, however, compressibility of the fluid and not of the flow. Two other situations where compressibility effects must also be considered are problems with length-scales comparable to the scale height of the atmosphere and rapidly varying flows as in sound propagation (Lighthill 1963).

Boundary Conditions

The continuum equations of motion described earlier require a certain number of initial and boundary conditions for proper mathematical formulation of flow problems. In this subsection, we describe the boundary conditions at a fluid-solid interface. Boundary conditions in the inviscid flow theory pertain only to the velocity component normal to a solid surface. The highest spatial derivative of velocity in the inviscid equations of motion is first-order, and only one velocity boundary condition at the surface is admissible. The normal velocity component at a fluid-solid interface is specified, and no statement can be made regarding the tangential velocity component. The normal-velocity condition simply states that a fluid-particle path cannot go through an impermeable wall. Real fluids are of course viscous, and the corresponding momentum equation has second-order derivatives of velocity, thus requiring an additional boundary condition on the velocity component tangential to a solid surface.

Traditionally, the no-slip condition at a fluid-solid interface is enforced in the momentum equation and an analogous no-temperature-jump condition is applied in the energy equation. The notion underlying the no-slip/no-jump condition is that within the fluid there cannot be any finite discontinuities of velocity/temperature. Those would involve infinite velocity/temperature gradients and so produce infinite viscous stress/heat flux that would destroy the discontinuity in infinitesimal time. The interaction between a fluid particle and a wall is similar to that between neighboring fluid particles, and therefore no discontinuities are allowed at the fluid-solid interface either. In other words, the fluid velocity must be zero relative to the surface and the fluid temperature must equal to that of the surface. But strictly speaking, those two boundary conditions are valid only if the fluid flow adjacent to the surface is in thermodynamic equilibrium. This requires an infinitely high frequency of collisions between the fluid and the solid surface. In practice, the no-slip/no-jump condition leads to fairly accurate predictions as long as $Kn < 0.001$ (for gases). Beyond that, the collision frequency is simply not high enough to ensure equilibrium and a certain degree of tangential-velocity slip and temperature jump must be allowed. This is a case frequently encountered in MEMS flows, and we develop the appropriate relations in this subsection.

For both liquids and gases, the linear Navier boundary condition empirically relates the tangential velocity slip at the wall $\Delta u\big|_w$ to the local shear:

$$\Delta u\Big|_w = u_{fluid} - u_{wall} = L_s \left.\frac{\partial u}{\partial y}\right|_w \tag{15.6.37}$$

where L_s is the constant slip length, and $\left.\frac{\partial u}{\partial y}\right|_w$ is the strain rate computed at the wall. In most practical situations, the slip length is so small that the no-slip condition holds. In MEMS applications, however, that may not be the case. Once again we defer the discussion of liquids to a later section and focus for now on gases.

Assuming isothermal conditions prevail, the above slip relation has been rigorously derived by Maxwell (1879) from considerations of the kinetic theory of dilute, monatomic gases. Gas molecules, modeled as rigid spheres, continuously strike and reflect from a solid surface, just as they continuously collide with each other. For an idealized perfectly smooth wall (at the molecular scale), the incident angle exactly equals the reflected angle and the molecules conserve their tangential momentum and thus exert no shear on the wall. This is termed *specular reflection* and results in perfect slip at the wall. For an extremely rough wall, on the other hand, the molecules reflect at some random angle uncorrelated with their entry angle. This perfectly diffuse reflection results in zero tangential-momentum for the reflected fluid molecules to be balanced by a finite slip velocity in order to account for the shear stress transmitted to the wall. A force balance near the wall leads to the following expression for the slip velocity:

$$u_{gas} - u_{wall} = L \left.\frac{\partial u}{\partial y}\right|_w \tag{15.6.38}$$

where L is the mean free path. The right-hand side can be considered as the first term in an infinite Taylor series, sufficient if the mean free path is relatively small enough. Equation 15.6.38 states that significant slip occurs only if the mean velocity of the molecules varies appreciably over a distance of one mean free path. This is the case, for example, in vacuum applications and/or flow in microdevices. The number of collisions between the fluid molecules and the solid in those cases is not large enough for even an approximate flow equilibrium to be established. Furthermore, additional (nonlinear) terms in the Taylor series would be needed as L increases and the flow is further removed from the equilibrium state.

For real walls some molecules reflect diffusively and some reflect specularly. In other words, a portion of the momentum of the incident molecules is lost to the wall and a (typically smaller) portion is retained by the reflected molecules. The tangential-momentum-accommodation coefficient σ_v is defined as the fraction of molecules reflected diffusively. This coefficient depends on the fluid, the solid and the surface finish, and has been determined experimentally to be between 0.2 and 0.8 (Thomas and Lord 1974; Seidl and Steiheil 1974; Porodnov et al. 1974; Arkilic et al. 1997b; Arkilic 1997), the lower limit being for exceptionally smooth surfaces while the upper limit is typical of most practical surfaces. The final expression derived by Maxwell for an isothermal wall reads

$$u_{gas} - u_{wall} = \frac{2-\sigma_v}{\sigma_v} L \left.\frac{\partial u}{\partial y}\right|_w \tag{15.6.39}$$

For $\sigma_v = 0$, the slip velocity is unbounded, while for $\sigma_v = 1$, Equation 15.6.39 reverts to 15.6.38.

Similar arguments were made for the temperature-jump boundary condition by von Smoluchowski (1898). For an ideal gas flow in the presence of wall-normal and tangential temperature gradients, the complete (first-order) slip-flow and temperature-jump boundary conditions read

$$\begin{aligned} u_{gas} - u_{wall} &= \frac{2-\sigma_v}{\sigma_v} \frac{1}{\rho\sqrt{\frac{2\,R\,T_{gas}}{\pi}}} \tau_w + \tfrac{3}{4} \frac{\Pr\left(\gamma-1\right)}{\gamma\,\rho R\,T_{gas}} \left(-q_x\right)_w \\ &= \frac{2-\sigma_v}{\sigma_v} L \left(\frac{\partial u}{\partial y}\right)_w + \tfrac{3}{4} \frac{\mu}{\rho\,T_{gas}} \left(\frac{\partial T}{\partial x}\right)_w \end{aligned} \tag{15.6.40}$$

$$\begin{aligned} T_{gas} - T_{wall} &= \frac{2-\sigma_T}{\sigma_T} \left[\frac{2\left(\gamma-1\right)}{\left(\gamma+1\right)}\right] \frac{1}{\rho\,R\sqrt{\frac{2\,R\,T_{gas}}{\pi}}} \left(-q_y\right)_w \\ &= \frac{2-\sigma_T}{\sigma_T} \left[\frac{2\,\gamma}{\left(\gamma+1\right)}\right] \frac{L}{\Pr} \left(\frac{\partial T}{\partial y}\right)_w \end{aligned} \tag{15.6.41}$$

where x and y are the streamwise and normal coordinates, ρ and μ, are the fluid density and viscosity, respectively; R is the gas constant; T_{gas} is the temperature of the gas adjacent to the wall; T_{wall} is the wall temperature; τ_w is the shear stress at the wall; Pr is the Prandtl number; γ is the specific heat ratio; and q_x and q_y are the tangential and normal heat flux at the wall, respectively.

The tangential-momentum-accommodation coefficient σ_v and the thermal-accommodation coefficient σ_T are given by, respectively

$$\sigma_v = \frac{\tau_i - \tau_r}{\tau_i - \tau_w} \tag{15.6.42}$$

$$\sigma_T = \frac{dE_i - dE_r}{dE_i - dE_w} \tag{15.6.43}$$

where the subscripts i, r, and w stand for, respectively, incident, reflected, and solid wall conditions; τ is a tangential momentum flux; and dE is an energy flux.

The second term in the right-hand side of Equation 15.6.40 is the *thermal creep*, which generates slip velocity in the fluid opposite to the direction of the tangential heat flux, that is, flow in the direction of increasing temperature. At sufficiently high Knudsen numbers, a streamwise temperature gradient in a conduit leads to a measurable pressure gradient along the tube. This may be the case in vacuum applications and MEMS devices. Thermal creep is the basis for the so-called Knudsen pump — a device with no moving parts — in which rarefied gas is hauled from one cold chamber to a hot one.[†] Clearly, such a pump performs best at high Knudsen numbers, and is typically designed to operate in the free-molecule flow regime.

In dimensionless form, Equation 15.6.40 and Equation 15.6.41 read, respectively

$$u^*_{gas} - u^*_{wall} = \frac{2-\sigma_v}{\sigma_v} Kn \left(\frac{\partial u^*}{\partial y^*} \right)_w + \tfrac{3}{2\pi} \frac{(\gamma - 1)}{\gamma} \frac{Kn^2 \, \mathrm{Re}}{Ec} \left(\frac{\partial T^*}{\partial x^*} \right)_w \tag{15.6.44}$$

$$T^*_{gas} - T^*_{wall} = \frac{2 - \sigma_T}{\sigma_T} \left[\frac{2\gamma}{(\gamma + 1)} \right] \frac{Kn}{\mathrm{Pr}} \left(\frac{\partial T^*}{\partial y^*} \right)_w \tag{15.6.45}$$

where the superscript * indicates dimensionless quantity, *Kn* is the Knudsen number, Re is the Reynolds number, and *Ec* is the Eckert number defined by

$$Ec = \frac{v_o^2}{c_p \, \Delta T} = (\gamma - 1) \frac{T_o}{\Delta T} Ma^2 \tag{15.6.46}$$

where v_o is a reference velocity, $\Delta T = (T_{gas} - T_o)$, and T_o is a reference temperature. Note that very low values of σ_v and σ_T lead to substantial velocity slip and temperature jump even for flows with small Knudsen number.

The first term in the right-hand side of Equation 15.6.44 is first-order in Knudsen number, while the thermal creep term is second-order, meaning that the creep phenomenon is potentially significant at large values of the Knudsen number. Equation 15.6.45 is first-order in *Kn*. Using Equation 15.6.8 and Equation 15.6.46, the thermal creep term in Equation 15.6.44 can be rewritten in terms of ΔT and the Reynolds number. Thus,

$$u^*_{gas} - u^*_{wall} = \frac{2-\sigma_v}{\sigma_v} Kn \left(\frac{\partial u^*}{\partial y^*} \right)_w + \tfrac{3}{4} \frac{\Delta T}{T_o} \frac{1}{\mathrm{Re}} \left(\frac{\partial T^*}{\partial x^*} \right)_w \tag{15.6.47}$$

It is clear that large temperature changes along the surface or low Reynolds numbers lead to significant thermal creep.

The continuum Navier-Stokes equations with no-slip/no-temperature jump boundary conditions are valid as long as the Knudsen number does not exceed 0.001. First-order slip/temperature-jump boundary conditions should be applied to the Navier-Stokes equations in the range of $0.001 < Kn < 0.1$. The transition regime spans the range of $0.1 < Kn < 10$, and second-order or higher slip/temperature-jump boundary conditions are applicable there. Note, however, that the Navier-Stokes equations are first-order accurate in *Kn*, as will be shown later, and are themselves not valid in the transition regime. Either higher-order continuum equations, for example, Burnett equations, should be used there or molecular modeling should be invoked, abandoning the continuum approach altogether.

For isothermal walls, Beskok (1994) derived a higher-order slip-velocity condition as follows:

$$u_{gas} - u_{wall} = \frac{2-\sigma_v}{\sigma_v} \left[L \left(\frac{\partial u}{\partial y} \right)_w + \frac{L^2}{2!} \left(\frac{\partial^2 u}{\partial y^2} \right)_w + \frac{L^3}{3!} \left(\frac{\partial^3 u}{\partial y^3} \right)_w + \cdots \right] \tag{15.6.48}$$

[†] The terminology Knudsen pump has been used by, for example, Vargo and Muntz (1996), but according to Loeb (1961), the original experiments demonstrating such pump were carried out by Osborne Reynolds.

Attempts to implement the previous slip condition in numerical simulations are rather difficult. Second-order and higher derivatives of velocity cannot be computed accurately near the wall. Based on asymptotic analysis, Beskok (1996) and Beskok and Karniadakis (1994; 1999) proposed the following alternative higher-order boundary condition for the tangential velocity, including the thermal creep term:

$$u^*_{gas} - u^*_{wall} = \frac{2-\sigma_v}{\sigma_v}\,\frac{Kn}{1-b\,Kn}\left(\frac{\partial u^*}{\partial y^*}\right)_w + \tfrac{3}{2\pi}\,\frac{(\gamma-1)}{\gamma}\,\frac{Kn^2\,\mathrm{Re}}{Ec}\left(\frac{\partial T^*}{\partial x^*}\right)_w \tag{15.6.49}$$

where b is a high-order slip coefficient determined from the presumably known no-slip solution, thus avoiding the computational difficulties mentioned earlier. If this high-order slip coefficient is chosen as $b = u''_w/u'_w$, where the prime denotes derivative with respect to y and the velocity is computed from the no-slip Navier-Stokes equations, Equation 15.6.49 becomes second-order accurate in Knudsen number. Beskok's procedure can be extended to third- and higher-orders for both the slip-velocity and thermal creep terms.

Similar arguments can be applied to the temperature-jump boundary condition, and the resulting Taylor series reads in dimensionless form (Beskok 1996)

$$T^*_{gas} - T^*_{wall} = \frac{2-\sigma_T}{\sigma_T}\left[\frac{2\gamma}{(\gamma+1)}\right]\frac{1}{\mathrm{Pr}}\left[Kn\left(\frac{\partial T^*}{\partial y^*}\right)_w + \frac{Kn^2}{2!}\left(\frac{\partial^2 T^*}{\partial y^{*2}}\right)_w + \ldots\right] \tag{15.6.50}$$

Again, the difficulties associated with computing second- and higher-order derivatives of temperature are alleviated using an identical procedure to that utilized for the tangential velocity boundary condition.

Several experiments in low-pressure macroducts or in microducts confirm the necessity of applying slip boundary condition at sufficiently large Knudsen numbers. Among them are those conducted by Knudsen (1909), Pfahler at al. (1991), Tison (1993), Liu et al. (1993, 1995), Pong et al. (1994), Arkilic et al. (1995), Harley et al. (1995), and Shih et al. (1995, 1996). The experiments are complemented by the numerical simulations carried out by Beskok (1994, 1996), Beskok and Karniadakis (1994, 1999), and Beskok et al. (1996). Here we present selected examples of the experimental and numerical results.

Tison (1993) conducted pipe flow experiments at very low pressures. His pipe has a diameter of 2 mm and a length-to-diameter ratio of 200. Both inlet and outlet pressures were varied to yield Knudsen number in the range of Kn = 0–200. Figure 15.6.3 shows the variation of mass flow rate as a function of $(p_i^2 - p_o^2)$, where p_i is the inlet pressure and p_o is the outlet pressure.[†] The pressure drop in this rarefied pipe flow is nonlinear, characteristic of low-Reynolds-number, compressible flows. Three distinct flow regimes are identified: (1) slip flow regime, $0 < Kn < 0.6$, (2) transition regime, $0.6 < Kn < 17$, where the mass flow rate is almost constant as the pressure changes, and (3) free-molecule flow, $Kn > 17$. Note that the demarcation between these three regimes is slightly different from that mentioned earlier. As stated, the different Knudsen number regimes are determined empirically and are therefore only approximate for a particular flow geometry.

Shih et al. (1995) conducted their experiments in a microchannel using helium as a fluid. The inlet pressure varied but the duct exit was atmospheric. Microsensors where fabricated in-situ along their MEMS channel to measure the pressure. Figure 15.6.4 shows their measured mass flow rate vs. the inlet pressure. The data are compared to the no-slip solution and the slip solution using three different values of the tangential-momentum-accommodation coefficient, 0.8, 0.9, and 1.0. The agreement is reasonable with the case $\sigma_v = 1$, indicating perhaps that the channel used by Shih et al. was quite rough on the molecular scale. In a second experiment (Shih et al. 1996), nitrous oxide was used as the fluid. The square of the pressure distribution along the channel is plotted in Figure 15.6.5 for five different inlet pressures.

[†] The original data in this figure were acquired by S.A. Tison and plotted by Beskok et al. (1996).

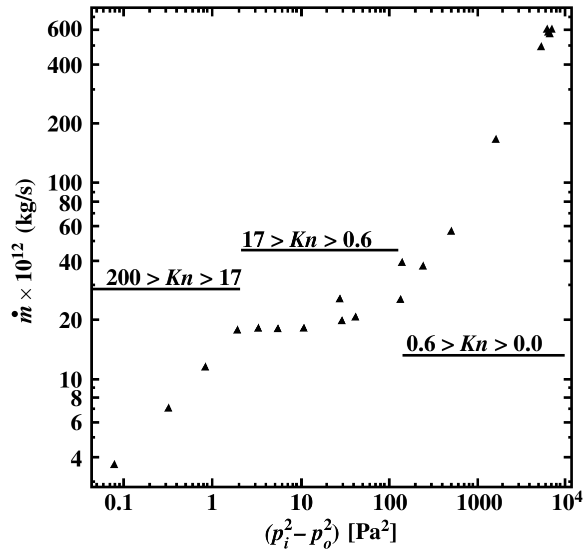

FIGURE 15.6.3 Variation of mass flow rate as a function of $(p_i^2 - p_o^2)$. Original data acquired by S.A. Tison and plotted by Beskok et al. (1996).

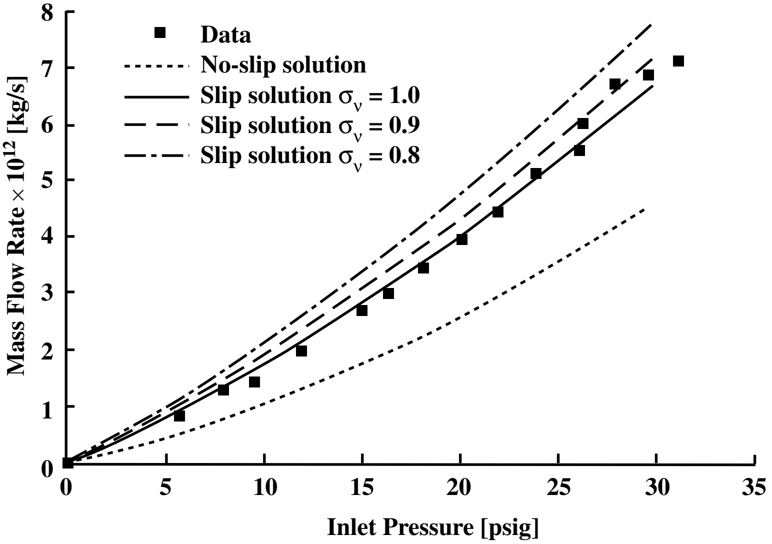

FIGURE 15.6.4 Mass flow rate vs. inlet pressure in a microchannel. From Shih et al. (1995).

The experimental data (symbols) compare well with the theoretical predictions (solid lines). Again, the nonlinear pressure drop shown indicates that the gas flow is compressible.

Arkilic (1997) provided an elegant analysis of the compressible, rarefied flow in a microchannel. The results of his theory are compared to the experiments of Pong et al. (1994) in Figure 15.6.6. The dotted line is the incompressible flow solution, where the pressure is predicted to drop linearly with streamwise distance. The dashed line is the compressible flow solution that neglects rarefaction effects (assumes $Kn = 0$). Finally, the solid line is the theoretical result that takes into account both compressibility and rarefaction via slip-flow boundary condition computed at the exit Knudsen number of $Kn = 0.06$. That theory compares most favorably with the experimental data. In the compressible flow through the

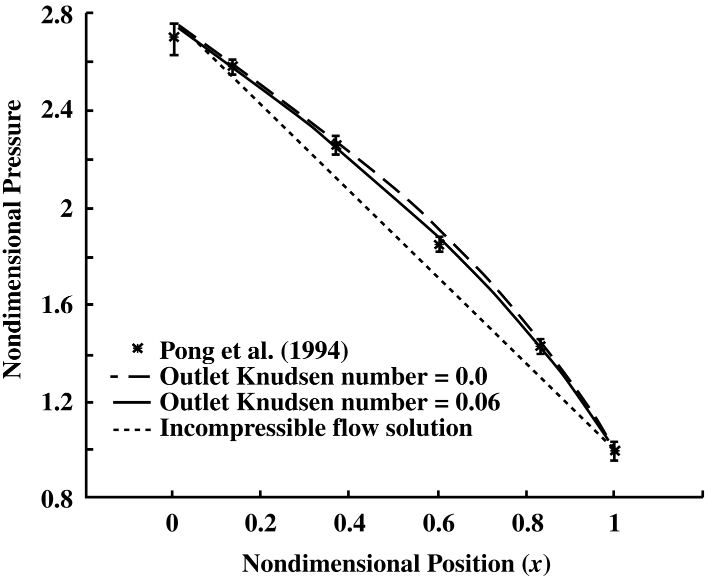

FIGURE 15.6.6 Pressure distribution in a long microchannel. The symbols are experimental data while the lines are different theoretical predictions. From Arkilic (1997).

constant-area duct, density decreases and thus velocity increases in the streamwise direction. As a result, the pressure distribution is nonlinear with negative curvature. A moderate Knudsen number (i.e., moderate slip) actually diminishes, albeit rather weakly, this curvature. Thus, compressibility and rarefaction effects lead to opposing trends, as pointed out by Beskok et al. (1996).

Molecular-Based Models

In the continuum models discussed thus far, the macroscopic fluid properties are the dependent variables while the independent variables are the three spatial coordinates and time. The molecular models recognize the fluid as a myriad of discrete particles: molecules, atoms, ions, and electrons. The goal here is to determine the position, velocity, and state of all particles at all times. The molecular approach is either deterministic or probabilistic (refer to Figure 15.6.1). Provided that there is a sufficient number of microscopic particles within the smallest significant volume of a flow, the macroscopic properties at any location in the flow can then be computed from the discrete-particle information by a suitable averaging or weighted averaging process. This subsection discusses molecular-based models and their relation to the continuum models previously considered.

The most fundamental of the molecular models is a deterministic one. The motion of the molecules are governed by the laws of classical mechanics, although, at the expense of greatly complicating the problem, the laws of quantum mechanics can also be considered in special circumstances. The modern molecular dynamics computer simulations (MD) have been pioneered by Alder and Wainwright (1957, 1958, 1970) and reviewed by Ciccotti and Hoover (1986), Allen and Tildesley (1987), Haile (1993), and Koplik and Banavar (1995). The simulation begins with a set of N molecules in a region of space, each assigned a random velocity corresponding to a Boltzmann distribution at the temperature of interest. The interaction between the particles is prescribed typically in the form of a two-body potential energy and the time evolution of the molecular positions is determined by integrating Newton's equations of motion. Because MD is based on the most basic set of equations, it is valid in principle for any flow extent and any range of parameters. The method is straightforward in principle but there are two hurdles: choosing a proper and convenient potential for particular fluid and solid combinations, and gathering the colossal computer resources required to simulate a reasonable flow-field extent.

For purists, the former difficulty is a sticky one. There is no totally rational methodology by which a convenient potential can be chosen. Part of the art of MD is to pick an appropriate potential and validate the simulation results with experiments or other analytical/computational results. A commonly used potential between two molecules is the generalized Lennard-Jones 6–12 potential, to be used in the following subsection and further discussed in the subsection following that.

The second difficulty, and by far the most serious limitation of molecular dynamics simulations, is the number of molecules N that can realistically be modeled on a digital computer. Since the computation of an element of trajectory for any particular molecule requires consideration of *all* other molecules as potential collision partners, the amount of computation required by the MD method is proportional to N^2. Some saving in computer time can be achieved by cutting off the weak tail of the potential (see Figure 15.6.11) at, say, $r_c = 2.5\sigma$, and shifting the potential by a linear term in r so that the force goes smoothly to zero at the cutoff. As a result, only nearby molecules are treated as potential collision partners, and the computation time for N molecules no longer scales with N^2.

The state of the art of molecular dynamics simulations in the early 2000s is such that with a few hours of CPU time, general-purpose supercomputers can handle around 100,000 molecules. At enormous expense, the fastest parallel machine available can simulate around 10 million particles. Because of the extreme diminution of molecular scales, the above translates into regions of liquid flow of about 0.02 μm (200 Angstroms) in linear size, over time intervals of around 0.001 μs, enough for continuum behavior to set in for simple molecules. To simulate 1 s of real time for complex molecular interactions, for example, including vibration modes, reorientation of polymer molecules, and collision of colloidal particles, requires unrealistic CPU time measured in hundreds of years.

MD simulations are highly inefficient for dilute gases where the molecular interactions are infrequent. The simulations are more suited for dense gases and liquids. Clearly, molecular dynamics simulations are reserved for situations where the continuum approach or the statistical methods are inadequate to compute from first principles important flow quantities. Slip boundary conditions for liquid flows in extremely small devices is such a case, as will be discussed in the following subsection.

An alternative to the deterministic molecular dynamics is the statistical approach where the goal is to compute the probability of finding a molecule at a particular position and state. If the appropriate conservation equation can be solved for the probability distribution, important statistical properties such as the mean number, momentum, or energy of the molecules within an element of volume can be computed from a simple weighted averaging. In a practical problem, it is such average quantities that concern us rather than the detail for every single molecule. Clearly, however, the accuracy of computing average quantities, via the statistical approach, improves as the number of molecules in the sampled volume increases. The kinetic theory of dilute gases is well advanced, but that for dense gases and liquids is much less so due to the extreme complexity of having to include multiple collisions and intermolecular forces in the theoretical formulation. The statistical approach is well covered in books such as those by Kennard (1938), Hirschfelder et al. (1954), Schaaf and Chambré (1961), Vincenti and Kruger (1965), Kogan (1969), Chapman and Cowling (1970), Cercignani (1988, 2000), and Bird (1994), and review articles such as those by Kogan (1973), Muntz (1989), and Oran et al. (1998).

In the statistical approach, the fraction of molecules in a given location and state is the sole dependent variable. The independent variables for monatomic molecules are time, the three spatial coordinates, and the three components of molecular velocity. Those describe a six-dimensional phase space.[†] For diatomic or polyatomic molecules, the dimension of phase space is increased by the number of internal degrees of freedom. Orientation adds an extra dimension for molecules that are not spherically symmetric. Finally, for mixtures of gases, separate probability distribution functions are required for each species. Clearly, the complexity of the approach increases dramatically as the dimension of phase space increases. The simplest problems are, for example, those for steady, one-dimensional flow of a simple monatomic gas.

To simplify the problem we restrict the discussion here to monatomic gases having no internal degrees of freedom. Furthermore, the fluid is restricted to dilute gases and molecular chaos is assumed. The former restriction requires the average distance between molecules δ to be an order of magnitude larger than their diameter σ. That will almost guarantee that all collisions between molecules are binary collisions, avoiding the complexity of modeling multiple encounters.[††] The molecular chaos restriction improves the accuracy of computing the macroscopic quantities from the microscopic information. In essence, the volume over which averages are computed has to have sufficient number of molecules to reduce statistical errors. It can be shown that computing macroscopic flow properties by averaging over a number of molecules will result in statistical fluctuations with a standard deviation of approximately 0.1% if one million molecules are used and around 3% if 1000 molecules are used. The molecular chaos limit requires the length-scale L for the averaging process to be at least 100 times the average distance between molecules (i.e., typical averaging over at least one million molecules).

Figure 15.6.7, adapted from Bird (1994), shows the limits of validity of the dilute gas approximation ($\delta/\sigma > 7$), the continuum approach ($Kn < 0.1$, as discussed previously), and the neglect of statistical fluctuations ($L/\delta > 100$). Using a molecular diameter of $\sigma = 4 \times 10^{-10}$ m as an example, the three limits are conveniently expressed as functions of the normalized gas density ρ/ρ_o or number density n/n_o, where the reference densities ρ_o and n_o are computed at standard conditions. All three limits are straight lines in the log-log plot of L vs. ρ/ρ_o, as depicted in Figure 15.6.7. Note the shaded triangular wedge inside which both the Boltzmann and Navier-Stokes equations are valid. Additionally, the lines describing the three limits very nearly intersect at a single point. As a consequence, the continuum breakdown limit always lies between the dilute gas limit and the limit for molecular chaos. As density or characteristic dimension is reduced in a dilute gas, the Navier-Stokes model breaks down before the level of statistical fluctuations becomes significant. In a dense gas, on the other hand, significant fluctuations may be present even when the Navier-Stokes model is still valid.

The starting point in statistical mechanics is the Liouville equation that expresses the conservation of the N-particle distribution function in $6N$-dimensional phase space,[†††] where N is the number of particles under consideration. Considering only external forces that do not depend on the velocity of the molecules,[††††] the Liouville equation for a system of N mass points reads

$$\frac{\partial F}{\partial t} + \sum_{k=1}^{N} \vec{\xi}_k \cdot \frac{\partial F}{\partial \vec{x}_k} + \sum_{k=1}^{N} \vec{F}_k \cdot \frac{\partial F}{\partial \vec{\xi}_k} = 0 \tag{15.6.51}$$

[†] The evolution equation of the probability distribution is considered; hence time is the seventh independent variable.

[††] Dissociation and ionization phenomena involve triple collisions and therefore require separate treatment.

[†††] Three positions and three velocities for *each* molecule of a monatomic gas with no internal degrees of freedom.

[††††] This excludes Lorentz forces, for example.

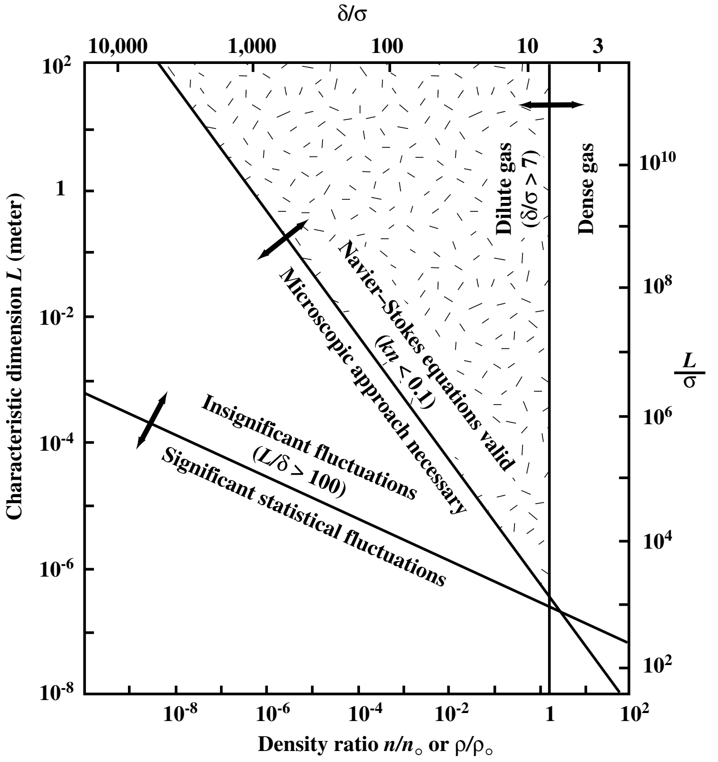

FIGURE 15.6.7 Effective limits of different flow models. From Bird (1994).

where F is the probability of finding a molecule at a particular point in phase space, t is time, $\vec{\xi}_k$ is the three-dimensional velocity vector for the kth molecule, $\vec{x}_k$ is the three-dimensional position vector for the kth molecule, and $\vec{F}$ is the external force vector. Note that the dot product in the previous equation is carried out over each of the three components of the vectors $\vec{\xi}$, $\vec{x}$, and $\vec{F}$, and that the summation is over all molecules. Obviously such an equation is not tractable for realistic number of particles.

A hierarchy of reduced distribution functions may be obtained by repeated integration of the previous Liouville equation. The final equation in the hierarchy is for the single particle distribution that also involves the two-particle distribution function. Assuming molecular chaos, that final equation becomes a closed one (i.e., one equation in one unknown), and is known as the Boltzmann equation, the fundamental relation of the kinetic theory of gases. That final equation in the hierarchy is the only one that carries any hope of obtaining analytical solutions.

A simpler direct derivation of the Boltzmann equation is provided by Bird (1994). For monatomic gas molecules in binary collisions, the integro-differential Boltzmann equation reads

$$\frac{\partial(nf)}{\partial t} + \xi_j \frac{\partial(nf)}{\partial x_j} + F_j \frac{\partial(nf)}{\partial \xi_j} = J\left(f,f^*\right), j = 1,2,3 \tag{15.6.52}$$

where $n\,f$ is the product of the number density and the normalized velocity distribution function ($dn/n = f\, d\vec{\xi}$); x_j and ξ_j are the coordinates and speeds of a molecule, respectively;[†] F_j is a known external force; and $J(f,f^*)$ is the nonlinear collision integral that describes the net effect of populating and

---

[†] Constituting, together with time, the seven independent variables of the single-dependent-variable equation.

depopulating collisions on the distribution function. The collision integral is the source of difficulty in obtaining analytical solutions to the Boltzmann equation, and is given by

$$J\left(f,f^*\right)=\int_{-\infty}^{\infty}\int_{0}^{4\pi} n^2\,\left(f^* f_1^* - f\,f_1\right)\vec{\xi}_r\;\sigma\;d\Omega\,\left(d\vec{\xi}\right)_1 \tag{15.6.53}$$

where the superscript * indicates postcollision values, f and f_1 represent two different molecules, $\vec{\xi}_r$ is the relative speed between two molecules, σ is the molecular cross section, Ω is the solid angle, and $d\vec{\xi} = d\xi_1\,d\xi_2\,d\xi_3$.

Once a solution for f is obtained, macroscopic quantities such as density, velocity, and temperature can be computed from the appropriate weighted integral of the distribution function. For example:

$$\rho = m\,n = m\int\left(n\,f\right)d\vec{\xi} \tag{15.6.54}$$

$$u_i = \int \xi_i\,f\,d\vec{\xi} \tag{15.6.55}$$

$$\tfrac{3}{2}\,k\,T = \int \tfrac{1}{2}\,m\,\xi_i\,\xi_i\,f\,d\vec{\xi} \tag{15.6.56}$$

If the Boltzmann equation is nondimensionalized with a characteristic length L and characteristic speed $[2(k/m)T]^{1/2}$, where k is the Boltzmann constant, m, is the molecular mass, and T is temperature, the inverse Knudsen number appears explicitly in the right-hand side of the equation as follows:

$$\frac{\partial\hat{f}}{\partial\hat{t}} + \hat{\xi}_j\,\frac{\partial\hat{f}}{\partial\hat{x}_j} + \hat{F}_j\,\frac{\partial\hat{f}}{\partial\hat{\xi}_j} = \frac{1}{Kn}\,\hat{J}\left(\hat{f},\hat{f}^*\right),\; j = 1,2,3 \tag{15.6.57}$$

where the topping symbol ^ represents a dimensionless variable, and $\hat{f}$ is nondimensionalized using a reference number density n_o.

The five conservation equations for the transport of mass, momentum, and energy can be derived by multiplying the previous Boltzmann equation by, respectively, the molecular mass, momentum, and energy, and then integrating over all possible molecular velocities. Subject to the restrictions of dilute gas and molecular chaos stated earlier, the Boltzmann equation is valid for all ranges of Knudsen number from 0 to ∞. Analytical solutions to this equation for arbitrary geometries are difficult mostly because of the nonlinearity of the collision integral. Simple models of this integral have been proposed to facilitate analytical solutions; see, for example, Bhatnagar et al. (1954).

There are two important asymptotes to Equation 15.6.57. First, as $Kn \to \infty$, molecular collisions become unimportant. This is the free-molecule flow regime depicted in Figure 15.6.2 for $Kn > 10$, where the only important collision is that between a gas molecule and the solid surface of an obstacle or a conduit. Analytical solutions are then possible for simple geometries, and numerical simulations for complicated geometries are straightforward once the surface-reflection characteristics are accurately modeled. Second, as $Kn \to 0$, collisions become important and the flow approaches the continuum regime of conventional fluid dynamics. The Second Law specifies a tendency for thermodynamic systems to revert to equilibrium state, smoothing out any discontinuities in macroscopic flow quantities. The number of molecular collisions in the limit $Kn \to 0$ is so large that the flow approaches the equilibrium state in a time short compared to the macroscopic time-scale. For example, for air at standard conditions (T = 288 K; p = 1 atm), each molecule experiences, on the average, 10 collisions per nanosecond and travels 1 micron in the same time period. Such a molecule has already *forgotten* its previous state after 1 ns. In a particular flowfield, if the macroscopic quantities vary little over a distance of 1 µm or over a time interval of 1 ns, the flow of STP air is near equilibrium.

At $Kn = 0$, the velocity distribution function is everywhere of the local equilibrium or Maxwellian form:

$$\hat{f}^{(0)} = \frac{n}{n_o}\,\pi^{-3/2}\,\exp\left[-\left(\hat{\xi} - \hat{u}\right)^2\right] \tag{15.6.58}$$

where $\hat{\xi}$ and $\hat{u}$ are, respectively, the dimensionless speeds of a molecule and of the flow. In this Knudsen number limit, the velocity distribution of each element of the fluid instantaneously adjusts to the equilibrium thermodynamic state appropriate to the local macroscopic properties as this molecule moves through the flow field. From the continuum viewpoint, the flow is isentropic, and heat conduction and viscous diffusion and dissipation vanish from the continuum conservation relations.

The Chapman-Enskog theory attempts to solve the Boltzmann equation by considering a small perturbation of $\hat{f}$ from the equilibrium Maxwellian form. For small Knudsen numbers, the distribution function can be expanded in terms of Kn in the form of a power series:

$$\hat{f} = \hat{f}^{(0)} + Kn\,\hat{f}^{(1)} + Kn^2\,\hat{f}^{(2)} + \cdots \tag{15.6.59}$$

By substituting the above series in the Boltzmann equation (Equation 15.6.57) and equating terms of equal order, the following recurrent set of integral equations result:

$$\begin{aligned} \hat{J}\left(\hat{f}^{(0)},\hat{f}^{(0)}\right) &= 0\,, \\ \hat{J}\left(\hat{f}^{(0)},\hat{f}^{(1)}\right) &= \frac{\partial \hat{f}}{\partial \hat{t}} + \hat{\xi}_j\,\frac{\partial \hat{f}^{(0)}}{\partial \hat{x}_j} + \hat{F}_j\,\frac{\partial \hat{f}^{(0)}}{\partial \hat{\xi}_j}\,, \cdots \end{aligned} \tag{15.6.60}$$

The first integral is nonlinear and its solution is the local Maxwellian distribution, Equation 15.6.58. The distribution functions $\hat{f}^{(1)}$, $\hat{f}^{(2)}$, etc., each satisfies an inhomogeneous linear equation whose solution leads to the transport terms needed to close the continuum equations appropriate to the particular level of approximation. The continuum stress tensor and heat flux vector can be written in terms of the distribution function, which in turn can be specified in terms of the macroscopic velocity and temperature and their derivatives (Kogan 1973). The zeroth-order equation yields the Euler equations, the first-order equation results in the linear transport terms of the Navier-Stokes equations, the second-order equation gives the nonlinear transport terms of the Burnett equations, and so on. Keep in mind, however, that the Boltzmann equation as developed in this subsection is for a monatomic gas. This excludes the all-important air that is composed largely of diatomic nitrogen and oxygen.

As discussed earlier, the Navier-Stokes equations can and should be used up to a Knudsen number of 0.1. Beyond that, the transition flow regime commences ($0.1 < Kn < 10$). In this flow regime, the molecular mean free path for a gas becomes significant relative to a characteristic distance for important flow-property changes to take place. The Burnett equations can be used to obtain analytical/numerical solutions for at least a portion of the transition regime for a monatomic gas, although their complexity have precluded much results for realistic geometries (Agarwal et al. 1999). There is also a certain degree of uncertainty about the proper boundary conditions to use with the continuum Burnett equations, and experimental validation of the results have been very scarce. Additionally, as the gas flow further departs from equilibrium, the bulk viscosity ($= \lambda + \frac{2}{3}\mu$, where λ is the second coefficient of viscosity) is no longer zero, and the Stokes' hypothesis no longer holds (see Gad-el-Hak [1995] for an interesting summary of the issue of bulk viscosity).

In the transition regime, the molecularly based Boltzmann equation cannot easily be solved either, unless the nonlinear collision integral is simplified. So, clearly the transition regime is one of dire need of alternative methods of solution. MD simulations as mentioned earlier are not suited for dilute gases. The best approach for the transition regime right now is the direct simulation Monte Carlo (DSMC) method developed by Bird (1963, 1965, 1976, 1978, 1994) and briefly described below. Some recent reviews of DSMC include those by Muntz (1989), Cheng (1993), Cheng and Emmanuel (1995) and Oran et al. (1998). The mechanics as well as the history of the DSMC approach and its ancestors are well described in the book by Bird (1994).

Unlike molecular dynamics simulations, DSMC is a statistical computational approach to solving rarefied gas problems. Both approaches treat the gas as discrete particles. Subject to the dilute gas and molecular chaos assumptions, the direct simulation Monte Carlo method is valid for all ranges of Knudsen number, although it becomes quite expensive for $Kn < 0.1$. Fortunately, this is the continuum regime where the Navier-Stokes equations can be used analytically or computationally. DSMC is therefore ideal for the transition regime ($0.1 < Kn < 10$), where the Boltzmann equation is difficult to solve. The Monte Carlo method is, like its namesake, a random number strategy based directly on the physics of the individual molecular interactions. The idea is to track a large number of randomly selected, statistically representative particles, and to use their motions and interactions to modify their positions and states. The primary approximation of the direct simulation Monte Carlo method is to uncouple the molecular motions and the intermolecular collisions over small time intervals. A significant advantage of this approximation is that the amount of computation required is proportional to N, in contrast to N^2 for molecular dynamics simulations. In essence, particle motions are modeled deterministically while collisions are treated probabilistically, each simulated molecule representing a large number of actual molecules. Typical computer runs of DSMC in the 1990s involve tens of millions of intermolecular collisions and fluid-solid interactions.

The DSMC computation is started from some initial condition and followed in small time steps that can be related to physical time. Colliding pairs of molecules in a small geometric cell in physical space are randomly selected after each computational time step. Complex physics such as radiation, chemical reactions, and species concentrations can be included in the simulations without the necessity of nonequilibrium thermodynamic assumptions that commonly afflict nonequilibrium continuum-flow calculations. DSMC is more computationally intensive than classical continuum simulations, and should therefore be used only when the continuum approach is not feasible.

The DSMC technique is explicit and time marching, and therefore always produces unsteady flow simulations. For macroscopically steady flows, Monte Carlo simulation proceeds until a steady flow is established, within a desired accuracy, at sufficiently large time. The macroscopic flow quantities are then the time average of all values calculated after reaching the steady state. For macroscopically unsteady flows, ensemble averaging of many independent Monte Carlo simulations is carried out to obtain the final results within a prescribed statistical accuracy.

Liquid Flows

From the continuum point of view, liquids and gases are both fluids obeying the same equations of motion. For incompressible flows, for example, the Reynolds number is the primary dimensionless parameter that determines the nature of the flow field. True, water, for example, has density and viscosity that are, respectively, three and two orders of magnitude higher than those for air, but if the Reynolds number and geometry are matched, liquid and gas flows should be identical.[†] For MEMS applications, however, we anticipate the possibility of nonequilibrium flow conditions and the consequent invalidity of the Navier-Stokes equations and the no-slip boundary conditions. Such circumstances can best be researched using the molecular approach. This was discussed for gases earlier, and the corresponding arguments for liquids will be given in this subsection. The literature on non-Newtonian fluids in general and polymers in particular is vast (for example, the bibliographic survey by Nadolink and Haigh [1995]

[†] Barring phenomena unique to liquids such as cavitation, free surface flows, etc.

cites over 4900 references on polymer drag reduction alone) and provides a rich source of information on the molecular approach for liquid flows.

Solids, liquids, and gases are distinguished merely by the degree of proximity and the intensity of motions of their constituent molecules. In solids, the molecules are packed closely and confined, each hemmed in by its neighbors (Chapman and Cowling 1970). Only rarely would one solid molecule slip from its neighbors to join a new set. As the solid is heated, molecular motion becomes more violent and a slight thermal expansion takes place. At a certain temperature that depends on ambient pressure, sufficiently intense motion of the molecules enables them to pass freely from one set of neighbors to another. The molecules are no longer confined but are nevertheless still closely packed, and the substance is now considered a liquid. Further heating of the matter eventually releases the molecules altogether, allowing them to break the bonds of their mutual attractions. Unlike solids and liquids, the resulting gas expands to fill any volume available to it.

Unlike solids, both liquids and gases cannot resist finite shear force without continuous deformation; that is the definition of a fluid medium. In contrast to the reversible, elastic, static deformation of a solid, the continuous deformation of a fluid resulting from the application of a shear stress results in an irreversible work that eventually becomes random thermal motion of the molecules; that is viscous dissipation. There are around 25-million molecules of STP air in a one-micron cube. The same cube would contain around 34-billion molecules of water. So, liquid flows are continuum even in extremely small devices through which gas flows would not be continuum. The average distance between molecules in the gas example is one order of magnitude higher than the diameter of its molecules, while that for the liquid phase approaches the molecular diameter. As a result, liquids are almost incompressible. Their isothermal compressibility coefficient α and bulk expansion coefficient β are much smaller compared to those for gases. For water, for example, a hundred-fold increase in pressure leads to less than 0.5% decrease in volume. Sound speeds through liquids are also high relative to those for gases, and as a result most liquid flows are incompressible.[†] The exception is the propagation of ultra-high-frequency sound waves and cavitation phenomena.

The mechanism by which liquids transport mass, momentum, and energy must be very different from that for gases. In dilute gases, intermolecular forces play no role and the molecules spend most of their time in free flight between brief collisions, at which instances the molecules' direction and speed abruptly change. The random molecular motions are responsible for gaseous transport processes. In liquids, on the other hand, the molecules are closely packed though not fixed in one position. In essence, the liquid molecules are always in a collision state. Applying a shear force must create a velocity gradient so that the molecules move relative to one another, *ad infinitum* as long as the stress is applied. For liquids, momentum transport due to the random molecular motion is negligible compared to that due to the intermolecular forces. The straining between liquid molecules causes some to separate from their original neighbors, bringing them into the force field of new molecules. Across the plane of the shear stress, the sum of all intermolecular forces must, on the average, balance the imposed shear. Liquids at rest transmit only normal force, but when a velocity gradient occurs, the net intermolecular force would have a tangential component.

The incompressible Navier-Stokes equations describe liquid flows under most circumstances. Liquids, however, do not have a well-advanced molecular-based theory as that for dilute gases. The concept of mean free path is not useful for liquids, and the conditions under which a liquid flow fails to be in quasi-equilibrium state are not well defined. There is no Knudsen number for liquid flows to guide us through the maze. We do not know, from first principles, the conditions under which the no-slip boundary condition becomes inaccurate, or the point at which the stress–rate of strain relation or the heat flux–temperature gradient relation fails to be linear. Certain empirical observations indicate that those simple

---

[†] Note that we distinguish between a fluid and a flow being compressible/incompressible. For example, the *flow* of the highly compressible air can be either compressible or incompressible.

relations that we take for granted occasionally fail to accurately model liquid flows. For example, it has been shown in rheological studies (Loose and Hess, 1989) that non-Newtonian behavior commences when the strain rate approximately exceeds twice the molecular frequency-scale:

$$\dot{\gamma} = \frac{\partial u}{\partial y} \geq 2\,T^{-1} \qquad (15.6.61)$$

where the molecular time-scale T is given by

$$T = \left[\frac{m\,\sigma^2}{\varepsilon}\right]^{\frac{1}{2}} \qquad (15.6.62)$$

where m is the molecular mass, and σ and ε are the characteristic length- and energy-scale for the molecules, respectively. For ordinary liquids such as water, this time-scale is extremely small, and the threshold shear rate for the onset of non-Newtonian behavior is therefore extraordinarily high. For high-molecular-weight polymers, on the other hand, m and σ are both many orders of magnitude higher than their respective values for water, and the linear stress-strain relation breaks down at realistic values of the shear rate.

The moving contact line when a liquid spreads on a solid substrate is an example where slip flow must be allowed to avoid singular or unrealistic behavior in the Navier-Stokes solutions (Dussan and Davis 1974; Dussan 1976, 1979; Thompson and Robbins 1989). Other examples where slip-flow must be admitted include corner flows (Moffatt 1964; Koplik and Banavar 1995) and extrusion of polymer melts from capillary tubes (Pearson and Petrie 1968; Richardson 1973; Den 1990).

Existing experimental results of liquid flow in microdevices are contradictory. This is not surprising given the difficulty of such experiments and the lack of a guiding rational theory. Pfahler et al. (1990; 1991), Pfahler (1992), and Bau (1994) summarize the relevant literature. For small-length-scale flows, a phenomenological approach for analyzing the data is to define an *apparent* viscosity μ_a calculated so that if it were used in the traditional no-slip Navier-Stokes equations instead of the fluid viscosity μ, the results would be in agreement with experimental observations. Israelachvili (1986) and Gee et al. (1990) found that $\mu_a = \mu$ for thin-film flows as long as the film thickness exceeds 10 molecular layers (≈5 nm). For thinner films, μ_a depends on the number of molecular layers and can be as much as 10^5 times larger than μ. Chan and Horn's (1985) results are somewhat different: the apparent viscosity deviates from the fluid viscosity for films thinner than 50 nm.

In polar-liquid flows through capillaries, Migun and Prokhorenko (1987) report that μ_a increases for tubes smaller than 1 micron in diameter. In contrast, Debye and Cleland (1959) report μ_a smaller than μ for paraffin flow in porous glass with average pore size several times larger than the molecular length-scale. Experimenting with microchannels ranging in depths from 0.5 micron to 50 microns, Pfahler et al. (1991) found that μ_a is consistently smaller than μ for both liquid (isopropyl alcohol; silicone oil) and gas (nitrogen; helium) flows in microchannels. For liquids, the apparent viscosity decreases with decreasing channel depth. Other researchers using small capillaries report that μ_a is about the same as μ (Anderson and Quinn 1972; Tuckermann and Pease 1981, 1982; Tuckermann 1984; Guvenc 1985; Nakagawa et al. 1990).

Very recently, Sharp (2001) and Sharp et al. (2002) asserted that, despite the significant inconsistencies in the literature regarding liquid flows in microchannels, such flows are well predicted by macroscale continuum theory. A case can be made to the contrary, however, as will be seen at the end of this subsection, and the final verdict on this controversy is yet to come.

The above contradictory results point to the need for replacing phenomenological models by first-principles ones. The lack of molecular-based theory of liquids — despite extensive research by the rheology and polymer communities — leaves molecular dynamics simulations as the nearest weapon to first-principles arsenal. MD simulations offer a unique approach to checking the validity of the traditional continuum assumptions. However, as was pointed out earlier, such simulations are limited to exceedingly minute flow extent.

Thompson and Troian (1997) provide molecular dynamics simulations to quantify the slip-flow boundary condition dependence on shear rate. Recall the linear Navier boundary condition introduced earlier:

$$\Delta u\Big|_w = u_{fluid} - u_{wall} = L_s \frac{\partial u}{\partial y}\Big|_w \tag{15.6.63}$$

where

L_s = the constant slip length

$\frac{\partial u}{\partial y}\Big|_w$ = the strain rate computed at the wall.

The goal of Thompson and Troian's simulations was to determine the degree of slip at a solid-liquid interface as the interfacial parameters and the shear rate change. In their simulations, a simple liquid underwent planar shear in a Couette cell as shown in Figure 15.6.8. The typical cell measured 12.51 × 7.22 × h, in units of molecular length-scale σ, where the channel depth h varied in the range of 16.71σ to 24.57σ, and the corresponding number of molecules simulated ranged from 1152 to 1728. The liquid is treated as an isothermal ensemble of spherical molecules. A shifted Lennard-Jones 6–12 potential is

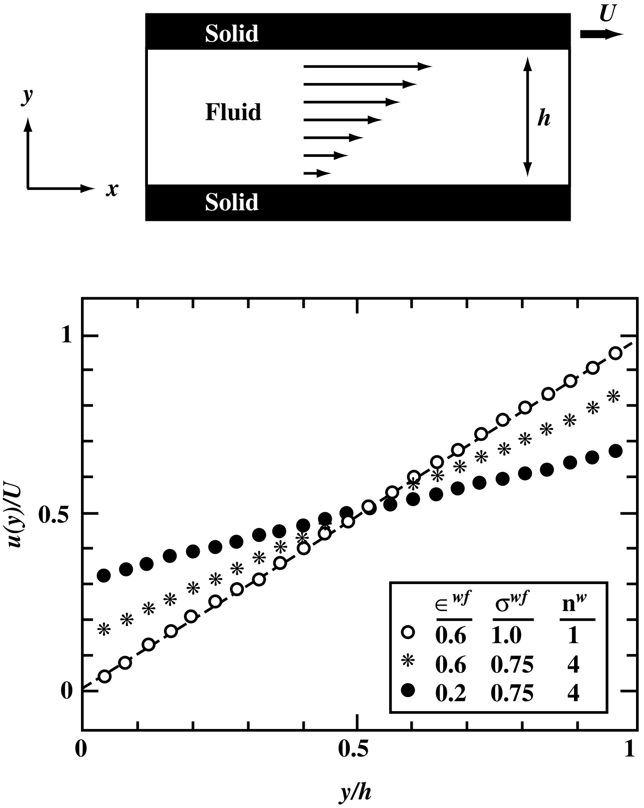

FIGURE 15.6.8 Velocity profiles in a Couette flow geometry at different interfacial parameters. All three profiles are for $U = \sigma T^{-1}$, and $h = 24.57\ \sigma$. The dashed line is the no-slip Couette-flow solution. From Thompson and Troian (1997).

used to model intermolecular interactions, with energy- and length-scales ε and σ, and cutoff distance $r_c = 2.2\sigma$:

$$V(r) = 4\,\varepsilon\left[\left(\frac{r}{\sigma}\right)^{-12} - \left(\frac{r}{\sigma}\right)^{-6} - \left(\frac{r_c}{\sigma}\right)^{-12} + \left(\frac{r_c}{\sigma}\right)^{-6}\right] \tag{15.6.64}$$

The truncated potential is set to zero for $r > r_c$.

The fluid-solid interaction is also modeled with a truncated Lennard-Jones potential, with energy- and length-scales ε^{wf} and σ^{wf}, and cutoff distance r_c. The equilibrium state of the fluid is a well-defined liquid phase characterized by number density $n = 0.81\sigma^{-3}$ and temperature $T = 1.1\ \varepsilon/k$, where k is the Boltzmann constant.

The steady state velocity profiles resulting from Thompson and Troian's (1997) MD simulations are depicted in Figure 15.6.8 for different values of the interfacial parameters ε^{wf}, σ^{wf} and n^w. Those parameters, shown in units of the corresponding fluid parameters ε, σ, and n, characterize, respectively, the strength of the liquid-solid coupling, the thermal roughness of the interface, and the commensurability of wall and liquid densities. The macroscopic velocity profiles recover the expected flow behavior from continuum hydrodynamics with boundary conditions involving varying degrees of slip. Note that when slip exists, the shear rate $\dot{\gamma}$ no longer equals U/h. The degree of slip increases (i.e., the amount of momentum transfer at the wall-fluid interface decreases) as the relative wall density n^w increases or the strength of the wall-fluid coupling σ^{wf} decreases; in other words when the relative surface energy corrugation of the wall decreases. Conversely, the corrugation is maximized when the wall and fluid densities are commensurate and the strength of the wall-fluid coupling is large. In this case, the liquid *feels* the corrugations in the surface energy of the solid owing to the atomic close-packing. Consequently, there is efficient momentum transfer and the no-slip condition applies, or in extreme cases, a "stick" boundary condition takes hold.

Variations of the slip length L_s and viscosity μ as functions of shear rate $\dot{\gamma}$ are shown in parts (a) and (b) of Figure 15.6.9, for five different sets of interfacial parameters. For Couette flow, the slip length is computed from its definition, $\Delta u|_w / \dot{\gamma} = (U/\dot{\gamma} - h)/2$. The slip length, viscosity, and shear rate are normalized in the figure using the respective molecular scales for length σ, viscosity $\varepsilon\ T\ \sigma^{-3}$, and inverse time T^{-1}. The viscosity of the fluid is constant over the entire range of shear rates (Figure 15.6.9b), indicating Newtonian behavior. As indicated earlier, non-Newtonian behavior is expected for $\dot{\gamma} \geq 2\,T^{-1}$, well above the shear rates used in Thompson and Troian's simulations.

At low shear rates, the slip length behavior is consistent with the Navier model, in other words, is independent of the shear rate. Its limiting value L_s^o ranges from 0 to ~17σ for the range of interfacial parameters chosen (Figure 15.6.9a). In general, the amount of slip increases with decreasing surface energy corrugation. Most interestingly, at high shear rates the Navier condition breaks down as the slip length increases rapidly with $\dot{\gamma}$. The critical shear-rate value for the slip length to diverge, $\dot{\gamma}_c$, decreases as the surface energy corrugation decreases. Surprisingly, the boundary condition is nonlinear even though the liquid is still Newtonian. In dilute gases, the linear slip condition and the Navier-Stokes equations, with their linear stress-strain relation, are both valid to the same order of approximation in Knudsen number. In other words, deviation from linearity is expected to take place at the same value of $Kn = 0.1$. In liquids, in contrast, the slip length appears to become nonlinear and to diverge at a critical value of shear rate well below the shear rate at which the linear stress-strain relation fails. Moreover, the boundary condition deviation from linearity is not gradual but is rather catastrophic. The critical value of shear rate $\dot{\gamma}_c$ signals the point at which the solid can no longer impart momentum to the liquid. This means that the same liquid molecules sheared against different substrates will experience varying amounts of slip, and vice versa.

Based on the above results, Thompson and Troian (1997) suggest a universal boundary condition at a solid-liquid interface. Scaling the slip length L_s by its asymptotic limiting value L_s^o and the shear rate $\dot{\gamma}$ by its critical value $\dot{\gamma}_c$, collapses the data in the single curve shown in Figure 15.6.10. The data points are well described by the relation

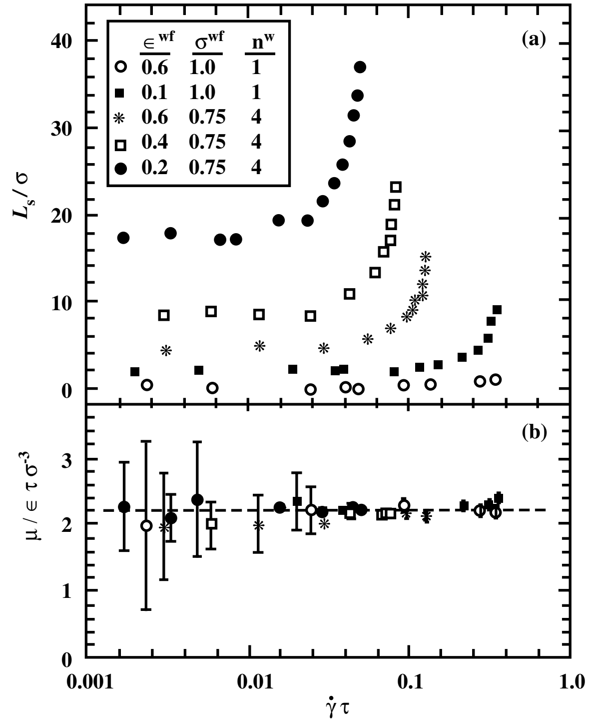

FIGURE 15.6.9 Variation of slip length and viscosity as functions of shear rate. From Thompson and Troian (1997).

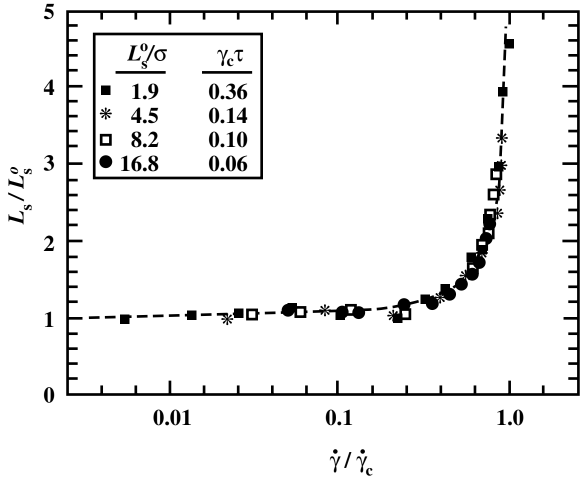

FIGURE 15.6.10 Universal relation of slip length as a function of shear rate. From Thompson and Troian (1997).

$$L_s = L_s^o\left[1 - \frac{\dot\gamma}{\dot\gamma_c}\right]^{-\frac{1}{2}} \tag{15.6.65}$$

The nonlinear behavior close to a critical shear rate suggests that the boundary condition can significantly affect flow behavior at macroscopic distances from the wall. Experiments with polymers confirm this observation (Atwood and Schowalter 1989). The rapid change in the slip length suggests that for flows in the vicinity of $\dot{\gamma}_c$, small changes in surface properties can lead to large fluctuations in the apparent boundary condition. Thompson and Troian (1997) conclude that the Navier slip condition is but the low-shear-rate limit of a more generalized universal relationship that is nonlinear and divergent. Their relation provides a mechanism for relieving the stress singularity in spreading contact lines and corner flows, as it naturally allows for varying degrees of slip on approach to regions of higher rate of strain.

To place the above results in physical terms, consider water[†] at a temperature of $T = 288$ K. The energy-scale in the Lennard-Jones potential is then $\varepsilon = 3.62 \times 10^{-21}$ J. For water, $m = 2.99 \times 10^{-26}$ kg, $\sigma = 2.89 \times 10^{-10}$ m, and at standard temperature $n = 3.35 \times 10^{28}$ molecules/m^3. The molecular time-scale can thus be computed, $T = [m\sigma^2/\varepsilon]^{1/2} = 8.31 \times 10^{-13}$ s. For the third case depicted in Figure 15.6.10 (the open squares), $\dot{\gamma}_c\, T = 0.1$, and the critical shear rate at which the slip condition diverges is thus $\dot{\gamma}_c = 1.2 \times 10^{11}\,\mathrm{s}^{-1}$. Such an enormous rate of strain[††] may be found in extremely small devices having extremely high speeds. On the other hand, the conditions to achieve a measurable slip of 17σ (the solid circles in Figure 15.6.9) are not difficult to encounter in microdevices: density of solid four times that of liquid, and the energy-scale for wall-fluid interaction that is one fifth of the energy-scale for liquid.

The limiting value of slip length is independent of the shear rate and can be computed for water as $L_s^o = 17\sigma = 4.91 \times 10^{-9}$ m. Consider a water microbearing having a shaft diameter of 100 μm and rotation rate of 20,000 rpm and a minimum gap of $h = 1$ μm. In this case, $U = 0.1$ m/s and the no-slip shear rate is $U/h = 10^5\,\mathrm{s}^{-1}$. When slip occurs at the limiting value just computed, the shear rate and the wall slip-velocity are computed as follows:

$$\dot{\gamma} = \frac{U}{h + 2\,L_s^o} = 9.90 \times 10^4\ \mathrm{s}^{-1} \tag{15.6.66}$$

$$\Delta u\big|_w = \dot{\gamma}\, L_s = 4.87 \times 10^{-4}\ \mathrm{m/s} \tag{15.6.67}$$

As a result of the Navier slip, the shear rate is reduced by 1% from its no-slip value, and the slip velocity at the wall is about 0.5% of U, small but not insignificant.

Surface Phenomena

The surface-to-volume ratio for a machine with a characteristic length of 1 m is 1 m^{-1}, while that for a MEMS device having a size of 1 μm is 10^6 m^{-1}. The million-fold increase in surface area relative to the mass of the minute device substantially affects the transport of mass, momentum, and energy through the surface. Obviously surface effects dominate in small devices. The surface boundary conditions in MEMS flows have already been discussed earlier. In microdevices, it has been shown that it is possible to have measurable slip-velocity and temperature jump at a solid-fluid interface. In this subsection, we illustrate other ramifications of the large surface-to-volume ratio unique to MEMS, and provide a molecular viewpoint to surface forces.

In microdevices, both radiative and convective heat loss/gain are enhanced by the huge surface-to-volume ratio. Consider a device having a characteristic length L_s. Use of the lumped capacitance method to compute the rate of convective heat transfer, for example, is justified if the Biot number ($\equiv hL_s/\kappa_s$, where h is the convective heat transfer coefficient of the fluid and κ_s is the thermal conductivity of the solid) is less than 0.1. Small L_s implies a small Biot number and a nearly uniform temperature within the solid. Within this approximation, the rate at which heat is lost to the surrounding fluid is given by

---

[†] Water molecules are complex ones, forming directional, short-range covalent bonds, thus requiring a more complex potential than the Lennard-Jones to describe the intermolecular interactions. For the purpose of the qualitative example described here, however, we use the computational results of Thompson and Troian (1997), who employed the L-J potential.

[††] Note however that $\dot{\gamma}_c$ for high-molecular-weight polymers would be many orders of magnitude smaller than the value developed here for water.

$$\rho_s\, L_s^3\, c_s\, \frac{dT}{dt} = -h\, L_s^2\, \left(T_s - T_\infty\right) \qquad (15.6.68)$$

where ρ_s and c_s are respectively the density and specific heat of the solid, T_s is its (uniform) temperature, and T_∞ is the ambient fluid temperature. Solution of the above equation is trivial, and the temperature of a hot surface drops exponentially with time from an initial temperature T_i:

$$\frac{T_s(t) - T_\infty}{T_i - T_\infty} = \exp\left[-\frac{t}{T}\right] \qquad (15.6.69)$$

where the time constant T is given by

$$T = \frac{\rho_s\, L_s^3\, c_s}{h\, L_s^2} \qquad (15.6.70)$$

For small devices, the time it takes the solid to cool down is proportionally small. Clearly, the million-fold increase in surface-to-volume ratio implies a proportional increase in the rate at which heat escapes. Identical scaling arguments can be made regarding mass transfer.

Another effect of the diminished scale is the increased importance of surface forces and the waning importance of body forces. Based on biological studies, Went (1968) concludes that the demarcation length-scale is around 1 mm. Below that, surface forces dominate over gravitational forces. A 10-mm piece of paper will fall down when gently placed on a smooth, vertical wall, while a 0.1-mm piece will stick. Try it! *Stiction* is a major problem in MEMS applications. Certain structures such as long, thin polysilicon beams and large, thin comb drives have a propensity to stick to their substrates and thus fail to perform as designed (Mastrangelo and Hsu 1992; Tang et al. 1989).

Conventional dry friction between two solids in relative motion is proportional to the normal force, which is usually a component of the moving device weight. The friction is independent of the contact-surface area because the van der Waals cohesive forces are negligible relative to the weight of the macroscopic device. In MEMS applications, the cohesive intermolecular forces between two surfaces are significant and the stiction is independent of the device mass but is proportional to its surface area. The first micromotor did not move — despite large electric current through it — until the contact area between the 100-micron rotor and the substrate was reduced significantly by placing dimples on the rotor's surface (Fan et al. 1988, 1989; Tai and Muller 1989).

One last example of surface effects that to my knowledge has not been investigated for microflows is the adsorbed layer in gaseous wall-bounded flows. It is well known (Brunauer 1944; Lighthill 1963) that when a gas flows in a duct, the gas molecules are attracted to the solid surface by the van der Waals and other forces of cohesion. The potential energy of the gas molecules drops on reaching the surface. The adsorbed layer partakes the thermal vibrations of the solid, and the gas molecules can only escape when their energy exceeds the potential energy minimum. In equilibrium, at least part of the solid would be covered by a monomolecular layer of adsorbed gas molecules. Molecular species with significant partial pressure — relative to their vapor pressure — may locally form layers two or more molecules thick. Consider, for example, the flow of a mixture of dry air and water vapor at STP. The energy of adsorption of water is much larger than that for nitrogen and oxygen, making it more difficult for water molecules to escape the potential energy trap. It follows that the lifetime of water molecules in the adsorbed layer significantly exceeds that for the air molecules (by 60,000 folds, in fact), and as a result, the thin surface layer would be mostly water. For example, if the proportion of water vapor in the ambient air is 1:1000 (i.e., very low humidity level), the ratio of water to air in the adsorbed layer would be 60:1. Microscopic roughness of the solid surface causes partial condensation of the water along portions having sufficiently strong concave curvature. So, surfaces exposed to nondry airflows are mainly liquid water surfaces. In most applications, this thin adsorbed layer has little effect on the flow dynamics, despite the fact that the density and viscosity of liquid water are far greater than those for air. In MEMS applications, however, the layer thickness may not be an insignificant portion of the characteristic flow dimension and the water layer may have a measurable effect on the gas flow. A hybrid approach of molecular dynamics and continuum flow simulations or MD-Monte Carlo simulations may be used to investigate this issue.

It should be noted that recently, Majumdar and Mezic (1998, 1999) have studied the stability and rupture into droplets of thin liquid films on solid surfaces. They point out that the free energy of a liquid film consists of a surface tension component as well as highly nonlinear volumetric intermolecular forces resulting from van der Waals, electrostatic, hydration, and elastic strain interactions. For water films on hydrophilic surfaces such as silica and mica, Majumdar and Mezic (1998) estimate the equilibrium film thickness to be about 0.5 nm (2 monolayers) for a wide range of ambient-air relative humidities. The equilibrium thickness grows very sharply, however, as the relative humidity approaches 100%.

Majumdar and Mezic's (1998, 1999) results open many questions. What are the stability characteristics of their water film in the presence of airflow above it? Would this water film affect the accommodation coefficient for microduct air flow? In a modern Winchester-type hard disk, the drive mechanism has a read/write head that floats 50 nm above the surface of the spinning platter. The head and platter together with the air layer in between form a slider bearing. Would the computer performance be affected adversely by the high relative humidity on a particular day when the adsorbed water film is no longer "thin"? If a microduct hauls liquid water, would the water film adsorbed by the solid walls influence the effective viscosity of the water flow? Electrostatic forces can extend to almost 1 micron (the Debye length), and that length is known to be highly pH-dependent. Would the water flow be influenced by the surface and liquid chemistry? Would this explain the contradictory experimental results of liquid flows in microducts discussed earlier?

The few examples above illustrate the importance of surface effects in small devices. From the continuum viewpoint, forces at a solid-fluid interface are the limit of pressure and viscous forces acting on a parallel elementary area displaced into the fluid, when the displacement distance is allowed to tend to zero. From the molecular point of view, all macroscopic surface forces are ultimately traced to intermolecular forces, which subject is extensively covered in the book by Israelachvilli (1991) and references therein. Here we provide a very brief introduction to the molecular viewpoint. The four forces in nature are (1) the strong and (2) weak forces describing the interactions between neutrons, protons, electrons, etc.; (3) the electromagnetic forces between atoms and molecules; and (4) gravitational forces between masses. The range of action of the first two forces is around 10^{-5} nm, and hence neither concerns us overly in MEMS applications. The electromagnetic forces are effective over a much larger though still small distance on the order of the interatomic separations (0.1–0.2 nm). Effects over longer range — several orders of magnitude longer — can and do arise from the short-range intermolecular forces. For example, the rise of liquid column in capillaries and the action of detergent molecules in removing oily dirt from fabric are the result of intermolecular interactions. Gravitational forces decay with the distance to second power, whereas intermolecular forces decay much quicker, typically with the seventh power. Cohesive forces are therefore negligible once the distance between molecules exceeds few molecular diameters, while massive bodies like stars and planets are still strongly interacting, via gravity, over astronomical distances.

Electromagnetic forces are the source of all intermolecular interactions and the cohesive forces holding atoms and molecules together in solids and liquids. They can be classified into (1) purely electrostatic arising from the Coulomb force between charges, interactions between charges, permanent dipoles, quadrupoles, etc.; (2) polarization forces arising from the dipole moments induced in atoms and molecules by the electric field of nearby charges and permanent dipoles; and (3) quantum mechanical forces that give rise to covalent or chemical bonding and to repulsive steric or exchange interactions that balance the attractive forces at very short distances. The Hellman-Feynman theorem of quantum mechanics states that once the spatial distribution of the electron clouds has been determined by solving the appropriate Schrödinger equation, intermolecular forces may be calculated on the basis of classical electrostatics, in effect reducing all intermolecular forces to Coulombic forces. Note, however, that intermolecular forces exist even when the molecules are totally neutral. Solutions of the Schrödinger equation for general atoms and molecules are not easy, of course, and alternative modeling are sought to represent intermolecular forces. The van der Waals attractive forces are usually represented with a potential that varies as the inverse-sixth power of distance, whereas the repulsive forces are represented with either a power or an exponential potential.

A commonly used potential between two molecules is the generalized Lennard-Jones (L-J 6–12) pair potential given by

$$V_{ij}(r) = 4\,\varepsilon \left[c_{ij} \left(\frac{r}{\sigma} \right)^{-12} - d_{ij} \left(\frac{r}{\sigma} \right)^{-6} \right] \tag{15.6.71}$$

where V_{ij} is the potential energy between two particles i and j, r is the distance between the two molecules; ε and σ are characteristic energy- and length-scales, respectively; and c_{ij} and d_{ij} are parameters to be chosen for the particular fluid and solid combinations under consideration. The first term in the right-hand side is the strong repulsive force that is felt when two molecules are at extremely close range comparable to the molecular length-scale. That short-range repulsion prevents overlap of the molecules in physical space. The second term is the weaker, van der Waals attractive force that commences when the molecules are sufficiently close (several times σ). That negative part of the potential represents the attractive polarization interaction of neutral, spherically symmetric particles. The power of 6 associated with this term is derivable from quantum mechanics considerations, while the power of the repulsive part of the potential is found empirically. The Lennard-Jones potential is zero at very large distances, has a weak negative peak at r slightly larger than σ, is zero at $r = \sigma$, and is infinite as $r \to 0$.

The force field resulting from this potential is given by

$$F_{ij}(r) = -\frac{\partial V_{ij}}{\partial r} = \frac{48\,\varepsilon}{\sigma} \left[c_{ij} \left(\frac{r}{\sigma} \right)^{-13} - \frac{d_{ij}}{2} \left(\frac{r}{\sigma} \right)^{-7} \right] \tag{15.6.72}$$

A typical L-J 6–12 potential and force field are shown in Figure 15.6.11, for $c = d = 1$. The minimum potential $V_{\min} = -\varepsilon$, corresponds to the equilibrium position (zero force) and occurs at $r = 1.12\,\sigma$. The attractive van der Waals contribution to the minimum potential is -2ε, while the repulsive energy contribution is $+\varepsilon$. Thus the inverse 12th-power repulsive force term decreases the strength of the binding energy at equilibrium by 50%.

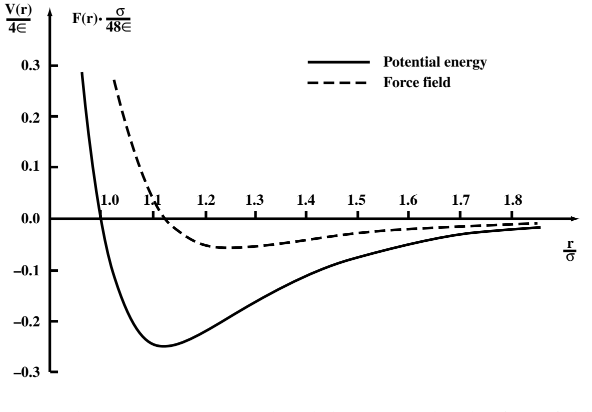

FIGURE 15.6.11 Typical Lennard-Jones 6–12 potential and the intermolecular force field resulting from it. Only a small portion of the potential function is shown for clarity.

The L-J potential is commonly used in molecular dynamics simulations to model intermolecular interactions between dense gas or liquid molecules and between fluid and solid molecules. As mentioned earlier, such potential is not accurate for complex substances, such as water, whose molecules form directional covalent bonds. As a result, MD simulations for water are much more involved.

Parting Remarks

The 40-year-old vision of Richard Feynman of building minute machines is now a reality. Microelectromechanical systems have witnessed explosive growth during the last decade and are finding increased applications in a variety of industrial and medical fields. The physics of fluid flows in microdevices has been explored in this subsection. While we now know considerably more than we did just few years ago, much physics remains to be explored so that rational tools can be developed for the design, fabrication, and operation of MEMS devices.

The traditional Navier-Stokes model of fluid flows with no-slip boundary conditions works only for a certain range of the governing parameters. This model basically demands two conditions:

1. The fluid is a continuum, which is almost always satisfied as there are usually more than 1 million molecules in the smallest volume in which appreciable macroscopic changes take place. This is the molecular chaos restriction.
2. The flow is not too far from thermodynamic equilibrium, which is satisfied if there is sufficient number of molecular encounters during a time period small compared to the smallest time-scale for flow changes. During this time period the average molecule would have moved a small distance compared to the smallest flow length-scale.

For gases, the Knudsen number determines the degree of rarefaction and the applicability of traditional flow models. As $Kn \to 0$, the time- and length-scales of molecular encounters are small compared to those for the flow, and the velocity distribution of each element of the fluid instantaneously adjusts to the equilibrium thermodynamic state appropriate to the local macroscopic properties as this molecule moves through the flow field. From the continuum viewpoint, the flow is isentropic, and heat conduction and viscous diffusion and dissipation vanish from the continuum conservation relations, leading to the Euler equations of motion. At small but finite Kn, the Navier-Stokes equations describe near-equilibrium, continuum flows.

Slip flow must be taken into account for $Kn > 0.001$. The slip boundary condition is at first linear in Knudsen number, then nonlinear effects take over beyond a Knudsen number of 0.1. At the same transition regime, that is, $0.1 < Kn < 10$, the linear stress-rate of strain and heat flux–temperature gradient relations — needed to close the Navier-Stokes equations — also break down, and alternative continuum equations (e.g., Burnett or higher-order equations) or molecular-based models must be invoked. In the transition regime, provided that the dilute gas and molecular chaos assumptions hold, solutions to the difficult Boltzmann equation are sought, but physical simulations such as Monte Carlo methods are more readily executed in this range of Knudsen number. In the free-molecule flow regime, that is, $Kn > 10$, the nonlinear collision integral is negligible and the Boltzmann equation is drastically simplified. Analytical solutions are possible in this case for simple geometries, and numerical integration of the Boltzmann equation is straightforward for arbitrary geometries, provided that the surface-reflection characteristics are accurately modeled.

Gaseous flows are often compressible in microdevices even at low Mach numbers. Viscous effects can cause sufficient pressure drop and density changes for the flow to be treated as compressible. In a long, constant-area microduct, all Knudsen number regimes may be encountered and the degree of rarefaction increases along the tube. The pressure drop is nonlinear, and the Mach number increases downstream, limited only by choked-flow condition.

Similar deviation and breakdown of the traditional Navier-Stokes equations occur for liquids as well, but there the situation is more murky. Existing experiments are contradictory. There is no kinetic theory of liquids, and first-principles prediction methods are scarce. Molecular dynamics simulations can be used, but they are limited to extremely small flow extents. Nevertheless, measurable slip is predicted from MD simulations at realistic shear rates in microdevices.

Much nontraditional physics is still to be learned and many exciting applications of microdevices are yet to be discovered. The future is bright for this emerging field of science and technology. Richard Feynman was right about the possibility of building mite-size machines, but was somewhat cautious in forecasting that such machines, while they "would be fun to make," may or may not be useful.

15.7 Solid Mechanics of Microdevices

C. Channy Wong, Andrew D. Oliver, and David W. Plummer

Characteristics of Surface Micromachined Devices

Advances in micromachining technology allow many engineering systems and components to be built smaller and more compact, and having less weight. A system with less weight will have a smaller inertia; thus this system can start running and stop quickly. A smaller system can also be more resistant to shock and vibration, because the strength of a system decreases as the square of its dimensions while the mass and inertia decreases as the cube of its dimensions.

Another difference at the microscale is that other forces, such as van der Waal forces, electrostatic attraction, and surface tension, can be dominant. Hence, the cause of failure can be very different, for example, (1) large frictional forces leading to more rubbing between surfaces and wearing out faster, (2) stiction an unwanted adhesion between two structural layers, and (3) excessive stress and stress gradient in the thin-film layers.

Among existing micromachining processes, surface micromachining (SMM) is very popular because micromachines built by SMM processes can be created and assembled at the same time that the constituent components are being fabricated. This batch fabrication process can minimize the assembly labor costs. However, SMM does have a disadvantage in that there is a limit on the number and types of layers available to designers. In the following discussion, our focus will be on the surface micromachined devices.

Wear

Similar to conventional machines, micromachines quite often have surfaces touching, rubbing, or impacting on each other. These generate friction and wear (see Figure 15.7.1). However, unlike convention machines, which use dissimilar materials to reduce friction and wear, thin-film layers of micromachines are usually made of the same material. Hence friction and wear become an important issue when addressing reliability of microsystems (Dugger 1999, Tanner 2000). Different lubrication methods have been investigated. Because of the extremely small gap size, liquid lubricants are difficult to apply. This leaves gas films and self-assembly monolayer films as the choices for lubrication.

Stiction

Stiction is an unintended adhesion between thin-film layers in the surface micromachined devices (see Figure 15.7.2). Two major categories of stiction have been observed: (1) stiction in the final-release process, and (2) in-use stiction. In surface micromachining, a popular final processing step is to apply aqueous chemical solution (e.g., hydrofluoric acid) to remove the sacrificial layers so that the designed

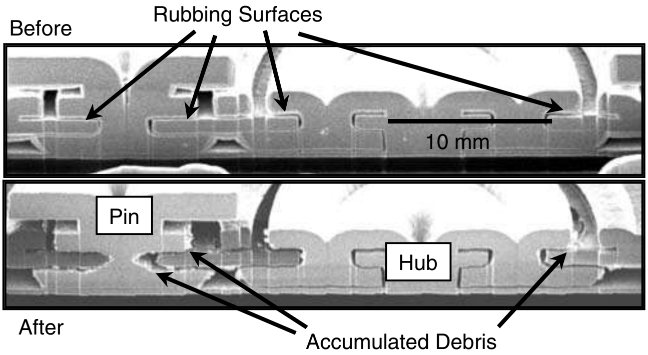

FIGURE 15.7.1 A pin joint and hub joint before and after accelerated wear. (Photograph courtesy of D. Tanner, Sandia National Laboratories.)

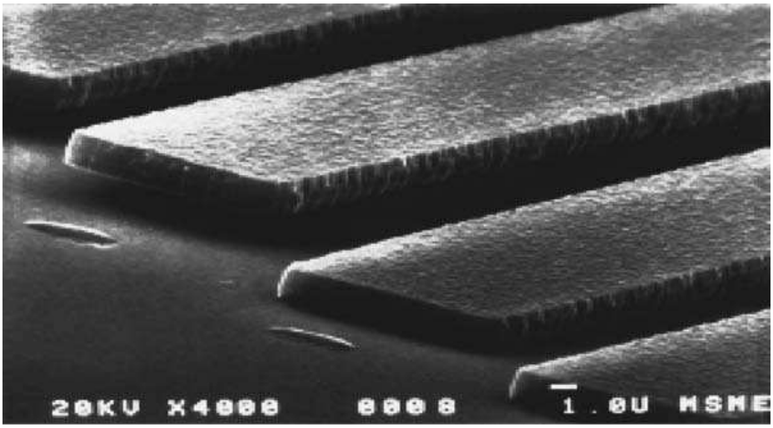

FIGURE 15.7.2 SEM picture of cantilever beams with different lengths. Sticting occurs at those beams on the left. (Photograph courtesy of Sandia National Laboratories.)

parts can move freely and perform work. However, during the release and drying process, capillary forces can pull and hold thin-film layers together and prevent them to move freely and functioning as desired.

The in-use stiction occurs when two thin-film layers unexpectedly adhere together during the normal operation. This can be caused by many factors. One explanation is that electrostatic charges are trapped and built up in the insulating materials, such as silicon nitride, after a long usage. Other factors, such as electrostatics discharge (ESD), can cause stiction as well. Stiction failure is one of the major concerns when addressing the reliability of the surface micromachined devices.

To minimize stiction and wear and to improve performance and reliability of surface micromachined devices, one popular approach is to treat surfaces by applying a hydrophobic coating. Surface treatment is an efficient and effective approach, though it is equally important to incorporate good judgments when developing and designing a microsystem. A few good engineering practices are: (1) to reduce surface area, (2) to add dimples (a small protrusion on the bottom of a structure that act to reduce the area in contact with the structure below), and (3) to increase the stiffness of structure in the out-of-plane direction. In packaging, it is essential to enclose the parts silicon dies in an environment with a dew point well below the minimum storage or operating temperature of the mechanism.

Microsystems Design Considerations

General Guidelines

In addition to the design considerations listed earlier — reducing surface areas, adding dimples, and increasing stiffness — another good practice is to always ground thin-film layers to prevent any electrostatic charge being trapped and built up in the insulating materials, such as silicon nitride, after a long usage. One approach of grounding is to use a conductive ground plane to cover any exposed insulating layers and to connect every object to ground.

Stress in Films and Stress Gradient

Stress can be developed in the thin films for many reasons. A typical source of stress is the differences in the thermal expansion coefficient between various thin films or between thin film and substrate, especially with the thin film is deposited at an elevated temperature (see Figure 15.7.3). Another source is from the doping of semiconductor films if the size of the dopant atoms is quite different from the host atoms. A significant stress buildup or a large stress gradient will lead to cracking, delamination, and/or buckling.

To relieve stresses in microstructures, a sound design practice is to use folded flexures (see Figure 15.7.4). A folded flexure helps because each flexure is free to expand or contract in the axial direction. This can minimize the stress caused by the fabrication process and by thermal expansion mismatches

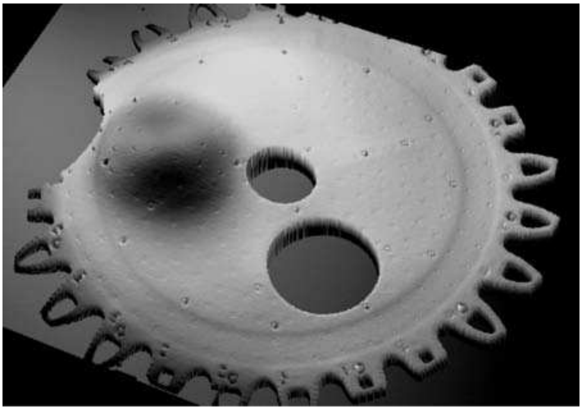

FIGURE 15.7.3 Picture showing the surface profile of a micro-optical shutter as a result of the thermal stress generated from laser spot heating. (Photograph courtesy of O.B. Spahn, Sandia National Laboratories.)

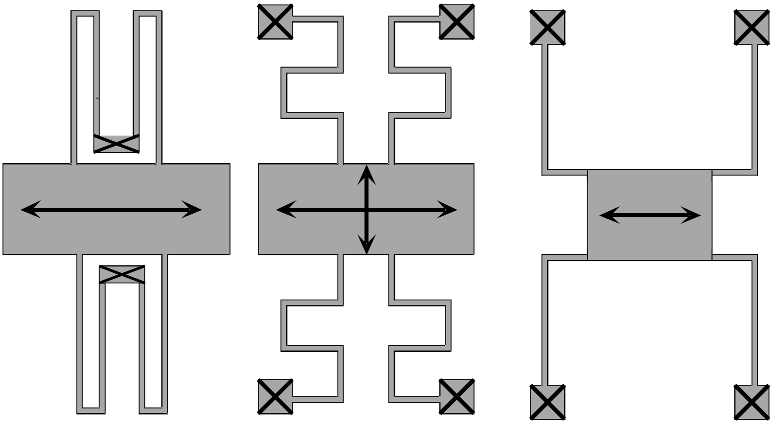

FIGURE 15.7.4 Three flexure designs. From left to right they are folded, meandering flexures, and crab leg flexures.

between the flexures and the substrate. Crab leg flexure and meandering flexure (Figure 15.7.4) can also help to relieve the residual stress in flexures.

Unavoidable stress concentration can still exist even though if we apply the design practice described earlier to help manage stress. Most unavoidable stress concentration is created by the microfabrication process. For example, etch release holes may serve as stress concentrations in plates. Sharp corners in Manhattan (right-angle) geometries can also create stress concentrations. Hence, the design engineer needs to adjust the stress calculated from the standard equations as follows:

$$\sigma_{CONCENTRATION} = K_t \sigma_{NOMINAL} \tag{15.7.1}$$

where K_t is the stress concentration factor.

Next, we will examine three typical component structures: cantilever beam springs, fixed-beam springs, and flexures, which are commonly found in the microsystems, and evaluate their mechanical responses.

Cantilever Beam Springs

For a cantilever beam with a fixed anchor on one end (Figure 15.7.5), the deformation (y) at any arbitrary point (x) is

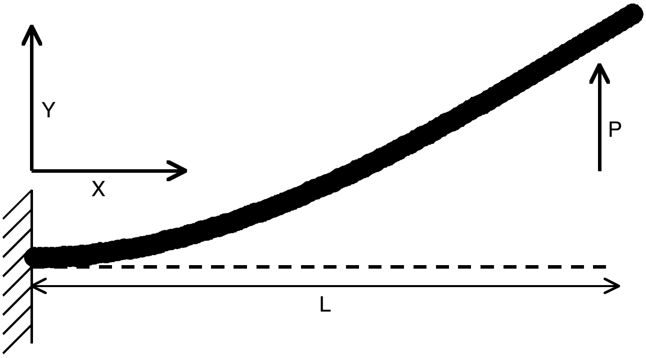

FIGURE 15.7.5 Cantilever beam spring. The deformation of the beam is due to the load "P."

$$y = \frac{P}{6EI}\left(3Lx^2 - x^3\right) \tag{15.7.2}$$

where *L* is the length of the beam, *E* is Young's modulus of the beam material, and *P* is the applied load. The maximum deflection will occur at the end of the beam:

$$y_{MAX} = \frac{PL^3}{3EI} \tag{15.7.3}$$

The maximum stress is at the fixed end where the internal bending moment is *PL*. For a rectangular cross section of thickness *h* and width *w*, the maximum stress is

$$\sigma_{MAX} = \frac{6PL}{h \cdot w^2} \tag{15.7.4}$$

The fundamental resonant frequency in Hertz (Bathe 1982) becomes

$$f_1 = \frac{3.52}{2\pi}\sqrt{\frac{EI}{\rho AL^4}} \tag{15.7.5}$$

where *E* is Young's modulus, *A* is the cross-sectional area (*h·w*), and ρ is the density.

For a microfabricated cantilever beam made of polycrystalline silicon with dimensions of 50 μm wide, 6 μm thick, and 200 μm long, the electrostatic force required to pull down the beam and touch the electrode 2 μm below is as follows:

$$P = \frac{3EIy}{L^3} = \frac{3\left(0.155\mathrm{N}/\mu\mathrm{m}^2\right)\left(900\ \mu\mathrm{m}^4\right)(2\ \mu\mathrm{m})}{(200\ \mu\mathrm{m})^3} = 105\ \mu\mathrm{N}$$

assuming that the Young's modulus for polycrystalline silicon is 155 GPa or 0.155 N/μm^2 and the density of solid polycrystalline silicon is 2.33×10^{-18} kg/μm^3. The area moment of inertia for a rectangular cross section is $I = wt^3/12 = (50\ \mu\mathrm{m})(6\ \mu\mathrm{m})^3/12 = 900\ \mu\mathrm{m}^4$.

If the beam is suddenly released, it will vibrate at the following frequency:

$$f = \frac{3.52}{2\pi}\sqrt{\frac{EI}{\rho AL^4}} = \frac{3.52}{2\pi}\sqrt{\frac{\left(0.155N/\mu\mathrm{m}^2\right)\left(900\ \mu\mathrm{m}^4\right)\left(1000\ \mu\mathrm{m}/\mathrm{m}\right)}{[2.33\left(10^{-18}\right)\mathrm{kg}/\mu\mathrm{m}^3]\left(50\ \mu\mathrm{m}\times 6\ \mu\mathrm{m}\right)\left(200\ \mu\mathrm{m}\right)^4}} = 198\ \mathrm{kHz}$$

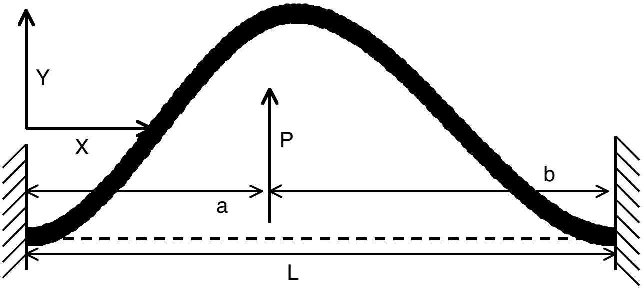

FIGURE 15.7.6 Deflection of a fixed-beam spring due to a point load. The applied load is "P," the load's location is shown by "a" and "b" on the x-axis, and the spring deflects in the direction of the y-axis.

Fixed-Fixed Beam Springs

The deflection of a fixed beam (Figure 15.7.6) at any point, $0 < x <$ a, with a point-applied load (Timoshenko 1959) is

$$y = \frac{Pb^2x^2\left[3aL-(3a+b)x\right]}{6L^3EI} \tag{15.7.6}$$

The fundamental frequency for a fixed beam (Bathe 1982) is

$$f_1 = \frac{22.4}{2\pi}\sqrt{\frac{EI}{\rho AL^4}} \tag{15.7.7}$$

The form of this equation is similar Equation 15.7.5 for cantilever beams. Note that fixing the other end of the beam increases the fundamental frequency by more than a factor of six, with the fixed-fixed beam having the same dimension as the cantilever beam.

For a beam anchored on both ends with dimensions of 50 μm wide, 6 μm thick, and 200 μm long, the force applied at the center needed to pull it down to the substrate 2 μm below is

$$P = \frac{192EIy}{L^3} = \frac{192\left(0.155\text{N}/\mu\text{m}^2\right)\left(900\ \mu\text{m}^4\right)\left(2\ \mu\text{m}\right)}{\left(200\ \mu\text{m}\right)^3} = 6700\ \mu\text{N}$$

and the resulting frequency of vibration when released is

$$f = \frac{22.4}{2\pi}\sqrt{\frac{\left(0.155\text{N}/\mu\text{m}^2\right)\left(900\ \mu\text{m}^4\right)\left(1000\ \mu\text{m}/\text{m}\right)}{\left[2.33\left(10^{-18}\right)\text{kg}/\mu\text{m}^3\right]\left(6\ \mu\text{m}\times 50\ \mu\text{m}\right)\left(200\ \mu\text{m}\right)^4}} = 1.26\ \text{MHz}$$

This illustrates that the fundamental frequency for the beam anchored at both ends is much higher than for the cantilever beam.

Flexures

Flexures can be found in many microsystems. For instance, they can be used for rotation. When a torque is applied to a flexure, it causes twisting, which creates shear stress in the element. The shear stress in a circular bar arising from an applied torque is

$$\tau = \frac{Tc}{J} \tag{15.7.8}$$

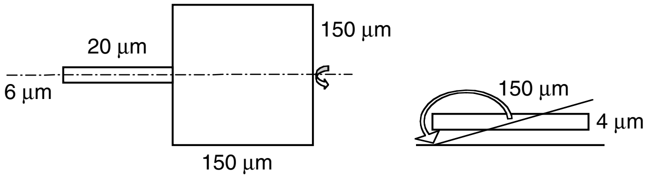

FIGURE 15.7.7 Dimensions of a polysilicon plate supported by torsional flexures.

where τ is the shear stress, T is the applied torque, c is the distance from the central axis to the point where the stress is desired, and J is the polar area moment of inertia.

For a rectangular bar, the resulting shear stress can be found as follows:

$$\tau = \frac{9T}{2wt^2} \tag{15.7.9}$$

where w is the width (larger dimension) of the flexure and t is the thickness (smaller dimension). The deflection created by the applied torque is

$$\theta = \frac{TL}{JG} \tag{15.7.10}$$

where L is the length of the flexure, G is the shear modulus, and J is polar moment of inertia. The polar moment of inertia is defined as

$$J = I_x + I_Y \tag{15.7.11}$$

Consider a 150-μm square, polysilicon plate (Figure 15.7.7), which is supported by 6 μm wide torsional flexures; the axis of rotation is through the plate's midpoint. The plate is 4 μm thick and the flexures are 20 μm long. If one edge is pulled down to the substrate 3 μm from the bottom of the plate, neglecting the deformation of the plate, the flexures are required to rotate through an angle of 2.3° for the plate to touch the substrate:

$$\theta = \tan^{-1}\left(3\ \mu\text{m} \Big/ (150\ \mu\text{m}/2) \right) = 2.3° = 0.040\ \text{rad}$$

The resulting shear stress in the flexure can be found using Equation 15.7.9, which requires us to determine J and T first.

Assuming that the shear modulus of rigidity is 0.0772 N/μm², the polar area moment of inertia for a rectangular section is

$$J = \frac{wt}{12}\left(w^2 + t^2\right) = \frac{(6\ \mu\text{m})(4\ \mu\text{m})}{12}\left[(6\ \mu\text{m})^2 + (4\ \mu\text{m})^2\right] = 104\ \mu\text{m}^4$$

The torque required to rotate one flexure through the angle θ is

$$T = \frac{JG\theta}{L} = \frac{\left(104\ \mu\text{m}^4\right)\left(0.0772\text{N}/\mu\text{m}^2\right)\left(0.04\ \text{rad}\right)}{20\ \mu\text{m}} = 1.6\times10^{-2}\ \mu\text{Nm}$$

The resulting shear stress in each flexure is

$$\tau = \frac{9T}{2wt^2} = \frac{9\times1.6\times10^{-2}\ \text{N}\cdot\mu\text{m}}{2(6\ \mu\text{m})(4\ \mu\text{m})^2} = 7.5\times10^{-4}\text{N}/\mu\text{m}^2 = 0.75\ \ \text{GPa}$$

To predict the vibration frequency, the plate-flexure system can be treated as a rigid body vibrating about a spring. The differential equation of motion for a simple mass-spring system and the associated natural frequency are as follows:

$$i\ddot{\varphi} + K\varphi = 0 \tag{15.7.12}$$

$$f_n = \frac{1}{2\pi}\sqrt{\frac{K}{i}} \tag{15.7.13}$$

where i is the mass moment of inertia (different from the area moment of inertia used to calculate stress) and K is the torsional spring rate.

The spring rate of the flexures is

$$K = \frac{T}{\theta} = \frac{JG}{L} = \frac{\left(104\ \mu\text{m}^4\right)\left(0.0772\text{N}/\mu\text{m}^2\right)}{20\ \mu\text{m}} = 0.40\ \mu\text{Nm}/\text{rad}$$

The mass moment of inertia for a thin rectangular plate vibrating about its center is

$$i = \frac{1}{12}mw^2 = \frac{\left[2.1\times10^{-13}\text{kg}\right]\left(150\ \mu\text{m}\right)^2}{12} = 3.93\times10^{-10}\text{kg}\cdot\mu\text{m}^2$$

The natural frequency is

$$f_n = \frac{1}{2\pi}\sqrt{\frac{(0.40\text{N}\cdot\mu\text{m})(10^6)\mu\text{m}/\text{m}}{3.93\times10^{-10}\text{kg}\cdot\mu\text{m}^2}} = 5.1\text{MHz}$$

Application

This section will apply the material covered in the previous section and show how to design a microsystem. A microflex mirror is used as an example.

Microflex Mirrors

The microflex mirror is a device that deforms out of plane (Garcia 1998). It can be configured as a mirror, an optical shutter, a valve, or any structure that requires a plate or beam to move out of the plane of the base substrate. Figure 15.7.8 shows an SEM photograph of the device. The design consists of a long flexible beam connected to a mirror plate that in turn is connected to two anchors via two additional flexible beams. When a force is placed on the long flexible beam in direction of the anchors, the structure is placed under a compressive force. When the force exceeds the critical value, $F_{CR} = (\pi^2 EI)/(4L^2)$, the structure buckles. Because the long flexible beam is larger in the direction parallel to the plane of the substrate than it is in the direction away from the substrate, it preferentially buckles out of the plane of the substrate. Since the plate and the two anchor beams are wider than the long flexible beam, the majority of the bending occurs in the long flexible beam and not in the plate or the anchor beams.

Consider a main beam with dimensions of 300 μm long, 4 μm wide, and 1 μm thick and that has a Young's modulus of 155 GPa, its moment of inertia will be

$$I = \frac{wt^3}{12} = 3.3\times10^{-25}\text{m}^4$$

By treating it as a cantilever beam and neglecting the buckling of the anchors and the mirror, the axial force required for a micromachined polysilicon mirror to buckle is as follows:

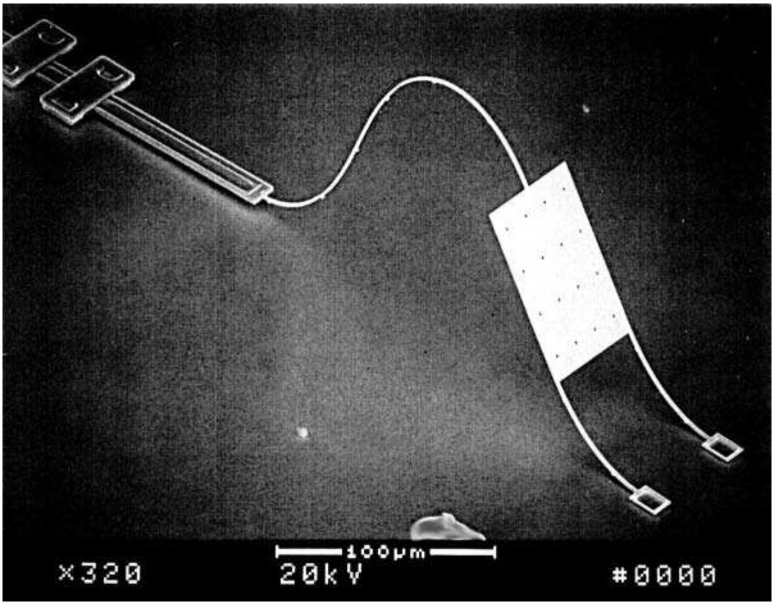

FIGURE 15.7.8 A flexible pop-up mirror that operates via buckling. (Photograph courtesy of E. Garcia, Sandia National Laboratories.)

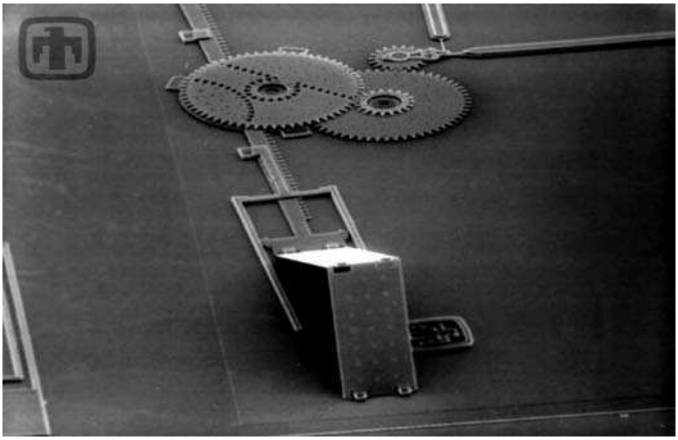

FIGURE 15.7.9 Hinged polysilicon micromirror fabricated in the Sandia National Laboratories SUMMiT process. (Photograph courtesy of Sandia National Laboratories.)

$$F_{cr} = \frac{\pi^2 EI}{4L^2} = \frac{\pi^2 \times 155\times10^9\,\mathrm{N/m^2} \times 3.3\times10^{-25}\,\mathrm{m^4}}{4\times\left(300\times10^{-6}\,\mathrm{m}\right)^2} = 1.4\ \mu\mathrm{N}$$

This analysis shows that it is necessary to have a great deal of force in order to buckle the flexible mirror. To achieve and exceed this buckling force, a transmission developed by Garcia was used to increase the force on the mirror (Garcia 1998), as shown in Figure 15.7.9. The transmission is used to trade displacement for force to ensure that the mirror buckled. The magnitude of deflection after buckling is highly nonlinear and is difficult to predict.

An interesting point about buckling is that it is hard to determine if the beam will initially buckle toward or away from the substrate. If the beam buckles away from the substrate, it will continue to deflect away from the substrate. If it initially buckles toward the substrate, it will contact the substrate and further compression of the beam will result in the structure buckling away from the substrate.

Acknowledgments

We would like to thank many of our colleagues in Microsystems Engineering Science Applications–Technology and Operation Prototype (MESA-TOP) facility at Sandia National Laboratories for their help and efforts. Many of the devices and concepts discussed in this section are due to their efforts. Sandia National Laboratories is a multi-program laboratory operated by the Sandia Corporation, a Lockheed Martin Company, for the United States Department of Energy under contract DE-AC04-94AL8500.

16.1 Introduction

Ari Rabl and Jan F. Kreider

Environmental Engineering and the Role of Mechanical Engineers

The subject of environmental science and management is vast and interdisciplinary, ranging from highly technical matters, such as the design of emission control equipment, to socioeconomic matters, such as the valuation of the impacts of pollution. The goal is to prevent or reduce undesirable impacts of human activities on the environment. Within this endeavor are several areas where mechanical engineers can make important contributions. One type of contribution concerns the design of equipment, in particular for the control of emissions; an example is an electrostatic precipitator to reduce emissions of particulates from the flue gas of a boiler or furnace. Another type of contribution concerns the modeling of the dispersion of pollutants in the environment. This chapter covers air pollution, surface water pollution, and groundwater pollution. Since space is limited and mechanical engineers are most likely to be involved in air pollution analysis and abatement projects, our emphasis is on air pollution problems.

			Impacts				
	Extent				Environment		
Burdens	**Space**	**Time**	**Climate**	**Health**	**Natural**	**Agricultural**	**Man-Made**
Greenhouse gases (CO2, CH4, N2O, ...)	G	P,F	X				
Primary air-pollutants							
Particulates	R	P		X			X
SO2	R	P		X	x	x	x
NOx	R	P		x			x
CO	R	P		x			
Toxic metals (As, Cd, Pb, Hg, ...)	R	P, F		X	X		
Toxic organic compounds (e.g., dioxins)	R	P, F		X	X		
VOC	R	P					
Secondary air pollutants							
O3 (from NO + VOC)	R	P	X	X	X	X	x
Acid rain (from NOx, SOx)	R	P			X	X	X
Nitrates (from NOx)	R	P	x	X	x	x	x
Sulfates (from SOx)			x	X	x	x	x
Liquid residues							
Toxic metals (Pb, Hg, Cd, ...)	L, R	P, F		X	X		
Toxic organic compounds (e.g., dioxins)	L, R	P, F		X	X		
COD	L, R	P, F		x	X	x	
BOD	L, R	P, F		x	X	x	
Solid residues	L	P, F		x	x	x	
Other							
Thermal	L	P			x		
Noise, odor	L	P		x			x

VOC = volatile organic compounds, COD = chemical oxygen demand, BOD = biological oxygen demand;

Impacts: X = important; x = may be important; blank = usually not important;

Extent: L = local (up to tens of kilometers); P = present generation; R = regional (hundreds to thousands of kilometers); G = global; F = future generations.

FIGURE 16.1.1 Overview of environmental burdens and major impact categories, with approximate indication of typical geographic extent and typical importance of impact.

Environmental Burdens and Impacts

Ari Rabl

As general guidance to the field of environmental engineering, it may be helpful to present the most important environmental burdens and impacts in the form of a matrix, as shown in Figure 16.1.1. Burdens, for example, the emission of a pollutant, are listed in the column on the left; impact categories are listed as a row at the top. Each element in this matrix corresponds to a specific impact of a specific burden. An X indicates that the impact from the corresponding burden is likely to be significant. Particulate air pollution, for instance, has been shown to cause a significant increase in mortality.

As an added feature we have indicated the spatial and temporal extent to the burdens. The classic air pollutants (particulates, NO_x, and SO_x) are dispersed over distances on the order of a thousand kilometers, and they affect essentially only the present generation; thus, the second and third columns show the letters R (for regional) and P (for present generation). Global warming from greenhouse gases, on the other hand, affects the entire globe and will persist over decades or centuries, hence the letters G (for global) and P, F (for present and future generations).

The classification in Figure 16.1.1 is not without ambiguities or problems. For example, we have indicated the impact of greenhouse gases as "climate change" only, even though this category includes such effects as deaths from flooding. The relative importance of impacts may change with improved scientific understanding and with the evolution of societal preferences. One should also note that the assignment of effects to causes is in many cases quite uncertain; for instance, the observed mortality from air pollution could be due to particulates or due to SO_2.

Some impacts, especially thermal pollution and noise, can be highly site dependent. The cooling water from a power plant, for instance, could damage the ecosystem of a river, or it could be used to improve the output of a fishery.

Each of the categories in Figure 16.1.1 could be broken down into subcategories:

- Health
  - Mortality
  - Injury
  - Cancer
  - Respiratory illness
- Natural environment
  - Recreational value of land (including forests)
  - Recreational value of water (including fishing)
  - Biodiversity
- Agricultural environment
  - Crops
  - Cattle (milk, meat, fur, …)
  - Wood production by forests
  - Commercial fishing
- Man-made environment
  - Functional buildings
  - Historical buildings
  - Other objects (bridges, cars, …)
  - Noise

16.2 Benchmarks and Reference Conditions

Ari Rabl, Nevis Cook, Ronald R. Hewitt Cohen, and Tissa Illangasekare

Natural Environment

Air Basins

Unpolluted air is an idealization, but its composition has been defined as indicated in Table 16.2.1. Unfortunately, measurements of truly unpolluted air were not, and can never be, made because measurement techniques and even the interest in measurements did not exist when air was unpolluted. Now even the most remote sites have mildly polluted air.

Although measurements of the undisturbed atmosphere were not made, we can gain some insight into trends of air pollutant burden growth by examining emissions. Figure 16.2.1 shows the emissions of the classical air pollutant species in the U.S. since 1940. The emissions of SO_2, PM, and VOC have been decreasing since 1970, but not those of NO_x. Note that Table 16.2.1 uses two sets of units for gaseous pollutants, one volumetric, the other mass based. To convert from one to the other, the ideal gas law is used with the result (at 1 atm and 25°C):

$$1 \text{ ppm} = \text{MW} * 40.9 \ \mu\text{g/m}^3$$

where MW is the molecular weight.

TABLE 16.2.1 Gaseous Composition of Unpolluted Air (Dry Basis)

	ppm (vol)	µg/m^3
Nitrogen	780,000	8.95×10^8
Oxygen	209,400	2.74×10^8
Water	—	—
Argon	9,300	1.52×10^7
Carbon dioxide	315	5.67×10^5
Neon	18	1.49×10^4
Helium	5.2	8.50×10^2
Methane	1.0–1.2	$6.56–7.87 \times 10^2$
Krypton	1.0	3.43×10^3
Nitrous oxide	0.5	9.00×10^2
Hydrogen	0.5	4.13×10^1
Xenon	0.08	4.29×10^2
Organic vapors	~0.02	—

Surface Water Basins

Human activity has also dramatically altered the distribution, quantity, and quality of Earth's water, especially since the industrial revolution. Accurate measurement of many water impurities, particularly trace impurities, has only become possible in the latter part of the twentieth century. Given the quantities and wide distribution of human-generated wastes delivered directly or indirectly (via atmospheric deposition or surface runoff and erosion) to water bodies, recent water quality surveys might not be representative of truly "natural" conditions. As an example, a "pristine," undeveloped alpine lake may show traces of plutonium that are residuals of 1950s through 1960s atmospheric testing of nuclear weapons. Lead from automobile emissions can be detected in the bottom sediments of the Atlantic Ocean, more than 1500 km from the nearest landmass. A tabulation of the averages and ranges of concentrations of many naturally occurring substances detected in minimally impacted waters can serve as a benchmark, admittedly imperfect, against which to compare "polluted" waters, water-quality criteria, and regulatory standards.

Choice of Reference Conditions. The authors propose, as reference conditions, the concentrations of measured impurities in the oceans, "average" rainwaters, and "average" river waters. This choice of reference waters was based on one of two distinct criteria:

1. The volume of water was so large (such as the open oceans) that human activity has had little detectable effect on average water quality conditions.
2. The waste input is small and the water body is rapidly and continuously renewed by unpolluted sources (such as a tributary to a major river).

The major and minor constituents of water and their quantities are easily presented in tables. The use of the word "major" indicates materials present or required in large quantities. Table 16.2.2 summarizes data on the constituents of selected natural waters. Note that the concentration data for major constituents (Table 16.2.2) is given in milligrams per liter and the concentration data for the minor constituents (Table 16.2.3) is given in micrograms per liter. Inclusion of boron and fluoride as major constituents is somewhat arbitrary and was based on their occurrence at greater than 1 mg/L in seawater. In these tables, individual entries are *average values* reported by U.S. regional or national surveys. *Ranges* are derived from the majority of the data from similar surveys, excluding data obtained from waters apparently contaminated by pollution. Some surveys presented results by stating that "very few" samples exceeded certain concentration values or simply reported measurements as "less than" due to analytical detection limits. These results are preceded by the symbol < in the tables. Although the data given are believed to be representative of water found in natural settings, keep in mind that, especially for industrially important trace constituents, the upper limits of the concentration ranges may include some small level of **anthropogenic** inputs.

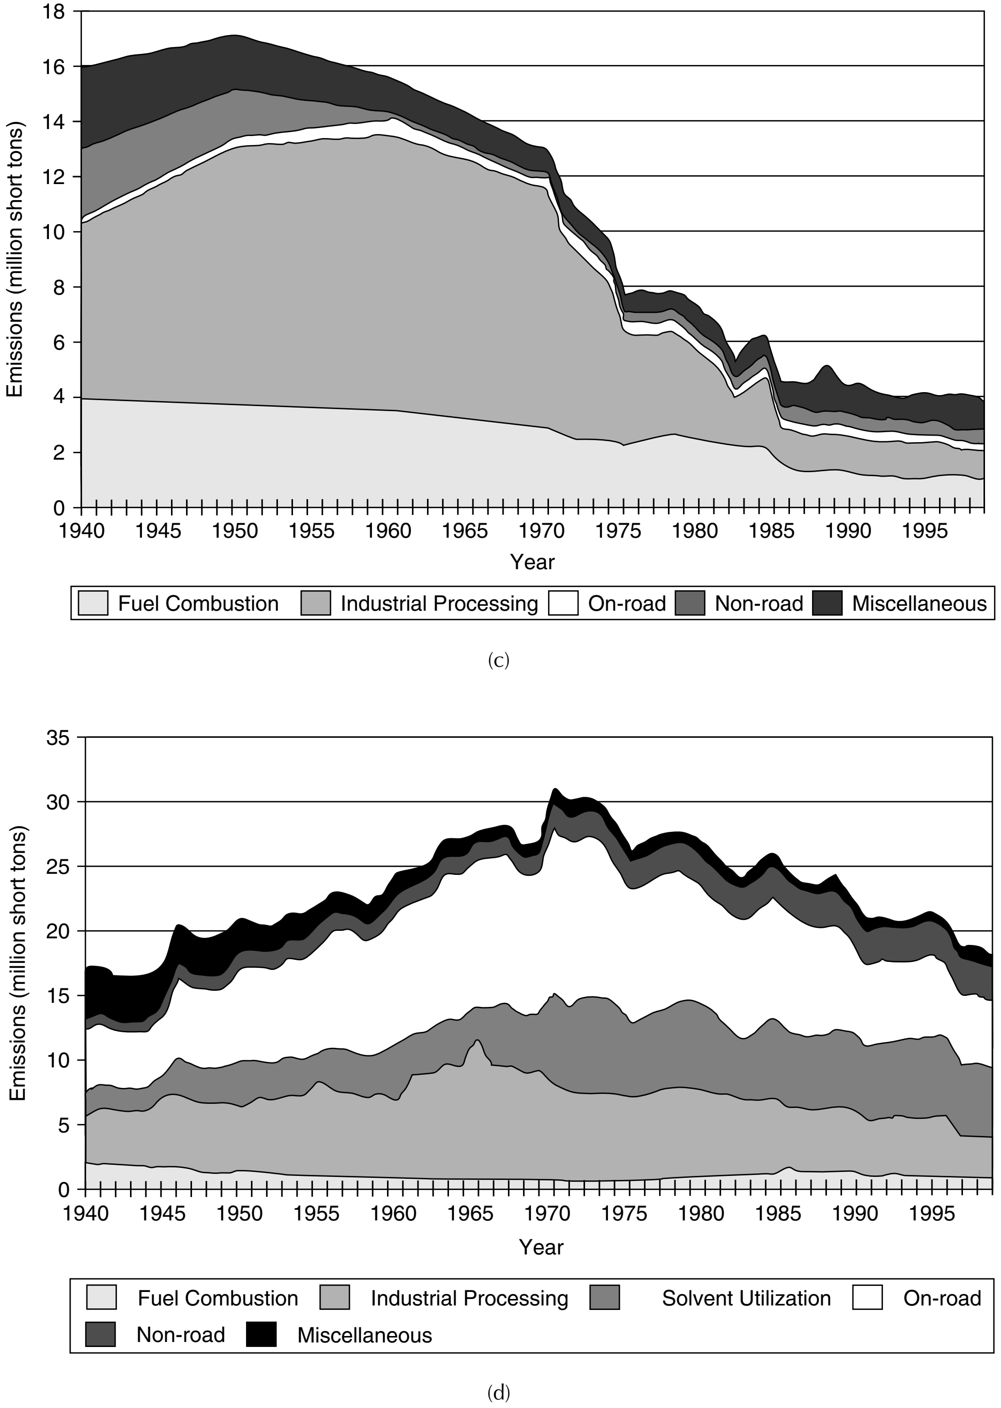

FIGURE 16.2.1 (continued).

Additional categories of natural and contaminant components of water exist. There are complex, difficult-to-characterize, organic humic materials in natural water bodies that represent the endpoint of decay of formerly living organic matter. There are synthetic chemicals by the thousands, produced currently and in the past, by the chemical industry. Some of these compounds and polymers are completely

new to the natural environment. Many are considered toxic to aquatic organisms and/or humans. For lists of contaminants considered toxic and their effluent limitations, see the many documents available from the U.S. Environmental Protection Agency (USEPA) and other sources.

Soils and Water Basin Definitions

The unconsolidated sediment that covers a comparatively thin mantle of the land surface in general is referred to as soil. Soils are complex mixtures of solid, liquid, and gases. The solid phase consists of a mineral inorganic fraction that is produced by weathering of rocks or transported material. The predominant inorganic elements are silicon, aluminum, and iron. The organic fraction consists of partially or fully decomposed products of flora and fauna. The liquid phase is the water that occupies the pore spaces between and within grains of the solid material. In its natural form, this water, which is referred to as *soil water*, contains dissolved substances introduced from the solids or transported from the ground surface. The pore spaces that are not occupied by water will be filled by water vapor, gases, and air. The complexity of soil systems derives from the fact that the mixture of the solid, liquid, and gases is very heterogeneous and that the composition of the individual phases and the mixture changes in space and with time.

The soils in their natural environment can be subjected to drastic changes not only as a result of the interaction among the solid, liquid, and gas phases but also by external factors that are controlled by pressure, temperature, and light. The physical and chemical characteristics of the changing solid phase have a significant influence on the thermal behavior, water retention and flow, adsorption and entrapment of chemicals and wastes, and transport of dissolved substances. All of these processes are important to the study, understanding, and solution of problems in environmental sciences and engineering associated with soil contamination.

The physical characteristics of soils as a porous medium are affected by the shape, size and size distribution, and arrangement of the solid phase or the soil grains. The *shapes* and *sizes* of the soil grains vary widely, from small colloids to large sand and gravel. Particles that are less than the arbitrary size of 2 μm are the clay fraction that is formed as a secondary product of weathering of rocks or derived from the transported deposits. These particles are platelike or disk shaped. The non-clay fraction formed from inert minerals and fragments of rock consists of silt, sand, and gravel. In a particle size classification used by agricultural scientists that was developed by the U.S. Department of Agriculture (USDA), non-clay particles that are in the size range 2 to 50 μm are classified as silts, in the range 50 to 2000 μm as sands, and above 2000 μm as gravel. In this classification system the sands are further divided into subgroups of very fine, fine, medium, coarse, and very coarse sands. A second system, by the International Society of Soil Science (ISSS) that is also used by agricultural scientists, classifies silts to be in the range 2 to 20 μm, fine sands 20 to 200 μm, and coarse sands 200 to 2000 μm. The American Society of Testing and Materials (ASTM) classifies colloids as particles that are less than 0.1 μm in size.

The surface area of the solid particles contained in a known volume of the soil has a significant influence on the physical and chemical processes that occur on the surfaces of the soil grains. The ratio of the internal solid surface area to the total volume is referred to as the *specific surface*. This parameter is also sometimes expressed as the ratio of the surface area to the mass of the soil grains. This parameter of the soil is affected by the size and shape of the individual soil grains. Because of the platelike or disk-shaped nature of small clay particles, clays in general have very large specific surface compared with the non-clay particles (silts, sand, and gravel). For example, the three common clay minerals kaolinite, illite, and montmorillonite have specific surfaces of 45, 175, and 800 m^2/gm, respectively (Corey, 1994). Because of these enormously large surface areas, the clay fraction in soils has a significant influence on the chemical reactive processes that are controlled by the surface area of the soil grains. The silt and sand fraction will not have a significant influence on the chemical processes, and also the smaller surface areas result in small water retention capacities as compared with clay.

The spaces between the grains that are referred to as intergranular pore spaces control the flow behavior and capacity to hold water by a soil. A physical parameter that is known as the *average porosity* or *porosity* characterizes the secondary pore space enclosed between the aggregates. The porosity of a soil sample is defined as the ratio of the volume of interconnected pores to the total volume of the sample. Soil porosity depends on many factors that include its structure, shape of soil grains, size distribution of the grains, the degree of mixing of the various-sized particles, and the way the soil grains are packed. Under conditions of normal packing, the porosities of unconsolidated sand vary in the range 0.39 to 0.41 and soil with structure in the range 0.45 to 0.55. The organic matter in soil binds the inorganic fraction to form larger aggregates. The primary pore spaces within the soil aggregate play a significant role in retardation and attenuation of dissolved chemicals that are contained in the aqueous phase.

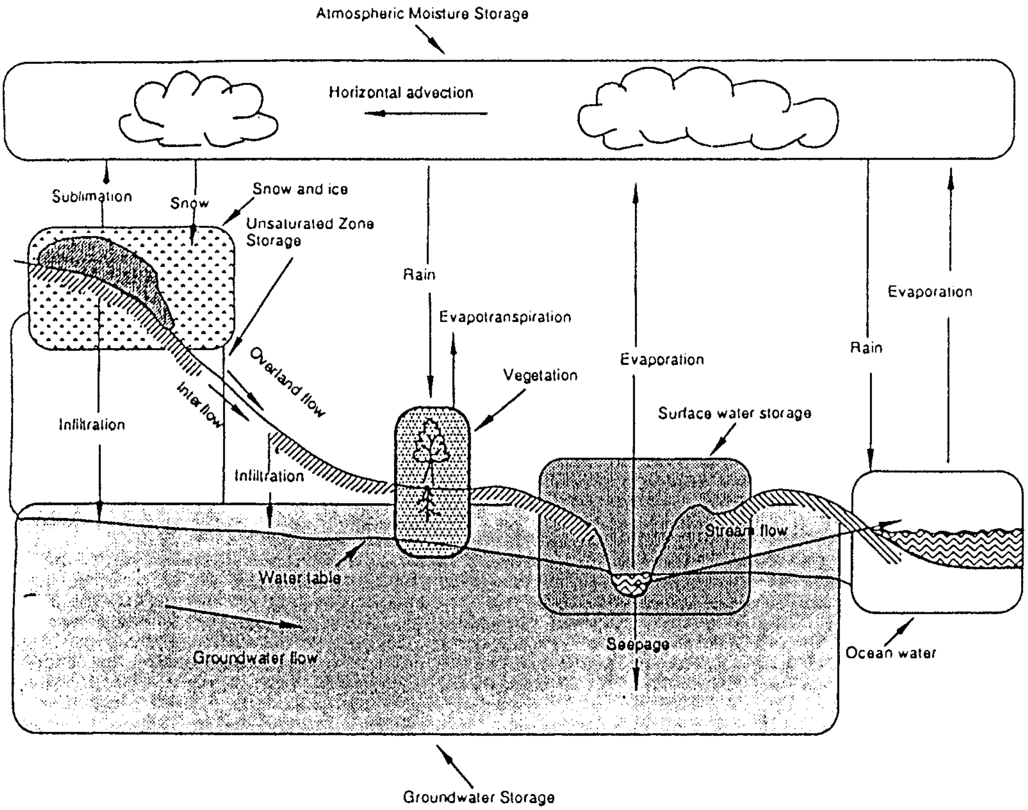

FIGURE 16.2.2 A column of Lagrangian boxes simulating atmospheric dynamics.

The subsurface soil–water environment that exists below the ground surface is divided into two zones, namely, the *unsaturated* or *vadose zone* and the *saturated zone*. In the unsaturated zone pore spaces contain both water and air. The capillary forces created by the surface tension in the water-air interfaces produce water pressures that are less than atmospheric (suction). The water flowing through the unsaturated zone is subjected to capillary driving forces in addition to the gravitational forces. In the saturated zone, the water pores are fully saturated with water and the water pressures are greater than atmospheric. The water in the saturated zone is driven by gravitational forces. The surface that separates the unsaturated and saturated zones is referred to as the *water table*. By definition, the water pressure at the water table is atmospheric. The location of the water table below the ground surface at waste and spill sites becomes critical in determination of the fate and transport of pollutants in the subsurface soil–water environment as described later. Figure 16.2.2 shows the essentials of the situation schematically.

Acceptable Levels of Pollutants

Water

Criteria vs. Standards. The *objective* of water quality control programs, for example, is to protect current or potential *beneficial uses* of water. Criteria define the specific characteristics necessary to protect such uses. Criteria are not absolute but are based on a combination of experience, current scientific knowledge, and the judgment of experts. Toxicological data for many of the water components often are limited. There may be results of tests for acute, or immediate, impact to organisms (including humans), but little

TABLE 16.2.4 Water Quality Criteria and Standards (inorganic contaminants in µg/L)

	Beneficial Use or Protection Category		
Constituent	Aquatic Life	Irrigation	Drinking Water

[a] Considered beneficial in drinking water at somewhat lower concentrations.
[b] Temperature and pH dependent; only unionized form (NH_3) is toxic to aquatic life.
[c] Secondary standards based on use impacts (tastes, staining); not health related.
[d] Controversial, based on toxicity of Ag+; rarely present in natural waters.
[e] Extremely low levels partly due to food chain bioaccumulation potential.

information on impact on reproduction, long-term health or tolerance at low concentrations, organism adaptability, acclimatization, or interaction with other substances. General criteria are intended to protect sensitive species subjected to long-term exposure and may be overly conservative in specific situations. The aquatic life column of Table 16.2.4 presents typical, continuous, maximum concentration criteria for freshwaters intended to support a variety of aquatic life. Surface water quality criteria and their relationship to permitted discharges are further discussed later in this chapter. The irrigation criteria given in Table 16.2.4 are intended to protect the yields of agricultural crops.

Due to resource limitations (time, money, data, or a shortage of knowledgeable experts), conservative criteria are often adopted as *standards*. Standards development should, however, include considerations of actual local needs and conditions, economics, technical feasibility, and the defined objectives of environmental policy. In contrast to criteria, standards are usually incorporated into laws and regulations and are often absolute. Either standards are violated or they are not.

Summarized as simple, USEPA (1979) definitions follow:

1. *Water Quality Criterion:* That concentration of a water quality measure that will meet a specific water use.
2. *Water Quality Standard:* The translation of a water quality criterion into a legally enforceable mass discharge of effluent limitation.

The drinking water column of Table 16.2.4 presents a subset of the current U.S. National Standards for drinking water supplied to the public. The health-based standards are enforceable. It should be noted that the drinking water standards list in Table 16.2.2 is not comprehensive. Maximum concentration levels (MCLs) for some inorganics, microbial contaminants, and the many regulated toxic organics have been omitted. Many drinking water MCLs are controversial because they rely on dose-response models that cannot be directly verified at the low levels of exposure that are typical.

Air

Table 16.2.5 to Table 16.2.9 summarize the current U.S. ambient air quality criteria and standards for carbon monoxide, sulfur dioxide, nitrogen dioxide, ozone, and particulate matter. These criteria represent myriad effects depending on the receptor, species of pollutant, and duration and severity of impact. These criteria are descriptive and are used for emission and air quality standards that are summarized briefly. As better data become available, these tables may change.

TABLE 16.2.5 U.S. Ambient Air Quality Criteria for Carbon Monoxide

CoHb in Blood,%	Associated Human Symptoms

16.3 Sources of Pollution and Regulations

Sources

Jan F. Kreider, Nevis Cook, Tissa Illangasekare, and Ronald R. Hewitt Cohen

Air

Air pollutants are found in the form of gases (e.g., SO_2) and particulate matter (e.g., fine dust). They are emitted into the atmosphere from natural sources (e.g., volcanoes) and *anthropogenic* sources (e.g., industrial activities). These pollutants are called "primary" because they are harmful in the form in which they are emitted. Primary pollutants may undergo chemical reactions that result in the subsequent formation of other species called "secondary" pollutants (e.g., O_3).

Air pollution is found at all spatial scales, ranging from a few meters (e.g., indoor pollution) to local, urban, regional, and global scales (Milford and Russell, 1993). *Indoor pollution* is of great concern because a large fraction of our time is spent indoors. Indoor sources of pollutants include combustion processes, aging materials (e.g., formaldehyde emitted from particleboard and plywood), and radon — a natural indoor pollutant that migrates through the soil and may penetrate and accumulate inside buildings. The *local scale* ranges from 100 m to a few kilometers. At this scale, pollution dynamics are dominated by atmospheric diffusion and the role of primary pollutants. The local scale is the one where we experience major exposure to toxic substances and flammable compounds during catastrophic and emergency releases.

The *urban scale* ranges from 10 to 100 km and is characterized by both primary and secondary pollutants. In fact, characteristic residence times are on the order of one or a few days, thus, allowing enough time for chemical transformation to play a role. Two types of urban smog are well known: the "London" smog and the "Los Angeles" smog. The former is characterized by stagnant, foggy meteorological conditions in winter that allow a buildup, over a few days, of SO_2 and particulate matter. The latter, which has become the most common type of atmospheric pollution throughout the cities of the world, is a **photochemical** smog associated with clear, sunny days. Photochemical smog is a mixture of many gaseous compounds and particulate matter, among which the two most important constituents are ozone (a colorless secondary pollutant) and fine secondary particulate matter (such as sulfates, nitrates, and organic particles), which are responsible for most of the visual haze.

The *regional scale* ranges from hundreds to thousands of kilometers (the upper regional scale is also called *continental scale*). Characteristic residence times are on the order of one week. At this scale, pollution dynamics are dominated by chemical transformation and ground deposition phenomena. Acidic deposition, often referred to as *acid rain*, is a phenomenon in which acid substances, such as sulfuric and nitric acid, are brought to Earth by dry and wet deposition. Some lakes are very sensitive to acidic deposition because of their limited buffering capacity. *Global air pollution* is characterized by relatively unreactive compounds, such as CO_2, methane (CH_4), and chlorofluorocarbons (CFCs). The long lifetime of these pollutants allows their global dispersion and accumulation.

Air pollution at any scale creates several adverse effects. Air pollution can just be a nuisance (e.g., odors) or be aesthetically offensive (e.g., visibility impairment). Some adverse effects, however, are of fundamental importance to the welfare of the population and public health. For example, many pollutants cause respiratory effects; some pollutants have mutagenic effects; others have shown carcinogenic effects; some pollutants also have synergistic effects (e.g., the damage of SO_2 to the human respiratory system can be greatly enhanced by the presence of fine particles).

In the rest of this chapter, an overview is presented of analytical and numerical techniques for simulating air pollution phenomena. Air quality modeling is an essential tool for most air pollution studies today. Models can be divided into **deterministic** models, based on fundamental mathematical descriptions of atmospheric processes, and statistical models, based on semiempirical relationships extracted from data and measurements. Deterministic models, in particular, have become a major tool in providing

TABLE 16.3.1 Sources of Water Pollution vs. Contaminant Emission Categories

	General Emissions Type or Category

Notation: BOD = biochemical oxygen demand; TSS = total suspended solids; TDS = total dissolved solids; synthetic organics = synthetic organic compounds; volatile organics = volatile organic compounds; metals = industrial metals; pH = high (alkaline) or low (acid) pH

objective assessment of air pollution scenarios and evaluating the effectiveness of different air pollution control measures. In fact, only deterministic models provide an unambiguous assessment of the fraction of responsibility of each pollution source in each receptor area, thus allowing the definition and implementation of the most cost-effective cleanup strategy. Statistical models, instead, are useful in situations where deterministic models do not perform well, for example, for real-time forecasting of air pollution episodes.

Waterborne

Table 16.3.1 summarizes important sources of surface water pollution species by economic or technical sectors of the U.S. economy. An X indicates a key source, and no entry indicates a second-order effect at most. Table 16.3.2 lists groundwater pollution sources by cause, extent, and waste type.

Soil and Groundwater

Various waste products and chemicals are generated from industrial, agricultural, commercial, and domestics activities. Unmonitored and uncontrolled long-term application on the land, accidental spillage, and improper storage and disposal result in these chemicals and wastes acting as potential sources of soil and groundwater contamination. LaGrega et al. (1994) use an engineering classification system in which hazardous wastes are grouped under six categories, namely, inorganic aqueous waste, organic aqueous waste, organic liquids, oils, inorganic sludges/solids, and organic sludges/solids. In addition to these, pathogens and nuclear wastes act as sources of contamination. As most of these materials are fully or partially soluble in water, they ultimately will contaminate the water phase contained within the soil pores and the water passing through the soil both in the unsaturated and saturated zones of the subsurface. Figure 16.3.1 shows in schematic form how groundwater pollution occurs.

Inorganic aqueous wastes generated from manufacturing activities involving galvanizing, metal finishing, electroplating, and so forth mostly contain acids, alkalis, or concentrated solutions of inorganic wastes such as heavy metals. Organic aqueous wastes are liquids that primarily contain mixtures of dilute concentrations of organic substances such as pesticides. Organic liquid wastes are complex mixtures or concentrated solutions of **organic compounds**. A common example of organic liquid wastes is halogenated solvents that are used in metal degreasing. Most of the oily wastes are derived from petroleum.

TABLE 16.3.2 Groundwater Pollution Sources in the U.S.

Source	Cause	Extent	Chemical/Wastes
Underground storage tanks	Hole due to internal and external corrosion leaks chemical into soil and groundwater	2.5 million 47 states, 35% of 800,000 fuel tanks leaked	Gasoline, oil, hazardous chemicals, waste products
Landfills	Rainwater leaching chemicals to groundwater	2,395 open dumps 24,000–36,000 closed or abandoned landfills 75,000 on-site industrial landfills 12,000–18,000 municipal landfills containing hazardous wastes	Garbage and trash, sludge, incinerator ash, foundry waste, hazardous substances
Surface impoundments	Direct infiltration to the saturated zone of aquifer	180,000 waste impoundments (1982) 37,000 municipal, 19,400 agricultural 27,912 industrial 25,000 mining 65,688 brine pits for oil and gas Industrial sites evaluated 95% within 1 mile of drinking wells, 70% unlined, 50% on top of aquifers	Settling ponds from municipal wastewater and sewage treatment, animal feed lots and farms, oil and gas industries, mining, paper, chemical operation
Waste-disposal injection wells	Direct dumping through wells to aquifers	Groundwater contamination in 20 states Millions of tons through thousands of wells	Toxic, hazardous, radioactive, metals, wood preservatives, petroleum
Septic systems	Surfacing and flooding due to failure; leaching into aquifers	22 million in U.S. 0.5 million installed every year 30% of population served	Variety of organic and inorganic compounds, fecal coliform, nitrates and nitrites, trichloroethylene, benzene, and methylene chloride
Agricultural waste	Leaching through unsaturated zone to groundwater	50,000 pesticides with 600 active ingredients 10 million t of nitrogen	Nitrates, salts, dissolved solids
Land application	Leachates reaching groundwater	Major threat to groundwater in 20 states 40% of hazardous wastes in California treated by land farming	Heavy metals, toxic chemical, nitrogen, pathogens
Radioactive contaminants	Potential migration to groundwater	Massive production of radioactive isotopes after World War II	Uranium, plutonium

Source: Bedient, P.B., Rifai, H.S., and Newell, C.J. 1994. *Ground Water Contamination: Transport and Remediation*, Prentice Hall, Englewood Cliffs, NJ, 541.

Oils are used as fuels, lubricating oils in engines, and cutting oils in manufacturing. Inorganic sludges/solids wastes are produced from wastewater treatment, smelters, coking, and metal fabrication. Tars and sludges that are produced from manufacturing activities are some examples of wastes that are in the form of organic sludges.

Waste materials and chemicals are released to the soil and groundwater from various sources. The most common sources are leaking underground chemical storage tanks, septic tanks, municipal landfills, industrial landfills, surface impoundments, and abandoned hazardous waste sites. In addition, injection wells, regulated hazardous waste sites, land application, road salting, saltwater intrusion, and oil and gas brine pits contribute to soil and groundwater contamination.

The most frequent use of underground tanks is for storage of gasoline in service stations. Hazardous wastes and chemicals and oils are also stored in buried tanks at industrial sites, farms, and homes. The potential for leakage exists when these tanks corrode internally or externally. In addition, chemicals can leak from pipe joints or holes in the pipes that are connected to the tanks.

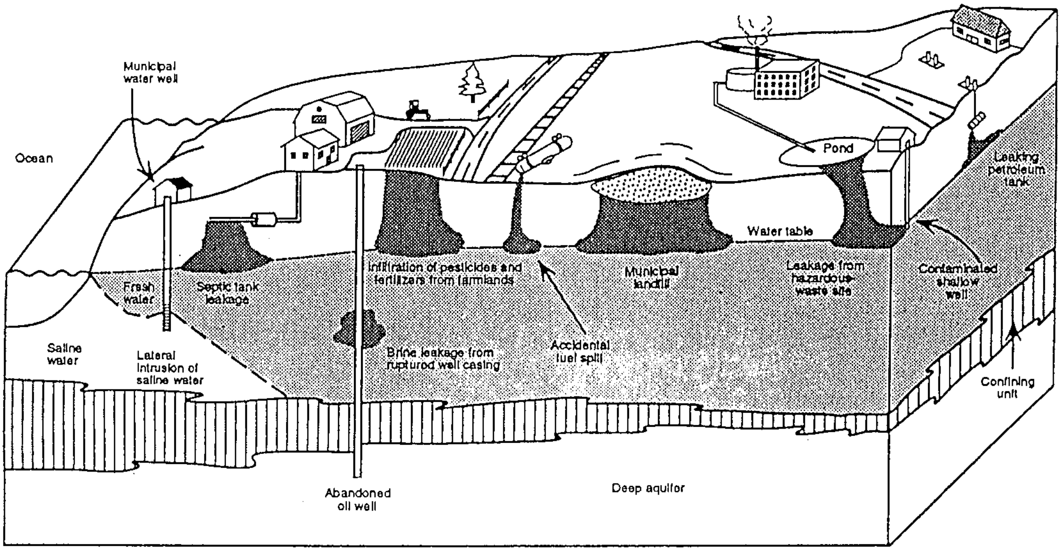

FIGURE 16.3.1 Mechanisms of groundwater contamination. (From Fetter, 1993.)

Older landfills that were not properly designed for containment of liquids or leachates were used to dispose of garbage, sludges from wastewater treatment plants, construction wastes and debris, incinerator ash, waste from foundries, and many other industrial and domestic hazardous and nonhazardous waste products. The chemicals in the landfill become a source of contamination when rain or surface water infiltrating through the landfill produces leachate. These leachates containing the dissolved constituents of the waste eventually contaminate the underlying soil and groundwater. Modern well-designed landfills have synthetic liners and leachate-collection systems.

Surface impoundments in the form of open pits, lagoons, or ponds are designed to accept liquid wastes or mixed solids and liquids. The chemical wastes in these temporary storage sites are treated and discharged or allowed to evaporate or infiltrate into the ground. In addition, to store and dispose of wastewater and products from sewage treatment, surface impoundments are used in paper, mining, and oil and gas industries. They are also used in farms and large feed lots. In unlined impoundments, the liquids leak, and when undetected, can result in soil and groundwater contamination in large zones of the subsurface.

Because of the large number of septic tanks that are in operation in homes, small businesses, service stations, laundries, and industry, septic tanks have become a major source of soil and groundwater contamination. When these systems fail, the sludges or septage floods the drainage field and leachates that are generated act as a source of contamination. The discharges from septic tanks contain many organic and inorganic chemical products, suspended solids, fecal coliform, pathogenic bacteria and viruses, nitrates, and nitrites. Industrial septic systems used in commercial operations discharge hazardous waste chemicals that include synthetic organics (e.g., trichloroethylene, tetrachloroethylene, toluene, etc.) and heavy metals (e.g., lead, copper, and zinc).

Injection wells that are drilled into deep aquifers or aquifers that are not used for water supply are used to discharge liquid wastes into the subsurface. Large volumes of toxic, hazardous, and radioactive wastes that are generated in chemical, petroleum, metals, mining, and wood-treatment industries are disposed of using this method. The contamination of aquifers that are used for drinking water can occur when the injection wells are not designed properly and are placed in formations where the hydrogeolgic conditions are not well known or understood.

Many types of agriculture-related activities use chemicals and produce wastes that contaminate soil and groundwater. Among these products are pesticides, fertilizer, and feed lot waste. Various types of pesticides are used in farming, golf courses, gardens, and parks to control insects and weeds. Many of the modern-day pesticides are biodegradable, but some of the stable ones are carried by rain and irrigation water through the soil to the groundwater. Fertilizers primarily contain nitrogen, potassium, and phosphorus. Because of comparatively high mobility in soil, nitrogen leachates are the primary contaminant of concern that is associated with application of fertilizers. Waste generated at large feed lots can introduce nitrogen, bacteria, and salts to the underlying aquifers. In addition to these sources, the salts that are accumulated in soils from long-term application of irrigation water act as a source of soil and groundwater degradation.

In a treatment and disposal method known as land treatment, the wastewater and sludges that are generated from treatment plants and industrial operations are directly applied on the ground surface. Contamination of the soil and groundwater occurs when heavy metals, toxic chemicals, nitrogen, and pathogens leach through the unsaturated zone.

Another source of soil contamination is the radioactive wastes that are produced in the weapons and nuclear industries. These wastes are primarily associated with the elements uranium and plutonium. The ionizing radiation in the form of alpha and beta particles and gamma rays are damaging to human and animal life. As these contaminants follow a first-order exponential decay law, they remain hazardous for very long time periods, on the order of hundreds to thousands of years. Table 16.3.2 summarizes several of the key sources of groundwater pollution, their extent, and the major associated pollutants.

Pollutant Monitoring

Jan F. Kreider and Tissa Illangasekare

Groundwater

Contaminants that are released to the aqueous phase from the soil or external sources move with the flowing groundwater creating a solute plume. Monitoring the groundwater flow velocity and the propagation of the solute plume is necessary to design schemes and strategies to protect the quality of groundwater that is used for drinking.

Monitoring wells are installed in aquifers to measure water pressure and to sample groundwater water quality. Wells in general consist of a standpipe with a screened interval. The screened interval allows for the aquifer water to flow into the well pipe. The water pressures are used to determine the head gradients, which in turn can be used to estimate the magnitude and direction of groundwater flow. Water samples that are collected at monitoring wells can be used to obtain information on the quality of groundwater.

Piezometric head is the sum of pressure and the elevation heads. The pressure head at any point in the aquifer intercepted by the screen is the height of the water surface in the well bore (or standpipe) above the point on the screen. The elevation head at a point is the elevation of the point above or below a datum. The gradient of the piezometric head determines the magnitude and direction of groundwater flow. By measuring the piezometric heads at many monitoring wells, it is possible to draw the contour lines of equal piezometric head or potential. A flow net is obtained by constructing a set of flow lines that are orthogonal to the equipotential lines. The groundwater flow direction at a point is determined by drawing a tangent to the flow line passing through the point. By constructing the flow net so that the intersection of equipotential lines and the flow lines form curvilinear squares, it is possible to estimate the groundwater flow velocities and discharge in an aquifer. The monitoring well data can also be used to calibrate a groundwater model that then can be used to estimate and monitor groundwater flow.

Groundwater samples collected from monitoring wells can be analyzed in the laboratory to determine the chemical contents. Probes can be inserted into the monitoring wells for the in situ measurement of conductivity and pH.

Process Emissions Monitoring. Methods and instrumentation for the monitoring of industrial waste discharge streams are discussed in detail in the *USEPA Handbook for Sampling and Sample Preservation of Water and Wastewater.* ASTM publishes a frequently updated *Annual Book of ASTM Standards* that extensively details recommended sampling techniques.

The topic of sampling is complex and includes sampling timing and frequency; sample preservation (until analyses can be done); sample preprocessing (i.e., filtering to separate particulate and dissolved components); questions of whether waste streams are continuously monitored for particular environmental variables or whether discrete samples are taken; whether a single "grab" sample is taken or a series of samples in time or space are retrieved and combined into a single "representative" sample; whether there is a single, worker-sampled, grab sample of an automated, continuous sampling apparatus; and whether there is retention of volatile compounds for later analysis. Additionally, there are issues of laboratory analytical techniques, quality control, and quality assurance from the moment of sampling through the reporting of the data, acceptable detection limits, sample contamination, and materials used to sample particular chemicals. The only way to account for all these variables is to know thoroughly the data-reporting requirements of the industrial discharge permits or agreements. Also, the objectives of the sampling and the compounds of concern will dictate the entire structure of the sampling regime. The authors will discuss, briefly, some of these topics.

The ideal characteristics of a process waste discharge stream for monitoring are steady, uniform flow that is chemically homogeneous throughout the cross section. Under such conditions, several grab samples over the day may yield representative results. In many industries, the waste streams vary due to process switching, change of shifts of workers, and cleaning and preparation of process equipment and machinery. Several specified times a day a local beer brewery flushes process wastes from the floor using high-pressure hoses. Occasional grab sampling might miss completely this pulse of waste load to the treatment system. There are continuous sampling devices that take a grab sample at specified time periods, and then rotate to another sample bottle in preparation for the next sample. There are more sophisticated samplers that draw in a sample at timed intervals proportional to stream discharge. Often, the type and frequency of discharge sampling is specified in the discharge permit. For best results, the sampling planner or coordinator should know the plant operation cycles in order to be able to characterize the time variation of discharges.

The material of which a sampling device and storage vessel is constructed must be matched to the materials sampled. Some organics require the use of tetrafluoroethylene (Teflon) tubing and glass storage vials that have been washed with an organic-free cleanser. Using the wrong tubing may result in the leaching of plasticizers into the sample. It is recommended that metal sampling devices *not* be used for collection of metal-laden discharge samples that require later analysis for metal ions. Samplers must be washed between samplings to avoid sample cross-contamination.

Environmental Quality Monitoring. Most of the mechanics and issues of sampling we just discussed for monitoring discharges hold true for environmental sampling, that is, after the discharge has entered a stream or lake. Detailed sampling plans must be prepared. Existing data is gathered (from company files; land-use maps; USEPA; U.S. Geological Survey gauging and water quality station results; state departments of environment, resources, and health; and other federal and local agencies). It helps to have site characteristics prior to the inception of the waste discharge.

The data collection for environmental monitoring often is governed by legal considerations concerning the validity and admissibility of the data. To this end, a quality assurance/quality control (QA/QC) plan must be prepared according to USEPA or state guidelines. These plans will specify the frequency of taking duplicate samples (taken at approximately the same time and place), split samples (one sample is split into two, separate containers), spiked samples (an additional injection of chemicals anticipated to be in the environmental sample are added to a duplicate sample, and the recovery of that known amount of spike is reported). A good QA/QC operation will ensure that the best effort is being made to

1. Obtain representative samples.
2. Use appropriate sampling methods.
3. Use appropriate analytical methods.
4. Ensure adequate records of chain of custody of samples.
5. Develop a sound and acceptable database.

The USEPA can be contacted to send *Interim Guidelines and Specifications for Preparing Quality Assurance Project Plans* (or QAPPS — pronounced "kwaps").

Other documents that may be required include

1. Sampling plans.
2. Site background information.
3. Planned sampling locations.
4. Planned sampling methodology and sample preservation. (Some chemicals decay on exposure to light, microbes may induce decomposition of organic compounds at ambient temperatures, chemically reduced compounds may oxidize on exposure to a head space of air, volatile compounds may escape from an insufficiently sealed vial, solid materials may dissolve, or dissolved materials may precipitate.)
5. Health and safety plans.
6. Plans for sample-handling procedures and chain of custody of samples.
7. Request forms for sample analyses.
8. Frequency and format of data reports.

Air Quality Monitoring

Air quality monitoring has many of the same goals and general techniques as water quality monitoring. A stationary monitoring network should yield the following information:

1. Background concentration
2. Highest concentration levels
3. Representative levels in populated areas
4. Impact of local sources
5. Impact of remote sources
6. Relative impact of natural and anthropogenic sources

Spatial scales range from micro- (up to 100 m) to regional scales (tens to hundreds of kilometers). Site selection is a key part of network design because microclimates can affect readings and cause them to be nonrepresentative of the region.

Mobile monitoring is useful when sites not monitored with the fixed network need assessment. The key drawback of such systems is the scarcity of equipment suitable for reliable and durable mobile monitoring. Remote sensing offers a second alternative to stationary networks.

Quality assurance is a continuous concern of monitoring systems. Good instrumentation installation and maintenance practice along with careful record keeping is essential.

Space precludes presentation of further details on air quality monitoring, but Boubel et al. (1994) has a thorough overview.

16.4 Regulations and Emission Standards

Water

Nevis Cook and Ronald R. Hewitt Cohen

The Clean Water Act (CWA) of 1972 and its amendments establish the framework of current U.S. water pollution control. This act is sometimes referred to as the Federal Water Pollution Control Act Amendments after the original 1965 act, which the CWA amended. The objective of the CWA is to "restore and maintain the chemical, physical, and biological integrity of the nation's waters." The CWA regulates both nonpoint (runoff from farmlands, roads, and city streets) and point sources (discharges from pipes conveying pollutants to surface waters) of water pollution. The discussions in this chapter are limited to regulation of point sources of pollution to *surface* waters. Discharges to groundwaters are regulated under the Safe Drinking Water Act (SDWA) underground injection control (UIC) program and are beyond the scope of this chapter. The discussion is still quite broad, since all domestic and industrial wastewater discharges are considered point sources under the CWA.

Discharge Permits. The CWA prohibits point source discharges to surface waters unless a *discharge permit* is obtained. Permits typically are issued at the state level and are known as state pollution discharge elimination standards (SPDES) permits. If the state has not taken over this responsibility, national (NPDES) permits are issued by the USEPA. The permit for each point source prescribes allowable discharges in terms of amount and concentration of flows and pollutants. In some cases, an industrial facility may avoid obtaining its own permit by discharging into the local public sewer system. Control of these *indirect discharges* is accomplished by requiring publicly owned treatment works (POTWs) receiving such discharges to enter into formal *pretreatment agreements* with industrial users of the sewer. Such pretreatment agreements are intended to prevent industrial discharges to POTWs, which would represent a hazard to the sewer system or its workers, interfere with treatment operations or sewage sludge disposal, or pass through the treatment process, causing a violation of the POTW discharge permit.

Permitted Discharges. Prior to the CWA of 1972, point source water pollution control laws were established at the state level and permitted discharge of pollutants on a discharger-by-discharger and water body-by-water body basis. This approach worked poorly in most states, demonstrating the need for enforceable *federal minimum effluent standards*. For this reason, the CWA and subsequent amendments have established *technology-based* national minimum pretreatment and discharge standards. Technology-based standards reflect the current state of the art with respect to controlling specific pollutant discharges from specific pollution sources. Since technology-based standards represent the capabilities of typical "well-operated" facilities and are not issued on the basis of in-stream water quality, it is not surprising that in some cases compliance with national minimum standards does not adequately protect all potential uses of a water body. In such cases the uses of the receiving water body are said to be *water quality limited*, and *local discharge limits*, more stringent than national limits, may be imposed. In addition, pretreatment agreements reflect the capabilities of local treatment works with respect to pass through, destruction, or partitioning of nondegradable toxic metal pollutants into POTW sludges. Following the development of local water quality–based limits, these are compared with national minimum technology-based standards and the more restrictive criteria are imposed as discharge permit or pretreatment limitations. Further considerations with respect to setting permit values are presented next.

Industrial dischargers may obtain an industrial NPDES permit and directly discharge wastewater to a receiving water body. Alternatively, where municipal sewer service is available, industries may choose to negotiate a pretreatment agreement with the local sewer authority permitting discharge of industrial wastewater to the sewer system. Most industrial facilities employing either discharge option (direct or indirect) are subject to national technology-based minimum effluent standards. In addition, more stringent standards may be imposed at the state or local level.

State permits containing discharge constraints more stringent than the national minimum standards are commonly derived from local water quality considerations. Ideally, local water quality–based standards are developed from science-based use protection criteria, wastewater flow data, and actual receiving water characteristics (such as low-flow conditions for streams). Rational direct discharge permits to streams or rivers can be developed by application of the following procedure: convert use-based, in-stream quality criteria to standards according to local policy; obtain data on upstream water quality and low-flow conditions (conditions at which the waste assimilative capacity of a stream is at a minimum) and determine potential for dilution of the wastewater flow by the receiving water body; compute the allowable water quality–based industrial discharge on a pollutant-by-pollutant basis and compare with national minimum standards; and finally, impose permit restrictions according to the most stringent of the two types of standards developed.

Development of water quality–based permits for direct discharges to lakes, estuaries, bays, or oceans follows a procedure similar to that just outlined. However, estimates of mixing patterns and the dilution

TABLE 16.4.1 U.S. Federal Primary and Secondary Ambient Air Quality Standards

				Concentration	
Pollutant	Type of Standard	Averaging Time	Frequency Parameter	$\mu g/m^3$	ppm
Sulfur oxides (as sulfur dioxide)	Primary	24 hr	Annual maximum	365	0.14
		1 year	Arithmetic mean	80	0.03
	Secondary	3 hr	Annual maximum	1,300	0.5
Particulate matter <10 µm	Primary and Secondary	24 hr	Annual 99th percentile	150	—
		24 hr	Annual arithmetic mean	50	—
Particulate matter <2.5 µm	Primary and Secondary	24 hr	Annual 98th percentile	65	—
		24 hr	Annual arithmetic mean	15	—
Carbon monoxide	Primary and secondary	1 hr	Annual maximum	40,000	35.0
		8 hr	Annual maximum	10,000	9.0
Ozone	Primary and secondary	1 hr[1]	Annual maximum	235	0.12
	Primary and secondary	8 hr[2]	Three-year average of 4th highest daily maximum	15	0.08
Nitrogen dioxide	Primary and secondary	1 year	Annual arithmetic mean	100	0.053
Lead	Primary and secondary	3 months	Quarterly arithmetic mean	1.5	—

[1] Will be phased out in favor of eight-hour standard after three years of compliance with one-hour standard.

potential of these water bodies are likely to be more difficult because of the complex flow patterns involved. Water quality–based pretreatment standards for discharges to sewers also follow the same general procedure. However, in this case, the application of use criteria, policy, and potential for in-stream dilution lead to a pollutant-by-pollutant permit for the *local* POTW. Based on this permit and the removal capabilities of the treatment facility, maximum allowable (usually daily) loading of pollutants arriving at the plant is determined on a pollutant-by-pollutant basis. Allowable loads are then allocated to the various municipal and industrial users of the sewer. Setting water quality–based pretreatment standards is obviously complicated by the presence of multiple sewer uses and users. Thus, POTWs receiving significant industrial discharges are required to set up formal programs to negotiate industrial pretreatment agreements and monitor compliance.

Air

Jan F. Kreider

The U.S. Clean Air Act Amendments of 1977 set forth two air quality standard types:

- Primary (to protect health)
- Secondary (to protect health and prevent other adverse impacts)

Table 16.4.1 summarizes the present primary and secondary standards in the U.S. The amendments also specified for certain geographical areas further standards to prevent significant deterioration (PSD areas). These are standards that are to be considered increments over baseline air quality but are more stringent than secondary or primary standards in most cases. Table 16.4.2 lists these PSD standards.

16.5 Mitigation of Water and Air Pollution

This section discusses the methods for abating or mitigating air and water pollution burdens on the environment. Because mechanical engineers are most concerned with air pollution control systems and civil engineers deal with water treatment systems, this section emphasizes the air pollution mitigation side.

TABLE 16.4.2 U.S. Federal PSD Concentration Increments

Pollutant	Increment ($\mu g/m^3$) Class I areas	Class II areas	Class III areas
Particulate matter			
TSP, annual geometric mean	5	19	37
TSP, 24-hr maximum	10	37	75
Sulfur dioxide			
Annual arithmetic mean	2	20	40
24-hr maximum	5	91	182
3-hr maximum	25	512	700
Nitrogen dioxide			
Annual arithmetic mean	2.5	25	50

Overview

Jan F. Kreider

There are several methods for controlling air- or waterborne pollution:

- Process change
- Fuel change
- Pollution removal and disposal
- Pollution prevention

Process change includes everything from modifications that reduce emissions to substitution of a less polluting one for a more polluting one. The latter could be classified as pollution prevention, described shortly. In many cases, for example, in the steel industry, it has proved most economical to replace completely old plants with totally new ones. Likewise, complete substitution has been widely adopted in the pulp and paper industry.

Fuel change as a control strategy is based on the fact that airborne pollutants often are related to the combustion aspects of a process. For example, coal-fired power plants emit SO_2 because coal contains sulfur. Substitution of natural gas for coal eliminates any sulfur in the fuel and, therefore, any oxides of sulfur in the stack gases.

Fuel changes must consider fuel supply, capital cost, and competition for clean fuels among many industries before an engineering design decision can be made. Life-cycle methods that consider all parts of the life of a plant are necessary. For example, a nuclear power plant may produce very low emission electricity but after decommissioning may cause long-term waste disposal problems.

Pollution removal is necessary when process or fuel changes cannot provide adequate emission control. A physical, chemical, or electrical feature of the pollutant to be removed must differ from those types of characteristics of the carrying gas or liquid stream. An example is a baghouse or electrostatic precipitator for particulate emissions. Not only collection of pollutants but also disposal of the collected pollutant must be considered by the design engineer. A whole systems viewpoint is necessary for a successful pollution removal design.

Pollutant disposal is governed by different criteria depending on whether it is hazardous. Hazardous waste disposal is covered by the Resource Conservation and Recovery Act of 1976, which established the Office of Solid Waste with the USEPA. On the other hand, nonhazardous waste disposal is governed by the states. Table 16.5.1 categorizes the ultimate disposal methods for classes of hazardous wastes. Many of the methods apply for nonhazardous wastes as well.

Pollution prevention is the ultimate solution to abatement. This can be accomplished at the source by various technical means, depending on process specifics. This approach is currently the most commonly used term by the USEPA. The Pollution Prevention Act of 1990 provides these policies:

- Prevent or reduce pollution at the source whenever possible.
- Recycle to the environment pollution that cannot be prevented in a safe manner whenever possible.

TABLE 16.5.1 Ultimate Waste Disposal Methods

Process	Purpose	Wastes	Problems (Remarks)
Cementation and vitrification	Fixation Immobilization Solidification	Sludges Liquids	Expensive
Centrifugation	Dewatering Consolidation	Sludges Liquids	—
Filtration	Dewatering Volume reduction	Sludges Liquids	Expensive
Thickening (various methods)	Dewatering Volume reduction	Sludges Liquids	—
Chemical addition (polyelectrolytes)	Precipitation	Sludges	Can be used in conjunction with other processes
	Fixation		
	Coagulation	Liquids	
Submerged combustion	Dewatering	Liquids	Acceptable for aqueous organics
	Major Ultimate Disposal Methods		
Deep well injection	Partial removal from biosphere Storage	Oil field brines; low toxicity, low-persistence wastes; refinery wastes	Monitoring difficulty; need for special geological formations; groundwater contamination
Incineration	Volume reduction Toxicity destruction	Most organics	If poor process control, unwanted emissions produced Can produce NO_x, SO_x, halogen acids
Recovery	Reuse	Metals Solvents	Sometimes energy prohibitive
Landfill	Storage	Inert to radioactive	Volatilization
	Major Waste Disposal Methods		
Land application	Dispersal		Access to biota
Land burial	Isolation		Leaching to groundwater
Ocean disposal	Dispersal	Acids, bases	Contact with ocean ecosystem; containers unstable
	Dilution	Explosives	
	Neutralization	Chemical war agents	
	Isolation(?)	Radioactive wastes	
	Minor Disposal Methods		
Biological degradation	Reduction of concentration Oxidation	Biodegradable organics	Most hazardous wastes do not now qualify.
Chemical degradation (chlorination)	Conversion Oxidation	Some persistent pesticides	—
Electrolytic processes	Oxidation	Organics	—
Long-term sealed storage	Isolation Storage	Radioactive	How good are containers?
Salt deposit disposal	Isolation Storage	radioactive	Are salt deposits stable in terms of waste lifetimes?

- Pollution that can neither be prevented nor recycled should be treated in as environmentally safe a manner as possible.
- Disposal or other release into the environment should be used as only a last resort.

TABLE 16.5.2 Key Characteristics of Pollution Control Devices and/or Systems

Factor Considered	Characteristic of Concern
General	Collection efficiency
	Legal limitations such as best available technology
	Initial cost
	Lifetime and salvage value
	Operation and maintenance costs
	Power requirement
	Space requirements and weight
	Materials of construction
	Reliability
	Reputation of manufacturer and guarantees
	Ultimate disposal/use of pollutants
Carrier gas	Temperature
	Pressure
	Humidity
	Density
	Viscosity
	Dewpoint of all condensables
	Corrosiveness
	Inflammability
	Toxicity
Process	Gas flow rate and velocity
	Pollutant concentration
	Variability of gas and pollutant flow rates, temperature, etc.
	Allowable pressure drop
Pollutant (if gaseous)	Corrosiveness
	Inflammability
	Toxicity
	Reactivity
Pollutant (if particulate)	Size range and distribution
	Particle shape
	Agglomeration tendencies
	Corrosiveness
	Abrasiveness
	Hygroscopic tendencies
	Stickiness
	Inflammability
	Toxicity
	Electrical resistivity
	Reactivity

Air Pollution Control

Jan F. Kreider

The most common method of meeting emission standards in industries that must control air pollution is by *pollution removal*. This section describes the most widely used approaches. Table 16.5.2 lists the important characteristics of control systems for airborne pollutants.

Dry particulate matter is removed by

- Filters — baghouse, fixed beds, or mats
- Electrostatic precipitators — plate-type, tube-type; see Figure 16.5.1
- Inertial collectors — cyclones and baffles; see Figure 16.5.2
- Scrubbers — wet or dry

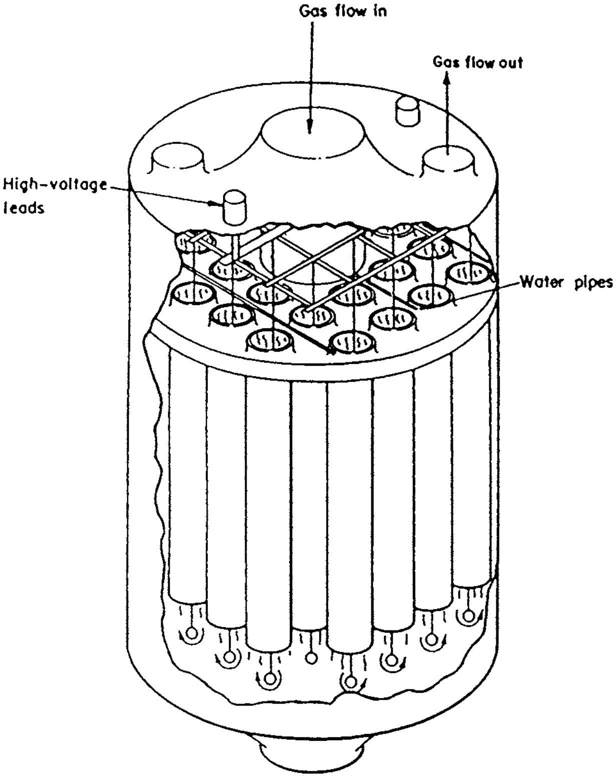

FIGURE 16.5.1 Wet-wall eledtrostatic precipitator with tubular collection electrodes. (From Oglesby, S. Jr., and Nichols, G.B., in *Air Pollution*, 3rd ed., Vol. IV, Stern, A.C., ed., p.238, Academic Press, New York, 1977. With permission.)

Table 16.5.3 lists the key characteristics of these technologies and where they are best applied. Of course, a design is needed upon which a quotation for final cost studies can be based. Table 16.5.4 compares gaseous pollutant removal systems.

Table 16.5.4 compares gaseous pollutant removal systems.

Cataloging of industry-specific designs is beyond the scope of this handbook because of space limitations. The reader is referred to Boubel et al. (1994) for details. One must make an inventory of emissions and then identify the most appropriate control methods based on operating and capital costs considerations.

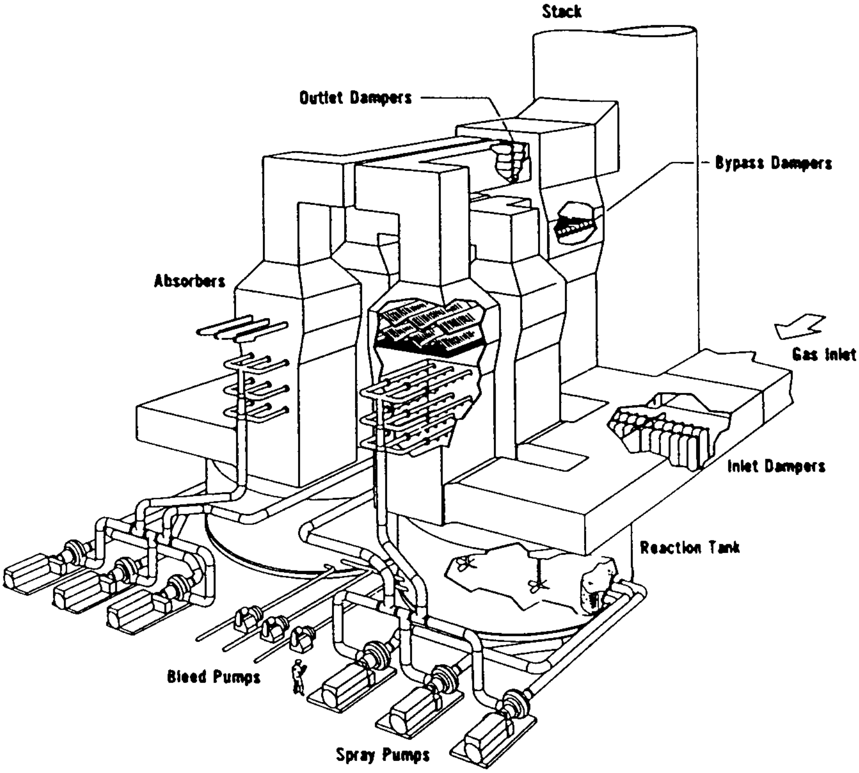

FIGURE 16.5.3 Cutaway drawing of a flue gas desulfurization spray tower absorber. (Courtesy of CE Power Systems, Combustion Engineering Inc.)

For example, Table 16.5.5 shows common emissions and control methods for the petrochemical industry. The energy, power generation, incineration, ferrous and nonferrous metallurgical, agricultural, and mineral/mining industries produce considerable emissions that must be controlled in accordance with federal regulations.

Water Pollution Control

Nevis Cook and Ronald R. Hewitt Cohen

Control of waterborne pollutants is at present undertaken by nine distinct techniques:

- Biological oxidation
- Chemical oxidation
- Chemical reduction
- Conventional treatment
- Precipitation
- Air stripping
- Activated carbon
- Ion exchange
- Reverse osmosis

Table 16.5.6 summarizes these approaches and their applications by contaminant type. The letter A in the table indicates the best available technology, whereas a B indicates an alternative that may apply to a subclass of industries. The reader is referred to the notes for the table to learn further details.

TABLE 16.5.5 Air Pollution Emissions and Controls: Petrochemical Processes

Petrochemical Process	Air Pollutant Emissions	Control Methods in Use
Ethylene oxide (most emissions from purge vents)	Ethane, ethylene, ethylene oxide	Catalytic afterburner
Formaldehyde (most emissions from exit gas stream of scrubber)	Formaldehyde, methanol, carbon monoxide, dimethyl ether	Wet scrubber for formaldehyde and methanol only; afterburner for organic vent gases
Phthalic anhydride (most emissions from off-gas from switch condensers)	Organic acids and anhydrides, sulfur dioxide, carbon monoxide, particulate matter	Venturi scrubber followed by cyclone separator and packed countercurrent scrubber
Acrylonitrile (most emissions from exit gas stream from product absorber)	Carbon monoxide, propylene, propane, hydrogen cyanide, acrylonitrile, acetonitrile NO_x from by-product incinerator	Thermal incinerators (gas-fired afterburners or catalytic afterburners)
		None
Carbon black (most emissions from exit gas stream from baghouse, some fugitive particulate)	Hydrogen, carbon monoxide, hydrogen sulfide, sulfur dioxide, methane, acetylene	Waste heat boiler or flare (no control for SO_2)
	Particulate matter (carbon black)	Baghouse
Ethylene dichloride (most emissions from exit gas stream of solvent scrubber)	Carbon monoxide, methane, ethylene, ethane, ethylene dichloride, aromatic solvent	None at present, but could use a waste heat boiler or afterburner, followed by a caustic scrubber for hydrochloric acid generated by combustion

TABLE 16.5.6 General Effectiveness of Treatment Technology vs. Contaminant Type

Constituent	Biological Oxidation	Chemical Oxidation	Chemical Reduction	Conventional Treatment	Precipitation	Air Stripping	Activated Carbon	Ion-Exchange	Reverse Osmosis
BOD	A	—	—	—	—	—	—	—	—
COD	B	B	—	—	—	—	B	—	—
Mos[a]	—	A	—	A	A	—	—	—	I
Turb.[b]	—	—	—	A	B	—	—	I	I
TDS[c]	—	—	—	—	—	—	—	A	A
Ca, Mg	—	—	—	—	A	I	—	A	A
Fe, Mg	—	P	I	B	A	I	—	I	I
NH_3	A	B	—	—	—	B	—	B	B
	—	—	A	—	—	—	—	B	B
Me++[d]	—	—	—	B	A	—	—	A	A
Cr	—	I	P	B	A	—	—	A	A
As, Se	—	P	I	B	A	—	—	A	A
CN	—	A	—	—	—	I	—	—	B
Phenols	B	A	—	—	—	—	B	—	—
SOC[e]	B	B	—	—	—	—	A	—	A
VOC[f]	B	B	—	—	—	A	B	—	B

A = treatment technology commonly applied to reduce contaminant to acceptable levels; perhaps best conventional technology.

B = treatment technology that has been used to remove a particular contaminant, but might not be fully effective under all conditions.

I = substance could interfere with efficient removal of other contaminants.

P = pretreatment required if technology is to be used.

[a] MO = microbiological contaminants including pathogenic bacteria, protozoa, and viruses.

[b] Turb. includes fine colloidal matter and suspended solids, for true suspended solids use sedimentation.

[c] Total dissolved solids (TDS) includes removal of the highly soluble ions: Na+, K+, Cl–,

[d] Includes the valence +2 transition metals: Cu++, Ni++, Pb++, Zn++.

[e] SOC = synthetic organic compounds, including pesticides.

[f] VOC = volatile organic compounds, including solvents.

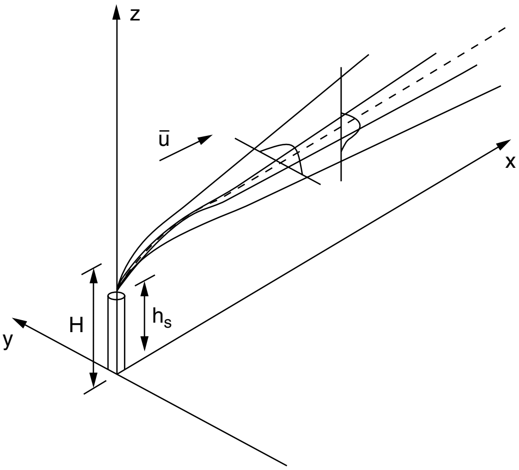

FIGURE 16.6.1 The Gaussian plume in a wind-oriented coordinate system (i.e., the wind is blowing toward the *x* axis). The plume is released from a source located at (0, 0, h_s) and possesses an initial buoyancy. Therefore, the plume behaves as if it were originated from (0, 0, *H*), where *H* is the effective emission height and $\delta h = H - h_s$ is the plume rise. The plume is advected by the average wind speed $\bar{\mathbf{u}}$ and expands in the horizontal and the vertical direction while maintaining a Gaussian distribution along both.

16.6 Environmental Modeling

Air Pollution Dispersion Modeling

Paolo Zannetti

To understand air pollution, it is mandatory, at any scale, to simulate correctly the dispersion characteristics of the emitted chemicals. Therefore, the role of meteorology is essential. Pollutants are typically transported by two types of flows: an "ordered" flow, which is characterized by average wind speed and direction, and a semi-random, turbulent flow, which is characterized by wind fluctuations. All dispersion models aim at simulating these two components. As further discussed next, dispersion modeling techniques can be categorized into four general classes: (1) Gaussian models; (2) Eulerian grid models; (3) Lagrangian box models; and (4) Lagrangian particle models.

Gaussian Models

All Gaussian models assume that the concentration of pollutants maintains a Gaussian distribution in space. The Gaussian distribution, as illustrated in Figure 16.6.1, is a symmetrical bell-shaped distribution, which is described at any given point *x*,*y*,*z* by two parameters: the location of the peak (in this case, the centerline of the plume indicated by the segmented line) and the standard deviation (in this case, the spread of the plume mass about its center). Therefore, the dilution rate of the plume is fully characterized by the two standard deviations, σ_y and σ_z, expressed as a function of the downwind distance, *x*.

In mathematical notation, the Gaussian plume formula in Figure 16.6.1 can be written as

$$c = \frac{Q}{2\pi\sigma_y\sigma_z\bar{u}}\exp\left[-\frac{1}{2}\left(\frac{y}{\sigma_y}\right)^2\right]\exp\left[-\frac{1}{2}\left(\frac{H-z}{\sigma_z}\right)^2\right] \tag{16.6.1}$$

where *c* is the concentration computed at the receptor (*x*, *y*, *z*) [mass/volume], *Q* is the emission rate [mass/time], $\bar{u}$ is the average horizontal wind speed [length/time], *H* is the effective emission height [length], and σ_y and σ_z [length] are functions of the downwind distance, *x*, with parameters that vary with the meteorological conditions (in fact, the stronger the turbulence intensity of the atmosphere, the larger the growth rate of σ_y and σ_z with x).

As can easily be seen, Equation 16.6.1 refers to a stationary state (i.e., c is not a function of time), uses meteorological parameters that must be considered homogeneous and stationary in the modeled area (i.e., between the source and the receptors at which concentrations are computed), and cannot work in calm conditions where the wind speed approaches zero (in general, the wind speed cannot be less than 1 m/sec when Equation 16.6.1 is applied). In spite of these limitations, the simplicity of the Gaussian approach, its relative ease of use, and especially the elevation of this methodology to the quantitative decision-controlling level in the U.S. (USEPA, 1978) have stimulated research aimed at removing some of the limitations of the Gaussian theory in modeling the real-world situations.

Equation 16.6.1 has been modified and expanded to incorporate, among others, the following factors: ground reflection, multiple reflections, hourly simulations as a sequence of steady-state conditions, deposition and decay, chemical transformation, fumigation, complex terrain, gravitational settling, calm conditions, nonstationary and nonhomogenous conditions, and long-term simulations. We next summarize some of these improvements.

Reflection terms can be added to Equation 16.6.1 to account for partial or total reflection of concentration at the ground. Similarly, reflection can be added at the top of **the planetary boundary layer**, or **PBL** (typically, about 500 to 1000 m above the ground). If both reflections are implemented, the plume is trapped inside the PBL. Equation 16.6.1 is generally applied for periods of 1 hr. This allows the incorporation of time-varying emission and meteorological parameters. Chemistry and decay can be incorporated by introducing exponential decay terms (e.g., it can be assumed that an emission of primary gaseous SO_2 is transformed into particulate sulfate at a rate of 1% per hour). Gravitational settling will affect a plume of primary particulate matter. In this case, the plume centerline can be tilted to account for the settling velocity of the particles, which is a function of both particle size and density.

In addition to the Gaussian plume model, Gaussian segment and puff models can be used (Zannetti, 1986a). These models break up the plume into independent elements (plume segments or puffs) whose initial features and time dynamics are a function of time-varying emission and meteorological conditions encountered by the plume elements. These techniques allow us to account properly for nonhomogeneous, nonstationary conditions. Gaussian puff models, in particular, have the additional advantage of being able to simulate calm or low-wind conditions.

Complex terrain conditions affect the plume dynamics — both the motion of the centerline trajectory and the growth of σ_y and σ_z. Finally, the Gaussian plume model equation can be rewritten in a way to simulate long-term concentration averages (e.g., annual averages) by incorporating the joint frequency of occurrence of a predetermined set of emission and meteorological conditions.

Many Gaussian models have been developed and are available for free downloading or purchase. For example, the ISC3 model is one of the most used computer packages and can be found at http://www.epa.gov/scram001/tt22.htm#isc.

Also, a new state-of-the-art Gaussian model (AERMOD) has been recently developed by the US EPA; learn more at http://www.epa.gov/scram001/tt26.htm#aermod.

Among puff models, the CALPUFF modeling system is probably the most comprehensive and can be found at http://www.src.com/calpuff/calpuff1.htm.

Other Models

Eulerian grid models (Lamb [from Longhetto], 1980) simulate pollutant diffusion by superimposing a grid over the computational domain and numerically solving a mass-balance equation (typically, a partial differential equation, PDE, or a set of PDEs) in each grid cell at each time step. This is also called numerical integration. In general, the smaller the grid and time intervals, the more accurate the numerical solution.

Difficulties may be encountered with Eulerian grid models in simulating atmospheric diffusion with the K-theory. In particular, the application of the K-theory to simulate vertical dispersion during daytime, unstable meteorological conditions is highly questionable. To improve the simulation ability of Eulerian grid models, equations of high-order moments of concentration, wind, and temperature fluctuations

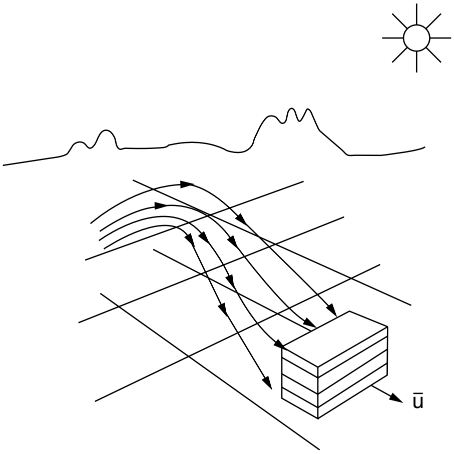

FIGURE 16.6.2 Lagrangian box modeling.

can be solved simultaneously. This approach, called high-order closure, requires the definition of more complex, nonlinear relationships between the turbulent fluxes and the concentration fields.

Lagrangian box models are mostly used to perform fast simulations of photochemical smog. These models define a set of "boxes" (e.g., a column of boxes, as illustrated in Figure 16.6.2), which are advected horizontally according to the local wind speed and direction. Each box encounters emissions along its trajectory. These emissions inject new pollutants inside the box. A full set of chemical reactions inside each box allows the simulation of the photochemical smog and the formation of secondary pollutants, such as ozone.

Lagrangian particle models provide a very interesting alternative method for simulating atmospheric diffusion. Particle motion can be produced by both deterministic velocities and semi-random pseudo-velocities generated using Monte Carlo techniques. In the latter case, the trajectory of a single particle represents a realization from an infinite set of possible solutions, and if enough particles are used, important characteristics can be inferred from the computation of particle **ensemble average** properties.

When using Lagrangian particle models to simulate air pollution, pollutant emissions (both gases and particulate matter) are represented by the injection of fictitious particles into the computational domain. Each particle represents a specified amount of pollution and is moved at each time step by a pseudo-velocity that is time and space dependent. Zannetti (1990) discusses alternative modeling approaches in more detail than is possible here.

Atmospheric Chemistry

Atmospheric chemistry deals essentially with four major issues (Seigneur 1987): (1) photochemical smog in sunny, urban areas; (2) **aerosol** chemistry; (3) acidic deposition; and (4) air toxics. Chemical reactions can be simulated in two ways: (1) with simple first-order terms (e.g., a decay term), and (2) with a full chemical reaction scheme.

First-order terms for simulating atmospheric chemistry can be easily incorporated into any of the models previously discussed. For example, a radioactive pollutant with a specified decay rate (or half-life) can be simulated by introducing the following multiplicative term in any concentration equation

$$\exp\left(-t/T\right) \tag{16.6.2}$$

where t is the travel time and T is the time scale of the decay (easily related to the half-life of the chemical species). Similarly, chemical transformation from a primary to a secondary pollutant (e.g., from gaseous SO_2 to sulfate particulate matter SO_4^{2-}), can be accomplished by introducing two exponential terms — $[\exp(-t/T)]$ and $[1 - \exp(-t/T)]$ — having the effect of simultaneously decreasing the SO_2 concentration and increasing the SO_4^{2-} concentration as time increases. First-order schemes, though relatively simple, may use parameters that are space and time dependent; for example, the SO_2-to-SO_4^{2-} conversion rate may vary as a function of relative humidity and solar radiation.

Photochemical smog, which in the past only affected large cities at low latitudes, such as Los Angeles, has become today the most important and common air pollution problem in urban areas throughout the world. Overall, the photochemical smog reactions can be summarized as

$$\text{ROG} + \text{NO}_x + \text{sunlight} \rightarrow \text{O}_3, \text{PAN}, \text{HCHO}, \text{HNO}_3, \text{PM}, \ldots \tag{16.6.3}$$

where ROG are primary reactive organic gases and NO_x include primary NO and mostly secondary NO_2. This smog includes carbon monoxide (CO), ozone (O_3) formaldehyde (HCHO), peroxyacetyl nitrate (PAN), nitric acid (HNO_3), secondary particles, such as nitrates and organic particles, and other products.

A full chemical reaction scheme is required to simulate complex phenomena, such as the photochemical smog just described, and can be incorporated today only inside Eulerian grids or Lagrangian box models. A typical reaction set, applied in each grid cell at each time step, can be written in terms of linear combinations:

$$\sum_{m=1}^{M} r_{nm} c_m \rightarrow \sum_{m=1}^{M} p_{nm} c_m \qquad n = 1, 2, \ldots, N \tag{16.6.4}$$

where M species participate in N reaction steps, c_m is the concentration of the mth species, and r_{nm} and p_{nm} are numerical constants. Each reaction rate is generally expressed as a product of the concentrations of the species involved, with a temperature-dependent rate constant.

The main difficulty in using Equation 16.6.4 to simulate the photochemical smog is the treatment of **organic compounds**. In fact, due to their very large number, organic species cannot all be included explicitly. Three different types of gas-phase chemical mechanisms are generally used: (1) surrogate mechanisms, which use the chemistry of one or two compounds in each class of organics to represent the chemistry of all species in that class; (2) lumped mechanisms, in which the grouping of chemical compounds is done on the bases of their similar structure and reactivity; and (3) the carbon bond approach, which splits each organic molecule into functional groups using the assumption that the reactivity of the molecule is dominated by the chemistry of each functional group. Each classification technique necessarily introduces a simplification and, therefore, a potential simulation error.

Some key reactions involve the **photolysis** of such species as NO_2, HCHO, and nitrous acid (HONO). These one-species reactions require the calculation of the photolysis rate constant, which is a function, among other things, of solar elevation and temperature.

A few models are available for simulating urban photochemical smog, for example:

- UAM-V (http://uamv.saintl.com/)
- CAMx (http://www.camx.com/overview.html)
- CALGRID (http://www.arb.ca.gov/eos/soft.html)

Aerosol chemistry is particularly difficult to simulate and computationally expensive. However, inclusion of aerosol dynamics within air quality models is of primary importance because of the health effects associated with fine particles in the atmosphere, visibility impairment, and the acid deposition problem. Simple first-order reaction terms can be used to simulate the transformation of SO_2 into sulfates and NO_x into nitrates. These terms can be included in any model. However, a comprehensive simulation of aerosol processes can only be performed within an Eulerian grid or a Lagrangian box model and must include the following fundamental equation of aerosol dynamics (Milford and Russell 1993) which describes aerosol transport, growth, coagulation, and sedimentation:

$$\frac{\delta n}{\delta t} + \nabla \cdot un + \frac{\delta l}{\delta \nu} = \frac{1}{2}\int_0^{\nu} \beta(\bar{\nu}, \nu - \bar{\nu})\, n(\bar{\nu})\, n(\nu - \bar{\nu})\, d\bar{\nu} - \int_0^{\infty} \beta(\bar{\nu}, \nu)\, n(\bar{\nu})\, n(\nu)\, d\bar{\nu} - \nabla \cdot \mathrm{C}n \tag{16.6.5}$$

where n is the particle size distribution function, $\bar{\mathbf{u}}$ is the wind velocity, I is the droplet current that describes particle growth and nucleation due to gas-to-particle conversion, ν is the particle volume, β is the rate of particle coagulation, and $\mathbf{C}$ is the sedimentation velocity.

The simulation of heterogeneous and aqueous-phase chemistry is of key importance for regional-scale acid deposition and **stratospheric** ozone models, but is usually neglected in urban photochemical applications where the main goal is the simulation of tropospheric ozone.

Deposition

Chemical species are removed from the atmosphere by two mechanisms: reaction and deposition. While chemical reactions may produce new pollutants, deposition is the real process in which the atmosphere cleans itself. Some pollutants are highly reactive and, consequently, have short lifetimes. For example, ozone has a typical lifetime of 1–2 days (but it may be much lower in a polluted urban atmosphere). Therefore, ozone concentration will drop unless it is continuously regenerated. Other pollutants have longer lifetimes. For example, SO_2 has a typical lifetime of 5–10 days (however, in a clean atmosphere, the lifetime of SO_2 can be a few weeks). Therefore, under certain circumstances, SO_2 can easily accumulate during multiday episodes (e.g., the "London" smog of the 1950s). Finally, there are pollutants, such as methane and carbon dioxide, with very large lifetimes (years or decades). Because of their low reactivity, they do not cause adverse effects on human health but, nevertheless, can diffuse on a global scale and affect the thermal balance of the Earth. Deposition terms can be introduced in any model discussed above. For example, *dry deposition* can be described by the following formula:

$$F_i = V_d \, c_i \tag{16.6.6}$$

where F_i is the flux of a species i to the ground, c_i is the concentration of the species i at some reference height (e.g., 1 m), and V_d is the deposition velocity. The term V_d has been measured under various meteorological conditions and for a number of surface types (Wesley et al. 1985). Therefore, the calculation of F_i is straightforward.

Wet deposition (i.e., precipitation scavenging) depends on the intensity and size of raindrops. Fog and cloud droplets can also absorb gases, capture particles, and accelerate chemical reactions. Wet deposition is quantified by computing the wet flux of pollution to the surface. This calculation requires the estimate of the washout coefficient, which can be inferred (Scott 1982) as a function of storm type and precipitation amounts.

Because of dry and wet deposition, acidic components such as sulfuric acid particles, particulate nitrate, and nitric acid gas are transferred from the atmosphere to the earth. Areas that are tens and hundreds of kilometers downwind of large SO_2 and NO_x sources (e.g., power plants and smelters) often suffer the greatest deposition impact.

Statistical Models

Statistical models are often used in air pollution studies. They include frequency distribution studies, time series analysis, Kalman filters, receptor-modeling techniques, and others. A general distinction between statistical and deterministic approaches is that air pollution deterministic models initiate their calculations at the pollution sources and aim at the establishment of cause/effect relationships, while statistical models are characterized by their direct use of air quality measurements to infer semi-empirical relationships. Although very useful, especially for real-time short-term forecasting, statistical models are generally unable to quantify cause/effect relationships, with the exception of *receptor modeling*.

The basic concept of the receptor-modeling approach is the apportionment of the contribution of each source, or group of sources, to the measured concentrations without reconstructing the dispersion pattern and trajectory of the pollutants. Typically, receptor models start with *observed* ambient aerosol concentrations measured on filters of particle detectors at different receptor points and seek to apportion the concentrations among several source types (e.g., industrial, transportation, soil, etc.), based on the known chemical composition (i.e., the chemical fractions) of source and receptor materials. In other words, receptor models analyze aerosol data to search and quantify the "fingerprints" of several emission groups.

In mathematical notation, the concentration c_{ik} of the species i in the kth aerosol sample at a certain monitoring station can be written as

$$c_{ik} = \sum_{j=1}^{p} a_{ij} D_{jk} E_{jk} \tag{16.6.7}$$

where p sources (or groups of sources) are assumed to contribute to c_{ik}, a_{ij} is the fractional amount of the component i in the emission from the jth source, D_{jk} is the atmospheric dispersion term, and E_{jk} is the emission rate (i.e., $D_{jk}E_{jk} = S_{jk}$ is the total contribution of the source j to the kth sample at the receptor location). Dispersion models assume a_{ij}, D_{jk}, and E_{jk} to be known (or obtainable from emission and meteorological data) and calculate the output c_{ik}. For receptor models instead, the concentrations c_{ik} and source "profiles" a_{ij} are known, and the $D_{jk}E_{jk}$ products are computed as a model result.

Groundwater Pollution Modeling

Tissa Illangasekare

Saturated Groundwater Flow

The description of the exact movement of fluid particles in a porous medium is difficult (or impossible) because it is not practical to define exactly the boundaries of the flow domain that is described by the geometry of the internal solid surfaces of the grains. The problem of water flow in a porous medium can be treated at the molecular, microscopic, or macroscopic level.

The treatment of the behavior of a system of molecules using theories of classical fluid mechanics is extremely difficult because of the large number of molecules involved and the difficulties in identifying all forces and defining the exact pore geometry. Instead of treating individual molecules, the statistical properties of a very large number of molecules may be inferred from laws governing the motion of individual molecules. Still, this approach will also have similar limitations with respect to the need to define exact pore geometries. A coarser treatment at the microscopic level where fluid is treated as a continuum is feasible, but most applications in groundwater flow may not require this level of refinement. This approach will also require the accurate definition of the pore geometry.

A coarse level of averaging at the macroscopic level that is referred to as the *representative elementary volume (REV)* is used in most practical applications in porous media flow analysis. Porous medium is defined as a portion of a space occupied partly by a solid phase (solid matrix) and partly by voids. The voids in general are occupied by one (single phase) or more fluid phases (multiphase). This level of treatment assumes that the solid phase is distributed throughout the problem domain, and it should be possible to define an REV so that no matter where we place it within the porous media domain, it will contain both solids and voids.

At the macroscopic scale, the rate at which water flows in a soil is quantified using a variable that is referred to as the *Darcy velocity*, or *specific discharge*. This variable, which has the dimensions of velocity, is defined as the discharge per unit gross area of soil that includes both void spaces and the grains in a flow section. For incompressible fluids, a relationship that is referred to as *Darcy's law* expresses the Darcy velocity in terms of a parameter referred to as hydraulic conductivity, K, and the gradient of the piezometric head, h. Darcy's law for saturated flow (a single fluid filling the pore space) in soils in a three-dimensional domain is given by

$$\mathbf{q} = -\mathbf{K}\nabla h \tag{16.6.8}$$

where $\mathbf{q}$ is the vector of specific discharge or Darcy velocity (L/T), h is the piezometric head (L), and $\mathbf{K}$ is a second-rank tensor of hydraulic conductivity.

In groundwater flow, since the velocities are generally very small, the velocity head is neglected and the driving head becomes the sum of the elevation and the pressure heads. The piezometric head is defined as

$$h = h_z + h_p = z + \frac{p}{g} \tag{16.6.9}$$

where ρ is the density of water, z is the elevation, and p is the water pressure.

In anisotropic aquifers where the hydraulic conductivity changes with flow direction, the second-rank tensor **K** is given as

$$\left[\mathbf{K}\right] = \begin{bmatrix} K_{xx} & K_{xy} & K_{xz} \\ K_{yx} & K_{yy} & K_{yz} \\ K_{zx} & K_{zy} & K_{zz} \end{bmatrix} \tag{16.6.10}$$

It can be shown that it is possible to find three mutually orthogonal directions in space so that

$$K_{ij} \neq 0 \; \textit{for all } i = j$$

$$K_{ij} = 0 \; \textit{for all } i \neq j$$

where $i, j = x, y$ and z.

These directions in space are called the principal directions of the anisotropic geologic medium. When principal directions are parallel to the axes of the coordinate system, the tensor reduces to a hydraulic conductivity vector given as

$$\left[\mathbf{K}\right] = \begin{bmatrix} K_{xx} & 0 & 0 \\ 0 & K_{yy} & 0 \\ 0 & 0 & K_{zz} \end{bmatrix} \tag{16.6.11}$$

Under transient conditions, for conservation of mass, the rate of change of mass flux of water should be balanced by the change in storage within a control volume. This gives

$$-\nabla.\rho\mathbf{q} = \frac{\partial(n\rho)}{\partial t} \tag{16.6.12}$$

For homogeneous, incompressible fluid and a nondeformable porous medium

$$\nabla.\mathbf{q} = \mathbf{0} \tag{16.6.13}$$

Noting that the change in head produces a change in storage, we can write the mass conservation equation as

$$\nabla.\mathbf{q} + \mathbf{S}_s \frac{\partial h}{\partial t} = 0 \tag{16.6.14}$$

where $\mathbf{S}_s$ is the specific storage, defined as the volume of water added to storage, per unit volume of porous medium, per unit rise in piezometric head. This is given as

$$S_s = \rho g(\alpha + n\beta) \tag{16.6.15}$$

where β is the compressibility of water and α is the compressibility of the soil matrix.

Combining Darcy's law and the equation of mass conservation, the general equation of saturated groundwater flow is obtained as

$$\nabla.\mathbf{K}\nabla h = S_s \frac{\partial h}{\partial t} \tag{16.6.16}$$

The initial and boundary value problem obtained by combining this second-order partial differential equation with the initial head in the aquifer and the head or flux conditions at the aquifer boundary is solved to obtain the unknown head in the aquifer. The head distribution can then be used with Darcy's law to obtain the groundwater flow velocity in the aquifer.

Solute Transport in Groundwater

Transport of dissolved chemicals in porous material is generally considered to be the result of two processes, namely, advection and dispersion. Advection is the process by which the solute is transported as a result of the movement of water through the intergranular pore spaces of the soil. In the mathematical representation of this process at the REV scale, a macroscopically average velocity that is referred to as the *average linear pore velocity* is used. An approximate value for this average pore water velocity for granular material based on macroscopic variables is given as

$$\bar{\mathbf{v}} = \frac{\mathbf{q}}{n} \tag{16.6.17}$$

where n is the effective porosity. The average liner pore water velocity is also referred to as the *average solution velocity.*

The flux due to advective transport is given by

$$\mathbf{J_a} = C\mathbf{q} \tag{16.6.18}$$

where $\mathbf{J_a}$ is the vector of solute mass flux (mass per unit time per unit area, [MT^{-1} L^{-2}]), and C is the mass concentration of solute per unit volume of the solution (ML^{-3}).

Dispersion is the result of two processes that occur at the pore scale: molecular diffusion and mechanical (or hydrodynamic) mixing. Due to molecular diffusion, the solute will move from the high-concentration to low-concentration regions in the fluid phase. Fick's first law modified to account for the presence of the solid phase is used to represent the solute flux as a function of the concentration gradient given by

$$\mathbf{J_d} = -n\mathbf{D}_d\nabla C \tag{16.6.19}$$

where $\mathbf{J_d}$ is diffusive mass flux, [MT^{-1} L^{-2}]; n is the porosity, $\mathbf{D}_d$ [L^{2}T^{-1}]; a second-rank tensor is the effective diffusion coefficient of the solute in the porous medium; and C is the solute concentration, [M/L^{-3}]. In sandy aquifers, under normal flow conditions, the contribution by molecular diffusion is neglected compared to hydrodynamic mixing. Molecular diffusion becomes dominant when the flow velocities are very small, as in clays where hydraulic conductivities are much smaller compared to that of sandy soils.

The component of dispersion due to mechanical mixing is the result of velocity variation at the microscopic pore-scale. These velocity variations are the result of three basic mechanisms that occur within the pores: (1) viscous shear forces that produce velocity gradients across flow channels, (2) pores size variations that produce pore channels with different sizes transmitting water at different pore velocities, and (3) the changing flow directions due to the tortuosity of the flow channels. The combined effect of these variations results in the solute being mixed at the macroscopic scale and producing mass flux along decreasing concentration gradients. As this process is analogous to the diffusion in the microscopic scale, an equation similar to the Fick's first law is used to describe mass flux due to mechanical mixing. This analogous equation is given as

$$\mathbf{J}_m = -n\mathbf{D}_m \nabla C \tag{16.6.20}$$

where $\mathbf{J}_m$ is the flux due to mechanical mixing, [MT^{-1} L^{-2}], and $\mathbf{D}_m$ is the coefficient of hydrodynamic (mechanical) dispersion.

The total flux due to molecular diffusion and hydrodynamic dispersion is given as

$$\mathbf{J} = \mathbf{J}_d + \mathbf{J}_m \tag{16.6.21}$$

Substituting for $\mathbf{J}_m$ and $\mathbf{J}_d$, we have

$$\mathbf{J} = -n(\mathbf{D}_d + \mathbf{D}_m).\nabla C \tag{16.6.22}$$

Define the dispersion coefficient **D** as

$$\mathbf{D} = \mathbf{D}_d + \mathbf{D}_m \tag{16.6.23}$$

Equation 16.6.24 reduces to

$$\mathbf{J} = -n\mathbf{D}\nabla C \tag{16.6.24}$$

In a three-dimensional system the dispersion coefficient is a second-order tensor that takes the form

$$\left[\mathbf{D}\right] = \begin{bmatrix} D_{xx} & D_{xy} & D_{xz} \\ D_{yx} & D_{yy} & D_{yz} \\ D_{zx} & D_{zy} & D_{zz} \end{bmatrix} \tag{16.6.25}$$

By orienting the x′ axis of the local coordinates at the aquifer point along the direction of groundwater flow (longitudinal direction), the dispersion coefficient tensor can be reduced to

$$\left[\mathbf{D}\right] = \begin{bmatrix} D_{x'x'} & 0 & 0 \\ 0 & D_{y'y'} & 0 \\ 0 & 0 & D_{z'z'} \end{bmatrix} \tag{16.6.26}$$

The local axes x', y', and z' are the principal axes of dispersion, and $D_{x'x'}$, $D_{y'y'}$, and $D_{z'z'}$ are the principal values of the coefficient of dispersion. These coefficients can be expressed in terms of the longitudinal average linear pore velocity as

$$\begin{aligned} D_{x'x'} &= D_d + \alpha_L \bar{v}_{x'} \\ D_{y'y'} &= D_d + \alpha_T \bar{v}_{x'} \\ D_{z'z'} &= D_d + \alpha_T \bar{v}_{x'} \end{aligned} \tag{16.6.27}$$

where α_L and α_T are longitudinal and lateral dispersion coefficients, respectively. The dispersion coefficients that have dimensions of length can be viewed as characteristic lengths of the porous medium at the pore scale. However, in real applications these values are much larger and have been found to depend on the size of the plume (scale dependent).

Combining advective flux given by Equation 16.6.18 and dispersive flux given by Equation 16.6.24 and applying the principal of mass conservation for the solute, one obtains

$$(n\mathbf{D}\nabla C - C\mathbf{q}) \tag{16.6.28}$$

By substituting the approximation for Darcy's velocity in Equation 16.6.28, we can obtain the governing equation for solute transport in saturated porous media as

$$(\mathbf{D}\nabla C - C\overline{\mathbf{v}}) \tag{16.6.29}$$

Equation 16.6.29 is referred to as the *advection-dispersion equation*. The initial and boundary value problem obtained by combining the above second-order PDE with the initial concentration distribution in the aquifer and the concentration and mass flux at the aquifer boundary is solved to obtain the time and space distribution of the solute concentration in contaminant plumes. It should be noted that to solve the advection-dispersion equation it is necessary to first solve for the groundwater velocities using the groundwater flow equation.

Surface Water Pollution Transport Modeling

Ronald R. Hewitt Cohen and Nevis Cook

The study of water quality modeling bloomed in the late 1960s and through the 1970s. Administrators and bureaucrats with minimal mathematical and science backgrounds were greatly impressed by presentations of pages of PDEs, and model outputs were often treated as absolute truth. As the field and model users matured, it was recognized that a model is just a group of hypotheses about the way the modeler believes the world works, all put in mathematical terms. The limitations, shortcomings, and difficulties with environmental models are well recognized and accepted. Models are now used as *tools* for decision making and planning.

An industrial facility may want to assess how reducing or increasing the mass or concentration of some pollutant in a discharge will affect the receiving waters. It may be that a dramatic, negative impact might be predicted. Reducing the level of pollutant in the discharge may result in little to no improvement to water quality. Obviously, the results of the modeling effort will dictate the level of effort and cost going toward the treatment of the pollutant.

The same facility may be instructed by the USEPA or the state to control discharges such that water quality criteria in the receiving waters are met. Good models can be used to address the question "What are the implications to the receiving waters if various facility process modifications are applied?" Thus, a decision could be made as to the process modifications to be focused on to match the criteria or standards.

It is not anticipated that every industrial facility has an individual with the capabilities to construct a water quality transport model. Many models are available to run on microcomputers and can be obtained through the USEPA.

Impact Pathway Methodology

Ari Rabl and Peter S. Curtiss

A step beyond conventional dispersion modeling includes the physical and economic impacts of air pollution. Rational management of the environment requires an assessment of the damage caused by pollution. The logically correct way to analyze environmental impacts is the *impact pathway methodology*, whose principal steps are as follows:

- Specification of the relevant technologies and the environmental burdens they impose (e.g., kilograms per second of particulates emitted by a power plant).
- Calculation of increased pollutant concentration in all affected regions (e.g., micrograms per cubic meter of particulates, using models of atmospheric dispersion and chemistry).
- Calculation of physical impacts (e.g., number of cases of asthma due to these particulates, using a dose-response function).
- In some cases a fourth step may be called for: the monetary valuation of these impacts (e.g., multiplication by the cost of a case of asthma).

The numbers are summed over all receptors (population, crops, buildings, etc.) that are affected by this pollutant. Formally, the procedure can be represented as an equation for the incremental impact I due to an incremental quantity Q of a pollutant emitted by the plant

$$I(Q) = \sum_i \left[f_{DR,i}\left(c_i + \Delta c_i(Q)\right) - f_{DR,i}(c_i) \right] \tag{16.6.30}$$

where c_i = background pollutant concentration for receptor i and Δc_i = incremental pollutant concentration due to Q for receptor i; $f_{DR,i}(c)$ = dose-response function for receptor i (the magnitude of this impact that receptor i will suffer at concentration c). The summation index i runs over all receptors (people, crops, buildings, etc.) of concern.

Which receptors are of concern depends on the purpose of the calculation. One can distinguish three kinds of situation:

1. Episodic values (typically for litigation after pollution episodes)
2. Peak values (typically for obtaining a permit for a new plant, by showing that impacts are below a damage threshold or regulatory limit)
3. Expectation values (typically for policy applications such as setting of regulations, by showing that average impacts are acceptable)

For the first two, the summation will typically be over a limited set of receptors, for instance, the residents in a town. For the third application, one will usually want to know the total damage, and the sum should cover all receptors that make a significant contribution to the total. For most air pollutants the impact region has to cover a range of at least 1000 km. For globally dispersing gases, for example, CO_2, the impact region is the entire globe.

Equation 16.6.30 expresses the damage in functional form; hence, this methodology is also known under the name *damage function*. Of course, while this methodology is logically correct, the practical implementation may not always be feasible for lack of appropriate data or models.

In general a dose-response function $f_{DR,i}(c)$

$$Y = f_{DR,i}(X) \tag{16.6.31}$$

relates the dose X of a pollutant that affects a receptor (e.g., population) to the magnitude Y of the impact on this receptor (e.g., incremental number of deaths). In the narrow sense of the term, X should be the dose actually absorbed by a receptor. But often one uses, as we do in the present section, the term dose-response function in the sense of a concentration-response function (also called the exposure-response function), where X represents the concentration of a pollutant in the ambient air; in that case $f_{DR}(X)$ accounts implicitly for the absorption of the pollutant from the air into the body. Dose-response functions for the classic air pollutants (NO_x, SO_x, O_3, and particulates) are typically of that kind. In the next sections we take a closer look at the major steps of the impact pathway analysis.

The Source Term

The first step of the impact pathway analysis is relatively straightforward. One identifies the site and circumstances of a pollution source, e.g., the tons of PM per kWh emitted by particular power plant. For the major air pollutants (CO_2, CO, NO, SO_2, VOCs, particulate matter PM) the emission rates for a given technology are quite well known. For the example of power plants the rate of CO_2 emission is especially well determined. Emissions of CO, NO, SO_2, VOCs, and particulate matter are somewhat less certain, and they can vary with operating conditions. NO emissions, for instance, are likely to increase above the manufacturer's specifications if a selective catalytic reduction unit is not well maintained. There are different grades of oil and coal, and their sulfur content can vary by an order of magnitude; obviously, the emissions of SO_2 depend on the quality of the fuel that will be used. Usually, there are strict regulations that enforce an upper limit on the emissions; due to cost constraints power plants are unlikely to operate significantly below these limits.

The situation is less clear with regard to trace pollutants such as lead and mercury, since their content in different grades of coal can vary by much more than an order of magnitude. Furthermore, some of these pollutants are emitted in such small concentrations that their measurement is difficult. The dirtier the fuel, the greater the uncertainty of emissions. Especially with waste incineration, there has been concern over toxic metals and dioxins that are emitted into the air.

Probably the most uncertain emissions are emissions from the disposal and storage of wastes, because they depend on events in the future. Solid waste from coal-fired boilers could be dumped into a simple hole in the ground, or it could be placed into an engineered landfill with watertight liners; the possible impacts will be totally different. There may or may not be a breach of containment, depending on the quality of construction and management and on natural events such as floods or earthquakes. The main risk from a landfill is the leaching of toxic minerals into groundwater; such risk can be kept negligible by proper construction and management.

Dispersion of Pollutants

Pollutants can be emitted to air, water, or soil. The majority of pollutants are first emitted into the air, even if they later pass into the water or the soil. Therefore, most of this section focuses on atmospheric dispersion. Dispersion in soil is difficult to model because it can involve complex processes that depend on the physical and chemical properties of the soil at each site.

Transport by surface water, that is, rivers, lakes, and the sea, is relatively simple to analyze if fine geographical resolution is not required. Thus, one can divide these bodies of water into a reasonably small number of compartments that are treated as uniformly mixed. For example, a river may be divided into ten sections. A differential equation with empirical coefficients relates the concentration in a section under consideration to the concentration in the section immediately upstream and to the emission into this section. Sedimentation, removal, and decay processes are included.

Similarly, for the dispersion into marine waters one uses a compartment model where each compartment communicates with one or several neighbors, and the volumes and flow rates are known. For instance, in a model used for the analysis of nuclear power plants (EC 1995c), the European seas have been divided into 34 compartments.

For dispersion in the atmosphere, in general both physical and chemical processes need to be considered (Seinfeld and Pandis 1998; Zannetti 1990), see the beginning of Section 16.6. Some pollutants, for example, CO_2, CH_4, and ^{133}Xe, are sufficiently inert chemically that only the physical transport needs to be analyzed. Some are moderately reactive, and their chemical transformation needs to be taken into account. SO_2, for instance, leads to the formation of SO_3, H_2SO_4, and other sulfates (especially from the interaction with NH_3, emitted mostly by agricultural activities); this can have significant implications for impact analysis on a regional and global scale. For example, sulfate aerosols can reduce the impact of global warming. Ozone is a secondary pollutant, formed by the interaction of NO_x, VOC, and light, and the chemistry is extremely complex.

Even though the modeling of the physical transport of pollutants is difficult, it is far simpler than weather modeling. The reason is that pollutants can be considered a small admixture, passively transported by the currents of the surrounding medium. Such transport is linear: the incremental concentration at a receptor site is proportional to the incremental emission (the only exception arises from secondary pollutants such as ozone whose formation depends on other variables, coupled through nonlinear phenomena).

Furthermore, for most policy applications one needs only expectation values of environmental impacts. While it is well known that chaotic phenomena in the atmosphere render the prediction of the weather impossible beyond a short time, this does not prevent the prediction of expectation values. The climate is much more certain than the weather. For expectation values of air pollution damage, it suffices to know the average motion of the surrounding medium from past observations, by contrast to weather modeling where that very motion needs to be predicted in real time.

Dispersion in Air

A simple model for atmospheric dispersion is the Gaussian plume, discussed earlier. According to this model the concentration of a pollutant is described by the product of two Gaussian distributions, one for the spread in the vertical direction and one for the spread in the horizontal direction perpendicular to the prevailing wind direction. The plume width parameters are based on empirical correlations and take into account the relevant meteorological conditions.

The Gaussian plume is considered adequate for the short range, up to tens of kilometers from the source, even for episodic events (Zannetti 1990). The use of this model at distances beyond 100 km is generally not recommended, although it is acceptable for the prediction of the average values if correction terms are included for reflection at the surface and at the PBL of the earth, and if the depletion mechanisms (deposition, chemical transformation, radioactive decay) are correctly accounted for. As an example of dispersion software based on a Gaussian plume, one can cite the ISC model of the USEPA (Brode and Wang 1992).

For regional modeling most analysts prefer to rely on more-detailed computer simulations, for example the Harwell Trajectory Model (1993) or the EMEP model of the Norwegian Meteorological Service (Barrett 1992; Sandnes 1993; Iversen 1993). The latter model is used for the official allocation of acid rain budgets among the countries of Europe.

A crucial question concerns the geographic range over which the analysis needs to be extended in order to capture most of the impacts. This involves a balance among the rates of emission, of dispersion, and of removal of a pollutant. A look at the results of long-range transport models for SO_2 and NO, for instance, those calculated by EMEP (Sandnes 1993), shows that these pollutants are transported over hundreds, even thousands of kilometers. This is illustrated in Figure 16.6.3 using the EMEP data for a source at Nantes, assuming uniform receptor density and a linear dose-response function. The range of the analysis must be extended to over 1000 km if one wants to capture 80 to 90% of the total impact. The same holds for any air pollutants with comparable removal rate.

Secondary Pollutants

Many pollutants are transformed into secondary pollutants by chemical reactions in the atmosphere. For example, the reactions shown in Figure 16.6.4 create acid rain (wet deposition of H_2SO_4) and ammonium sulfate particulates from SO_2.

Another important secondary pollutant is ozone. It is formed when several chemical reactions take place in sequence. The only reaction that forms ozone directly is

$$O + O_2 + M \rightarrow O_3 + M$$

where M is a molecule such as N_2 or O_2 whose participation is necessary to conserve energy and momentum. The oxygen atom involved in the formation of ozone is derived from photolysis of NO_2 under the action of sunlight (indicated by $h\nu$)

$$NO_2 + h\nu \rightarrow O + NO$$

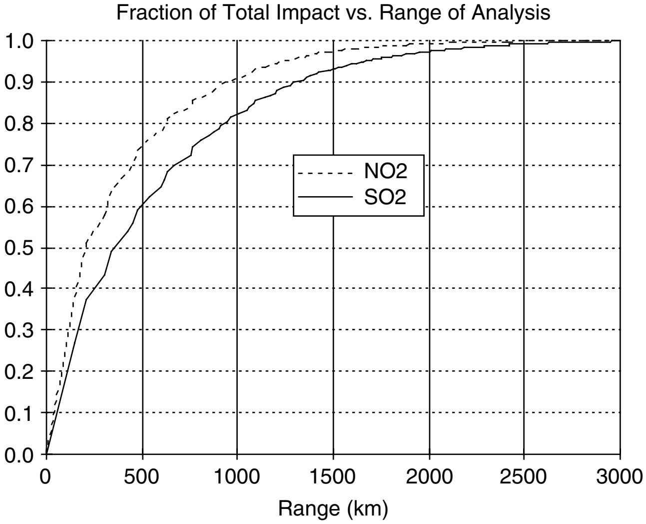

FIGURE 16.6.3 Fraction of total impact vs. range of analysis, for uniform receptor density and linear dose-response function, based on EMEP data (Barrett 1994). Wiggles are due to discretization.

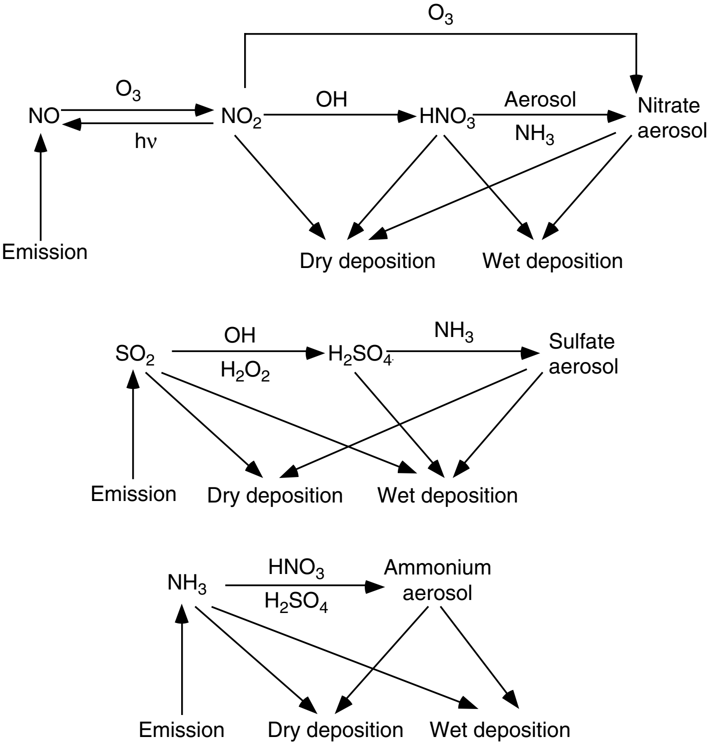

FIGURE 16.6.4 Chemical reactions included in Harwell Trajectory Model. (From EC, 1995c.)

The presence of volatile organic compounds (VOCs) is necessary to prevent the ozone formed from being immediately consumed by NO to produce NO_2 in the following reaction:

$$NO + O_3 \rightarrow O_2 + NO_2$$

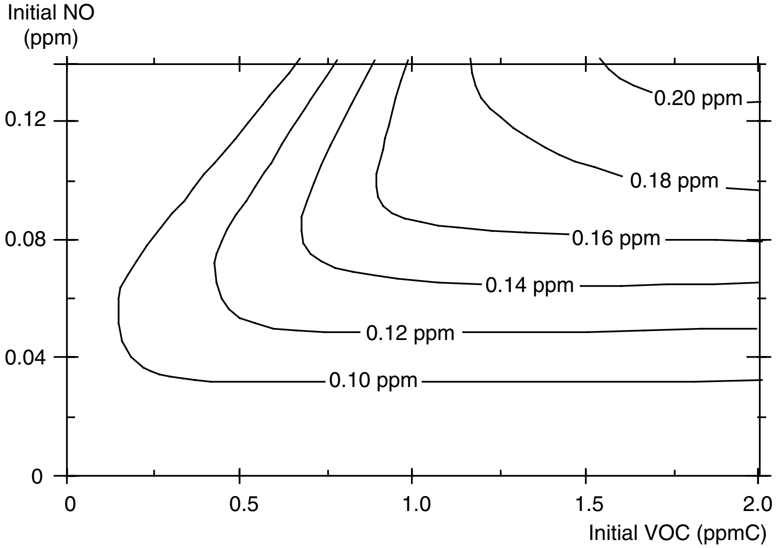

FIGURE 16.6.5 Isopleth plot for the maximum ozone concentration reached during a fixed length of time as a function of initial NO and VOC concentrations. Details of such a plot depend on site and on weather. (From EPRI, 1992.)

VOCs enable the transformation of NO into NO_2 without consuming ozone. Finally, note also that NO_2 plays a double role, since, while being necessary to form ozone, it consumes the radicals needed by VOCs to transform NO into NO_2. In fact, an equilibrium is created between these reactions. The concentration of ozone therefore is very dependent on changes in the concentrations of other products, and, due to the complexity of the phenomena, it is observed, for example, that if VOCs are low (as in the case of an electricity power plant plume), the increase in NO may reduce O_3. Figure 16.6.5 shows the influence of the concentrations of nitrogen oxides and VOCs on the concentration of ozone. In particular, we observe the phenomenon mentioned above: the consequence of an increase in NO on atmospheric ozone depends on the concentration of the organic compounds. The ozone content is also strongly dependent on the $[NO_2]$:[NO] ratio. If this ratio is low, the $[O_3]$ content will remain low.

Dose-Response Functions

Form of the Dose-Response Function. By definition, a dose-response function starts at the origin, and in most cases it increases monotonically with dose X, as sketched schematically in Figure 16.6.6. At very high doses the function may level off in S-shaped fashion, implying saturation. Dose-response functions are determined from epidemiological studies or from laboratory studies. Since the latter are mostly limited to animals, the extrapolation to humans introduces large uncertainties. Another major difficulty is that one needs relatively high doses in order to obtain observable nonzero responses in a sample of realistic size; such doses are usually far in excess of the levels one is concerned with in environmental impact studies. Thus, there is a serious problem of how to extrapolate from the observed data toward low doses. Figure 16.6.6 indicates several possibilities. The simplest is the linear model, that is, a straight line from the origin through the observed data point(s). Cancer from radioactivity is an example. Linearity also seems to be observed for mortality from fine particulates (Dockery et al. 1993; Dockery and Pope 1994; Lipfert 1994).

Another possibility is a straight line down to some threshold, and zero effect below that threshold. Thresholds occur when an organism has a natural repair mechanism that can prevent or counteract damage up to a certain limit. Many dose-response functions for noncancer toxicity are of this type.
